ple interrupted sutures are placed circumferentially through the aortic anulus, the Dacron patch, and the sewing ring of the prosthesis, and the valve is seated and secured in place. Potential bleeding sites in the corner of the anulus-patch junction are double sutured with individual interrupted sutures to prevent hemorrhage from this site. The overlapping Dacron patch is trimmed and used for enlargement and closure of the aortotomy incision. The aortic clamp is released, and any leakages in the patch are

repaired. The defect in the right ventricular outflow tract is closed with a pericardial patch, covering the entire Dacron patch and draining any leakages into the right ventricle (■ Fig. 16.18).

16.3.6.5 Resection of the Conal Septum/Fibromuscular Stenosis

After opening the aorta using an inverted hockey stick type of incision, the subvalvular area is carefully inspected. The fibromuscular stenosis

or ridge of muscle projecting into the left ventricular outflow tract is excised as widely as possible without interfering with the aortic valve integrity and the conduction system. Two parallel incisions are made into the anterolateral aspect of the ventricular outflow tract. The first incision is made beneath the intercoronary commissural triangle, and the second one is made beneath the belly of the right coronary cusp. The incisions are extended apical as far down as needed, and the chunk of muscle in between is excised with scissors.

16.3.6.6 Resection of Hypertrophic Obstructive Cardiomyopathy/ Extensive Myectomy in Hypertrophic Obstructive Cardiomyopathy

The operation is conducted in a similar way to the resection of fibromuscular stenosis, but the extent of the septal myectomy is deeper. The septal myectomy is guided by ECHO findings with particular emphasis on the thickness of the ventricular septum and the anatomy and function of the mitral valve. Before bypass, direct measurement of the pressure gradient is performed to make a reliable comparison with post myectomy measurements. Particular attention is paid to myocardial protection of the severely hypertrophied myocardium. After opening the aorta and identification of the friction lesion caused by the opposition of the anterior leaflet of the mitral valve, two parallel incisions are made in the septum under the left, lateral half of the right coronary sinus. These incisions are connected superiorly under the aortic cusp, and a deep wedge of muscle is resected beyond the tip of the anterior leaflet of the mitral valve to abolish the dynamic obstruction due to the systolic anterior motion of the anterior leaflet of the mitral valve. This classical resection is extended leftward toward the mitral valve and apically to the base of the papillary muscle. In the presence of a midcavity obstruction, the apical portion of the myectomy is wider and includes the distal third of the right side of the septum. All attachments between the papillary muscles and septum are divided. After weaning from bypass, direct measurement of the pressure gradient and TEE is performed to evaluate the effectiveness of the myectomy. A resting mean gradient of <20 mmHg is acceptable (Dearani et al. 2005).

16.3.7 Discussion Subvalvular Obstruction

On the basis of the underlying physiology and morphology of a discrete subaortic membrane (Cape et al. 1997), any surgical treatment should, in addition to relieving the subaortic stenosis, address the anatomic abnormality causing increased septal shear stress (Serraf et al. 1999a, b). Discrete subvalvular aortic membrane can be cured in most patients by membranectomy accompanied by myectomy. Aggressive resection of all structures causing flow turbulence (anomalous septal insertion of the mitral valve, accessory mitral valve tissue, anomalous papillary muscle, anomalous muscular band, etc.) (Marasini et al. 2003) and removal of pathological tissue from the valve leaflets and from the subcommissural trigones may prevent development or progression of aortic regurgitation and may eliminate the substrate for recurrent obstruction. In patients without a myectomy, the left ventricle outflow tract gradient increased postoperatively at a greater rate than those with a myectomy (Barkhordarian et al. 2007). Early mortality is low, less than 5% with the survival rate above 90% at 15 years (Parry et al. 1999). Late mortality is influenced by anatomic factors, namely, by hypoplastic aortic anulus and concomitant mitral stenosis (Lupinetti et al. 1992; Parry et al. 1999). Freedom from reoperation is about 85% at 15 years. Recurrence of significant restenosis is associated with the immediate postoperative gradient across the left ventricle outflow tract ≥ 30 mm, with the mean delay for reappearance of a gradient leading to surgery approximately 4 years (Lupinetti et al. 1992; Rayburn et al. 1997). The mild or moderate aortic insufficiency preoperatively has a negative impact on the progression of aortic insufficiency postoperatively. Therefore, in the presence of aortic regurgitation, surgery is recommended regardless of gradient to prevent the development of aortic regurgitation or to improve aortic valve function (Parry et al. 1999; Brauner et al. 1997). Higher incidence of complete heart block reflects a too aggressive approach during extended, circumferential myectomy.

Tunnel or multilevel subaortic stenosis represents a more challenging cause of left ventricular outflow tract obstruction, occurring in isolation or in association with or secondary to correction

of complex congenital defects (double-outlet right ventricle, transposition of the great arteries, interruption of the aortic arch, complete atrioventricular canal, resection of subaortic membrane, etc. (Jonas et al. 1994; van Arsdell et al. 1995; Belli et al. 1996). Ideally, relief of left ventricular obstruction should allow preservation of the aortic valve function, allow for growth of the aortic valve, and lessen the possibility of a subsequent operation. The size and function of the aortic valve determine the appropriate surgical technique. In isolated, simple forms, with a normal aortic valve, extended myectomy may be effective.

In complex forms with a normal aortic valve, the modified Konno procedure is effective for the relief of diffuse subvalvular aortic stenosis and can safely be performed in infants and children. The risk of damaging the conduction tissue is minimal (Jahangiri et al. 2000). Children with multilevel left ventricular outflow tract obstruction consisting of subaortic narrowing and aortic valve stenosis may require initial palliation to relieve the critical level of obstruction. This may involve open/balloon aortic valvotomy, and/or subaortic membrane and muscle resection. Often this initial approach will achieve medium-term clinical improvement despite some degree of residual stenosis or insufficiency avoiding a more extensive operation in the first years of life. If enlargement of the aortic root and aortic valve replacement is indicated to relieve the obstruction, the Konno or Ross-Konno operations should be considered.

The anterior aortoventriculoplasty described by Konno and Rastan (Konno et al. 1975; Rastan and Kaney 1976) addresses all levels of left ventricle outflow tract obstruction and is associated with a significant decline in left ventricle outflow tract gradient, stabilization of left ventricular function, and improvement in functional class. Operative mortality for this procedure has declined over the last two decades to less than 10%, with survival at 10 years close to 90% (Suri et al. 2006). The operation is designed to offer definitive correction of complex left ventricle outflow tract obstruction, but in children the hazard phase for aortic reoperation is constant, with the 10-year survival rate, free of reoperation, approximately 60–80% (Suri et al. 2006; Erez et al. 2002). Apart from thrombosis and endocarditis, the reoperative risk is related either to prosthesis obstruction by pannus or to patient-

prosthetic mismatches occurring with somatic growth. Pannus formation is particularly likely to cause problems in patients, who bear small prostheses. Unfortunately, adequately sized valves suited to patients' body size do not eliminate the risk of pannus ingrowth, due to children's ability to create pseudointima far more than adults. Careful attention should be given to maximizing the prosthesis effective orifice area according to patient size without posing the additional risk of compromising the native pulmonary anulus, impinging on the pulmonary valve or the right coronary. Only an adult size prosthesis (21 mm or larger) should be inserted; otherwise patient-prosthesis mismatch will inevitably develop, resulting in aortic stenosis even in the presence of a normally functioning valve. There is a non-trivial risk of pulmonary complications after the Konno procedure related to an initial injury to the pulmonary valve, disruption of the muscular subpulmonary conus, or distortion of the pulmonary anulus by the right ventricular patch. The pulmonary valve is quite exposed to injury during the procedure because of the very limited space between the right coronary ostia and the lateral commissure of the aortic valve. In an effort to avoid injury to the coronary ostia, the surgeon places his anular transecting incision as close to the commissure as possible, risking damaging the pulmonary valve. Another problem seen with the Konno procedure is development of complete heart block with an incidence of about 10% (De Vivie et al. 1993). The recovery of ventricular function after the Konno procedure is analogous to that seen after aortic valve replacement alone (Sharma et al. 2004). The Konno procedure in children is an effective option for enlargement of the left ventricular outflow tract in the face of multilevel obstruction, but morbidity tends to be higher compared with the Ross-Konno operation. If adult size prosthesis cannot be implanted, the Konno procedure should not be considered.

The Ross-Konno procedure is an excellent technique to treat complex multilevel left ventricular outflow tract obstruction even in neonates and infants with significant anular and subanular hypoplasia (Hraska et al. 2010).

Recently, the Ross-Konno procedure has found application in patients with an interrupted aortic arch as the initial procedure or after primary repair in patients with a severely restricted

subaortic area, hypoplastic aortic anulus, and bicuspid valve. The Ross-Konno procedure increases our therapeutic choices for neonates or infants with critical aortic stenosis who show unacceptable results following open valvotomy or balloon valvotomy. Some newborns with critical aortic stenosis, a hypoplastic aortic anulus, and significant endocardial fibroelastosis can be effectively treated with the Ross-Konno procedure and resection of endocardial fibroelastosis, thus avoiding single-ventricular palliation (Aszyk et al. 2012).

The Ross-Konno procedure allows easy access to the left ventricular myocardium for resection of endocardial fibroelastosis, normalizing the left ventricular outflow tract and the long axis of the left ventricle.

The type of enlargement of the left ventricular outflow tract depends on the presence of a significant ventricular septal defect or on the magnitude of discrepancy of the aortic valve and pulmonary artery size. If a significant ventricular septal defect is present, the incision of the conal septum is extended toward the ventricular septal defect, and patch closure of the ventricular septal defect provides outflow tract enlargement prior to the autograft implantation. If there is primary muscular obstruction, the ventriculoplasty incision is patched by an extension of attached infundibular free wall muscle harvested with the autograft. Occasionally, in very small babies, the thickness of the right ventricular muscle can restrict inflow through the tricuspid valve or cause recurrent outflow obstruction beneath the autograft. In these patients, patch enlargement of the left ventricular outflow tract is preferable. If there is a significant mismatch between the pulmonary anulus and a truly hypoplastic aortic anulus (≤ 4 mm in \varnothing), excision and reimplantation of the coronary ostia can be more difficult since extensive enlargement of the aortic anulus is necessary and the coronary arteries are close together. Often there is associated severe arch hypoplasia, coarctation, and a ventricular septal defect. In these patients, a modified Norwood type of repair with Rastelli modification and baffling of the ventricular septal defect to the pulmonary valve is simpler, although ventricular septal defect enlargement should be performed in all cases to prevent development of a restrictive pathway to the pulmonary artery (Serraf et al. 1999a, b). The Ross-Konno procedure can be

accomplished with mortality less than 5% and low morbidity (Hraška et al. 2010).

Early complications are especially related to malignant arrhythmias (nonsustained ventricular tachycardia, nonsustained supraventricular tachycardia, etc.). The incidence of complete heart block varies from 0 to 6% (Marino et al. 1999). The freedom from reoperation is between 60 and 70% at 5 years, being less favorable for small children due to earlier homograft failure. The choice of conduit appeared to impact the need for replacement. The aortic homograft rather than pulmonary homograft and smaller homograft size are factors adversely affecting homograft longevity. The policy is to place the largest pulmonary homograft possible at the time of procedure.

There are disadvantages of the Ross-Konno procedure as well. The nature of the operation places two valves at risk for single-valve disease. However, many pediatric patients are not candidates for a Konno operation because of anatomic considerations and the lack of readily available, appropriately sized prostheses. Particularly in the growing pediatric patient, the need for pulmonary conduit replacement is high. Replacement of a pulmonary conduit is, however, less difficult than repeated aortic root replacement. Other concerns regarding the use of the Ross-Konno procedure in children include the uncertain long-term outcome of the pulmonary autograft in the aortic position. The pulmonary autograft demonstrates durability without developing aortic stenosis, aortic insufficiency, or progressive dilatation. Enlargement of the aortic anulus parallels somatic growth. However, it is unclear whether use of the Ross-Konno procedure at an earlier age alters the natural history of complex left ventricular outflow tract disease. It is also not known if the risk of late reoperation on the neo-aortic valve is higher, if performed in the neonate, infant, or child because of aortic root sinus dilation and valve distortion over time. Based on experience from arterial switch operations for transposition of the great arteries, the neonatal pulmonary valve might rapidly be able to adapt to the aortic position. Long-term changes in left ventricular mechanics await further study. Despite the technically demanding nature of the operation, the Ross-Konno procedure is the method of choice for the multilevel type of left ventricle outflow tract obstruction, especially in

newborns and infants (Marino et al. 1999; Ohye et al. 2001; Hraska et al. 2004, 2010; Brown et al. 2006; Aszyk et al. 2012).

Isolated left ventricular septal myectomy provides excellent outcomes for symptomatic patients with severe obstructive hypertrophic cardiomyopathy. After surgery, significant and persistent improvement in symptoms and exercise capacity can be expected. The operation is performed with low operative mortality (reported to be 1–3% and even less in the most recent cases) in patients of all ages, including children, at those centers which have the most experience with this procedure. Surgical risk may be higher in patients with a prior myectomy, or those undergoing additional cardiac surgical procedures. Complications such as complete heart block (requiring a permanent pacemaker) and iatrogenic ventricular septal perforation have become uncommon (equal to or less than 1–2%), while partial or complete left bundle-branch block is an inevitable consequence of the muscular resection and is not associated with adverse sequelae. Intraoperative guidance with echocardiography (transesophageal or with the transducer applied directly to the right ventricular surface) is standard and is useful in assessing the site and extent of the proposed myectomy, the structural features of the mitral valve, and the effect of muscular resection on systolic anterior movement of mitral valve and mitral regurgitation (Maron et al. 2003). The incidence of recurrent left ventricular outflow tract gradient is less than 5%. Recurrent obstruction is associated with limited myectomy at the initial operation, midventricular obstruction, anomalies of papillary muscles, and ventricular remodeling. The recurrence rate of left ventricular outflow tract obstruction after successful myectomy in pediatric patients is higher (Theodoro et al. 1996). Technically, the extended septal resection might be compromised by the small size of the aorta and limited visibility of the midventricular region. Left ventricular remodeling, such as changes in wall thickness and reduction of cavity size, might be another explanation for the increased need for reoperation in pediatric patients (Maron and Spirito 1998). A repeat myectomy can be performed with excellent outcomes. Mitral valve replacement (in the absence of intrinsic mitral valve disease), even in the presence of a relatively thin ventricular septum, is not recommended. Carefully performed surgical septal reduction is the preferred method. The need for reoperation may be reduced with current surgi-

cal approaches that include a more extended resection of the midventricular septum, relief of papillary muscle anomalies, and routine use of intraoperative transesophageal echocardiography.

16.4 Supravalvular Aortic Stenosis

16.4.1 Introduction

Supravalvular aortic stenosis is a complex anomaly of the entire aortic root with predominant stenosis at the sinotubular junction. This represents the least common form of left ventricular outflow tract obstruction and occurs in about 5–8% of patients (Samanek et al. 1989). The underlying cause of congenital supravalvular aortic stenosis is a loss-of-function mutation of the elastin gene on chromosome 7q11.23 (Keating 1995). In patients with Williams syndrome, the elastin gene is deleted or disrupted together with a number of neighboring genes that probably are important for the other features of the syndrome (elfin-face, mild mental retardation, hypercalcemia) (Nickerson et al. 1995), whereas in patients with familial, non-Williams supravalvular aortic stenosis, the elastin gene only is subjected to a loss-of-function translocation or point mutation (Chowdhury and Reardon 1999). Patients with «sporadic» supravalvular aortic stenosis are either members of a family carrying an elastin gene mutation with a subclinical phenotype, or carrying the elastin gene defect as a new mutation (Keating 1995). The resulting decrease in elastin expression during development is associated with an increased number of elastin lamellae and excessive accumulation of collagen and smooth muscle cells in the vascular wall, resulting in formation of severely thickened and rigid arterial vessels (Li et al. 1998; O'Connor et al. 1985). Elastin arteriopathy is not a localized process but rather a generalized disease of both the systemic and pulmonary arterial systems (Stamm et al. 1997, 2001).

16.4.2 Anatomy

Supravalvular aortic stenosis is categorized broadly as either diffused (23%) or localized (77%). In the localized type, there is a severe narrowing of the sinotubular ridge. The outer diameter of the aorta may be normal or reduced, giving an hourglass appearance to the ascending

aorta. The coronary arteries may be either dilated due to the high systolic pressure proximal to the sinotubular junction or stenotic because of the thickening of the wall of the sinuses of Valsalva, or they develop atherosclerosis. On occasion, the free edge of the aortic valve cusps almost completely adheres to the sinotubular junction, effectively isolating the coronary artery from the sinus of Valsalva and the lumen of the aorta. Abnormalities of the aortic valve are present nearly in half of the cases. Thickening of the aortic cusps and aortic insufficiency due to the high systolic pressure and bicuspid aortic valve is most commonly presented (Stamm et al. 1997; van Son et al. 1994b). In the diffuse form, the entire ascending aorta and the brachiocephalic vessels may be thickened, with narrowed lumen. There may be supravalvular narrowing of the main pulmonary artery and central and peripheral pulmonary artery stenosis.

16.4.3 Pathophysiology

The basic pathophysiology of supravalvular aortic stenosis is similar to other types of congenital aortic stenosis. Left ventricular hypertrophy and ischemic myocardial damage due to coronary ostial stenoses, decreased blood flow into the coronary sinuses, or hypertension-related coronary arteriosclerosis may present in early childhood and accelerate with age (van Son et al. 1994b). The risk of sudden death secondary to myocardial hypoperfusion and subsequent fibrillation is higher in comparison with other forms of left ventricular outflow tract obstruction (van Son et al. 1994a). In case of pulmonary artery stenosis, right ventricular hypertension and hypertrophy develop.

16.4.4 Clinical Presentation and Diagnosis

The disease occurs as an isolated defect or as a part of William's syndrome in association with mental retardation, elfin facies, failure to thrive, and occasionally infantile hypercalcemia (Williams et al. 1961). The clinical appearance corresponds to other forms of left ventricular outflow tract obstruction. Limited capacity, syncope, and angina symptoms may increase during the course and may be associated with detectable myocardial ischemia or heart failure.

While echocardiography is diagnostic in many cases, it may be inadequate as the only diagnostic tool in more complex forms of supravalvular aortic stenosis with involvement of the aorta, the aortic arch, and head vessels. In order to clarify the anatomy in any complex form of supravalvular aortic stenosis and to delineate any existing branch pulmonary artery stenosis, cardiac catheterization and angiography are indicated. If there is evidence for an obstruction of the coronary ostia, coronary angiography should be performed with great care. Magnetic resonance imaging may possibly also represent an attractive alternative to invasive angiography.

16.4.5 Indications for Surgery

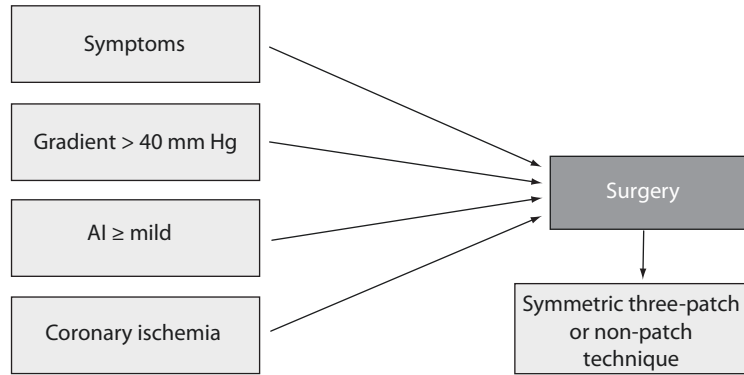

An unfavorable natural history due to accelerated coronary artery atherosclerosis, damage of the aortic valve, and the high risk of sudden death is a reasonable argument for proceeding with early surgery, before the left ventricular hypertrophy has become severe.

A peak Doppler gradient above 40 mmHg, aortic insufficiency, and signs of compromised coronary artery blood flow are indications for surgery (■ Fig. 16.19).

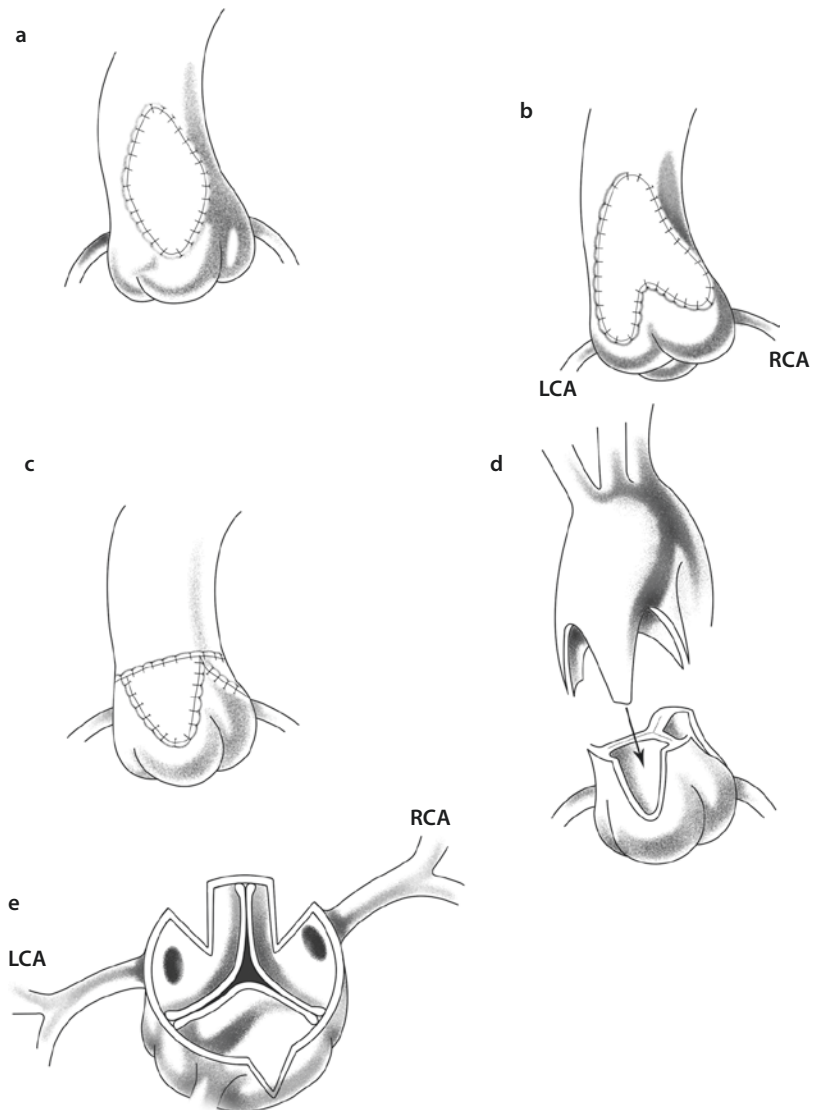

16.4.6 Surgical Management: Symmetric Restoration of Distorted Aortic Root

A single, asymmetric patch technique (■ Fig. 16.20a), enlarging only the noncoronary sinus in conjunction with resection of the stenotic ridge, does not address the constriction of the thickened aortic wall at the level of the cusp hinge point. This original method is rarely used any more. Currently, the preferred method is the symmetric anatomic restoration of the aortic root addressing all involved sinuses of Valsalva. The risk of developing postoperative aortic regurgitation is minimal despite the significant enlargement of the diameter of the sinotubular junction. All techniques require a cardiopulmonary bypass with cardioplegic arrest of the heart. Deep hypothermia with circulatory arrest and, alternatively, hypothermic low-flow bypass with direct perfusion of the brachiocephalic vessels are used for diffuse forms where reconstruction of the aortic arch or origins of the head vessels is required.

■ **Fig. 16.19** Treatment protocol for supravalvular aortic stenosis at the German Pediatric Heart Center, Sankt Augustin. *AI* aortic valve insufficiency

■ **Fig. 16.20** Surgical techniques to correct supravalvular aortic stenosis. **a** Enlargement of the noncoronary sinus by a diamond-shaped patch. **b** Insertion of an inverted bifurcated patch with enlargement of the right sinus and noncoronary sinus (Doty plastic). **c** Transection of the ascending aorta and extending all the sinuses using patch and reanastomosis of the aorta (Brom technique). **d** Transection of the ascending aorta, incision of all sinuses and the commissures of the aortic valve complementary ascending aorta, and direct reanastomosis. **e** Incisions performed into the aortic root relative to coronary arteries for both Brom and tri-sinus Doty techniques. *LCA* left coronary artery, *RCA* right coronary artery

16.4.6.1 Inverted Bifurcated Patch

An inverted Y-shaped vertical incision is made into the aorta (■ Fig. 16.20b), extending to the noncoronary and right coronary sinus and crossing the thickened sinotubular ridge. It is important to stay away from the origin of the right coronary artery to prevent any problems with the suturing of the patch in close proximity to the coronary ostium. An inverted bifurcated patch made of autologous or bovine pericardium is trimmed. The goal is to create bulging new sinuses of Valsalva. The tips of the patch are placed into the apex of each incision, near the hinge point of the aortic valve. The patch is sutured into the anterior sinuses of Valsalva and the remaining ascending aorta (Doty et al. 1977).

Doty later developed the bifurcated three sinus technique by incising all three sinuses and using one part of the patch bifurcation as enlargement of the noncoronary sinus as before, while the other patch «leg» not only enlarges the right coronary sinus to the left of the right coronary ostium but enlarges also the left coronary sinus to the left of the left coronary ostium. This is achieved by suturing the right/left coronary commissure to the inner side of the left patch «leg,» similar as suggested later for all commissures in the David technique for aortic valve reconstruction (Doty 1985).

16.4.6.2 Symmetric Three-Patch Technique

In the case of extensive narrowing of the left coronary sinus, a three-patch technique is preferable (■ Fig. 16.20c). The aorta is transected immediately above the level of the commissures. Vertical incisions are made into each of the three sinuses, staying away from the origin of the coronaries. Three teardrop-shaped patches from the pericardium are sutured into each of the sinuses of Valsalva. The ascending aorta is opened longitudinally on its anterior surface. An anterior patch is used to supplement this aortotomy, enlarging the reanastomosis of the ascending aorta (Brom 1988). It is important that the patches are not too broad, because this may result in commissural splaying with valvular insufficiency (Hraška and Murin 2012).

16.4.6.3 Symmetric Reconstruction Technique Without a Patch

The aorta is transected at the narrowest point above the commissures (■ Fig. 16.20d). Any thickened area on the distal aorta is excised. Three vertical incisions are made into each sinus of Valsalva, similar to those in a three-patch technique. Care is

taken to stay away from the coronary ostia; thus the incisions are made off-center of the sinuses (■ Fig. 16.20e). Three complementary vertical incisions are made in the distal aorta, out of phase with the proximal incisions. This allows interdigitation of the proximal and distal flaps when the aorta is reanastomosed. A zigzag anastomosis enlarges the aortic root without the use of prosthetic material (Myers et al. 1993; Hraška and Murin 2012).

16.4.6.4 Diffuse Forms

In the diffuse form of supravalvular aortic stenosis, the aortic enlargement should be extended into the ascending aorta or beyond as required, to relieve the gradient. The pericardial patch is inserted along the entire ascending aorta and the undersurface of the aortic arch distal to the left of the subclavian artery whenever a significant degree of hypoplasia is suspected. In many cases of diffuse supravalvular aortic stenosis, the origins of the supra-aortic vessels are also stenotic, exposing the patients to the risk of cerebral ischemia. Patch enlargement of the proximal branch arteries should be performed in association with augmentation of the aortic arch (Pretre et al. 1999). In some patients, complex tube graft constructions bypassing the aortic arch (ascending-descending aortic conduit), with additional grafts supplying the supra-aortic branches, could be effective (see ► Chap. 19).

16.4.7 Discussion: Supravalvular Aortic Stenosis

Congenital supravalvular aortic stenosis is not a simple lesion. The underlying elastin arteriopathy is a generalized disease of both the pulmonary and systemic arteries. Furthermore, the «supravalvular» stenosis has profound effects on the architecture and function of the aortic valve itself. In addition to left ventricular pressure overload, there is always a risk of myocardial ischemia due to coronary hypertension and premature arteriosclerosis, or obstruction to coronary blood flow as part of the aortic root malformation. Indication for operation and surgical treatment strategies must take all these features into account, so that an optimal long-term outcome can be achieved (Stamm et al. 1997, 2001). Optimal surgical management should strive for preservation and restoration of the aortic valve and root, rather than simply for relief of the

supravalvular stenosis. The more symmetric reconstructions of the aortic root with three-sinus reconstructions result in superior hemodynamics, a more physiological flow pattern, and they are associated with a lower mortality rate and fewer reoperations than only augmentation of the non-coronary sinus. To avoid aortic regurgitation due to oversizing of the reconstructed sinuses, the appropriate patch size can be calculated based on the age-normalized circumference of the aortic root, but in most cases, it is sufficient to use the circumference of the distal aortic end as a guideline (Stamm et al. 1999, 2001; Hazekamp et al. 1999). Management of abnormalities of the aortic valve, the subaortic region, and the coronary arteries is critical to the long-term outcome of these patients (McElhinney et al. 2000). Involvement of the aortic valve, including stenosis or an abnormal number of cusps, is presented in one-third of patients with supravalvular aortic stenosis. Degenerative changes in the valve are common, most probably due to abnormal stresses on and restriction of the cusps in the setting of impaired distensibility of the sinotubular junction (Braunstein et al. 1990). Reconstruction of the valve is the preferable method of treatment. The Ross procedure is the method of choice, if aortic valve replacement is indicated.

Stenosis or atresia of a coronary ostium and proximal coronary artery may occur, necessitating either ostial endarterectomy, patch enlargement of coronary ostial stenoses, or coronary bypass grafting (Martin et al. 1988). Early surgical intervention is indicated to prevent accelerated coronary artery disease, its detrimental ischemic effects on the myocardium, and dissection of the ascending aorta or coronary arteries (van Son et al. 1994b). Any obstruction to coronary blood flow should be identified preoperatively, and patency of both coronary arteries should be confirmed by intraoperative probing in every case.

In diffuse supravalvular aortic stenosis, aortic enlargement and extensive endarterectomy should be extended into the ascending aorta or beyond as required, to relieve the gradient. The long-term survival of patients with diffuse supravalvular aortic stenosis is similar to that of patients with the discrete form, although the operative risk is increased (Stamm et al. 1999). A number of patients with William's syndrome or other forms of elastin arteriopathy have stenoses of the pulmonary arteries in addition to supravalvular aortic stenosis. Surgical

treatment of pulmonary artery obstructions, with a pericardial patch placed throughout both pulmonary arteries from the right to the left hilum, offers a good long-term outcome. In patients with generalized obstructive arteriopathy with systemic and pulmonary artery stenoses and suprasystemic right ventricular pressure, preoperative dilation of peripheral and central pulmonary artery stenoses should be considered to decrease the right ventricle pressure load prior to the ischemic insult of surgical repair of supravalvular aortic stenosis (Stamm et al. 2000). The severe thickening of the arterial wall in infradiaphragmatic arteries and localized stenoses of mesenteric and renal arteries have been reported in up to 30% of the patients with supravalvular aortic stenosis (Zalstein et al. 1991; Rein et al. 1993). It is important to diagnose concomitant stenoses prior to surgery for supravalvular aortic stenosis, so that the consequences of peri- and postoperative hypoperfusion of the abdominal organs can be minimized (Stamm et al. 2001). Severe generalized arterial forms and associated aortic valve disease are correlated with late death and the need for reoperation. The long-term survival rate is between 70 and 97% and freedom from reoperation is above 65% at 20 years, respectively. Reoperations are more due to aortic valve problems than progressive supra-aortic stenosis. The patient's quality of life is generally good, with the majority of patients in the New York Heart Association functional class I (van Son et al. 1994a; Stamm et al. 1999; Hazekamp et al. 1999; Brown et al. 2002).

16.5 Sinus Valsalva Aneurysm

16.5.1 Introduction and Anatomy

The sinus of Valsalva is defined as that portion of the aortic root between the aortic valve anulus and the sinotubular ridge. The sinus wall of the aorta is thinner than the distal aorta and is therefore subject to various anomalies, the most common being aneurysm of sinus Valsalva.

The term «sinus of Valsalva aneurysm» should not be mistakenly used for what is called an aortic root aneurysm, for example, in Marfan syndrome, or as part of any other acquired multianeurysmal aortic disease (see ► Chapters «Acquired Lesions of the Aortic Valve», Sect. 24.3.1 and «Aneurysm and Dissection of the Thoracic and Thoracoabdominal Aorta», Sect. 27.2.2).

Sinus of Valsalva aneurysms are thin-walled outpouchings usually protruding into adjacent cardiac chambers via either a direct connection or a «windsock» tract that extends from the ventricular-aortic junction. Because the sinuses are partially intracardially located, their topographical relationship to the neighboring structures influences the direction, the extension, and the location of the threatened perforation (■ Fig. 16.21).

Aneurysms may be congenital or acquired and are histologically characterized by the absence of the elastic lamellae of the aortic media (Edwards and Burchell 1957). In majority of all patients, congenital aneurysms of sinus Valsalva originate in the right sinus and perforate into the right ventricle or originate in the right half of the noncoronary sinus and perforate into the right atrium. The aneurysms of the left sinus are extremely rare, but can perforate into the pericardial sac or left atrium. Alternatively, aneurysms which develop from the anterior part of the left sinus can compress the left coronary artery. They can also perforate into the pulmonary artery.

Approximately half of patients with aneurysm of sinus Valsalva have associated defects. The most common, especially in Asian population, is ventricular septal defect, aortic regurgitation, and bicuspid aortic valve (Chu et al. 1990).

Sinus of Valsalva aneurysms may also result from aortic valve endocarditis, atherosclerosis, deceleration trauma, or connective tissue disorders, such as Marfan syndrome and Ehlers-Danlos syndrome (Harkness et al. 2005).

■ Fig. 16.21 Position of the aortic sinus in relationship to the cavities of the heart. Perforation of an aneurysm originating from the right sinus penetrating into the right atrium

16.5.2 Pathophysiology and Clinical Diagnosis

Pathophysiology reflects either the location of perforation or compression of surrounding structures or both. Typically the aneurysm of sinus Valsalva ruptures into the low-pressure chamber and left to right shunt develops. Compression of coronaries by aneurysms causes ischemic symptoms, arrhythmias, or an infarct.

Extracardiac perforation, typically seen in acquired aneurysm of sinus Valsalva, leads to acute, usually fatal cardiac tamponade (Brabham and Roberts 1990).

Most patients are asymptomatic until rupture occurs. Rupture may happen any time but is more likely in young adulthood than in childhood. Additionally, intense physical activity can cause rupture of an existing aneurysms (Ferreira et al. 1996).

Rupture of an aneurysm can remain unnoticed, if the perforation is small. A massive perforation, especially in the right atrium is accompanied by an acute syndrome (dyspnea, stenocardia, constant cardiac murmurs) which can later lead to acute decompensation.

It is not unusual for bacterial endocarditis to develop in the further course of the illness.

ECHO reliably identifies involved sinuses, degree of aortic regurgitation, and the chamber into which the perforation occurs or associated lesions such as ventricular septal defect. Catheterization is rarely indicated, unless signs of ischemia are present. Magnetic resonance imaging is highly effective for identifying aneurysms of sinus of Valsalva (Parissis et al. 2004).

16.5.3 Indications for Surgery

The perforation of aneurysms is an indication for surgery no matter of symptoms to minimize further development of left to right shunt and congestive heart failure. There may be an emergency indication for surgery.

Surgery is electively indicated even for unruptured, asymptomatic aneurysm of sinus Valsalva to prevent the numerous complications associated with progressive development of this lesion. Tamponade is a true emergency.

Guidelines for surgical intervention are less clear for simple dilatation of aortic root. When

severe dilatation of aortic root creates aortic regurgitation due to splaying of the leaflets, the same recommendations for surgical intervention as for the aortic regurgitation are applied (see ► Sect. 16.2.4).

Another indication for surgery is the size of aortic root. The risk of rupture as a function of aortic diameter is significant, if aortic root exceed 5 cm. The threshold is lower when there is a family history of dissection. These indication criteria for surgery developed for adults are applied for children as well. However, relative aortic size taking into account the body surface area is more important than absolute aortic size in predicting the risk of rupture and complications. Therefore, smaller patients may benefit from operative repair at even smaller sizes of aortic root (Coady et al. 1997; Davies et al. 2006).

16.5.4 Surgical Correction

The operation is performed through median sternotomy on cardiopulmonary bypass with mild hypothermia (32 °C) and standard aortic and bicaval cannulation. Left atrial vent is placed through the right upper pulmonary vein/interatrial groove. The aortic cross-clamp is applied, and cardioplegia is delivered either directly to coronary ostium or via the coronary sinus. Aortic root cardioplegia with digital compression of fistula is not reliable. Transverse aortotomy and right atriotomy are performed. The fistula should be closed at both ends. The defect is identified from aorta first. Subsequently, the downstream end of fistula is approached through the right atrium. At the aortic end, the larger defects should be patched (glutaraldehyde-fixed pericardium or prosthetic material), small defects might be directly sutured. Care is taken not to distort geometry of aortic cusps and anulus. The atrial or ventricular end often has aneurysmal tissue that should be debrided, and the base of the defect is then oversewn. Care is taken to avoid injury to the atrioventricular node, if there is perforation from noncoronary sinus to the right atrium.

Nonruptured aneurysms involving the right or noncoronary sinus with extensive penetration into the adjacent chambers are repaired through the aorta and the chamber of penetration. Right atrial or transpulmonary exposures are usually sufficient to approach any aneurysmal sac. The sac is opened and resected. Primary sinus defect is

closed with the patch and reinforced with a separate patch through the chamber of penetration.

Closure of associated ventricular septal defect should be performed through right side with the separate patch.

Intraoperative TEE is strongly recommended for evaluation of aortic valve, associated anomalies, and residual fistulous communications.

If moderate aortic regurgitation is present, the principles and guidelines of aortic valve surgery elaborated in ► Sect. 16.2.6, «Complex reconstruction» are applied. All valve procedures should be performed after the aneurysm of sinus of Valsalva is repaired.

Different techniques such as aortic root replacement with composite graft and by autograft or valve-sparing root replacement are used if dilatation of aortic root with aortic regurgitation is present (see ► Sect. 16.2.6).

16.5.5 Discussion

Congenital aneurysm of the sinus of Valsalva is a rare defect of the aortic root. Apart from the acute tamponade which is usually lethal, surgical treatment of ruptured aneurysm of Valsalva is highly successful. In the absence of complicating factors such as endocarditis, the results of surgical repair are excellent with mortality approaching zero (Takach et al. 1999; Lukacs et al. 1992; Quiang et al. 1994) and 10-year survival close to 100% (van Son et al. 1994c). Late complications with progressive aortic valve insufficiency are more common when the patch is not used for repair or when there is bicuspid aortic valve (Quiang et al. 1994).

The natural history of unruptured sinus of Valsalva aneurysm is unknown because most of these lesions are asymptomatic and undetected. Numerous complications such as myocardial infarction, complete heart block, malignant arrhythmias, endocarditis, progressive enlargement, and sudden death due to rupture of not repaired aneurysms of sinus Valsalva have been described. Surgery is safe and effective; therefore, it is indicated even in asymptomatic patients at the time of diagnosis.

The optimal technique for dealing with sinus dilatation in patients with Marfan syndrome or other degenerative connective tissue diseases of the aortic root remains controversial. If there is no concern about significant aortic valve disease or

aortic insufficiency, the valve-sparing techniques are preferable. David operation may provide better support for the anulus and remaining aortic root tissue than Yacoub operation. Otherwise complete replacement of the aortic root with composite graft may be the best option.

16.6 Aortico-Left Ventricular Tunnel

16.6.1 Introduction and Anatomy

This very rare congenital heart disease represents an abnormal connection between the ascending aorta and the left ventricle. The tunnel originates in the aorta, in most cases just above the right coronary artery in the right coronary sinus of Valsalva, and passes down along the base of the aortic valve toward the left ventricle and enters the left ventricle immediately below the right coronary leaflet of the aortic valve. Rarely the tunnel may arise from the left coronary sinus or end in the right ventricle or left atrium. Tunnel bypassing the valve can compromise structural support of the right coronary sinus with development of aortic regurgitation. Aneurysmal dilatation of the intracardiac tunnel can cause subpulmonary obstruction by displacing the infundibular septum anteriorly. Rarely the coronary artery can arise from within the tunnel. Externally a bulge in the area of aortic root and the right ventricular infundibulum can be seen. Two anatomical types have been described: either a slit-like opening with no aortic distortion or large oval opening at the aortic end with or without aortic valve distortion predisposing to development of intracardiac and/or extracardiac aneurysm (Hovaquimian et al. 1988).

16.6.2 Pathophysiology and Clinical Diagnosis

Half of the patients present in early infancy with congestive heart failure caused by severe aortic insufficiency. Associated lesions such as aortic stenosis, aortic atresia, right ventricular outflow tract obstruction, and ventricular septal defect are rare but can modify clinical presentation (Waldner et al. 1996).

The ECG demonstrates the left ventricular hypertrophy, with left ventricular strain or

ischemia. ECHO and Doppler flow studies are highly reliable in estimating morphology, flow in the tunnel, and functional and morphometric parameters of the left ventricle. The presence of paravalvular regurgitation renders it difficult to evaluate the status of native aortic valve by ECHO. Catheterization is useful in identifying the coronary ostia.

16.6.3 Indications for Surgery

Symptomatic neonates and infants are operated on urgent or semi-urgent bases after a brief period of preoperative stabilization with medical after-load reduction therapy. In general the operation should be timed as early as possible after diagnosis of the defect, even when the communication is small to minimize secondary deterioration of the aortic valve.

16.6.4 Surgical Correction

The operation is performed on cardiopulmonary bypass with mild hypothermia (32 °C). The heart is approached through median sternotomy. After systemic heparinization, the patient is cannulated for cardiopulmonary bypass with a single, angled venous cannula in the right atrium and with an arterial cannula in the distal ascending aorta. The bypass is commenced, and the patent ductus arteriosus is ligated and a left atrial vent is placed. The aortic cross-clamp is applied soon, to avoid distention of left ventricle and to prevent subendocardial damage of myocardium. An oblique, inverted hockey stick type of incision is made from the anterior aspect of the aorta toward the noncoronary sinus of Valsalva. The cardioplegia is delivered directly to coronaries, or alternatively in retrograde fashion via coronary sinus. The ends of tunnel are identified above and below the valve and the aortic valve is carefully examined. Positions of coronary arteries ostia are noted. Both the aortic and ventricular ends of tunnel should be closed with separate patches of Dacron or pericardium using running suture technique. Ventricular end is approached through aortic valve or tunnel itself if injury to the conduction system is a concern. Approach through right atrium, pulmonary valve, or tunnel itself is used when the tunnel enters the right ventricle. A small

slit-like type of tunnel can be closed primarily, if distortion of the aortic valve can be avoided. Aortotomy is closed, left heart is de-aired, and the cross-clamp is released. Attention is paid to avoid the distention of left ventricle if aortic regurgitation is present. Weaning from bypass is conducted in standard fashion.

16.6.5 Discussion

Aortico-left ventricular tunnel remains a rare congenital cardiac anomaly, presenting with early cardiac failure due to severe aortic regurgitation. Echocardiography usually demonstrates the lesion. Surgery should be undertaken soon after diagnosis to prevent further deterioration of ventricular function.

The surgical mortality rate ranges between 11 and 20% in most series (Horváth et al. 1991; Turley et al. 1982). Patch closure of both ends of the tunnel is recommended to prevent aortic annulus and valve distortion, or even reopening of the tunnel. If ventricular end is left opened, blind chamber can develop from systolic inflow and pulsatility with aneurysm formation of the ventricular septum, which can distort the aortic valve and cause progressive aortic insufficiency. Progressive aortic regurgitation remains a potential long-term problem and seems to be more prevalent when initial operation is performed at an older age (Sreeram et al. 1991; Serino et al. 1983). The sufficient long-term outcome data are missing owing to the rarity of this lesion.

17.1 Cardiac Pathoanatomy

Aortic atresia is defined by a complete occlusion of the aortic valve and a hypoplastic ascending aorta. The isolated form with two normally developed ventricles is extremely rare and exclusively combined with a nonrestrictive ventricular septal defect and a normally developed mitral valve.

The term «hypoplastic left heart syndrome» was introduced by Noonan and Nadas in 1958. It describes a spectrum of malformations in which the left ventricle is unable to support the systemic circulation due to its size. In these cases, not only the left ventricle but also its adjacent structures, mitral valve, aortic valve, and ascending aorta, are severely hypoplastic. A combination of hypoplastic AV and semilunar valve features (mitral stenosis or atresia, aortic stenosis or atresia) defines the hypoplasia of the left ventricle and its adjacent structures.

Traditionally four subtypes are differentiated:

- Mitral atresia, aortic atresia
- Mitral hypoplasia/stenosis, aortic atresia
- Mitral atresia, aortic hypoplasia/stenosis
- Mitral hypoplasia/stenosis, aortic hypoplasia/stenosis

Further lesions leading to hypoplasia of the left ventricle during fetal live are:

- Critical aortic coarctation
- Asymmetric septation in unbalanced AV canal
- Straddling mitral valve
- Complex ventricular septal defect (VSD) and hypoplastic or interrupted aortic arch
- Multiple stenotic lesions in series in the left ventricular system (Shone syndrome)
- Isolated Severe Mitral Stenosis

Borderline cases without a primary valvular lesion were defined as hypoplastic left heart complex by C. Tchervenkov in 1998.

In hypoplastic left heart syndrome, the ascending aorta is usually very thin walled and fragile. Especially in aortic atresia with retrograde perfusion, functionally the hypoplastic ascending aorta can be looked at as a common coronary artery. A diameter of less than 2 mm is most frequent in these cases. If there is antegrade blood flow (aortic stenosis), it is usually bigger in diameter. Aortic arch and aortic isthmus may

also be hypoplastic, however, not as severely as the ascending aorta, as they receive the blood flow for the supra aortic vessels.

Pulmonary artery and ductus arteriosus are big and well developed. The septum primum is typically muscularized and thickened. Sometimes it is shifted toward the left atrium: atrial septum malposition. Without severe restriction at the level of the foramen ovale, the left atrium is smaller than the right one.

In most cases, the leading lesion is a valvular hypoplasia/obstruction either of the mitral or of the aortic valve. As a consequence of the reduced blood flow, growth of the left ventricle and its adjacent structures is reduced or had stopped at some stage. This has been proven in chicken embryos. By obstructing their mitral valve, hypoplastic left heart syndrome could be produced (Harh et al. 1973). The same process could be observed by fetal echocardiography in aortic stenosis in humans, originally described by L. Allan and coworkers at Guy's Hospital in London (Allan et al. 1989). They found a critical aortic stenosis with severely impaired left ventricular contractility in a fetus in the 22nd week of gestation. At 32 weeks of gestation, the ventricle was not grown but small and highly echogenic, as in typical hypoplastic left heart syndrome. Its dimensions were the same as in the 22nd week of gestation. Our group made the same observations in our fetal cardiac program. The hypothesis of a valvular lesion as the reason for ventricular hypoplasia is the basis for fetal valvular interventions. If such an intervention (balloon valvuloplasty) is done early, an otherwise lost ventricle could be rehabilitated (Makikallio et al. 2006)

This also explains that there is no strict cutoff line between critical aortic stenosis and hypoplastic left heart syndrome with a spectrum of borderline cases concerning the size of the left ventricle.

17.2 Extracardiac Malformations

Congenital cardiac malformations are frequently combined with extracardiac malformations. For hypoplastic left heart syndrome, rates reported are between 12 and 37%.

While one post mortem study shows an overall malformation rate in hypoplastic left

heart syndrome (HLHS) of 28% (Natowicz et al. 1988), in another autopsy series, cerebral malformations alone were found in 29% of patients. However, severe cerebral malformations like agenesis of the corpus callosum were seen only in 10% (Glauser et al. 1990). In more than half of the cases in Natowicz's series, genetic disorders were described either chromosomal anomalies or autosomal dominant or recessive lesions. Malformations of all organ systems are described. Among our own series of 233 patients with hypoplastic left heart syndrome, we saw one Goldenhar syndrome and one VACTERL syndrome. There was one case each of anal atresia, intestinal malrotation, growth retardation, and several kidney malformations. The overall malformation rate in our own series is 5.6% (unpublished data). Glauser's study also demonstrated that the risk for cerebral malformations is higher if hypoplastic left heart syndrome is part of a malformations syndrome. Among our own patients, there was one with agenesis of the corpus callosum.

17.3 Pathophysiologic Considerations

The principal problem is a ductus-dependent systemic circulation. This means antegrade blood flow in the ductus arteriosus – from the main pulmonary artery into the descending aorta and retrograde flow into the aortic arch and into the great cervical arteries as well as into the ascending aorta. In aortic atresia, the ascending aorta merely is a single coronary artery. The duct has to be kept patent on prostaglandin infusion preoperatively. In cases with aortic stenosis, there might be antegrade blood flow in the ascending aorta and in the proximal aortic arch. During diastole, blood runs from the aorta (systemic circulation) into the pulmonary arteries – diastolic runoff, like in a nonrestrictive aortopulmonary shunt. While pulmonary vascular resistance decreases, shunt volume increases and leads to pulmonary congestion and volume load of the right ventricle. Systemic diastolic blood pressure decreases and perfusion of the coronaries, brain, kidneys, and intestinal organs worsens. This increases the risk of cerebral injury and necrotizing enterocolitis.

17.4 Clinical Diagnosis

Nowadays, diagnosis of hypoplastic left heart syndrome is made almost exclusively by echocardiography alone. In many cases, diagnosis is made by echocardiography during fetal live. This is possible after the 16th week of gestation. Fetal diagnosis is extremely helpful for the newborn as emergency situations like ductal closure can be avoided. All aspects, which are important for the operation, can be seen echocardiographically, at best immediately after birth. Cardiac catheterization is required and justified only in exceptional cases. There may be a therapeutic indication, as in hybrid procedure. If the anatomy of the pulmonary veins cannot be completely clarified by echocardiography or in cases with borderline left ventricle, MRI may be helpful. The decision, whether a left ventricle and its mitral valve are suitable for biventricular repair, may be very difficult, especially in borderline cases of critical aortic stenosis. Different authors developed different criteria – usually morphologic criteria – for this decision (Rhodes et al. 1991).

Usually there is no problem with cardiopulmonary circulation during fetal period, except in the situation of an obstructive or near atretic foramen ovale. Newborns with hypoplastic left heart syndrome are generally of unremarkable appearance; sometimes a mild degree of cyanosis may be noticed. A systolic-diastolic murmur can be heard, due to the persisting ductus arteriosus. If there is no fetal diagnosis, the first symptoms may be severe metabolic acidosis, shock, and cardiovascular collapse due to ductal closure.

17.5 Preoperative Management

As the preoperative condition of the newborn with hypoplastic left heart syndrome is an important prognostic factor, postnatal preoperative treatment is very important (Tworetzky et al. 2001).

Preoperative management is based upon maintaining the ductus arteriosus patent. This is achieved by infusion of Prostaglandin E. A further goal is to avoid severe congestive heart failure due to nonrestrictive pulmonary blood flow secondary to decreasing pulmonary vascular resistance.

That means all pulmonary vasodilating agents should be avoided: no additional oxygen, no hyperventilation, and no intubation if tolerated. Vascular resistance in systemic circulation should be kept low: afterload reduction with sodium nitroprusside or other vasodilators. If possible, no vasopressors should be used. An optimal situation: The diagnosis is made during fetal life. The baby is delivered at or close to the tertiary center, where the operation is performed, so that no extensive transport is necessary. Intensive care treatment is started immediately after birth.

17.5.1 Timing of the Operation

This depends on the pathophysiology of an unrestrictive aortopulmonary shunt. If pulmonary overcirculation and decompensation of the systemic ventricle can be avoided, patients are operated around day 5 of life. If there are serious signs of congestive heart failure (fluid retention), the operation has to be scheduled earlier.

17.6 Operative Therapy

17.6.1 History and Principal Pathways

Since the early 1970s, case reports are published about successful palliation of hypoplastic left heart syndrome (Cayler et al. 1970; Doty and Knott 1977). Cayler and colleagues published a case of mitral atresia and aortic atresia, in which they did a successful palliation already in 1970. However in none of these early cases a Fontan procedure as a subsequent, more definite procedure could be performed. It was in 1982 at Children's Hospital Boston, when the first patient with hypoplastic left heart syndrome underwent a Fontan procedure. This patient had an initial palliation prior to the Fontan procedure, described by William I Norwood, his surgeon, as a stage I palliation (Norwood et al. 1980, 1983).

There are two principal pathways in surgical treatment of hypoplastic left heart syndrome:

- Multistage reconstruction
- Primary transplantation

Today in most centers, the reconstructive approach is the standard therapeutic pathway. The

final goal is the Fontan operation with a right ventricle as systemic ventricle. This goal, originally aimed at in two stages, nowadays is achieved by a staged palliation consisting of three operations:

- Stage I: Norwood procedure
- Stage II: bidirectional cavopulmonary anastomosis (modified Glenn anastomosis)
- Stage III: total cavopulmonary anastomosis (Fontan-type operation)

The Norwood procedure produces a balanced univentricular physiology with restricted pulmonary and unrestricted systemic blood flow. In stage II, the source of the pulmonary blood flow (Blalock-Taussig shunt or RV-PA conduit) is replaced by a bidirectional Glenn shunt at the age of 3–6 months. The completion to Fontan operation as stage III is achieved by connecting the inferior vena cava to the right pulmonary artery. As we use the extracardiac version of this procedure employing PTFE tube prosthesis, we usually perform stage III at the age of 2–3 years.

17.6.2 Stage I: Norwood Procedure

Hypoplastic left heart syndrome comprises univentricular hemodynamics with nonrestrictive pulmonary blood flow and ductus-dependent, potentially restrictive, systemic circulation. The goal of the Norwood procedure is a balanced univentricular physiology which is not dependent on a persisting ductus arteriosus.

It is based mainly on three principles:

1. Unrestricted flow from the right ventricle into the systemic circulation
2. Restrictive pulmonary blood flow (Blalock-Taussig shunt or RV-PA conduit)
3. Nonrestrictive pulmonary venous runoff to the tricuspid valve

17.6.2.1 Operative Technique

■ ■ Surgical access and dissection

A median sternotomy, slightly extended upward into the jugulum is used as access. The thymus is resected, leaving part of the cervical extensions in place. Right, left, and main pulmonary arteries are dissected. The right pulmonary artery is temporarily occluded by a tourniquet, thus reducing pulmonary blood flow, unloading the ventricle, and increasing the systemic blood pressure. The

aortic arch with the supraaortic branches and the first 10–15 mm of the descending aorta are dissected and mobilized, as well as the ductus arteriosus. Marking stitches are placed on the ascending aorta and the main pulmonary artery at the planned anastomotic sites to avoid distortion.

If it is planned to perfuse via the brachiocephalic trunk, it has to be decided whether this is done by direct cannulation or through a small PTFE tube prosthesis (Pigula et al. 1999). Heparin is now administered. In case prosthesis is used for cannulation, the end-to-side anastomosis between a 3.5 mm PTFE prosthesis and the brachiocephalic trunk is now performed.

17.6.2.2 Cardiopulmonary Bypass, Perfusion

■ ■ Deep hypothermic circulatory arrest

This is the classical form of extracorporeal circulation used for stage I palliation in this malformation. Cannulation is simple. Originally we placed a soft arterial cannula into the most distal part of the main pulmonary artery and a big solitary venous cannula into the right atrium. If this method is used, aortic arch reconstruction and atrioseptectomy are done in circulatory arrest. Even with enough training and exercise, one can get quickly into borderline duration of circulatory arrest and beyond the borders of safety. Therefore, we abandoned this method 13 years ago and introduced what we feel is a safer form of perfusion in these patients.

■ ■ Antegrade cerebral perfusion (regional low flow perfusion)

This method was introduced by Pigula and coworkers in 1999. Cannulation is done in the brachiocephalic artery, either directly or via a 3.5-mm PTFE prosthesis. A single venous cannula is put into the right atrium as usual. In our experience, cooling to a rectal temperature of 22 °C is enough (Hofer et al. 2005). During aortic arch reconstruction, flow is reduced to 30 ml/kg/min. The descending aorta is cross clamped and the cervical vessels are controlled by tourniquets. Circulatory arrest is necessary only for excision of the atrial septum.

■ ■ Moderate hypothermia and additional cannulation of the descending aorta (Imoto et al. 2001)

This method is used in our unit now for 10 years. Initial cannulation is performed as described

■ Fig 17.1 Arterial cannulation. First cannula: brachiocephalic truncus through PTFE prosthesis (PTFE polytetrafluorethylene). Second cannula: supradiaphragmatic descending aorta

above. Both pulmonary arteries are controlled by tourniquets. The posterior pericardium is incised, the left pleural space is opened, the inferior pulmonary ligament is divided, and the aorta is carefully dissected out. A second arterial cannula is brought into the supradiaphragmatic aorta (■ Fig. 17.1). Using this method of perfusion, cooling to a rectal temperature of 25 °C is enough.

The ductus arteriosus is closed with a typical purse string suture at the aortic side. At the pulmonary artery end, it is excised completely and sewn over transversely to the left pulmonary artery.

The main pulmonary artery is divided close to its bifurcation. As we have seen kinking in some cases due to excess length of the pulmonary arteries, we don't use a patch for closing the main pulmonary artery. We perform direct closure by a suture line exactly transverse to the right and left pulmonary artery.

■ ■ Cardioplegia

Brachiocephalic artery, left common carotid artery, and left subclavian artery are occluded by tourniquets. The descending aorta is cross clamped with an atraumatic vascular clamp. The residual stump of the ductus arteriosus is excised. Aortic arch and superior part of the ascending aorta are incised longitudinally at the concave side of the arch up to a level of 6–7 mm superior to the marked anastomotic site. Cold crystalloid cardioplegic solution is administered via a small olive shaped cannula. After that, the incision is continued to the anastomotic site.

■ ■ Reconstruction of the aortic arch

When excising the residual ductal stump, attention must be drawn not to leave any ductal tissue at this level, which is usually seen as a rim on the opposite side of the ductus. If there is any rim, the whole isthmus should be resected and the continuity of the aorta is reestablished by a typical extended end-to-end anastomosis between the incised distal part of the aortic arch and the descending aorta. After almost completing the anastomosis posteriorly, the incision in the arch should be extended for about 5–10 mm into the descending aorta (■ Fig. 17.2).

■ ■ Anastomosis between the pulmonary artery and aorta

If the ascending aorta is of sufficient size and if a good sized anastomosis between descending aorta and distal arch has been performed, a direct anastomosis between the aorta and pulmonary artery can be done. However one has to pay attention not to compress the pulmonary artery that is underneath the aorta and above the left bronchus. Compression of the pulmonary artery is a very unfavorable situation, which has a considerable negative influence on short- and long-term prognosis of the patient. So if there is any doubt about space for the pulmonary artery, a patch should be used (■ Fig. 17.3).

■ ■ Patch material and shape

The goal of the reconstruction is a symmetrically curved arch without any kinking, a so-called roman arch. Some important technical aspects must be considered:

- The patch must not be too long, especially on its concavity. Otherwise this would result in kinking and «gothic deformation.»

■ Fig. 17.2 Extended end-to-end anastomosis between aortic arch and descending aorta; incision extended into the descending aorta

- As the aortic arch forms a curvature of 180°, the patch has to be naturally curved in two planes: cross section and longitudinal section.

The best patch material, fulfilling these criteria, is the right-sided part of a pulmonary artery homograft bifurcation and its adjacent parts of the main and right pulmonary arteries (■ Fig. 17.4). Alternatively, there is a PTFE prosthesis available, which has a curved and trumpet formed distal end. From this prosthesis, a similar looking patch can be cut out and used for aortic arch reconstruction. We have used this in more than 40 cases with excellent anatomic results. We don't use aortic arch homografts, as they calcify heavily, due to their huge amount of elastic fibers. The patch is inserted with 6/0 non-absorbable monofilament material. If a PTFE patch is used, it is sewn in with a PTFE thread.

More recently, Emile Bacha in New York and James Tweddell in Milwaukee started to employ

■ Fig. 17.3 Aortic arch reconstruction with a patch

■ Fig. 17.4 Cutting the patch out of a pulmonary artery bifurcation homograft

bioengineered porcine small bowel submucosa for reconstruction with no long-term results available yet.

Great care is taken not to get any stenosis in the proximal part of the ascending aorta. This is avoided best by using only a few (three to four) interrupted stitches of 7/0 non-absorbable monofilament material in this area.

■ ■ **Excision of the atrial septum**

This is usually done via the cannulation site in the right atrium. If the abovementioned newer techniques of perfusion are used, this is the only part of the operation done in circulatory arrest.

It is of particular importance that no residual septal tissue is left. This guarantees an uninhibited pulmonary venous runoff. To be absolutely sure, the coronary sinus can be unroofed additionally.

■ Fig. 17.5 Norwood operation with an RV-PA conduit to the right pulmonary artery (RV right ventricle)

17.6.2.3 Reestablishment of Pulmonary Blood Flow—Two Options

- (A) *Modified Blalock-Taussig shunt.* This shunt arises from the brachiocephalic artery and goes to the right pulmonary artery. It is made with PTFE tube prosthesis. A diameter of 3.5 mm is usually adequate for a newborn.
- (B) *RV-PA conduit.* This method was described first by Norwood (Norwood et al. 1981). However, at that time valved conduits were used, and they were too big for this purpose. The smaller non-valved RV-PA conduit – a 5 mm PTFE prosthesis – was introduced by Sano in 2001 (Sano et al. 2003, 2004). Technically this conduit can be placed on the left side between infundibulum and distal main pulmonary artery. However we prefer to place the conduit on the right side of the ascending aorta (■ Fig. 17.5) between the infundibulum and right pulmonary artery (Griselli et al. 2006). The original method of Sano with the conduit on the left side of the reconstructed aortic arch leads to a lateral shift of the distal conduit anastomosis and to stretching of the right pulmonary artery. In our experience this frequently results in stenosis of the right pulmonary artery. Since we do the distal anastomosis on the right side and on the right pulmonary artery, this problem has become extremely rare. Furthermore the Glenn pro-

cedure is easier, if you don't have to dissect on the left side. In general we use 5 mm prostheses.

The right pulmonary artery is incised longitudinally between two stay sutures over a length of about 7-8 mm. Usually, there is no clamping necessary. A simple end-to-side anastomosis is done between a 5 mm PTFE prosthesis and the pulmonary artery with a 6/0 polypropylene thread. The site of the oblique incision in the infundibulum is marked by two stay sutures. A ventricular pacemaker is applied and fibrillation is induced. An oblique incision of about 10 mm in length is performed. The edges are undermined slightly to avoid proximal conduit stenosis. The prosthesis is cut obliquely to the correct length. Kinking and pressure upon the aorta must be avoided. The anastomosis is performed with a continuous PTFE suture.

■ ■ Modified Blalock-Taussig shunt versus RV-PA conduit

The hemodynamics differ in that the shunt patients show a diastolic runoff in their systemic circulation, while the conduit patients have the hemodynamics of a banded pulmonary artery with pulmonary regurgitation.

Patients with an RV-PA conduit have a higher diastolic blood pressure by about 10 mmHg than patients with a modified Blalock-Taussig shunt (Mair et al. 2003). This should lead to an improved organ perfusion predominantly in the coronaries but also in brain, kidneys, and intestinal organs. However for the RV-PA conduit, a ventriculotomy in the infundibulum is necessary. This causes a scar in a univentricular heart and may worsen ventricular function. The question arising from this is whether the improved coronary perfusion weighs out the local infundibular scar. The multicentric study of R. Oyhe and coworkers showed that transplantation free survival at 12 months was higher in patients with an RV-PA conduit compared to a Blalock-Taussig shunt. After this interval no significant difference in transplantation free survival could be detected between these two groups. In the same study, RV-PA conduits showed more reinterventions and complications than the BT shunt group (Oyhe et al. 2010). The physiologic difference between these two methods however has an impact on the early postoperative management of these patients. Whereas

shunt physiology generally demands a low resistance strategy, patients with an RV-PA conduit are not that sensitive to an increase in systemic vascular resistance. Vasopressors are better tolerated by these patients. So the decision between RV-PA conduit and modified Blalock-Taussig shunt is not a purely surgical one. The ability and routine of the intensive care team with the management of shunt physiology should influence the surgeon's decision as well.

■ ■ Delayed chest closure

If there is any doubt in hemodynamic stability, chest closure is delayed and the chest is closed temporarily with a waterproof membrane. This is sewn in with a simple continuous non-absorbable suture in between the skin edges. We drape the patient additionally with a sterile adhesive membrane. Criteria for definitive chest closure are completely stable hemodynamic and respiratory parameters and a negative fluid balance during 2-3 days. Delayed chest closure is usually done at the intensive care unit. Signs of pulmonary hyperfusion, especially in shunt patients, may require urgent chest closure.

17.6.3 Stage II: Bidirectional Glenn Shunt

In the late 1980s, it was observed that patients with a univentricular heart had better results after a Fontan operation, when they had a bidirectional cavopulmonary anastomosis as an intermediate step after stage I palliation than patients without this operation. This was not influenced by the type of stage I palliation that was used (aortopulmonary shunt, pulmonary artery banding or stage I Norwood procedure). The highest benefit had patients, who were not optimal candidates for a Fontan operation, either due to anatomic or physiologic reasons (Bridges et al. 1990).

Since that time, the bidirectional cavopulmonary connection became standard stage II palliation between Norwood procedure and Fontan Operation.

17.6.3.1 Physiologic Considerations

The heart is unloaded by the bidirectional cavopulmonary anastomosis. The blood of the superior vena cava bypasses the heart and goes through the lungs directly following the pressure gradient

between *superior vena cava and the common atrium*. Once shunt or conduit is closed, the ventricle does no longer pump into the pulmonary circulation. Systemic oxygen saturation after a bidirectional Glenn shunt is usually between 80 and 85%. This is similar to the situation after stage I palliation, but it is achieved with a significantly smaller workload of the ventricle. So the efficiency of heart labor is optimized and the ventricle should be better prepared for Fontan completion.

17.6.3.2 Timing of the Procedure

The timing of the bidirectional cavopulmonary anastomosis varies from center to center. As the flow through the pulmonary vessels is reduced by the Glenn procedure, it is mainly an outweighing between potential further growth of the pulmonary arteries on the one side and early unloading the ventricle to keep the ventricular performance and possibly reduce interstage mortality on the other side. Many authors recommend an interval of 6 months between stage I and stage II. In our unit, we think it is important to unload the systemic ventricle early as it is a right ventricle. Regarding the pulmonary vascular resistance, the earliest possible time would be after 6 weeks. We prefer an interval of 3–4 months between stage I and stage II.

17.6.3.3 Operative Technique

As a rule, we generally perform a simple bidirectional Glenn shunt. We do not perform Hemi-Fontan techniques. Surgery is described in ► Chapter «Definite Palliation of Functional Single Ventricle» Sect. 13.7.2.1 and Sect. 13.7.2.2. A special feature in hypoplastic left heart syndrome with aortic atresia is that great attention must be paid in order to not compress the small aorta, while clamping the right pulmonary artery during the bidirectional cavopulmonary anastomosis. This could result in severe ventricular failure.

■ ■ Technique after a Blalock-Taussig shunt

Besides the abovementioned aspects, there is no difference to other univentricular hearts with aortopulmonary shunts.

■ ■ Technique after RV-PA conduit

The RV-PA conduit is cross clamped and divided. The proximal end is sewn over very close to the infundibular anastomosis, so that no blind stump is left. If the distal conduit anastomosis has been made on the left side, this region has to be dis-

sected and the distal end of the conduit is sewn over transversely. If the distal anastomosis has been made on the right side, the conduit must be removed completely. The site of the anastomosis can be used for the bidirectional cavopulmonary anastomosis. Usually it has to be enlarged by 2–3 mm. In case of a stenosis of the pulmonary arteries, this has to be repaired simultaneously either by a patch plasty or, if there is compression under the aortopulmonary truncus, with a stent placed intraoperatively.

While the Glenn anastomosis can be performed off pump in cases with a left-sided conduit anastomosis, shunt or conduit anastomoses on the right pulmonary artery at stage I surgery require normothermic extracorporeal circulation (beating heart) for stage II.

17.6.4 Stage III: Fontan Operation

The completion of the bidirectional cavopulmonary anastomosis, namely, from partial to total cavopulmonary connection, is the third step in definite surgical palliation for univentricular hearts. The operative technique is described in ► Chapter «Definite Palliation of Functional Single Ventricle» Sect. 13.7.3. The age of operation depends to some extent on the method used for this Fontan completion (lateral tunnel or extracardiac conduit). As we prefer a fenestrated extracardiac conduit, we usually perform the procedure during the third year of life. The patient should weigh 12 kg, so that PTFE tube prosthesis of 20 mm in diameter can be used. The following aspects made the extracardiac conduit the method of choice for us.

In this version, we avoid major suture lines on the atrial wall. Only when closing the junction of the inferior vena cava (IVC), atrial tissue may be incorporated in the suture line. In addition, no part of the atrial wall is under the elevated systemic venous pressure employing this technique. This should minimize rhythm problems in this cohort of patients.

Using an extracardiac conduit, the aorta is not to be cross clamped, and there is no period of ischemia for the heart in this procedure. We deem this to be especially important in face of a right ventricle supporting the systemic circulation. Furthermore, an extensive dissection would be necessary to cross clamp the aorta after a Norwood

procedure if at all possible after complex neo-aortic reconstruction.

17.6.5 Results of Univentricular Palliation

The total mortality of univentricular palliation comprises the mortalities of each surgical stage as well as the interstage mortality.

Before the Norwood operation (stage I), neonates and infants with hypoplastic left heart syndrome suffer from univentricular circulation with increasingly nonrestrictive pulmonary blood flow resulting in diastolic systemic runoff and consequently poor systemic perfusion.

The result of a successful Norwood procedure is a balanced univentricular circulation. Pulmonary blood flow is restricted, either in form of shunt physiology (when a BT shunt is used) or in form of a functional pulmonary artery banding (PAB) (using an RV-PA conduit). This leads to some relief of ventricular volume load; however, the ventricle has still to be considered volume overloaded until stage II surgery is performed. The problems of balancing the two circulations after extensive palliative surgery on extracorporeal circulation attribute to the higher mortality compared to corrective neonatal surgery.

In the early days of Norwood procedures performed, the survival rate was somewhere between 50 and 70 %. Today, several centers come up with rates above 90 %. In our group, the survival rate of the Norwood procedure improved from initially 66 % in 1998 to 87.4 % in a consecutive series of 206 unselected patients since 2003 (complete body perfusion by add. cannulation of the descending aorta). As independent risk factors for mortality after the Norwood procedure, we identified age older than 20 days at time of operation, the anatomic subgroup of unbalanced AV canal and former trial of biventricular repair.

Apart from the learning curve of the surgeon and other responsible team members, we identified the following factors to have influenced the improvements of our results:

- *Prenatal diagnostics.* Prenatally identified patients usually come to the specialized center in better condition than those who get diagnosed only once severe cardiac failure or circulatory shock after ductal closure

occurred. The preoperative status clearly influences postoperative outcome.

- *Introduction of the RV-PA conduit.* The severe changes in pathophysiology, creating a physiology similar to a PAB, lead to a more stable condition especially in the early postoperative period. We are well aware that the RV-PA conduit is not shown to be superior in larger studies; however, it clearly helped us to improve our results.
- *Evolution of extracorporeal circulation.* We replaced deep hypothermic circulatory arrest initially by selective antegrade cerebral perfusion and later on by complete body perfusion via an additional arterial cannula in the supradiaphragmatic aorta. This change in perfusion technique makes the operation comparable to other procedures using extracorporeal circulation and reduces the detrimental effects of intraoperative ischemia.

Summarizing these changes, the significant improvement of the results over time can be explained.

Postoperative morbidity can be caused by aortic arch stenosis, which can be kept low by using the right patch form. In our series, aortic arch reoperations were required in 2.5 %, and cathlab interventions in 6 % of patients. Stenoses of the pulmonary arteries seem to be more common in the RV-PA conduit group (about 12 % in our series) than with Blalock-Taussig shunts. They can usually be addressed at the time of the bidirectional cavopulmonary anastomosis.

The bidirectional cavopulmonary anastomosis is technically a rather straightforward procedure that reduces ventricular volume load. The mortality of the Glenn shunt ranges between 0 and 2 %. This operation contributes only minimally to the overall mortality of the univentricular palliation pathway.

This consideration is also valid for the completion to the total cavopulmonary connection. The extracardiac version of the Fontan palliation can be safely performed without cross clamping the aorta, gaining near normal arterial saturation by the same cardiac workload. Mortality rate is between 0 and 2 %.

Causes for death between stage I and stage II can be:

- Residual or recurrent anatomic lesions like a restrictive interatrial septum, obstruction of

the aortic arch or stenosis of the BT shunt, RV-PA conduit or pulmonary artery.

- Trivial gastrointestinal infections can suddenly lead to dehydration and circulatory instability.
- Respiratory infections can rapidly cause severe respiratory insufficiency and death.

A strict home monitoring program looking at certain parameters (pulse oximetry, weight gain, food habits) was introduced by the Milwaukee group and showed significant advantage (Ghanayem et al. 2003). The early performance of the bidirectional cavopulmonary anastomosis at the age of 3–4 months is also commonly seen as an advancement and is practiced at our unit. Our own experience showed that the – what we call – banded physiology of the RV-PA conduit was able to lower the interstage mortality in comparison to the BT shunt group.

Only few reliable data are published about the interstage mortality between stages II and III. Death can be caused by compromised ventricular function, cardiac failure due to multiple aortopulmonary collaterals, or rhythm disturbances. Overall, lethal events seem to be rare in this period.

17.6.6 Alternatives to the Norwood Procedure: Ductal Stenting and Bilateral Pulmonary Artery Banding (Hybrid Procedure)

The principal goal of the Norwood procedure, to create unrestricted ejection of the right ventricle into systemic circulation, and restrictive pulmonary blood flow (balanced univentricular circulation) with unrestricted pulmonary venous return (unrestrictive atrial septal defect (ASD)), can be achieved also by a hybrid procedure (conventional surgery combined with interventional techniques).

A stent is placed in the ductus arteriosus in catheter technique and both pulmonary arteries are banded. If the foramen ovale is restrictive, an additional stent may be placed there (Akintürk et al. 2002; Michel-Behnke et al. 2003; Bacha et al. 2006). This procedure could be applied as an alternative to the stage I Norwood procedure.

Aortic arch repair, aortopulmonary anastomosis, and atrial septectomy are done together with the bidirectional cavopulmonary anastomosis at stage II, which now may be called comprehensive stage II. The number of centers applying this procedure, as well as the numbers of cases, is still small. Therefore, a fair comparison with the Norwood procedure is difficult.

It is the advantage of this method that it avoids cardiopulmonary bypass, deep hypothermia, and circulatory arrest in a newborn for a palliative procedure only. Consequently, this approach lessens the surgical trauma for stage I palliation. This could be of increased importance in high-risk patients especially in low birth weight or immature neonates.

In some centers, it is therefore used predominantly in this high-risk group of patients.

Pizarro and coworkers however found out that there is no significant difference in survival in high-risk patients whether a Norwood procedure or a hybrid approach is used (Pizarro et al. 2007). They also reported that between stage I and stage II procedures, a substantial number of reinterventions concerning stents and pulmonary artery band were necessary. The comprehensive stage II

Additionally, the death rate between stage I and II has to be considered. Numbers vary between 10 and 16% («interstage mortality»).

in this group of patients has also a considerable morbidity and mortality rate.

This might be attributed to some inherent problems of this method reported by the applying surgeons and interventional cardiologists themselves.

The stent in the ductus arteriosus may lead to retrograde preductal aortic coarctation (Bacha et al. 2006). In aortic atresia, this could cause serious perfusion problems of the coronaries and the brain.

The interatrial stent, which is necessary sometimes, might be difficult to place.

During the comprehensive stage II procedure, an aortic arch repair has to be performed in a redo situation and an ingrown ductal stent has to be removed. The latter can be very demanding, at least in our experience.

Furthermore, if the new perfusion methods are used, as they are described above, the avoidance of cardiopulmonary bypass is the only remaining advantage of this procedure, as neither deep hypothermia nor circulatory arrest are absolutely necessary for stage I Norwood palliation.

Regarding all these aspects, it is presently difficult to define the advantages of this procedure over the Norwood operation either with modified Blalock-Taussig shunt or RV-PA conduit.

17.6.7 Alternatives to Univentricular Palliation

17.6.7.1 Heart Transplantation

Primary heart transplantation for hypoplastic left heart syndrome was first performed in 1984 by L. Bailey et al. (1986) and Mavroudis et al. (1988). The donor heart for this patient came from a baboon weighing 3.8 kg. In addition to standard heart transplantation (► Chapter «Heart and Heart-Lung Transplantation», Sect. 37.2.2), an extensive aortic arch repair is necessary in hypoplastic left heart syndrome. This can be done usually with the donor aortic arch. The availability of donor hearts is an unsolved problem in this therapeutic pathway and sometimes this requires prolonged waiting time. Furthermore, the patient needs lifelong immunosuppression. Coronary sclerosis in donor hearts is also a well-described problem.

17.6.7.2 Fetal Intervention

If critical aortic stenosis is the primary lesion of a hypoplastic left heart syndrome, it can be diagnosed by fetal echocardiography after the 16th week of gestation. At that time, the left ventricle is still big, distended, and of severely impaired contractility. It is known from many echocardiographic studies that these ventricles stop growing and develop endocardial fibroelastosis and coronary fistulas. If the aortic valve can be opened up at that time and antegrade blood flow through the left ventricle can be reestablished, the ventricle can be rehabilitated. Growth can go on and ventricular function will be preserved.

The first fetal aortic valvuloplasties were performed at Guy's Hospital in London, England, in the late 1980s by Allan and Maxwell in a small series (Allan et al. 1995). At that time the Norwood procedure already showed encouraging results and became more and more widespread. Therefore this concept of treatment was abolished temporarily. Around 2000 it was restarted in a few places (Makikallio et al. 2006; Tworetzky et al. 2004; Arzt et al. 2011). The experience of our own unit includes now 43 fetal aortic valvuloplasties in 40 fetuses. After an initial decompression the ventricle becomes smaller. During the residual fetal period, almost normal growth was observed. In most cases, aortic valve and left ventricular outflow tract are still stenotic at birth and need reintervention. We are convinced that fetal valvuloplasty is the central part of ventricular rehabilitation in these babies, but the program does not end at birth. To allow normal growth and biventricular physiology, the left ventricle has to be aggressively freed from any possible obstruction. Seventeen of the 40 patients were delivered in our maternity hospital and further managed by our unit. Ten of the 17 patients remained with a biventricular circulation. All of these ten patients needed aortic valvuloplasty in the first days of life. Eight of these patients underwent a Ross-Konno procedure in the newborn period. In four, we did an additional resection of endocardial fibroelastosis. One patient died from a mucormycosis infection due to necrotizing enterocolitis after 40 days.

We think that in critical aortic stenosis, this therapeutic concept is very promising and will lead to a higher rate of biventricular repairs in these babies.

17.6.8 Treatment of Borderline Cases: Hypoplastic Left Heart Complex (Tchervenkov et al. 1998)

The decision whether a left ventricle is able to support systemic circulation and biventricular repair is suitable, or single ventricle palliation has to be done, is made by morphologic criteria. The most widespread criteria were published by L. Rhodes (Rhodes et al. 1991):

- Mitral valve area $>4.75 \text{ cm}^2/\text{m}^2$
- Left ventricular long axis dimension to long axis of the heart >0.8
- Left ventricular mass $> 35 \text{ g}/\text{m}^2$
- Aortic root diameter $3.5 \text{ cm}/\text{m}^2$

These parameters are valid *only* for critical aortic stenosis.

The left ventricular outflow tract however can be enlarged surgically by a Konno or Ross-Konno procedure and is therefore of very limited value as a criteria for biventricular repair in critical aortic stenosis.

These criteria are also of very limited value in aortic coarctation with hypoplastic left ventricle. For coarctation and hypoplastic left heart complex, Tchervenkov and coworkers showed, that even smaller ventricles than those selected by the Rhodes criteria are amenable for biventricular repair, if certain requirements are fulfilled

- Good left ventricular function
- No mitral or aortic valve stenosis
- No endocardial fibroelastosis
- Antegrade blood flow in the ascending aorta and the proximal aortic arch

Undisturbed antegrade blood flow through the mitral valve is also crucial for the success of biventricular repair in these cases. It is a requirement for left ventricular growth. That means that any ASD should be closed. Furthermore, all obstructions in the outflow tract – aortic root, ascending aorta, aortic arch, and isthmus – must be removed aggressively.

Different criteria were elaborated by van Son for the repair of the unbalanced AV canal. Van Son and coworkers found that a left ventricular volume index greater than $15 \text{ ml}/\text{m}^2$ is required for biventricular repair of this malformation. A big VSD component and a dysplastic mitral valve component worsen the prognosis of biventricular repair (Van Son et al. 1997).

17.6.9 Aortic Atresia and Normally Sized Left Ventricle

This rare form of aortic atresia can only exist with an unrestrictive VSD. A biventricular reconstruction is possible in this malformation. The principles of aortic arch repair and aortopul-

monary anastomosis are the same as in a conventional Norwood procedure. An intracardiac baffle is necessary to direct the left ventricular flow through the VSD into the pulmonary artery, similar to Rastelli procedure. A valved or non-valved conduit is used to reestablish the continuity between RV and central pulmonary arteries.

This procedure can be performed as a complete repair in one stage, as we have done it successfully in our unit several times. Other authors recommend a two-stage procedure:

The first step would be a conventional Norwood procedure. In second step, the intracardiac baffle is made and the RV-PA conduit is implanted.

18.1 Introduction

In truncus arteriosus one vessel arises from the heart that supplies the pulmonary and systemic circulation. By definition, at least one pulmonary artery has to come off immediately distal to the truncal valve. The valve has often more than three cusps and appears like a fusion of aortic and pulmonary valve. Almost always there is a large ventricular septal defect directly underneath the truncal valve. The pulmonary arteries originate from different locations from the truncus and are therefore exposed to systolic and diastolic systemic pressure. Interrupted aortic arch is not an uncommon association with this anomaly.

18.2 Embryology

Truncus arteriosus is the result of an incomplete septation of the conotruncus (Pexieder 1995). There is almost never a patent ductus arteriosus unless the aortic arch is interrupted. Truncus arteriosus is morphologically related to the spectrum of aortopulmonary window. In case of a very large aortopulmonary window, there is only a very small conotruncal septum. With the absence of the septum, aortic and pulmonary valves fuse to form the truncal valve (Van Praagh and Van Praagh 1965).

18.3 Anatomy

18.3.1 Pulmonary Arteries

There are two classification systems in use: one from Van Praagh and Van Praagh (1965) and another from Collett and Edwards (1949) (■ Fig. 18.1).

Van Praagh and Van Praagh divide truncus arteriosus according to the existence or absence of the conotruncal septum and define *type A* as cases with and *type B* as cases without ventricular septal defect. In *type 1* with a conotruncal septum, there is a short main pulmonary artery which originates from the truncus. In *type 2* two separate right and left pulmonary arteries come off the truncus. In *type 3* only one branch pulmonary artery arises from the truncus, the other originates from a duct-like structure from the aortic arch. *Type 4* is associated with interrupted aortic arch.

Collett and Edwards divide truncus arteriosus in types I–IV. In *type I* a short main pulmonary artery with branches arises from the truncus. In *type II* left and right pulmonary arteries originate separately from the posterior aspect of the truncus. Most commonly an intermediate type of these two forms is found. In *type III* the branch pulmonary arteries come off from opposite sides of the truncus. In most cases the central and peripheral pulmonary arteries are well developed. In *type IV*, also known as «pseudotruncus,» there

■ Fig. 18.1 Truncus arteriosus types according to classification by Van Praagh and Van Praagh (A1–A4) and by Collett and Edwards (I–IV). Types A1 and A2 are similar to types I–III. *Type A1/I* common origin of pulmonary arteries from the truncus, *type A2/II* separates right and left branch pulmonary arteries from the dorsal truncus; type III is similar to type II, but with further distance of the ostia of the separate pulmonary arteries (not shown). *Type A3*, only the branch pulmonary artery contralateral to aortic arch sidedness arises directly from the truncus. The other branch pulmonary artery (in this case the left) is connected through a usually narrow, ductus-like vessel with the aortic arch. *Type A4*, the truncus continues via a ductus arteriosus into the descending aorta. The right and left pulmonary arteries come off the truncus before the ductus. The ascending aorta is small. It appears to arise from the main pulmonary artery. The aortic arch is interrupted. For type IV see text

is no main pulmonary artery. Aortopulmonary collaterals supply the lungs; therefore, this form is now classified into the group pulmonary atresia with ventricular septal defect.

18.3.2 Truncal Valve

The truncal valve resembles a fused pulmonary and aortic valve. The number of cusps varies from two to six. Rarely there are more than four individual cusps. More commonly some cusps or commissures are not completely developed, which can result in significant truncal valve regurgitation. Additionally these cusps can be myxomatous which allows placement of stitches for reconstruction.

18.3.3 Ventricular Septal Defect

The ventricular septal defect is located usually directly underneath the truncal valve and has some distance from the tricuspid valve. Therefore, the risk of AV block after closure of the ventricular septal defect is low. In rare cases, when the ventricular septal defect is very small, closure can create left ventricular outflow tract obstruction.

18.3.4 Coronary Arteries

Often the origin of the coronary arteries is abnormal; however, the course is usually normal. The origins can be located very close to the origins of the right and left pulmonary arteries. The left anterior descending (LAD) branch can originate from the right coronary and run across the infundibulum – like in tetralogy of Fallot (Suzuki et al. 1989).

18.3.5 Associated Anomalies

Most commonly the right aortic arch (25%) and aberrant right subclavian artery (5–10%) are found (Calder et al. 1976). Interrupted aortic arch (type A and B) is also frequently associated (10–15%). In up to 90% of cases, a DiGeorge syndrome can be found (Jahangiri et al. 2000; Sano et al. 1990).

18.4 Pathophysiology

The lungs are perfused during systole and diastole with systemic pressures. This becomes more prominent with fall of pulmonary vascular resistance which increases symptoms. Truncal valve regurgitation reduces diastolic pressure which leads to diastolic retrograde flow in the abdominal aorta. A pressure gradient across the truncal valve is rather attributed to these hemodynamics than a morphological narrowing. Despite increased pulmonary blood flow, a mild cyanosis is secondary to the fact that both ventricles eject into the truncal artery. An irreversible *pulmonary hypertension* can result as early as in the sixth month of life (Marciletti et al. 1976).

18.5 Diagnostics

Physical examination and chest radiographs show signs of increased pulmonary blood flow. Echocardiography is usually sufficient for diagnosis (and indication for surgery). Cardiac catheterization is indicated to evaluate pulmonary resistance in patients older than 3 months.

18.6 Operation

18.6.1 Preoperative Management

Truncus arteriosus is a cyanotic heart defect, which does not improve with prostaglandins. When there is associated interrupted aortic arch, the patent ductus arteriosus has no tendency to close. Rarely patients present with circulatory collapse or acidosis. More commonly heart failure secondary to increased pulmonary blood flow is found. Medical therapy – except for short-term stabilization to optimize the preoperative status – is not beneficial.

18.6.2 Indication for Surgery and Timing

Diagnosis is an indication for surgical correction. After stabilization in the intensive care unit, the procedure should be performed within the first 2–3 weeks of life.

18.6.3 Intraoperative Management

After standard anesthesia induction monitoring, catheters will be inserted. The low diastolic systemic pressure and elevated end-diastolic ventricular pressure which are typical for this heart defect can lead to subendocardial ischemia and arrhythmias. In patients with DiGeorge syndrome, hypocalcemia and a defect of immune function are of concern. Therefore, blood products need to be irradiated.

18.6.4 Operative Access

After standard median sternotomy, the existence or absence of the thymus in patients with DiGeorge syndrome should be noted. This is followed by harvesting of a pericardial patch, which is fixated in 0.6% glutaraldehyde solution. Snaring of the right pulmonary artery reduces the diastolic runoff of blood and increases the diastolic and systolic systemic pressure. After administration of heparin, the aorta is cannulated distally, and after establishment of cardiopulmonary bypass, the left pulmonary artery is exposed, snared, and mobilized.

18.6.5 Cardiopulmonary Bypass

Different strategies can be employed:

- Bicaval cannulation with no or moderate hypothermia
- Single atrial cannulation and deep hypothermia with or without circulatory arrest

Routinely crystalloid cardioplegia is administered and repeated after 30–45 min if necessary. Hypothermia and single-dose cardioplegia could be an advantage, because repeated doses of cardioplegia in neonates have been reported to have negative effects (Jonas 1998). It has been noted historically that with application of deep hypothermic circulatory arrest in neonates and infants, cardioplegia is not necessary (G. Ziemer, personal communication 2008); however, one has to be aware of disadvantages regarding side effects of hypothermia and neurologic deficits.

18.6.6 Repair

If there is truncal valve regurgitation, the aorta should be cross-clamped right after commencement

of cardiopulmonary bypass. Despite the regurgitation, usually half of the cardioplegia can be given through the aortic root, the other half will be administered directly into the coronary ostia.

In type A1 the short main pulmonary artery can be excised from the truncus (■ Fig. 18.2a, b). In type A2/II, III the aorta is transected completely above the pulmonary arteries (■ Fig. 18.2d, e). This has many advantages:

- The distal part of the ascending aorta is usually smaller than the truncal root. By anastomosis the truncal root dimensions are reduced and the diameter of the sinotubular junction decreased, which preserves the competence of the truncal valve.
- It avoids the risk put at the left coronary ostium when the pulmonary artery is excised from the right side.
- The direct anastomosis of the truncal root with the ascending aorta can be accomplished in a more symmetrical fashion.

The closure of the ventricular septal defect is achieved through a small incision in the right ventricle (■ Fig. 18.2c) with preservation of conal branches and safe distance to the left anterior descending artery. Suitable patch material includes Dacron, Gore-Tex, or autologous pericardium, which is sewn into place with an interrupted or continuous suture. Normally the tricuspid valve is separated from the ventricular septal defect by the muscle. Thus, the risk of damage to the bundle of His is low (■ Fig. 18.2f, g).

For reconstruction of the right ventricular outflow tract, there are different options. Ideally, a small homograft (diameter, 9–13 mm) is available, which is easy to implant. The graft is trimmed as short as possible. Then the distal anastomosis is constructed first. Afterward the graft is anastomosed proximally with a third of the circumference to the right ventricle (■ Fig. 18.3a). The remaining opening is closed with an autologous pericardial or polytetrafluoroethylene (Gore-Tex) patch (■ Fig. 18.3b).

If a small homograft is not available, a valved bovine jugular vein graft (Contegra®) can be used alternatively. The smallest diameter is 12 mm. The graft is very soft and easy to handle. A disadvantage is the potential for dilation when exposed to high pressures. Because of the high profile of the valve, the conduit used is trimmed as short as possible. Proximally additional tissue can be used for recon-

Fig. 18.2 a Intraoperative situs after cannulation in truncus arteriosus type A1/I and lines of incision for excision of the pulmonary arteries. b With the heart arrested, the truncus is transected with preservation of the coronary arteries. In the next step, the right ventricle will be incised between stay sutures. c The excision site of the pulmonary artery is closed. The right ventricular outflow tract is incised between stay sutures. The pulmonary artery bifurcation is marked with a stay suture. d The excision of the pulmonary arteries from the common truncus arteriosus (type A2/II, III) is accomplished by transection of the truncus at the level of the pulmonary arteries. e The truncus is transected, and the bifurcation of the pulmonary arteries is separated. f The ventricular septal defect is closed with interrupted sutures with pledgets or with a continuous suture. As the bundle of His is not located in the inferior border of the ventricular septal defect, the sutures can be placed safely there. g Patch in place for closure of ventricular septal defect

■ Fig. 18.2 (continued)

struction, and no additional patch is needed. Some centers reported intima proliferation at the site of the distal anastomosis which we have not documented.

It seems important to construct the distal anastomosis first and use everting sutures ventrally *and* dorsally.

The profile of the jugular vein valve is relatively high; therefore, the Contegra conduit is significantly longer than a homograft – even when cut to the shortest length possible.

There is controversy about the use of *valveless conduits*. Generally it can be anticipated that the postoperative intensive care stay is slightly prolonged. Nevertheless, this option – because small homografts are not readily available – is a useful alternative in selected patients with large pulmonary arteries, without pulmonary hypertension, and without a coronary artery crossing the right ventricular outflow tract (Chen et al. 2005; Danton et al. 2001).

If the pulmonary arteries can be well mobilized, a direct anastomosis of the posterior aspect with the ventriculotomy might be possible. This is technically most feasible in type I with existence of a main pulmonary artery. Ventrally the connection is completed with a hood created by autologous pericardium or polytetrafluoroethylene (Gore-Tex). Figure 18.4 shows the implantation of a polytetrafluoroethylene graft. Special attention should be paid to the trimming of the graft.

In a different technique without the use of a homograft for types I and II, the left pulmonary artery is opened anterosuperiorly and then in direction of the left sinus of Valsalva of the truncus

(Barbero-Marcial et al. 1990). After identification of the origin of the right pulmonary artery and the left coronary ostium, an autologous pericardial patch is sutured into place at the base between left coronary ostium and origin of right pulmonary artery. This patch divides the truncus into an aortic and pulmonary arterial part with the left sinus of Valsalva remaining on the pulmonary side. A redundant patch can lead to obstruction of the right pulmonary artery and should be avoided. The right ventricle is incised directly underneath the left sinus of Valsalva in direction left-inferior, and the ventricular septal defect is closed with Dacron or pericardium. Finally, the inferior border of the incision into the left pulmonary artery is directly anastomosed with interrupted sutures to the right ventricle. The right ventricular outflow tract is reconstructed with a monocusp valve made of pericardium. Recently a modification of the conduit-free Barbero-Marcial technique with interposition of the left atrial appendage between the right ventricle and the pulmonary trunk for repair of type III common arterial trunk has been described (Aguilar et al. 2015).

18.6.7 Special Intraoperative Problems

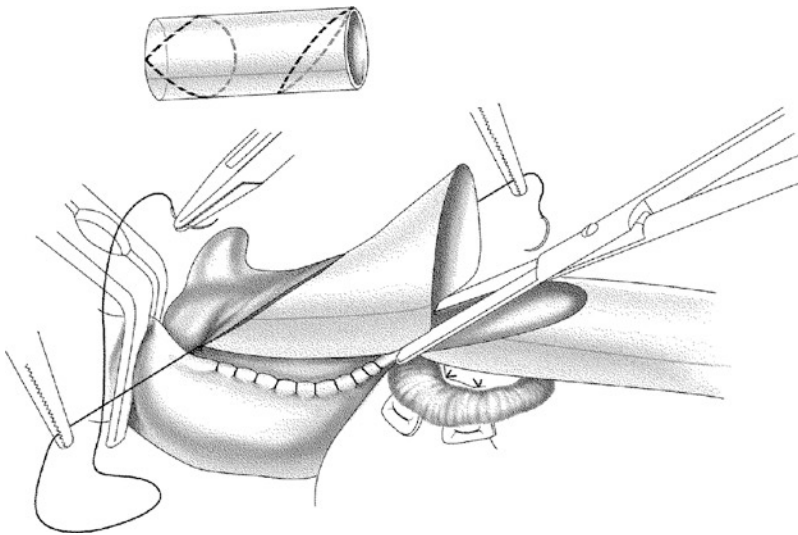

A regurgitant truncal valve can usually be repaired, and replacement of the valve by homograft is rarely necessary during primary repair. The reason for the regurgitation is often cusp prolapse. It can be corrected by suturing the prolapsing cusp to the neighboring cusp. This way out of a quadricuspid or tricuspid valve a tricuspid or bicuspid truncal valve will be created.

In associated interrupted aortic arch, the patient is cooled with one cannula in the truncus and one in the right atrium. The right and left pulmonary arteries are snared, and during short circulatory arrest, the repair is performed. It is not advisable to implant the descending aorta into the site, where the pulmonary arteries have been excised. As described in ► Chapter «Congenital Anomalies of the Great Vessels» Sect. 21.2.1.2 the anastomosis should be with the longitudinally incised distal ascending aorta, if necessary with extension into the left common carotid artery (■ Fig. 18.5).

Alternatively, the correction can be done with selective cerebral perfusion through the right common carotid artery. For the aortic arch recon-

■ **Fig. 18.3** a Implantation of a valved homograft. The distal anastomosis has already been accomplished. Proximally one third of the circumference of the homograft is anastomosed to the right ventricle. b The reconstruction of the right ventricular outflow tract is completed proximally with an autologous pericardial patch

■ **Fig. 18.4** Trimming of the proximal end of a valveless polytetrafluoroethylene graft. The insert shows that the distal level of beveling is in a 90° angle to the proximal one

struction, the cannula is advanced into the innominate artery and snared with a tourniquet. At 18 °C cardiopulmonary bypass flow is reduced to 30–50% of calculated whole body flow. A right radial artery line is used for invasive blood pressure monitoring. The goal is a pressure of 30–35 mmHg to prevent potential cerebral edema. To improve exposure the arterial cannula can be connected through a polytetrafluoroethylene shunt (3.5 mm), which is anastomosed to the

innominate artery. For reconstruction the descending aorta is controlled with a Castaneda clamp, and both supraaortic branches (left common carotid artery, left subclavian artery) are clamped with small neurosurgical Yasargil clips.

Weaning from cardiopulmonary bypass is carried out in standard fashion with low dose of dopamine (4–6 µg/kg kg/min). The chest is closed primarily. Other groups perform routinely a secondary chest closure – especially in

Fig. 18.5 a–c Repair of truncus arteriosus with associated interrupted aortic arch. **a**, **b** The pulmonary arteries are excised from the truncus along the depicted lines, and the ductus arteriosus is transected. **c** The proximal ascending aorta and the proximal ductus arteriosus are oversewn

very small patients (body weight <2.5 kg) – after 1–3 days.

18.6.8 Special Postoperative Problems

Postoperative care can be challenging because of pulmonary hypertension and right ventricular dysfunction (secondary to the ventriculotomy).

Before considering medical treatment of pulmonary hypertension, the operative result should be evaluated, and a large residual ventricular septal defect should be excluded by echocardiography. Life-threatening pulmonary

hypertension is more common in late infancy (Bando et al. 1996). Therefore, a thin catheter should be placed via the right ventricular outflow tract into the pulmonary artery. Otherwise clinical criteria can be used to diagnose pulmonary hypertension (e.g., high central venous pressure, arterial desaturation, tachycardia, hypotension, acidosis, oliguria). It is our policy to keep the patients ventilated during the first postoperative night, or up 48 h postoperatively, to lower the pulmonary vascular resistance. Nitric oxide (10–40 ppm) is administered if there is an otherwise therapy-resistant elevation of pulmonary vascular resistance. Only rarely extracorporeal membrane oxygenation is used. (Aguilar JM et al. 2015)

19.1 Congenitally Corrected Transposition of the Great Arteries (ccTGA)

19.1.1 Pathology

Congenitally corrected transposition of the great arteries (ccTGA) is a rare cardiac malformation with an incidence of 0.5% of congenital heart defects (CHD). Morphologically, it consists of atrioventricular as well as ventriculoarterial discordance. The systemic venous, morphologically the right atrium, is connected to the morphologically left ventricle via the mitral valve; the left ventricle in turn is connected to the pulmonary valve and the pulmonary artery. On the other hand, the pulmonary venous atrium (morphologically left) drains into the morphologically right ventricle via the tricuspid valve. Thus, the right ventricle functions as systemic ventricle and ejects via the aortic valve into the aorta. This double discordance results in a *physiologically corrected* circulation whereby the unoxygenated blood flows to the lungs and the oxygenated blood to the body (■ Fig. 19.1).

In most of the cases of ccTGA, there is situs solitus with a segmental {SLL-} anatomy (S, situs solitus; L, levo, left-sided looping of the cardiac tube; and L, left-sided malposition of the aorta at the level of the aortic valve, respectively). Less frequently, there is situs inversus with segmental {IDD-} anatomy (I, situs inversus; D, dextro [right sided, «nor-

mal»] looping; and D, dextroposition of the aorta, respectively) (Van Praagh 1992; Van Praagh and Van Praagh 1966, 1967; see also below, ► Sect. 19.2.3, «Embryology and Anatomy»). CcTGA can present without other intracardiac malformations (1–2%; Allwork et al. 1976). Associated *cardiac malformations* as ventricular septal defects (VSD), valvar and subvalvar pulmonary stenosis, as well as dysplasia of the tricuspid valve are frequently present. The abnormal location of the conduction system predisposes to rhythm disturbances.

Most patients with ccTGA have *situs solitus* with levocardia. The morphologic right ventricle (mRV) is left sided; the morphologic left ventricle (mLV) is right sided (L-loop). In about 25% of cases, the lesion is associated with dextro- or mesocardia. In situs inversus (about 5% of cases), there is a mirror-image anatomy with the apex of the heart pointing to the right side, which has to be distinguished from isolated dextrocardia in situs solitus. In situs solitus and ccTGA, the aorta is left and anterior to the posteriorly positioned pulmonary trunk (L-malposition). In situs inversus and ccTGA, the aorta is positioned right and anterior to the pulmonary trunk (I, D, D).

19.1.1.1 Ventricular Septal Defect (VSD)

A VSD is the most common associated cardiac malformation in ccTGA and is present in about 70% of all patients with ccTGA (Warnes 2006).

■ Fig. 19.1 a, normal heart; b, Congenitally corrected transposition of the great arteries (ccTGA). Ao aorta, LA left atrium, LV left ventricle, PA pulmonary artery, RA right atrium, RV right ventricle

Although a VSD can take up most of the ventricular septum, there is typically a single, nonrestrictive perimembranous VSD of at least moderate size, i.e., has no pressure gradient across it. The VSD may extend into the inlet or into the infundibular septum. Multiple VSDs can be present. A big, subaortic VSD reaching into the perimembranous septum is frequently associated with a significant pulmonary stenosis or with pulmonary atresia. Rarely, there is an atrioventricular septal defect (AVSD) with or without a (subpulmonary) left ventricular outflow tract obstruction (LVOTO).

19.1.1.2 Atrioventricular Valves

The mitral valve in ccTGA is almost always of normal anatomy and function, but a significant number of patients with ccTGA have a morphologically abnormal and dysplastic tricuspid valve. The most affected part of the valve is the septal leaflet which presents with shortened and thickened chordae that are occasionally adherent to the ventricular septum. The septal components of the valve can be displaced towards the right ventricular apex resembling Ebstein anomaly; however, in contrast to the original Ebstein's disease, there is no atrialization of the right ventricle. The tricuspid valve is frequently regurgitant, and displacement of the interventricular septum towards the left ventricle exaggerates tricuspid valve annular dilatation and results in more regurgitation. These pathological changes make tricuspid valvuloplasty, if needed, less likely to be successful. Straddling of the tricuspid valve where one or more components of the valve such as the leaflets or subvalvar apparatus override the interventricular septum (see ► Chapter «Anomalous Pulmonary Venous Connections and Congenital Defects of the Atria, the Atrioventricular Septum, and the Atrioventricular Valves», Sect. 12.5.2) may be present. It is associated with hypoplasia of the right ventricle. Rarely, there is straddling of the mitral valve with left ventricle hypoplasia in cases with inlet VSD.

19.1.1.3 Left Ventricular Outflow Tract

The anatomic position of the pulmonary outflow tract in ccTGA, being wedged deeply between the mitral and tricuspid valve, predisposes to the development of a stenosis of the morphologically left ventricular outflow tract (LVOT). An obstruction of the LVOT is present in about 30–50% of all patients with ccTGA (Freedom 1999). It may be a fixed or a dynamic obstruction, and it can be caused

by subvalvar as well as valvar components. A subvalvar stenosis can additionally be due to accessory mitral valve tissue or fibrotic tissue resulting in a diffuse hypoplastic fibromuscular tunnel. If a VSD is present, accessory valvar tissue may prolapse from the systemic ventricle through the defect into the LV outflow tract or the pulmonary valve. Abnormal chordal attachments onto the crest of the septum can also be present. At the level of the pulmonary valve, morphologic obstruction is caused by fused and/or thickened dysplastic valve leaflets. In some cases there is even pulmonary valve atresia.

19.1.1.4 Coronary Arteries

The morphology of the coronary arteries follows the respective inverted ventricles. Typically, the right-sided coronary artery has left coronary artery anatomy and supplies the left ventricle. It rises from the anterior sinus of the aortic valve and branches into an anterior descending coronary artery, which follows the interventricular septum, and a circumflex coronary artery, which follows the atrioventricular groove between the right atrium and the left ventricle. The left-sided posterior sinus of the aortic valve gives origin to the morphologic right coronary artery, which courses in the atrioventricular groove between the left atrium and the right ventricle and branches into several marginal arteries that supply the ventricle.

19.1.1.5 Conduction System

In atrial *situs solitus*, the His bundle does not arise from the existing and normally located AV node on the tip of the triangle of Koch, because of the malalignment of the atrial and ventricular septum. Instead, there is an *accessory AV node* (Hosseinpour et al. 2004), which is located anterior and superior in the area of transition of the atrial septum to the annulus of the mitral valve close to the commissure between the anterior and posterior mitral valve leaflets. This accessory AV node gives rise to a long, penetrating His bundle, which runs through the fibrous trigone and passes subendocardially anterior and caudad to the pulmonary valve annulus into the morphologic left side of the septum. The His bundle divides into a left bundle, which is located on the morphologic left side of the septum and into a right bundle, which penetrates the septum to reach the morphologic right ventricular side. In the presence of a perimembranous VSD, the His bundle runs in close contact to the pulmonary valve annulus around the LVOT and on the

left-sided anterior-superior rim of the VSD. When closing the defect, this important difference from normal anatomy has to be taken into consideration to prevent surgical AV block.

In few cases, there is an anterior and posterior AV node, both of which giving rise to a penetrating bundle, so that in case of a VSD, the defect can be surrounded by a ring of conduction tissue (Hosseinpour et al. 2004).

In *situs inversus*, the posterior AV node is normally positioned at the tip of the coronary sinus and gives rise to the penetrating bundle, which is located on the inferior rim of the VSD on the surface of the morphologic left side of the septum similar to hearts with atrioventricular concordance.

About 4–7.5% of newborns with ccTGA present at birth with a *complete AV block* caused by anatomical discontinuity between the AV node and the His bundle (Huhta et al. 1983; Lundstrom et al. 1990; van Son et al. 1995). The anomalous course of the conduction system, due to septal malalignment, predisposes to the development of a complete AV block with increasing age at a rate of 2% per year (Huhta et al. 1983). Overall, the incidence of a complete AV block is reported between 15 and 32% (Friedberg and Nadas 1970; Huhta et al. 1985; Lundstrom et al. 1990; van Son et al. 1995). Another 20% of patients have first- or second-degree AV block.

19.1.2 Clinical Presentation and Natural History

The natural history and the clinical course of ccTGA are quite variable and depend on the presence and severity of associated cardiac malformations. In the absence of associated malformations, patient could be asymptomatic up to the fifth decade of life or present with bradycardia due to onset of spontaneous complete atrioventricular block. However, progressive deterioration of the systemic morphological right ventricle may occur with age and is accelerated by concomitant development of tricuspid valve regurgitation or other abnormalities (Graham et al. 2000; Presbitero et al. 1995).

In the presence of associated malformations, the major clinical symptoms are *progressive heart failure, cyanosis, or bradycardia* (Webb 1999). If a VSD is present, the left-to-right shunt and pulmonary volume overload may cause congestive heart

failure in the first year of life (Friedberg and Nadas 1970). The initial therapy consists of medical treatment of the congestive heart failure followed by either banding of the pulmonary artery or closure of the VSD and double-switch operation before the onset of hypertensive pulmonary vascular disease. This pathophysiology is altered if LVOTO is present. Frequently in these cases, there is a balanced circulation with only mild clinical symptoms, so that these patients may not require medical or surgical therapy for several years and even decades except for the potential need of a pacemaker. On the other hand, if LVOTO is moderate to severe, inadequate pulmonary blood flow may lead to desaturation or cyanosis in the first year of life in 30% of patients (Friedberg and Nadas 1970). In these patients an initial systemic-to-pulmonary shunting or total repair, depending on patient's age, is indicated. Severe pulmonary stenosis or atresia with VSD leads to severe cyanosis or to a ductal dependent pulmonary circulation necessitating an early systemic-to-pulmonary shunt in the neonatal period. Some of the patients are born with or develop rhythm disturbances, mainly bradycardia due to complete AV block, as their first clinical symptoms.

In summary, there is a wide variety in the clinical presentation of ccTGA, depending on the presence and the severity of associated defects ranging from the infant with signs of severe congestive heart failure or cyanosis to totally asymptomatic adult.

As the patient grows older, the most decisive factor with major impact on the clinical course is the development of mRV failure in association with tricuspid valve regurgitation. The mRV failure can occur as part of the neonatal history or after physiologic surgical «correction.» The pathophysiologic mechanism is related to RV inability to sustain the system circulation over a long period of time. This results in a vicious cycle of mRV failure and consequent tricuspid regurgitation due to annular dilatation causing additional volume loading of the mRV. The change in RV geometry leads to a shift of the ventricular septum towards the LV. As a result, the septal components of the tricuspid valve are stretched out leading to a decrease in the coaption of the leaflets with further increase in tricuspid regurgitation, which in turn leads to further ventricular dilatation. This interrelation between progressive valvar regurgitation

and ventricular dysfunction is supported by the observation that an increase in LV pressure following pulmonary artery banding shifts the interventricular septum towards the RV and leads to a decrease in tricuspid regurgitation (van Son et al. 1996; Daebritz et al. 2001).

There is an increasing incidence of progressive deterioration of right ventricular function and failure with increasing age. In the first five decades, 56% of all patients with ccTGA and associated major defects have moderate to severe deterioration of right ventricular function. This late presentation could also occur in 32% of patients without significant associated defects (Graham et al. 2000). It is due primarily to lack of natural anatomic adaptation of the mRV to the high-pressure systemic circulation, exaggerated by limited coronary reserve to the right ventricular myocardium due to single coronary artery supply (Hornung et al. 1998; Hauser et al. 2003) or by complete AV block causing an increase in stroke volume and secondary dilatation of the tricuspid valve annulus (Voskuil et al. 1999; van Son et al. 1995). In case of dysplasia of the tricuspid valve or Ebstein-like malformation, the onset of mRV failure can be accelerated due to the mechanisms and interactions described above.

Progression of preexisting regurgitation or the onset of new one can occur after traditional physiologic repair (VSD closure, relief of LVOT) and is reported in 42% of postoperative patients (Hraska et al. 2005). The decrease of the mLV pressure after physiologic correction leads to a shift of the septum to the left towards the mLV with consequent increase in tricuspid regurgitation and volume overload of the mRV. Therefore, tricuspid valvuloplasty after classic repair is not an optimal solution because it is either technically not feasible or is likely (van Son et al. 1995) to fail if the right ventricle remains as systemic ventricle (Acar et al. 1998). Although the results of primary tricuspid valve replacement have improved, particularly if surgery is performed early at the onset of first signs of mRV dysfunction (van Son et al. 1995), they are still not satisfactory, because valve replacement does not address progressive mRV dysfunction. In a series of 14 patients with initial tricuspid valve replacement (Hraska et al. 2005), the 1- and 5-year survival rates were 71 and 53%; the 1 and 5 years rate of freedom from repeat valve replacement were 100 and 40%. Eleven of these patients (79%) had dysfunction of the mRV. The reported inci-

dence of mRV dysfunction was 32% of 65 patients older than 18 years with ccTGA; 55 patients had undergone conventional repair (Piran et al. 2002).

Development of progressive right ventricular dysfunction with progressive increase of tricuspid regurgitation after classic repair, led to treatment strategies that aim at incorporating the mLV into the systemic circulation. The recruitment of the mLV into the systemic circulation is achieved by rerouting of the pulmonary venous and the systemic venous blood return by an atrial switch procedure (Senning or Mustard operation) and rerouting of the arterial connection by an arterial switch operation or a Rastelli operation. These so-called double-switch operations (Ilbawi et al. 2002) result in anatomic repair, creating atrioventricular and ventriculoarterial concordance (see below). The major advantage of this strategy is the immediate decompression of the mRV, which becomes the low-pressure pulmonary ventricle. The decompression results in shifting of the ventricular septum towards the mRV and thus reduces any tricuspid regurgitation, making valve repair or replacement unnecessary.

19.1.3 Diagnostics

Prenatal or postnatal diagnosis of ccTGA is usually made by *echocardiography* (Allan et al. 1994). Additional diagnostic details may be obtained by transesophageal echocardiography. Advanced non-invasive diagnostic tools, such as 3D echocardiography, 3D CT scan, and 3D MRI, are helpful in selected more complex cases. *Cardiac catheterization* gives precise assessment of hemodynamics, such as the degree of pulmonary stenosis, shunt volumes of one, or more VSDs (Qp/Qs), and enables calculation of the pulmonary vascular resistance. If an anatomical correction is planned, coronary arteriography is helpful, especially in redo surgery, but not absolutely necessary. Measurement of the mRV and mLV pressures and assessment of mLV muscle mass has to be performed in all patients in whom pulmonary artery banding for retraining or anatomical correction is planned.

19.1.4 Surgical Treatment Strategies

Until the end of the 1980s, the surgical treatment strategies of ccTGA were limited to the repair of associated defects, resulting in a classic or *physio-*

logic repair. Thereafter, treatment options incorporating the mLV into the systemic circulation, so-called the anatomical correction, were introduced due to disappointing long-term results of the physiologic repair (see ► Sect. 19.1.2, «Clinical Presentation and Natural History») (Ilbawi et al. 1990). The classic repair, in which the mRV remains as systemic ventricle, carries the risk of unpredictable onset and progression of mRV dysfunction. In contrast, anatomic correction carries the potential disadvantages of the venous switch operation. Currently, the anatomic repair has become the standard approach in spite of absence of long-term results proving its advantages. ■ Fig 19.2 gives a decision algorithm of the currently applied criteria for surgical treatment of ccTGA.

19.1.4.1 Palliative Procedures

Depending on morphology and hemodynamics, an initial palliative procedure such as systemic-to-pulmonary shunt or pulmonary artery banding may be necessary.

■ ■ Modified Blalock–Taussig–Shunt

Newborns with severe pulmonary artery stenosis or pulmonary atresia (ductal dependant pulmonary circulation) need early palliation with systemic-to-pulmonary artery shunt, to allow for growth of the patient making physiology or anatomic repair (Senning/Mustard operation, Rastelli) easier to perform. It is also needed in newborns in whom a septation or rerouting of the ventricles cannot be performed (i.e., huge VSD, noncommitted VSD) and thus are destined for eventual Fontan palliation.

The insertion of a modified Blalock–Taussig shunt is performed via median sternotomy. The graft is preferably a thin-walled 3.5–4 mm polytetrafluoroethylene stretch graft, which is interposed between the proximal part of the right subclavian or distal innominate artery and the right or main pulmonary artery. The use of cardiopulmonary bypass machine is usually not needed unless the patient becomes hemodynamically unstable when the pulmonary artery is partially clamped.

■ ■ Banding of the pulmonary artery

Pulmonary artery banding (PAB) is performed in patients with a large VSD and pulmonary overcirculation, to allow some somatic growth

and to prevent from development of pulmonary vascular obstructive disease. In this group of patients, the band is tightened until the pulmonary artery pressure drops to about one-third of the systemic pressure. It is also used in patients who are destined for double-switch operation (i.e., atrial and arterial switch or atrial switch plus Rastelli). Another indication for banding is the retraining of the mLV in older patients with low mLV pressure, who are planned for an anatomical correction. Pulmonary artery banding could also be considered a definitive palliation in selected patients with unfavorable anatomy, to establish «balanced» circulation as seen in some patients with valvar or subvalvar pulmonary stenosis (naturally banded) who have a very good natural palliation without any intervention (Hraska et al. 2005).

In retraining of the left ventricle and PAB, the PAB is tightened to achieve mLV pressure of 80–100% of the systemic pressure. Frequently, a repeat stepwise banding is necessary because the left ventricle may not initially tolerate tight banding. These patients are usually sick and require prolonged stay in the intensive care unit for ventilatory and hemodynamic stabilization. This is due to the fact that the response of the mLV to acute increase in afterload and volume shifting through an intracardiac shunt is unpredictable and is dependent on the age of the patients and other perioperative variables that could lead to short- and long-term mLV dysfunction (Quinn et al. 2008).

The common approach to perform PAB is via median sternotomy. We use a 4-mm polytetrafluoroethylene band and adjust it by serial pulmonary artery pressure measurements proximal and distal to the band. Transesophageal echocardiogram is used to evaluate mLV function at the time of banding. An externally adjustable banding device might be helpful particularly with regard to longterm stepwise training occasionally needed in older children, although its use has been discouraging and has not been widely accepted (Bonnet et al. 2004; Daebritz et al. 1999). Recently, a newer adjustable band has been applied effectively for stepwise banding in 11 patients with ccTGA (DiBardino et al. 2012).

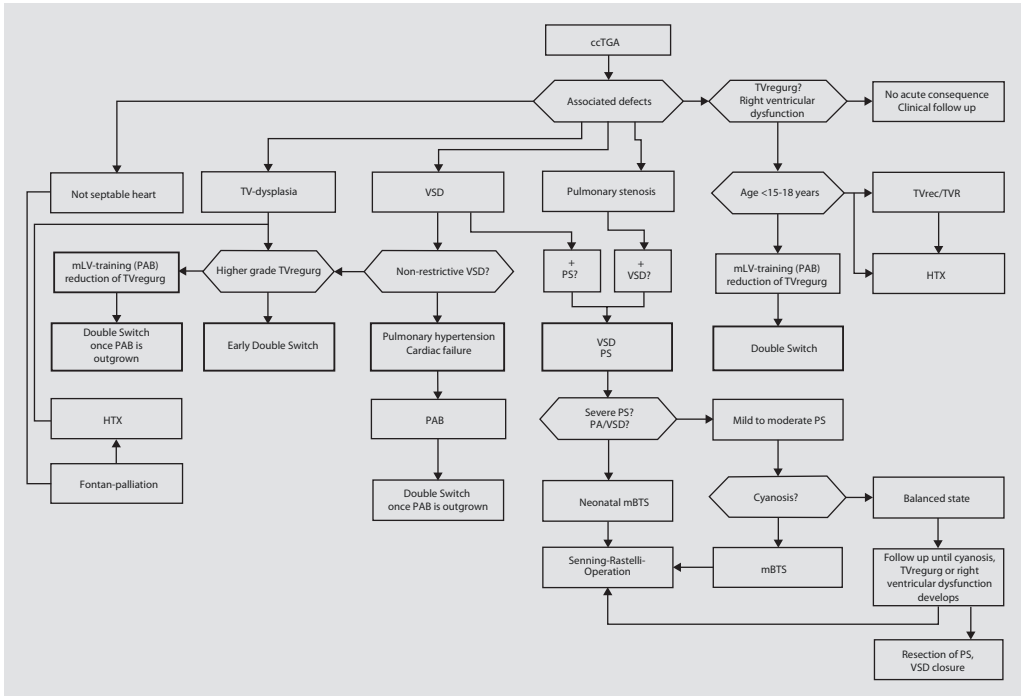

Fig. 19.2 Algorithm for the surgical management of congenitally corrected transposition of the great arteries. *Horizontal arrow* | No; *vertical arrow* | Yes; *ccTGA* congenitally corrected transposition of the great arteries, *HTX* cardiac transplantation, *mBTS* modified Blalock–Taussig shunt, *mLV* morphologic left ventricle, *PA* pulmonary atresia, *PAB* pulmonary artery banding, *PS* pulmonary stenosis, *TVregurg* tricuspid valve regurgitation, *TV* tricuspid valve, *TVR* tricuspid valve replacement, *TVrec* tricuspid valve reconstruction, *VSD* ventricular septal defect

19.1.4.2 Physiologic Correction (Classical or Traditional)

Circulation in congenitally corrected transposition is already physiologic in the sense that oxygenated blood flows to the body albeit through a right ventricle and the unoxygenated blood goes to the lungs through a left ventricle. In physiologic surgical correction, this balance is maintained. Surgical steps are taken to repair the associated malformation such as ventricular septal defect, pulmonary stenosis, and tricuspid valve regurgitation.

■ ■ General surgical approach and cardiopulmonary bypass

The approach to the heart is via median sternotomy. The thymus is resected and the pericardium is opened in the midline and fixed with stay sutures. After dissection of the great vessels and systemic heparinization, aortic and bicaval cannulation is performed. With establishing cardiopulmonary bypass, any preexisting systemic-to-pulmonary artery shunt is divided after being clamped distally and proximally. Both ends are

oversewn and/or clipped. All procedures are performed using mild to moderate hypothermia (28–32 °C). Cardioplegia is given (crystalloid cardioplegia, i.e., Bretschneider 30 cc/kg bodyweight, or repeat blood cardioplegia). Foramen ovale or superior pulmonary vein is used to insert a ventricular vent.

Once the surgical procedure is completed, coronary perfusion is reestablished by opening aortic cross-clamp. After rewarming to normal core temperature, the weaning from cardiopulmonary bypass is done by stepwise reduction of the support. A modified ultrafiltration is performed, while the operative result is assessed by transesophageal echocardiography. Prior to discontinuation of cardiopulmonary bypass, bipolar epicardial pacing wires are placed on the ventricle and the atrium. Drains are placed into the retrocardiac and retrosternal spaces, in the pleural spaces as necessary. The pericardium is reconstructed with 0.1 mm polytetrafluoroethylene membrane, to prevent damage to the heart or the great vessels during potential future re sternotomies.

■ ■ Atrial switch operation

Either the Mustard or the Senning operation is used for the venous switching (see ► Sect. 19.2.5.1, «Atrial Switch Operation»). Although Senning was more popular, intermediate outcome data from the Congenital Heart Surgeons' Society (Wells and Blackstone 2000) indicate better early and late survival with the Mustard operation.

■ ■ Closure of ventricular septal defects

The usual approach for closure of a VSD is through the right atrium and the mitral valve. Alternatives include a transpulmonary or a transaortic approach or a left ventriculotomy if implantation of a left ventricular to pulmonary artery valved conduit is needed. The VSD is closed with a tailored woven Dacron or a Gore-Tex patch. This can be done with a running suture or with multiple mattress sutures and pledgets. It is important to remember that the conduction tissue is running on the anterior-superior rim of the defect with the bundle on the left ventricular side of the septum. The sutures are placed through the VSD on the right ventricular side of the septum superiorly and anteriorly. In the rest of the perimeter of the defect which is free of conduction tissue, sutures can be placed safely into the rim of the defect on the left ventricular side. They also can be placed through the annulus of the septal mitral leaflet.

■ ■ Relief of subpulmonary stenosis and implantation of a valved conduit

The pathology of LVOT obstruction is quite variable. It could be due to fibromuscular ridge, accessory valve tissue, diffuse hypoplasia (tunnel), or valvar stenosis (see ► Sect. 19.1.1, «Pathology»). Resection of the stenosis is complicated by the anatomical position of the subpulmonary outflow tract, and the presence of penetrating bundle of His is in the area. Therefore, an extensive resection to achieve complete relief of an obstruction of the LVOT is hardly possible without damage to the conduction tissue.

As a result, the relief of the LVOTO is achieved in most cases by implantation of an extracardiac valved left ventricle-to-pulmonary artery conduit. A homograft or a bovine jugular vein conduit is preferably used.

When a left ventriculotomy is performed, special care has to be taken of the coronary arteries and the location of the papillary muscles, to avoid

injuring them. While the coronaries can be seen from outside the heart, transmitral digital palpation (index finger) is suggested to decide on the location for the ventriculotomy.

The conduit is implanted with a continuous polypropylene suture and is positioned either to the right or the left of the aorta depending on the available retrosternal space that allows minimal compression of the conduit by the sternum.

■ ■ Tricuspid valve reconstruction and tricuspid valve replacement

Access to the tricuspid valve through a midsternotomy approach could be challenging due to its posterior lateral position, especially in cases where the tricuspid valve is displaced distally into the right ventricle similar to Ebstein's disease in atrioventricular concordance (see ► chapter «Anomalous Pulmonary Venous Connections and Congenital Defects of the Atria, the Atrioventricular Septum, and the Atrioventricular Valves», Sect. 12.4.4). A better exposure of the left-sided AV valve in ccTGA may be achieved by a left thoracotomy approach, the historical, original approach to the mitral valve in normally related vessels. In principle, all known techniques of valve reconstruction including a ring anuloplasty, leaflet extension, or repositioning can be applied. Due to the discouraging results of tricuspid valve reconstruction in ccTGA, valve replacement should be strongly considered if a reconstruction does not achieve optimal and most satisfying result. A mechanical or tissue valve is usually used and is implanted in a routine fashion. Lesions such as severe LVOT obstruction or procedures such as pulmonary artery banding or anatomic repair may restore normal septal geometry and reduce annular dilatation of the tricuspid valve, thus improving outcome of tricuspid valvuloplasty.

■ ■ Pacemaker implantation

Spontaneous sudden or progressive complete atrioventricular block can occur in patients with ccTGA due to the abnormal location of the conduction system leading to continued mechanical stress. Iatrogenic block can also result from surgical procedures such as resection of subpulmonary obstruction or VSD closure with or without enlargement. The incidence of complete AV block seems to be higher (22–26%) after classical repair compared to anatomical repair in patients operated after 1981 (Hraska et al. 2005; Yeh et al. 1999),

because the closure in anatomic repair is done on the right ventricular side of the septum. The technique of implantation of pacemaker systems is extensively described in see ► Chapter «Device Therapy of Rhythm Disorders», Sect. 30.3. It has to be kept in mind that pacemaker wires with screws have to be used if they are inserted into the morphologically left ventricle because it lacks the trabeculation which normally holds the wires in place.

In children with a body weight <15 kg, a DDD system with epimyocardial wires and an epigastric battery implantation onto the posterior fascia of the rectus muscle is recommended. Over 15 kg of body weight, thin, transvenous electrodes implanted through the right subclavian vein may prevent thrombosis of the left innominate vein. The battery is placed under the right pectoral muscle on the thoracic wall.

19.1.4.3 Retraining the Left Ventricle for Anatomic Repair

Following physiologic repair of ccTGA, progressive failure of the systemic right ventricle may occur with or without tricuspid valve regurgitation. Retraining of the pulmonary LV to become a systemic ventricle and subsequent anatomic correction has been tried in D-TGA with RV failure following venous switch operation (Daebritz et al. 2001; Mavroudis and Backer 2000; Mee 1986; Poirier and Mee 2000; Poirier et al. 2004; Quinn et al. 2008; Brawn et al. 2008). The concept is based on progressive tightening of PAB that gradually allows the left ventricle to acquire the necessary muscle mass, posterior wall thickness, and normal geometry of its cavity as well as of the interventricular septum. Normalizing the septal orientation, namely, bulging towards the right ventricle improves the function of the tricuspid valve and right ventricle.

Which patients are suitable for a retraining of the left ventricle for anatomical repair is still largely an unanswered question due to the limited number of cases reported. One major issue is to what age a successful retraining of the left ventricle is still possible. Most series suggest the left ventricle loses its adaptability to become a systemic ventricle by 10–15 years of age (Mavroudis and Backer 2000; Poirier and Mee 2000), although there are occasional case reports of successful retraining of the mLV in patients up to early adulthood (23 years) (Padalino et al. 2000). The age limitation may be due to potential damage of the ventricle by the PAB after a certain age. Although the mechanism is unclear, failure of the mLV after retraining

may be due to inadequate coronary perfusion caused by the sudden increase of the afterload or by the induced hypertrophy. The reduced coronary reserve in older patients compared to young children may lead to greater ischemic damage of the myocardium following the sudden increase in afterload and consequently impaired short- and long-term ventricular function (Poirier et al. 2004; Quinn et al. 2008). However, training of the left ventricle already in early infancy, as performed in the «rapid two-stage switch operation,» is also associated with a long-term impairment of left ventricular function (see ► Sect. 19.2.5.3, «Choice of the Operative Procedure»). Another unanswered question is how fast should the pulmonary artery be banded. It seems that a multistage slow tightening of the band to appropriate pressure levels is better than a one-stage very tight initial banding. It allows healthier left ventricular hypertrophy and prepares the left ventricle better for short- and long-term performance. The measurement of left ventricle mass by MRI is a reliable way to judge the preparedness of the left ventricle (Duncan et al. 2003; Langley et al. 2003; Poirier et al. 2004).

19.1.4.4 Anatomical Correction

In the physiologic repair, the emphasis of the treatment strategies is placed on the management of the associated malformation and their complications. The mRV and the tricuspid valve remain in the systemic circulation. Disappointment with the long-term performance of the right ventricle and tricuspid valve as systemic structures and resultant heart failure led to the introduction of anatomic repair which incorporates the left ventricle and mitral valve into the systemic circulation. The systemic venous blood is rerouted into the mRV, and the pulmonary venous blood is rerouted into the mLV by a venous switch operation (Senning or Mustard operation) (see ► Sect. 19.2.5.1, «Atrial Switch Operation»). In patients without pulmonary outflow obstruction (without LVOTO), the ventriculoarterial discordance is counteracted by an additional arterial switch operation. On the other hand, the venous switch operation has to be completed by a Rastelli operation in those patients with LVOTO, pulmonary stenosis or atresia, and VSD. Both variations comprise the so-called double-switch operation or the Ilbawi operation (Ilbawi et al. 1990; Yagihara et al. 1994). The surgical techniques are described in detail in ► Sect. 19.2.5, «Surgical Management», and Sect. 19.2.6.4, «Transposition of the Great Arteries with Left Ventricular Outflow Tract Obstruction».

Although there are no absolute contraindications for the anatomical repair of ccTGA, certain morphologic features are regarded as *relative contraindications*. In candidates for a Senning/ Mustard–Rastelli operation, the size and location of the VSD can limit the feasibility of connecting the left ventricle via the VSD to the aorta. Thus, a Senning/ Mustard–Rastelli operation cannot be performed successfully if the VSD is very distant to the aortic valve in the muscular or apical septum. In patients with small VSD, enlargement of the defect to accommodate left ventricular stroke volume without obstruction has resulted in ventricular dysfunction and increased incidence of complete AV block (Ilbawi et al. 2002; Shinòka et al. 2007). Another relative contraindication is the insertion of chordae of one or both AV valves on the crest of the VSD or at the infundibular septum, whereby tunneling of the mLV via the VSD to the aorta may disturb the functional integrity of one or both AV valves. Severe hypoplasia of the mRV or the mLV makes the patients candidates for a Fontan palliation. In mild hypoplasia of the mRV, a «double-switch» operation, in combination with bidirectional pulsatile Glenn procedure, 1½ ventricle repair is recommended. The use of bidirec-

tional Glenn leading to a *hemi-Mustard procedure* has also been advocated as part of the double-switch operation in order to assist right heart hemodynamics. Its benefits also include improved conduit life, reduced venous obstruction, decreased sinus node dysfunction, and technical simplicity (Malhotra et al. 2011) (■ Figs. 19.3 and 19.4).

Patients with coronary anomalies such as single or intra-aortomural coronary artery with or without signs of myocardial ischemia, as well as those with subsystemic LV pressure and those with atrial arrhythmias, are considered suboptimal candidates for anatomic correction (Langley et al. 2003; Poirier et al. 2004; Mee 2005).

19.1.4.5 Alternative Procedures

In patients, in whom biventricular repair is not possible due to a straddling AV valve, hypoplasia of one ventricle, or a difficult anatomy of one or more VSDs, the Fontan palliation is an alternative surgical approach (see ► Chapter «Definite Palliation of Functional Single Ventricle», Sect. 13.6). Compared with traditional physiologic repair, the Fontan palliation provides better midterm results in this subgroup of patients. This may be due to the fact that in these cases, the left ventricle remains in the

■ Fig. 19.3 Illustration of the hemi-Mustard/bidirectional Glenn (BDG) operation with the arterial–atrial switch procedure in a dextro-rotated heart. IVC inferior vena cava, LV left ventricle, RV right ventricle (Adapted from Malhotra et al. (2011); with permission)

■ Fig. 19.4 Illustration of hemi-Mustard/bidirectional Glenn (BDG) operation with the Rastelli–atrial switch procedure in a dextro-rotated heart. IVC Inferior vena cava, LV left ventricle, RV right ventricle (Adapted from Malhotra et al. (2011); with permission)

systemic circulation providing additional energy source. Another alternative is 1½ ventricle repair, in which a limited relief of LVOTO is combined with a pulsatile bidirectional Glenn anastomosis (Mavroudis et al. 1999). In this strategy, it is important to keep the pressure in the mLV high, but subsystolic to prevent septal shift towards the mLV and consequent tricuspid regurgitation and progressive deterioration of mRV function. This strategy may be used in combination with a Rastelli operation for patients who are not suitable for an atrial switch due to the location and size of the VSD or abnormal subvalvar attachments to the crest of the septum. A better alternative in these patients is aortic translocation (see ► Sect. 19.2.6.4, «Nikaidoh Operation»). The last treatment option with or without prior surgery is orthotropic heart transplantation (see ► Chapter «Heart and Heart-Lung transplantation», Sect. 37.1.5.2). However, heart donor shortage, particularly in neonates and children, and the morbidity of lifelong immunosuppression have to be taken into account when deciding on optimal treatment strategy for each individual patient.

19.1.5 Results

19.1.5.1 Physiologic Repair

There are many reported results of classical physiologic repair of ccTGA. They show a low early mortality and consistently emphasize the problem of progressive failure of the mRV in the systemic circulation (Acar et al. 1998; Graham et al. 2000; Ilbawi et al. 2002; Shinoka et al. 2007; van Son et al. 1995; Voskuil et al. 1999; Yeh et al. 1999). The largest series published (Hraska et al. 2005) reports 123 patients with physiologic repair. Survival after 1, 5, 10, and 15 years was 84%, 75%, 68%, and 61%, respectively. Patients with preoperative tricuspid regurgitation had the worst outcome. A dysfunction of the mRV was found in 44% of all patients. Freedom from mRV dysfunction after 5, 10, 15, and 20 years (after physiologic repair) was 88%, 73%, 57%, 43%, and 39%, respectively. Dysfunction of the tricuspid valve was present in 42% of the patients on follow-up, and freedom from development of tricuspid valve dysfunction after 5, 10, 15, and 20 years was 91%, 69%, 52%, 42%, and 37%, respectively. Sano et al. (1995) reported a mortality rate of 17%, significant tricuspid regurgitation of 71%, and mRV dysfunction of

50% at 10 years of follow-up. The major risk factor for long-term poor outcome of physiologic traditional repair was *preexisting tricuspid valve regurgitation* (Hraska et al. 2005; Shinoka et al. 2007). Survival rate of patients with preoperatively competent tricuspid valve was 72% at 30 years.

19.1.5.2 Anatomical Correction

The discouraging long-term results of physiologic repair and the progressive failure of the mRV in the systemic circulation have prompted the adoption of anatomic repair as the treatment of choice. Excluding the learning curve results, short- and midterm outcome of anatomic repair has been excellent (Devaney et al. 2003; Duncan et al. 2003; Imai et al. 1994; Imamura et al. 2000; Ilbawi et al. 2002; Langley et al. 2003; Shinoka et al. 2007; Hiramatsu et al. 2012). The operative mortality is reported as low as 0–7% (Duncan et al. 2003, 46 patients, 26 «double-switch» operations, 20 Senning–Rastelli procedures; Karl et al. 1997, 14 patients, all «double-switch» operations; Ilbawi et al. 2002, Langley et al. 2003, 54 patients, 29 «double-switch» operations, 22 Senning–Rastelli procedures, 3 Senning tunnel operations; Hiramatsu et al. 2012, 90 patients, 72 atrial switch–Rastelli procedures, 18 «double-switch» operations). Hiramatsu reported a follow-up of 90 patients with double-switch operation for congenitally corrected transposition. Survival was 75.7% for patients with atrial switch and intracardiac rerouting (Rastelli operation) and 83.3% when a combined arterial and atrial switch were used for those with double switch at 20 years postoperatively (Hiramatsu et al. 2012). Langley et al. (2003) reported a series of 54 patients with a 5- and 9-year survival of 94.4%, 89.7%, respectively, and demonstrated reduction of tricuspid valve regurgitation by the shift of the interventricular septum to the mRV after anatomical correction. Similar findings were reported by others. None of the patients had to be reoperated for tricuspid regurgitation (Devaney et al. 2003; Duncan et al. 2003; Imamura et al. 2000; Langley et al. 2003; Shinoka et al. 2007). The incidence of post-op complete AV block is quite variable (2–5%) and is lower following anatomic corrections, but increased when aggressive enlargement of the VSD is needed to prevent potential subaortic stenosis in venous switch/Rastelli operation (Shinoka et al. 2007).

New onset of left ventricular dysfunction has been reported post anatomic repair. The exact etiology is not clear but could be related to long cross-

clamp time, inadequate myocardial protection, injury to septal perforators, other coronaries, subaortic stenosis, or suboptimal coronary arteries translocation (Langley et al. 2003; Duncan et al. 2003; Imamura et al. 2000; Shinoka et al. 2007). Also, moderate regurgitation of the neo-aortic valve can occur following double-switch operation and may be related to pulmonary artery banding causing proximal pulmonary trunk dilatation and disruption of the sinotubular bar (Langley et al. 2003). Occasional neo-aortic regurgitation may occur without prior banding (Quinn et al. 2008). Restoration of sinotubular bar and anuloplasty using a double suture line at the anular level can be used to minimize the incidence of regurgitation and consequent left ventricular failure. The incidence of complications related to the venous switch operation such as arrhythmias and venous obstruction has decreased markedly following the introduction of the modifications with hemi Mustard by Frank Hanley's group (Malhotra et al. 2011) (■ Figs. 19.3 and 19.4).

19.1.6 Summary

The current surgical strategy of choice in ccTGA is the anatomical correction/repair. However, long-term data are still limited to small series, so there remains uncertainty with regard to the performance of the mLV in the systemic circulation, to the development of neo-aortic valve regurgitation, and to the potential complications of venous switch operation, although the later has decreased markedly with recent modifications. Risk factors such as RV dysfunction and tricuspid regurgitation favor strongly anatomic repair. Certain subgroups of patients, however, are not suitable for anatomical correction. These include older patients, in whom a retraining of the mLV cannot be performed successfully. These patients are still candidates for a classical repair or heart transplantation. If the physiologic repair is deemed necessary, it is advantageous to aim at leaving mLV pressure at least half of the systemic pressure, to preserve the geometry of the mRV and interventricular septum. In younger patients, in whom anatomical correction is contraindicated because of morphological features, i.e., straddling of an AV valve, an unfavorable location of the VSD or a hypoplastic ventricle, the Fontan palliation is an alternative with good results. Asymptomatic patients with associated defects but balanced systemic and

pulmonary circulations such as those with a VSD and moderate pulmonary stenosis can be followed without intervention as long as they are free of clinical symptoms and do not develop mRV dysfunction, although such conservative approach is not recommended any more. Patients with ccTGA without associated defects can also be observed without intervention. A good alternative, however, is to apply a loose PAB in the neonatal period to keep the pressure in the mLV elevated to preserve septal geometry and keep LV trained to perform as systemic ventricle in case anatomic repair is needed at an older age. Long-term results of this aggressive approach are not available yet.

19.2 Dextro-(D-)Transposition of the Great Arteries (D-TGA)

19.2.1 Epidemiology

D-TGA is the second most common cyanotic cardiac malformation after tetralogy of Fallot. It has an incidence of around 10% of all congenital heart malformations which occur in about 8/1,000 live births (Sellke et al. 2005). The overall ratio of male to female newborns with TGA is 2:1 and is increased to 3:1 in D-TGA with intact ventricular septum, «simple» TGA (Fyler 1980).

19.2.2 Embryology and Pathology

In normal hearts, the aorta is posterior and to the right, and the pulmonary artery is anterior and to the left (N position of Van Praagh). In transposition or malposition, the aorta is anterior to the pulmonary artery at the semilunar valve levels. If the aorta is anterior and to the right, it is D-transposition of the great arteries (D-malposition of Van Praagh); if it is anterior and to the left, the transposition is L-transposition of the great arteries (L-transposition of Van Praagh) regardless of the relationship of the great arteries to the ventricles they arise from.

D-TGA is considered a conotruncal malformation, i.e., a malformation in which the outflow tracts of both ventricles and their respective semilunar valves are affected. The aorta and the aortic valve arise from the mRV. There is a subaortic muscular conal septum separating the aortic valve from the tricuspid valve. The pulmonary artery

and the pulmonary valve arise from the mLV, and there is a fibrous continuity between the mitral valve and the pulmonary valve (no conus), a relation which is normally present with the aortic valve. Normally, the pulmonary valve is the only valve, which is not in fibrous continuity with the other cardiac valves, because it is separated by the conal septum. In TGA this applies to the aortic valve. The great vessels are almost anterior–posterior to each other, and the pulmonary artery is larger in diameter. Frequently, the commissures of the two outflow valves are facing each other, and the coronary arteries arise laterally and posteriorly on the right and left side of the aortic root from the facing sinuses. These abnormalities are due to lack of absorption of the subaortic conus prenatally leaving the aortic valve and aorta anteriorly.

As a result, there is atrioventricular concordance and ventriculoarterial discordance due to the normal position of the RV and abnormal anterior position of the aorta. Using the segmental nomenclature of Van Praagh and Van Praagh (1966), simple D-transposition is described as (S, D, D), with S being situs solitus (normal atrial position), D dextro (normal) looping of ventricles, and D dextro position of great arteries.

Associated malformations are present in 25% and consist of a VSD with or without obstruction of the left or right ventricular outflow tract, hypoplasia of the aortic arch or coarctation of the aorta (see ► Sect. 19.2.6.5, «Transposition with Right Ventricular Outflow Obstruction and Hypoplasia of the Aortic Arch or Coarctation of the Aorta»), and coronary artery abnormalities.

Anatomic LVOTO is rare in simple TGA, TGA with an intact ventricular septum. Often, a subvalvar LVOTO is just a functional obstruction caused by bulging of the ventricular septum to the left. It decreases after anatomical correction due to the decrease in right ventricular pressure and resultant septal shift towards the right ventricle. This form of LVOTO is not a contraindication to arterial switch operation. The pulmonary valve can be abnormal. Rarely, it is dysplastic; more frequently it is bicuspid with or without significant stenosis. The subpulmonary area may be obstructed with accessory valvar tissue or abnormal attachment of the mitral valve (as in Taussig–Bing anomaly). It could also be due to fibromuscular ridge or tunnel-like obstruction.

VSD in TGA can be located anywhere in the ventricular septum (25% incidence). The pres-

ence of a VSD increases the probability of further associated malformations. If a VSD is hemodynamically significant, the pulmonary artery is larger in diameter compared to the aorta, and the ratio can reach 3:1. RVOT obstructions can be extensive and tunnel-like. Multilevel of obstructions of the systemic (aortic) outflow with hypoplasia of the aortic arch or coarctation of the aorta is more frequent in TGA with VSD compared to simple TGA and may be associated with hypoplastic right ventricle at the extreme end of the spectrum precluding biventricular repair in some cases. The presence of interrupted aortic arch is also possible, but rare (see, ► Sect. 19.2.6.5, «Transposition with Right Ventricular Outflow Obstruction and Hypoplasia of the Aortic Arch or Coarctation of the Aorta»).

The coronary arteries have abnormal patterns in 25–30% of patients with TGA. These abnormalities are more frequently observed in patients with associated VSD or double-outlet right ventricle (DORV) and side-to-side position of the great vessels (see ► Sect. 19.2.6.6, «Taussig-Bing Anomaly»; Gittenberger-de Groot et al. 1983; Sim et al. 1994).

There are several classifications of the *coronary morphology*, based on the nomenclature of the sinus, from which the coronaries arise. In the usual coronary pattern, the coronaries come off of the respective posterior right and left sinus, whereas the anterior sinus does not give rise to any coronary artery. The axes of the great vessels and the coronary arteries are in a right angle. The most common anomaly is a circumflex artery arising from the right coronary artery out of the right posterior sinus. In these cases the circumflex artery runs behind the two great vessels into its supply area. In cases with single coronary artery, both right and left coronary arteries arise from a single ostium. Frequently there is an associated small additional ostium that gives rise to a conal branch. Only very rarely, there is no second ostium at all. Another very important variation of coronary anatomy is an intramural course of a coronary artery, present in 2–3% of cases (Gittenberger-de Groot et al. 1986; Sachweh et al. 2002) regardless of branching pattern. The intramural part of the coronary artery characteristically runs the first millimeters within the aortic wall and does not have its own separate wall. Typically, the coronary artery crosses one aortic valve commissure within the aortic wall and its ostium is slanted and beveled. Therefore, the

■ **Fig. 19.5** Coronary morphology. **a** Most common pattern of coronary arteries in D-transposition of the great arteries; **b** Rare pattern of coronary branching with single ostium. *a* anterior, *Cx* circumflex artery, *l* left, *L* left anterior descending artery, *p* posterior, *r* right, *R* right coronary artery

ostium cannot be excised in the regular fashion at the time of the arterial switch operation, because of the common wall of the aorta and the coronary in the area of excision of the button. The variations of coronary anatomy are depicted in ■ Fig. 19.5.

19.2.3 Physiology

The normal circulation resembles the figure of 8: The heart is in the cross middle and the

rings are the longer systemic and the shorter pulmonary circulations. The two circulations are in series. In contrast, in D-TGA, pulmonary and systemic circulations are in parallel; the oxygenated blood recirculates in the pulmonary vessels, and the deoxygenated blood recirculates in the systemic vessels. Survival after birth is possible only if there is mixing of blood between the two circulations. The mixing can occur at the level of foramen ovale or an ASD, a persistent ductus arteriosus, or a VSD (■ Fig. 19.6). The mixture of the blood

Fig. 19.6 In contrast to normal anatomy, in D-transposition (D-TGA) the systemic and pulmonary circulations are separate and are connected parallel. The oxygenated blood circulates in the pulmonary circulation, and the deoxygenated blood in the systemic circulation. The mixing and the survival are accomplished by cross-links, of which the atrial septal defect (ASD) is the most important, followed by the persistent ductus arteriosus (PDA) and a ventricular septal defect (VSD)

through these shunts usually ensures adequate arterial oxygen saturation. The most important shunt is the one on the atrial level. If this is too small, the atrial connection can be enlarged by a balloon atrioseptostomy. This can be done without fluoroscopy but under echocardiographic control. Usually, an ASD ensures adequate mixing and survival for the first year of life. Very rarely, adequate mixing of oxygenated and unoxygenated blood does not occur in spite of wide open atrial communication, and maintenance of open ductus arteriosus with PGE1 might be needed. In the era of the atrial switch operation, i.e., the Senning or Mustard operations, children with D-TGA were operated on between 3 months and 1 year of age, surviving until the procedure with just an ASD. Rarely, in the so-called nonmixers, urgent arterial switch operation may be indicated.

At birth, patients with D-TGA with or without a VSD have systemic pressures in both ventricles because of the elevated pulmonary vascular resistance of fetal circulation. Both right and left ventricles, therefore, are adapted to pump blood against systemic vascular resistance. In the neonatal period, the right ventricle maintains muscular hypertrophy, while the left ventricle gradually loses muscle mass as the pulmonary arterial resistance decreases. The resulting decrease in LV

pressure leads to a shift of the ventricular septum towards the mLV, a phenomenon that becomes apparent echocardiographically by the fourth week of life. This natural decrease in muscle mass of the LV is important for timing of the arterial but not the atrial switch operation.

19.2.4 Diagnostics

Diagnoses of D-TGA can be established prenatally by the characteristic absence of crossing of the great arteries on fetal echocardiogram and the origin of the aorta from the anterior right ventricle. After birth there is no typical heart murmur, and the cyanosis can be mild due to adequate mixing while the ductus is still open. Newborns present with unspecific clinical symptoms as tachypnea, failure to thrive, and cyanosis while feeding. Associated, noncardiac malformations are extremely rare in simple D-TGA. The diagnosis is typically made by echocardiography. Cardiac catheterization is usually not necessary, neither in simple D-TGA nor in D-TGA with VSD even in patients with unclear coronary artery anatomy.

Today's surgical therapy is always the arterial switch operation, for which no additional preoperative diagnostics besides echocardiography are necessary.

Coronary anomalies suspected but not diagnosed preoperatively can be thoroughly evaluated and managed at the time of surgery, as they do not constitute contraindication to arterial switch operation. In case of complex LVOTO or other malformations, which potentially necessitate a change of operative strategy or even a univentricular pathway, cardiac catheterization may be indicated, although in most cases 2 or 3D echo can provide this information without the need for cardiac catheterization.

Sometimes, an MRI can add useful information regarding left ventricular mass in cases of delayed presentation (after 3 weeks of life).

19.2.5 Surgical Management

Surgical management of D-TGA has undergone changes over the years. These changes reflect the current *basic principles* of surgery for congenital malformations, namely, that an early, complete, and anatomic repair should be performed whenever possible.

Historically, the initial therapeutic steps were palliative and consisted of an atrioseptostomy without the heart and lung machine (Blalock and Hanlon 1950) and switching the IVC and RPV location using a homograft (Baffes 1956; O'Shea et al. 1983). The development of cardiopulmonary bypass and its widespread application enabled the introduction of the atrial switch operation (Senning 1959; Mustard 1964) and later the arterial switch anatomic correction (Jatene et al. 1975, 1976).

19.2.5.1 Atrial Switch Operation (Senning and Mustard Procedures)

The two types of atrial switch operations were first and successfully performed by Senning in 1958 and Mustard in 1963. Their principle is to switch the venous inflow to both atria so that the unoxygenated blood goes to the LV and pulmonary circulation while the oxygenated blood goes to the RV and systemic circulation (■ Fig. 19.6). The outcome is a *physiologic circulation* without the normal anatomical repair, where the right ventricle remains the systemic ventricle, an anatomy and pathophysiology comparable to the findings in ccTGA or L-TGA (see ■ Fig. 19.1). The Senning procedure can be

done in the neonatal period or could be delayed until the child is older as long as the oxygen saturation is satisfactory. Its main advantage is avoidance of any patch material. On the other hand, it utilizes the atrial septum and right atrial wall to redirect the venous blood (Senning 1959). The surgical principle of the Mustard procedure (Mustard 1964) is to create an inner tunnel from the ostia of the caval veins to the posteriorly lying mitral valve and to reroute the pulmonary venous blood around this inner tunnel to the anteriorly positioned tricuspid valve (■ Figs. 19.7, 19.8, 19.9, 19.10, 19.11, 19.12, 19.13, 19.14, 19.15, 19.16, 19.17, 19.18, 19.19, and 19.20). In contrast to the Senning, which utilizes viable tissue, it uniformly utilizes prosthetic patch material.

For extracorporeal circulation, the venous cannulae are placed into the inferior caval and into the innominate vein or preferably in the superior vena cava; the arterial cannula is inserted into the ascending aorta. The operation is mostly done using mild to moderate hypothermia without circulatory arrest.

In the *Senning operation*, the aorta is cross-clamped, and the venous inflow is excluded. Cardiac arrest is maintained with crystalloid or blood cardioplegia. The atrium is dissected anterior to the orifices of the venae cavae and opened longitudinally. The incision is extended from the anterior wall of the IVC to base of the atrial appendage. A band of atrial wall tissue of 2–3 cm is created by longitudinal incision of the left atrium just anterior to the entry of the right pulmonary veins. This band of atrial tissue forms the anterior circumference of the respective caval veins. The residual atrial septum is cut anteriorly, and the coronary sinus is split open towards the left atrium. A segment of atrial septum between the AV valves is left intact. The rim of the coronary sinus and the posteriorly displaced atrial septum is sutured anterior to left pulmonary veins using running monofilament sutures. In patients with a deficient atrial septum (native ASD or s/p Rashkind), a septum defect is replaced with a patch of any kind most commonly pericardium or Gore-Tex. The roofing of the left pulmonary veins is completed suturing of the anterior rim of the atrial wall band to the remnant of the septal rims between the two atrioventricular valves.

At the lower rim, the sutures are to be placed into the opened coronary sinus away from the tricuspid side of the sinus, to prevent from AV block.

As a result, the pulmonary venous blood is directed around the tube into the mitral valve. This is achieved by fixing the anterior edge of the right atrium onto the superior and inferior caval veins and suturing it to the cut edge of the left atrium. Care has to be taken to avoid stenosis of the caval veins and the pulmonary veins. The right atrial appendage can be used to enlarge the superior caval vein. Patches of various tissues can be used to augment both caval veins when necessary (autologous/fixed pericardium, bovine pericardium, or artificial materials).

During rewarming, a left vent can be inserted via the right atrial appendage into the newly created anatomically right but functionally left atrium.

In the *Mustard procedure*, the entire atrial septum is excised and the coronary sinus is split completely, unroofing it into the left atrium. An autologous or bovine pericardial patch or artificial patch material is sutured beginning just anterior to confluence of left pulmonary veins, then around the rim of the coronary sinus, then around both orifices of the caval veins, and finishing at the residual rim of the anterior atrial septum, thus roofing the pulmonary veins.

Care has to be taken that the anterior suture line is placed at the floor of the split coronary sinus all the way back to its inferior edge before turning ventrally to the orifice of the caval vein to minimize damage to the conduction tissue.

Behind this newly created septum, both caval veins and the coronary sinus drain through the mitral valve into the left ventricle which is connected to the pulmonary artery (■ Figs. 19.18, 19.19, and 19.20). The pulmonary venous tunnel is completed by closing the anatomic right atrium using a patch of autologous pericardium. This drains the pulmonary venous blood through the tricuspid valve into the right ventricle. In situ pericardium can be used to close the right atrium by suturing the open atrium to adjacent pericardium with the hope of maintaining patch viability and thus function. Care must be taken to avoid phrenic nerve injury. Several modifications of the techniques of Senning and Mustard have been described (Shumaker 1961; Oelert 1991).

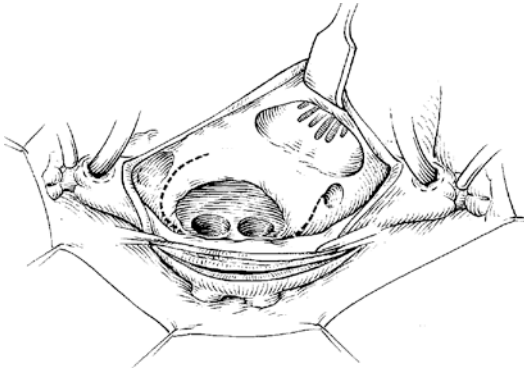

■ Fig. 19.7 Technique of cannulation for the atrial switch (Senning and Mustard). The superior vena cava is cannulated directly or at atriocaval junction, and the inferior vena cava at its entry into the right atrium

■ ■ Results

The major drawback of the atrial switch operation is leaving the right ventricle as the systemic ventricle which is not designed to generate high pressure, but to transport volume. It is normally flat, resting against the left ventricle, and has only one

■ Fig. 19.19 Atrial switch (Mustard). The new atrial septum is constructed with the use of a pericardial or artificial patch, which is fixed posteriorly between the confluence of the left-sided pulmonary veins and the mitral valve and brought from the back around the pulmonary veins. Finally, it is fixed between the AV valves

■ Fig. 19.20 Atrial switch (Mustard). The new atrial septum is inserted completely. Behind this, the blood drains from the caval veins and the V. magna cordis through the mitral valve into the morphologic left ventricle into the pulmonary artery, whereas the pulmonary venous blood drains through the tricuspid valve into the morphologic right ventricle and into the aorta

of three coronary artery branches. In addition, the tricuspid valve has only one real papillary muscle with the other papillary attachments being septophilic. Therefore, the right systemic ventricle is bound to fail in the long term with an incidence of about 0.8%/patient-year followed by tricuspid valve annulus dilatation and subsequent regurgitation (Ebenroth and Hurwitz 2002; Martin et al. 1990; Oechslin and Jenni 2000). Tricuspid valve replacement has proven ineffective in solving the problem, as it does not prevent from but may delay the progression of systemic right ventricular failure. Another serious drawback of the atrial switch operation is an increased incidence of rhythm disturbances in the form of the so-called brady-tachy syndrome, an unforeseeably changing brady- and tachycardic atrial arrhythmia, which is attributed to the multiple incisions and suture lines in the atrium (Gadzoulis et al. 2000). Although these arrhythmias can be treated with catheter ablation and pacemaker insertion, they have been incriminated as the cause of sudden death after venous switch operations. In cases of progressive systemic right ventricular failure, the atrial switch can be taken down and anatomic arterial switch performed. This necessitates a prior retraining of the left ventricle by stepwise banding of the pulmonary artery. Although technically demanding, it can be performed successfully before 10 years of age. Conversion in older patients can potentially damage the left ventricle and has not been associated with good results (Daebritz et al. 2001; Imai et al. 2001; Poirier and Mee 2001). Cardiac transplantation is an alternative solution independent of age.

Today, because of its long-term poor outcome, the atrial switch has limited indications (presentation for simple TGA late in infancy or part of double switch) and should not be used as an alternative to treat neonatal D-TGA patients who are not good candidates for arterial switch operation. Whether or not univentricular pathway is preferable to an atrial switch operation in certain complex TGA is an open question (see ► Sect. 19.1.4, «Surgical Treatment Strategies», and Sect. 19.1.4.5, «Alternative Procedures»). Fontan approach in these situations could be advantageous because of the availability of the left ventricle to support the right ventricle as both become one systemic ventricle.

In summary, the atrial switch procedures are currently rarely indicated in D-TGA but are applied in late presentation of simple TGA (if no LV retraining is elected), in special complex ana-

tomic situations, and in double-switch operation (Ilbawi procedure in ccTGA).

19.2.5.2 Arterial Switch Operation

In the arterial switch operation, the cardiac malformation is corrected anatomically, by connecting the great vessels to their normal ventricle, creating ventriculoarterial concordance. In this procedure, in addition to the switch of the great arteries, the coronary arteries have to be transferred as well as they would otherwise arise from the neopulmonary artery/root. The semilunar valves and sinus remain in their original location. Reimplantation of the coronary arteries involves translocation into the neo-aortic root. It carries the risk of kinking or distortion of the coronary arteries with resultant stenosis or occlusion and potential for myocardial ischemia or even infarction. The risk is increased in the presence of coronary anomalies, particularly if there is only a single ostium giving rise to all three coronary branches (Daebritz et al. 2000; Mayer et al. 1990; Wernovsky et al. 1995; Fricke et al. 2012). It is additionally increased if there is intramural course of the first coronary artery segment (see ► Sect. 19.2.2, «Embryology and Pathology») (Sachweh et al. 2002).

To intraoperatively detect an intramural course of a coronary artery and not to cut the vessel accidentally, an inspection of the coronary ostium from inside is essential.

Postoperative ischemia in the supply area of a transferred coronary artery necessitates revision. Complete new reimplantation with or without an augmentation with the aid of a pericardial patch can improve the angle and width of the orifice. An internal thoracic artery bypass graft in newborns, although feasible, should be discouraged.

In most places the arterial switch is done without circulatory arrest. Rarely however, there are institutions in which the arterial switch operation is routinely performed using hypothermic circulatory arrest of about 40 min (Fuller et al. 2010). Cannulation is done with two venous cannulae in either both caval veins or in the innominate vein and the inferior caval vein; an arterial cannula is inserted into the distal ascending aorta just at the brachiocephalic trunk. Following initiation of cardiopulmonary bypass, the ductus arteriosus is closed by ligatures or secured clips and is divided. The space between the great vessels is dissected, and the main pulmonary artery branches are dissected and mobilized distally to beyond the branching of the upper lobe arteries. It is impor-

tant to divide any tissue tethering or pulling on the pulmonary arteries to allow successful Lecompte maneuver without pulmonary artery kinking or distortion (see below). After cross-clamping of the aorta and achieving cardioplegic arrest, the right atrium is opened and a left heart vent is placed via the atrial septal defect or persistent foramen ovale. The aorta is cut distal to the sinotubular junction, clearly distal to the coronary ostia, and after inspection, the coronary arteries are excised with a wide U-shaped aortic wall button. This should be done under direct visualization from the inside and the initial cut to be limited to the aortic wall, to decrease potential damage to the coronary arteries especially in case of an intramural course. If the coronary ostium is very close to the commissure, the commissure is mobilized and an adequate coronary button is harvested. The commissure may be resuspended later during the reconstruction of the neopulmonary root.

The coronaries are mobilized for 5–10 mm peripherally. Sometimes it is necessary to sacrifice a conal branch to gain sufficient mobility. The pulmonary artery is cut 2–3 mm proximal to bifurcation. The coronary buttons are approximated to the neo-aorta to select the optimal place for reimplantation. In difficult coronary anatomy, it is useful to mark the best position for reimplantation prior to division of the great vessels. It is important to choose the position on the neo-aorta rather a little distal than too proximal as the risk of kinking caused by very proximal implantation is higher than the risk of stretching of the elastic neonatal coronaries caused by distal placement. The aorta is pierced with a knife at the selected position. Care is taken that the cusps of the semi-lunar valve are away to avoid damage to the valve (neo-aortic valve). The hole is stretched with a fine instrument and a 4-mm punch is used to achieve a rounded hole. The implantation is performed with an absorbable running 7/0 polydioxane suture or with similar size nonabsorbable monofilament suture (Daebritz et al. 2000). Some surgeons prefer the excision of a U-shaped hole; others perform a trapdoor plasty, in which no tissue is removed and the hole is created by a wing-door incision (■ Fig. 19.21). The later techniques are advantageous in some cases because they allow modifications in the orientation of the coronary artery as needed to obtain optimal angle especially when the anatomy is complex.

After implantation of the coronary arteries, the Lecompte maneuver (Lecompte et al. 1981) is performed, in which the pulmonary bifurcation is advanced in front of the distal aorta by passing the aorta posteriorly between the two main pulmonary artery branches. The next step is the end-to-end anastomosis of the ascending aorta with the reconstructed neo-aortic root. Discrepancy between neo-aortic root and ascending aortic diameter can be adjusted by taking smaller bites on the distal small aorta. It may be helpful to make two longitudinal incisions at the cut end of the distal aorta to decrease the discrepancy and achieve appropriate orientation. The atrial septum is closed with a running double suture after removing the vent; the right atrium is closed in the same way. After de-airing, the cross-clamp is removed. The areas of excision of the coronary buttons are patched with fresh or glutaraldehyde-fixed autologous pericardium. Augmentation with two separate patches is preferred, but a single, large pantaloons patch can be used as well. Other patch materials have not proven of value and have led to stenosis. The reconstructed proximal neopulmonary artery is then anastomosed end to end with the distal pulmonary artery using 6/0 polydioxane sutures. Polypropylene can be used as well. At the end of the procedure, coronary arteries are inspected for flow, and the myocardium for color. The success of the operation is

■ Fig. 19.21 Trap door technique

visible right away by the good filling of the coronary arteries and the pink myocardium of both ventricles.

In intramural course of a coronary artery (■ Fig. 19.22), the aortic wall has to be excised beyond the commissure together with the coronary artery. The commissure is detached and resuspended later to the autologous pericardial patch used for the reconstruction of the pulmonary trunk. Some authors recommend the splitting and unroofing of the intramural part of the coronary artery (Asou et al. 1994).

Several techniques have been used for single coronary artery or both coronary arteries arising in proximity from the same sinus. These techniques include separation of both coronary ostia (■ Fig. 19.23) and separate reimplantation or reverse flap (■ Fig. 19.24). Rarely used is the in situ exclusion technique (■ Fig. 19.25).

■ ■ Results

Hospital mortality in patient with simple D-TGA, undergoing arterial switch operation, is less than 2% in most experienced institutions, even in small babies with low birth weight (Blume et al. 1999; Daebritz et al. 2000; Roussin et al. 2007; Fricke et al. 2012; Khairy et al. 2013). Most patients do not need any cardiac medication and have normal exercise tolerance (Muller et al. 2013). Coronary artery stenosis or obstruction is rare (5%), and freedom from reoperation at 10 years is >90% (Daebritz et al. 2000; Kado et al. 1994; Fricke et al. 2012; Khairy et al. 2013) but is lower in patients with associated cardiac malformations (Fricke et al. 2012). Pulmonary stenoses caused by the Lecompte maneuver occur in 5–10% of cases. Development of regurgitation of the neo-aortic valve (Losay et al. 2001; Marino et al. 2006; Lim et al. 2013) occurs in up to 5% of patients and is more common after pulmonary artery banding. Rhythm disturbances are rare compared to the atrial switch operation and are mostly supra-ventricular in origin (Rhodes et al. 1995; Khairy et al. 2013; Bonhoeffer et al. 1997; Castaneda et al. 1994; Di Donato et al. 1989; Hovels-Gurich et al. 1997; Mayer et al. 1990; Planche et al. 1998; Pretre et al. 2001; Prifti et al. 2002; Quaegebeur et al. 1986; Sellke et al. 2005; Wernovsky et al. 1995; Williams et al. 1997; Fricke et al. 2012). Moreover, exercise tolerance and quality of life of patients undergoing the

■ Fig. 19.22 Intramural course of right coronary artery, giving rise for left circumflex artery also

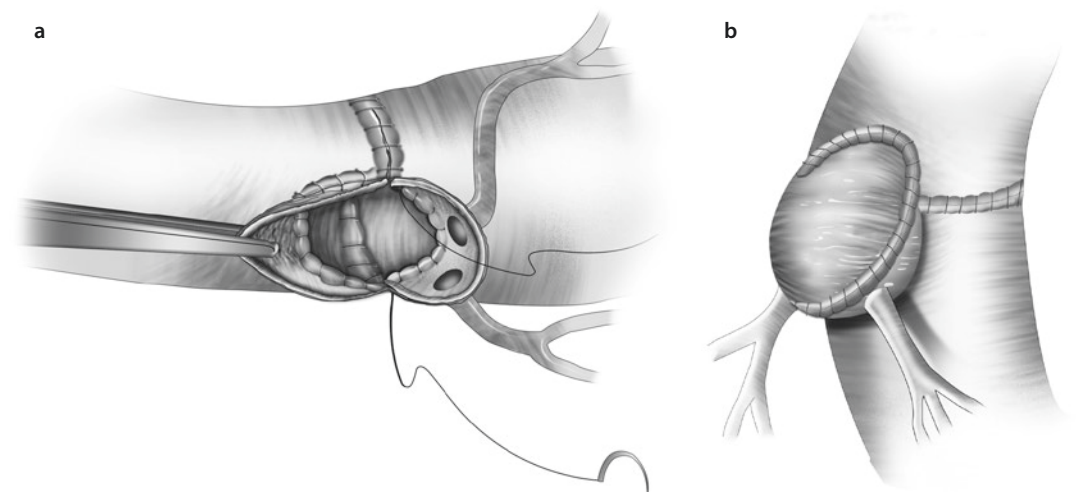

arterial switch operation are superior when compared with the atrial switch operation (Muller et al. 2013). The incidence of obstructive pulmonary vascular disease in D-TGA has markedly decreased over the years due to earlier surgical repair using the anatomic correction (Newfeld et al. 1974; Rivenes et al. 1998; Squarcia and Macchi 2011).

19.2.5.3 Choice of the Operative Procedure

The atrial switch is almost an obsolete procedure (Williams et al. 2003). The arterial switch operation is indicated in almost all cases of D-TGA independent of coronary artery pattern such as intramural course or single coronary artery or the presence of a bicuspid but pliable and nonthickened pulmonary (neo-aortic) valve (van Praagh 1992). It can also be performed as primary procedure successfully in patients with closed ductus arteriosus and decreased pulmonary artery pressure safely up to an age of 8 weeks (Edwin et al. 2010), provided the left ventricular muscle mass is within normal limits. Isolated cases with hypotrophy of the left ventricle and a decreased posterior wall thickness to as low as 2–3 mm were successfully operated on as late as 12 weeks of age after an intraoperative temporary pulmonary artery banding was used to assess, whether or not the left ventricle is able to sustain systemic pressure (Däbritz et al. 1997). All patients within this age range tolerated the procedure, nullifying the need for two-step arterial switch operation in early infancy. In borderline cases, beyond 12 weeks of age, an arterial «rapid two-stage» switch operation is utilized, in which the left ventricle is retrained in 1–2 weeks by tight pulmonary artery banding and implanta-

■ Fig. 19.23 a, b Separation of both coronary ostia

■ Fig. 19.24 a, b Surgery for single coronary artery abnormality (reverse flap)

tion of a modified Blalock–Taussig shunt if a dramatic drop of the arterial saturation occurs with banding (see above; Castaneda et al. 1994; Lacour-Gayet et al. 2001; Sellke et al. 2005). While this rapid two-step retraining acutely induces sufficient LV myocardial hypertrophy during the first 6–8 months of life, it results in impaired LV function and contractility, which, has not shown progression progress over a period of 0.5–6 years of observation (Boutin et al. 1994). Banding also increases the incidence of neoartical valve regurgitation (Jenkins et al. 1991). Because of these drawbacks of banding, it is better to perform primary arterial switch operation even up to 6 weeks of life.

Banding for retraining of the left ventricle after a failed atrial switch or for preparation for a double-switch procedure in ccTGA (see ► Sect. 19.1.4.3, «Retraining the Left Ventricle for Anatomic Repair») is age dependent and seems to be possible up to early teenage age (Poirier and Mee 2001; Sellke et al. 2005). Deterioration of left ventricular function has been described after late banding and retraining procedures in most of these cases (Daebritz et al. 2001). In this age group, the retraining is frequently performed in several steps over a time period of months and years before the atrial switch is taken down and replaced with an arterial switch

■ Fig. 19.25 a, b In situ exclusion

operation (Daebritz et al. 2001; Imai et al. 2001; Mee 2005).

19.2.6 Complex D-Transposition of the Great Arteries

19.2.6.1 Definition and Epidemiology

The term «complex TGA» opposite to «simple TGA» refers to D-TGA with associated malformations such as a VSD, ventricular outflow tract obstruction caused by a deviation of the conal septum, and Taussig–Bing or aortic arch anomalies. D-TGA with a perimembranous VSD (incidence 10–15%) is inconsistently classified with complex TGA (Fyler 1980). Complex forms of D-TGA associated with hypoplasia of one ventricle or with malformations of the AV valve like straddling are not dealt with in this chapter as they are not amenable for biventricular correction but usually undergo primary palliation leading eventually to a Fontan-type operation.

19.2.6.2 Pathophysiology and Diagnostics

The clinical symptoms of complex D-TGA cover a broad spectrum and depend on the presence of associated outflow tract obstruction and hypoplasia of various structures. On one hand, there can be pulmonary over circulation with reduced systemic perfusion and its attendant symptoms of heart failure and low cardiac output. These

patients need early corrective surgery. On the other hand, there can be reduced pulmonary blood flow with variable degree of cyanosis. These cases can be stabilized by the administration of prostaglandins if the ductus is still responsive.

Diagnosis is established primarily by echocardiography, demonstrating the morphology of a VSD, the conal septum, the coronary arteries, the AV valves, and the aortic arch. In most cases, a cardiac catheterization is redundant and can be avoided, as it does not give additional information. However, it may be necessary for functional assessment of the different cardiac structures, pressure measurements, and calculation of pulmonary vascular resistance. In addition, cardiac catheterization should always be performed in patients with complex TGA who have had prior palliative procedures.

19.2.6.3 Transposition of the Great Arteries with Ventricular Septal Defect

Up to 50% of patients with D-TGA have a VSD, which is often small and closes spontaneously, so that only about 25% of these patients have a VSD which needs to be surgically addressed (Daebritz et al. 2000; Moene et al. 1985).

In the presence of a large, nonrestrictive VSD, the left ventricle remains trained to support the systemic circulation. The arterial switch operation

can be delayed in these patients and need not be performed in the first 2 weeks of life. The time-limiting factor in these patients is onset of severe symptoms related to pulmonary overcirculation and consequently development of pulmonary vascular obstructive disease (Newfeld et al. 1974; Bajpai et al. 2011). Therefore, these patients should be operated within the first 2–3 months of life. In patients without any other additional malformations, the therapy is an arterial switch operation with concomitant transarterial closure of the VSD. Palliative procedures are rarely indicated unless there is a complicating noncardiac comorbidity.

19.2.6.4 Transposition of the Great Arteries with Left Ventricular Outflow Tract Obstruction

An LVOTO in TGA is caused by a posterior deviation of the conal septum, presence of a fibromuscular tunnel, or by a hypoplasia or dysplasia of the pulmonary valve. Most commonly, it is located in the subvalvar area. In TGA with LVOTO, the pulmonary vascular bed can be hypoplastic as a consequence of limited pulmonary blood flow.

■ ■ Surgical therapy

A systemic-to-pulmonary shunt such as modified Blalock–Taussig shunt is used as a palliative procedure to increase pulmonary blood flow. It is usually performed through a median sternotomy incision. The shunt runs parallel to the superior caval vein from the brachiocephalic trunk and the proximal subclavian artery to the right pulmonary artery. In newborns (3–3.5 kg), a 3.5–4.0-mm, thin-walled polytetrafluoroethylene tubular prosthesis is used. It is beveled at 45° proximally, cut diagonally at the distal end, and anastomosed end to side with a 7/0 running polypropylene or polytetrafluoroethylene suture. The procedure is performed without the use of cardiopulmonary bypass. Whether or not bypass is needed can be ascertained by temporarily clamping the right pulmonary artery while observing changes in systemic oxygen saturation. Usually, if blood flow through the ductus arteriosus is not compromised, there is no need for extracorporeal circulation. Heparin (50–100 IE/kg BW) is given prior to clamping of vessels to prevent thrombus formation. After completion of the shunt, oxygen satu-

■ **Fig. 19.26** Rastelli operation. Diagonal division of the pulmonary artery and closure of the proximal end; longitudinal incision of the right ventricular outflow tract (original systemic ventricle)

ration rises and the diastolic pressure falls. Closure of the ductus is recommended to prevent pulmonary overflow and/or competitive flow with the shunt. Timing of definitive repair is controversial. While some may prefer primary neonatal correction, we suggest early complete repair usually at 3–6 months of age or whenever symptoms dictate.

In patients with D-TGA and VSD with LVOTO, there are two definitive options, namely, the Rastelli operation and Nikaidoh procedure:

■ ■ Rastelli Operation

This operation is indicated in TGA with perimembranous VSD and LVOTO. The principle of the operation is to direct left ventricle blood through VSD into the aorta using a tunnel patch within the right ventricle and establishing the left ventricle as the system ventricle (■ Figs. 19.26, 19.27, and 19.28). Cardiopulmonary bypass is established using aortobicaval cannulation. Continuous perfusion with mild to moderate hypothermia is used. A small longitudinal incision in right ventricular outflow tract avoiding coronary branches is made. The VSD is enlarged if it restricts systemic blood flow. This is done by resectioning the conal septum anteriorly and superiorly to avoid damage to the conduction sys-

■ **Fig. 19.27** Rastelli operation. Left relocation of the aorta with concomitant sealing of the ventricular septal defect (VSD). The artificial patch is fixed on the rim of the VSD dorsally and caudally; cranially the sutures are placed on the anterior part of the aortic root, which thus is pulled/dislocated to the left. The blood from the left heart drains now via the original, extended orifice of the VSD to the aorta

■ **Fig. 19.28** Rastelli operation. Continuity between right ventricle and pulmonary valve is established with a valved conduit. Individual anatomy dictates whether conduit runs distally to the right or the left of the aorta

tem. If the VSD extends into the inlet septum, the patch assumes three-dimensional orientation. In the inlet septum, it lies at the same plane as the ventricular septum to avoid distortion of attached chordae. In the outflow part, it turns into a tunnel almost perpendicular to inlet portion, to connect the left ventricle to the aortic valve without obstruction. The patch used is usually Dacron or PTFE. To form a wide tunnel, it is advantageous to tailor a wide and short patch to bring the two orifices (the VSD and aortic valve) closer to each other and attain a spacious tunnel. A long and narrow patch flattens the tunnel against the septum causing obstruction to LVOT. Superiorly, the sutures are placed around the aortic annulus. The sutures are either interrupted or continuous. A running suture line is preferred, because it facilitates fashioning the patch into a three-dimensional tunnel. The pulmonary artery is transected just distal to the pulmonary valve and the proximal end sewn over. The suture line should incorporate the pulmonary valve leaflets to prevent thrombus formation in the blind proximal pouch. The pulmonary valve remains within the tunnel. The right ventricle is connected to the pulmonary artery with a valved conduit or, depending on the age, with a valveless graft (■ Figs. 19.26, 19.27, and 19.28). Usually a pulmonary homograft or a valved bovine jugular vein graft (Contegra) is used. Recently, the first tissue-engineered valves for the RVOT have been implanted in bigger children (Cebotari et al. 2006). They employed decellularized pulmonary homografts seeded with autologous progenitor cells.

■ ■ Nikaidoh Operation

The principle of this operation is that the entire aortic root is uprooted and displaced posteriorly into the pulmonary root and the LVOT (■ Figs. 19.29 and 19.30). Potential advantages are the achievement of an anatomical position for the outflow of the LVOT without a tunnel. It also brings the RV-PA connection with or without conduit into a more anatomical position. In addition, the operation can be applied to patients who are not suitable for a Rastelli operation due to unfavorable location or size of the VSD. Since the first description of the technique in 1984, the operation has gained increasing application recently because of the reported incidence of LVOT obstruction and resultant LV dysfunction following the Rastelli operation. After initiation of cardiopulmonary

Fig. 19.29 a, b Nikaidoh operation. **a** The aortic root is excised and mobilized together with the coronary arteries left in situ, if anatomically possible. The pulmonary artery is cut close to the valve. **b** The left ventricular outflow tract is enlarged by dividing the ventricular septum starting from the pulmonary valve up to the VSD. The anterior leaflet of the mitral valve is shown

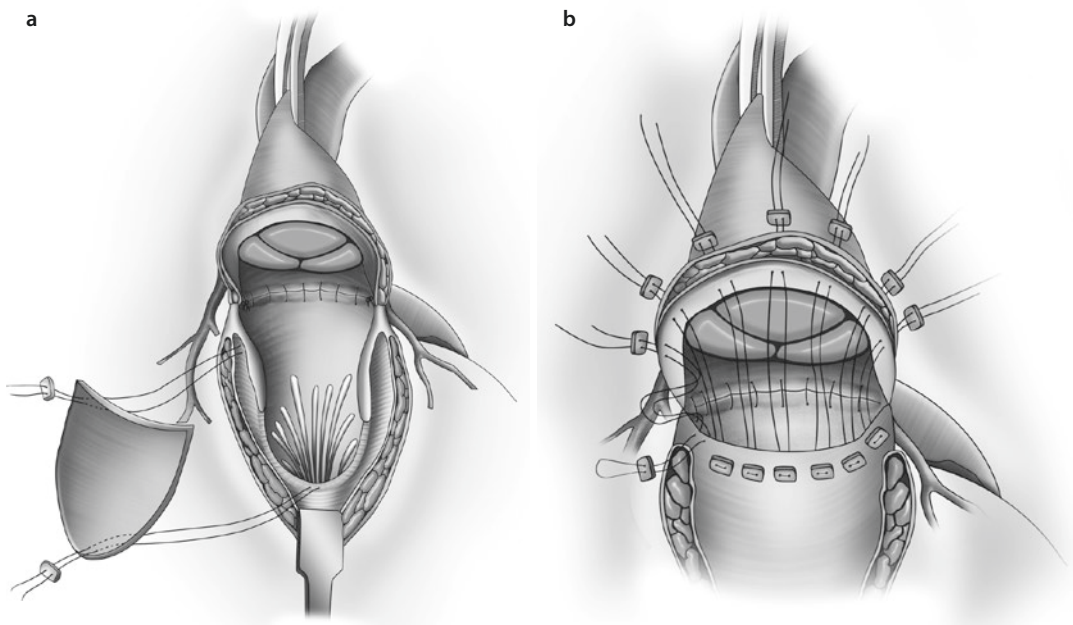

Fig. 19.30 a, b Nikaidoh operation. **a** After mobilization of the aortic root, the aorta is translocated posteriorly and about 30–50 % of the aortic root circumference of it sutured into the combined opening of RVOT and pulmonary annulus posteriorly. The LVOT is reconstructed and enlarged with a generously tailored VSD patch. **b** Finally, the suture of the aortic root is completed for the remaining 50 % to two-third of the circumference by the superior rim of the VSD patch

bypass, the coronary arteries are excised with a button as in arterial switch operation (s.e.). In some cases, with favorable anatomy, the coronary arteries can be transferred en bloc with the aortic root without need for excision and reattachment as was originally described by Nikaidoh (1984). The aortic root is uprooted with or without the coronary arteries and aortic valve. The LVOT is enlarged by incising the conal septum longitudinally towards the VSD or, if VSD is absent, towards the cavity of the LV. The aortic autograft is then sutured into the native LVOT. The LVOT is reconstructed with a triangular piece of PTFE sutured to the autograft distally and septum proximally, functionally closing the enlarged VSD. If they have been excised from the aorta, the coronary arteries are reimplanted into the neo-aortic root as in an arterial switch operation. In the classic Nikaidoh operation, the RVOT is reconstructed with a patch, but a valved conduit can be used as well (homograft or bovine jugular vein conduit). The conduit lies in a physiological position. A Lecompte maneuver is performed depending on the anatomy of the great vessels and is usually not recommended in side-by-side position.

■ ■ Results for Rastelli and Nikaidoh Operations

Rastelli operation carries a low operative mortality of less than 5%, but has a potential long-term morbidity caused by LVOTO and right ventricular outflow tract obstruction (RVOTO). Up to 50% of patients require a reintervention of the RVOT at 5 years (cardiac catheterization or operation), although in some series freedom from reoperation is 86% at 5 years and 74% at 10 years (Brown et al. 2011). For the LVOT, reoperation rates of 5–10% have been reported from single centers (Hörer et al. 2007; Kreutzer et al. 2000; Brown et al. 2011; Lim et al. 2013); a European multicentre study showed the incidence of long-term LVOTO to be around 5.2% (Hazekamp et al. 2010). RVOT morbidity is also expected after the Nikaidoh operation, but LVOT should not be at risk for reoperation. The low rate for LVOT and RVOT reoperation led to an increased application of the Nikaidoh operation in this patient population. However, so far there are no long-term results that support the Nikaidoh operation in favor of Rastelli operation (Yeh et al. 2007). One study reports superiority of the Nikaidoh (Hu et al. 2008), while

others are in favor of the Rastelli procedure (Brown et al. 2011).

19.2.6.5 Transposition with Right Ventricular Outflow Obstruction and Hypoplasia of the Aortic Arch or Coarctation of the Aorta

RVOTO in TGA is due to either a malalignment of the conal septum in association with a conoventricular (perimembranous) VSD or hypoplastic subaortic conus as in DORV. The presence of a conal septum under the pulmonary valve separating the pulmonary from the mitral valve results in Taussig–Bing anomaly with incidence of 5–7% of all TGA (Pigott et al. 1987). Subaortic obstruction due to conal septum deviation or hypoplastic tunnel results in hypoplasia or atresia of downstream structures. Thus, RVOTO is usually associated with hypoplasia of the aortic arch and coarctation or interruption. The incidence of arch anomalies is around 7–10% in TGA with VSD and is increased in DORV and TGA or in Taussig–Bing anomaly (see ► Sect. 19.2.6.6, «Taussig–Bing Anomaly») (Pigott et al. 1987). These lesions are often ductal dependant and need prostaglandin administration soon after birth.

■ ■ Surgical therapy

RVOTO due to conal septum deviation or subaortic conus is best treated by patch enlargement of the RVOT anteriorly. Coarctation or interruption is treated with end-to-end anastomosis and patch enlargement of the arch and the ascending aorta at the time of VSD closure and arterial switch operation. Surgery may be performed in deep hypothermic circulatory arrest (DHCA) or as we prefer with regional cerebral perfusion avoiding DHCA. The patching of the ascending aorta minimizes the difference in caliber between proximal neo-aorta and distal aorta. Diffuse hypoplasia of all structures, especially the aortic valve, may require Damus–Kaye–Stensel operation or modified Norwood approach. In case of hypoplasia of the entire arch, patch augmentation with autologous pericardium or pulmonary homograft extending from the ascending aorta along the arch to beyond the coarctation is recommended. Postoperative supra-valvar pulmonary stenosis or obstruction due to Lecompte maneuver requires stenting or surgical patching in a small number of cases. Technically it is advantageous to augment

the pulmonary end-to-end anastomosis ventrally with a patch of autologous pericardium.

19.2.6.6 Taussig–Bing Anomaly

The term Taussig–Bing anomaly refers to double-outlet right ventricle (DORV) with D-transposition of the great artery in which the VSD is committed to the pulmonary valve (subpulmonary) and the great arteries are side by side. The aorta is on the right and slightly anterior to the pulmonary artery. There is variable degree of pulmonary valve overriding of the septum (see also ► Sect. 19.2.6.5).

TGA with DORV is also associated with coronary anomalies such as single ostium or intramural artery in 27% of cases (Uemura et al. 1995). Abnormal mitral valve attachments to the LVOT and hypoplasia of the aortic arch often combined with an aortic coarctation are frequently present (Alsoufi et al. 2008).

■ ■ Surgical therapy

The correction normally consists of an arterial switch operation with VSD closure. The VSD is tunneled towards the pulmonary valve (the neo-aortic valve). The close proximity of the VSD to the valve facilitates such connection (Mavroudis et al. 1996). The VSD can be closed via the right atrium, a right-sided ventriculotomy, or via the pulmonary (neoaortic) valve. Our former routine *trans*-neoaortic approach led to very good results (Daebritz et al. 2000). In this technique, the stitches for the VSD suture are placed on the right side on the lower rim of the VSD by passing the needle prior to each stitch through the VSD onto the right side. The patch has to be sutured in such a way that the free edge come to be on the right ventricular side along the inferior and posterior border. This means that the patch and sutures are not visible from the left side once the VSD is closed. This can only be achieved with a running suture technique along the anterior and superior VSD boarder. Due to the subpulmonary position of the VSD, the sutures are placed on the upper rim into the pulmonary or neoaortic anulus. The drawback of this technique is potential damage to the neoaortic valve because the sutures are very close to the valve. More recently the VSD is closed through the right atrium most of the time. RVOT reconstruction is needed initially; however, as the native anatomic pulmonary valve is smaller than normal, the patients are prone to future develop-

ment of RVOTO later on. Usually, this occurs in the first postoperative year and is treated with a patch augmentation like in tetralogy of Fallot. The Lecompte maneuver may have to be modified as it may add to the incidence of supra-avalvular stenosis because of the side-to-side position of the great vessels when the aortic arch and a coarctation are present, a concomitant patch augmentation of the aortic arch (see ► Sect. 19.2.6.5, «Transposition with Right Ventricular Outflow Obstruction and Hypoplasia of the Aortic Arch or Coarctation of the Aorta») with a patch of pulmonary artery homograft or another patch material is performed. Rarely a two-staged procedure may be needed (Daebritz et al. 2000) and has reasonable results. Thus, a one-stage correction is considered the procedure of choice (Tchervenkov and Korkola 2001; Tchervenkov et al. 1997).

■ ■ Results of surgical therapy

Despite complexity of these lesions, the results are comparable with those of the arterial switch operation in larger series (Daebritz et al. 2000; Tchervenkov and Korkola 2001; Lim et al. 2013), with an operative mortality of 7% (Vogel et al. 1984; Blume et al. 1999; Takeuchi et al. 2001; Wetter et al. 2004; Soszyn et al. 2011). There is an increased rate of reoperation in patients with hypoplasia of the aortic arch and the RVOTO and is significantly higher than after the arterial switch operation for simple D-transposition (Alsoufi et al. 2008; Rodefeld et al. 2007; Soszyn et al. 2011; Lim et al. 2013).

20.1 Introduction

The development of the embryonic coronary artery circulation is complex and remains not fully understood. Early theories suggest that the main coronary arteries develop from endothelial tissue growing out of the aorta forming so-called coronary buds (Hutchins et al. 1988). Newer animal models point to a retrograde connection to the aorta (Waldo et al. 1990). Coronary capillaries emanate from the proepicardium forming a subepicardial capillary bed (Bernanke and Velkey 2002). The coronary arteries then arise from a capillary ring that encircles the outflow tracts and invade the aortic wall secondarily. Thereby, basic anlagen can be seen in all three coronary sinuses that are subject to apoptotic mechanisms (Waldo et al. 1990). A recent report could further prove that coronary arteries may arise from angiogenic sprouts of the sinus venosus by developmental reprogramming (Red-Horse et al. 2010).

Coronary abnormalities are rare disorders occurring in approximately 1% of all patients (Yamanaka and Hobbs 1990). It is still unclear whether this over- or underestimates the real incidence since most studies are biased by referral patterns and asymptomatic patients may remain undetected (Angelini 2002). Considering the anatomical variations of the normal coronary system, pathology may be even more variable. Alterations have been reported with regard to number, location, size and angle of the ostia, coronary artery size, course, arteriolar ramifications and termination, as well as secondary abnormalities (Angelini 2002; Ogden 1970).

Describing coronary variations requires a definition of the normal anatomy. Herein, we rely on the common description as reviewed by Loukas et al. (2009) and the definitions of the Congenital Heart Surgery Nomenclature and Database Project (Dodge-Khatami et al. 2000). The aortic sinuses are described as suggested by the Leiden classification (Gittenberger-de Groot and Sauer 1983) and Smith et al. (1989).

20.2 Anomalous Pulmonary Origins of the Coronaries

20.2.1 Anomalous Left Coronary Artery from the Pulmonary Artery (ALCAPA)

The anomalous origin of the left coronary artery from the pulmonary artery, also known as

ALCAPA syndrome, is a rare congenital disorder. In 1959, its incidence originally was stated to be only 1 in 300,000 live births (Keith 1959). In 1980, the New England Regional Infant Cardiac Program revealed 1 in roughly 100,000 and more recently a study from Ireland 1 in 4,243 live births (Brotherton and Philip 2008; Fyler 1980). It was first reported by Brooks in 1886 based on two cases. However, it was interpreted as a functional vein returning blood back into the pulmonary system (Brooks 1885). Almost 50 years later, it was up to Bland, White, and Garland to describe the clinical features (Bland et al. 1933). Therefore, ALCAPA was originally known as Bland-White-Garland syndrome. The etiology is suspected to be an abnormal aortopulmonary septation process.

ALCAPA syndrome usually is an isolated defect. There have been several reports that show coincidences with mitral valve arcade (Su et al. 2011) and other mitral valve pathologies, patent ductus arteriosus (Awasthy et al. 2010), atrial or ventricular septal defects (Kajihara et al. 2009; Schneider et al. 2006), or aortopulmonary window with interrupted aortic arch (McMahon et al. 2002). Considering the different anatomical variations in ALCAPA, a classification by Smith et al. was proposed in 1989 (Smith et al. 1989). Similar to the Leiden classification, the sinuses are named corresponding to the nonfacing sinus of the pulmonary artery. Most common is an origin of the left coronary artery from sinus 1 (right-handed sinus). Other possible takeoffs are sinus 2, the supra-commissural wall of sinus 1 and the nonfacing sinus, and posterior aspects of pulmonary artery branches.

Coronary perfusion in utero is unremarkable. This changes early postnatally when the high pulmonary vascular resistance still allows for antegrade perfusion of the anomalous artery but supplies the myocardial mass with hypoxic blood. Later on, with continuing reduction of pulmonary vascular resistance, antegrade flow into the anomalous artery will be reduced or even reversed. This may cause a myocardial perfusion deficit. In case of flow reversal, a coronary steal effect with left-to-right shunting can be seen. The coronary blood flow depends highly on increased right coronary blood flow and on the collateral network between the right and left coronary artery. Stenosis of the left coronary origin can further alter coronary hemodynamics (Dodge-Khatami et al. 2000). According to the extent of these intercoronary collaterals, an infantile type with little and an adult type with good collateralization are defined (Agustsson 1962).

The demand-supply mismatch leads to myocardial damage and its sequelae such as ventricular dysfunction, ventricular dilation, ventricular aneurysm, mitral valve insufficiency due to papillary muscle ischemia, and malignant arrhythmias. If the collateral blood flow is satisfactory, ALCAPA can stay unrecognized up to an advanced age (Tsigkas et al. 2011).

Once coronary blood supply is insufficient, Bland-White-Garland syndrome patients usually present with signs of heart failure such as increased diaphoresis, dyspnea with feeding, tachycardia, and failure to thrive. It can be difficult to distinguish between dilated cardiomyopathy and ALCAPA. Specific electrocardiographic changes have been defined by Johnsrude et al. (1995) as Q-wave width ≥ 30 ms in lead I and Q-wave depth ≥ 3 mm and ST segment amplitude in lead aVL. The diagnostic value was challenged by Chang et al. (2001) who added echocardiographic findings of an RCA to aortic annulus ratio greater than 0.14, increased echogenicity of papillary muscles and Doppler color flow through the left coronary artery to electrocardiographic changes. Nevertheless, ALCAPA can be diagnosed by echocardiography alone if there is awareness of the examiner. In addition to the confirmation of the aberrant artery, an increased diameter of the right coronary artery can be seen. Indirect changes such as signs of myocardial dysfunction and mitral valve insufficiency can complete the clinical picture. In rare cases, coronary angiography and MRI viability studies can help in securing the diagnosis (Dodge-Khatami et al. 2002). At least within the first 3 years of life, any patient presenting with the clinical signs of dilated cardiomyopathy should have diagnostic evaluation to rule out ALCAPA.

Surgical correction is indicated once the diagnosis is made. The infantile type is characterized by insufficient collateral perfusion and has a fatal prognosis if left untreated. Ongoing myocardial damage due to chronic hypoperfusion occurs and hinders postoperative improvement of left ventricular function. Ultrastructural changes could be detected in specimen taken intraoperatively (Shivalkar et al. 1994) as well as post mortem (Smith et al. 1989). Left ventricular recovery can be achieved best by early detection and early correction.

Early operative strategies aimed at a reduction of left-to-right shunting and an elimination of coronary steal. Several techniques have been reported including ligation of the left coronary artery which leads to an increase of its perfusion pressure (Sabiston et al. 1960). The corrective measure, however, is to estab-

lish a two coronary system with antegrade perfusion. It is not surprising that ligation compared with establishment of a two coronary system performed worse (Bunton et al. 1987). Therefore, the most physiologic and anatomical correction, the direct reimplantation as described by Neches et al. (1974) is the favorable therapeutic strategy in ALCAPA. If despite all surgical sophistication a direct anastomosis cannot be achieved, several different options have been reported. Most of them deal with poor mobilization of the coronary. The most relevant strategies will be discussed below. Surgical techniques of ligation of the coronary artery and bypassing of the vessel are nowadays rarely used and should be reserved for special anatomical variations and individual cases.

Special attention has to be paid not only to administration of cardioplegia but also to persistent coronary malperfusion once extracorporeal circulation has been established. Adequate myocardial protection during correction is crucial to the insufficiently perfused myocardium. As soon as cardiopulmonary bypass starts, left-to-right shunting increases since the pulmonary arterial pressure drops. Therefore, the main pulmonary artery or in complex cases the right and left pulmonary arteries have to be clamped immediately to avoid further coronary steal. During delivery of cold blood cardioplegia, our strategy includes clamping both the aorta and the pulmonary artery. Other possible approaches act by direct clamping of the left coronary artery at its origin or cardioplegia infusion via the aorta and the pulmonary artery simultaneously.

20.2.1.1 Direct Reimplantation of the Anomalous Left Coronary Artery

Today, most of the patients presenting with Bland-White-Garland syndrome can be treated with early correction via direct reimplantation (Turley et al. 1995). Surgical access is gained by standard median sternotomy. We prefer establishment of extracorporeal circulation with bicaval venous cannulation.

Cardioplegia is administered as described above. After adequate myocardial protection, the pulmonary artery is transected and the aberrant left coronary artery identified. The ostium is carefully excised leaving a large pulmonary wall button. The most challenging part starts with mobilization of the coronary artery. Special attention has to be paid when choosing the adequate localization for aortic reimplantation. Tension should be avoided by any means, but kinking or distortion may as well lead to

devastating consequences. The aortic wall can be punched or incised in a flap-like fashion (trapdoor technique) to get a suitable opening (■ Fig. 20.1). Anastomosis is usually done with 6/0 or 7/0 polydioxanone sutures. Finally, the defect of the pulmonary wall has to be closed by autologous or xenogenic pericardium. Polytetrafluoroethylene (PTFE) or polyester (Dacron®) patches can be used as well. Owing to the pathophysiology, early reperfusion and minimal cross-clamping time can minimize myocardial stress. Therefore, coronary circulation should be reestablished as soon as proper left coronary reinsertion is achieved.

20.2.1.2 Coronary Button Transfer with Lecompte Maneuver

The farther away the anomalous coronary artery is located, the more technically challenging is the direct reimplantation. Malankar et al. proposed a technique combining an extended coronary button transfer with Lecompte maneuver (Malankar et al. 2010). The pulmonary trunk is transected close to the pulmonary bifurcation. The anomalous artery then has to be excised generously to ensure a tension-free anastomosis. The aorta has to be transected above the sinotubular junction and longitudinally incised opposite to the aberrant artery.

■ Fig. 20.1 a–d Direct reimplantation in ALCAPA syndrome. a Incision of the pulmonary trunk. b Excision of the coronary ostium. c Reimplantation into the ascending aorta. d Pulmonary trunk closure

In this way, the aortic wall can be anastomosed to the pulmonary button of the left coronary artery without considerable mobilization. The pulmonary trunk is reconstructed with autologous pericardium. Lecompte maneuver places the ascending aorta posterior to the right pulmonary artery. Malankar et al. emphasize that their technique leads to less tension on the anastomosis, an approximation of the aorta to the aberrant artery, and a reduced risk of external compression by the main pulmonary artery.

20.2.1.3 Takeuchi Repair

Another surgical approach to create a two coronary system is the intrapulmonary tunnel technique first described by Takeuchi et al. in 1979 (Takeuchi et al. 1979). In a 2-year-old boy, ALCAPA could be corrected via rerouting of the oxygenated blood through an artificially created aortopulmonary tunnel within the pulmonary trunk. This technique is to be used in patients with unfavorable coronary anatomy, e.g., ostia located laterally or in the nonfacing coronary sinus (■ Fig. 20.2). Since most ALCAPA patients can be treated with direct reinsertion, the Takeuchi repair remains relatively rarely used. A long-term disadvantage is potential pulmonary valve impairment and supra-valvar pulmonary artery stenosis.

After establishment of extracorporeal circulation and proper administration of cardioplegia, the pulmonary artery is incised so that a rectangular-shaped flap is created. The attachment side of the flap lies adjacent to the aorta. To create an aortopulmonary window, which will functionally work as the left coronary ostium, an opening at the flap's base and the corresponding aortic wall is created and anastomosed. The flap itself is then sutured to the back wall of the pulmonary trunk creating a tunnel to the ostium of the anomalous left coronary artery. The missing anterior wall of the pulmonary artery is finally reconstructed with a generously sized autologous pericardial patch (■ Fig. 20.3). As an alternative, a bovine pericardial patch can be used for construction of the tunnel within the pulmonary trunk.

20.2.1.4 Other Tubular Elongation Techniques

To circumvent the problems coming along with insufficient mobilization, many different techniques have been described. One of the earliest reports is made by Armer et al. in (1963). They use a flap of anterior pulmonary artery wall to extend the coronary ostium and reroute it to the

■ Fig. 20.2 Preferred anatomical variations for Takeuchi repair. Origin of the left coronary artery from lateral aspect of the pulmonary sinus 1 or the nonfacing sinus. PA pulmonary artery, AO aorta

aorta. Tashiro et al. (1993) and similarly Barth et al. (2003) suggested to extend the artery by means of two pulmonary artery flaps. Additional techniques with different types of plastic reconstruction and elongation of the left coronary artery with aortic and pulmonary artery wall offer plenty of surgical options for special indications (El-Rassi et al. 2012; Katsumata et al. 1999; Sese and Imoto 1992; Shinkawa et al. 2002).

20.2.1.5 Bypass Techniques

Coronary artery bypass has been reported by Meyer et al. in 1968 using the left subclavian artery. Saphenous vein grafts are difficult to harvest in children and carry the risk of graft occlusion (■ Fig. 20.4). Coronary bypass grafting can be achieved by use of the left internal mammary artery. The anastomosis can be challenging in children and is a better option in adult patients. Bypassing the left coronary artery implies its proximal ligation.

■ **Fig. 20.3** a–e Takeuchi repair via intrapulmonary tunneling. **a** Operative site with incision marks corresponding to anomalous coronary artery. **b** Flap-like incision of the pulmonary trunk. **c** Creation of an aortopulmonary window. **d** Posterior displacement of pulmonary wall flap and tunnel creation. **e** Pulmonary trunk patch augmentation

20.2.1.6 Percutaneous Approach

Similar to the first therapeutic surgical approaches, percutaneous closure of the left coronary ostium can be a practicable strategy in select cases (Collins et al. 2007). Collins et al. presented this approach in a 30-year-old woman with a history

of atrioventricular septal defect and surgical repair at the age of 2 years. The interventional technique was favored because of the assumed higher risk with repeat surgery and a surgically disadvantageous anatomy. Nevertheless, the authors stress that this approach implies an

Fig. 20.4 a–d Aortic-coronary anastomosis using the left subclavian artery. **a** Access can be gained by left anterolateral thoracotomy. **b** Proximal ligation of the anomalous coronary artery. **c, d** End-to-side or end-to-end anastomosis of the subclavian artery with the anomalous coronary artery

adult-type ALCAPA with good collateralization and should only be performed if there is no ante-grade blood flow through the aberrant artery.

20.2.1.7 Assist Devices and Transplantation

Despite the multitude of treatment options in ALCAPA patients, myocardial viability can be significantly reduced. Especially in younger infants, insufficient collateral flow can lead to myocardial ischemia and therewith problems with weaning from cardiopulmonary bypass. In a series of seven patients, del Nido et al. (1999) presented a centrifugal left ventricular assist device cannulated in the left atrium and in the ascending aorta, respectively, as a feasible treatment strategy. Imamura et al. could show similar survival rates between ECMO-supported and non-ECMO patients (Imamura et al. 2011).

Heart transplantation still remains the last option in those patients suffering from ongoing severe myocardial dysfunction (Mavroudis et al. 1988; Nair et al. 2003).

20.2.1.8 Outcomes

It is widely accepted that establishing a two coronary system should be the surgical approach of choice (Ben Ali et al. 2009; Bunton et al. 1987; Imamura et al. 2011; Kuroczynski et al. 2008; Novick et al. 2009; Ojala et al. 2010). Bunton reported a 27% early mortality with ligation compared to no deaths with Takeuchi repair (Bunton et al. 1987). Operative mortality ranges between 0 and 17% (Alexi-Meskishvili et al. 2011; Ginde et al. 2012; Imamura et al. 2011; Kuroczynski et al. 2008; Novick et al. 2009; Ojala et al. 2010). Long-term follow-up shows excellent results with only low late mortality rates (Alexi-Meskishvili et al. 2011; Ben Ali et al. 2009; Ojala et al. 2010). Operative risk factors are severity of left ventricular dysfunction and presentation at an early age.

Mitral insufficiency is a well-known problem in patients with ALCAPA. Management of the mitral valve remains controversial. Since the underlying pathology can be attributed to myocardial dysfunction secondary to malperfusion,

most authors suggest a conservative approach. Restoration of adequate coronary blood supply has been shown to lead to recovery of LV function and improvement of mitral valve competence (Azakie et al. 2003; Ben Ali et al. 2009). Even in severe mitral regurgitation, the valve should not be addressed initially. The Toronto group could show that mitral valve function can improve within 7.5 months after coronary transfer (Azakie et al. 2003).

20.2.2 Anomalous Right Coronary Artery from the Pulmonary Artery (ARCAPA)

An origin of the right coronary artery from the pulmonary artery is a rare congenital anomaly as well. An incidence of 0.002% compared to 0.008% in ALCAPA has been stated (Williams et al. 2006). Few case reports and small series can be found. Associations with tetralogy of Fallot, pulmonary stenosis or atresia, patent ductus arteriosus, atrial and ventricular septal defects, aortic coarctation, hypoplastic left heart syndrome, double-outlet right ventricle and bicuspid aortic valve, as well as other noncardiac congenital anomalies (Bossert et al. 2005; Cleuziou et al. 2006; Williams et al. 2006) have been reported. Pathophysiologic changes are comparable to those in ALCAPA syndrome, even though congestive heart failure, sudden death, and ischemia are less common, probably due to lower oxygen consumption of the right ventricular myocardium. Surgical strategies should aim at direct reimplantation, although there is little data on survival benefits.

20.2.3 Other Anomalous Pulmonary Origins of the Coronaries

20.2.3.1 Isolated Origin of Left Anterior Descending Artery from Pulmonary Artery

There are few reports about an isolated origin of the left anterior descending artery from the pulmonary artery (Ozer et al. 2008; Roberts and Robinowitz 1984; Sahin et al. 2012; Turley et al. 1995). Basically, these anomalies can be treated similar to the strategies in ALCAPA syndrome (Ozer et al. 2008). Diagnosis is usually incidental

and due to the more complicated mobilization in adults, the aberrant vessel may be revascularized with an internal mammary artery bypass (Sahin et al. 2012).

20.2.3.2 Anomalous Circumflex Artery from the Pulmonary Artery

Isolated origins of the circumflex artery are described in the Congenital Heart Surgery Nomenclature and Database Project (Dodge-Khatami et al. 2000), even though reports are exceptionally rare.

20.2.3.3 Both Coronary Arteries Arising from the Pulmonary Artery

Both coronary arteries arising from the pulmonary trunk have been reported (Grayzel and Tennant 1934; Limbourg 1937). We suggest surgical treatment as in ALCAPA and ARCAPA, but experience with this pathophysiological complex is considerably low.

20.2.3.4 Isolated Origin of Coronary Arteries from the Right or Left Pulmonary Artery

Although a rare abnormality, several case reports demonstrate isolated origins of coronary arteries from the right or left pulmonary artery (D'Alessandro and Di Lorenzo 1976; Kory et al. 1984; Bharati et al. 1984; Villa et al. 2005). Several variations have been described ranging from an isolated offspring of the circumflex branch (Villa et al. 2005) to an origin of a single coronary artery from the right pulmonary artery (Kory et al. 1984). Preoperative diagnosis is challenging, especially if there is a duct-dependent circulation, since antegrade blood flow can be seen in the coronaries and there are no signs of ischemia (Villa et al. 2005). Therapeutic strategies usually aim at establishing a systemic coronary perfusion although surgical approaches have to consider associated malformations and individual variations.

At our center, a rare case of isolated separate origins of both the circumflex and the left anterior descending artery from the right pulmonary artery in association with aortic coarctation has been diagnosed. In a staged procedure, the coarctation could be resected and the coronaries reimplanted into the aorta successfully (L. Sieverding and G. Ziemer, personal communication 2011).

20.3 Anomalous Aortic Origins of the Coronaries

There are many possible variations of the coronary anatomy with varying clinical relevance. Anomalous aortic origins account for approximately one third of all coronary anomalies (Dodge-Khatami et al. 2000). Usually asymptomatic, coronary anomalies can present with signs of ischemia, myocardial infarction, or sudden death. In a large series, Eckart et al. (2004) could prove that 31 % of sudden non-traumatic deaths in a cohort of 6.3 million men and women aged 18–35 were related to coronary artery anomalies. Surprisingly, all deaths due to a coronary anomaly were attributed to a left coronary artery from the right coronary sinus. This is in accordance with results reported by Taylor et al. (1992) who could not show a significant difference between the incidence of a right coronary artery from the left coronary sinus and that of a left coronary artery from the right coronary sinus but a much higher occurrence of sudden death in the latter group.

Diagnosis should be confirmed by computed tomography or magnetic resonance imaging. Echocardiography can be a helpful tool, too. Detection rates are much higher in angiography and cross-sectional imaging as additional information on course and supplied area is given. Echocardiography alone is mainly used to detect regular or irregular ostia. Intravascular ultrasound may be a helpful tool in risk stratification (Angelini 2007).

20.3.1 Left Coronary Artery from Right Sinus of Valsalva

The left main coronary artery may arise from the right coronary sinus with a separate ostium or as a branch of the right coronary artery. Different courses of the anomalous artery have been described. The left coronary artery may be found anterior to the pulmonary trunk, between the great vessels, posterior to the aorta, transeptal or posterior to the right ventricular outflow tract (Taylor et al. 1992). The most problematic anatomical variation definitely is the one wedging the artery between the aorta and the pulmonary trunk, accounting for up to 82 % of sudden deaths in these patients (Taylor et al. 1992) (■ Fig. 20.5). It seems evident that the incidence of sudden cardiac death is associated with exercise. Nevertheless, it remains

unclear whether ischemia is a result of mechanical forces compressing the coronary between the great vessels, a sharp angulation of the artery, or other factors. Angelini et al. (Angelini 2007) refer the malperfusion to several mechanisms of stenosis. According to them, especially the proximal usually intraaortomural part of the aberrant coronary artery is hypoplastic. Furthermore, the cross-sectional area of the vessel is oval shaped and the length of its intramural course contributes to the functional narrowing, too.

There are several operative techniques among which are coronary artery bypass grafting (Davies et al. 2009; Romp et al. 2003), unroofing of the intraaortomural proximal segment of the coronary artery (Davies et al. 2009; Mumtaz et al. 2011), creation of a neo-ostium (Mumtaz et al. 2011), reimplantation, or a pulmonary translocation technique (Rodefeld et al. 2001). Despite choosing the right therapeutic strategy, the right indication is crucial. Many authors of necropsy studies show high mortality rates if the anomaly is left untreated. However, Penalver et al. and other groups stress that mortality rates may be overestimated due to selection bias (Penalver et al. 2012). This also has been mentioned before by Mirchandani et al. (Mirchandani and Phoon 2005), who calculated the incidence to be between 0.09 and 1.07 %. Therefore, a critical look at survival rates and operative risks is necessary. Large population studies report a risk of sudden cardiac death due to a not further specified coronary artery anomaly up to 1 in 208,567 (Chugh et al. 2009; Eckart et al. 2004; Harris et al. 2010; Redelmeier and Greenwald 2007; Wren et al. 2000). Furthermore, it has to be considered that many studies refer to data of active young people who are undoubtedly at increased risk.

Coronary artery bypass grafting has been the first therapeutic strategy used in anomalous aortic origin of a coronary artery. There are several limitations of this operation. Only limited data exists on graft patency, due to the small number of cases. In addition, patients facing surgery are younger than average coronary bypass candidates. Some authors recommend ligation of the native artery proximally to the graft to minimize competitive flow (Shah et al. 2000). In active patients, steal phenomena have been reported (Tavaf-Motamen et al. 2008).

Mustafa et al. (1981) described the unroofing procedure in 1981. The anomalous ostium is

■ **Fig. 20.5** Anomalous origin of the left coronary artery from the right sinus of Valsalva. *LAD* left anterior descending artery, *LCX* left circumflex artery, *PA* pulmonary artery, *RCA* right coronary artery, *AO* aorta

incised following the intramural course. The intercoronary commissure needs to be detached and resuspended. Outcome of the procedure regarding patency of the coronary is excellent. The downside is the potential of aortic valve incompetence, which might warrant aortic valve replacement (Romp et al. 2003). Therefore, creation of a neo-ostium has been suggested (Davies et al. 2009; Mumtaz et al. 2011).

Coronary reimplantation or pulmonary translocation are other options used in select cases.

These surgical procedures can be performed easily. Nevertheless, reported outcomes are difficult to interpret. Most studies are based on small patient numbers and lack a long follow-up. Adverse events differ in frequency between 0 and 42% (Penalver et al. 2012). In view of the fact that the risk of sudden cardiac death is not as

high as it might be suspected from necropsy studies, surgery should be indicated cautiously. Surgical correction is justified in symptomatic patients. Even though the risk of sudden cardiac death is higher with exercise, there still remains a residual risk with restriction from exertion. We recommend evaluation of prophylactic ICD implantation in conservatively managed patients. However, nowadays most authors suggest primary surgical therapy in asymptomatic left coronary artery arising from the right sinus of Valsalva (Davies et al. 2009).

20.3.2 Right Coronary Artery from Left Sinus of Valsalva

The incidence of this anomaly is equal or higher than the anomalous origin of the left coronary

artery from the right sinus of Valsalva (Taylor et al. 1992; Yamanaka and Hobbs 1990). Although data is scarce, the rate of sudden cardiac deaths in these patients is lower and surgery should be indicated with caution. In contrast to an anomalous left coronary artery, an asymptomatic right coronary artery from the left sinus of Valsalva may be treated conservatively with medical therapy and restriction from exercise. Symptomatic patients should undergo surgery, which follows the techniques described for an anomalous left coronary artery (■ Fig. 20.6).

20.3.3 Other Anomalous Aortic Origins of the Coronaries

Individual origins have been described for both the left anterior descending and the circumflex artery from the right coronary sinus or from the right coronary artery itself (■ Fig. 20.7). There are reports of all three coronary vessels arising separately from the right or left sinus of Valsalva, respectively (Panduranga and Al-Mukhaini 2012; Surana et al. 2012). Since numbers of patients are very small, treatment strategies have to be evaluated for each patient dependent on individual risk factors.

■ Fig. 20.6 a, b Scheme of anomalous origins of the right coronary artery from the left sinus of Valsalva; LAD left anterior descending artery, LCX left circumflex artery, PA pulmonary artery, RCA right coronary artery, AO aorta

■ Fig. 20.7 a–c Scheme of anomalous courses of the circumflex artery. The artery may originate either with a separate ostium, a common ostium, or as a branch of the right coronary artery. LCX left circumflex artery, RCA right coronary artery, LAD left anterior descending artery, PA pulmonary artery, AO aorta

20.4 Congenital Atresia of the Left Main Stem

There have been early reports of atresia of the left coronary ostium (Byrum et al. 1980; Mullins et al. 1972; van der Hauwaert et al. 1982). One of the earliest surgical corrections by saphenous vein grafting is described by Mullins et al. in 1972 (Mullins et al. 1972). Collaterals from the right coronary artery provide perfusion of the left coronary system (■ Fig. 20.8). Atresia of the left coronary artery can be differentiated from a single coronary artery by coronary angiography showing a retrograde perfusion of the left coronary system. Therefore, patients present with signs similar to those of Bland-White-Garland syndrome, such as syncope, failure to thrive, angina, dyspnea, or myocardial infarction (Musiani et al. 1997). However, they miss the feature of left coronary artery steal, namely left-to-right shunt into the pulmonary artery. Surgery is indicated once the diagnosis is established. Therapeutic strategies aim at creating a two coronary system. Most commonly, coronary artery bypass grafting is performed. Left main trunk reconstruction has been described, too.

■ **Fig. 20.8** Congenital atresia of the left main stem. LAD left left anterior descending artery, LCX left circumflex artery, PA pulmonary artery, RCA right coronary artery, AO aorta

20.5 Single Coronary Artery

Single coronary arteries are defined as a coronary artery system that arises from a single coronary ostium supplying the entire myocardium (■ Fig. 20.9). Since the anomaly is considered benign and symptoms are extraordinarily rare, diagnosis is usually made accidentally. Incidence is reported with 0.04% (Dodge-Khatami et al. 2000). Associations with congenital malformations have been described in transposition of the great arteries, tetralogy of Fallot, truncus arteriosus, arteriovenous fistula, endocardial fibroelastosis, and bicuspid aortic valve (Dodge-Khatami et al. 2000). The classification proposed by Smith et al. (Smith 1950) is usually applied. It divides the pattern in three subtypes. Type I refers to a single coronary artery that follows the course of one of the two regular arteries. In type II, the course follows the normal distribution of both coronary vessels. Anomalous courses that cannot be assigned to either type I or II are classified as type III. The Congenital Heart Surgery Nomenclature and Database Project follows a more detailed classification based on the one suggested by Smith and described by Sharbaugh in 1974 (Dodge-Khatami et al. 2000; Sharbaugh

■ **Fig. 20.9** Single right coronary artery with interarterial course of the left coronary artery. LAD left anterior descending artery, LCX left circumflex artery, PA pulmonary artery, RCA right coronary artery, AO aorta

and White 1974). Other more detailed and complex classifications have been created, too (Ogden 1970).

The risk of sudden cardiac death is only increased in patients with an anomalous course in between the great vessels. This may be the only indication for surgery once a single coronary artery is diagnosed. If needed, coronary bypass grafting is the most common therapeutic approach.

20.6 Coronary Arteriovenous Fistulas

Coronary arteriovenous fistulas are defined as connections between the coronary arteries and the cardiac chambers or the great vessels, bypassing the myocardial capillary bed. Small fistulas are quite frequent and are considered normal. They usually neither result in clinical signs and symptoms nor do they increase in size and therefore commonly remain undetected (Yamanaka and Hobbs 1990). Spontaneous closure may occur in some cases (Qureshi 2006).

Coronary arteriovenous fistulas with relevant intracardiac shunts are rare. Incidence is specified between 0.18 and 0.87% (Angelini et al. 2002; Yamanaka and Hobbs 1990). As with most coronary anomalies, reports of incidence are biased since asymptomatic patients may circumvent diagnostic detection. Coronary fistulas have first been described by Krause in 1865 (Krause 1865). Björck et al. described the first surgical approach (Björck and Crafoord 1947). Most commonly, this anomaly is considered congenital even though fistulas can be acquired by trauma or may be secondary to surgical or interventional procedures.

Associated congenital malformations are described, such as atrial and ventricular septal defects, tetralogy of Fallot, double-outlet right ventricle, pulmonary or aortic stenosis, mitral regurgitation, and patent ductus arteriosus (Fernandes et al. 1992).

Most coronary fistulas, approximately 50–60%, arise from the right coronary artery, followed by the left anterior descending (~35%) and the circumflex artery (~18%) (Dodge-Khatami et al. 2000; Gowda et al. 2006). Fistulas usually drain to the right side, most commonly to the right ventricle, followed by the right atrium. The anomaly may present isolated or multiple. The

Congenital Heart Surgery Nomenclature and Database Project refers to an angiographic classification by Sakakibara et al. who differentiate between a proximal and a distal type (Sakakibara et al. 1966).

Patients usually present with signs and symptoms due to left-to-right shunting. The size of the fistula correlates with its clinical manifestation. Most patients are asymptomatic and are referred because of an unusual murmur during auscultation. Since drainage to the right atrium or ventricle is common, signs of right heart volume overload can be seen. Nonspecific signs such as fatigue, dyspnea, angina, endocarditis, arrhythmias, and myocardial ischemia or infarction may precede congestive heart failure. A rare complication of coronary arteriovenous fistulas is endocarditis.

Diagnosis is made by echocardiography, which can be helpful in larger fistulas, showing the extent and course of the vessel. Angiography is regarded as gold standard, since shunt volumes can be quantified and exact course, origin, drainage, and size of the fistula can be observed. CT or MRI can give additional valuable information before initiating therapy.

Spontaneous closures of coronary fistulas, although rare, have been reported (Griffiths et al. 1983; Hackett and Hallidie-Smith 1984; Schleich et al. 2001). Indications for therapeutic closure are symptomatic malformations and signs of heart failure, myocardial ischemia, or when large but clinically still asymptomatic shunt volumes are detected. If asymptomatic, therapeutic strategies remain controversial due to the potentially benign course of the diseases.

There are several treatment options using interventional approaches as well as surgical techniques. Since its first description in the 1980s, catheter-based closure of coronary fistulas was performed numerously. A multitude of different devices have been used, ranging from detachable balloons and coils of various types to Amplatz duct occluders (Qureshi 2006; Wiegand et al. 2009). The risk of interventional procedures is embolization of the device, especially in high-flow fistulas. Surgical approaches aim at direct closure of the anomaly. Depending on size, location, and myocardial perfusion, closure can be achieved with or without cardiopulmonary bypass. Especially in large fistulas with impaired myocardial perfusion, a *trans* ventricular approach with closure of its drainage site should be considered.

If the coronary vessel is considerably dilated, aneurysmorrhaphy or resection with interposition or bypass grafting may be needed.

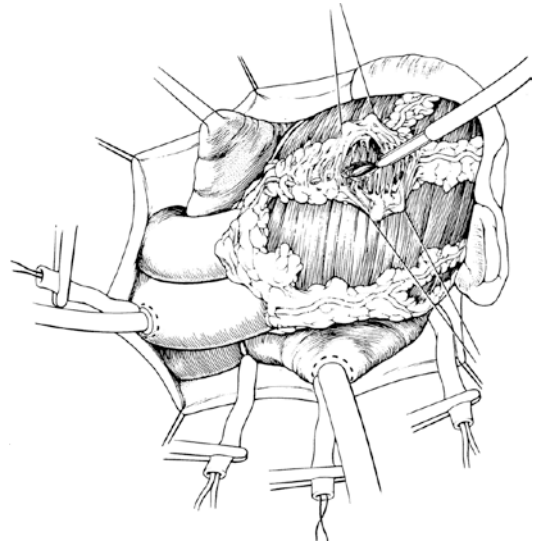

Outcome of interventional and surgical procedures is excellent with only low mortality rates (Mavroudis et al. 1997; Qureshi 2006). Treatment strategies should be evaluated carefully and discussed in an interdisciplinary team to guarantee optimal care.

20.7 Coronary Bridging

Intramyocardial courses of coronary arteries exemplify the gradual transition from a variation of what is considered normal to a substantial anomaly (Angelini 2007). Coronary bridging is defined as muscle fibers crossing the usually subepicardially running arteries. This can lead to external compression of the coronary artery during systole. There is great variance when it comes to incidence of myocardial bridges. On average, one third of adult patients are suspected to have these (Möhlenkamp et al. 2002). Since most coronary bridges do not compress the artery substantially, the incidence is much lower in coronary angiograms. Prevalence is higher in hypertrophic obstructive cardiomyopathy, although its effect on ischemia or risk of sudden death is discussed controversially (Mohiddin et al. 1999; Yetman et al. 1998). Coronary narrowing due to myocardial bridges is a systolic phenomenon. Coronary blood flow mainly occurs during diastole and therefore is not affected at this time. Tachycardia can provoke symptoms since coronary flow reserve and the diastolic filling time are decreased. Severity of symptoms depends on length of the bridging segment, depth, localization, and other characteristics. In the majority of cases, coronary bridges affect the left anterior descending artery.

Diagnosis must be suspected in patients presenting with signs and symptoms of myocardial ischemia lacking traditional risk factors. Further work-up should include coronary angiography although there are a high number of false negatives. Intravascular ultrasound can be a helpful tool.

Most coronary bridges are considered benign. If symptomatic, therapy may be indicated, although there is little data on survival benefits. Therapy can be medicinal, surgical, or interventional. Medical treatment aims at reduction of myocardial work-

■ Fig. 20.10 Division of bridging muscle bundles of the left anterior descending artery

load with the use of negative inotropic or chronotropic drugs. Surgery can be performed with or without cardiopulmonary bypass. Since the left anterior descending artery is most commonly affected, accessibility of the bridging segment is usually straightforward. The muscle bundles are incised and divided (■ Fig. 20.10). In severe cases, other approaches such as coronary artery bypass grafting, using the left internal mammary artery, can be taken into consideration.

Prognosis of myocardial bridges is good independent of treatment strategy. Series report excellent outcome with most of the deaths being related to noncardiac causes (Juillière et al. 1995; Kramer et al. 1982; Ural et al. 2009).

20.8 Coronary Aneurysms

Coronary aneurysms were first described in 1761 by Morgagni et al. (Morgagni 1761). A coronary artery dilation of more than 50% compared to the distally located normal vessel diameter is considered as a coronary aneurysm. This definition can be imprecise especially in cases of diffuse dilation in which normal coronary size is hard to assess (Angelini et al. 1999). Giant aneurysms are not well defined with some authors referring to more than 5 up to more than 15 mm of vessel diameter (Li et al. 2005; McNeal-Davidson et al. 2013).

Incidence ranges between 1.5 and 5% (Syed and Lesch 1997). Congenital aneurysms only form a minor part. Atherosclerosis is reported as the main cause of aneurysms, although numbers vary depending on the study population. Kawasaki disease, for example, mainly affects Japanese and Korean people, but increasing incidence has been reported for the United States, too (Newburger and Fulton 2004; Taubert 1997). Other associations have been reported for systemic vasculitis (e.g., Churg-Strauss syndrome, polyarteritis nodosa, syphilis, systemic lupus erythematosus, Takayasu's arteritis), connective tissue disorders (e.g., Marfan's or Ehlers-Danlos syndrome), bacterial infections, drugs, or trauma (Cohen and O'Gara 2008; Hartmann et al. 2012; Syed and Lesch 1997).

The right coronary artery is most commonly affected accounting for 40–87% of coronary aneurysms (Cohen and O'Gara 2008; Cohn 2007). Among 978 patients examined by Swaye et al. (1983), the proximal and middle segments of the right coronary artery were most frequently involved, followed by the proximal left anterior descending and the circumflex artery. Left main coronary aneurysms have been described but are considerably rare.

Clinical presentation depends on size of the aneurysm and can range from asymptomatic patients to signs of myocardial ischemia, congestive heart failure, or even sudden cardiac death. There is an increased risk of thrombosis, thromboembolism, fistula formation, and rupture (Cohen and O'Gara 2008). Large aneurysms may be seen on chest x-rays or during routine echocardiography. Standard imaging is made with CT or MRI, which offers the possibility of reconstructing the extent of the dilated vessel and its relation to adjacent structures. Coronary angiography is usually performed adding information on coronary anatomy, coexisting atherosclerotic coronary artery disease, and associated fistulas.

It is not clear if patients with coronary aneurysms with associated atherosclerotic coronary artery disease are at higher risk for adverse events than those without atherosclerosis. Nevertheless, coronary aneurysms show worse outcomes when compared to the general population (Baman et al. 2004; Demopoulos et al. 1997; Hartnell et al. 1985; Swaye et al. 1983). Conservative regimes in larger aneurysms advo-

cate antiplatelet or anticoagulant treatment even though there are no clear criteria for initiation of therapy. If symptomatic, surgical therapy is indicated. Especially if patients are at increased risk of rupture, e.g., in case of giant aneurysms or rapid progression, if there are signs of local compression or if additional coronary artery pathologies exist, surgery should not be delayed. In case of asymptomatic, moderately sized aneurysms, therapy may not be necessary and close follow-up combined with medical treatment can be sufficient.

Via a median sternotomy, all aneurysms should be accessible. Exposure of the left main coronary artery can be challenging. Strategies include coronary artery bypass grafting with ligation, resection, or marsupialization of the aneurysm. Off-pump coronary artery bypass techniques have been reported (Emaminia et al. 2011; Ishikawa et al. 2004), as well as interventional approaches.

20.8.1 Kawasaki Disease

Kawasaki disease, also known as mucocutaneous lymph node syndrome, is the leading cause of acquired heart disease in children in the United States and Japan (Taubert 1997). First described by Kawasaki (1967) in 1967, the disease is an acute febrile vasculitis of medium-sized vessels. Its role in pediatric cardiac surgery is related to the occurrence of coronary artery aneurysms which can affect 15–25% of untreated children (Newburger et al. 2004). The mainstays of therapy are anti-inflammatory drugs, intravenous immunoglobulin, anticoagulation, and TNF- α inhibition. Administration of intravenous immunoglobulin can reduce the prevalence of coronary artery abnormalities (Duronpisitkul et al. 1995). In Kawasaki disease, impressive regression of aneurysms has been reported, depending on initial aneurysmal size (McNeal-Davidson et al. 2013). Regression has been described in 55% of affected patients during follow-up (Kato et al. 1996). This is commonly due to myointimal proliferation, causing stenosis of the coronary. In giant coronary aneurysms, antithrombotic management most commonly includes low-dose aspirin combined with warfarin, aiming at an international normalized ratio of 2.0–2.5 (Gordon et al. 2009; Newburger et al. 2004).

Operative therapy should be considered if there is left main trunk occlusion or obstruction of a main coronary artery. Giant aneurysms tend to have a higher risk of developing stenosis later on, as well as occlusion of the artery or rupture of the aneurysm itself. A common therapeutic approach is coronary artery bypass grafting. Graft patency has been reported as good, even though there is little data on long-term outcomes (Tsuda 2009; Tsuda and Kitamura 2004, 2007).

Congenital Anomalies of the Great Vessels

Gerhard Ziemer and Renate Kaulitz

21.1 Introduction – 665

21.2 Anomalies of the Aorta – 665

21.2.1 Anomalies Resulting in Aortic Hypoplasia and/or Stenosis – 665

21.2.1.1 Coarctation of the Aorta/Aortic Isthmus Stenosis – 665

21.2.1.2 Interrupted Aortic Arch – 680

21.2.1.3 Segmental Hypoplasia of the Aorta («Midaortic Syndrome») – 686

21.2.1.4 Cervical Aortic Arch – 686

21.2.1.5 Persistence of the Fifth Arterial Arch (Fifth Aortic Arch or Double-Lumen Aortic Arch) – 687

21.2.2 Aortic Anomalies Causing Compression of Neighboring Structures – 688

21.2.2.1 Foreword – 688

21.2.2.2 History of Surgery for Vascular Ring Formations – 688

21.2.2.3 Aim of Surgery for Vascular Rings – 689

21.2.2.4 Double Aortic Arch/Complete Vascular Ring – 690

21.2.2.5 Incomplete Vascular Ring – 692

21.2.2.6 Kommerell Diverticulum – 692

21.2.2.7 Less Common Findings of a Vascular Ring – 694

21.2.2.8 Compression Caused by an Aberrant Origin of the Brachiocephalic Trunk/Innominate Artery – 694

21.3 Anomalies of the Pulmonary Artery – 695

21.3.1 Obstructive Anomaly of the Pulmonary Artery: Coarctatio Pulmonalis/Pulmonary Artery Coarctation – 695

21.3.2 Pulmonary Artery Anomaly Causing/Being Associated with Compression/Hypoplasia of Neighboring Structures: Pulmonary Artery Sling – 696

21.4 Left to Right Shunt – 699

21.4.1 Ductus Arteriosus Botalli – 699

21.4.1.1 Patent Ductus Arteriosus of the Premature Baby – 700

21.4.1.2 Persistent Ductus Arteriosus in Infants and Children – 702

21.4.1.3 Persistent Ductus Arteriosus in Adults – 704

21.4.1.4 Atherosclerotic Ductus Arteriosus – 705

21.4.1.5 Infection of the Ductus Arteriosus – 705

21.4.1.6 Aneurysm of the Ductus Arteriosus – 706

21.4.2 Aortopulmonary Window – 707

21.4.2.1 Classification – 707

21.4.2.2 Surgical Treatment – 708

21.5 Right to Left Shunt – 711

21.5.1 Pulmonary Arteriovenous Fistula – 711

21.5.2 Pulmonary Artery to Left Atrium Communication – 711

References – 713

21.1 Introduction

There is a vast spectrum of congenital anomalies affecting the major intrathoracic arteries. These anomalies may be the result of a complicated embryologic development from primitive ventral and two dorsal aortas and their interconnecting branchial arches (Dische et al. 1975). They also may result from hemodynamic pathophysiology secondary to intracardiac lesions interfering with originally normal or abnormal ontogenetic vessel development. For the final pathoanatomy, we may distinguish between two principle groups of lesions. One group comprises autochthonous lesions of great vessels (narrowings, interruptions, atresias, abnormal connections) which result in hemodynamic symptoms, while the other group reveals anomalous positionings of the aorta and its branches causing symptoms by compressing neighboring structures.

Anatomical shortcuts leading to hemodynamic shunts will only be dealt with in this chapter when they occur as isolated lesions.

We will proceed according to the following division/classification:

- Anomalies of the aorta
 - Anomalies resulting in aortic hypoplasia/stenosis
 - Anomalies causing compression of neighboring organs
- Anomalies of the pulmonary artery
 - Anomalies resulting in pulmonary artery hypoplasia/stenosis
 - Anomalies causing compression of neighboring organs
- Congenital shortcuts involving major intrathoracic vessels
 - Left to right shunt
 - Right to left shunt

21.2 Anomalies of the Aorta

21.2.1 Anomalies Resulting in Aortic Hypoplasia and/or Stenosis

21.2.1.1 Coarctation of the Aorta/Aortic Isthmus Stenosis

Without being obstructive, the most proximal part of the descending aorta, between takeoff of the left subclavian artery and the junction of the arterial

duct (later arterial ligament), has a rather typically diminished diameter at birth. In the old days, this led to the naming «isthmus», in analogy to a geographical term for the narrow land connection between the Peloponnese peninsula and the Greek mainland, the Isthmus of Corinth. Developmentally, the relative aortic narrowing can be explained with the small fraction of circulating blood passing this aortic segment in fetal circulation.

The obstructive lesion at this site had been described for some time as stenosis of the aortic isthmus. Although isolated significant hypoplasia of the isthmus, resulting in hemodynamic obstruction, does occur, the typical lesion to deal with is a rather distinct narrowing, a coarctation at the junction of aortic isthmus and the further descending aorta, the latter receiving most of its blood flow in utero from the arterial duct. When aortic coarctation is accompanied by aortic arch hypoplasia, either only distal or complete arch hypoplasia, frequently intracardiac congenital heart disease is associated (► Chapter «Ventricular Septal Defects», Sect. 14.6.3). In cases of arch hypoplasia, the isthmus usually has more pronounced hypoplasia as well.

The localized narrowing/stenosis is at the cranial circumference of the open arterial duct or later the arterial ligament where it is connecting to the aorta. Former classifications distinguished between pre- and post-ductal coarctations as well as empirically between adult or infant coarctation types. According to the lasso theory, backed by histology (Elzenga et al. 1986), as well as by the flow theory (Rudolph et al. 1972), these classifications should not be used anymore.

Pathogenesis of aortic coarctation starts with abnormal fetal hemodynamics. It may or may not be associated with intracardiac left-sided obstructive lesions. These lesions result in decreased blood flow in the ascending aorta, aortic arch, and isthmus and consequently increased flow through the main pulmonary artery and finally the arterial duct into the descending aorta. This increased flow causes ductal myoepithelial cells to migrate within the whole circumference of the arterial duct into the adjacent descending aorta. These prostaglandin-sensitive cells contract postnatally when the prostaglandin serum level drops and the oxygen saturation rises. This contraction, physiologically meant to close the ductus, in the presence of ductal cells in the aortic circumference, will also narrow or even close the aortic lumen. The mechanism for this localized stenosis can be viewed as a protrusion of the aortic wall

into the lumen, caused by a lasso, leading to an intraluminal membrane once the inverted wall is fibrosed. The term «coarctatio aortae», aortic coarctation, is a description of this process: the Latin word *coarctare* means pulling together.

An important acute therapeutic option to secure lower body perfusion in critical neonatal aortic coarctation is medical reopening of the arterial duct and thereby diminishing the restriction in the adjacent aorta: a prostaglandin infusion *paralyzes the ductal myoepithelial cells* in the ductus and aorta. A concomitant aortic arch hypoplasia can be explained by fetal hemodynamics; however, at no point can it be treated medically. It remains a point of discussion as to whether or not a hypoplastic arch segment has growth potential once the aortic coarctation has been taken care of (DeLeon et al. 1991; Siewers et al. 1991). Therefore the surgical approach, to simultaneously take care of both the coarctation and the hypoplastic arch if present, is the safe strategy.

An isolated aortic coarctation can present clinically in various forms. The most serious form is *critical neonatal aortic coarctation*. The acutely developing aortic stenosis at ductal closure within the first days of life may lead to cardiac decompensation. Lack of collateral flow to the lower body adds to rapidly increasing acidosis and multi-organ failure. Intensive care treatment comprising of prostaglandin infusion, also, may stabilize the patient within hours. Surgical treatment can be safely delayed and metabolic compensation and urine production can be anticipated. If medical treatment does not result in immediate clinical improvement of the patient, and echocardiography shows only mild or no ductal opening, surgery is indicated with urgency. An increased mortality has to be anticipated in these cases. A palliative catheter procedure if more readily available than surgery in dramatic cases may be considered.

More recent work has identified that patients with prenatally diagnosed isolated coarctation have a more severe anatomical form of coarctation, often accompanied by borderline hypoplastic left heart structures than the neonates with coarctation diagnosed only after the first week of age. The prenatally diagnosed neonates were more likely to require extensive arch reconstruction under ECC, and they had longer hospital stays (McCandless et al. 2012). An aortic coarctation that remains silent at ductus closure, not causing hemodynamic or metabolic symptoms, may fur-

ther on remain clinically asymptomatic for months or years. A good clinical exam, however, should suffice to detect the disease early on (weak pulses in lower extremities, hypertension of upper extremities, systolic murmur best heard paravertebrally next to the left scapula). Surgery in these cases is elective; however, it should not be delayed significantly, as complications of long-standing not operated aortic coarctation, like irreversible arterial hypertension or left ventricular hypertrophy, reduce life expectancy.

The mechanism and cause of these late dysfunctions remain unclear. A humoral pathophysiologic chain, based on the currently known mediators for arterial hypertension, has been excluded, and the existence of an intrinsic vascular pathology is being speculated upon (Pedersen et al. 2011). The patient group followed in this paper, however, had been operated on between 1965 and 1985. Median age at repair had been 10 years and 44 years at follow-up.

As technological advances in the field of MR techniques are being applied on a wider scale also for the study of the post-coarctation aortas, subtle but considerable differences can be detected in comparison to the normal aorta but also between different repair techniques, which might influence the long-term prognosis of these patients. It becomes clear that abnormal pulse wave propagation, even in the absence of measurable pressure gradients, is strongly influencing the cardiac hemodynamics and the aortic pressure and flow conditions (Kenny et al. 2010). These abnormal hemodynamics may especially persist in those not quite precisely defined moderately hypoplastic arches in long-term follow-up (Liu et al. 2010; Lee et al. 2012).

Patients with native coarctation of the aorta continuously develop a more and more complex and complete system of collaterals contributing to lower body perfusion. Main collateral courses are the mammary and intercostal arteries as well as thoracic wall muscle artery branches. They are able to significantly diminish or even abolish an original pressure gradient at rest. Pulse quality and exercise pressure gradient will still be a source for clinical diagnosis.

■ ■ Surgical Access

Standard approach for coarctation surgery is a posterolateral thoracotomy in the fourth intercostal space (■ Fig. 21.1). In neonates with a

■ **Fig. 21.1** The curved, 4–5 cm skin incision needs sufficient distance to both tips of the scapula and spine. Closer to the spine, its course is almost parallel to it

bodyweight <3 kg, thoracotomy in the third intercostal space may be advantageous. A limited, curved skin incision starting 1 cm below the tip of the left scapula and pointing cranially to end about 1 cm lateral to the vertebra gives sufficient access. Thoracotomy in neonates and infants is rather simple, right in the middle of the intercostal space chosen. When dividing the chest wall muscles, special care has to be taken in older children, adolescents, and adults, as intramuscular arteries as part of the collateral artery system in coarctation may have reached significant size leading to undesirable bleeding.

Neonates, infants, and small children can be ventilated with routine tracheal intubation for coarctation surgery. For older children sometimes, but for adults always, double-lumen intubation for isolated right-sided ventilation is required.

Intrathoracic dissection starts with sharp or electrocautery division of the mediastinal pleura covering the proximal descending aorta. Dissection extends further to the subclavian artery and reaches caudally for about three intercostal spaces, at times as far as the diaphragm. The latter is required when long-segment resec-

tions or plasties are planned. An advantage of young and very young age is excellent elasticity of the aorta. Special care has to be taken not to injure the nerves next and close to the aorta (vagus nerve, recurrent laryngeal nerve, phrenic nerve). The extent of the dissection required depends on the repair technique planned as well as on individual pathoanatomic features. While only a limited dissection is necessary for a patch plasty (in neonates, infants, and small children nowadays rarely indicated), a resection of the coarctation to be followed by an end-to-end anastomosis requires an extensive dissection/mobilization of the distal aortic arch as well as of the proximal or even farther descending aorta. The first two sets of intercostal arteries originating directly off the isthmus are usually mobilized and temporarily encircled with vessel loops, or they may be even closed with a clip.

The *Abbott artery* coined by Robert Gross after Maude Abbott (the author of the first book on pathoanatomy of congenital heart defects (Abott 1936)) quite often shows up as an anomalous artery in coarctation. It originates from the back of the aortic isthmus and can lead to quite disturbing bleedings in case of accidental rupture. Even in a case of a supposedly «simple» patch plasty, this could be troublesome.

A further abnormality asking for clinical complications is the aberrant subclavian artery, also called lusorian artery (lusorian from Latin *lusus naturae*, capricious act of nature; also, God's joke). An aberrant subclavian artery arises as the last supra-aortic branch off the aorta and takes its course to the opposite side of the arch passing behind the esophagus. As its involvement in the actual aortic narrowing of the coarctation is not clear at clinical presentation, extremity blood pressure measurements may be misleading. Intraoperatively, cross-clamping of the distal aortic arch in these cases obstructs flow to both subclavian arteries (normal and aberrant) and theoretically impairs the perfusion of the spinal cord even more than in cases of normal subclavian arteries. A study aimed to determine the influence of this anomaly on coarctation repair in five neonates did not result in paraplegia which most certainly can be attributed to a short cross-clamp time (Hjortdal et al. 2003), as it is our own experience.

Another not infrequent variation of aortic arch branching is the isolated origin of the left vertebral artery coming off as the third branch

between left common carotid artery and left subclavian artery. While it neither is a health issue on its own, nor should it complicate the procedure, it must not be confused with the left-sided common carotid artery when the arch is dissected from the left side. This would lead to an insufficient mobilization of a hypoplastic aortic arch.

A truncus bicaroticus which sometimes is associated with a hypoplastic aortic arch should be diagnosed preoperatively also. Again, dissecting from the left side, it could be mistaken for a left-sided carotid artery, and one could unnecessarily feel required to further dissect for a brachiocephalic trunk.

In general all of these anomalies should be described preoperatively by echocardiography in neonates and infants or with any type of angiography in older patients.

Regardless of the technique of repair chosen, cross-clamping of the aorta is necessary. Steps of the procedure and the required close communication with anesthesia may be described in detail.

The invasive arterial blood pressure measurement has to be performed on the right arm (we prefer right radial artery) because at least temporary occlusion of the left subclavian artery occurs during most procedures (*Cave*: aberrant right subclavian artery).

An additional invasive blood pressure measurement distal of the coarctation in neonates, infants, and small children is not required as long as the expected cross-clamp time for the descending aorta will be safely less than 30 min. If a longer clamp time has to be expected, especially in older patients or in cases of reoperation, a relevant ischemia of the spinal cord has to be avoided, and it is essential to document the distal perfusion during a test clamping. A distal descending aortic/femoral artery mean perfusion pressure of less than 40–50 mmHg at probatory cross-clamp in these cases requires an assist procedure, e.g., partial left heart bypass or even full ECC, to as much as possible avoid paraplegia, one of the worst complications of this operation.

While in our practice we do not heparinize during simple aortic cross-clamp for coarctation

repair, but other studies recommend heparin in a dosage of 100 U/kg KG (Wright et al. 2005).

Both aortic cross-clamp and release lead to *significant and acute changes in left ventricular afterload*. Whereas the mature myocardium tolerates such an increase in the afterload, immature neonates may develop acute cardiac decompensation (bradycardia and asystole). It is mandatory to timely prevent this complication with pharmacological measures. In the presence of concomitant atrial- and/or ventricular septal defects, aortic cross-clamping can be better tolerated as the blood can be shunted into the pulmonary circulation, thereby relieving the left ventricle's acute volume load and pressure overload. Release of the aortic cross-clamp is accompanied by an acute decrease in coronary perfusion. This should be prevented by volume loading concomitant to clamp release. Immediate or intermittent clamping with stepwise reopening of the aorta can be necessary and useful.

Following the correction, the intraoperative gradient for the mean pressure should not exceed 2 mmHg measured in a femoral artery line. In infants, a strong pulse in the descending aorta *as well as* absence of a palpable thrill over the anastomosis suggest a good result. An almost unchanged blood pressure in the radial artery after release of the descending aortic cross-clamp is extremely suspicious for a significant residual stenosis.

Intraoperative measurements seem to be not very predictive for a successful operation in terms of residual or recurrent coarctation. A recent retrospective study suggests that a noninvasive systolic gradient >13 mmHg at hospital discharge has excellent discriminative accuracy in identifying patients in whom subsequent recoarctation developed (Kumar et al. 2011). The authors also frequently observed rapid growth of both the ascending and the transverse aortas, which was associated with improvement in gradient over time.

The mediastinal pleura is closed with a continuous suture. A significant pericardial effusion may have been drained by pericardial incision ventral of the ductus Botalli or the phrenic nerve already before aortic cross-clamping.

In neonates and infants, we do not place chest tubes unless an air leak is present. The preplaced pericostal absorbable sutures shall be tied during an inflation hold of the lungs.

The individual surgical techniques are discussed below:

Surgical Techniques for Coarctation of the Aorta

- Resection and end-to-end anastomosis
- Resection and extended end-to-end anastomosis
- Patch plasty (indirect Vosschulte plasty)
- Direct Vosschulte plasty
- Interposition graft
- Extra-anatomic bypass
 - Subclavian-aortic (Blalock-Park)
 - Aorto-aortic (ascending to descending aorta)
- Subclavian flap plasty (Waldhausen)
- Reverse subclavian flap plasty

■ ■ Resection and end-to-end anastomosis

This technique was independently developed but successfully performed for the first time by Clarence Crafoord (Crafoord and Nylin 1945) in Stockholm, Sweden (October 19, 1944) and shortly thereafter by Robert Gross (1945a) in Boston, Massachusetts (July 6, 1945), after the first Boston patient, operated on June 28, 1945 had died (Bob Replogle, personal communication). Since then it was made more sophisticated and adjusted to the different ages and types of pathology. Today, for neonates and infants, this is the most frequently performed technique for coarctation repair.

The major advantage of this technique, besides avoiding artificial material, is the complete resection of the ductal tissue that may be present in the complete circumference of the aorta at the coarctation site. Any remaining ductal tissue in the aortic wall may become responsible for most of the early restenosis following coarctation repair in neonates (Ziemer et al. 1986). Extending this technique, it can be also applied for taking care of accompanying hypoplasia of the distal or even proximal aortic arch.

■ ■ Extended end-to-end anastomosis

In these cases, an extensive mobilization of the aortic arch from the left even beyond the origin of the left carotid artery – sometimes beyond the brachiocephalic trunk and the ascending aorta – is necessary as well as a quite distal dissection of the descending aorta circumferentially. The following

anastomosis after incision of the aortic arch should expand the concavity of the hypoplastic arch. Dissection usually starts at the proximal descending aorta and is continued circumferentially around the left subclavian artery. In absence of any side branches at the proximal subclavian artery, with the exception of some adventitia vessels, a fast exposure can be expected.

It is important to dissect in direct contact to the adventitia of the aorta and its side branches in order to avoid any injuries to the esophagus, the thoracic duct, and nerves (vagus, recurrent laryngeal). Sharp dissection with scissors or electrocautery is preferential over blunt dissection in order to avoid tearing off of aortic side branches. Bleeding can be much better taken care of if they originate from clean cuts rather than from tears. Avoid spreading tissue close to arteries.

The next step is to circumferentially dissect the distal aortic arch as well as the isthmus and also the arterial duct or ligament. The *Abbott artery* as mentioned above is the only side branch which may originate from the back of the aorta (see «general remarks» and Lerberg 1981) and which has to be detected and occluded. The presence of a lusorian artery should have been detected preoperatively. A separate origin of a vertebral artery in between the takeoffs of the left common carotid and left subclavian artery is more difficult to be recognized by preoperative echocardiography. Being aware of the possibility of this anomaly avoids confusion. The circumferentially exposed aortic arch is retracted with a loose vessel loop; we prefer leading the loop ventral to the arch and dorsal around the isthmus inferiorly and dorsal around the subclavian artery superiorly. In case of an extreme hypoplasia, the loop should go around the arch proximal to the left carotid artery to optimize exposure (■ Fig. 21.2). These maneuvers especially improve complete mobilization of the back of the aortic arch.

The ductus arteriosus may be dissected before or after the maneuver described above, depending on the mobilization achieved versus required. In neonates, most often the duct is kept open with prostaglandin infusion. In these cases, the ductus tissue is very vulnerable and manipulation should be avoided as much as possible. Once the decision

■ **Fig. 21.2** a, b The circumferentially exposed aortic arch is retracted with a vessel loop, crossing the arch ventral and distal to the left common carotid artery. This course of the vessel loop allows for extensive dissection and mobilization in preparation for an extended end-to-end anastomosis

■ **Fig. 21.3** Applying a clip (titanium) to the aortic side of the duct after the circumferential suture to the pulmonary side is already tied. Before ductus division, an additional clip may be applied to the pulmonary side, as this stump will remain. Topography of the vagus and recurrent laryngeal nerve is depicted

for closure is made, a circumferential polypropylene suture is placed superficially into the ductal wall or the ligamentum arteriosum on the pulmonary side, which is tied simultaneously with discontinuing the prostaglandin infusion if present.

On the aortic side, a clip is applied and the duct will be cut. Then or already before, a prophylactic second clip can be applied on the pulmonary side (■ Fig. 21.3). Dividing the duct improves the approach to the descending aorta, which should be mobilized beyond the next two or three sets of intercostal arteries. In case of a good exposure, neither the clip on the aortic side nor duct division is required at this point. After placing the aortic clamps, the duct can be cut en bloc with coarctectomy.

The intercostal arteries of a neonate are easily identified and clearly structured, but with advancing age, they become big, winding, and friable. If

necessary, while clamping the aorta, they can be closed either temporarily using Yasargil clips or permanently with titanium clips. For temporary occlusion in older patients, a vessel loop maneuver may be also adequate. We prefer a definitive collateral closure as a primary step with or without transection, depending on the exposure achieved.

After complete mobilization, but before any aortic resection, the mechanical tension of the future anastomosis should be estimated by approximation of the future resection sites, each being grabbed with forceps. This also could be done during a test clamping phase by approximating the proximal and distal clamps. Mobilization may be extended thereafter if necessary to reduce the risk of anastomosis strictures caused by mechanical tension. Cross-clamping the aorta proximally always includes the subclavian artery employing

■ **Fig. 21.4** a–c Clamps in place after coarctectomy and arch incision a. Dorsal «inner» suture line of the anastomosis performed with the clamps approximated b. Final anastomosis, clamps removed c

one curving clamp. In cases of more proximal arch hypoplasia, the aortic cross-clamp will include the left subclavian and carotid artery (■ Fig. 21.4a, b).

Now the complete resection of the juxtaductal segment of the aorta is performed. The cutting edges should be free of any ductal tissue. If further resection and/or anastomosis is necessary, the distal clamp may have to be moved more caudally. Into the arch, an aortotomy is commenced in the concavity of the aortic arch and it is extended to cover the complete hypoplastic segment. In case of a now enlarged proximal circumference in comparison to the circumference of the descending aorta, a dorsal incision can be performed into the descending aorta out of the distal resection site to create a harmonic E-E-anastomosis including the subclavian artery. Occasionally a separate implantation of the subclavian artery is performed distal to or directly into the aortic anastomosis to facilitate aortic reconstruction.

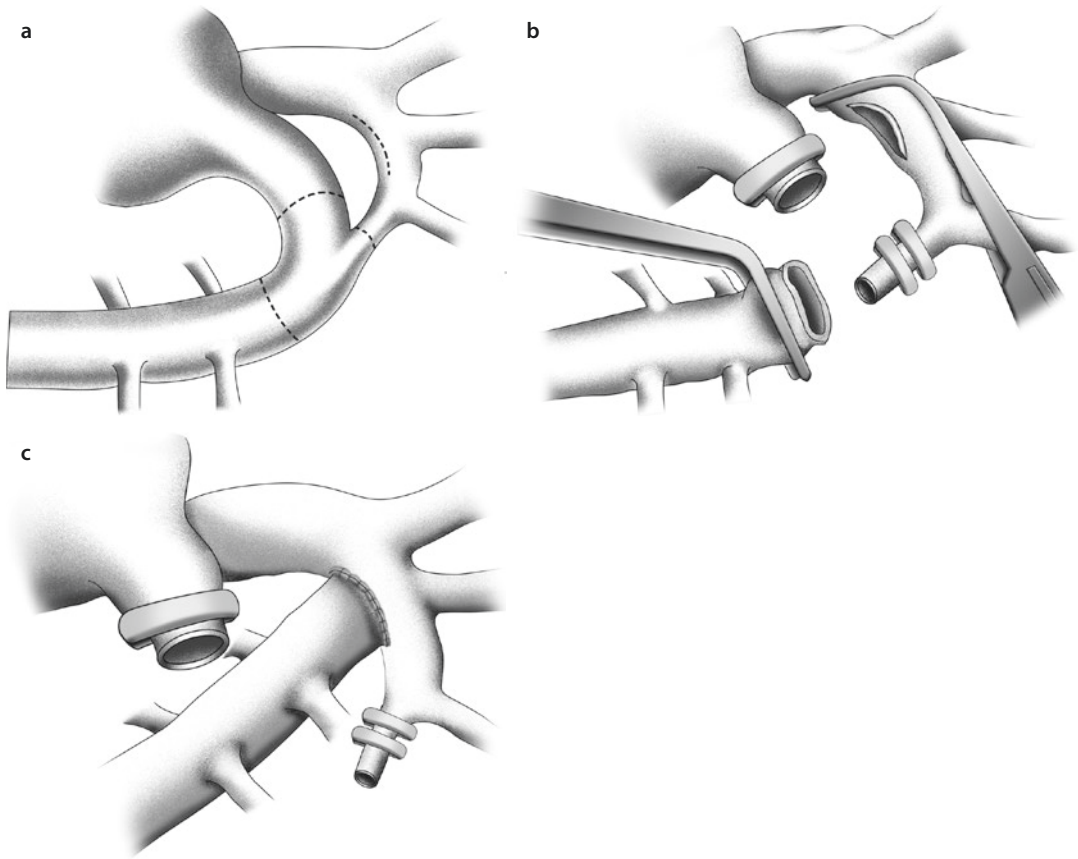

In the 1960s and 1970s, a direct E-E-anastomosis was not routinely performed in children, owing to the fear of lack of growth of a circumferential suture

line with the suture material available. Even interrupted single suture lines tended to scar down as materials like silk provoked a rather heavy foreign body reaction. Nowadays circumferential anastomosis with absorbable (polydioxanone suture, PDS [Ethicon]; neonates, 7/0; infants, 6/0; children and adolescents, 5/0) and with nonabsorbable monofilament sutures (polypropylene up to 6/0) shows a normal potential of growing, even when employed as a continuously running suture. The 6/0 polypropylene sutures obviously rupture during growth. For adults we use 4/0 polypropylene sutures.

A closure of the isthmus followed by an end-to-side anastomosis of the descending aorta to the aortic arch (neonates, infants) provides a technical variation as described by Frank Hanley's group (Rajasinghe et al. 1996) (■ Fig. 21.5).

■ ■ Indirect Vosschulte plasty

In 1957 Vosschulte described a technique to enlarge the isthmus and the coarctation site by a plasty with an artificial patch, originally Dacron,

■ **Fig. 21.5** Alternative repair of neonatal aortic coarctation, complicated by distal aortic arch hypoplasia: Hanley repair. **a** All vascular structures involved are circumferentially dissected and mobilized: aortic arch, distal ascending aorta, aortic arch branches, descending aorta as far as possible, and arterial duct. Sites of resection or incision are indicated by *dotted lines*. **b** Left subclavian and left carotid artery as well as proximal arch are occluded with fine Satinsky-type clamp allowing for unrestricted flow in brachiocephalic trunk. The aortic isthmus is definitely closed with two clips, the ductus and all ductal tissue containing descending aorta are resected, and the aortic arch is longitudinally incised in its concavity. Pulmonary end of the ductus is closed with clip and/or suture. **c** Final sites after end-to-side anastomosis of the descending aorta to underside of aortic arch in its concavity (From Rajasinghe et al. (1996); used with permission)

later polytetrafluoroethylene (Vossschulte 1957). The coarctation membrane was usually excised and the intima-media defect was often, but not always, oversewn. This technique originally was employed only for older children, adolescents, and adults.

For this patch-plasty, the so-called indirect Vossschulte plasty, a mobilisation of the aorta is not necessary. This is advantageous in a case of significant tortuous collaterals or major adhesions caused by former procedures. The length of the isthmus is unchanged and there is no risk of stenosis caused by mechanical tension (■ Fig. 21.6).

The disadvantages of this technique became obvious over time in the follow-up of patients receiving this operation at an age of more than 14 years: all studies report development of aneu-

rysms and risk of dissection (Aebert et al. 1993). This may be caused by the weakened aortic wall following the resection of the intima-media membrane. It also may be due to the different elasticity properties (anisoelectricity) of the patch material used compared with the aortic wall, especially when weakened by membrane resection (De Santo et al. 1987; Rheuban et al. 1986). There are no reports on late aneurysm formation after coarctation patch plasty in neonates or infants.

In fact this kind of repair seems to experience a renaissance. Carl Backer and Gus Mavroudis used the procedure as an elective procedure in all patients age 2–16 years, but unlike the original method, the intima-media membrane will remain untouched (Mavroudis and Backer 2003).

■ **Fig. 21.6** a–d Indirect isthmus (patch-) plasty according to Vosschulte: after proximal and distal aortic cross-clamping and temporary occlusion of major collaterals entering the clamped aortic segment, longitudinal aortotomy is performed, well covering the aortic isthmus and the coarctation site **a**. The membrane may be kept in place or cut out **b**. If cut out, a continuous suture of the intima and media may cover the defect and reinforce the weakened wall **c**. Suturing the patch into place, standard rules apply: avoid oversizing and no tapered edges **d**. Nowadays, this technique should be applied only exceptionally in lack of any other options

■ ■ Direct Vosschulte Plasty

In contrast to the indirect plasty, the direct Vosschulte plasty does not require a patch. It does, however, require an extended mobilization of the proximal and distal aorta. Analogous to the Heineke-Mikulicz plasty of the pylorus in visceral surgery, the narrow segment of the aorta is incised in length and sutured in a crosswise fashion (■ Fig. 21.7).

At present we do not see any benefit of this technique compared to the resection and E-E anastomosis, particularly because the technique can be performed only in cases of a short-segment narrowing.

■ ■ Resection and interposition graft

This is the operation of choice in adolescents and adults when an E-E anastomosis cannot be performed. It replaces the patch plasty and prevents a stricture in an anastomosis under tension. Proper suture technique provided and absence of infection, development of an aneurysm should also be avoidable. The diameter of the prosthesis depends on the circumference of the descending aorta. A diameter of 18 mm can be sufficient for a nonrestrictive blood flow even in bigger adults. For smaller patients, especially in redo procedures, one may be content to use a smaller graft like 14 or 16 mm. Significant oversizing is without

■ **Fig. 21.7** a, b Direct plasty according to Vosschulte. a Longitudinal incision commences in the aortic arch and extends throughout the isthmus beyond the coarctation into the proximal descending aorta. b Suture of the longitudinal incision in a crosswise fashion

advantage, as the long-term result depends on the quality and diameter of the original anastomosis anyways. And again, smaller people have smaller vessels!

The normal aorta is a rather delicate organ (Heinemann et al. 1997).

The operation should be performed in accordance with state-of-the-art general principles of vascular surgery. Outside neonatal, infant, and child age, the operation should be only performed in simple clamping, when a sufficient arterial pressure in the descending aorta is continuously monitored (see above). In all other cases, a temporary bypass procedure should be employed.

■ ■ Extra-anatomic bypass in aortic isthmus stenosis/coarctation of the aorta

Extra-anatomic bypass procedures should not be used in primary operations of an aortic isthmus stenosis in children or adolescents. However, occasionally it may be advisable even for older children in repeatedly recurrent stenosis of the Isthmus, the distal, or even in the proximal aortic arch to employ an extra-anatomic bypass as a functional cure. For adults with a long-segment hypoplasia of the isthmus, an extra-anatomic bypass procedure can be appropriate even as a primary operation.

A recurrent stenosis in the first weeks after neonatal operation (caused by remodeling duct

tissue or insufficient proximal extension during the primary operation) can usually be redone with a further more extended resection combined with a proximal enlargement. If necessary, a sternotomy and extracorporeal circulation with circulatory arrest have to be utilized. Beyond the infant age, this kind of recurrent stenosis should not be treated in that way. Adhesions make the dissection more difficult and can cause severe damage by accidental injuries of related structures (phrenic nerve, recurrent laryngeal nerve, esophagus, thoracic duct). A repeat resection in these patients beyond infant age increases the mechanical tension of the vessels because of a postoperative fibrosis with the aortic tissue not being elastic anymore. This leads to a higher risk of another recurrent stenosis, if the re-resected aortic ends could be directly anastomosed anyways. Today these re-coarctations are a primary indication for interventional dilatation and stent placement. It should be kept in mind, however, that even after stent placement, surgery may be necessary. Therefore, the length of the stent should be only as long as necessary to not further complicate future reoperation.

In patients beyond infancy with a simple stricture of an anastomosis (without interventional option/success) and normal aortic arch and subclavian artery, a Blalock-Park operation (bypass between left subclavian artery and descending aorta) through a left-sided thoracotomy can be performed as a successful and simple treatment (Blalock and Park 1944).

In general, the post-ductal descending aorta can be laterally clamped in a generous way because

of the poststenotic reduced arterial pressure. We recommend an extended circumferential exposure of the aorta in the region of anastomosis or at least a vessel loop maneuver proximal and distal of the planned anastomosis in elderly patients. After clamping, using an adequate large Satinsky clamp, the arterial pressure of the distal aorta has to be checked. Especially in redo procedures, an additional monitoring line for the arterial pressure should be placed in the femoral artery or descending aorta in addition to the always invasively monitored right radial artery pressure.

The prosthesis to subclavian artery anastomosis should be in end-to-side technique at the proximal intrathoracic segment of the artery. If further growth of the patient has to be expected, the prosthesis (polytetrafluoroethylene or Dacron) should be given some redundancy. This, however, should not lead to kinking!

Of special value is the extra-anatomic bypass in cases of accompanying hypoplasia of the aortic arch (so-called complex recoarctation). Here, the bypass directly connects the ascending and descending aorta.

For this ascending to descending aortic bypass, several courses may be considered:

To achieve a bypass in an «orthotopic» but still extraanatomic position, in which the bypass runs parallel and anterior to the aortic arch, usually extracorporeal circulation is required as some retrocardiac dissection is necessary. If extracorporeal circulation is needed anyways, to treat associated intracardiac lesions, aortic dissection can be performed on the beating heart without any additional myocardial ischemia. Daebritz et al. (1999) report about five patients who received an orthotopic bypass in case of a complex recoarctation through a left-sided thoracotomy without extracorporeal circulation.

Some groups suggest an extra-anatomic *transpericardial* connection between the ascending and descending aorta through a median sternotomy (McKellar et al. 2007; Burkhart et al. 2011). The proximal anastomosis is performed on the right side of the ascending aorta employing a side-biting clamp. For the distal anastomosis, the descending aorta is dissected transpericardially under careful retraction of the cardiac apex, using the OPCAB tools (e.g. vacuum, see also ► Chapter «Coronary Artery Disease», Sect. 22.4.2.1, and ■ Fig. 22.19). These groups claim an excellent approach to the supradiaphragmal descending aorta. The local dis-

section of the descending aorta and the distal bypass anastomosis should be performed in accordance to the abovementioned principles for the Blalock-Park bypass (Blalock and Park 1944).

Others prefer the *intra-abdominal* aorta for the distal bypass anastomosis (Levy Praschker et al. 2008). For us, this approach should be reserved for specific and exceptional cases due to the complexity of the additional intra-abdominal/retroperitoneal exposure. To optimize length and position of the intrapericardial course of the bypass, recommendation is to use two separated prostheses for the proximal and distal anastomosis which then can be adjusted and anastomosed in ideal length and position, not compromising any intrapericardial structure.

■ ■ Waldhausen-Plasty («subclavian-flap-plasty»)

Waldhausen's subclavian flap technique requires dissection and transection of the left subclavian artery, as in the original Blalock-Taussig shunt. Employing the longitudinally split open subclavian artery as an in situ patch was the first long-term successful technique of correcting neonatal coarctation (Waldhausen and Nahrwold 1966).

Reports on obstructions of growth and malfunctioning of the left arm following the section of the subclavian artery, as already historically reported for the classical Blalock-Taussig shunt, may be considered as a detriment. This is also true for the potential late occurrence of a subclavian steel phenomenon. The fact of leaving ductal tissue in the aorta is an important cause of rather early recurrence of coarctation in up to 25% of neonates operated upon (Ziemer et al. 1986).

Today the Waldhausen plasty may be employed in infant coarct reoperations when resection and end-to-end techniques or artificial patch plasties have failed without interventional treatment options available. This may be especially true when repair is required in cases of sepsis and the exceptional case of local mycotic aneurysm.

After dissection, the subclavian artery is transected proximal to the origin of the vertebral artery. The further incision line is performed along the lateral side of the subclavian artery, extended beyond the isthmus and the coarctation into the descending aorta (■ Fig. 21.8a, b). Once sutured into place, it has to be made sure that the

■ **Fig. 21.8** a–d Classic a, b and «inverse» c, d subclavian flap plasty. The incision extends clearly beyond the coarctation. As well as with the Vosschulte plasty, the membrane stays intact, or if resected, it is sewn from the inside (see ■ Fig. 21.6c) a. After turning down of the laterally incised proximal left subclavian artery, it is sewn into the incised aorta as a pedicled patch b. The «inverse» Waldhausen plasty is useful as a complementary technique in case of a long-segment hypoplastic distal aortic arch. In this technique, the left subclavian artery has to be incised medially to create the pedicled patch required for the arch c. The localized coarctation is dealt with by a resection and end-to-end anastomosis, not requiring much dissection d

subclavian flap reaches well beyond the ductal tissue containing descending aortic wall, potentially bypassing the later on occurring constriction of the ductal tissue at this location.

Michel Ilbawi's group modified the original Waldhausen technique by adding a direct Vosschulte plasty (see ■ Fig. 21.7a, b) to create an enlargement of the lumen and a reduction of length to be bridged by the subclavian flap (Allen et al. 2000). Asano in principle adds resection of the coarctation with direct suture to be completed by the subclavian flap (Asano et al. 1998).

Currently we would see an indication for the «subclavian flap» technique only in the rare infant who may require surgery for *recoarctation* late after neonatal coarctectomy and end-to-end anastomosis. But even in these rare events for surgery in the era of interventional cardiology,

we first would reevaluate the options for re-resection and end-to-end anastomosis. A prosthetic patch would be considered also before a subclavian flap in redo surgery as long as the segment to be patched does not look severely scared and therefore showing potential for future growth.

The distally disconnected proximal left subclavian artery as a pedicled biological flap for the aorta with growth potential is used also as an additional or independent component of different techniques (Zannini et al. 1993). The «reverse subclavian flap» technique (■ Fig. 21.8c, d) as described by Hart and Waldhausen (1983) is meant to be used in cases of a pre-isthmal aortic stenosis. However the incidence of this variation is minimal. This technique is also described by Kanter to correct a hypoplasia of the distal aortic arch (Kanter et al. 2001).

As usual, it is important to transect the left subclavian relatively distally, as the length of the proximal subclavian stump should bridge not only the segment to the left carotid but extend into the proximal few millimeters of this vessel as well. To create the reverse flap, the incision is carried along its medial border facing the left carotid artery, and it is continued into the convexity of the hypoplastic arch into the facing aspect of the left carotid artery. Distal dissection and transection, however, must not impair collateralisation. Therefore both thyrocervical trunk and costocervical trunk as important collateralisation arterial branches of the subclavian artery have to be saved.

A more recent variant for this indication follows the same technical principle, but preserves the left subclavian artery: After incision of left subclavian artery, convexity of the aortic arch, and the left carotid artery, a prosthetic patch is interposed. In this way, the distal arch is enlarged and both the takeoffs of the arteries are pushed distally (Dave et al. 2012). In shorter distal arch hypoplasia, both the cut open left subclavian artery and left common carotid artery may be sutured not only to the opened distal arch but also to each other, creating a so-called V/Y plasty which is used in vascular surgery for vessel stenoses immediately behind bifurcations (own experience). This creates a common trunk for the left subclavian and common carotid artery which at the same time enlarges the distal arch.

■ ■ Associated hypoplasia of the aortic arch

A certain degree of hypoplasia of the aortic arch is frequently associated with coarctation of the aorta. The normal diameters of the aortic arch segments are described in percentage in relation to the ascending aorta. The values are set by morphologists, being 60%, 50%, and 40% for the proximal and distal aortic arch and the aortic isthmus, respectively (Moene et al. 1982).

There are no clear morphological cutoff values established which would indicate surgical therapy for segments below these values. While some studies have shown a potential for growth, other authors like us prefer the primary correction of the hypoplastic aortic arch. The «extended» E-E anastomosis or the «reverse subclavian flap» (see above) may enlarge the distal and if necessary the proximal aortic arch also.

In case of an extreme hypoplasia of the proximal or the complete aortic arch, defined as less than 25% of the diameter of the ascending aorta, transsternal surgery employing extracorporeal circulation and if necessary deep hypothermic circulatory arrest also is recommended even in the absence of any additional intracardiac defects.

A particularly unfavorable arch branching variant, especially for decision-making regarding surgical approach, is the common origin of the brachiocephalic trunk and the left common carotid artery (truncus bicaroticus). When associated with coarctation, the distal aortic arch is extremely long and accordingly hypoplastic. The available techniques of extended plasties of the aortic arch with or without E-E anastomosis may work very well, when the clamped arch allows for a good proximal lumen for which to end the plasty in. An intimate relationship of brachiocephalic trunk and left carotid artery with a severely hypoplastic distal arch from its origin may have a transsternal approach to be considered also.

■ ■ Aortic coarctation as a part of complex intracardiac anomalies

Only about a third of isolated coarctation surgery used to be done in patients with normal intracardiac anatomy (Ziemer et al. 1986). As already mentioned above, the most important causes for a hypoplastic isthmus or arch including coarctation of the aorta are pathologic intracardiac flow patterns developing during fetal life. Therefore coarctation is rather more frequently part of an intracardiac defect (Anderson et al. 1983; Rudolph et al. 1972). Furthermore, coarctation is especially a complementary part of complex cardiac defects with any left ventricular outflow tract obstruction or complete underdevelopment of cardiac structures serving the systemic circulation. Those typical complex heart diseases are:

- Shone complex (see ► Sect. 12.3.5.4; 16.3.1; 17.1)
- Taussig-Bing anomaly (see ► Sect. 19.2.6.6)
- Unbalanced atrioventricular septal defects (see ► Sect. 12.1.5.8; 13.6; 13.7.5.1)
- Various forms of univentricular hearts . (see ► Sect. 13.3.3; 13.7.1.2)

These complex congenital heart defects combined with coarctation of the aorta usually

become symptomatic in the neonatal period and require immediate medical and surgical attention. While the extent of the first surgery, correction or palliation, is to be assessed individually, surgical correction of the aortic coarctation is always demanded. If only the correction of the aortic arch/coarctation of the aorta is planned without any intracardiac repair, a left-sided thoracotomy may be performed. This approach also allows for pulmonary artery banding if required.

Correction of intracardiac defects employing cardiopulmonary bypass in neonates requires a median sternotomy. Moderate hypothermia or if necessary deep hypothermic circulatory arrest with or without (our preference) isolated brain perfusion may be used. If deep hypothermic circulatory arrest is planned, arterial cannulation for extracorporeal circulation is in the ascending aorta. In case of planning isolated cerebral perfusion also, the arterial access can be established either via the brachiocephalic trunk using a PTFE prosthesis or via a direct cannulation of the distal ascending aorta on the right side. In both cases, the aortic clamp can be placed during cardiac/circulatory arrest to allow for «isolated» brain perfusion via the brachiocephalic trunk. In neonates, once on pump, the proximal descending aorta can be easily reached after performing the pericardial incision during cooling. To facilitate circumferential dissection of the descending aorta farther distally, a C-clamp (Cooley clamp – «C» either representing Cooley or the form/shape of the clamp) can be placed distal to the isthmus after having sufficiently lowered the core temperature to 25 °C. During this clamp phase, flow of ECC should be lowered to 50 %.

The cooling phase on ECC should be used to dissect and mobilize the aortic arch branches as far as possible and loop them with tourniquets.

During cooling, a temperature gradient measured between intraesophageal, nasopharyngeal, or tympanic on one side and intrarectal or intravesical (urine bladder) on the other side has to be noted. High gradients may indicate an inadequate circulation of the lower part of the body requiring an extended period of cooling (sometimes significantly longer than the usual 20 min used in any case). In cases of undisputed anatomic and hemodynamic significant descending aortic narrowings, the temperature gradient on pump is not of importance. In cases of preoperatively questionable coarctations, we use a temperature gradient

of more than 10 °C to proceed with coarctectomy in patients planned for intracardiac repair also.

While any simultaneous intracardiac and coarctation repair can be done via median sternotomy, this access clearly facilitates an additional repair of a proximal hypoplasia of the aortic arch. This can be performed either as a long extended anastomosis, comprising the entirely cut open concavity of the aortic arch (■ Fig. 21.9), an anastomosis comparable to an interrupted aortic arch repair (■ Fig. 21.11), or one may perform a direct E-S anastomosis between the descending aorta and the ascending aorta after clip closing of the isthmus (■ Fig. 21.5). While we find it almost always possible to perform some type of direct autologous connection/anastomosis, in certain cases, a patch plasty with either synthetic material as polytetrafluoroethylene, a tissue-engineered patch, or pulmonary homograft wall may be performed.

An interesting patch material available for arch reconstruction is autologous pulmonary artery wall harvested from the usually enlarged pulmonary arteries in these settings (Roussin et al. 2002). The postulated advantages as compared to other patch materials used have not been proven yet. Furthermore, it has to be evaluated whether the postulated superior growth potential for the whole arch justifies the risk to impair the integrity of pulmonary valve and/or branches.

The group from Texas Children's Hospital recently reported a novel technique to address the hypoplastic aortic arch in patients beyond infancy, when the elasticity of the involved vascular structures could prevent an «extended» end-to-end reconstruction (McKenzie et al. 2011). In fact this technique is a mirror image of their previously described «advancement flap» (Elgamal et al. 2002). They transect the distal ascending aorta at the level of the arch. A longitudinal incision on the right anterolateral margin of the proximal ascending aorta creates a tongue or flap, which is then anastomosed to the longitudinally incised undersurface, the concavity of the aortic arch. The operation is completed by a limited resection of coarctation and isthmus, which is followed by an end-to-end anastomosis incorporating the distal end of the ascending aortic patch/tongue. The advantages speculated about with this kind of operation is the avoidance of foreign material bearing the risk of pseudoaneurysm formation. Further speculation is a better elastic reservoir function of the proximal aorta. Besides these theoretical advantages, this approach has also practical

■ **Fig. 21.9** a–c Trans-median sternotomy repair of aortic coarctation, with hypoplasia of the isthmus and the aortic arch. Cannulation of the ascending aorta close, better opposite to the planned anastomosis/enlargement of the arch. The resection and incision lines are visualized **a**. The arterial cannula is removed during deep hypothermic circulatory arrest (not always necessary). The coarctation and isthmus are resected, the ductus transected, and the concavity of the aortic arch incision extends into the distal ascending aorta **b**. Final image after extended E-E anastomosis leading to enlargement of the arch also **c**

advantages in cases of recurrent coarctation beyond infancy, where the challenging mobilization of the previous extensively manipulated descending aorta can be avoided by performing the necessary extensive mobilization solely around the proximal structures; but this technique always requires extracorporeal circulation.

With reaching the desired rectal temperatures ($<20^{\circ}\text{C}$) and a cooling time of at least 20 min to ensure equal temperature distribution, the extracorporeal circulation is arrested after the temporary closure of the arch vessels with tourniquets. The blood is drained via the venous cannula into the reservoir of the heart-lung machine. Usually

During circulatory arrest, the brain is the most sensitive organ. Besides keeping the arrest period as short as possible, as an additional protective measure, the head should be covered with ice packs throughout circulatory arrest, starting already during the cooling phase. This is seen less as an additional cooling measure than a measure to avoid rewarming of the brain during the circulatory arrest period.

at this point, the temperature of the brain (in analogy measured as nasopharyngeal, esophageal, or tympanal) is $<18\text{ }^{\circ}\text{C}$ (or even $<15\text{ }^{\circ}\text{C}$).

If the correction of the aortic arch is accomplished expeditiously, the additional correction of a simple intracardiac defect can be performed during the same period of circulatory arrest. For longer times spent for coarctation/arch reconstruction (>15 min), another short (1–3 min) lasting reperfusion in deep hypothermia should follow before further intracardiac repair in DHCA as recommended by Ross Ungerleider and his group (Langley et al. 1999). In animal experiments, they showed a reduction of the risk for postoperative ischemic cerebral damage.

After publication of the midterm results of the Boston Circulatory Arrest Study (Bellinger et al. 1993), several groups entertained the idea of isolated or selective cerebral perfusion avoiding complete DHCA. Some experimental reports stress the harmful effects of ischemia and hypothermia although the counter arguments (cerebral edema after long-lasting hypothermic «low-flow» perfusion with undefined pressure/flow ratios) are also convincing to others.

At a temperature of less than $25\text{ }^{\circ}\text{C}$, about 20–30% of the calculated normal blood flow is said to be sufficient for an isolated unilateral cerebral perfusion via the brachiocephalic trunk. This is used by some groups for cerebral perfusion only (MacDonald et al. 2002; Pigula et al. 2000). Other groups prefer a combined cerebral and myocardial perfusion during the reconstruction of the aortic arch (Ishino et al. 2000; Kostelka et al. 2004). Installing a double cannulation of the ascending and descending aorta, directly above the diaphragm (Imoto et al. 1999, 2001), allows an almost normothermic perfusion. While we think that the advantage of such a complex perfusion has not been proven, yet, Rudi Mair (see ► Chapter «Surgery for Aortic Atresia, Hypoplastic Left Heart Syndrome,

and Hypoplastic Left Heart Complex», Sect. 17.6.2.2) claims his improved results in HLHS treatment are at least in part due to this cannulation technique.

While *recoarctation* and *coarctation in the adult* were already treated with balloon dilatation in the 1980s, routine interventional treatment of native coarctation is meanwhile advocated by some, leading to sequential dilation of stents implanted in childhood or definite placement of covered stents in adolescents and adults (Egan and Holzer 2009; Godart 2011; Luijendijk et al. 2012; Butera et al. 2012).

Surgery for recoarctation follows the same principles as for primary coarctation. Quite different than in primary coarctation, however, is the reduced collateralization, as some or many of the collaterals may have been closed during primary surgery. Therefore, we strongly recommend arterial pressure measurement in both right radial and one femoral artery even in infants or small children to be aware of the potential risk of descending aortic cross-clamping. It has to be judged early on whether the secondary operation, either patch plasty, re-resection, or graft interposition, can be performed in simple clamping. We liberally employ partial left heart bypass for recoarctation surgery to avoid time constraints and secure lower body perfusion including spinal artery perfusion. In our practice, the youngest patient operated upon for recoarctation employing partial left heart bypass (LA to distal descending aorta) was 7 years old. If in infants or small children a transsternal approach is preferred with full extracorporeal circulation, oxygenator, and cooling, femoral pressure control may not be necessary; however, it is a good means to immediately control the quality of repair here also.

21.2.1.2 Interrupted Aortic Arch

Interrupted aortic arch (IAA) has been defined as a complete structural discontinuity in the course of the aortic arch. An angiographic discontinuity of flow only, is sometimes referred to as pseudo-interruption when it relates to an extreme form of a hypoplastic aortic arch with coarctation of the aorta. However, in these cases, the structural continuity of the aortic arch is maintained.

In contrast to coarctation of the aorta, interrupted aortic arch as an isolated malformation is extremely rare (Dische et al. 1975). It is almost always accompanied by additional intra- or extracardiac defects. These associated anomalies are

shunts on the ventricular level (ventricular septal defect), in the ascending aorta (aortopulmonary window), or in both locations (truncus arteriosus).

IAA as part of complex anomalies determines an independent type within certain classifications:

- Truncus arteriosus type A4 after Van Praagh
- Aortopulmonary window type IV

In rare cases IAA can be also found in association with a functional single ventricle. Variants of hypoplastic left heart syndrome are the most frequent forms of this single-ventricle circulation.

In the aortic atresia variant of HLHS complicated by IAA, coronary perfusion is dependent on vascular structures of various origins. Described is a circle of Willis-dependent coronary perfusion associated with a well-developed aberrant right subclavian artery (Tanous et al. 2006) or the Willis collaterals, which were angiographically visualized to come from an anterior spinal artery (artery of Adamkiewicz) (Zsolt Prodan, Budapest, Hungary, personal communication). Interestingly both of these two circle of Willis-dependent cases had the same intracardiac anatomy with two well-developed ventricles and a large ventricular septal defect.

The first case (Tannous et al. 2006) underwent successful biventricular repair along the lines first outlined by Yasui (Yasui et al. 1987; Austin et al. 1989).

A simple and still useful classification for IAA associated with ventricular septal defect has been suggested by Celoria and Patton as early as 1959 (Celoria and Patton 1959). Determining factor for this classification is the missing segment of the most common left-sided aortic arch with an also left-sided descending aorta (■ Fig. 21.10).

In type A the interruption is located in the region of isthmus (■ Fig. 21.10a), in type B it is between the left common carotid artery and left subclavian artery (■ Fig. 21.10c), and in type C the aortic arch interruption is between the brachiocephalic trunk and the left carotid artery (■ Fig. 21.10d). Actually we have not seen any IAA type C after more than 25 years of clinical practice.

Statistically, type B is the most common form, and type C is extremely rare (Jonas et al. 1994). In addition to its rarity, type C is associated with an extreme hypoplasia of the ascending aorta and is therefore the IAA variation with the highest risk, analogous to hypoplastic left heart syndrome. A very hypoplastic ascending aorta may be also present in cases of type B interruption associated with a

lusorian artery (■ Fig. 21.10b). As in type C, the ascending aorta gets only blood flow for coronaries and two supra-aortic arteries. The systemic perfusion of the lower body and the supra-aortic branches beyond the interruption is duct dependent.

While the ventricular septal defect in coarctation of the aorta is due to a posterior deviation of the outlet septum in 47% of cases, a so-called posterior malalignment VSD is present in 93% of IAA (Kreutzer and Van Praagh 2000). This posterior malalignment narrows the left ventricular outflow tract; however, this subaortic obstruction may become hemodynamically relevant only after repair of the aortic arch with or without VSD closure if no subaortic resection was performed. Prediction for nonrequired resection is difficult. Regarding other VSDs, there are different subtypes reported, but apart from the second most frequently reported subpulmonary VSD, there is no other frequent location worth mentioned. Theoretically they could be anywhere.

Besides posterior septal deviation, other types of obstructions in the left ventricular outflow tract have been also reported. A valvular aortic stenosis with or without anular hypoplasia and commonly seen bicuspid aortic valves have to be evaluated for treatment requirements and/or options. The hemodynamic importance may surface only after arch and VSD repair in the same way reported earlier about the subaortic narrowing.

■ ■ Indication of Surgery

The history of surgical procedures to address IAA started some years after the surgery of the aortic isthmus. Samson was the first to successfully correct an isolated IAA in a 3-year-old girl in 1955 (Merrill et al. 1957). The first neonatal repair, including closure of a ventricular septal defect, was carried out by Barratt-Boyes in 1970 in New Zealand (Barratt-Boyes et al. 1972).

Despite these success stories, before introduction of prostaglandin by the end of the 1970s, mortality was very high. Ductus closure in this duct-dependent circulation leads to multi-organ failure with anuria and metabolic acidosis. Under those conditions, surgical therapy may not be successful. The infusion of prostaglandin allows for metabolic and circulatory stabilization. After attaining hemodynamic stability, which can take some days, surgery can be performed in an almost elective fashion. While refinement of surgical technique and strategy can secure a good long-term result,

Fig. 21.10 a–d Classification of interrupted aortic arch (Celoria and Patton 1959)

early mortality is influenced by prenatal diagnosis, which helps to present these patients in best possible condition for surgery, avoiding any period of metabolic and/or circulatory decompensation. The diagnosis of an interrupted aortic arch dictates indication for urgent surgery in the stabilized patient.

Despite the first neonatal repair of IAA/VSD being performed already in 1970, selective correction of the aortic arch combined with temporary pulmonary artery banding had been the method of choice for quite some years. We nowadays recommend this only in cases of a single ventricle where

the systemic circulation has to be ensured as a first step of palliation as in the Norwood procedure.

Isolated correction of an interrupted aortic arch via a lateral thoracotomy required reoperation in all of nine patients as reported by Karl et al. (1992).

Median sternotomy is the access of choice in total repair of IAA/VSD.

After completing the sternotomy, one can often see only a very thin or missing thymus as a sign of DiGeorge syndrome (microdeletion 22q11) especially with IAA type B. These children tend to

■ **Fig. 21.11** a–c Surgery for IAA type B. Cannulation: the delicate ascending aorta is cannulated on its right side, while the descending aorta is perfused via the ductus arteriosus **a**. After removing one or both arterial cannulas, the E-S anastomosis between the descending aorta and the distal part of the ascending aorta is performed, after complete resection of the ductal tissue. The proximal incision should be carried out at the posterior-medial aspect of the distal ascending aorta **b**. The completed anastomosis, which can reach into the left carotid artery proximally and the left subclavian artery distally **c**

develop hypocalcemia early postoperatively which demand special attention.

Similar to repair of complex aortic coarctation, the extra- and intracardiac procedure can be performed in deep hypothermic circulatory arrest with or without an isolated cerebral perfusion.

A special feature of extracorporeal circulation in repair of IAA is double arterial cannulation: the ascending aorta is directly cannulated, while the cannula for the descending aorta is introduced via the arterial duct. Flow to both cannulas is provided by a Y-connector. The selected cannulas have a size not exceeding 8F, which is advantageous even in the case of a very small aorta (■ Fig. 21.11a).

Alternatively, the ascending aorta/right carotid artery/brachiocephalic trunk can be perfused via a PTFE tube anastomosed in an end-to-side fashion. Routine use of a single ascending aortic cannula has also been described (Vouhé et al. 1990).

As said before, cannulation of the proximal aorta can be performed also indirectly using a polytetrafluoroethylene prosthesis sewn E-S to the brachiocephalic trunk. For direct cannulation, it is important to choose the right-sided aspect of the ascending aorta in order to facilitate the aorto-aortic anastomosis, which ideally will be just opposite to the place of cannulation. These cannulations can be used as the only

source for reperfusion and the rewarming process after repair.

We perfuse the distal aorta usually with a direct cannulation of the duct. Alternatively the cannulation can be installed in a large pulmonary artery, closing off both branches of the pulmonary artery with tourniquets when starting extracorporeal circulation. This, however, carries a risk of developing acute pulmonary valve insufficiency on bypass.

In preparing direct cannulation of the ductus, a tourniquet is placed around the ductus. The cannula can be inserted through an oblique incision at the pulmonary end of the ductus. It is then pushed in direction to the descending aorta and fixed with the tourniquet, thereby closing the ductus. The transection of the ductus is performed conveniently during the cooling period, and the pulmonary stump is oversewn. Now the descending aorta is more easily accessible. If direct cannulation of the ductus is chosen, the venous cannula should be inserted before, to be immediately able to commence extracorporeal circulation.

If not done already before going on extracorporeal circulation, complete mobilization of the aorta and the supra-aortic branches should be carried out during the cooling period, as described for complex coarctation before. A right-sided lusorian artery may have to be transected sometimes but not necessarily; it can be used also as a «reverse subclavian flap» (s.a. surgery of an isolated coarctation) for an aortic arch repair. In our experience, we never needed to transect a left-sided subclavian artery during a correction of an IAA type B but is advocated generously by others to facilitate performance of the anastomosis. Under no circumstances, both the left-sided subclavian artery and a right-sided lusorian artery should be transected, or at least one has to be reimplanted. After mobilization out of the retroesophageal bed, a transected right-sided lusorian artery can be anastomosed orthotopically E-S to the right carotid artery, thereby creating a brachiocephalic trunk.

After the cooling period is completed, the supra-aortic branches are occluded with tourniquets while deep hypothermic circulatory arrest is initiated and all cannulas are removed.

After complete resection of all ductal tissue visible, the circumference of the distal aorta is adjusted. The distal ascending aorta will be incised on its left dorsolateral side if necessary including the left carotid artery (type B). Placing and managing the incision line in an empty vessel can be difficult. Beware of cutting through the vessel while

intending to only incise it. The purse-string sutures of the cannulation site or additional sutures placed at the aortic wall during the cooling period can be helpful for orientation to perform a correct anastomosis free of torsion. Both the aortic ends are approximated after setting the initial stitches of a continuous suture using a slowly resorbable material (polydioxanone 7/0). Alternatively, both edges of the vessel can be fixed first followed by sewing the backside from the inside also (■ Fig. 21.11b, c).

A multicenter Congenital Heart Surgeons' Society study (McCrinkle et al. 2005) investigated the potential technical causes of a recurrent obstruction of the aortic arch in the context of the arch reconstruction in 472 patients. A partial direct anastomosis complemented by a patch plasty was reported as the optimal therapy. Using a polytetrafluoroethylene patch was identified as an isolated risk factor for later obstruction, and they advise to use autologous pericardium or a homograft as an ideal patch material. In view of the heterogeneity of the participants and the few definite anatomic details of type and location of the restenosis described, the results should be applied with caution.

In earlier times, when mobilization of the aorta and the supra-aortic branches was not extensively performed, different techniques to accomplish aortic continuity were suggested. For example, the duct was preserved (when persisting in older infants) or the left, distally detached carotid artery was turned down to form a new arch (Monro et al. 1989).

Long-term results of the historical series were deemed acceptable, and it was concluded that these techniques may eventually be also used (Monro et al. 1996).

The interposition of a prosthesis between the ascending and descending aorta can be done without extended mobilization but will inevitably require an even more complicated reoperation in these originally very small patients.

As a technical variation of a direct anastomosis, a side-to-side anastomosis between the left carotid and the left subclavian artery may be performed (in case of a type B). To obtain a wider communication, the incision should be extended about 5–6 mm cranial. Although described in his textbook, Castaneda's group didn't see any need to ever perform it (Castaneda et al. 1994).

After closing the ventricular septal defect and if necessary, an additional communication at the atrial level the cannula is reinserted in the ascending aorta, which is now sufficient enough for the complete circulation. The various techniques of closing a ventric-

ular septal defect are described in detail in ► Chapter «Ventricular Septal Defects», Sect. 14.4. Here, the relevant characteristics of the posterior malalignment ventricular septal defect and the associated subaortic stenosis will be addressed more closely.

There are four routes to access the typical posterior malalignment VSD in IAA. Certain authors exclusively describe a right transventricular (Castaneda et al. 1994; Vouhé et al. 1990), a right transatrial (Bove et al. 1993; Serraf et al. 1996), a transaortic, or a transpulmonary (Luciani et al. 1996) approach. We think it is important to be able to employ all four approaches as in the individual case it may be necessary to simultaneously use different routes for different parts of an otherwise difficult accessible VSD.

The decision to surgically address the subaortic region is critical. A significantly deviated septum can be clearly identified by preoperative echocardiography. However, there may be no subaortic pressure gradient preoperatively. Even immediately after correction, the flow conditions of the left outflow tract may appear regular, while after 1–2 months, certainly in between the first years, a stenosis may develop in these cases (Apfel et al. 1998). Data to support clear decision-making at primary surgery do not exist. Some preoperative echo studies try to predict development of a left ventricular outflow tract obstruction by measurements of the original anatomy in absence of a preexisting gradient. Suggested data indicating the need for surgical therapy are an absolute subaortic diameter of less than 3.5 mm and a subaortic area of $<0.7 \text{ cm}^2/\text{m}^2$ (Apfel et al. 1998) as well as a diameter of the aortic valve anulus of $<4.5 \text{ mm}$ (Salem et al. 2000).

As shown by a Congenital Heart Surgeons' Society multicenter study (Jonas et al. 1994), a primary subaortic muscle resection is connected with higher mortality. As in other multicenter studies before, a clear cause relation was not communicated. Postoperative subaortic stenosis is reported to occur in 26–57% of most studies (Geva et al. 1993). Therefore, the decision to perform a primary subaortic muscle resection is left with the individual surgeon operating on an individual patient, and it should include prognostic aspects also.

This thought process is also important when treating coarctation/VSD with the VSD being of the posterior malalignment type (Kreutzer and Van Praagh 2000). Should the malalignment be definitively identified, simultaneous intra- and extracardiac repair should be preferred over pulmonary artery banding and coarctation repair, as the

increased RV pressure after banding can accentuate the subaortic obstruction and result in cardiac failure.

In IAA, the majority of authors recommend a resection. The former group from Marie-Lannelongue (Serraf et al. 1996), as well as Vaughn Starnes' group (Salem et al. 2000), claims that with their special suture technique they are able to pull the subaortic septum from the left into the right ventricle. We doubt the effectiveness of this approach and deem the additional resection to be the most important part of the surgical treatment. For example, a short, thick septum cannot just be pulled over. We are not alone with this opinion (Jonas 2004).

The resection of the conus septum can be performed via different approaches as mentioned above. It is extremely important to visualize the defect, especially in the region of the aortic anulus to avoid any injury of the aortic valve in spite of a necessary resection close to the anulus. In an ideal manner, the resection should be performed right up to the anulus in a way that a suture of the septal patch can catch the rest of the muscle and the anulus. Using a small hook or a deep-rooted suture to pull the conal septum, a better exposure of the narrowing muscle for save resection can be achieved. In that case we perform usually an oblique infundibulotomy to inspect the subaortic area, and occasionally we inspect through the aortic valve as well if doubt about the quality and quantity of resection or potential damage exists. A sufficient and reliable transaortic resection is not possible and not advisable. The usually small aortic anulus in addition to a frequently present bicuspid valve limits exposure and increases the risk of damage to the valve during resection, while inspection may be helpful in decision-making.

In IAA/VSD with multistage hypoplasia of the left ventricular outflow tract, it is expedient to apply the surgical principle as suggested by Yasui (Yasui et al. 1987) and Ilbawi (Ilbawi et al. 1988). The blood flow of the left ventricle is guided through the ventricular septal defect into the pulmonary artery, and an end-to-side anastomosis between the proximal pulmonary artery and the ascending aorta *respectively* the concavity of the aortic arch *is* performed. An additional conduit connects the right ventricle with the pulmonary artery. We call this variation also «Norwood-Rastelli» procedure, knowing that the «Rastelli» is inverse (Steger et al. 1998). The technical possibilities/options for an aortopulmonary connection are wide and manifold. Some groups perform a Norwood-like construction using the classical or modified Damus-Kaye-Stansel anastomosis

(McElhinney et al. 1997) or the modification by Lamberti (Lamberti et al. 1991).

The Ross-Konno operation is an alternative to the Norwood-Rastelli procedure when lack of retrosternal space becomes an issue – an advantage particularly in neonates. How the long-term fate of the autograft in aortic position is comparable or inferior to the Norwood/Damus-Kaye-Stansel anastomosis remains open for discussion. Still in discussion is also the choice between a staged approach for these patients versus a primary repair. High-volume Norwood centers seem to prefer a temporary single-ventricle circulation like a classical Norwood procedure followed by secondary repair (inverse Rastelli part) within 1 year. In order to avoid any interstage mortality, we prefer primary repair.

■ ■ Complications

In case of a relapse, the subaortic stenosis is associated with higher mortality. Further complications worth mentioning are a restenosis in the region of the aortic arch and the airway compression. In the Toronto Sick Children's Hospital experience, greatest survival occurred in those patients with uncomplicated IAA who had repair since 1993 (5-year survival, 83%). Freedom from reintervention for arch obstruction was 60% at 5 years (Oosterhof et al. 2004).

The restenosis rate is up to 20–50 % in the most published studies. We have to differentiate between at least two types of restenosis: a stenosis localized to the anastomosis region may be treated sufficient by a balloon dilatation. A diffuse tubular stenosis requires an operative procedure. A patch plasty during circulatory arrest should be performed. In adolescents and adults, an extra-anatomic bypass between ascending and descending aorta can be a successful and permanently sufficient alternative, as described by us for complex or recurrent coarctation (Heinemann et al. 1997).

21.2.1.3 Segmental Hypoplasia of the Aorta («Midaortic Syndrome»)

As far as morphology and etiology are concerned, segmental hypoplasia of the aorta is a rather heterogeneous disease. It is based on a focal and diffuse hypoplasia of the descending aorta distal to the isthmus.

Most often only the abdominal aorta is affected in this syndrome, and therefore it is mainly described in textbooks of vascular surgery. Its presence, although very rare, as hypoplasia or stenosis of the thoracic or thoracoabdominal aorta caused the discussion in this chapter.

Different from other aortic lesions in pediatric cardiac surgery, being mainly congenital defects with a clearly explanation of embryologic genesis, the «midaortic syndromes» are addressed also as being acquired (Takayasu arteritis) as a secondary result of systemic diseases like neurofibromatosis or Williams-Beuren syndrome (Connolly et al. 2002). Arnot and Louw (1973) assume a missing fusion of the bilateral dorsal arteries in the segments affected. Because of the almost regularly observed anomalies of the renal arteries in the abdominal form (stenosis, multiple arteries) other authors think of a renal developmental disorder causing this syndrome. Given the different gender distribution of the Takayasu arteriitis and the noninflammatory related hypoplasia, a clear distinction from the inflammatory arteriitis is seen (Eibenberger et al. 1993). The segmental postisthmal hypoplasia caused renovascular hypertonus analog the typical ISTA, but it is rarely accompanied by congenital heart disease. Mesenteric ischemia is also observed only in rare cases. The histological examinations predominantly show dysplastic changes of the media, intima, and especially along the lamina elastica interna.

As a rule the disease is diagnosed after some years, mostly around the 20th year of life although the disease is also watched in infants. Our youngest patient requiring thoracoabdominal aortic surgery was 3 years old, after previous catheter interventions.

If only the distal descending aorta is involved only, a simple aorto-aortic prosthesis may bypass the affected segment via a lateral thoracic or thoracoabdominal access. More complex revascularizations may be necessary in cases of renal and visceral artery stenosis. The latter are usually compensated for by a natural Riolan anastomosis.

A reconstruction using the saphenous vein or a plastic/artificial prosthesis has been failed in children. In the largest published study so far, an autotransplantation or the use of the iliac artery as graft material for the diffuse stenosed renal artery is recommended (Stanley et al. 2006). In our experience also a reimplantation, at least of the left renal artery, direct into an aorto-aortic bypass is a possible alternative.

21.2.1.4 Cervical Aortic Arch

This malformation is an aortic arch that developed from the third instead of the fourth branchial artery. It also can be looked at as a persistence of the third arch with involution of the fourth arch. As an isolated defect, it may not cause any symptoms except

a pulsation felt at the base of the neck. This anomaly is described on the right as well as on the left side. However, it is more often associated with short-path stenosis, similar to coarctation, tubular hypoplasia, or tortuosity, which may require an adequate therapy. In view of the rarity and the morphological diversity of the obstructed cervical aortic arch, there is not really a kind of standard therapy. In neonates an E-S anastomosis of the descending aorta to the ascending aorta should be performed. Establishing the anastomosis in the distal ascending aorta will not compromise the main bronchus of the same side as the arch. In elderly patients, a patch plasty similar to a Vosschulte plasty (McElhinney et al. 2000) or an extra-anatomic (prosthetic) bypass (Walker et al. 2002) is recommended.

An aneurysmatic dilation of the cervical arch has been described in some case reports. In cervical arches, this complication seems to occur much earlier than in normal arches. Most cases were reported in patients at an age between 30 and 40 years (Mitsumori et al. 2008). A primary structural wall abnormality of the embryologic third aortic arch may be causing this (McElhinney et al. 2000). Additionally, cervical arches can be part of a complete or incomplete vascular ring, requiring treatment as described below.

21.2.1.5 Persistence of the Fifth Arterial Arch (Fifth Aortic Arch or Double-Lumen Aortic Arch)

This anatomic variant shows again the complexity of the embryological development of the great intrathoracic vessels. In the classic way, a persistent fifth arch runs parallel and above the normal left aortic arch. The fifth arch does not carry side branches. As it may just lead to a double-lumen aortic arch, it is in itself asymptomatic.

The origin of the additional fifth aortic arch is at the distal ascending aorta, respectively, at the proximal concavity of the aortic arch opposite to the brachiocephalic trunk. The distal connection is in the region of the aortic isthmus (Van Praagh and Van Praagh 1969). Besides the original form reported by the VanPraaghs, other variations are described associated with malformations of the pulmonary artery or the «normal» aortic arch. Related to the function of the malformed vascular structure, different forms exist as systemic-systemic, systemic-pulmonary, pulmonary-systemic, and mixed forms. As a *systemic to systemic variant*, the fifth arch can be a second or the only arch connecting the ascending and

descending aorta. A systemic-pulmonary form provides ductus-like flow to the pulmonary artery, while a pulmonary to systemic form may be a source for at least part of systemic flow. In a significant number of reported cases, the normal aorta, developing from the fourth pharyngeal artery, shows a coarctation, a hypoplasia of the isthmus, or an interruption. In that case the parallel running, abnormal arch is important in compensating the perfusion like a collateral vessel. Also, both the distal end of the fifth arch and the normal isthmus can obtain ductal tissue causing hemodynamically relevant coarctation (Atsumi et al. 2001). In the latter case, a correction as in case of a classical coarctation is required. If necessary, a hypoplasia of the aortic arch may be repaired with/by a longitudinal incision following by an S-S anastomosis of both arches (Lambert et al. 1999).

A persistent fifth aortic arch as a *systemic-pulmonary* connection has been reported in association with pulmonary atresia or interrupted pulmonary arteries. The «ductus-dependent» perfusion of the lung is confirmed by a morphology persistent fifth aortic arch. This anomaly is mistakenly named, preoperatively as well as intraoperatively, an atypical ductus arteriosus. Actually the fifth aortic arch doesn't own a connection to the aortic isthmus in contrast to the ductus arteriosus. This is relevant in the preoperative treatment, as this «atypical» ductus does not require prostaglandin to maintain patency. Nevertheless, cases with a prostaglandin-dependent systemic-pulmonary fifth arch connection have been reported (Zartner et al. 2000). In one case, a pulmonary coarctation could be verified histologically (Khan and Nihill 2006).

The third variation, a pulmonary-systemic connection, is the rarest form. It is seen with an interrupted aortic arch associated with aortic atresia. The persistent fifth aortic arch between the pulmonary artery and the brachiocephalic trunk supplies the ascending aorta with the coronary arteries as well as the proximal normal aortic arch. In such cases there exists a typical arterial duct simultaneously which guarantees the perfusion of the descending aorta as in any interrupted arch. There are two additionally known sources for coronary blood supply in IAA/aortic atresia with a persistent fifth arch. A second form is described as a pulmonary aortic fistula that runs between the pulmonary artery and the aortic root on the level of the sinus of Valsalva (Donofrio et al. 1995). The third variation is a cycle of Willis-dependent

retrograde collateral perfusion without any additional vascular structure (Tannous et al. 2006).

Neither pulmonary atresia nor aortic atresia/IAA requires special technical features in comparison with the typical ductus-dependent circulation. Regarding construction of an aortic arch, it could be an intriguing choice to include the cut open fifth arch as an autologous tissue patch to obtain potential growth for the reconstructed new aortic arch. But given the rareness of the disease and the uncertainty of the actual growth potential, a Norwood variant should be the accepted traditional and familiar treatment of choice.

21.2.2 Aortic Anomalies Causing Compression of Neighboring Structures

21.2.2.1 Foreword

At first sight vascular anomalies causing compression of neighboring structures do not appear to be simply categorized because of their diversity. Berdon is responsible for naming them «Vascular rings, slings, and things» (Berdon and Baker 1972). The expression, which substantiated the difficult issue of a summary, is later on used as a title of a chapter of the pediatric cardiology textbook by Bob Freedom (Moes and Freedom 1992). A comprehensive embryologically based classification was published by Jesse Edwards 1948, Edwards 1953.

The development of the aortic arch and its branches from two dorsal and two ventral parts and their interconnecting pharyngeal arches/arteries is substantiated by embryology. The classification suggested by anatomists and embryologists is intellectually perfectly able to grasp, but they have only isolated clinical relevance because of their numerous possibilities. A definite simplified classification serving >95% of the clinically described variations was proposed within the Congenital Heart Surgery Nomenclature and Database Project in 2000 (Backer and Mavroudis 2000):

- Double aortic arch
- Right-sided aortic arch/left-sided arterial ligament
- Aberrant origin of the right-sided brachiocephalic trunk/innominate artery causing tracheal stenosis

The common objective of these anomalies is the compression of the neighboring structures

such as the trachea and esophagus causing shortness of breath and sometimes difficulties in swallowing. In infancy with predominantly liquid food as mother's milk and a rather soft trachea, their most common symptoms are respiratory in origin. With increasing age, the difficulties in swallowing/dysphagia come forward with the introduction of solid food causing more pronounced dysphagia, especially because the relative narrowings of the vascular structures increase with the growth.

The typical symptom is an inspiratory stridor at rest accentuated at exertion; but a global respiratory insufficiency with dependence on mechanical ventilation may be possible as early as immediately postpartum. The difficulty in swallowing solid food is the typical symptom in adulthood. However, patients who never experienced normal swallowing before, may not be able to report their objective dysphagia.

The greatest challenge in diagnosing vascular anomalies is to think of them in the differential diagnosis of the relative heterogeneous symptoms often and much more frequently caused by other diseases. Modern imaging tools (CT/NMR) improve the accuracy of localizing defects. The timely and up-to-date implementation of surgery brings about immediate regression and abolishment of symptoms in most patients with excellent long-term results.

The variations in the course of the thoracic aorta do not necessarily cause symptoms. Contrary to other congenital heart diseases, anomalies of intrathoracic great vessels are only operated upon when clinical symptoms are present. However, there are two exceptions:

- An asymptomatic vascular anomaly associated with intracardiac defects requiring surgery anyways
- An asymptomatic complete double aortic arch as it will become symptomatic with age and growth but surgery is much easier in neonates and infants

A new clinical challenge is the increasing number of asymptomatic vascular rings being diagnosed already during fetal life (Mehmet Gulecyuz, pers. communication).

21.2.2.2 History of Surgery for Vascular Ring Formations

The first successful division of a double aortic arch was performed by Robert Gross on June 9, 1945 using the term vascular ring in the publica-

On 6-9-45, in his third of four Patients to operate upon, he divided "...ligamentum arteriosum Division of medial root of left subclavian artery». (Courtesy Dr. Robert and Carol Replogle)

tion (Gross 1945b). It had been case three of the day, preceded by an appendectomy, a right herniorrhaphy, and followed by a pyloromyotomy (■ Fig. 21.12). The forms/findings of aortic arch anomalies causing this problem and their individual treatment have been well delineated by his group early on (Gross and Ware 1946; Gross and Neuhauser 1951). The radical resection of the encircling vascular and fibrotic structures was recommended by Hallmann and Cooley 1966 (Hallmann et al. 1966). The importance of the Kommerell diverticulum (Kommerell 1936) as an independent cause for recurrent symptoms was recognized by different working groups over the years (Backer et al. 2002) and addressed now for primary surgery. This has been practiced by us for more than 25 years now.

The first sizeable study of video-assisted thoracoscopic repair of vascular ring anomaly was published by Redmond Burke and his working group in 1995, at that time still in Boston (Burke et al. 1995). Between 2002 and 2004, the first six vascular rings were operated upon employing a totally endoscopic robotic-assisted approach by Pedro del Nido's group, also in Boston (Suematsu et al. 2005). These approaches, however, do not meet the abovementioned principles of radical resection.

21.2.2.3 Aim of Surgery for Vascular Rings

The basic aim of surgery is definite relief of external compression to the trachea and esophagus. This should be achieved with most extensive resection of the compressing structures, especially by «cleaning» the retroesophageal space (Hallmann et al.

1966). In our view, with the exception of an aberrant brachiocephalic trunk, for all compressing thoracic vascular anomalies, the approach, a lateral thoracotomy, should always be performed on the side of the descending aorta. The argument in favor of such an approach is to obtain safe intraoperative control of the structures to be cut, especially of the descending aorta. A complete resection starts at the descending aorta and extends beyond the esophagus on the other side if not limited by specific anatomic structures/details we are not aware of.

The key is to achieve effective control of the most sensitive/critical structure – the descending aorta – which is of course more accessible on the side of the descending aorta.

The resection of a patent vascular segment can be carried out by side bite clamping or under certain circumstances in cross-clamping of the descending aorta above and below the structure to be resected. To perform a continuous running suture to close the resected structure, flush to the aorta should take only a few minutes, and for that there is no need for further protective measures like including a left heart assist.

It has to be mentioned that Carl Backer and Constantine Mavroudis perform a division of any vascular ring irrespective of the side of the descending aorta via a left-sided posterior thoracotomy, following the same radical principles for resection as we do. They claim no safety issues and in addition the advantage of reimplantation of the divided ipsilateral subclavian artery.

The immediate intraoperative sign of effectively having taken care of the symptomatic vascular ring is the significant retraction of the divided ring structures. Retraction is facilitated by preceding careful circumferential dissection of these structures. If retraction does not occur, any residual, peri-esophageal, soft, and tissue-related finest structures/fibrotic bands have to be cut or divided as well, even if seemingly harmless. This should avoid the development of adhesive scarring from previous distortions followed by recurrences. The remaining vascular stumps (lusorian artery, ligamentum arteriosum, hypoplastic aortic arch) will be placed permanently beyond the esophagus if it doesn't happen on its own right after ring division with or without additional dissection. Vascular rings are associated

only rarely with a primary structural tracheal stenosis caused by hypoplasia in contrast to a pulmonary (artery) sling. A certain degree of tracheomalacia can be the reason for a residual stridor in infants in the first postoperative month and in most cases does not require additional surgery.

21.2.2.4 Double Aortic Arch/Complete Vascular Ring

There is a broad diversity of known and hypothetical anatomic varieties/variations (Stewart et al. 1964) (■ Fig. 21.13). For all of them, the following anatomic and hemodynamic factors have to be taken into consideration when planning and actually performing surgery:

- Position of the descending aorta, especially in relation to the esophagus
- Position of the dominant aortic arch
- Possibility of transection of currently patent vascular structures

The sidedness of the descending aorta is sometimes difficult to define despite diagnostic imaging; this may be especially true in case of a midline aorta. The relation of the aorta to the esophagus is important because the access to the aorta can be challenging when the esophagus has to be passed. Imaging with a gastric tube in place can be very helpful.

The proportions of size between the anterior and posterior parts of the arches vary. While the double aortic arch may consist of two equally and well developed arches, the co-dominant form of double aortic arch, commonly there is a dominant right aortic arch with a hypoplastic left arch, which may be even atretic in part.

In the nondominant arch, an atretic segment can be seen at any length and location. Similar to the site of interruption in interrupted aortic arch (Celoria-Patton classification), the location of interruption/atresia defines a subtype. Most often atresia is seen in a distal segment of the aortic arch, the aortic isthmus, or immediately distal to it (■ Fig. 21.14a and Fig. 21.15). An atresia of the proximal arch segment corresponding to an IAA type C is absolutely rare and was clinically not seen by us in 30 years. See also «retroesophageal left aberrant innominate artery» under section «**Incomplete Vascular Ring**» «less common findings of a vascular ring».

In case of a double aortic arch, the nondominant part should be divided. If present, an atretic segment is the obvious choice of arch/ring division. The proximal descending aorta can be located left or right,

■ Fig. 21.13 Primitive aortic arch, the dashed lines indicate all possible interruptions

there is no side preference reported by date, and accessibility is dictated by the arch to be transected.

Surgery of a balanced (co-dominant) double aortic arch follows the above mentioned principles especially with the aim of careful retroesophageal dissection and resection/«cleaning». Prior to actual division, the strength of the right and left carotid and radial pulses should be evaluated with the vascular clamps applied. In the absence of any changes in proximal and distal blood pressure and pulse curves, even the bigger of the two aortic arches can be divided. To divide the bigger of two arches in double aortic arch may be thought of, if the bigger arch is the one with a retroesophageal course. Precise documentation is required.

In case of a dominant aortic arch with retroesophageal course, a simple transection of the anterior hypoplastic ring segment may not be sufficient to relieve all, but it may diminish some clinical symptoms. With persistent significant symptoms, complex surgery may be necessary as described for extremely rare cases as an anterior dislocation of the aortic arch in infants (Planche and Lacour-Gayet 1984). As an alternative in adolescents and adults, an «extra-anatomic» bypass between the ascending and descending aorta may be performed after division of the arch as a conceivable procedure.

■ **Fig. 21.14** a, b Double aortic arch. The most common form of double aortic arch: right-sided aortic arch with a hypoplastic left arch. The hypoplastic arch can become extremely hypoplastic or even atretic either between the supra-aortic vessels or distal to them a. ■ **Fig. 21.15** The most common double aortic arch has a dominant right-sided arch with a hypoplastic or atretic left-sided arch. The ligamentum arteriosum contributing to the tracheo-esophageal compression should be cut, and the hypoplastic left-sided aortic arch as well as the aortic diverticulum has to be resected. Back view corresponding to Fig. 21.14a

21.2.2.5 Incomplete Vascular Ring

■ ■ Right-sided aortic arch with left sided Ductus Botalli/Lig. Arteriosum

The right-sided aortic arch is curving to the right of the trachea. There are three theoretical possible varieties, two of which may create a vascular ring. The fundamental structure is always the retroesophageal vascular structure or its remnant (arterial duct vs. arterial ligament).

The first variety as the mostly seen pathoanatomic form (65 %) is the combination of an aberrant left subclavian artery (A. lusoria/lusorian artery) and an arterial duct located between the left pulmonary artery and aortic isthmus. A short aortic segment is addressed here indeed as the isthmus from which the left subclavian artery and the duct arise (■ Fig. 21.16).

Both structures can arise separately from the aorta or jointly from a Kommerell diverticulum (see also ► Sect. 21.2.2.6, «Kommerell Diverticulum»). The existence of a Kommerell diverticulum is not obligatory for this kind of symptomatic vascular ring.

The arrangement of the second variety (35 %) is the mirror image of the normal left aortic arch with a retroesophageal duct resp. ligamentum arteriosum. The left subclavian artery runs regularly to the left of the trachea coming off a left-sided brachiocephalic trunk.

The third variety also with a mirror image branching does not create a vascular ring, as the ductus originates from the left subclavian artery directly. This form occurs sporadically (2 %) and is associated with a tetralogy of Fallot up to 25 % without causing any vascular ring type symptoms.

21.2.2.6 Kommerell Diverticulum

The Kommerell diverticulum is named after B. Kommerell, staff radiologist at Charité Hospital, Berlin, Germany, in the 1930s (Kommerell 1936). It is a remnant of the dorsal right or left root of the aortic arch as a pendant to the contralateral existing complete aortic arch (■ Fig. 21.16). This structure, like when first described, is not referring to a certain kind of vascular ring but can occur, not obligatory, in a number of anomalies. The diverticulum is an aorta-sized outpouching of the descending aorta ending anteriorly in a nondominant/atretic aortic arch or in an arterial duct and lusorian artery. It was originally described in a patient with a left-sided aortic arch and retroesophageal located right sub-

clavian artery. Presence or absence of a ligamentum arteriosum or a vascular ring formation was not described. The author pointed out that there is no obligatory diverticulum with any lusorian artery. Most frequently the lusorian artery is described as a left lusorian artery associated with a vascular ring of a right-sided aortic arch and left-sided ductus arteriosus. In the original report, the relation of a potential duct, the subclavian artery, and the Kommerell diverticulum is not reported (Kommerell 1936). The diverticulum can cause obstruction as part of a vascular ring or probably only because of its volume as suggested in the original work by Kommerell. This is confirmed by the fact that a Kommerell diverticulum is a frequent cause of a symptomatic recurrence or persistence of symptoms following surgery of division of a vascular ring without resection of the diverticulum. Therefore it is expedient to perform the resection of the diverticulum following the radical principles even during the primary surgery (Backer et al. 2002).

An increasing number of case reports describe an aneurysmatic dilatation of an originally asymptomatic diverticulum occasionally leading to aortic dissection (Fisher et al. 2005; Naoum et al. 2008; Idrees et al. 2014). In pathohistological examinations of resected diverticula as part of vascular rings, degenerated media was observed in the wall, which can explain these complications (Backer et al. 2005). For this reason, also, it is highly recommended to resect a diverticulum during primary surgery of any vascular ring if present.

There are no definitive guidelines for treatment of asymptomatic aneurysmatic dilatation. Progression should be documented by imaging (CT, NMR). In younger and active patients, a local resection is recommended if necessary in combination with or without revascularization of the lusorian artery. Revascularization may be performed as a supraclavicular carotid-subclavian bypass or a reimplantation of the subclavian artery into the carotid artery on the same side. In elderly patients or additional comorbidities, an endovascular procedure is preferred, incorporating features as coiling of the subclavian artery and stenting of the descending aorta or the revascularization of the lusorian artery in subject to the clinical conditions. A primary surgical revascularization, which normally includes closure of the subclavian/lusorian artery proximal to the vertebral artery, eliminates the need of coiling in case of an intended endovascular treatment of the

■ **Fig. 21.16** a, b View of a Kommerell diverticulum with a right-sided aortic arch and left lusorian artery. View from ventral **a** and view from dorsal **b**

diverticulum. Transthoracic surgery for the diverticulum may be also preceded by subclavian artery revascularization. We primarily revascularize only in elderly patients.

21.2.2.7 Less Common Findings of a Vascular Ring

The diversity of these findings published mostly as a pathological case report or as an isolated clinical case (Moes and Freedom 1993; Ziemer et al. 1983) is quite understandable given the complex embryologic development. As these forms account for only about 1% of the clinical cases with vascular ring malformation, they can't be focused on individually. Their common feature is an unusual branching of the duct (right sided or doubled) or an uncommon site of interruption, leading to interesting made-up nomenclature like: «retroesophageal left aberrant innominate artery» (Moes et al. 1996). The above-discussed

diagnostic and technical principles should continue to be applied.

21.2.2.8 Compression Caused by an Aberrant Origin of the Brachiocephalic Trunk/Innominate Artery

This anomaly is caused by an atypical distal take-off of the innominate artery. It does not form a vascular ring. The artery leaves the arch distally posteriorly. Coming from the left, it takes a course ventral to the right around the trachea and heading into a posterior direction. This at times causes a compression of the trachea. The ventral indentation of the trachea seen by bronchoscopy is pathognomonic for this anomaly; no other vascular anomaly causes an isolated indent like that (■ Fig. 21.17a).

■ Fig. 21.17 a–c Aberrant brachiocephalic trunk/innominate artery. a, b Anterior translocation. c Anterior aortotruncopexy

This anomaly is mainly seen in infants and causes a typical stridor. Even episodes of short apnea are described.

For minor stridor symptoms, the treatment is mostly conservative because with the development of the cartilaginous rings during the second and third year of life symptoms diminish or may even disappear completely. This may be also due to the changing size relation of the structures with growth. A symptomatic, significant tracheal stenosis (70–80%) or apneic spells during infancy and early childhood should be an indication for surgical treatment.

An established therapy is the classical ventral truncopexy – tacking the innominate artery to the sternum (■ Fig. 21.17c) (Gross and Neuhauser 1948) – or, as a complex and more risky alternative, the resection followed by a proximal reimplantation of the innominate artery into the proximal aortic arch or the distal ascending aorta (Hawkins et al. 1992). Transsternal resection and proximal reimplantation is our method of choice to treat the symptomatic aberrant origin of the brachiocephalic trunk (■ Fig. 21.17b). We always employ extracorporeal circulation and mild hypothermia for this procedure. During the procedure, NIRS is used to monitor brain perfusion.

The original surgical approach described by Gross is the left thoracotomy (Gross and Neuhauser 1948), but several approaches are possible. Other authors prefer a right anterolateral thoracotomy with a submammary incision line (Mavroudis and Backer 2003). We perform a median partial upper sternotomy for this procedure. The argument in favor of such access is the safe anchoring of the transsternal sutures performing the pexy. The narrowed operation field achieved by a lateral thoracotomy seems to make it awkward and insecure in our mind.

When we do on parents' request a pexy rather than a translocation, we use three U-figured sutures augmented with patches of 3.0 or 4.0. Instead of a mere truncopexy, we perform an aortotruncopexy (■ Fig. 21.17c): we place the first suture subadventially at the distal ascending aorta, the second at the base of the innominate artery, and the third at the distal trunk just above the innominate vein. The sutures are fed transsternally through the right part of the sternum and tightened fast after the removal of the retractor. With that the pulse oximeter measurement applied at the right arm should be unchanged, and the bronchoscopy which should be performed obligatory

should show an extension of the tracheal lumen, ideally with disappearance of the pulsations.

21.3 Anomalies of the Pulmonary Artery

21.3.1 Obstructive Anomaly of the Pulmonary Artery: Coarctatio Pulmonalis/Pulmonary Artery Coarctation

A proximal stenosis of the left pulmonary artery close to the arterial duct was already known in the 1950s, but a systematic pathoanatomical and pathophysiological summary was first published in 1990 by the group of Leyden (Elzenga and Gittenberger-de Groot 1986; Elzenga et al. 1990). The so-called coarctatio pulmonalis/coarctation of the pulmonary artery can be seen as a counterpart of the coarctatio aortae/coarctation of the aorta. It is frequently seen being associated with anomalies comprising right ventricular outflow obstruction (Luhmer and Ziemer 1993). A reversed flow direction in the prenatal arterial duct leads - analog to coarctation of the aorta - to a lariat/lasso, like loop of invaded contractile ductal tissue/cells in the pulmonary artery wall, which subsequently cause pulmonary artery coarctation. Contrary to coarctation of the aorta, coarctatio pulmonalis is not known as an isolated lesion. Its significance may only develop after correction or palliation of an intracardiac lesion, as at the time of surgery pulmonary coarctation was not present or being thought of. With an ideal early postoperative result of RVOT reconstruction and an unrestrictive pulmonary bifurcation for a couple of weeks after neonatal repair, suddenly occurring right ventricular strain can be caused by acute narrowing to almost closure of the proximal left pulmonary artery. If the postoperative obstruction caused by plastic remodeling of ductal tissue occurs more slowly, it may be hemodynamically tolerated and stay clinically silent for a long time. Then, however, it may have led to the persistence of hypoplastic capillaries of the affected side during the critical phase of postnatal pulmonary development. This delay in development may complicate future surgical reconstructions as a permanent increase of pulmonary vascular resistance has already occurred.

This is of special importance in univentricular circulations which may require Fontan-type surgery.

Severity of the ductal tissue causing left pulmonary artery stenosis correlates with the severity of the right ventricular outflow tract obstruction. That means that patients with pulmonary atresia (with or without a ventricular septal defect) reveal the most severe manifestations of pulmonary artery coarctation. In these patients, preoperative diagnostic procedure is often limited: in most cases, they require preoperative prostaglandin infusion relaxing the myoepithelial cells. Prostaglandin infusion in duct-dependent pulmonary circulation cannot be temporarily stopped under very close clinical and echocardiography surveillance to get information about the potential extent of pulmonary artery narrowing.

Therefore, neonatal repair of pulmonary atresia, which also includes a plastic reconstruction of the main pulmonary artery in most patients, should also routinely include arterioplasty of the origin of the left and/or right pulmonary artery (with right-sided or bilateral duct) as recommended by some authors (Castaneda et al. 1994; Kirklin and Barratt-Boyes 1993; Luhmer and Ziemer 1993).

For pulmonary atresia patients receiving a systemic-pulmonary shunt as the primary operation, the strategy is not clearly defined. In case of a limited narrowing, we recommend to address surgery with the aid of cardiopulmonary bypass and to perform a patch plasty of the pulmonary coarctation including installation of distal anastomosis of the central shunt in the patched area.

If the significance of a pulmonary coarctation cannot be certified by echocardiography, it is questionable to perform a prophylactic pulmonary arterioplasty. As many as 30% of cases with right ventricular outflow tract obstruction revealed pulmonary artery coarctation (Luhmer and Ziemer 1993). Patients after shunt surgery should be very carefully and aggressively followed by cardiology and cardiac surgery to recognize any changes in pulmonary perfusion in order to timely repair any developing stenosis to maintain and provide a sufficient and balanced pulmonary arterial development.

The issue of secondary pulmonary artery coarctation, occurring after neonatal surgery, is further discussed in ► Chapter «Congenital Heart Disease with Anomalies of the Right Ventricular Outflow Tract» Sect. 15.6.2.3; ■ Fig. 15.4; ■ Fig. 15.14».

In postoperative patients, differential diagnosis of an iatrogenic stenosis of the pulmonary

arteries should be discussed, as neonatal Blalock-Taussig shunts or central shunts involving the pulmonary artery branches can lead to secondary stenosis (Sachweh et al. 1998).

21.3.2 Pulmonary Artery Anomaly Causing/Being Associated with Compression/Hypoplasia of Neighboring Structures: Pulmonary Artery Sling

Pulmonary artery sling is an uncommon anomaly in which the left pulmonary artery takes its origin from the common, main pulmonary artery far distal to the right of the trachea, then running behind the trachea and in front of the esophagus to the left side (see ■ Fig. 21.18a). Characteristically, this anomaly causes an anterior dent of the esophagus. Contrary to vascular rings caused by abnormal courses and connections of the aorta, leading to problems with swallowing, this anomaly is more often associated with pathological modifications of the respiratory system. Sometimes there may be only a temporary tracheomalacia in neonates, which does not require surgical attention. More often, however, the respiratory symptoms in the presence of a pulmonary artery sling are caused by associated stenosis of the respiratory tract due to more or less hypoplastic and ring forming tracheal cartilages. As this has to be expected in about 50% of these patients, preoperative imaging of the respiratory tract is mandatory in all cases of pulmonary artery sling.

For a long time, a mechanical cause of the tracheal stenosis was assumed because the accompanying stenosis was mainly seen in the area of the left pulmonary artery crossing the trachea. The length of the stenosis/hypoplasia, however, can extend even far proximal, and hypoplastic complete ring cartilages can be present in the full length of the trachea. The ring cartilages can reach distal the carina also. The main bronchial system is mostly inconspicuous. The therapy of such an anomaly should not only include the correction of the pulmonary artery course but also address the narrowed airways. If necessary, the complete segment of the stenosed trachea should be resected.

Nowadays a median sternotomy is performed as access of choice, although the original operation described by Potts (Potts et al. 1954) was done through a left-sided thoracotomy.

■ Fig. 21.18 a, b Pulmonary artery sling before and after orthotopic reimplantation

Usually extracorporeal circulation is established. In case of an isolated pulmonary artery sling without intracardiac disease to be taken care of, the operation can be performed in normothermia and with the heart beating. With good venous drainage and an empty right heart, ventilation is not required which facilitates retroaortic and retrotracheal dissection and final translocation of the left pulmonary artery. Even without intrinsic tracheal pathology – i.e., only tracheomalacia – but also in case of pathological, but sufficiently wide complete tracheal rings, the proximal segment of the left pulmonary artery should be dissected and transected close to its origin. Thereafter orthotopic reimplantation into the normal position pretracheal and left anterolateral has to follow (■ Fig. 21.18b).

The origin of the *left pulmonary artery* is translocated and reanastomosed E-S far proximal into the main pulmonary artery in what one would consider an orthotopic position. Preferably the area of the former insertion of the ligamentum arteriosum/arterial duct is used. Potts in his original operation described the reanastomosis of the left pulmonary artery E-E into its origin on the right of the trachea, now, however, being in a pretracheal position. This technique resulted in an unacceptable high occlusion rate of the left pulmonary artery. After a period in the late 1980s, where orthotopic reimplantation had been already the preferred method to deal with the sling, there was a period where during the resection of the trachea only an ante-position ventral to the trachea was performed, leaving the origin of the left pulmonary artery untouched. This was thought to facilitate the complex tracheal and vascular surgery. When stenosis

and occlusion of the ante-posed vessels occurred, orthotopic reimplantation regained its popularity.

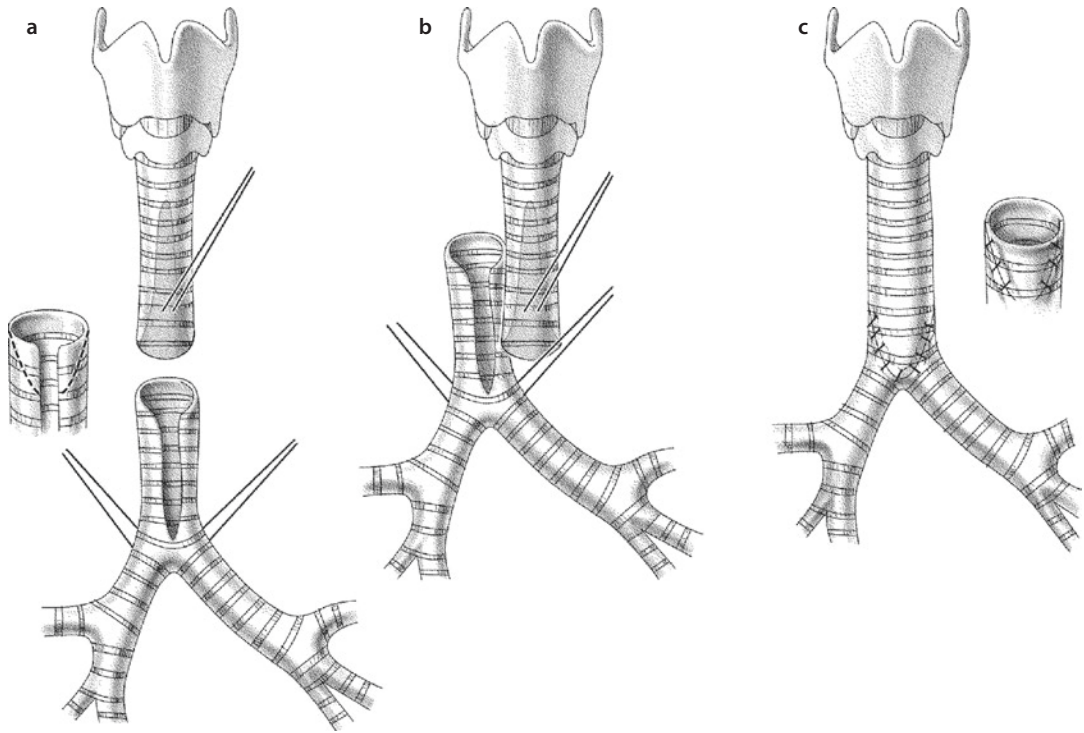

Tracheal surgery, at times involving the proximal right main bronchus, is indicated as a simultaneous procedure, adequate bronchoscopic and imaging findings provided. In planning and performing this part of surgery, some principles are notable:

- In contrast to adults, the trachea in children is much better vascularized, and therefore an extensive dissection of the trachea is possible without risking ischemic complications to the same extent.
- In infants the trachea can be resected in a length of up to eight to ten cartilages (or about half of the complete length) and still be anastomosed E-E after adequate mobilization.
- The region of anastomosis remains critical for restenosis caused by granulation tissue.
- An asymptomatic trachea albeit consisting completely of pathological ring cartilages does not require surgical treatment.

For tracheal surgery, the following techniques may be applied:

- Simple resection and E-E anastomosis
- Sliding plasty
- Insertion of a tracheal autograft
- Using autologous tissue (pericardium, costal cartilage) as an augmentation of the reconstructed trachea

As mentioned above, flexibility and good vascularization of the trachea in children allow for an

■ Fig. 21.19 a–c Sliding plasty of the trachea

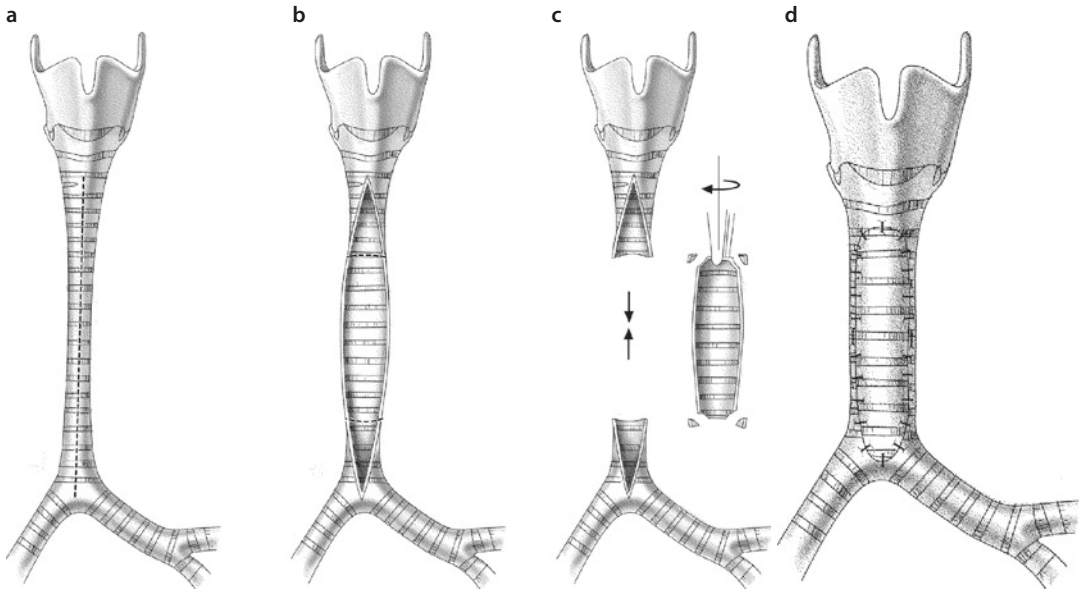

extended resection and end-to-end anastomosis. Because of the simple feasibility of the resection, it is our preferred technique, which allows a resection even up to 50% of tracheal length in case of hypoplasia. An extended mobilization of the trachea above and below the length of resection is required, and the procedure is carried out by inflection of the neck. In some cases, it was helpful for us to involve an ENT surgeon performing a laryngeal release. We perform the anastomosis with interrupted polydioxanone sutures. To facilitate a fast healing tendency and to reduce the creation of obstructive granulation tissue, some surgeons felt an advantage in using faster reabsorbing suture material such as Vicryl®. We seal the anastomosis with fibrin glue containing an aminoglycoside antibiotic. Although used by others, we so far did not employ any other tracheal anastomosis-protecting feature like a pedicled pericardial flap. We deem it appropriate to maintain the inflection of the neck up to 7 days after surgery. For that the preoperative customized production of a plaster frame is recommended as well as the application of sedation should be continued. Nevertheless an early extubation should be encouraged, i.e., at the morning of the first postoperative day. We are well aware that occa-

sional active extensions of the neck cannot be avoided; however, a temporary fixation of the chin at the chest – as sometimes performed in the adult thoracic surgery – is not indicated.

In cases of more extensive stenosis (more than 50% of the tracheal length), which prevents a «simple» resection, a sliding plasty can be performed (Beierlein and Elliot 2006). The stenotic segment of the trachea is cut obliquely in a very huge angle, almost longitudinally. Cutting the tips of both ends (being an equivalent of some central resection), the remaining sides are shifted and sutured longitudinally (■ Fig. 21.19). In those cases of an additionally preexisting stenosis of the right main bronchus, a sagittal incision starting at the upper surface of the right bronchus heading proximal to the left side of the trachea facilitates concomitant treatment of this problem (Jonas 2004).

The tracheal autograft technique described by Backer (Backer et al. 1998) uses the resected tracheal segment once longitudinally incised as an expanding patch anteriorly for a partial E-E anastomosis. This procedure effectively shortens the length of required resection (■ Fig. 21.20).

The rare form of a completely, in its entire length, hypoplastic and stenotic trachea may mandate an alternative technique like that

■ **Fig. 21.20** a–d Tracheal autograft technique: a segment resected out of the midst of the hypoplastic trachea is sewn as a ventral patch after performing the direct anastomosis of the posterior tracheal hemicircumference

described by Idriss. As such, this is an extended patch plasty using autologous pericardium reaching over the complete length of the trachea if necessary. This technique has a high rate of restenosis, and it requires postoperative trachea stabilizing ventilation for at least 2 weeks (Idriss et al. 1984). Good long-term results are reported on a small series of patients undergoing a similar procedure employing autologous costal cartilage as described by Forsen (Forsen et al. 2002).

21.4 Left to Right Shunt

21.4.1 Ductus Arteriosus Botalli

The ductus arteriosus Botalli, the arterial duct, is an essential part of normal fetal circulation. As a physiological shunt in prenatal life, it allows for about 90% of the right ventricular output (over 60% of the combined right and left ventricular output) to bypass the lungs, which are not inflated anyways. In the descending aorta, it combines with about 10% of the combined cardiac output coming from the aortic arch through the isthmus into the descending aorta. The intrauterine diameter of the ductus is comparable to the diameter of the descending aorta or the main pulmonary artery. Functional closure occurs soon after birth, usually between the first

and sixth day of life. This is followed by anatomical closure, an involution of the duct tissue that finally becomes the ligament arteriosum, a thin fibrotic structure between the aortic isthmus and the proximal left pulmonary artery in adults. A ductus not functionally closed by 3 months of age will most probably stay open as a persistent arterial duct.

Position (right/left), number (1–2), and size of the ductus can vary, especially in the aortic arch anomalies as discussed above. This is also true for conotruncal as well as obstructive cardiac defects. However, in most instances, the ductus is solitary and left sided, even in the case of a right aortic arch. It is not the intention of this chapter to discuss the particularities of the ductus arteriosus with regards to associated anomalies, but we note the absence of the duct in patients with a truncus arteriosus type A1–A2 as well in patients with an agenesis of the pulmonary valve. Histologically and functionally, the ductus arteriosus is a unique vascular structure. In prenatal life, histologically the vessel is a large-sized muscular artery with the media almost completely missing elasticity. The cells of the tunica muscularis are located circular with unique receptors, which react to postnatal changes (rising oxygen partial pressure, reduction of prostaglandin level in the blood). The muscle cells promote with their contraction the functional closure in 80% of the newborns mostly in the first 24 h postnatally.

Additionally, the intima of the ductus shows a very good developed gelatinous matrix, which seals the closing lumen during/at the muscle contraction. The final closure occurs within some weeks caused by apoptosis of the muscular cells and proliferation of fibrotic tissue. At first the closure is completed at the side of the pulmonary artery; an ampulla-like bulging remains on/at the aortic side for a few months and might lead to an aneurysm of the aorta in rare cases later in life.

The early phase of the closing process can be completely reversed by a postnatal infusion of prostaglandin I. On the other hand, the muscular cells in a ductus of a premature baby show a limited ability to react to oxygen, which is one reason for the high rate of a patent ductus in this group of patients.

The patent ductus (spontaneous or maintained) as part of a complex congenital heart disease will be discussed in the corresponding chapters.

As definite spontaneous closure of the duct can be seen clinically as late as at the end of the third month of life, this point of time is the relevant date for the final distinction between a mere patent (before) and a persistent (after) ductus arteriosus, interestingly both abbreviated PDA.

The persistent ductus arteriosus is a distinct pathological-clinical entity. In contrast to the normal ductal wall tissue, elastic fibers in the media are well developed. It almost resembles what can be seen in the media of the normal aorta. For that reason, persisting patency of the duct cannot be explained by a delayed or incomplete closing, but rather with a different (patho-) histology to start with.

Historically, surgery for a persistent arterial duct was the first successful operation to repair congenital heart disease. It was Robert Gross from Boston Children's Hospital who performed ligation of a symptomatic large-caliber arterial duct via a left-sided thoracotomy in a 7-year-old girl on August 26, 1938 (Gross and Hubbard 1939) (see also ► Chapter «The History of Cardiac Surgery» Sect. 1.5).

When Porstmann closed a persistent arterial duct in catheter technique in 1966, the arterial duct also became the first congenital heart defect to successfully undergo definitive interventional treatment (Porstmann et al. 1967).

Patent resp. persistent ductus arteriosus will be separately discussed for three different age groups with distinct therapeutic approaches: premature babies, infants/children, and adults. Furthermore, the special situations of an atherosclerotic duct, an infected duct, and of an aneurysmal duct will be dealt with.

21.4.1.1 Patent Ductus Arteriosus of the Premature Baby

This type has to be seen as a delayed closure of a histologically normal duct. The ductal tissue is just as immature as the baby, which postnatally makes the ductal myocytes not respond timely to the higher oxygen or lower prostaglandin levels, as it would occur in term babies. Because of the common association with respiratory insufficiency and arterial hypoxemia caused by an immature lung, it may be also speculated about an insufficient stimulus for ductal closure in some patients. Depending on the hemodynamic influence of the patent duct in the individual patient, surgery is indicated (increased left heart volume load by a large left-right shunt with persistent pulmonary hypertension). It cannot be ruled out that among the majority of these patents with a histologically normal duct, the occasional abnormal duct may be found which might otherwise have become a persistent arterial duct later on. But this is without any clinical impact.

The first surgical treatment of a patent duct in a premature baby was reported by DeCancq in 1963. Because of the dramatic improvement of the clinical condition after surgery, the procedure was rapidly accepted as the standard therapy for this situation (DeCancq 1963). Indomethacin as a medical therapy was introduced in 1976 (inhibition of prostaglandin synthesis), and because of positive results and reduced risks, the medical treatment remains the primary therapy in premature neonates weighing more than 1,000 g.

With lack of sufficient data, the discussion whether primary surgery or primary medical therapy should be preferred for premies <1,000 g is ongoing. The only randomized series of a controlled trial of very early prophylactic surgical duct closure is more than 25 years old (Cassady et al. 1989). This study could not show a survival benefit for surgery; however, it showed a significant reduction in the incidence of necrotizing enterocolitis in the surgical group. Significantly worse neurosensory outcome was seen after surgical duct closure versus medical therapy alone as

a result from the trial of indomethacin prophylaxis in preterms (Kabra et al. 2007). Interestingly, the surgically treated patients had received almost 50% more indomethacin than the nonsurgical, medicine-only group (0.64 mg/kg vs 0.45 mg/kg). The authors of this large multicenter study comprising of centers in Canada, Australia, New Zealand, Hong Kong, and the USA state that PDA ligation is a risk factor for poor long-term outcomes in extremely low birth weight infants. They also state that although indomethacin prophylaxis will prevent a few PDA ligations, most of these premies will not benefit from prophylactic indomethacin and may even be harmed.

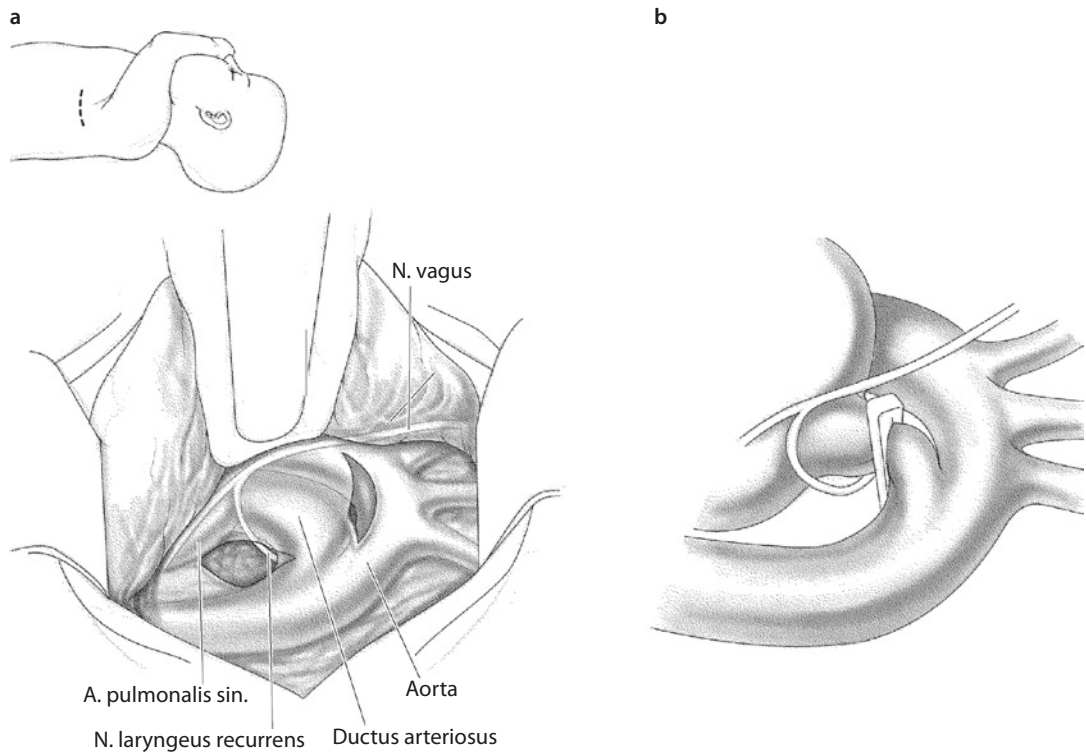

In these patients, there is a persistent urgent need for controlled trials with long-term follow-up to better delineate the role of surgical versus medical closure of a patent arterial duct. In current practice, a surgical procedure is usually only considered by neonatologists after two or three indomethacin or ibuprofen cycles, and a symptomatic duct remains patent. Given the undesirable, especially renal side effects of indomethacin and an only 50% primary success rate of the drug-induced closure especially in premature with a weight less than 1,000 g and definitely with a weight less than 500 g, a primary surgical therapy should be considered. Logistically even the transport of these patients to the OR can be challenging. If possible, the operation should take place on the neonatal intensive care unit because of the unstable thermoregulatory proportions and the often-critical respiratory conditions. This strategy advocated by us for many years is supported by clinical studies. They also showed that the often-noticeable retrolenticular dysplasia may be the result of an uncontrolled application of oxygen during the transport. The working group in Philadelphia recommends further providing care to patients of outlying hospitals in their facilities by «traveling surgeons» (Gould et al. 2003). We are focusing further on maintaining the therapeutic surrounding not only by performing the procedure in the ICU at the bedside, but we also foster an uninterrupted care and monitoring throughout this procedure by an experienced neonatologist and its NICU staff.

A direct measurement of the arterial blood pressure during operation is neither practical nor necessary. The ECG and the pulse oximetry system of the upper and lower extremities should deliver sufficient information during the proce-

cedure. Typically, these monitoring measures are already in place as part of the routine NICU care.

Positioning the baby on its right side is facilitated by its diapers in the radiant warming bed. There is no further bending of the chest necessary. The right side of the chest lies flat on the mattress. The posterolateral thoracotomy should be kept short according to the extreme elasticity of the tissue and may be no longer than 3.0 cm in premature infants with a weight of about 500 g. The exposure of the site is obtained by careful retraction of the inflated and relative stiff lung. This maneuver can compromise the cardiac function, and close monitoring regarding the development of bradycardia is required. In case of a repetitive compromise of the circulation and decrease of the heart frequency <100/min, which may occur very rapidly, all instruments should be removed out of the chest immediately, and a few minutes of recovery should be allowed for. The dissection should be minimized also. Only some local incisions of the mediastinal pleura cranial and caudal of the ductus are needed to apply a clip. The edematous subpleural tissue of very symptomatic patients further simplifies the dissection. The use of surgical loupes (2.5 better 3.5 magnification) is only mentioned for completeness. Circumferential dissection of the ductus is not only unnecessary; it clearly should be avoided for isolated ductus closure in premature infants. The ductal tissue is extremely fragile so that any direct manipulation should be avoided. The recurrent laryngeal nerve embracing the duct ventral of the vagal nerve (■ Fig. 21.21) shouldn't be manipulated either. The clip should be applied midway of the duct to avoid any narrowing to the aorta or left pulmonary artery. For that the pulse oximetry system of the lower extremities is useful. The clip should completely close the ductus. In case of an apparently incomplete closure, the removal of the clip is not recommended because of the risk of duct laceration. Instead a second clip has to be placed. If the application of the first clip induces any bleeding of the ductus, a second and better a third clip application also, one to each side of the original clip, may save the situation.

The advancement of clip technology allows for this approach as a routine. We check any clip applier for undistorting clip application on a string outside the operating field before using the very same applier to actually close the duct. Although the majority of the premie duct closures

■ **Fig. 21.21** a, b Surgical site for a patent ductus arteriosus in a premature baby. After minimal dissection above and below the ductus, only one clip is applied in the midst of the ductus

are performed as clip closure, they still may be referred to as «ligations». Actually the first report on premie ductus clip closures referred to «ligation with a clip» 30 years ago (Traugott et al. 1980).

An unpublished poll within the European Congenital Heart Surgeons' Association in May 2013 (personal communication) regarding duct closing preference resulted for premies less than 1,000 g in 20 clip closures only, five ligations only, and two ligations plus clip when 27 members responded. A retrospective study comprising six surgeons in two centers in New Zealand over 5 years demonstrated a significant reduction in the operative time for clip use, absence of bleeding (18% in ligature group), and a trend in lower postoperative morbidity (Mandhan et al. 2006).

In a standard situation, the chest should be closed without any pleural drain. Preplaced pericostal sutures are tied during a forced inflation of the lungs, in order to guarantee a complete expansion of the lungs. Irrigating the wound with normal saline during the first ventilations after chest closure may detect or exclude any air. Any attempt to close small air leaks in the visceral pleura in order to avoid any drain is useless. In these cases, a pleural

drain should be primarily inserted. After a running suture of the fascia, the skin can be closed directly. We avoid conventional intracutaneous suture of the immature skin as this is often traumatic in these cases; we also avoid adhesive dressings. We prefer a nonacrylic tissue glue (Dermabond®) as a substitute for a skin suture and wound dressing.

Any alternative surgical approach as intervention or video-assisted thoracic closure is not longer indicated. Even pioneering centers of video-assisted thoracoscopic ductus closure in the 1990s went back to the conventional procedure in these patients (Jonas 2004).

21.4.1.2 Persistent Ductus Arteriosus in Infants and Children

This is the typical aorta-like ductus arteriosus which depending on its size and effectiveness can cause a significant left-right shunt leading to heart failure with or without increased pulmonary pressure. Beyond the third month of life, the ductus does not show any tendency toward a spontaneous closure, and therefore the diagnosis of a hemodynamically relevant ductus should define automatically an indication for transcatheter closure or surgery. The

modern Doppler sonographic technology enables to identify a persistent ductus as small as a diameter of 1–2 mm. These tiny vessels are asymptomatic, and a prophylactic treatment due to threatening complications of/like an endarteritis remains controversial (Thilén and Aström-Olsson 1997).

During the last 10 years, the *interventional closure* has been established as a standard procedure in this age group, preferably with a body weight of 6 kg or more, which, however, seems not to be mandatory. Open surgery is performed only in exceptional circumstances or due to complications (s.b.). Since the introduction of the Rashkind device (ductus occluder, «umbrella») in the 1970s, the interventional techniques for ductus closure have become much more safer but also more extensive and especially more expensive. The rate of complications is very low. The occasional rescue *surgery to retrieve a lost device* out of the pulmonary artery or aorta, however, is far more extensive than a primary simple operative closure or division of the ductus.

An acutely embolized device usually ends up in the lower lobe artery of the left pulmonary artery; this can be removed directly out of the interlobar fissure (upper/lower lobe) via a posterolateral thoracotomy in the fifth intercostals space and an oblique incision of the artery during a temporary tourniquet closure. If the dislocation was originally unnoticed and the embolized device may be in its new position for more than 2 weeks, we recommend access via sternotomy and the use of normothermic extracorporeal circulation with the heart beating. With the transsternal approach, the ductus Botalli has to be closed before or with ongoing bypass. After a longitudinal incision of the distal main pulmonary artery and the proximal left pulmonary artery, the device can be retracted.

A device still sticking in the ductus, however, with a huge residual shunt can be removed via sternotomy using extracorporeal circulation also. An off-pump approach via a typical left lateral thoracotomy in the fourth intercostal space as usual for primary ductus closure is also possible. But additionally to the procedure as for primary surgical closure, the intrapericardial left pulmonary artery and the descending aorta have to be exposed proximal and distal to the ductus to be able to perform clamping maneuvers. Depending on the position of the intraductal device, sutures or ligatures may have to be preplaced. After clamping of the great vessels (aorta, if necessary even distal and proximal of the ductus branching) using Cooley clamps or straight

vessel clamps, the ductus is incised right above the most prominent part of the palpable device. After removing the device, the primarily placed surrounding sutures and/or ligatures are tied.

Rescue of a closing device after embolisation into the left pulmonary artery

1. *Acute embolization*: lateral thoracotomy in the fifth intercostal space and oblique incision in the left pulmonary artery in the interlobar fissure.
2. *Late embolization or late notice*, that means after more than 2 weeks: transsternal longitudinal incision of the distal main pulmonary trunk into the proximal left pulmonary artery employing normothermic extracorporeal circulation.
3. *Cave*: before removing the embolized device, the closure/division of the ductus is required.

Video-assisted thoracoscopic ductus closure as first done by Laborde (Laborde et al. 1993) may offer a cosmetically favorable alternative to an open surgical procedure. But as currently indication for surgery is limited to very small patients or to those cases with an apparently complicated anatomy, video-assisted technique may be extremely laborious, and the benefits of such a procedure are not demonstrated. Technically, the trocars are placed in the third or fourth intercostal space if possible along a line.

The *classical closure of the ductus* is performed via a posterolateral thoracotomy in the third or fourth intercostal space. The following rule of thumb – similar to the coarctation operation – approximately applies: the lighter the patient, the higher the intercostal space to be selected (<3 kg, third intercostals space; >4 kg, fourth intercostal space; in between gray zone). The lung is retracted ventral by a spatula, and the mediastinal pleura is opened longitudinally right over the proximal descending aorta. The ventral edge of the pleura is elevated by stay sutures protecting the lung with a wet gauze pad. With this the lung spatula can be removed as they are no longer necessary. The identification of the ductus, even though it seems to be simple, may not always be achieved at the first sight. The first glance often addresses the ductus as the aortic arch. The recurrent laryngeal nerve branching from the phrenic nerve and embracing the ductus from ventral/caudal to

dorsal may serve as a guideline. The aorta proximal and distal to the ductus should be dissected circumferentially before the ductus itself is manipulated. Even though it is possible to place two special clamps (Potts clamps) at the ductus in individual cases, it is more convenient to cross-clamp the aorta proximal and distal the ductus, as it also enables the closure of extremely short and wide structures. After transection, both stumps should be sewed by/with double-row polypropylene sutures.

In infants and small children, we prefer primarily to apply two circumferential sutures, one each on the pulmonary and aortic side, thereby avoiding aortic cross-clamping. The descending aorta, however, proximally and distally to the ductus insertion, is prepared for potential cross-clamping if necessary. The ductus is transected in between the tied sutures in small steps (■ Fig. 21.22). In case of significant bleeding, the cross-clamping has to take place as described above. Often an additional clip application is sufficient, which we additionally perform prophylactically anyways in most cases. An additional suture is rarely needed.

Most ductus closures are referred to as «ligations», as the historically first successful ductus closure had been a ligation (Gross and Hubbard 1939). A solitary ligation of a persistent ductus leads acutely to a compression closure of the ductus. Thereafter the locally compressed ductal wall tissue may thin out, and this will be followed by a recanalization of the ductus, although stenotic. If a ligation shall be performed, at least two ligations with some distance to each other are required, producing a thrombotic and later on organized closure between the two ligations.

The mechanism described for recanalization as a potential result of a solitary ligation in persistent ductus does not apply for a simple ligation of a patent ductus in a premature baby. In almost all of these cases, the ductal tissue at the time of surgery is still immature and irresponsive to the normal stimuli, but will later undergo the normal closing process accompanying normal gestational and postpartum life.

For the persistent duct, even the «father of ductus ligation», Robert Gross, suggested a transection as the standard procedure later on (Gross and Longino 1951). In his biographical memoir (Moore and Folkman 1995) he is cited to have performed only 12 ductus ligations in children. Thereafter, of his 1,610 ductus surgeries, all others were ductus divisions. After reading Dr. Gross's original surgery logbook 1937–1972 we slightly modified this leg-

■ Fig. 21.22 a–b Transection of a persistent ductus arteriosus in neonates and infants performing purse-string suture closures and if applicable additional clip placements on both the pulmonary and aortic side

acy (see ► Chapter «The History of Cardiac Surgery» Sect. 1.5). Reason of change in technique had been a fatal hemorrhage 2 weeks after ductus ligation due to a cut through ligation in this patient.

Once the duct is closed/divided, the parietal pleura is readapted over the aorta with a running suture, and the thoracotomy is closed without placing a drain/chest tube in the standard way. In older children/adolescents, a pleural chest tube may be placed.

If present, a pericardial effusion may be relieved by a small pericardiocentesis ventral and distant to the phrenic nerve or directly ventral to the pulmonary side of the duct.

21.4.1.3 Persistent Ductus Arteriosus in Adults

Despite all types of precautionary consults during childhood, a minor number of PDA remains undetected till symptomatology gets picked up at

adult age. The majority of these anomalies are tiny with an inner diameter of maximal 3–4 mm, and they are found due to a murmur rather than hemodynamic significance. At these sizes, potential pathologic changes in pulmonary vascularity are limited. After invasive examination which may show typically a predominant left-right shunt without any or at least not significant pulmonary hypertension, the ductus should be closed.

In case of a simple duct variation, an intervention with one of the different devices like coils or umbrella should achieve a stable closure.

But there are some variations, which are primarily (window type: extremely short) or secondarily modified (sclerotic, aneurysmatic, or infected ductus; see below). Their increased risk constellation mandates an alternative approach to that outlined above.

21.4.1.4 Atherosclerotic Ductus Arteriosus

After the 50th year of age, a patent ductus arteriosus starts revealing atherosclerotic changes, calcifications mainly at the aortic side. These mostly confluent circumferential calcifications prohibit a conventional surgical closure by a ligation/transection or even by multiple ligations via a thoracotomy. Any kind of clamping direct at the ductus has to be avoided due to the increased risk of rupture or dissection. The same is true for clamping the aorta close to the take-off of the ductus. In contrast to the aortic end, the pulmonary end of the ductus may not show any or less calcifications. Therefore, it is recommended to address the ductus closure via a sternotomy and from inside the main pulmonary artery employing normothermic extracorporeal circulation with the heart beating (Morrow and Clark 1966).

With this approach, it is required to clamp the patent ductus before the pulmonary artery is incised. In case of calcifications at the pulmonary site, it could be mandatory to occlude the ductus intraluminally, which creates a new risk on its own. The use of an appropriate/corresponding-sized Fogarty catheter can be helpful. If neither the clamping nor the occlusion is possible because of a very short or fragile ductus, the switch to a deep hypothermic circulatory arrest is warranted (O'Donovan and Beck 1978). The orifice should be closed by a patch plasty using synthetic material with running sutures.

Another option for closure of a calcified duct was performed via thoracotomy employing primary cross-clamping of the aorta proximal and

distal of the ductus (Hara et al. 1993) with or without (Johnson and Kron 1988) using a partial left heart bypass. Transluminal temporary balloon occlusion is followed by an intra-aortal patch plasty. Taking everything said above into account, this approach is not first choice.

Gold and Cohn (1986) as well suggest an approach via thoracotomy. Their approach takes advantage of the usually dilated and noncalcified pulmonary artery close to the ductus. They required an extensive dissection of the pulmonary artery so that two Cooley clamps can be placed side biting the left pulmonary artery close to the bifurcation beyond the calcifications. The transection and the double-row suture are performed in that case outside of the calcificated ductal tissue. A hemodynamically relevant narrowing of the pulmonary artery as a result is not to be expected as the diameter of the vessel has enlarged due to the pre existing significant left to right shunt in these cases requiring surgery.

While dependent on a limited extent of calcifications and size of the persistent duct, they may be amenable to routine interventional catheter closure techniques; special anatomies like very large and/or a very short ductus may need to undergo surgery. With the advanced progress in the technology of using endovascular prosthesis and growing/increasing experience of different diseases of the thoracic aorta, first reports are published about the successful endovascular treatment of the persistent ductus arteriosus (Ozmen et al. 2005; Roques et al. 2001). However, there is no conclusive evidence available regarding the specific problematic case of endoleaks due to the rarity of the procedure. Due to the large devices and catheters required for the original Porstmann technique, using an Ivalon® plug, this technique was only suitable for adult patients of any kind (Porstmann et al. 1967a, b).

21.4.1.5 Infection of the Ductus Arteriosus

The endarteritis inside the ductus and the pulmonary artery is a known but more talked about than actually seen complication. If present, vegetations usually occur on the pulmonary artery end of the ductus, and embolic events are usually to the lung rather than the systemic circulation (Schneider and Moore 2006). The risk of duct infection, even in the pre-antibiotic era, was only about 1%/year and has to be accordingly lower to almost nonexistent with current era availability and use of antibiotics in the western world (Campbell 1968; Thilen

and Astrom-Olsson 1997). Therefore, the assumed risk of endocarditis as indication for ductus closure in hemodynamically irrelevant arterial duct is not valid anymore for quite some time. For the rarely presenting infective PDA, in analogy to valvular endocarditis, first-line treatment is antibiotics, and surgery is only indicated if sepsis persists and/or PDA-associated circulatory problems persist/arise. The objective of the surgical therapy would not only be closure of the ductus but also the complete resection of the infected (vascular) parts of the vessel. Providing a safe operation with the aid of cardiopulmonary bypass is recommended.

Before and during establishing the extracorporeal circulation, manipulations at the pulmonary artery should have to be avoided. After clamping the ductus on the aortic side and blocking of the peripheral pulmonary arteries, the pulmonary artery itself may be opened to prevent peripheral embolizations. After removing the vegetations, the involved wall of the pulmonary artery is resected. If the ductal intima of the aortic side imposes itself macroscopically as obviously infected, a local resection of this part is also necessary. In cases such as these, the approach via left anterior thoracotomy is suggested by Stejskal and Stark (1992) in order to facilitate the establishment of extracorporeal circulation via the ascending aorta and the pulmonary trunk as well as the access to both the aortic isthmus and the left pulmonary artery.

21.4.1.6 Aneurysm of the Ductus Arteriosus

An aneurysm of the arterial duct may already be present prenatally and demonstrable in fetal echocardiography. It also can manifest itself as a late complication of a persistent or incomplete closed ductus, after surgery, intervention, and/or infection.

■ ■ The aneurysm of the neonatal ductus

With the advanced use of perinatal echocardiography, a primary aneurysm is seen more often (mostly asymptomatic). The incidence in children with genetic anomalies is higher. In 25% of patients, systemic diseases such as trisomy 21, trisomy 13, Ehlers-Danlos syndrome, or Marfan's disease are present (Dyamenahalli et al. 2000).

Early on the indication for surgery was seen very liberal because of an impressing diameter (Lund et al. 1992). Nowadays a primary conservative treatment in the sense of watchful waiting is recommended. The tendency of regression should

be documented by ultrasound performed two to three times daily in the neonate. If regression does not occur or a partial thrombosis without closure of the ductus persists (in the area of the aneurysm), surgery should be considered. This may also be true for the rare cases with symptoms (Koneti et al. 2011). Many in utero detected ductal aneurysms resolve with ductal closure and thrombosis without clinical sequelae (Rutishauser et al. 1977). The principal operative steps are the same as described in ► Sect. 21.4.1.1, «Patent Ductus Arteriosus of the Premature Baby», and ► Sect. 21.4.1.2, «Persistent Ductus Arteriosus in Infants and Children» as the aneurysm is constrained to the extent of the ductus, not involving the connecting great arteries. The generally elongated run of the ductus is easier to transect. If thrombus extending into the aorta is documented, the clamping of the isthmus and proximal descending aorta with inspection of the aortic lumen is obligatory. Resected aneurysms may show histological anomalies, above all connective tissue disease.

Aortic thromboembolism may occur even in premature infants after clip application of a large ductus/ductus aneurysm. Aortic occlusion may be treated by a short-term medical rising of the blood pressure, pushing the acute/fresh thrombus far peripheral by the bloodstream, in an ideal way to the iliac/femoral vessels where it may dissolve spontaneously. If the aorta remains symptomatically obstructed or even occluded, surgical treatment would be required, but was not necessary in our own experience yet.

In our experience in two institutions over 25 years, we have seen only one symptomatic aortic thromboembolism during ductus surgery and one spontaneous symptomatic pulmonary thromboembolism (Rauch et al. 2008), both in premature infants. A surgically treated patient has been reported in one case elsewhere (Fripp et al. 1985).

■ ■ Late Aneurysm

An originally incomplete closure or a persistent ductus Botalli can result in typical degenerative aneurysm with complications as thromboembolism and dissection/rupture at advanced age. Besides the typical spindle-shaped aneurysm of the ductus, a diverticulum is also described comprising the aortic side of the ductus expanded like a trumpet. Misinterpretations as an aortic rupture of this structure after thoracic traumata are described. At adult age the aneurysmatic dilatation can

involve the neighboring vessels and with that complicate the therapy; however, the aneurysm even in late adult life can still be constrained to the original duct area. Aneurysms of the pulmonary artery connected with Eisenmenger syndrome caused by a patent ductus Botalli are also known in adults.

Clinical signs of a hemodynamically ineffective aneurysm of the ductus in adults are those of a thoracic mass: thoracic pressure sensation, a typical hoarseness indicating the affected recurrent laryngeal nerve. Bronchial obstruction in a 4 months old (Roughneen et al. 1996) and vocal chord paralysis with phrenic nerve paralysis in a neonate (Berger et al. 1960) have also been reported. Indications for surgery are either hemodynamic reasons or symptoms created by aneurysmal tumor growth.

The operative procedure in adults may be complex as it may require aortic wall excision or a segmental resection and an implantation of a prosthetic patch or a tube graft. The technical details do not differ from principles of surgery of an aneurysm of the descending aorta, and they may be straightforward also.

21.4.2 Aortopulmonary Window

21.4.2.1 Classification

This rare malformation of the great arteries can be defined as a communication between the ascending aorta and the main pulmonary artery with almost no length, a «window», which is hemodynamically unrestrictive in most cases.

Clinical symptoms and pathophysiology are similar to truncus arteriosus, although these two defects derive from different embryological developments. While truncus arteriosus is a conotruncal malformation, the aortopulmonary window results from an error in fusion of parts of the farther distally located aortopulmonary septum.

The result is an oval hole between the ascending aorta and the pulmonary artery associated with two separated and completely normal semilunar valves. Absence of the intracardiac ventricular septal defect and presence of these two semilunar valves are the only morphological differences to truncus arteriosus.

In the Congenital Heart Surgery classification, Jacobs et al. (2000) suggested four different types for aortopulmonary window based on three types as described earlier (Mori et al. 1978). These four types differ in their localization (■ Fig. 21.23). In

the proximal variation (type I, proximal defect, ■ Fig. 21.23a), the window is directly located downstream of the sinotubular junction of both vessels connecting the left side of the ascending aorta with the right side of the main pulmonary artery. The distal variation is located farther downstream linking the two great arteries at the level of the takeoff of the right pulmonary artery. In relation to the aorta, the distal window can be identified in the back wall of the aorta (type II, distal defect, ■ Fig. 21.23b).

A third type, type III, is called the total defect (■ Fig. 21.23c). Here, the complete aortic pulmonary septum between sinotubular junction and takeoff of the right pulmonary artery is missing. Type IV is an «intermediate version». The defect/window is located in between types I and II (■ Fig. 21.23d).

The proximal and distal varieties correspond to the types I and II of the in most publications cited Richardson classification (Richardson et al. 1979). The third variety of the Richardson classification matches what is now called hemitruncus, an anomalous origin of the right or left pulmonary artery directly from the aorta with two essentially normal aortic and pulmonary semilunar valves. The anomalous origin is usually opposite to the side of the aortic arch.

Associated cardiac malformations are present in 50% of the patients. Most of them are simple isolated anomalies like a ventricular septal defect, ASD type II, or a persistent ductus. Others are typical for the aortopulmonary window. An IAA (see also ► Sect. 21.2.1.2, «Interrupted Aortic Arch») as a very complex anomaly associated with aortopulmonary window was described first by Berry et al. (1982). In this association, the IAA is usually of type A. The three branches of the aortic arch arise from the more or less normal-size ascending aorta. The right pulmonary artery seems to arise from the right side of the ascending aorta, while the origin of the left pulmonary artery is located – far away from that – at the left side of the pulmonary trunk before the origin of the ductus Botalli.

The proximal type windows may be accompanied by anomalies of the coronary ostia and their origins. The distal windows more often show complex spatial relations to the takeoff of the right pulmonary artery.

Independent of their location, these defects cause a nonrestrictive left to right shunt on the arterial level. This may result in a relative early rise in pulmonary vascular resistance (Doty et al. 1981). To

■ **Fig. 21.23** a–d Congenital Heart Surgeons' Society classification of aortopulmonary window (According to Mori et al. 1978; Jacobs et al. 2000; used with permission)

prevent this, early corrective surgery in neonates should be considered even in compensated situations. In truncus arteriosus type A, the primary mixing occurs on the ventricular level, causing a mixed shunt; in case of an aortopulmonary window, there is an exclusive left to right shunt with normal peripheral saturation, especially after reduction of neonatal pulmonary vascular resistance. As said before, however, pulmonary resistance may rise again early.

Echocardiography is usually sufficient for diagnosis (Apitz et al. 2007). If coronary anomalies cannot be ruled out, cardiac angiography is neces-

sary. Cardiac catheterization is recommended in patients beyond the third month of life to evaluate pulmonary vascular resistance.

The diagnosis of an aortic pulmonary window presents an indication for surgery. The only contraindication would be fixed Eisenmenger syndrome in older patients.

21.4.2.2 Surgical Treatment

The first successful surgical treatment dates back to 1948 when Robert Gross closed an aortopulmonary window by double ligation. As depicted

in drawings in that publication, there obviously had been some length to the window which allows for this type of off-pump procedure (Gross 1952). Another procedure that was performed before the introduction of extracorporeal circulation was the division of the aortopulmonary connection after side clamping as reported by Scott and Sabiston (1953) and Flechter et al. (1954). Despite these reports about successful treatments, these techniques had limited application due to the anatomical variations, and they remained risky. Only by employing extracorporeal circulation, this cardiac defect can be routinely corrected in a safe and reproducible manner with protection of the neighboring structures. From all the techniques, some of them are still used. We may mention the separation and direct closure described by Cooley (Cooley et al. 1957) as well as the transaortic (Deverall et al. 1969) patch closure.

By definition this anomaly is a window, i.e., a communication without length, and it is not a tubular structure. Sometimes, however, it can show some «depth», and its dimensions can be even delineated in between the aorta and main pulmonary artery. As the pulmonary artery is usually enlarged, this anatomic communication can then be isolated with C-clamps on both the aortic and pulmonary sides without compromising the lumen of the great vessels. With that the window gets even more of a length, and therefore the closure can be performed almost like a transection of the ductus Botalli without installing cardiopulmonary bypass. These must have been the circumstances of the first cases reported before the advent of cardiopulmonary bypass. This procedure may be still used in selected cases. One has to be absolutely certain that the clamps will neither obstruct the lumina of the pulmonary artery nor aorta and coronary arteries and they also will not interfere with the semilunar valves. If this is the case, suture closure of both sides will be safe. Even if we plan to go ahead with an off-pump approach in aortopulmonary window, we have a circuit for extracorporeal circulation ready to be connected on the OR table.

In general, repair of an aortopulmonary window is performed under direct vision as an on-pump procedure with cardioplegic arrest. In case of a proximal window, the ascending aorta may be cannulated at the usual aspect. With a distal window, the cannulation should be performed as distal as possible, rather in the proximal aortic arch to ensure a safe and nondistorting placement of

the aortic cross-clamp. If deep hypothermic circulatory arrest is instituted, the place of cannulation is not as critical as the cross-clamp can be placed on either side of the cannula during arrest, and thereafter the defect is repaired.

Venous cannulation depends on the presence of additional intracardiac defects to be taken care of as well as on the perfusion technique used (with or without circulatory arrest). Independent of the anatomic location of the aortopulmonary window, both pulmonary arteries should be dissected circumferentially and snared by tourniquets with initiating extracorporeal circulation analog to the correction of the truncus arteriosus. In case of a hemitruncus, only the aberrant pulmonary artery coming off the ascending aorta has to be closed temporarily.

In contrast to the biarterial cannulation required for primary IAA, a single cannulation is sufficient in case of a Berry syndrome (s.a.) because both parts of the aorta can be perfused via the nonrestrictive window. The temporary closure of the pulmonary arteries with initiating the extracorporeal bypass is self-evident.

Dissection of the window can be carried out during the cooling phase of bypass with the heart decompressed. In case of an aberrant right coronary artery out of the window or even out of the pulmonary artery, its epicardial course may suggest the best incision. With reaching the target temperature desired, the aorta is cross-clamped, and if applicable, cardioplegia is given. Thereafter the window is opened, and aorta and main pulmonary artery are separated (■ Fig. 21.24a, b).

Relatively small (about 25% of the aortic circumference) type I and type IV defects (see ■ Fig. 21.22a, d) can be closed directly at the aortic side. In case of an oval opening as in most cases, the closure should be performed with a double-row suture parallel to the longitudinal diameter, given the attention to the valve, the coronary arteries, and the remaining diameter of the aorta.

If the window is larger than 25% of the aortic circumference, patch plasties of both the aortic defect as well as the pulmonary artery is recommended, using pericardium or polytetrafluoroethylene. We use 0.4 mm thick polytetrafluoroethylene (■ Fig. 21.24b).

As an alternative, the window can be closed by a patch either with a transaortic or pulmonary access incorporating the risk of a remaining defect/leak as in any intracavity closure of a communication.

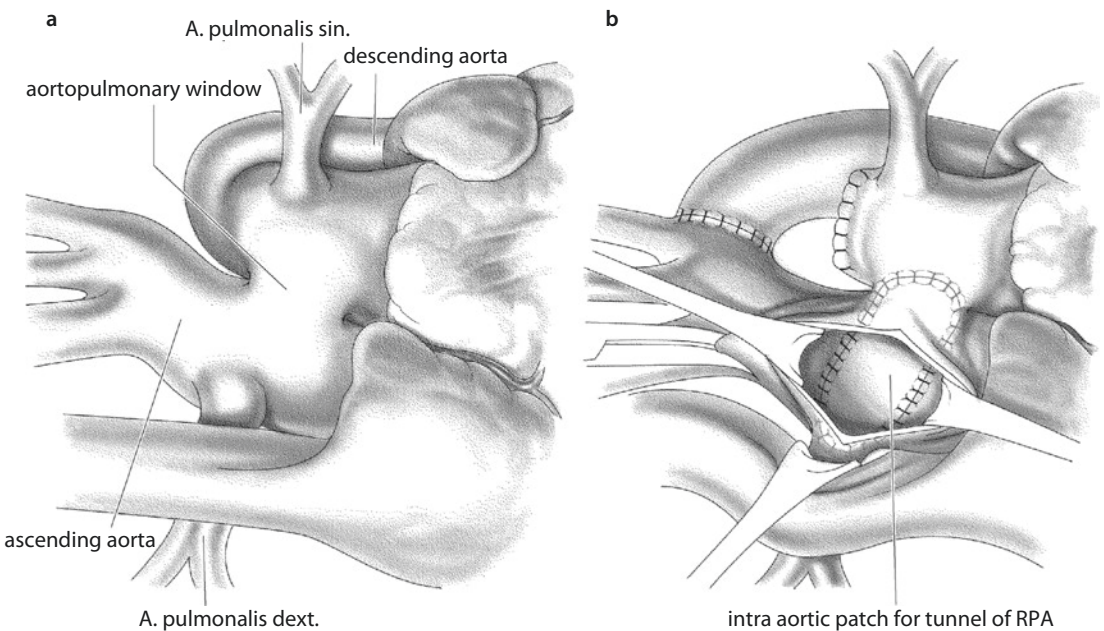

If the window is located more distally, it should be approached through an oblique incision of the aorta. The aortotomy facilitates the exact excision of the posterior part of the window to the pulmonary artery. Confining the excision to the dimensions of the window facilitates right pulmonary artery reconstruction, which should be carried out with a patch plasty. A second patch closes and reconstructs the aorta. A single intra-/

transaortic patch closure may be possible; however, right pulmonary artery reconstruction is less controlled and therefore less reliable.

If an IAA is associated, the origins of the pulmonary arteries are located far from each other, detaining a direct reimplantation of the right pulmonary artery (■ Fig. 21.25a). It is suggested to connect the orifice of the right pulmonary artery with the aortic pulmonary window via an intra-

■ Fig. 21.24 a, b Bilateral patch closure of an aortopulmonary window

■ Fig. 21.25 a, b Approach in case of an aortic pulmonary window associated with an interrupted aortic arch

aortic tunnel after performing a longitudinal aortotomy (■ Fig. 21.25b). Anterior enlargement of the aorta may be necessary as already mentioned in the original paper (Berry et al. 1982). After resection of the ductal tissue, the distal aorta should be anastomosed end to side to the almost regular-sized ascending aorta. In our own limited experience, we preferred to reconstruct the aorta and pulmonary artery separately with two patches.

21.5 Right to Left Shunt

21.5.1 Pulmonary Arteriovenous Fistula

Pulmonary arteriovenous fistulas are a rare, but correctable cyanotic disease. Their origins can be both congenital and acquired. The vast majority of the congenital arteriovenous fistulas (about 70%) are caused by an autosomal dominant hereditary disease (hereditary hemorrhagic telangiectasia, Rendu-Osler-Weber syndrome). This telangiectasia primarily affects the skin and mucous membranes, but also visceral organs. It rarely becomes symptomatic during the neonatal period, but does so with increasing age. About 35% of the patients show pulmonary manifestations (Gossage and Kanj 1998).

Acquired forms may be attributed to liver disease. It may also be seen in patients in the follow-up of pediatric/congenital cardiac surgery after Kawashima- or bidirectional Glenn operation for the spectrum of univentricular hearts. In these patients, hepatovenous blood is prevented from direct lung passage. The lack of a presumed «liver factor» is thought to be the reason for the development of these potentially ubiquitously existing pulmonary fistulas. Frequently, however, these new appearing fistulas may be restricted to one lobe only.

These fistulous communications are dealt with also in ► Chapter «Definite Palliation of Functional Single Ventricle», Sect. 13.7.5.2. Due to their frequency and clinical implications for the Fontan circulation, their treatment and first of all their primary prophylaxis continue to represent subject of ongoing debate as to the optimal timing and technical configuration of the total cavopulmonary connection both in the setting of normal or azygos-dependent inferior vena cava drainage.

Congenital fistulas are usually isolated pathologies. Depending on their size, they can cause a

more or less severe cyanosis and/or insufficiency of the heart.

When viewed morphologically, these abnormal connections can be classified as simple or complex forms, depending on the number of arterial inflow vessels (commonly pulmonary collateral arteries at times branching from the bronchial arteries). A solitary arterial inflow vessel identifies the simple form, while networks of arterial and venous collaterals designate the complex form.

A more or less severe cyanosis without signs for intracardiac or known pulmonary disease is typical for isolated congenital pulmonary arteriovenous fistula. Chest X-ray alterations of the lungs in most cases are very discrete. The appearance of intravenously injected air bubbles in the left atrium detected by a contrast echocardiography is pathognomonic for the pulmonary arteriovenous fistula. An additional CT or MRI or a conventional angiography is required to verify even the anatomical details.

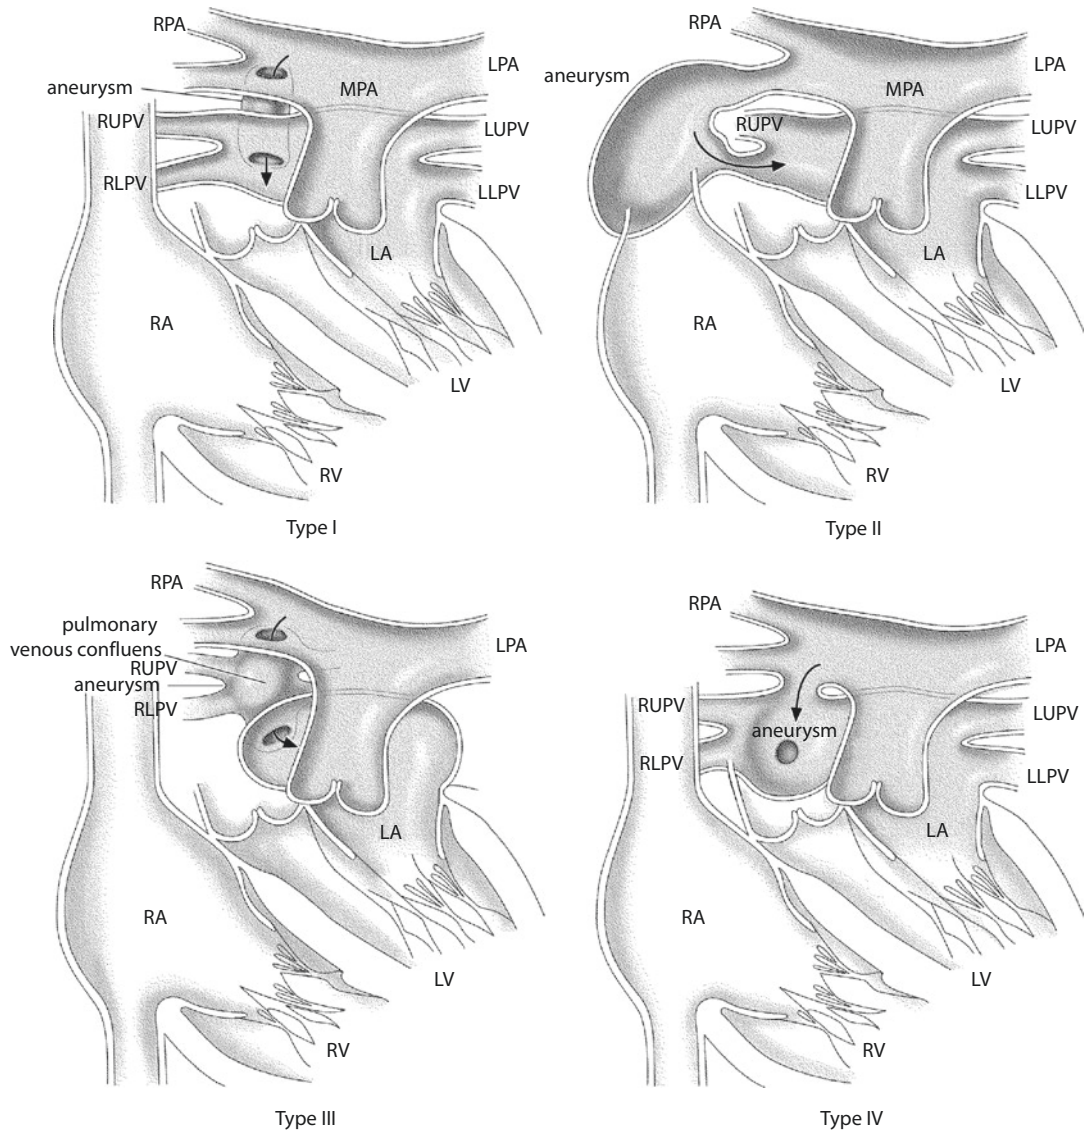

Catheter interventional therapy can produce excellent results in cases of smaller fistulas with defined in- and outflow vessels. For the more complex forms, surgical therapy is indicated. Closure of isolated large-sized fistulas can be performed by ligation after careful dissection of these very thin-walled and fragile fistulas. But more often preference will be given for an anatomical lung resection (lobectomy, segmentectomy), eliminating the abnormal connections and the cyanosis en bloc.

In the extreme case of bilateral diffuse fistulas causing severe cyanosis, bilateral lung transplantation is the only feasible therapeutic option (Svetliza et al. 2002).

21.5.2 Pulmonary Artery to Left Atrium Communication

This very rare anomaly of a shunt between the right pulmonary artery and the (superior aspect of the) left atrium is reported in about 60 cases in the literature, most of them described beyond the neonatal period as a cyanotic disease which also may lead to systemic thromboembolism (Chowdhury et al. 2005).

According to a fatal case report (Verel et al. 1964), there have been two reports mentioning one surgical survivor each before 1960 (Friedlich et al. 1950; Taussig 1960), the earlier and first one supposedly being operated by Alfred Blalock.

■ **Fig. 21.26** Classification of the pulmonary artery to left atrium communication. Type I: direct connection between the right pulmonary artery and the posterior aspect of the left atrium. Normal pulmonary veins. Type II: connection of the right lower lobe pulmonary artery branch with the right inferior pulmonary vein («end to end») close to the left atrium. Agenesis of the right lower lobe of the lung. Type III: connection with a retrocardiac pulmonary venous confluence that is not incorporated into the left atrium. Type IV: aneurysmatic retrocardiac connection of the fistula receiving right pulmonary veins also. Normally connected left pulmonary veins (According to de Souza e Silva et al. (1974) and Ohara et al. (1979); used with permission)

The neonatal form may manifest itself with a severe cyanosis, which cannot be managed conventionally. It has to be considered that this disease is probably underdiagnosed due to the lethal outcome immediately postpartum. This may change now with the increasing frequency of prenatal diagnosis, as it was the case in our experience (Meyberg-Solomayer et al. 2009). This anomaly is currently rarely mentioned in any of the important textbooks of pediatric cardiology or cardiac surgery although

a proposed classification of three pathoanatomic findings was already published in the 1970s by de Souza e Silva et al. (1974) and extended to four types by O'hara et al. (1979; ■ Fig. 21.26).

The symptomatic neonatal form has already significant abnormal hemodynamics prenatally: in addition to the obligatory right to left shunt of the fistula there is flow reversal in the arterial duct, leading to extreme biventricular cardiomegaly due to extreme volume overload of the heart.

At the same time, the pulmonary circulation being prenatally already minimal may be even further reduced. Cardiomegaly with the extremely enlarged left atrium may demand a detailed fetal echocardiography detecting the abnormal communication. Immediately postnatal neonatal pulmonary vascular resistance may not allow any pulmonary flow in this situation followed quickly by asphyxia within the first minutes of life.

If the respiratory situation of the baby after birth cannot be stabilized within minutes after spontaneous breathing or after intubation and ventilation, an operation via sternotomy is required without delay. Anesthetic IV medication may have to be given directly into the right atrium after sternotomy.

A temporary/probationary occlusion of the right pulmonary artery eliminating the left atrial runoff may improve left pulmonary perfusion and gas exchange and facilitate the intraoperative inspection of the anatomy. In case of a favorable anatomic variety (types I and II), a simple application of a clip even theoretically is sufficient to close the connection. In complex forms with participation of the pulmonary veins or with threatening loss of time, extracorporeal circulation should be established.

While the duct has to be temporarily snared with ongoing extracorporeal circulation, it may be opened as necessary once coming off bypass or it may stay closed. If closure is not tolerated as indicated by oxygen saturation and gas exchange, the duct should remain patent or even maintained open by infusion of prostaglandin. With decreasing pulmonary vascular resistance and maturation of the lungs within hours/days, the oxygenation will/may improve and the arterial duct can and should be closed. If the arterial duct has to remain open at the end of surgery, we vote for a preplaced snare at this time to facilitate duct closure on the PCICU.

Successful treatment of the prenatally diagnosed significant neonatal form requires preparation for potential immediate establishment of extracorporeal circulation and cardiac surgical procedure to close the abnormal communication and snare the arterial duct (cardiac surgery in «standby» with childbirth in the OR of cardiac surgery).

The alternative strategy of an interventional closure of the pulmonary artery to left atrial communication is only recommended in neonates achieving sufficient oxygenation and CO₂ elimination early postpartum. But in case of a continuously deteriorating O₂ saturation and a developing metabolic acidosis, immediate surgery is the most competent measure to eliminate or prevent the metabolic decompensation within 15 min, proper planning provided.

In patients at any age outside the immediate neonatal period, who are less compromised by the defect, the fistula may be taken care off electively in a catheter-guided interventional setting or depending on the anatomy by surgery also.

22.1 Introduction

Coronary artery disease (CAD) is caused by atherosclerosis leading to narrowing of the coronary arteries. Restricted flow to the myocardium causes myocardial ischemia and possibly to myocardial infarction. Current studies prove that besides known risk factors mainly genetic factors account for the development of CAD (Samani et al. 2007). Because life expectancy is generally rising in industrial nations, the incidence of CAD increased continuously over the years. The major portion of cardiac operations in adults in the industrial nations is coronary artery surgery.

Coronary artery bypass grafting (CABG) evolved continuously and became more and more complex. Besides technical innovations, there were changes in the approach to patients who undergo coronary artery bypass surgery. Apart from introducing the use of the left internal mammary artery (LIMA) as graft to the left anterior descending (LAD) coronary artery in multi-vessel disease, many other concepts of revascularization options using different conduits were developed. Serving patients of all age groups including old patients with severe comorbidities demands differentiated treatment strategies.

22.2 History

Coronary artery bypass grafting began in the late 1960s. Still of interest is the indirect revascularization in which the transected IMA was implanted in the ischemic myocardium, developed and performed by Vineberg in 1951 (Vineberg and Miller 1951). Although retrospectively not effective, single aspects of this technique are in a modified way still used in special revascularization procedures, e.g. in myocardial laser therapy or minimally invasive direct coronary artery bypass (MIDCAB).

The first coronary artery bypass using an autogenous saphenous vein graft was performed in 1964 by Garrett (Garrett et al. 1973) making him a pioneer in coronary surgery. Favalaro (1968) from the Cleveland Clinic finally introduced bypassing coronary obstructions in multi-vessel disease using saphenous vein grafts, also. Another cornerstone in bypass surgery was the first mammary artery – coronary artery anastomosis without extracorporeal circulation (Kolessov 1967). With the introduction of the

radial artery as bypass graft by Carpentier as soon as 1971, first discussions about complete arterial revascularization were initiated (Carpentier 1973; Acar et al. 1998; Zacharias et al. 2004).

By now coronary artery bypass surgery represents the main part of cardiac surgery in the western world. In industrial nations myocardial revascularization under cardioplegic arrest using extracorporeal circulation still represents the standard surgical approach to coronary artery disease.

Options for off-pump coronary revascularization, which avoid extracorporeal circulation and its side effects, were refined in the meantime and aimed for less invasiveness. Nevertheless off-pump coronary surgery in higher numbers is currently restricted to specialized centers. The proportion of off-pump surgery in the United States and Western Europe is currently estimated to be lower than 30% (Halkos and Puskas 2010; Abu-Omar and Taggart 2009). In this context the pioneering off-pump procedures like the first OPCAB («off-pump coronary artery bypass) in 1978 by Benetti (Benetti et al. 1980) and the clinical initiation of MIDCAB in the mid-1990s by Subramanian, Boonstra and Calafiore (Calafiore et al. 1996) should be mentioned.

22.3 Invasive Therapy

Treatment of coronary artery disease is based upon three different *therapeutic strategies* which differ fundamentally in their invasiveness and effectiveness. Nevertheless these strategies are often used in combination, either in a simultaneous or in a staged approach. Aside from medical therapy only, revascularization by percutaneous coronary intervention (PCI) and revascularization by surgical coronary artery bypass grafting (CABG) represent the cornerstones.

According to the national and international guidelines (Programm für Nationale Leitlinien 2008), surgical treatment is indicated in coronary multi-vessel disease with proximal vessel obstructions greater than 70%, or a left main stem stenosis greater than 50% with concomitant angina at rest or exercise. Additional diagnostic tools like

perfusion imaging, stress echocardiography or intracoronary flow measurements (Tonino et al. 2009) may be useful in verifying suspected myocardial ischemia in asymptomatic patients.

The decision to perform either PCI or CABG is mainly based on the morphology of coronary obstructions predominantly displayed by coronary angiography (Jones et al. 2006). Alternative diagnostic tools like cardiac computed tomography are of growing interest but currently they do not meet the quality criteria required. In selected cases an additional intravascular ultrasound may be helpful to more precisely determine the level of coronary vessel obstruction in proximal lesions (Kuecherer 2002). The final decision for the therapeutic approach chosen takes into account the number of the diseased coronary arteries (one-, two- and three-vessel disease) as well as the presence or absence of lesions of the left main stem or proximal portions of the LAD.

According to national differences in medical practice, a wide range of national and international guidelines for treatment of CAD had been developed. The basis of these guidelines, which provide level of evidence and class of recommendation, resides in newer prospectively randomized multicenter trials and analysis of large registries. Accordingly in patients with coronary multi-vessel disease with proximal lesions greater than 70% or main stem lesions >50%, a surgical revascularization (CABG) is primary recommended. It is assumed that bypass surgery in these patients provides a lower rate of recurrent of angina and myocardial infarctions. Also lower is the need for target repeat revascularization, which results in higher mid- and long-term survival (Booth et al. 2008). In patients with single- and double-vessel disease with proximal LAD lesions, current guidelines show no preference for PCI or CABG.

In patients with diabetes and severely compromised left ventricular function (<30%), surgical revascularization shows superior long-term results when compared to PCI (BARI trial 1997; Ben-Gal et al. 2006; Toda et al. 2002).

Medical therapy is still of value in the treatment of CAD but requires high compliance by the patient to be effective (Amoroso et al. 2001; Hueb

et al. 2004). All *surgical concepts* are considerably more traumatic than interventional therapy and are associated with longer periprocedural hospital stay and time of convalescence. Once surgical treatment is decided for, a variety of operative concepts are available with or without employment of extracorporeal circulation. Surgical interventions with extracorporeal circulation require exclusion of certain relevant vascular calcifications. Vascular regions of special interest are the ascending aorta, branches of the aortic arch (stenosis of the subclavian artery and internal carotid artery) and peripheral vascular bed. Further aspects will be outlined in connection with detailed description of revascularization concepts and techniques.

Many patients with CAD are on anticoagulant therapy beyond the usual dosage of aspirin especially after an acute coronary syndrome with implantation of drug eluting stent. In addition to anticoagulation with warfarin, heparin or fibrinolytic agents, there are a growing number of patients who receive combined anti-platelet-aggregating therapy, which may necessitate further preoperative measures to prevent increased risk of postoperative bleeding (Kunadian et al. 2006). Nowadays potential risk factors like smoking, obesity or age beyond 80 years are not considered strict *contraindications* for surgery anymore, particularly as surgical candidates with severe CAD are on even higher risk without treatment.

22.4 Surgical Strategy

Surgical strategy in CAD is to bypass coronary obstructions to a distal vessel area free of atherosclerosis. The anastomosis of the conduit should result in a nonrestricted bidirectional flow into the target vessel. The prime objective is to obtain complete revascularization using adequate number of bypasses to attain superior mid- and long-term results (Ong and Serruys 2006; Mohr et al. 2011). Moreover complete revascularization reduces the rate of perioperative myocardial infarctions.

Alternative surgical concepts for CAD, which are circumstantial, are listed below:

- Vascular patch plasty of the left main coronary artery (Malyshev et al. 2004)
- Coronary endarterectomy (Marinelli et al. 2002)
- Mammary artery patch plasty of coronary vessel (Barra et al. 2000)

■ **Fig. 22.1** IMA to LAD bypass in combination with venous grafts. *IMA* internal mammary artery, *LAD* left anterior descending coronary artery

- Epimyocardial myotomy for intramyocardial vessels (myocardial bridges) (Katznelson et al. 1996)
- Transmyocardial laser revascularization (Allen et al. 2000)
- Angiogenesis and arteriogenesis with vascular growth factors (Heilmann et al. 2003)

At present CABG with the use of the left IMA (LIMA) as bypass to the LAD in combination with venous grafts to other obstructed coronary vessels remains the most widely used form of surgical revascularization. Several studies in the 1980s showed that the use of the IMA as bypass to the LAD is associated with a survival benefit after 10 years when compared to a revascularization with venous grafts only (Loop et al. 1986). Nowadays, the percentage of IMA-LAD bypasses in a coronary surgery programme is regarded as an indicator of quality (■ Fig. 22.1).

Aiming for an even better long-term perspective, there is a growing use of bilateral mammalian arteries and the radial artery in coronary surgery. Another essential development of the past decade was beating-heart surgery to eliminate unfavorable side effects of extracorporeal circulation. Beating-heart

■ **Fig. 22.2** Catheter for retrograde cardioplegia delivery

surgery is subdivided into OPCAB, which allows revascularization of multiple target vessels (Ngaage 2003), usually via a median sternotomy and MIDCAB with single IMA bypass to the LAD via a limited anterolateral thoracotomy (Diegeler 1999).

22.4.1 Conventional Coronary Surgery with LIMA to the LAD in Combination with Saphenous Vein Grafts to Other Coronary Arteries

In most cases this operation is performed employing extracorporeal circulation with moderate hypothermia. Extracorporeal circulation is established using a single venous (two-stage) cannula and an arterial cannula placed in the distal ascending aorta or the proximal aortic arch. Most commonly cardioplegic arrest of the heart is utilized (Lapenna et al. 1994); nevertheless some institutions prefer intermittent aortic cross-clamping (Boethig et al. 2004). Especially in patients with multi-vessel disease and occluded coronary arteries, retrograde infusion of cardioplegia solution via a coronary sinus catheter (Franke et al. 2001) may be advantageous to obtain homogenous myocardial protection (■ Fig. 22.2). Moreover the additional application of cardioplegic solution via already completed venous grafts is possible. In patients with poor left ventricular function or acute myocardial ischemia, the use of cold or warm blood cardioplegia was proven to

be beneficial in several experimental and clinical studies. Aortic root catheters with additional venting line offer the opportunity to vent collateral coronary blood flow during aortic cross-clamping.

Preoperative use of an intraaortic balloon pump may be of benefit in patients with acute coronary syndrome or poor left ventricular function.

22.4.1.1 Harvesting of Bypass Grafts (Greater Saphenous Vein, Left Internal Mammalian Artery, and Alternative Arterial Grafts)

■ ■ Vein Harvesting

Although arterial conduits are used in almost all primary CABG procedures, venous bypass grafts still are key elements of surgery for coronary heart disease. If analyzed carefully, venous grafts still provide acceptable long-term results; usually they are available in greater numbers, and harvesting is considerably easy.

Long segments of the greater saphenous vein are by far the most often used bypass grafts. In selected cases utilization of the lesser saphenous vein may be reasonable.

In patients with significant atherosclerotic occlusive disease, vein harvesting at the leg affected should be avoided. Besides the increased risk of delayed wound healing and local infection when harvested in this setting, the intact vein might become important for possibly future limb saving vascular surgery.

Vein harvesting is principally possible with three different harvesting techniques:

Patency of the deeper veins is prerequisite for the harvesting of the superficial veins of the leg. History taking and physical examination spare generally additional diagnostic tools like duplex sonography of the veins or even phlebography.

- Open technique with continuous skin incision over the entire length of the harvested vein segment (■ Fig. 22.3).
- «Bridging or tunnelling technique» using multiple small incision over the saphenous vein, with experience harvesting can be performed with distances of up to 15 cm in between the incisions (■ Fig. 22.4).
- Endoscopic technique, depending on the harvesting device removal of the entire greater saphenous vein, is possible through a single incision of about 1 cm (■ Fig. 22.5).

Endoscopic vein harvesting is attractive as compared to the open procedure (Kiaii et al. 2002) in showing less to no impairment of postoperative mobilization in addition to a favorable cosmetic result. Nevertheless the method is not established in higher numbers due to the required equipment with increased need for more or less costly single-use materials. Moreover, at least during the learning phase, the procedure may be quite demanding and time-consuming. In comparison the established open technique is easily learnable; however, it is associated with an unfavorable cosmetic result and often associated with poor wound healing (Athanasίου et al. 2004). A compromise between these two techniques is represented by the bridge or tunnel technique (Tran et al. 1998). This method can be easily adopted; also, there is no auxiliary material necessary, and the prevalence of leg wound complications is comparatively low.

If the open procurement technique is applied, harvesting should start at the distal lower leg where the vein can be easily located. The initial skin incision of about 10 cm is made a few centimeters proximal of the medial malleolus where the vein is often visible or palpable. Subcutaneous fat is divided up to the level of the vein and the accompanying saphenous nerve. The vein is carefully isolated from the surrounding tissue and the adjacent nerve. To prevent intravenous clot formation, the

■ Fig. 22.3 Open saphenous vein procurement

■ Fig. 22.4 Bridging technique for saphenous vein procurement

■ Fig. 22.5 Endoscopic vein harvesting

vein should be ligated and divided at the level of the malleolus. After insertion of a small cannula, the vein should be gently flushed with diluted heparin solution. High pressures must be avoided to prevent damage to the vascular wall (Shuhaiber et al. 2002). To prevent backflow the syringe should stay connected and irrigation repeated every 5 min. If the vein is of good quality, the skin incision is lengthened over the needed distance and dissected in the described manner. Branches may be ligated with non-resorbable sutures and divided, or divided after hemostatic clip application. Meticulous care is required to ligate the distal end of the proximal vein left in place.

Using the bridging technique, it is also recommended to start dissection at the distal lower leg. After a short incision of about 3 cm starting above the malleolus, the vein is exposed using blunt dissection. After cannulating the graft, the next skin incision is created along the line of the vein in a distance of about 10 cm. For exposure of the vein in the tunnel, the use of a retractor is advisable. Since the application of sutures in the tunnel is laborious, the use of hemostatic clips to shut off side branches is recommended. To obtain the

desired graft length, the process is continued up towards the knee, respectively, the groin. With experience it is possible to remove the entire greater saphenous vein with five small incisions.

A variety of dissection devices are commercially available for endoscopic vein harvesting. Using this technique the vein is localized via a 2-cm skin incision above the knee and circularly freed of connective tissue. A lighted dissector is introduced into the incision over the saphenous vein and removes the covering tissue. Carbon dioxide insufflation improves the visualization; diathermia in combination with hemostatic clips is used to close the venous side branches before division. By advancing the endoscope towards the groin or towards the malleolus, it is possible to harvest the total length of the greater saphenous vein if necessary. Mini-incisions at the groin, respectively, at the ankle, are recommended to remove the vein and ligate the in situ remaining ends safely.

Irrespective of the mode of harvesting after closure of the incisions required with absorbable suture, an elastic wound dressing is wrapped around the whole leg towards the groin. This effectively prevents postoperative hematomas of the leg wounds.

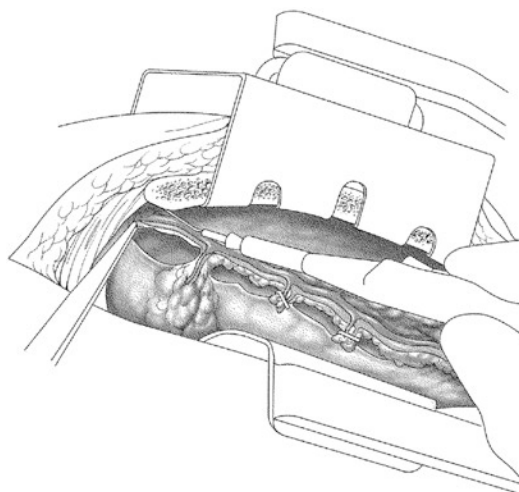

To prevent iatrogenic compartment syndrome, the compressing wound dressing has to be removed immediately after transfer to the intensive care unit.

When using the open or bridging technique, harvesting of the vein can be started at the upper leg, also. However, flushing the graft is impossible

from proximal which may be disadvantageous, as clots may develop. Starting at the lower leg and inserting a cannula for flushing do avoid bypass implantation without function due a wrong direction of flow against the venous valves. In addition intermitted flushing allows for visualizing the vein diameter and its wall quality. If testing shows a poor graft quality, one can switch to another harvesting site at an early stage. A negative feature of the endoscopic technique is that judgment of graft quality is not possible until the vein is completely removed.

■ ■ Harvesting of the left internal mammary artery (LIMA)

After dividing the sternum, a special retractor is introduced, which not only widely separates the edges of the split sternum but also elevates the left half of the sternum to expose the IMA. In the next step, the adjacent mediastinal fibro-fatty tissue is removed from the endotheracic fascia. Most surgeons prefer atraumatic preparation of the IMA as one pedicle containing the internal thoracic veins, perivascular tissue and parietal pleura (Jones 1991). An incision is made in the parietal pleura on the medial side of the IMA with a distance of around 1 cm at suitable site, favorably an intercostal space. Starting from here the fascia is incised over the entire length of IMA down to the bifurcation. Removing of the IMA can be performed predominantly with electrocautery (small and fine tip) using low power. Side branches should be divided with some distance to the main vessel either with electrocautery or hemostatic clips. Step by step, a parallel incision on the lateral site of IMA is carried out after separating the vascular structures from the thoracic wall resulting in a circular removal of the pedicle (■ Fig. 22.6). Dissection of the proximal IMA has to be performed very carefully to avoid injuries of the subclavian vein and artery and the phrenic nerve. To locally apply vasodilating agents (Hartmann et al. 1998) is advantageous in terms of feasibility of bypass anastomosis and perioperative graft function. Dilating agents (e.g. papaverine or nitroglycerine) can be applied as saturated sponge wrapped around the IMA or as a spray. When administrating these drugs intravascularly, meticulous care is necessary to avoid endothelial damage. Therefore insertions of metal probes or drug injections on a regular basis are not recommended. During harvesting a non-traumatic use of the electrocautery is manda-

■ Fig. 22.6 Takedown of the left internal mammary artery in tissue pedicle

■ Fig. 22.7 Incised left internal mammary artery

tory to prevent damage to the IMA (spasm, strictures) but also to the chest wall (carbonization, necroses). Before division of the distal IMA, heparin is administered systemically. The IMA is cut transversely or obliquely at the site for anastomosis and incised 4–8 mm (depending on the ratio of the graft and target vessel diameter) (■ Fig. 22.7).

There are several alternative methods to harvest a LIMA. One example is to leave the pleura intact (Bonacchi et al. 2001). Harvesting can be performed with classical instruments like scissors, forceps and hemostatic clips to close off arterial side branches. Dissection can be performed also with ultrasonic devices (Brose et al. 2002) to prevent damage due to thermal energy

(Yoshikai et al. 2004). To harvest the LIMA as a skeletonized graft without concomitant vessels and perivascular tissue presents another technique which differs in several aspects from the standard method (Canadas et al. 2005; ■ Fig. 22.8).

Harvesting starts with incision of the endothoracic fascia along the LIMA followed by encircling the conduit – a vessel loop may be passed around it. Thereafter takedown over the entire length is achieved by dividing the side branches with hemostatic clips. The main advantage of this technique consists of more available graft length and a preserved venous circulation left in place, which may improve conditions of wound healing. However skeletonizing may be associated with more traumas to the IMA due to the harvesting technique where a no-touch procurement is almost impossible.

Difficulties in harvesting are likely in patients with exostoses of the ribs, thoracic deformities, systemic rheumatic diseases and in post radiation or post thoracic trauma situations.

■ ■ Alternative Arterial Grafts

In addition to the LIMA, the right internal mammary artery (RIMA) can be used as another arterial graft (Lytle et al. 2004). The RIMA is prepared in the same manner as the LIMA conduit. Often the RIMA shows a bigger diameter and more length down to the bifurcation in comparison to the LIMA. Additional length, which may be

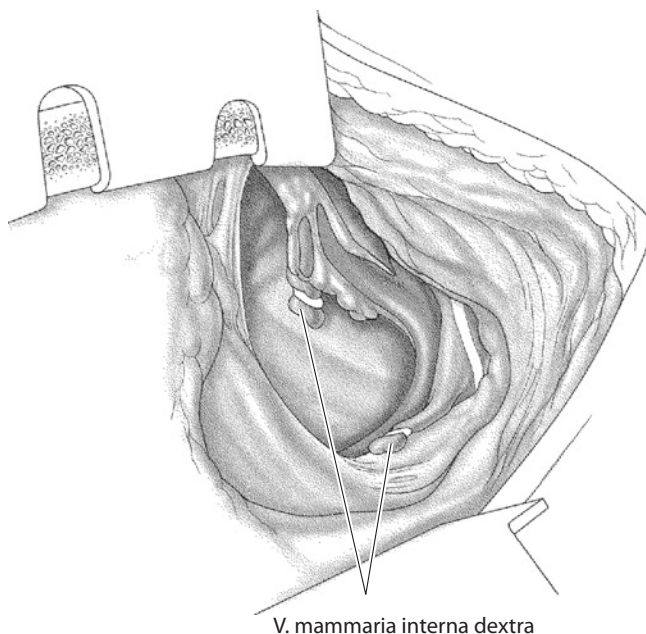

essential for the use of this graft, can be gained by dividing the proximal pedicle from mediastinal structures. This comprises division of the proxi-

A hemodynamically relevant stenosis of the proximal left subclavian artery is an absolute contraindication for utilization of the LIMA as conduit for coronary revascularization.

■ Fig. 22.8 Skeletonized left internal mammary artery

■ Fig. 22.9 Proximal dissection of the right internal mammary artery

mal mammalian vein and dissection of the parietal pleura up to the phrenic nerve (■ Fig. 22.9).

Bilateral preparation of the internal mammary artery principally leads to a diminished perfusion of the presternal tissue. This is clinically associated with an increased risk for superficial wound infections, dehiscence of the sternal edges, osteomyelitis of the sternum and/or mediastinitis (De Paulis et al. 2005). These detrimental side effects may be prevented if dissection is carried out with consideration to the tissue. Precise application of electrocautery and atraumatic handling of the sternum (sternum retractor) and the presternal tissue are crucial. Moreover, in our mind, the application of bone wax should be completely avoided in bilateral harvesting.

The use of the radial artery as conduit inaugurated in the early 1970s (Carpentier and Guernonprez 1973) was subsequently abandoned due to high rate of perioperative disorders like conduit spasms and early occlusion. Single long-term observations after 20 years showing competent radial grafts without signs of sclerosis lead to a renewed broad interest in utilization of radial artery in coronary bypass surgery (Acar et al. 1992). Before removal of the radial artery, an Allen's test must be performed to ensure collateral perfusion of the forearm and hand depending on a complete superficial palmar arch (Agrifoglio et al. 2005). If the test is positive or equivocal, ultrasonic or magnetic resonance imaging may be helpful (Rodriguez et al. 2001).

Open preparation usually performed at the non-dominant arm starts with skin incision at the wrist and proceeds to the elbow along the medial aspect of the brachioradialis muscle. After division of the subcutaneous tissue and the incision of the forearm fascia, the brachioradialis muscle is shifted aside to expose the whole course of the radial artery. Dissection starts at the wrist and the graft is removed together with the accompanying veins. Side branches are controlled by hemostatic clips or cautious use of electrocautery (■ Fig. 22.10). Alternatively ultrasonic devices can be used (Posacioglu et al. 1998). At any rate mechanical or thermal damage to the conduit has to be avoided. While the motoric nerve branches are deeper and distant to the area of dissection, the superficial branch of the radial nerve is more at risk for injury which may lead to sensible disorders. Dissection of the radial artery at the level of the carpal tunnel becomes more challenging due a great number of

■ Fig. 22.10 Removing a radial artery

side branches. Concerning the use of vasodilating agents and techniques, the same aspects apply as for IMA grafts. After removal under systemic heparinization, the graft should be immersed in a solution of blood, heparin and papaverine. To create additional length, the perivascular fascia can be removed. Concerning the function of radial grafts and their tendency to vascular spasm, it has been shown that optimal function and long-term patency can be achieved if the target vessels show sufficient diameters (>2 mm) and exhibit significant proximal obstructions (Maniar et al. 2002). In the presence of low runoff or significant competitive flow over the native vessel, spasm, early occlusion and string sign phenomena may occur. The applied technique of anastomosis does not differ from the way it is used in mammary artery grafts;

When compared to IMA grafts, the radial artery with its lamina muscularis and thinner lamina elastica interna more often tends to vasoconstriction and atherosclerotic alterations. Therefore one should be restrictive with its use in patients with diabetes or generalized atherosclerotic disease. The use of the radial artery is contraindicated in patients with insufficient collateral perfusion by the ulnar artery and in patients with terminal renal failure. In these patients the radial artery has to be preserved as a shunt vessel for dialysis.

■ Fig. 22.11 Proximal anastomosis of the radial artery as coronary conduit

however, the wall of the radial artery shows more thickness and stiffness. These wall qualities enable complex construction like sequential anastomosis, T and Y grafts as well proximal anastomosis to the ascending aorta (4 mm punch, 7-0 monofilament polypropylene suture; ■ Fig. 22.11). If atraumatic dissection was performed, there is no need for intravenous application of vasodilating agents.

The radial artery can be harvested endoscopically, also (Connolly et al. 2002) as it can be skeletonized (Rukosujew et al. 2004).

Utilization of other arterial grafts like the right gastroepiploic artery (Suma et al. 1987; Suma et al. 2007) and the inferior epigastric artery (Buche et al. 1995; Puig et al. 1990) was of growing interest at times. By extending the skin incision over the sternum and opening the peritoneum, the right gastroepiploic artery is exposed at the greater curvature of the stomach. After dissection as pedicle, the graft is passed into the pericardial cavity either anterior or posterior to the liver through an opening in the diaphragm. The right gastroepiploic artery can be anastomosed to distal branches of the right and circumflex artery or the distal LAD. Nevertheless the use of this graft is challenging and expands the operation into a thoraco-abdominal procedure. The inferior epigastric artery originates from the external iliac artery and can be harvested through or lateral to the rectus muscle. The available length is quite short and the distal diameter is small.

Because of the wide range of utility and the relatively ease of harvesting the radial artery, the use of the

right gastroepiploic artery and the inferior epigastric artery is rather limited. Due to the general availability of both IMAs as well as both radial arteries to be used as grafts, there is no real need to use arm veins, lesser saphenous veins or small calibre prostheses in modern coronary surgery (Laube et al. 2000), especially as their long-term prognosis is poor.

22.4.1.2 Techniques of Distal Anastomoses and Bypass Constructions

Anastomosing coronary artery bypass grafts is performed with the use of microinstruments and optical magnification with surgical loupes; rarely an operation microscope is necessary. There is a wide range of individual surgical techniques applied. Often the epicardium is incised over the target vessel for optimal exposure. The selected area of the artery should be free of atherosclerotic lesions, at least at the anterior wall. Cardioplegic arrest in combination with an aortic vent facilitates construction of the anastomosis. Alternatively this may be performed with the heart beating or fibrillating. For opening the coronary artery, special scalpels with a rounded blade are useful to avoid injuries to the posterior vessel wall. The incision usually should have a length of 5–10 mm depending on the size of the target vessel. The corresponding bypass graft is divided obliquely and may be incised at the heel. If the IMA graft shows a small calibre, it can be divided transversely before it is incised longitudinally. For the distal anastomosis of venous grafts, a running 7-0 polypropylene suture is employed (■ Fig. 22.12). It is advantageous to place the first stitches at the heel on distance and then to suture in direction towards the surgeon. Stitches in the coronary artery generally are placed from inside to outside, and suture ends should be tied at the lateral aspect of the anastomosis. For distal anastomosis of arterial grafts, we recommend using 8-0 polypropylene suture. A disturbing memory effect of the suture should be prevented by optimal handling.

For side-to-side anastomoses, the coronary artery is opened longitudinally while the bypass graft is opened perpendicular or longitudinally. The incision depends on the diameter of the target vessel and the bypass graft. The length of incision for parallel anastomoses, e.g. for diagonal branches, is less crucial (■ Fig. 22.13). On the contrary in perpendicular side-to-side anastomoses which result in a diamond-shaped opening, a rather long incision can result in a flattened anastomosis. For venous side-to-side anastomoses,

■ Fig. 22.12 Venous graft end-to-side anastomosis, distal anastomosis

■ Fig. 22.13 Pedicle internal mammary artery graft side-to-side anastomosis

the graft can be stretched between two fine nerve hooks; this is not advisable in arterial grafts. While venous anastomoses can be constructed obliquely, arteries should be connected parallel only as this is associated with better patency rates (Freshwater et al. 2006) (■ Fig. 22.14).

The course of a bypass graft has to be free of tension especially in between sequential anastomoses (■ Fig. 22.15). Using sequential techniques with arterial (Dion et al. 2000) and venous grafts (Christenson and Schmutzinger 1997), a complete revascularization can be achieved with good results by economization of graft material, also.

The use of veins with sclerotic and thickened wall and large diameter is associated with unfavorable result, in particular when grafted to small coronary arteries.

Proximal anastomoses at the ascending aorta can be performed during reperfusion with the help of side-biting clamps (■ Fig. 22.16). If the ascending aorta is significantly calcified, any manipulation has to be avoided, and the anastomosis should be constructed with the aorta cross-clamped despite a prolonged period of ischemia. For venous grafts predominantly 5 mm orifices are created with punches into the aortic wall, while 4 mm orifices are more suitable for arterial grafts. There are also punches with oval design available. For construction of the proximal anastomoses, 6-0 polypropylene suture is used for the veins, while we recommend 7-0 polypropylene for arterial grafts.

Especially in arterial revascularization, the creation of the so-called Y or T grafts is favorable: The radial artery or the RIMA is sutured in a right angle end-to-side (T graft) or as a Y graft more parallel/oblique to the proximal LIMA (Barner et al. 2001; Ochi et al. 2001; Yilmaz et al. 2002; ■ Fig. 22.17). These graft anastomoses can be constructed even before going on extracorporeal circulation. In this context the H graft (Cohn et al. 1998) and the λ graft (Egloff et al. 2002) may be mentioned, also, and can be looked up.

In obstructed coronary vessels with multiple stenoses, long anastomoses may be necessary, in which the bypass also acts as a functional patch plasty (Barra et al. 2000). This is technically less demanding than a coronary artery endarterectomy. For creation of proximal anastomoses, several devices are available, predominantly made out of nitinol, which allow the construction of venous (Eckstein et al. 2002; Mack et al. 2003) or arterial anastomoses (Watanabe et al. 2004) as single-shot technique without extracorporeal circulation. For several reasons, such automatic anastomotic techniques are not in wide use by

■ Fig. 22.14 Side-to-side anastomosis («diamond shape»)

■ Fig. 22.15 Sequential bypass free of tension

now; however, they are still of interest in patients with localized atherosclerosis of the aortic wall. For distal anastomoses, such automatic anastomotic devices are also available but amelioration of precision and patency rate in comparison to manually created anastomoses made them obsolete (Boening et al. 2005; Klima et al. 2003, 2004; Ono et al. 2002; Tozzi et al. 2002).

■ ■ Sequence of anastomoses (sequential grafts, single grafts)

A reasonable grafting sequence is to start with completion of the most distal, usually posterior anastomoses (e.g. right coronary artery or posterior descending artery) which are followed by

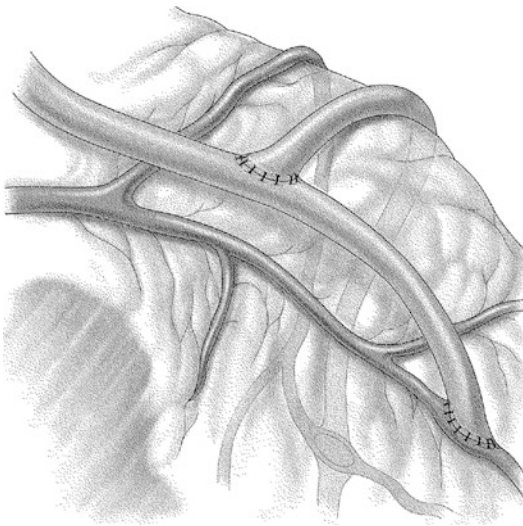

anastomoses to the sidewall and finally the completion of the most proximal, anterior anastomoses. However, in any case, it is useful to complete venous and radial artery grafts to the back- and sidewall before completing the in situ IMA grafts which are more susceptible to manipulations. The sequence of anastomoses during OPCAB procedures has its own principles.

In case of atherosclerotic alterations, it is more reasonable to shift to a more distal site of the target vessel despite a smaller diameter there. In this context it is highly questionable whether an IMA graft to a right coronary artery with multisite obstructions has a good prognosis. Whether sequential grafts really have superior flow profiles which are associated with better long-term results is thought of, but not proven to date. The advantage of using sequential graft is, however, that a considerable length of the vein is spared for possible future CABG or vascular reconstruction in concomitant atherosclerotic peripheral vascular disease.

The extended use of arterial grafts is well founded on the superior long-term perspective – at least for in situ IMA grafts. On the other hand, impaired quality of the venous graft to start with may force to consider alternatives. Selection of grafts has to take these aspects in account. Utilization of a radial graft is only reasonable and associated with a good functional perspective when anastomosed to a target vessel with adequate diameter and significant proximal stenosis. Because of its morphologic and functional properties, the IMA shows distinctly better long-term results than the radial artery when used as bypass graft (Khot et al. 2004; Ruengsakulrach et al. 1999). In consequence, revascularization with bilateral IMAs shows the best long-term results, especially when applied as in situ grafts. Aside from this the function and prognosis of a graft are

■ **Fig. 22.16** Technique of proximal anastomosis. **a** Punching of the side-clamped aorta. **b–c** Suture in running fashion starting at the graft's heel. **d** Parachuting of the graft. **e** Completion of the anastomosis

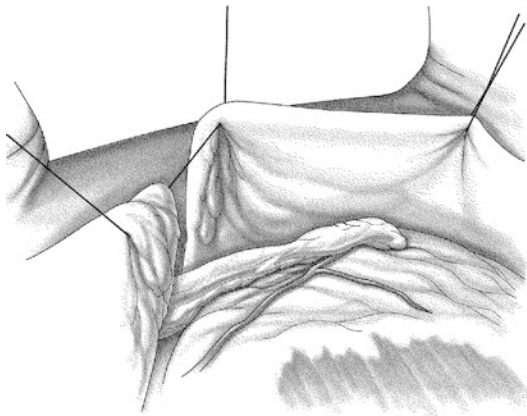

■ **Fig. 22.17** T graft: Radial artery end-to-side anastomosed to left internal mammary artery

influenced by its intrathoracic course and the quality of the target vessel. IMA conduits used as free grafts have an inferior long-term prognosis than in situ IMA grafts despite comparable inflow situations. Solely utilized T- or Y-graft constructions are technically feasible with good results; however, they are associated with additional risks

as the entire coronary perfusion may originate from one source graft, e.g. the LIMA. In most cases bilateral in situ IMA grafting provides the best long-term results. If the anatomy is suitable, a sequential LIMA can be anastomosed to the first diagonal branch and to the LAD. The RIMA should serve the second most important myocardial area. If an in situ IMA bypass crosses the mediastinum (e.g. RIMA graft to LAD), it may be under tension and is at risk in case of cardiac reoperations (e.g. valve replacement).

A prerequisite for complete arterial revascularization employing the radial artery is an adequate runoff without previous infarction and a target vessel with a diameter of >2 mm. Otherwise concepts with venous grafts are preferable. Overall arterial revascularization offers a wide variety of possibilities; the above-mentioned remarks aim to describe the basic principles of this operative strategy. Positioning of the graft should consider a tension-free and harmonic course and also should bear possibly reoperations in mind. Measures to prevent adhesions between bypasses and the sternum and the thoracic wall, respectively, like positioning the grafts in pericardial clefts or covering them with mediastinal fat tissue, are of paramount importance (■ Fig. 22.18).

■ Fig. 22.18 Pericardial cleft

22.4.2 Beating-Heart Revascularization

With the advent of emerging technical innovations, there is increasing interest in beating-heart procedures without the use of extracorporeal circulation. Thereby the OPCAB technique (20.4.2.1) as a more conventional approach to multi-vessel disease including sternotomy has to be distinguished from the MIDCAB concept (20.4.2.2). The MIDCAB concept mainly aims to bypass the LAD with a LIMA graft via an anterolateral mini-thoracotomy.

22.4.2.1 OPCAB (Off Pump Coronary Artery Bypass) Technique

Ideally beating-heart revascularization combines complete stabilization with optimal exposure of the target area. Several devices using suction or mechanical pressure for stabilization are available to perform a precise anastomosis (Lemm et al. 2005; Scott et al. 2002). Exposure of the lateral and back wall is achieved by elevation and displacement of the heart, which requires several maneuvers to preserve hemodynamic stability.

Displacement of the heart and exposure of the lateral and back wall can be achieved by deeply placed pericardial traction sutures and suction devices positioned at the cardiac apex which should result in satisfying exposure (Gründemann et al. 2004). Hemodynamic stability has to be further preserved by various measures like volume management, pharmacologic support and placing of the patient or if necessary by temporary pacing (Kwak 2005). Usually hemodynamic monitoring should be completed by trans-esophageal echocardiography and extended ECG monitoring

■ Fig. 22.19 Suction stabilizer for OPCAB (off-pump coronary artery bypass)

because of possible ischemic events during anastomosis (■ Fig. 22.19).

When coronary arteries without adequate collateral vessels are temporarily occluded intraoperatively to obtain good working conditions, ischemic episodes may occur (Wippermann et al. 2004). By using intracoronary shunts, continuous coronary perfusion can be maintained (Rivetti and Gandra 1997). However, the manipulation necessary to place these shunts can lead to injuries of the endothelium, and, in addition, performance of the anastomosis may be more demanding. Exposure of the target vessel can be improved with a blowing device that removes blood from the anastomotic site by dispersion of humidified carbon dioxide. In general, OPCAB technique allows for obtaining complete revascularization (Jansen et al. 1998). In case of small target vessels, significant atherosclerotic changes or intramyocardial course of coronary vessels, however, performance of anastomoses is distinctly more challenging when compared to cardioplegic arrest. Moreover there are limitations to create tension-free in situ IMA grafts on the beating, dislocated and volume-loaded heart. This scenario often requires additional length of the graft. Nevertheless concepts with extended or complete arterial revascularization are feasible (Mariani et al. 2004).

With regard to the sequence of anastomoses, many surgeons prefer initial revascularization of the LAD assuming that an ameliorated perfusion of the anterior wall will stabilize subsequent hemodynamics during further manipulation.

Single-center experiences as well as meta-analyses failed to prove prolonged advantage in comparison to conventional bypass surgery (Feng et al. 2009; Shroyer et al. 2009). Nevertheless the significance of OPCAB procedures differs between

■ **Fig. 22.20** Left anterolateral mini-thoracotomy

nations; in Germany beating-heart operations comprises 10% of all isolated coronary bypass operations. Superior results are thought to be most likely in patients with pre-existing neurological diseases, advanced renal dysfunction or in the presence of severe atherosclerosis of the ascending aorta. Especially in combination with T graft and Y graft, OPCAB allows a complete no-touch technique of the ascending aorta. Nevertheless OPCAB is not necessarily associated with superior results in terms of intraoperative blood loss, perioperative myocardial infarction or duration of intensive care stay.

22.4.2.2 MIDCAB (Minimally Invasive Direct Coronary Artery Bypass)

The prime object of MIDCAB is a beating-heart anastomosis between the LIMA as in situ bypass to the LAD. After its inauguration in the late 1960s, it took 30 years to reintroduce this concept into the spectrum of surgical revascularization due to lack of sufficient devices to perform beating-heart surgery safely.

In the original concept, the surgical access consists of a small left anterior thoracotomy in the fifth intercostal space (Cremer et al. 2000; ■ Fig. 22.20). Occasionally a lower partial sternotomy is also designated as MIDCAB. Harvesting of the LIMA with the help of electrocautery is the method of choice with this limited access. Modified grabbing handles (extra long) and specified tips of the electrocautery are useful in this setting. A thoracic wall tilting retractor that spreads the ribs vertically is helpful in order to reach the proximal parts of the LIMA (■ Fig. 22.21). Creating a pedicled graft with adequate length that guarantees a tension-free bypass is more important than complete division of all side branches.

■ **Fig. 22.21** Lifting retractor in MIDCAB (minimally invasive direct coronary artery bypass)

In many cases it is advisable to harvest the LIMA prior to opening of the pericardium to create clarity in the surgical field. If the quality of the target vessels is in doubt, an initial exposure of the anterior wall for inspection may be reasonable.

Some centers prefer to harvest the LIMA endoscopically followed by performing the distal anastomosis via the mini-thoracotomy.

Administration of 100 IU/kg body weight of unfractionated heparin is sufficient to perform a MIDCAB procedure. After immobilization of the target area using stabilizing devices, tolerance of the myocardium against ischemia is tested by temporarily occluding the LAD. Myocardial preconditioning is achieved by short periods of reperfusion, which should improve the myocardial tolerance against ischemia (Halkos et al. 2004). In addition the use of intracoronary shunts may be helpful in MIDCAB procedures (Menon et al. 2002). To achieve high quality comparable to conventional CABG, the anastomosis is created with running 8-0 monofilament polypropylene suture. Because of the limited access, it is advisable to place the LIMA with stay sutures across from the target area to perform the first stitches in distance (■ Fig. 22.22). Following completion of the anastomosis, fixation of the pedicles' course with the help of stay sutures or fibrin glue is advisable. It is recommended to cover the distal pedicle with local mediastinal fat tissue to prevent adhesions

■ **Fig. 22.22** Performing the anastomosis in MIDCAB technique (minimally invasive direct coronary artery bypass)

between the LIMA graft and the thoracic wall. Provided that freedom of pain and normothermia are established, in the majority of cases, the patients can be extubated in the operating room.

In experienced hands the MIDCAB operation provides absolute excellent long-term patency of the LIMA grafts with respective good outcome (Oliveira et al. 2002). In patients with multi-vessel disease and existing risks for conventional or beating-heart bypass surgery, a hybrid concept combining MIDCAB revascularization of the anterior wall and interventional treatment (PCI) of other cardiac regions may be attractive (Cisowski et al. 2002; Murphy et al. 2004; Holzhey et al. 2008).

22.4.3 CABG Reoperations

A second CABG procedure may be necessary when either due to degeneration of venous grafts, leading to significant bypass stenoses, or due to progression of CAD bypass occlusion occurs. In comparison to the initial procedure, patients not only are 10–15 years older, the situation quite often is even more complicated by progressive diffuse CAD, reduced left ventricular function and further comorbidities related to age and ongoing systemic atherosclerosis. Several aspects that separate reoperation from primary procedures have to be taken into consideration. Nowadays, in general, sufficient bypass graft material is available since in most cases just venous grafts or sometimes only a combination with a LIMA-LAD graft

had been utilized before. Often one greater saphenous vein, the radial arteries and the RIMA are available for complete revascularization in a second or even in a third procedure.

Before median re-sternotomy, the existence of patent bypass grafts crossing immediately behind the sternum has to be ruled out preoperatively. Especially patent LIMA grafts to the LAD are of importance, which may stick proximally to the thoracic wall and may curve to the right side. In this context a high-resolution CT scan is valuable since it provides information about the bypass course and the ascending aorta (Cremer et al. 1998). Adhesions of the aorta to the sternum and significant calcification of the ascending aorta and the aortic arch can be evaluated in this way, also. The findings may have implications for the operative strategy in terms of cannulation and clamping of the aorta as well as the site of proximal anastomoses. In some cases before re-sternotomy, femoral cannulation for extracorporeal circulation may be chosen.

If sternotomy seems to be not associated with elevated risk, no additional precautions have to be taken. After removal of retrosternal adhesions, the RIMA is harvested if needed in addition to venous grafts. This is followed by exposure of the ascending aorta, respectively, the aortic arch (optional mobilization of the innominate vein), to ensure safe and expeditious arterial cannulation in case of significant bleeding. The diaphragmatic aspect of the right ventricle offers in most cases a convenient re-entry into the pericardial cavity. Caution is required in the presence of bypasses running around the right-sided cardiac chambers. In comparison to a ventral approach, this preparation facilitates the access to the right atrium, which allows immediate initiation of extracorporeal circulation if necessary. Any manipulation of degenerated bypass grafts has to be avoided to prevent peripheral embolization of atherosclerotic or thrombotic material into the coronary artery periphery (this is also true in occluded bypass grafts). The ascending aorta should be exposed in a way that enables cross-clamping and provides space for proximal bypass anastomoses. In case of patent IMA graft, its localized exposure is mandatory to place a non-traumatic bulldog to stop bypass flow. Dissection of the posterolateral aspects of the heart is recommended to be performed once extracorporeal circulation is established; appliance of cardioplegic arrest and venting of the heart may be of additional help.

If in severe CAD, antegrade coronary perfusion is compromised (especially in cases with patent

LIMA bypass which is temporary occluded during ischemia), retrograde application of cardioplegic solution via a coronary sinus catheter is recommended (Fazel et al. 2004). In reoperations, identification of coronary arteries can be highly demanding. The proximal anastomoses of the primary operation may serve as reference point to find the distal native coronary vessel. Moreover valuable information can be provided by earlier angiograms performed when the old bypass grafts were still patent. The technique of distal anastomoses and the choice of target vessels follow the same principles as in conventional primary bypass surgery. In case of a problematic ascending aorta or limited space at the ascending aorta, the proximal new bypass graft anastomoses can be performed to the previous grafts sites. In selected cases a patent LIMA can serve as inflow for the newly created bypasses.

22.4.4 Coronary Artery Endarterectomy

Indication for surgical coronary endarterectomy (Marinelli et al. 2002) should be handled very restrictively because the procedure is associated with an increased morbidity and mortality rate. Only if reasonable bypass construction seems to be impossible as the entire target artery is completely calcified and vital myocardium requires revascularization, endarterectomy should be taken into account (■ Fig. 22.23).

Endarterectomy is performed by generous incision of the coronary artery with following removal of the plaque with the help of a dissector. Alternatively the coronary vessel can be opened with two shorter incisions, and plaque is removed by careful traction from the proximal incision after some dissection. The coronary artery may be either reconstructed with a separate autologous vein patch, which is anastomosed to a venous bypass graft, or the created opening is covered and enlarged with a broad anastomosis leading directly into the venous bypass graft.

22.4.5 Ostial Coronary Patch Plasty

Isolated, discrete ostial stenoses of the left or right coronary artery can be surgically treated by ostial patch plasty. During cardioplegic arrest, the ostium of the effected coronary vessel is exposed via aortotomy. The coronary artery is longitudinally opened from the lesion up to the normal

■ Fig. 22.23 a, b Coronary artery endarterectomy

aortic wall. The opening created is then closed with an enlarging oval patch either made of vein, RIMA (Liska et al. 1999), pericardium or synthetic material.

In today's routine such like procedure did become extremely rare, due to obvious reasons:

- Isolated ostial stenosis of the right coronary artery is usually treated by catheter intervention.
- Isolated proximal stenosis of the left main stem is a clear and proven indication for surgical treatment. Since surgical patch plasty of the left coronary ostium is technically complex and demanding, rather conventional peripheral bypass graft revascularization for the LAD and the circumflex artery is performed, as almost always suitable target vessels are available.

22.4.6 Surgery of Coronary Aneurysms

In adult patients coronary aneurysms can reach a diameter up to 15 cm (Mawatari et al. 2000). An existing coronary aneurysm bears the risk of

spontaneous rupture or embolization of thrombus material causing an indication for operation.

There are different techniques for surgical treatment. The aneurysm's in- and outflow vessel can be ligated with subsequent distal coronary bypass; however, techniques preserving the vessel are feasible, also. After resection of the aneurysm, an end-to-end anastomosis can be performed (Westaby et al. 1999). In cases where this is not possible due to the resulting distance between the two vessels ends, a vein segment can be interposed (Firstenberg et al. 2000) (see also ► Chapter «Congenital Anomalies of the Coronary Arteries and Coronary Diseases in Children and Adolescents», Sect. 20.8).

22.4.7 Coronary Revascularization and Atherosclerotic Ascending Aorta

The presence of significant atherosclerosis of the ascending aorta demands changes of the routine surgical procedure especially to prevent cerebral complication due to embolization of plaque material. In many cases the atherosclerosis is preoperatively known because of the findings in the chest x-ray, the angiogram or a thoracic CT scan. If ascending aortic wall atherosclerosis is an accidental intraoperative finding, an epiaortic ultrasound or trans-esophageal echocardiography may be helpful to judge the importance of calcification actually present.

The following measures are helpful in order to reduce manipulation of the calcified aorta, thereby reducing the risk of embolization to a minimum («no-touch philosophy»):

- In operations with extracorporeal circulation, the aortic cannula should be placed in the proximal arch or the right subclavian artery. Clamping of the aorta can be avoided by temporary hypothermic cardiac arrest and retrograde application of cardioplegia.
- Alternatively the procedure can be performed with the heart fibrillating in normothermia or moderate hypothermia (Beyersdorf et al. 1990); however, this technique is associated with limited exposure of the target vessels.
- The use of OPCAB technique avoids the risks of inserting cannulas in this setting. Depending on the pattern of atherosclerotic lesions, any aortic anastomosis can be

avoided by the use of in situ IMA grafts in combination with T or Y grafts.

22.5 Significance of Coronary Surgery and Current Studies and Analyses

As an example for Western Europe, CABG data from Germany are described. To date around 50,000 cases of isolated coronary surgery are performed in Germany annually, with a 30-day mortality of <3%. These numbers comprise all patients, including those with significant risk factors like poor left ventricular function, acute myocardial infarction or redo bypass surgery. Around 10% of coronary procedures are performed under beating-heart conditions without extracorporeal circulation (MIDCAB/OPCAB). The mean age for all patients is 67.4 years with more than 10% being 80 years and older. On average 3.1, distal anastomoses are constructed utilizing a LIMA graft in 92.3% of cases.

In the United States, the proportions are comparable. Within the last decade, around 1.5 million patients underwent isolated CABG according to the registry of the Society of Thoracic Surgeons (STS). The postoperative mortality rate declined to 1.9% in 2009. The LIMA is used 95% of cases (ElBardissi et al. 2012).

The Synergy between PCI with Taxus and Cardiac Surgery (SYNTAX) trial is a randomized prospective study, comparing CABG and PCI in 1,800 patients with three-vessel disease and/or left main stenosis. For these patients, it demonstrated a significant superiority of bypass surgery concerning the primary end point (rate of major adverse cardiac and cerebrovascular events; Serruys et al. 2009). In the meantime the 3-year results of the SYNTAX trial are available which confirm the original results (Kappetein et al. 2011). This was the first major multicenter randomized trial that compares CABG and PCI in the drug eluting stent era in patients with triple-vessel disease. Former studies like the Arterial Revascularization Therapy Study (ARTS trial, Serruys et al. 2005) and the Stent or Surgery trial (SOS trial, Stables et al. 2002) compared CABG to PCI with bare-metal stents. The long-term results of the SYNTAX trial demonstrate impressively that with a growing complexity of coronary lesions (quantified by the Syntax Score), surgery leads to a significant survival ben-

efit apart from lower incidence of myocardial infarctions, revascularization and recurrent angina pectoris. Latest analyses of major registries prove concordantly with risk adjustment a survival benefit for surgical treated patients with triple-vessel disease (Hannan et al. 2005, 2008).

Current interdisciplinary European (Task Force and Kolh et al. 2010) and North American (Kushner et al. 2009) guidelines particularly take the results of the SYNTAX trial into account. Aside from recommendations for revascularization, it is unmistakably declared that an individual therapeutic strategy has to be developed in a formal heart team. This should result in an optimal therapy for every individual patient and avoid the use of PCI when there is clear recommendation for surgical treatment (Hannan et al. 2010). If these guidelines will be followed, coronary bypass surgery will be of paramount importance in industrial nations as demographic changes with an aging population will lead to a growing number of patients with complex coronary findings. They may be due just to advanced age, but also due to previous catheter interventions and/or surgery. Consequently the overuse of PCI may be limited.

23.1 Introduction: Results of Medical Therapy

In more than 60 % of all patients with terminal heart failure, the underlying cause is coronary heart disease (CHD). The majority of these patients have had previous myocardial infarction (Gheorghiadé and Bonow 1998). End-stage congestive heart failure (NYHA IV) is a life-threatening disease: One-year survival is around 40–50 % only, and this is worse than life expectancy for most patients with malignancies.

The options for medical therapy in patients with terminal heart failure have improved tremendously in recent years. The overall results, however, are still unfavorable, as shown in several studies. Angiotensin-converting enzyme (ACE) inhibitors were shown to prolong the survival of patients in NYHA IV heart failure; however, mortality at the end of the first year was still 36 % (The CONSENSUS Trial Study Group 1987). The COPERNICUS study revealed advantageous outcome, when adding carvedilol, a β -blocker with additional α -blocking and vasodilating effects, to ACE inhibitor therapy: Patients with a left ventricular ejection fraction (LVEF) of less than 25 % had an improved survival after 28 months of 72 % compared to 58 % in the placebo group (Packer et al. 2001).

A disadvantage of several studies evaluating medical therapy of chronic heart failure is the fact that only a few or sometimes even no patients in NYHA IV were enrolled, like in the CARMEN study where 60–70 % of patients were in NYHA II; however, there were no patients in NYHA IV (Remme 2003) or in the RALES where even no data about the NYHA classes at the beginning of the study were presented (Pitt et al. 1999).

Therefore, optimal heart failure treatment usually is maintained for end-stage heart failure with the medication that was studied for the less sick patients. Basically, all patients receive a combination of ACE-inhibitors with beta-blockers as studied extensively in studies such as the CONSENSUS, COPERNICUS or CARMEN trial (Packer et al. 2001; Komajda et al. 2004; The Consensus Trial Study Group 1987). Also, the addition of Aldactone to loop diuretics in medical treatment is beneficial for patients with congestive heart failure as shown in the RALES trial (The RALES Investigators 1996). Despite optimal medical therapy, several patients' left ventricular remodeling leads to severe heart failure, and only surgical strategies can

restore left ventricular geometry (Jones 2001; Athanasuleas et al. 2004).

Therefore, surgical procedures are extremely important in the treatment of severe heart failure.

23.2 Surgical Reconstruction of Dilated Ischemic Left Ventricle

23.2.1 Pathogenesis of Left Ventricular Remodeling After Myocardial Infarction

Coronary heart disease is responsible for the development of terminal heart failure in two thirds of patients. Most of these patients have suffered from acute myocardial infarction (Gheorghiadé and Bonow 1998). Despite earlier revascularization, patients develop left ventricular dilatation in 20 % of cases. In these patients, this dilatation may lead to terminal heart failure (Gaudron et al. 1993). The remote, non-infarcted myocardium changes its volume and shape – a process known as «ventricular remodeling». With progressive dilatation of the left ventricle, the normal elliptical shape takes on a more spherical one. Global left ventricular ejection fraction decreases, eventually resulting in terminal heart failure (Sallin 1969). Secondary to dilatation of the left ventricular (remodeling), wall tension also increases in those regions of the left ventricle that have not suffered from acute infarction. The increased wall tension leads to elevated oxygen consumption of the myocardium, reduced sub-endocardial blood flow and diminished systolic shortening. On a molecular level, apoptosis of myocytes is the cause of ventricular remodeling (Baldi et al. 2002; Narula et al. 1996; Olivetti et al. 1997). This increased apoptosis is regarded a result of rising wall tension, and therefore, remodeling can be seen as a vicious circle (*circulus vitiosus*). While in the beginning apoptosis is primarily seen in regions adjacent to acute infarction, after weeks or months apoptotic myocardial cells can also be observed in remote areas, originally not involved in the acute myocardial infarction process.

Therefore, surgical left ventricular reconstruction aims at reducing wall tension to allow for

improved contractility of the remote, non-infarcted myocardium.

23.2.2 Prognosis

In follow-up, approximately 20% of patients with acute myocardial infarction show progressive dilatation of the left ventricle months and years later (Gaudron et al. 1993). The prognosis for patients with ischemic cardiomyopathy depends more on left ventricular volume and less on left ventricular ejection fraction (White et al. 1987). In 1987, White and co-workers demonstrated that the mortality rate after myocardial infarction was directly related to the size of the left ventricle (left ventricular end-systolic volume). In the GUSTO-I trial, it was shown that a left ventricular end-systolic volume index (LVESVI) of more than 40 ml/m² following myocardial infarction was associated with a high incidence of heart failure and reduced long-term survival (Migrino et al. 1997).

23.2.3 Dyskinesia (Aneurysm) Versus Akinesia

After acute coronary occlusion, necrosis of the dependent myocardium advances as a wavefront from the endocardium to the epicardium (Reimer and Jennings 1979). Early reperfusion after acute coronary occlusion (percutaneous coronary intervention (PCI) or coronary lysis) may be able to salvage some of the epicardial muscle and therefore prevent the development of a full-thickness necrosis, which would lead to a thin-walled dyskinetic aneurysm. The reperfused myocardium may retain a certain wall thickness and even normal epicardial muscle layers. The result is an akinetic segment with different grades of mid-myocardial and epicardial fibrosis. However, akinetic ventricles develop ventricular remodeling of the remote myocardium, also (see above ► Sect. 23.2.1). Therefore, from a functional standpoint, akinetic and dyskinetic areas can be considered identical. Currently, immediate reperfusion techniques are used in the majority of patients with acute myocardial infarction, and therefore akinetic areas are more often seen than classic aneurysms (dyskinesia).

It was Vincent Dor who first noted that akinesia and dyskinesia led to the same remodeling

process of the non-infarcted myocardium. He developed the «endocardial patch plasty procedure» for surgical reconstruction of akinetic and dyskinetic areas (DiDonato et al. 1997; Dor 1997, 2011).

23.2.4 Diagnostics and Indications for Left Ventricular Reconstruction

The majority of patients, who undergo left ventricular reconstruction, also require myocardial revascularization and/or reconstructive mitral valve surgery. In case of anterior wall infarction, revascularization should include the left anterior descending (LAD) coronary artery to improve perfusion and function of the interventricular septum.

Most patients scheduled for left ventricular reconstruction surgery have an anterior-septal scar with both progressive left ventricular dilatation and reduction in left ventricular ejection fraction. Clinically they experience symptoms of heart failure. In rare cases, they also may have additional scars in the lateral or posterior wall of the left ventricle. In larger studies, most patients enrolled presented with left ventricular aneurysms (60–70%), while the remaining displayed akinetic areas with progressive left ventricular dilatation.

Presurgical diagnostic procedures should comprise the following:

- Coronary angiography
- Left ventricular angiography
- Transesophageal echocardiography (two- or three-dimensional)
- Magnetic resonance imaging (MRI) including «late enhancement» to assess myocardial viability and the extent of myocardial scars

With those procedures, the following data should be obtained:

- Status of the coronary arteries
- Function of the heart valves
- Viability of the remote myocardium
- Extent of the scarring process («asynergy scar» in comparison to the remaining left ventricle (left ventricular circumference) (in %))
- Akinesia vs. dyskinesia (aneurysm)
- Left ventricular ejection fraction (LVEF; in %)
- Left ventricular end-diastolic diameter (LVEDD; in mm)

- Left ventricular end-systolic diameter (LVESD); in mm)
- Left ventricular end-diastolic volume index (LVEDVI; in ml/m²)
- Left ventricular end-systolic volume index (LVESVI; in ml/m²)
- Existence or absence of thrombi within the left ventricular cavity

The degree of the asynergy of the left ventricle can be measured using different methods:

- Ventriculography (centerline method in RAO projection)
- Echocardiography
- Radionuclide ventriculography
- Multislice computed tomography
- Magnetic resonance imaging

A general rule can thus be stated. Left ventricular reconstruction is indicated when:

- Approximately 35–40% of the left ventricle circumference is asynergetic.
- LVESVI > 60 ml/m².
- LVEF < 35%.
- The patient has symptoms according to NYHA classes II or III.

Patients in cardiogenic shock (intra-aortic balloon counter pulsation, cardiac index <2 l/min/m², inotropes, pulmonary hypertension, poor peripheral perfusion) are not candidates for a left ventricular reconstruction procedure.

23.2.5 Surgical Technique

Surgery can address all three components responsible for the development of heart failure:

- Ventricle
- Coronary arteries
- Heart valves

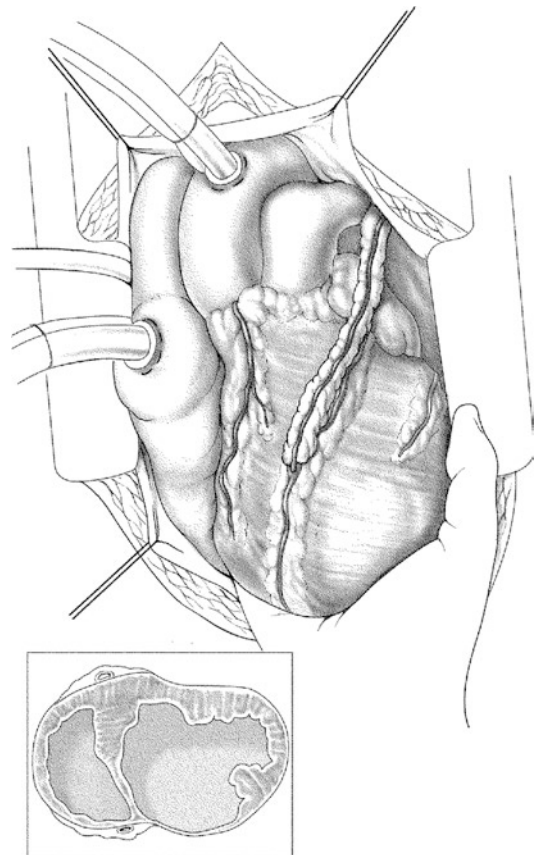

Preoperative workup (see above ► Sect. 23.2.4) determines if only one component, two or all three need to be surgically treated.

During surgery, transesophageal echocardiography should be continuously available. A preoperative examination is of utmost importance in order to detect intraventricular thrombi, which are present in approximately 30% of patients.

If thrombotic material can be seen in cavities of any heart chamber, the heart must not be manipulated until the aorta has been cross clamped.

After median sternotomy, the heart may have to be dissected from pericardial adhesions, which develop secondary to myocardial infarction. The type of venous cannulation depends on whether a simultaneous repair of the mitral valve is required (two-stage cannula or separate cannulation of the superior and inferior vena cava). A left ventricular vent is introduced via the right upper pulmonary vein or the interatrial groove (■ Fig. 23.1).

Surgery can be performed with the heart beating or with an arrested heart using cardioplegia. In both instances, we use a left ventricular vent. If mitral valve procedures are necessary, antegrade followed by retrograde cold blood cardioplegia is used. Required coronary revascularization and mitral

■ Fig. 23.1 Cannulation of the heart

valve procedures are completed before left ventricular reconstruction is performed. Left ventricular reconstruction can be carried out on the beating heart or with aorta cross clamped using cardioplegia. The advantage of the beating heart technique is the chance to palpate a border between scarred and viable myocardium between the thumb and the index finger to delineate the area of resection. In addition continuous coronary perfusion and the heart beating may provide better myocardial protection for the right ventricle, especially in patients with pulmonary hypertension. We prefer to perform left ventricular reconstruction on the beating heart and use cardioplegia for mitral revascularization and mitral valve reconstructions. An exception to this strategy applies to patients with left ventricular thrombi, in whom left ventricular reconstruction has to be accomplished using aortic clamping.

In patients with mitral valve regurgitation grade II–III, surgical reconstruction is done as the first step. The techniques employed are the same as in all other mitral valve procedures. In our practice, the Alfieri stitch applied from the ventricular side is rarely used.

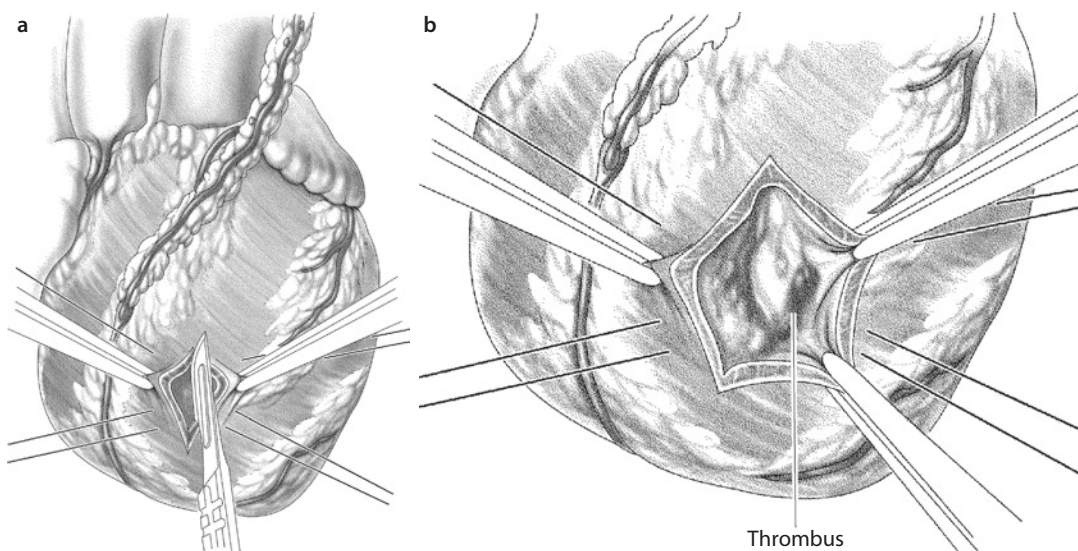

In the majority of cases (more than 80%), coronary revascularization of the left anterior descending coronary artery is performed using the internal mammary artery, especially in patients with anterior myocardial infarction in order to achieve revascularization of the septum as well as the adjacent areas of the myocardial infarction. If there are stenoses of

other coronary arteries, these will also be revascularized (right or circumflex coronary artery).

Thereafter, the apex of the left ventricle is exposed using two to three large sponges or a towel to elevate it out of the pericardium. Once the left ventricle has been evacuated by the vent, the scarred area can be easily identified. The flaccid scar area, which usually lies lateral to the left anterior descending coronary artery, is then incised (■ Fig. 23.2a). After a small first incision is done, the extent of the scarred tissue is palpated manually. With this technique, the border between contractile and non-contractile myocardium can be detected very easily. Using a pair of scissors, the incision is now enlarged, where necessary. This border between viable and non-viable myocardium has very clearly been identified in order to know where the purse-string suture (Fontan suture) should be placed (■ Fig. 23.2a, b).

After the left ventricle has been incised, it is opened using clamps (Mikulicz clamp) or pledgeted sutures. If thrombotic material is present, this has to be carefully and completely removed (■ Fig. 23.2b).

Thereafter, a purse-string suture (Fontan suture) at the border between viable and non-viable myocardium is carried out. A suture is started in the periphery at the left ventricular apex using a 2/0 polypropylene suture with a big needle. This purse-string suture continues via the lateral wall and the inner surface of the anterior wall, to the septum and finally back to the apex of the

■ Fig. 23.2 a, b. Elevation of left ventricular apex using pads and incision in the scar of the left ventricle lateral to the left anterior descending coronary artery with a scalpel a; thrombotic material in the cavity of the left ventricle b

■ **Fig. 23.3** Purse-string suture within the scar at the border between vital and nonvital myocardium (Fontan suture)

left ventricle. The suture is tied using Teflon felt pledgets to avoid its tearing (■ Fig. 23.3). In the majority of patients with an old infarction, this line for the purse-string suture can be located easily. In patients with chronic transmural aneurysms, almost no trabeculations are found within the ventricle, which makes purse-string suturing very simple. Conversely, trabeculations may still be present in patients with akinetic areas or more recent myocardial infarctions, rendering it slightly more difficult to put the purse-string sutures into place. Purse-string sutures have to be placed deep in the myocardial wall. However, the perforation of the left ventricular wall with the suture line should be avoided under all circumstances.

It is important to avoid transmural stitches when carrying out the purse-string suture. These transmural stitches may lead to localized ruptures and bleeding, once the purse-string sutures are tied.

■ **Fig. 23.4** One purse-string suture and three U-sutures finally reconstruct and occlude the LV defect and create a new left ventricular Apex

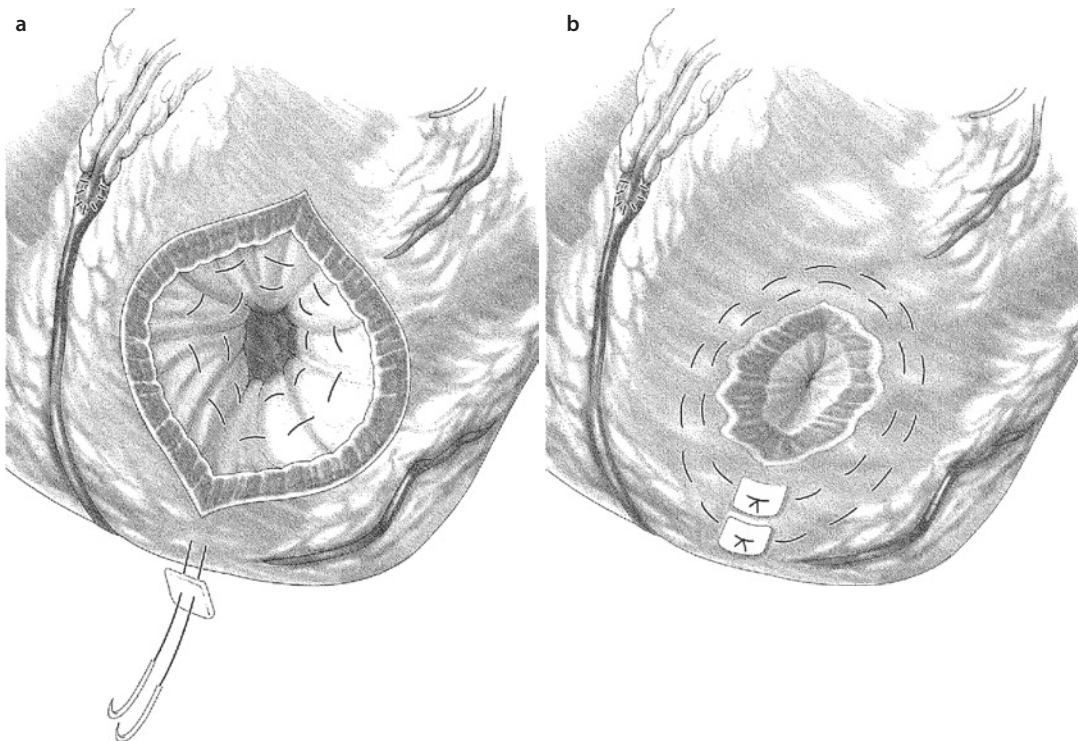

Such operations would be significantly more difficult in patients with acute myocardial infarctions. In these patients, the suture may not stay within the rather friable non-scar tissue. Therefore the technique of left ventricular reconstruction described in this chapter is contraindicated in patients with acute myocardial infarction (less than 3–6 weeks).

By using the purse-string suture, the infarcted tissue is isolated from the contracting myocardium. The size of the remaining left ventricular cavity should be more than 100 ml. In order to measure the remaining volume of the left ventricle, some surgeons use a sterilized balloon filled with 100 ml of crystalloid solution (e.g. normal saline solution). Some surgeons even use a metallic olive with the appropriate volume. This technique can only be used on a cardioplegic heart or the balloon will be ejected from the beating heart. In addition to these measures, it is important to know the preoperative volumes of the ventricles to estimate the required degree of reduction.

In patients with severe ventricular arrhythmias, an ablation using cryo- or radio- techniques can be performed at the border between vital and

■ **Fig. 23.5** Schematic drawings of the normal elliptical shape of the heart (*left*), the spherical shape of the dilated heart after anterior-septal myocardial infarction (*middle*) and the reconstructed elliptical configuration after left ventricular reconstruction (*right*)

■ **Fig. 23.6** **a** After the second purse-string suture has been tied, **b** the remaining myocardial opening in the left ventricle in most cases is less than 1–2 cm in size.

nonvital myocardium. Prophylactic or secondary implantation of a defibrillator is rarely necessary.

After the purse-string suture has been tied, most often the myocardium of the left ventricle is already closed. If an opening remains, which is less than 1–1.5 cm in diameter, further direct closure is possible: Three U-stitches (polypropylene sutures) can be positioned at an angle of 60° to each other (■ Fig. 23.4). They occlude the remaining myocar-

dial opening effectively and create a new left ventricular apex. Using these techniques, the left ventricle will regain its elliptical shape (■ Fig. 23.5).

If the first purse-string suture does not completely occlude the left ventricular myocardial defect, a second purse-string suture can be carried out above the first one (■ Fig. 23.6). With these double-layer purse-string sutures, the opening almost always can be occluded.

The last step of the procedure is the closure of the epicardium over the newly created left ventricular apex. Reinforced with Teflon felt strips, a 2/0 polypropylene suture with a big needle may be used, if necessary. First, a mattress suture is carried out and then, a running suture is laid over it. Any injury or occlusion of the left anterior descending coronary artery must be avoided.

Careful deairing has to be performed before the ventriculotomy is definitely closed. We flood the operative field with CO₂, assuming an advantage in reducing the risk of air embolism. The left ventricular vent has to be stopped before the epicardium is finally closed. We employ transesophageal echocardiography to monitor the presence of any residual air or CO₂.

As mentioned before, a patch for final closure is not necessary in all patients. However, there are certain patient groups who always require a patch for ventricular closure. These include patients with:

- Calcified left ventricular aneurysms, in which a purse-string suture is unable to sufficiently reduce the remaining opening of the left ventricle.
- Huge dilated left ventricles, in which the purse-string suture is also unable to sufficiently reduce the opening (rare).
- Left ventricular volumes after reconstruction that are seemingly too small (<100 ml/m²). In these cases, the patch is used to enlarge the cavity of the left ventricle (rare).

Implantation of a patch (autologous pericardial patch, bovine pericardium, Dacron patch or endocardial scar tissue) is preferentially performed with a running suture 3/0 polypropylene. After the patch is completely implanted, the epicardium is closed over the patch as described above (■ Fig. 23.7).

23.2.6 Perioperative Complications

Re-remodeling after primary successful left ventricular reconstruction has been described in 15–25% of all cases (DiDonato et al. 2001, 2010). This re-remodeling/de novo remodeling is a re-dilatation of a reconstructed ventricle. Even though the exact mechanism of this re-remodeling is unclear, an insufficient reduction of the left ventricular volume at the first procedure may be one of the reasons.

■ Fig. 23.7 Patch occlusion of the ventriculotomy with final running suture line

Very rarely, reduction of left ventricular cavity volume may have been overdone (<100 ml/m²). This would result in decreased LV stroke volume and diastolic dysfunction. In borderline cases, symptoms may improve spontaneously over the next 3–6 months due to slight dilatation of the left ventricle. In more severe cases, the left ventricular cavity has to be enlarged by implanting a patch (very rare).

However, a more frequent scenario is an inadequately reduced cavity volume after left ventricular reconstruction. If the LVESVI remains higher than 80–100 ml/m², surgery does not alter long-term prognosis, and mortality and morbidity remain high. The goal is to achieve a left ventricular volume reduction of at least 30% in relation to the preoperative value.

Postoperative ventricular rhythm disturbances are rare, even in patients who have had ventricular arrhythmias preoperatively. Therefore implantation of a defibrillator or even the prescription of antiarrhythmic drugs is only rarely necessary. Some groups prefer to add intraoperative ablation (cryo- or radio-ablation) in patients with pre-existing ventricular arrhythmias (see above ► Sect. 23.2.5).

23.2.7 Results and Outlook

The results of left ventricular reconstruction surgery have been published in many articles over the

last years (Athanasuleas et al. 2001, 2004; DiDonato et al. 1997, 2001; Dor 1997; Dor 2004; Maxey et al. 2004; Yamaguchi et al. 1998). These studies showed significantly lower 30-day mortality, improved 5-year survival and reduced LVESVI values as compared to the control group without left ventricular reconstruction.

Based on these results, the National Institute of Health (NIH) in the United States supported a worldwide prospective study (Surgical Treatment for Ischemic Heart Failure: STICH trial, Velazquez et al. 2007). In 2009, results were published showing the outcome of coronary bypass surgery alone and in combination with the left ventricular reconstruction (hypothesis 2 substudy of the STICH trial) (Jones et al. 2009). However, there were several methodological problems associated with this study: missing description of the preferred surgical technique, measurement of the left ventricular volume in only 161 of 501 enrolled patients and postoperative LVESVI reduction of only 19% of these 161 patients. A total of 66% of all patients did not have any measurement of LVESVI. In patients with dilated ventricle (LVESVI > 90 ml/m²), 56% still had an enlarged left ventricle after reconstruction (postoperative LVESVI > 60 ml/m²). Thirteen percent of patients enrolled had no history of preoperative myocardial infarction. Only 49% of the patients were in NYHA III–IV. These problems with the study have also been published (Buckberg and Athanasuleas 2009; Dor 2011), and the value of the STICH study remains uncertain.

Most recent publications have shown a considerable survival advantage of the left ventricular reconstruction in ischemic dilated ventricles, compared to conservative treatment or coronary revascularization alone; careful application of the described surgical techniques provided including a LVESVI reduction of more than 30% of the baseline value, preferably <60 ml/m² (normal value according to White et al. 1987 is 25 ml/m²).

23.3 Conventional Heart Failure Surgery

Coronary heart disease and mitral valve regurgitation in patients with ischemic cardiomyopathies are independent risk factors for poor survival. Therefore, in these patients, a combined approach of left ventricular reconstruction, coronary revas-

cularization and mitral valve reconstruction is warranted.

23.3.1 High-Risk Coronary Bypass Surgery

23.3.1.1 Indication

Coronary revascularization is meant to improve coronary blood flow but is not a primary therapy to enhance ventricular remodeling. With current techniques of myocardial protection, coronary bypass operations can also be done with good success in patients revealing severely reduced left ventricular function to start with.

Yamaguchi et al. (1998) showed the results of the coronary bypass surgery being directly related to preoperative LVESVI. In their study, 5-year survival was only 54%, when preoperative LVESVI was larger than 100 ml/m². It was, however, 85%, if the preoperative LVESVI was less than 100 ml/m². Maxey et al. reported superior long-term results when left ventricular reconstruction was added to coronary bypass surgery in dilated ventricles (Maxey et al. 2004).

It should be kept in mind, however, that 5-year survival in patients with significantly reduced ejection fraction (less than 25%) is only 50–60%, despite very good perioperative results (Elefteriades and Edwards 2002; Shah et al. 2003).

Even in patients with left ventricular ejection fractions of less than 15%, good perioperative results can be expected, as long as good target vessels for revascularization, «hibernating» myocardium, and good right ventricular function are present. Then not only moderate elevation of the pulmonary artery pressure but also the scenario of a redo-operation can be overcome.

If the patient, however, has very poor right ventricular function, and even clinical signs of right heart failure in face of fixed pulmonary hypertension, one should refrain from LV reconstruction surgery and rather consider other forms of surgical therapy for ischemic cardiomyopathy, such as heart transplantation or mechanical circulatory support (DiCarli et al. 1998).

23.3.1.2 Surgical Procedures

As is true for any coronary revascularization surgery, the left internal mammary artery should be used as a bypass graft for the left anterior descending coronary artery. The other coronary arteries should be grafted with the right internal mammary artery, a vein or the radial artery. In all cases, it should be aimed at a complete revascularization in relation to the quality of the distal target vessels. Manipulations on the large and often arrhythmic ventricles should be avoided before extracorporeal circulation is started. As long as intracavitary thrombi are ruled out and hemodynamics are stable, the revascularization part of these operations can be performed either off pump or on the beating heart with extracorporeal circulation. We prefer cardioplegic arrest. If cardioplegia is used, ante- and retrograde cold blood cardioplegia should be applied in order to facilitate optimal distribution of the cardioplegic solution and to supply oxygen to the heart in between reinfusions.

23.3.2 Mitral Valve Reconstruction

23.3.2.1 Indications

Functional mitral valve insufficiency is secondary to progressive dilatation and dysfunction of the left ventricle. Therefore in these cases, it may not be considered a primary valvular disease but rather a disease of the ventricle (■ Fig. 23.8a, b). Mitral valve insufficiency and left ventricular dilatation will result in a *circulus vitiosus*, which can only be treated by mitral valve repair/replacement and left ventricular reconstruction. It is of utmost importance in these patients to preserve the subvalvular apparatus (anulus, chordae, papillary muscles) during any mitral valve operation.

Mitral valve reconstruction and left ventricular reconstruction surgery are indicated in patients with mitral valve insufficiency grade II–III or higher, in some cases already in grade II (Bolling et al. 1998).

23.3.2.2 Surgical Technique

In most of the cases mitral valve insufficiency is caused by anulus dilatation. Surgery aims at creating a satisfactory coaptation area between the anterior and posterior mitral valve leaflet. Undersizing is beneficial and can be achieved by a complete ring.

It is important to anchor the sutures for the mitral ring securely inside the fibrous anulus (not in the atrial wall or in the leaflet). The force on these sutures during anulus reduction is significant, and tearing of the sutures will result in recurrent mitral valve insufficiency (■ Fig. 23.8c).

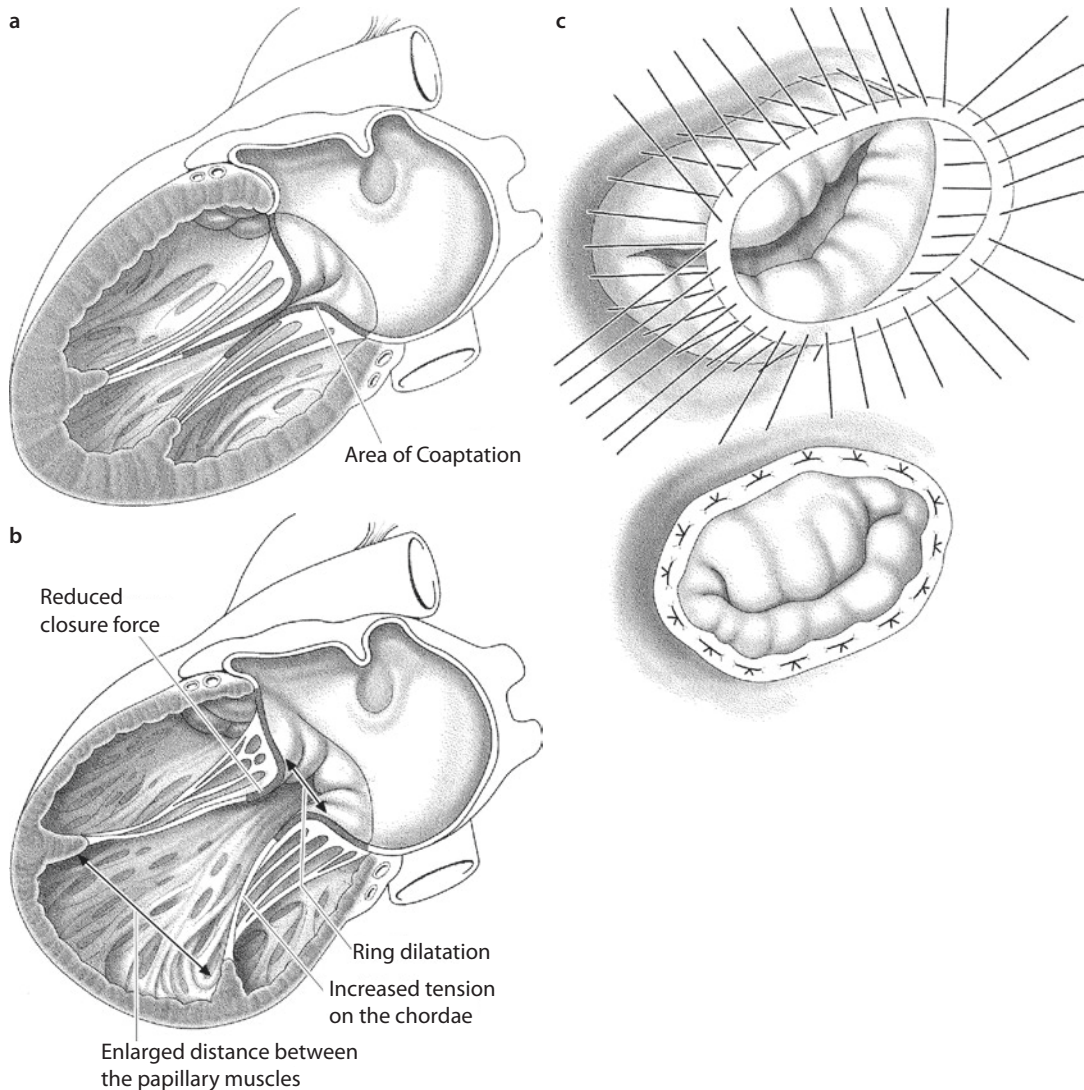

23.3.3 Post-Infarction Ventricular Septal Defect

In almost 1% of patients, transmural myocardial infarction is complicated by a ventricular septal defect (post-infarct VSD). A coronary vessel occlusion without prior collateral network generation leads to sustained myocardial necrosis. Whenever the repair mechanism is too brief to form a solid scar but tissue is rapidly weakened, the necrotic area may rupture and result in a ventricular septum defect. This event usually occurs 1–2 weeks after the infarction. Very small post-infarction VSD can heal spontaneously and may not cause any symptoms; they may even go undiagnosed. Anatomically, most acquired VSDs affect the anterior apical septum resulting from LAD occlusion (60%), while the rest are distributed equally to the mid-septal and posterior areas.

Often, infarction VSD leads rapidly to hemodynamic instability or even shock, and it is associated with high mortality. In these situations, the only treatment is surgical or interventional VSD closure. If the structural defect in hemodynamically unstable patients remains, the natural course for this patient cohort is disastrous, with a 1-year survival of less than 10% (Brandt et al. 1979; Madsen and Daggett 1997).

23.3.3.1 Treatment

The care for patients with post-infarct VSD is challenging, requiring a multidisciplinary team to regularly assess the patient's condition and evaluate the indication for surgery. Whenever possible, as allowed for by the hemodynamic status, surgery should be postponed in order to gain time for the edges of the septal defect to heal as a scar and thereby attain more suturable morphology. Medical treatment is based on afterload-reducing agents, inotropes and intra-aortic balloon pump (IABP) insertion to reduce afterload in systole and augment coronary perfusion in diastole. Vasoconstrictors would increase afterload. This usually results in higher shunt volumes and should be avoided. Achieving

■ **Fig. 23.8** a–c Normal functional anatomy with good coaptation areas a; development of functional mitral valve insufficiency b; sutures in the annulus before and after tying with use of a complete mitral valve ring c

optimum preoperative hemodynamics is of upmost importance to the operative outcome. Whether a preoperative phase of mechanical circulatory support as a routine treatment tool is beneficial awaits investigation in future series.

Preoperatively, repetitive transesophageal echocardiography (TEE) and thorough hemodynamic monitoring are mandatory. Peripheral organ function has to be screened and taken care of as necessary. The hemodynamic status determines the time for surgery, with instability being the indication for defect closure. This in itself is one of the main prognostic factors for outcome. The sooner a post-infarction VSD requires

surgery, the poorer the outcome (Deja et al. 2000; Labrousse et al. 2002). The fragility of the septal tissue where the patch is anchored is the main reason for residual shunts (up to 40%) and causes significant mortality rates (Deja et al. 2000; Pretre et al. 1999).

23.3.3.2 Surgical Strategy

Historically, the first successful post-infarct VSD closure was achieved by Denton Cooley in 1957 (Cooley et al. 1957). Many surgical techniques and perioperative tools have been described over the past 55 years to treat this defect and improve patient care. A preoperative IABP may

■ **Fig. 23.9** Patch closure of an anterior (*left Panels*) and posterior (*right Panels*) post-infarction VSD. The access through the infarcted LV free wall may or may not be closed with a second patch in anterior infarctions. For posterior VSDs a patch repair of the LV access is always recommended (Adapted from Wahlers and Franke 2003)

be inserted and maintained for some days post-operatively. Using general anesthesia and total hemodynamic monitoring including pulmonary artery catheter and TEE, the operation is conducted employing full sternotomy using standard cardiopulmonary bypass and cardioplegic arrest. Surgery using induced ventricular fibrillation has not proven to be superior to cardioplegic arrest (Deja et al. 2000; Labrousse et al. 2002; Gula and Yacoub 1981).

The scar tissue of the infarction is routinely used for surgical access to the defect. Most described surgical procedures can be performed through an anterior or posterior scar region. In some patients trans-right atrial and trans-tricuspid valve access is possible. However, the right ventricular trabeculae at times make localising the defect and safe patch insertion difficult (Masseti et al. 2000).

The techniques performed most often closely follow the work of Dagget (Daggett et al. 1977). After incision in the left ventricular wall parallel to the LAD, the defect is localized and a patch inserted using big stitches for Teflon-augmented single or running sutures. The patch (of bovine pericardium or Dacron) should be large enough and placed broadly overlapping the healthy myocardial tissue around the VSD and its infarcted borders. In anterior defects, access in the left anterior wall can be closed using Teflon felt-augmented direct sutures or a second patch. When choosing an incision in the posterior wall for posterior defects, it is recommended to always use a second patch for LV wall reconstruction. The patch on the fragile septum issue can be secured using biologic glue material injected into the tissue (Daggett et al. 1977; Tanaka et al. 2001)

■ (Fig. 23.9).

■ **Fig. 23.10** Double patch and glue technique. Two patches are inserted from the right and left ventricular side toward the VSD, and glue is placed in between. The technique requires a biventricular access (Adapted from Deville et al. 2005)

■ **Fig. 23.11** For apical VSD a cut through both ventricular apices can be placed, and the neo-apex formed using felt strips in and outside both ventricular apical edges (Adapted from Khonsari and Sintek 2008)

Some surgeons recommend using a double patch technique with one patch from each side of the septum (Deville et al. 2005). In doing so, both ventricles need to be opened within the scar region. Special care must be paid to the moderator band, which requires several incisions in the right-sided patch. Once both patches are inserted, both are connected with a running suture, and glue is injected between the two patches to reinforce the friable tissue defect (■ Fig. 23.10).

Whenever the heart's apex is infarcted causing an apical VSD, the apex can be completely ampu-

tated (■ Fig. 23.11). The apex is then reconstructed using four strips of Teflon felt – one on each ventricular free wall side and one on each side of the septum, excluding the infarcted VSD area once the sutures are tied (Khonsari and Sintek 2008).

23.3.3.3 Postoperative Results

Most published series on post-infarction VSD surgery are more or less out of date and report 30-day mortality rates between 20 and 60%. Most of these patients died early postoperatively from multi-organ failure. Known risk factors for mortality are preoperative shock, older age and timing of surgery early after VSD occurrence. Anatomical features do not seem to play a role.

23.3.3.4 Interventional Post-infarction VSD Closure

As surgery early after post-infarction VSD bears this high mortality, it seems obvious to look for minimally invasive options and alternative treatments. From the late 1990s, initial experiences with percutaneous occluders have been published (Lee et al. 1998). These reports inspired several institutions to employ this technology in patients ineligible for surgery. Especially in the very early phase after infarction with hemodynamically instable patients, avoiding surgery seems attractive. A series of 29 patients was published (Thiele et al. 2009). However, the authors concluded that the strategy might offer shunt reduction only. The procedure itself was still associated with significant technical problems and high mortality and morbidity. A hybrid strategy with open chest and beating heart manipulation might facilitate correct device placement (Lee et al. 2010). In a current «best evidence» review of the few existing case series, Attia and Blauth reported that the available devices are not very suitable for closing an infarction VSD (2010). Since results for catheter-based interventional treatment have been unconvincing so far, the standard of care for post-infarction VSD closure at any time remains surgical.

23.3.4 Other Techniques

Over the years, many other methods have been developed to surgically treat terminal heart failure in various ways. However, all these techniques have not provided enough scientific background,

and more prospective data is necessary before these alternative treatments are being accepted for routine use. Some of these methods are still in the experimental stage. These include dynamic cardiomyoplasty procedures (Lange et al. 1995), biological pulsation with aortoplasty (Guldner et al. 2000), skeletal muscle ventricle (Guldner et al. 2001), left ventricular constraint device (Konertz et al. 2001), myosplint implantation (Fukamachi and McCarthy 2005) and transmyocardial laser revascularization (Lutter et al. 2002) – just to name a few.

24.1 Introduction

Surgery on the aortic valve is now a routine cardiac procedure performed in Germany (population >81,000,000) in 2010 in almost 11,700 patients (Gummert et al. 2011). The etiology of aortic valve disease is either aortic valve stenosis, aortic regurgitation, or a combination of these. Replacement options include mechanical or biological prostheses. Biological prostheses (xenografts or heterografts: tissue from another species) are available as stentless or as stented valves. Stented prostheses utilize a stent frame to mount the biological tissue that will provide the valve mechanism, while stentless prostheses utilize either a complete porcine aortic root or an aortic root completely constructed from xenopericardium of porcine or bovine origin. Biological aortic valve substitutes also include homografts (homografts or allografts: tissue from the same species) and autografts (tissue from the same individual) as in the Ross procedure.

24.2 Historical Insights

The first aortic valve intervention was performed by the French surgeon Theodore Tuffier (1857–1929) and published by Alexis Carrel. They performed the first dilatation of a stenotic aortic valve on July 13, 1912 in a 26-year-old patient by invaginating the aortic wall through the aortic valve. Later on, Carrel performed the first anastomosis between the left ventricle and the descending aorta in animal experiments, as a mean to bypass a stenotic valve. No realistic attempts were performed thereafter until the end of the Second World War. During 1950, an aortic valve dilatator was developed by Charles Bailey. It presented a variation of the mitral valve dilator (originally developed by Lord Brock) but incorporated a three-piece head that could be rotated to match and eventually dilate/disrupt the three commissures. On September 11, 1952, Charles A. Hufnagel (1917–1989) at Georgetown University implanted a self-made valve in the descending aorta which resulted in a reduction of aortic valve regurgitation present by 70%. Originally the valve inside the valve cage was made from metal; later on, however, it was replaced by a silicone sphere. On March 10, 1960, Dwight E. Harken (1910–1993) implanted a self-made mechanical aortic valve in the anatomic position. The thoracic surgeon Albert Starr and the valve engineer Miles Lowell Edwards developed a mechanical prosthesis originally meant for the mitral position. Model 1260 was implanted for the first time in 1966 in aortic position. Viking Björk and

Don Shiley later developed a mechanical convex-concave tilting valve. The first valve had an opening angle of 60° and was on market from 1969 till 1986. The subsequent model with only one strut (mono-strut), improved metal frame, and opening angle of 70° was available from 1982; however, due to sporadic reports of design failure and fracture, it was removed from the market in 1986. During 1977, St. Jude Medical Company entered the market with the first b-leaflet valve with an opening angle of 85°.

On July 24, 1962, Donald performed the first subcoronary aortic valve homograft replacement in London, England, employing a single suture technique as personally suggested to him by Gunning and Duran (Ross 1962). Brian Barratt-Boyes, working independently, performed his first subcoronary aortic valve homograft implantation on August 23, 1962, employing a what he later called a more modern double suture technique derived from his own experience (Barratt-Boyes 1964; Kirklin and Barratt-Boyes 1986). They both used sterilized freeze-dried cadaveric homografts.

Marion Ionescu from Leeds, UK, developed an autologous valve using tissue harvested from the patient's fascia lata mounted on a metal stent frame. Later on, xenopericardium was utilized as valve leaflet material. Carlos Duran and Alfred Gunning in Oxford concentrated their efforts on conservation of xenograft tissue, and on September 23, 1964, the first stented porcine valve could be implanted. Alan Carpentier from Paris in cooperation with Miles L. Edwards developed and later marketed their first biological valve in the late 1960s. Quicksilver was initially employed for the conservation of the tissue utilized for the first biological valves; however later on, quicksilver was replaced by formaldehyde and glutaraldehyde.

24.3 General Knowledge

The aortic root provides the connection between the left ventricle and the ascending aorta. The aortic valve resides inside the aortic root and consists of several structures. The anatomic and physiological borders between the aortic valve and the left ventricle are not identical (Sievers et al. 2012).

24.3.1 Aortic Root Anatomy

The three leaflets provide the main closing mechanism of the aortic valve. The form of the leaflets

and leaflet attachments give the aortic valve a crown shape, and thus it is described as a «semilunar valve.» Anatomically a valve leaflet can be divided into three parts:

- The free margin, with a thickened circular node (*nodulus Aranti*), which provides the coaptation area to the corresponding neighboring valve leaflet
- The «belly» of the leaflet
- The basal parts of the leaflet or leaflet attachments

The leaflet attachments insert in the wall of the aortic root and thus form a crown-shaped structure, often called «anulus.» This description can be misleading as the word anulus refers to a circular structure in contrast to the «crown»-formed shape of the leaflet attachment (Sievers et al. 2012).

The three bulges of the aortic wall are the sinuses of Valsalva. Two of the three sinuses host the origins

of the coronary arteries, and the sinuses are termed accordingly as left, right, and noncoronary sinus.

The areas where neighboring leaflet attachments run parallel are called commissure. The area underneath each commissure is called an interleaflet triangle. The triangle between the right and noncoronary sinus is part of the membranous septum and hosts the His bundle. This area is of special importance during aortic valve procedures, as injury here may lead to temporary or permanent conduction abnormalities, potentially requiring implantation of a permanent cardiac pacemaker system. Under the left/noncoronary trigonum, the aortomitral curtain leads to the anterior mitral valve leaflet. The distal border of the sinuses toward the ascending aorta as well as the top of the commissures forms a circular structure named «sinotubular junction» which separates the aortic root from the ascending aorta (■ Fig. 24.1) (Sievers et al. 2012).

■ Fig. 24.1 Schematic drawing of the aortic root and the left ventricular outflow tract. Injuries to the His bundle, which runs in close proximity to the membranous septum on its left ventricular aspect, may cause temporary or permanent postoperative conduction abnormalities. The aortomitral valve continuity reflects the close anatomic relationship of the mitral and aortic valve in normal hearts

24.3.2 Aortic Valve Disease

Aortic valve disease is classified in pure stenosis, pure regurgitation, and a combination of the above, where both forms of disease and hemodynamics coexist. Aortic valve stenosis can be further classified into valvular, subvalvular, and supra-*valvular* stenosis.

24.3.2.1 Aortic Valve Stenosis

Before 1950, rheumatic aortic valve disease after rheumatic fever due to streptococcal infection was the most frequent etiology for aortic valve disease (Rahimtoola and Frye 2000). After the introduction of penicillin prophylaxis and treatment, rheumatic heart valve disease has been dramatically reduced in the western world. Here today, calcified aortic valve stenosis represents the most frequent form of stenotic aortic valve disease, mainly due to the increased life expectancy of the population. This form of disease, however, in contrast to the popular belief, does not represent a mere time-dependent degeneration process but rather an active disease with aspects similar to the development of atherosclerosis. Deposits of lipoproteins lead to a chronic tissue inflammation and valve calcification (Freeman and Otto 2005). There is however evidence of a genetic component in the development of the aortic valve calcification (Probst et al. 2006).

24.3.2.2 Aortic Valve Regurgitation

In the first half of the twentieth century, endocarditis as complication of tertiary syphilis was often the etiology of aortic valve regurgitation (Reader et al. 1947). In the rheumatic form of aortic regurgitation, retracted, shortened aortic valve leaflets lead to the development valve incompetence and progressive aortic valve regurgitation. Other reasons for the development of aortic regurgitation are destruction of the aortic leaflets due to infective endocarditis, posttraumatic leaflet injury, as well as complications of type A aortic dissection. In many cases, dilatation of the aortic root cannot any longer warrant a sufficient closing mechanism of the aortic valve leading to aortic valve regurgitation.

24.3.2.3 Bicuspid Aortic Valve

A bicuspid aortic valve has an incidence of about 2% and is the most common congenital heart defect. Diverse factors play a role in the embryogenesis of a bicuspid aortic valve. There is a tendency for bicuspid aortic valves to develop calcified

aortic stenosis, and thus it is not surprising that the frequency of interventions in patients with bicuspid aortic valves is much higher than in patients with normal, tricuspid aortic valves (Roberts and Ko 2005). Various phenotypes of bicuspid aortic valves have been classified, which allow a more detailed classification of the pathology and reconstruction techniques (Sievers and Schmidtke 2007).

Principally, all techniques employed for aortic valve surgery in tricuspid aortic valves can also be employed in patients with bicuspid aortic valves. Bicuspid aortic valve repair can lead to satisfactory short- and midterm results (Davierwalla et al. 2003; El Khoury et al. 2006). Similarly, valve-sparing aortic root replacement can also be performed in the setting of a bicuspid aortic valve.

In the setting of bicuspid aortic valves, all conventional aortic valve replacement procedures (mechanical, biological, homograft) can be performed without concern. The anatomy of the coronary ostia, however, must be taken into special consideration, since in these patients, different to the three leaflet setting, the two coronary ostia are often at a 180° angle apart, and as such some matching and special orientation of the prosthesis at implantation might be required.

24.3.2.4 Natural History

Calcified aortic valve stenosis represents a dynamic process. Mild or moderate aortic valve stenosis can be well tolerated; however severe stenosis leads to increased morbidity and mortality. When combined with other comorbidities, often interdependent, such as low ventricular function, chronic renal disease, or advanced age, aortic valve stenosis can shorten life expectancy (Carabello and Paulus 2009).

Patients with aortic valve insufficiency can be asymptomatic for quite some time. Once the patient becomes symptomatic, chronic dilatation of the left ventricle is already present, and an acceleration of the natural history and symptom development takes place.

24.3.3 Diagnostic Modalities for Aortic Valve Disease

Symptom development can often be misleading, as some patients develop symptoms even with mild aortic valve disease, while others may be asymptomatic even in presence of severe aortic stenosis or regurgitation. In patients with aortic valve disease,

symptoms often include angina. Symptoms also can be related to the development of heart failure, like dyspnea and orthopnea. Syncope often occurs in patients with significant aortic valve stenosis.

Some patients with severe aortic valve stenosis can present with gastrointestinal bleeding. The etiology of this has only recently been unmasked. This clinical syndrome consists of gastrointestinal angiodysplasia in combination with a bleeding disorder mainly attributed to von Willebrand factor dysfunction and has been coined «Heyde syndrome» (Pate et al. 2004); therapy of choice is aortic valve replacement.

The clinical examination reveals a pathological systolic murmur at the second intercostal space radiating to the base of the neck and carotid arteries in cases of aortic stenosis and an early diastolic murmur radiating to the heart apex in patients with aortic regurgitation.

Chest x-ray may reveal signs of left ventricular hypertrophy or dilatation as well as calcification of the aortic valve. Echocardiography establishes the diagnosis of aortic valve disease, as well as the grading of its severity with measurement of transvalvular gradients, aortic valve area, and grade of valvar regurgitation. Aortic root dimensions, grade of calcification, as well as leaflet mobility and presence of vegetations in cases of endocarditis can also be evaluated.

Left heart catheterization with cardioangiography provides invasive measurements of transvalvular gradients as well as grading of the aortic regurgitation. It should be performed prior to intervention in all patients to evaluate potential coexisting coronary artery disease that can be treated at the time of operation.

Magnetic resonance imaging is becoming more and more popular for the evaluation of patients with aortic valve disease; however, for the time being, it cannot replace echocardiography or left heart catheterization for valve disease severity grading and lead on its own to indication for surgery.

24.3.4 Indications for Surgery

The indications for surgery include the presence of clinical symptomatology and hemodynamic parameters in conjunction with the evaluation of comorbidities. Symptomatic patients have been shown to profit most of aortic valve replacement (Rahimtoola 1998).

Primarily, an effective aortic valve orifice area of $<1.0 \text{ cm}^2$ or a mean transvalvular gradient of $>50 \text{ mmHg}$ should be considered as indication

for aortic valve surgery. It should be taken into consideration that the transvalvular gradient depends on the systolic left ventricular function, and in patients with severely depressed left ventricular systolic function, severe aortic valve stenosis can coexist with low transvalvular gradient. These patients also profit from aortic valve replacement despite low contractile reserve (Quere et al. 2006). With respect to the aortic valve area, there is a consensus that an area below 1.0 cm^2 represents a severe aortic valve stenosis as depicted in the ACC/AHA guidelines (Bonow et al. 2006) (■ Table 24.1).

Most patients with asymptomatic severe aortic valve stenosis will eventually develop clinical symptomatology within the first 5 years after the diagnosis and carry a risk for sudden death of about 1%/year (Pellika et al. 2005). An exercise test can help differentiate and uncover symptoms, as many «asymptomatic» patients will develop typical symptoms at exercise (Das et al. 2005).

Patients with acute, severe aortic insufficiency typically develop pulmonary congestion and hypotension, which may lead to cardiogenic shock and should be referred for urgent surgical intervention. The time point of surgical intervention in patients with chronic aortic valve regurgitation is of great importance. Surgical intervention in these patients should be performed before the left ventricular ejection fraction falls below 55% and before the (corrected) left ventricular end diastolic diameter increases above 55 mm (Bekeredijan and Grayburn 2005). According to the AHA/ACC guidelines, patients referred for surgical intervention before the development of a depressed left ventricular function or left ventricular dilatation profit the most in terms of long-term survival in comparison to patients operated after symptom development (Bonow et al. 2006; Tornos et al. 2006). It is important to mention that patients with severe aortic regurgitation and depressed left ventricular function also profit from surgical intervention (Bhudia et al. 2007).

■ Table 24.1 Grading of aortic valve stenosis by valve area (adult patients)

Valve area (cm^2)	Aortic stenosis severity
>2.5	No stenosis
1.6–2.5	Mild stenosis
1.0–1.5	Moderate stenosis
<1.0	Severe stenosis
<0.75	Severe, critical stenosis

24.3.5 Preoperative Management

In addition to general preoperative considerations, in patients prior to heart valve interventions it is important to rule out the presence of any acute or chronic infection especially in the ear-nose-throat as well as dental area. Such chronic or acute infections should be treated before an elective aortic valve intervention in order to minimize the risk of postoperative valvar or prosthetic infection. In urgent or emergency cases, the procedure should be performed under broad antibiotic coverage, and the chronic infection should be treated postoperatively under endocarditis prophylaxis. Patients on oral anticoagulation should be switched to intravenous heparin prior to intervention.

24.4 Operative Technique and Access

Conventional aortic valve replacement is performed under general anesthesia with the use of extracorporeal circulation. Invasive blood pressure monitoring as well as central venous catheters and in many institutions transesophageal echocardiography are standard monitoring modalities.

The patient is placed in supine position, and not only the chest but also the groin is prepped and draped in standard fashion, in case femoral artery or vein cannulation might become necessary.

The most common surgical access for conventional aortic valve replacement is the median sternotomy. Partial sternotomy incisions such as inverted-T or inverted-L sternotomies have been shown to lead to increased postoperative thoracic wall stability and can be used for uncomplicated aortic valve interventions (Bakir et al. 2006). For complex or combined operations, the standard median sternotomy should be preferred. After careful hemostasis of the sternum, the sternal retractor is placed, and the pericardium is incised in the form of an inverse T and retracted. If the heart has to be freed from adhesion, it may be preferable to place the patients under pump support, in order to provide adequate hemodynamic support and facilitate manipulation of the heart and its position. A complete preparation of the heart is not always necessary, especially in reoperations as the left pleura space can be opened for de-airing maneuvers, and de-airing can be performed via the ascending aorta while manipulating the apex of the left ventricle.

24.4.1 Techniques for Myocardial Protection

The patient is placed on extracorporeal circulation using standard access. After full heparinization, the ascending aorta and right atrium are prepared dissected and cannulated using double purse-string sutures. Prior to cannulation, it is important to palpate the aorta for calcium plaques and avoid these. Alternative cannulation areas are the right lateral aspect of the ascending aorta, the brachiocephalic trunk, the proximal aortic arch, as well as the distal right subclavian artery.

The right atrium is cannulated using double stage venous catheter. Alternatively, the superior and inferior cavae can be cannulated individually (■ Fig. 24.2). Standard aortic valve interventions can be performed in normothermia (35 °C) or mild hypothermia (30–32 °C). Electrically induced ventricular fibrillation is performed before clamping the ascending aorta, avoiding areas with calcium plaques. In most cases, selective coronary infusion of cardioplegia is used. In patients with pure aortic stenosis without concomitant aortic insufficiency, the initial cardioplegia solution can be given directly into the aortic root. In patients with aortic regurgitation, this should be avoided, as it can cause significant left

■ Fig. 24.2 Intraoperative situs. The aorta is cannulated just proximal to the aortic arch, and the superior and inferior vena cavae are cannulated selectively. The ascending aorta is clamped, and an S-shaped incision is performed in the ascending aorta into the noncoronary sinus. Transverse aortotomy in *insert*

ventricular distention. Care should be taken when cannulating the left coronary ostium as in some patients with short left main stem this can lead to selective cannulation of either the left anterior descending or the circumflex artery and result in insufficient myocardial protection. In cases where significant calcification or stenosis of the coronary ostia, retrograde cardioplegia and cooling of the patient on bypass should provide adequate myocardial protection. Alternatively coronary artery bypass grafting should be performed before aortic valve replacement and cardioplegia can be given via the vein grafts.

Placement of a left ventricular venting catheter via the right superior pulmonary vein or the interatrial groove should be considered. Alternatively, antegrade venting of the left ventri-

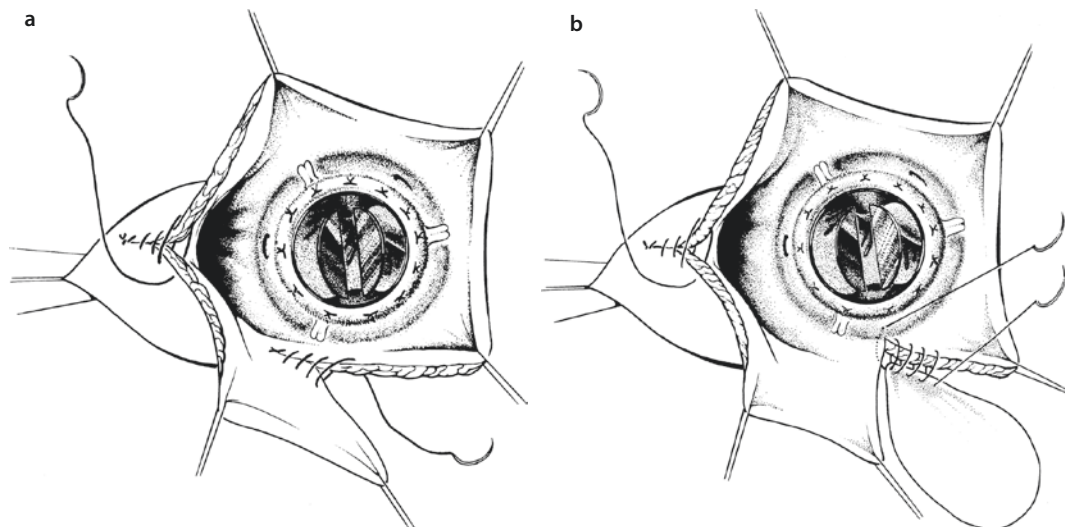

cle through the aortic valve can also provide a bloodless operating field. Some surgeons prefer the flooding of the operative field with CO₂ (2–4 l/min). As CO₂ is heavier than air, it displaces air in the operative field and may lead to decreased incidence of air embolism (Martens et al. 2008).

24.4.2 Exposure of the Aortic Valve, Suturing of the Aortotomy, and De-airing

The aortic valve can be exposed through a transverse incision above the sinotubular junction or an S-shaped or hockey-stick-shaped incision from the sinotubular junction down to the noncoronary sinus (■ Fig. 24.3). In some patients with bicuspid

■ Fig. 24.3 a–c Valve exposure after S-shaped aortotomy a or after supracommissural transverse aortotomy b, c

■ **Fig. 24.4** a, b Closure of the aortotomy after prosthetic valve implantation employing two single layer running atraumatic sutures coming from each end of the incision a; noncoronary sinus enlargement with the use of a pericardial patch. The proximal patch is sutured to the prosthetic valve ring b

aortic valve, the right coronary artery is often located at the level of the sinotubular junction and has to be looked for in order not to be injured.

Before incising the aorta, the right coronary artery should always be identified, and the base of the aorta should be inspected for calcifications.

When using the S-shaped incision, the anatomy and position of the left coronary artery should be taken into consideration, also. If there is a possibility of aortic valve repair, the aortotomy should not be extended in the noncoronary sinus in order to prevent distortion of the aortic root geometry. This is very important for the evaluation of the underlying pathology prior to aortic valve repair. Stay sutures are placed in the wall of the aortic root, usually in the commissural area in order to improve exposure of the aortic valve. According to the planned aortic intervention, the approach and exposure of the aortic valve can be different (see ► Sect. 24.5.4, «Biological Prostheses»). When an enlargement of the aortic anulus is necessary, the aortotomy can be carried out in the noncoronary sinus. In cases of significant calcification of the aortic root, an oblique incision can be used to prevent disruption of the calcium plaques. All these criteria should be taken into consideration prior to choosing the appropriate surgical approach.

After the repair or replacement of the aortic valve, the closure of the aortotomy is performed using atraumatic, monofilament, size 4/0 or 5/0 sutures utilizing two running lines, either both in a continuous, over-and-over fashion or using first a mattress suture line followed by a second over-

■ **Fig. 24.5** Direct closure of the aortotomy with two single-layered running sutures

and-over running suture (■ Fig. 24.4). In case of fragile tissue, felt or pericardium pledgets may be used at the beginning of the suture line at the lowest points of the aortotomy ending the suture lines at the highest point (■ Fig. 24.5). Furthermore, if the aortic tissue is very fragile, the closure of the aortotomy may be performed using felt or pericardium reinforcement. In extreme cases, replacement of parts of the ascending aortic with pericardium or Dacron is necessary (■ Fig. 24.6). In young patients, with rather pliable, noncalcified aortic wall, a single-layered aortotomy closure may be sufficient, also.

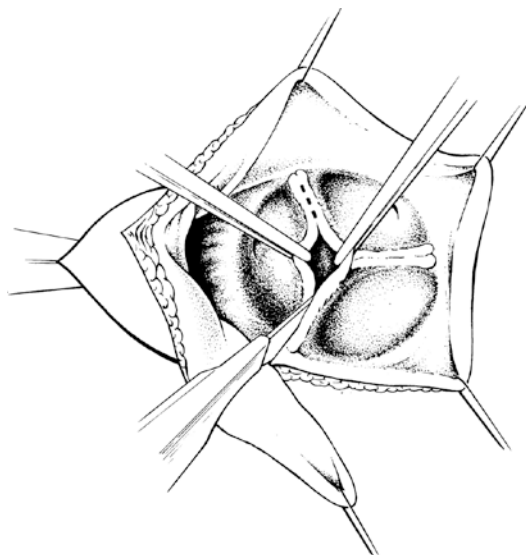

■ **Fig. 24.6** In patients with poor quality aortic wall, part of the aorta can be replaced by a pericardial patch for closure of the aortotomy

Before closing the aortotomy, venting of the left ventricle should be terminated. The purse-string suture in the right superior pulmonary vein or interatrial groove is tied down, while mechanical ventilation is restarted with a few deep breaths initiating de-airing before tying. In Trendelenburg position and with reduced pump flow, the ascending aorta is unclamped, and de-airing maneuvers are continued. The left ventricle may be de-aired via puncture of the left ventricular apex using a cannula. After sufficient de-airing, the puncture site is sutured using monofilament 4/0 or 5/0 suture with or without felt pledges or pericardium reinforcement. The patient's position is returned to normal, and additional de-airing should be performed via the ascending aorta. Transesophageal echocardiography may be employed to verify de-airing. Returning volume to the patient and initiating mechanical ventilation can further accelerate the de-airing process. A complete de-airing of the left ventricle even before unclamping the ascending aorta is possible, with manipulation of the left ventricle, reduction of venous return, and initiation of mechanical ventilation.

During reoperations and before unclamping the ascending aorta, the left ventricle can be de-aired by placing the patient in reverse Trendelenburg position with a left lateral tilt. Manipulation of the left ventricle can be performed via the left pleural space and de-airing through an opening in the ascending aorta. When performing this de-airing maneuver through the ascending aorta, it is important that the left ventricular apex is at the lowest point possible.

24.5 Aortic Valve Procedures

Repair or reconstruction of the patient's native aortic valve should be the procedure of first choice whenever possible; however, the final decision to repair or replace the aortic valve can be made only intraoperatively. The primary concern is not only the feasibility of the reconstruction but also the expected long-term durability of it. In patients with pure aortic valve regurgitation, the aortic valve in many cases can be repaired utilizing special reconstructive techniques, while in patients with calcified aortic valve stenosis, a replacement of the aortic valve may be the option of choice in most patients.

■ **Fig. 24.7** Aortic valvotomy: sharp transection of the fused/nonseparated cusps in a patient with aortic valve stenosis revealing otherwise mobile leaflets without calcification

24.5.1 Reconstruction of the Aortic Valve

The first attempts to repair an aortic valve were performed by Taylor in the late 1950s (Taylor et al. 1958). The advantages of repair vs. replacement are avoidance of lifelong anticoagulation and superior hemodynamics, both due to the preservation of the native aortic valve tissue. A systematic approach to aortic valve repair—similar to that during mitral valve repair—should be carried out. During the inspection of the aortic valve, the various components of the aortic root (leaflets, sinuses, trigona, anulus, commissures,

and sinotubular junction) are inspected, as well as their relation to each other. The etiology of the insufficiency is identified, and the possibility of a durable reconstruction is evaluated. Off bypass, intraoperative transesophageal echocardiography allows to evaluate the repaired aortic valve before the end of the procedure. In case of a suboptimal result (moderate aortic regurgitation), the valve repair needs to be improved or the valve has to be replaced.

Aortic valve repair in experienced centers carries a low *postoperative risk and acceptable 5- and 10-year results*.

24.5.1.1 Reconstruction of the Aortic Valve Leaflets

Reconstruction of a stenotic aortic valve should be attempted when fusion of the free margin of the leaflets is the etiology of the valve stenosis, as long as leaflet tissue quality is not compromised and there are no calcifications. In these cases, sharp division of the fused or nonseparated leaflet's free margins as well as careful excision of sites of leaflet thickening can increase the valve opening area as well as the closing capability (■ Fig. 24.7).

In patients with pure aortic valve regurgitation due to leaflet prolapse or leaflet elongation (■ Fig. 24.8), and misalignment of the leaflets during diastole, the repair can be performed with plication of the leaflets in the commissural area or in the area at the nodules of Aranti or with shortening of the leaflet free margin, and thus improving the alignment and closure of the leaflets during diastole.

Temporary stay sutures are placed through the nodules of Aranti to align the neighboring leaflets («Frater stitch») and identify redundant tissue. Redundant tissue in the commissural area can be plicated and with the use of Teflon felt or pericardial pledget reinforcement fixated on the aortic wall (■ Fig. 24.9). Plication in the area of the nodules of Aranti should also be performed using reinforcement with pericardial strips/pledgets. When the tissue is fragile, 5/0 or 6/0 PTFE or Prolene sutures may be used as suturing material. PTFE sutures are also indicated for shortening and reinforcing the leaflet's free margin. In these cases, the suture line starts in the commissural area from the outside of the aortic wall and then continues either in a double running over-and-over fashion or first as a running mattress and then over-and-over suture throughout the free margin length. At the commissure level, the sutures are passed

■ Fig. 24.8 Aortic valve regurgitation due to coaptation deficiency caused by one elongated cusp in an otherwise intact native aortic valve

■ Fig. 24.9 Aortic valve repair with plication of the free margin of a cusp in the commissural area («Trusler plasty»). The aortic leaflets are brought into closing position with a temporary suture at the tip—nodule of Aranti—of each cusp («Frater stitch»). Here the elongated noncoronary cusp is folded over at the commissures, plicated, and sutured to the aortic wall using pericardium or pledget-reinforced U-sutures

through the aortic wall and tied over a Teflon felt or pericardial pledget reinforcement (■ Fig. 24.10). If primary shortening of the leaflets is identified as the valve's pathology, a leaflet extension can be

■ **Fig. 24.10** a–c Reconstruction of a regurgitant aortic valve by plication of the prolapsing left-coronary cusps in the area of the Aranti nodule a. Shortening of the free cusp margin with the use of double-layered over-and-over running b or first mattress and then over-and-over running suture c. In both cases the sutures are finally passed through the aortic wall and tied on the outside

attempted (Duran et al. 1995) using glutaraldehyde-treated autologous pericardium or xenopericardium, similar as used for biological valves (■ Fig. 24.11). For this, we prefer monofilament or PTFE sutures (5/0 or 6/0 size). According to the extent of the leaflet shortening or calcifications, in certain cases a complete leaflet can be replaced with pericardium. The diseased leaflet is resected leaving only a small rim at the level of the annulus,

which is then used to suture the piece of pericardium as leaflet substitute, using 5/0 running monofilament suture (■ Fig. 24.12). Midterm results of aortic leaflet extension in patients with rheumatic aortic valve disease have shown satisfactory results (Bozbuga et al. 2004; Grinda et al. 2002); however, changes of the xenologous or autologous tissue properties overtime can influence the long-term results (Cohen et al. 2007).

■ **Fig. 24.11** Aortic valve repair with enlargement of the cusp leading to extension of the cusp-free margin using autologous or xenopericardium

Further reconstruction techniques can be used for decalcification of the aortic leaflets or closing of fenestrations or perforations as there are after healed aortic valve endocarditis, using materials as described above.

24.5.1.2 Reconstruction of the Aortic Root

Changes in the aortic root dimensions can lead to aortic regurgitation, mostly due to dilatation of the sinotubular junction and less due to dilatation in the aortic anulus area. Repair techniques aim at restoring the normal dimensions and relations of and within the aortic root (■ Fig. 24.13). In isolated dilatation of the sinotubular junction, the enlarged commissural diameters lead to central aortic valve regurgitation, and supracommissural replacement of the ascending aorta with narrowing of the sinotubular junction can restore valve competence.

A disproportional, asymmetric dilatation of the basal aortic anulus is often seen in the noncoronary sinus. Plication of the dilated trigona of the sinus

■ **Fig. 24.12** a–c Restoration of valve competence in a valve with asymmetric leaflet retraction. **a** Isolated retraction of the left coronary cusp, while both the other cusps are intact. **b** The retracted cusp is almost completely resected leaving only a small rim to suture to at the anulus attachment. It is then replaced with a pericardial patch using running suture technique from commissure to commissure **c**

■ **Fig. 24.13** a–c Pathomechanisms responsible for central aortic regurgitation due to dilatation. **a** Normal aortic root. **b** Dilatation at the anulus level. **c** Dilatation at the sinotubular junction. Both result in inadequate valve closing due to lack of coaptation of the cusps

using subcommissural 4/0 monofilament U-sutures reinforced with autologous pericardium or Teflon felt pledgets can restore normal dimensions. In patients with basal anulus dilatation, anuloplasty can reduce the basal anulus diameter. The aortic root in the area of the noncoronary sinus is dissected, and monofilament pledgeted U-sutures are passed from the inside of the aorta through the aortic wall and tied over a short strip of Dacron prosthesis, leading to a shortening of the basal anulus circumference in this segment, ultimately reducing the diameter, also (■ Fig. 24.14).

Midterm results of partial reconstruction of the aortic root are satisfactory (Carr and Savage 2004; Langer et al. 2004). In contrast to mitral valve reconstruction, there is limited experience with partial aortic root reconstruction, and thus these patients require periodical follow-up (Minakata et al. 2004; Charitos et al. 2009b).

In cases of complex aortic root dilatation with macroscopically intact valve leaflets, valve-sparing aortic root replacement can be performed. These techniques replace the wall of the aortic root with a Dacron prosthesis, and the valve tissue is sutured to the individually pre-shaped tube prosthesis (Yacoub procedure or «remodeling procedure») or reimplanted inside a tube or «Valsalva» graft (David procedure or «reimplantation technique»).

■ ■ Yacoub procedure

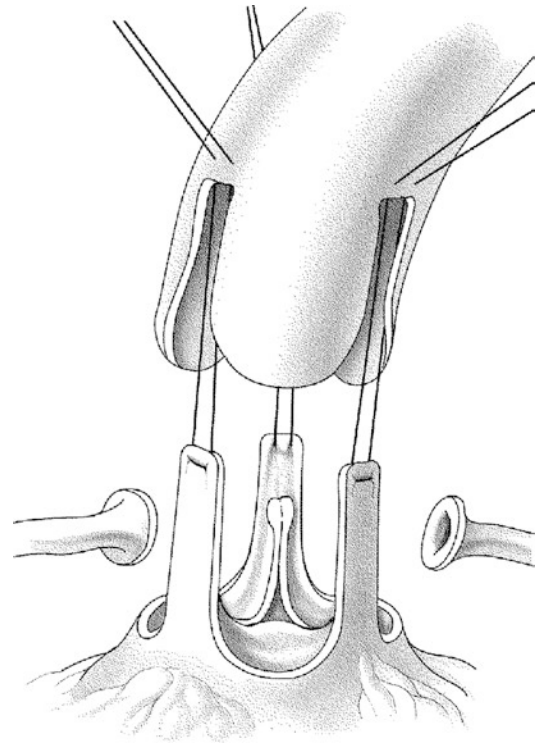

The Yacoub procedure was first described in 1982 (Fagan et al. 1982). The aortic root is mobilized, and the aortic sinuses are excised leaving a 2 mm rim. Likewise, the coronary ostia are mobilized and

excised with a 2 mm rim of aortic wall around them («button»). After measuring the anulus diameter, stay sutures are placed at the upper end of the commissures and put under tension so that the commissures stay in anatomical position and the leaflet coaptation is satisfactory. The diameter of the Dacron vascular prosthesis to be used is determined using Hegar sizers. The prosthesis is then cut in three tonguelike forms (also: «tulip shape»), so that the «tongues» replace the excised sinuses (■ Fig. 24.15). The prosthesis is sutured to the rim of the aortic root wall left over after excising the sinuses using 4/0 monofilament suture. It is important to note that the sutures should pass through the anulus and the attachment of the leaflets. The mobilized coronary ostia are then further mobilized, and the proper site of implantation is determined. Using electrocautery, holes are burned into the prosthesis, and the coronary ostia are anastomosed to the prosthesis using 5/0 monofilament suture. Caution should be taken so that the coronary ostia after implantation should remain without tension and distortion, even after filling of the heart. The suture lines for reimplantation of the coronary ostia can be reinforced with strips of pericardium or Teflon felt pledgets. Mid- as well as long-term results are excellent (Erasmı et al. 2003, 2007; Yacoub et al. 1998; Hanke et al. 2009).

In patients with connective tissue disorders (Marfan syndrome), the Yacoub procedure should be performed with caution, because the aortic anulus will not be stabilized and can further dilate over time. For the same reasons, this procedure may not be appropriate in cases of acute type A aortic dissection or patients with very dilated aortic anuli.

■ **Fig. 24.14** a, b Aortic valve repair by subcommissural narrowing for isolated noncoronary anulus dilatation. a Teflon felt-reinforced U-sutures are passed from the noncoronary sinus through the cusps underneath the commissures and through the subcommissural trigona to the neighboring (right and/or left coronary) sinus and tied down. b During an aortic anuloplasty, U-sutures reinforced with pledgets are passed inside out through the anulus and sutured over a shortening Dacron strip, so that the anulus is plicated and reinforced (*insert*)

■ **Fig. 24.15** The Yacoub («sinus remodeling») procedure. After excision of the native sinuses and mobilization of the coronary arteries, a prosthesis with three «tongues» is implanted at the rim of the native sinuses with a running suture. The native commissures are fixed with a U-suture and the coronary arteries reimplanted

■ ■ David operation

The David procedure, initially published by David et al. in 1992, replaces the aortic root while preserving the native aortic valve. It also stabilizes the aortic anulus (David and Feidel 1992). The aortic root is dissected in the same manner as in the Yacoub procedure. The sinus walls are excised leaving a 3–4 mm aortic wall rim at the anulus. The coronary ostia are mobilized and excised with a «button» of aortic wall. After determining the right prosthesis size/diameter (see Yacoub operation), U-sutures (monofilament 3/0 sutures with or without felt reinforcement) are passed from inside out through the aortic wall, close to the aortic anulus and the base of the aorta. If pledgeted sutures are used, care should be taken that the pledgets are not in contact to the valve leaflets. Alternatively, three base sutures only can be used. The commissures are placed inside the prostheses, and the U-sutures are then passed through the prosthesis (■ Fig. 24.16). The commissure stay sutures

■ **Fig. 24.16** The David («valve reimplantation») procedure. After resection of the sinuses, the prosthesis is then lowered over the aortic valve into position. The prosthesis is tied down, and the commissures are fixated inside the prostheses. The rim of the native sinus is sutured to the prosthesis, and the coronary arteries are reimplanted.

are passed through the prosthesis and tied over felt or pericardium reinforcement. The rim of the excised sinus is then sutured into the prosthesis using running technique inside out, starting at the lowest point of the sinus and upwards, using monofilament 4/0 or 5/0 suture. The coronary buttons are implanted in a way similar to the Yacoub procedure.

There are various technical modifications of the David technique, which attempt to create pseudo-sinuses by changing the dimensions of the prosthesis in the anulus and commissural area. Prostheses with preshaped sinuses are also available. The presence of sinuses have some theoretical advantages in terms of valve durability (Erasmia et al. 2005); however, clinical studies comparing the newer variations with the classical David procedure have yet to show significant clinical advantages (David et al. 2001a, 2002; Erasmi et al. 2003, 2007). A rigid prosthetic material decreases the aortic root compliance and distensibility, and thus long-term follow-up of these patients is of importance.

The advantage of the David operation is that it stabilizes the aortic anulus area, and thus this procedure is particularly appealing in patients with connective tissue disorders (i.e., Marfan syndrome), patients with dilated aortic anuli, and patients with type A aortic dissection.

24.5.2 Aortic Valve Replacement

24.5.2.1 Excision of the Native Valve and Decalcification

After surgical exposure of the aortic valve and application of selective cardioplegia, the native valve is resected. This can be performed easily in patients with aortic regurgitation and none or only minor calcifications. In patients with calcified aortic valve stenosis, however, the calcification of the valve and the anulus can extend into the left ventricular outflow tract or even the anterior mitral valve leaflet. To start with, the calcifications have to be removed using scalpel or rongeur while avoiding a perforation of the aortic base. Small surgical gauze secured with a stay suture may be placed through the left ventricular outflow tract into the left ventricle to prevent small plaques from falling down and remaining in the left ventricle after the decalcification process with the risk of embolization once the heart starts to eject. Additional decalcification maneuvers can be performed using various surgical instruments (Luer or Mikulicz forceps, ■ Fig. 24.17). In the aortic anulus area, the calcified plaques can firstly be crushed and then resected, whereas at the aortomitral curtain and the anterior mitral valve leaflets, the plaques often can be mobilized and removed with fine resection. In case of perforation of the aortic anulus or the anterior mitral valve leaflet, repair may employ autologous pericardium patch and a running suturing technique (suture size 4/0 or 5/0).

Meticulous decalcification should be performed in order:

- To achieve a satisfactory effective orifice area for implantation of the largest valve possible
- To minimize the risk of paravalvular leaks
- To reduce the risk of embolization of the atheromatic plaque

After satisfactory decalcification, the gauze, if employed, is removed from the left ventricle, and after temporarily pausing left ventricular venting,

■ **Fig. 24.17** a–c Excision of the calcified native valve and decalcification of the aortic anulus. **a** Sharp resection of the native valve can be performed in cases where the calcification does not extend into the leaflet attachments. **b** Excision of the native valve with scissors, working parallel to the aortic wall. **c** Removal of calcium plaques in the aortic anulus and wall

the left ventricle, under direct vision, is washed out extensively with saline solution.

Thereafter, the valve orifice area is measured, taking into consideration that the various prosthesis sizers for the different valves are not identical in size with each other (Bartels et al. 1998). Each prosthesis sizer compares to the given size of the specific commercial valve product only (■ Fig. 24.18).

24.5.2.2 Enlargement of the Aortic Anulus

If after meticulous anulus decalcification, an adequate-sized prosthesis cannot be implanted, enlargement of the aortic anulus should be considered. An incision in the noncoronary sinus or the commissure between the left and noncoronary sinus in the anterior mitral leaflet can be used for this purpose (Manouguian and Seybold-Epting techniques: Manouguian and Seybold-Epting 1979). After incision in this area, the base of the aortic root can be enlarged using a 2–3 cm wide tear-shaped patch either from native or glutaraldehyde-treated pericardium or from Dacron; A4/0 monofilament, run-

ning suture is employed starting in the anterior mitral leaflet ending in the anulus, where the suture line is anchored using a second suture. If the left atrium is opened, this should be closed using monofilament, running 4/0 or 5/0 suture. The diameter of the aortic root is now measured again, and the rest of the patch is integrated in the closure line of the aortotomy (■ Fig. 24.19).

24.5.2.3 Subvalvular Stenosis

In most patients with aortic valve stenosis, significant left ventricular hypertrophy coexists. In some of these patients, hypertrophy of the bulbo-spiralis muscle in the left ventricular outflow tract can lead to additional left ventricular outflow tract obstruction. To avoid a residual left ventricular outflow tract obstruction after aortic valve replacement, an enlargement of the subvalvular part is indicated, via a myectomy similar but limited compared to that described by Bigelow or Morrow (Bigelow et al. 1966; Morrow 1978, ■ Fig. 24.20). For extensive discussion of surgery for congenital types of subvalvular stenosis see ► Chapter «Anomalies of the Left Ventricular Outflow Tract», Sect. 16.3.7.

24.5.2.4 Supravalvular Stenosis

Supravalvular aortic valve stenosis is a rare congenital defect, which should be corrected in childhood. This defect is described in ► Chapter «Anomalies of the Left Ventricular Outflow Tract», Sect. 16.4. The cause of this malformation is of genetic origin and often affects both systemic and pulmonary blood vessels (Stamm et al. 2001). Coronary artery malformations

as well as subvalvular anomalies are also often in patients with supravalvular aortic valve stenosis (McElhinney et al. 2000).

24.5.2.5 Choice of Prosthesis

The choice of prosthesis is a major decision in the surgical treatment of aortic valve disease. This decision should be tailored to the patient's needs and wishes after adequate information about risks (e.g., bleeding or thromboembolism) and benefits of each prosthesis, durability, and risk for degeneration as well as the risk of and for reoperation. Data and experience of the institution should be presented. The patient's individual risk should be estimated, also, after taking into consideration comorbidities. Last but not least, life expectancy, as well as professional and social criteria (family planning, hobbies), plays a role in decision-making for a type of valve prosthesis.

In patients between the ages 60- and 70-years-old, the decision of the optimal valve type can be difficult. In these patients life expectancy is usually greater than the biological valve durability, and on the other hand many of these patients wish to avoid lifelong anticoagulation.

24.5.3 Mechanical Valves

Mechanical valves potentially offer the advantage of unlimited durability. Their disadvantage is the need for lifelong anticoagulation and thus the

■ Fig. 24.18 Measurement for aortic valve replacement with a valve sizer. The outside diameter of the sizer indicates the outside diameter of the specific prosthesis the sizer was made for

■ Fig. 24.19 a–c Enlargement of a small aortic root through a posterior patch plasty. a With an incision through the left/noncoronary commissure, the incision is extended into the anterior mitral valve leaflet. b A 2–3 cm wide, tear-shaped patch (native or glutaraldehyde fixated autologous or xenopericardium or other prosthetic material) is sutured into the incision. The suture should start at the deepest point of the incision, in the anterior mitral valve leaflet, and progress till just below the aortic annulus (*asterisks*). c The valve is then implanted with standard technique and the rest of the patch is integrated in the aortotomy closure

■ **Fig. 24.20** a–c Treatment of subvalvular muscular obstruction with a Bigelow myotomy a, b or a Morrow myectomy c. After exposure and visualization of the hypertrophied muscle, the incision is performed into the muscle lying underneath the right coronary anulus part. For the Bigelow myotomy, now only compression into the incision is applied by the surgeon's finger. For the Morrow myectomy, a trapezoid piece, a block of muscle is excised, taking care to avoid injury to the conduction system more anteriorly

risks for bleeding and thromboembolism. The prostheses most often implanted nowadays are of the bileaflet type and in some centers also the tilting-disk type. Mechanical valves are primarily indicated for implantation in younger patients, who may wish to avoid a reoperation. Long-term studies show a risk for thromboembolic complications between 0.5 and 4.4% per patient-year and a risk for major bleeding between 0.4 and 2.3% per patient-year (Lund et al. 2000; Santini et al. 2002). This risk depends on various factors like coexisting diseases (prior thromboembolism or bleeding disorders), patient age, and target anticoagulation range. Patient self-management of anticoagulation has shown to reduce bleeding and thromboembolic complications (Aagard et al. 2003; Kvidal et al. 2000b; Murdy et al. 2003).

Implantation techniques: For the implantation of mechanical and stented biological prostheses, similar principles apply. Principally these prostheses can be implanted either in intra-anular position (using everted, aortoventricular, U-type, size 3/0 or 2/0, pledget mattress sutures) passed first through adequate amount of anular tissue and thereafter through the prostheses. For better orientation, sutures of alternating colors can be used. The prosthesis is held using a special valve stabilizer and lowered into position after all sutures have been passed through the ring of the valve prosthesis (■ Fig. 24.21). Tying down the sutures should be performed in an alternating crossover fashion to avoid tilting the prosthesis,

and it should ensure to implant the prosthesis low into the plane of the aortic anulus. The orientation of the bileaflet prosthesis should be at a 90° angle to a virtual line connecting the coronary ostia. Valve-specific terms «supra,» «epi,» or «intra»-anular implantation can be misleading as on one hand the so-called supra-anular implantation still leaves the prosthesis sitting on the anulus. On the other hand, both techniques are possible with both prostheses, mechanical or biological. A historical and real supra-anular aortic valve implantation had been suggested in the 1970s, when in severe forms of aortic valve endocarditis with anular abscesses, the valve prostheses was implanted high in the ascending aorta, even distal to the coronary ostia. The coronary ostia had to be suture closed, and coronary perfusion was facilitated with saphenous vein grafts (Danielson et al. 1974; Reitz et al. 1981).

An alternative to the U-suture technique is the running suture technique (usually three monofilament sutures size 2/0, one per sinus (■ Figs. 24.22 and 24.23).

It is important to note that mechanical prosthesis has a circular ring that is implanted in a crown-shaped anulus. The ring of biological valves has a similar crown shape that resembles that of a symmetrical aortic anulus.

At the base of the interleaflet trigone between the right and the noncoronary sinus lies the conduction system (His bundle). Care should be taken not to cause injury in this area.

24.5.4 Biological Prostheses

Biological valves are the prostheses of choice in patients 70 years and older. In younger patients, biological valves can be considered when there is an underlying bleeding disorder that would prohibit lifelong anticoagulation. With regards to reoperation, biological valves have a higher degeneration rate the younger the patient is at the time of implantation.

24.5.4.1 Stented Biological Prostheses

Stented biological prostheses are either of porcine or bovine origin. Due to progress in conservation and mounting methods, porcine and bovine prostheses do not show significant differences in durability these days (Aupart et al. 2006; David et al. 2001b; Rizzoli et al. 2006). Stented prostheses differ in the design of their suturing ring, as well as in the complete valve design and most important in their effective valve orifice area.

Implantation technique: For the implantation of a stented bioprosthesis, the same standard principles apply as for the mechanical prostheses. Some prostheses have instead of a circular a semi-lunar suture ring, mimicking the shape of the original valve insertion. This should be taken into consideration at the time of implantation.

24.5.4.2 Sutureless Aortic Valve Bioprostheses

The standard implantation techniques of aortic valve bioprostheses in general employ sutures for fixation of the prosthesis. The increasing number of patients with multiple comorbidities, such as renal insufficiency, chronic obstructive pulmonary disease, or reduced left ventricular function, has made the concept of a less time consuming sutureless implantation of the aortic valve attractive.

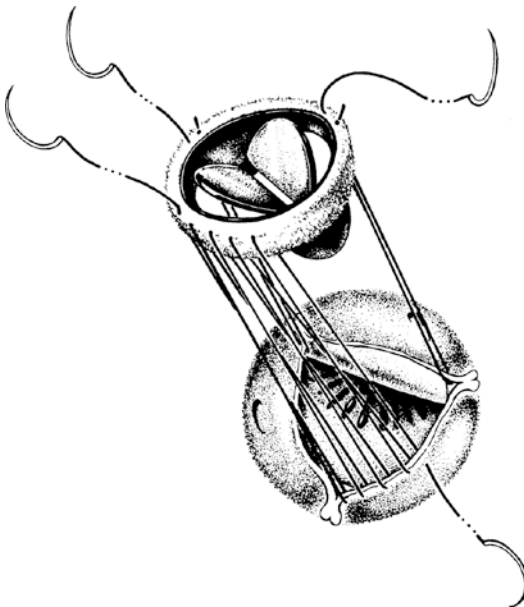

During open implantation of sutureless prostheses, the native valve leaflets are, in contrast to the closed transcatheter implantation, removed.

■ **Fig. 24.21** Implantation of a mechanical prosthesis using everting or the more commonly noneverting mattress sutures. The commissure sutures are marked and placed under tension to facilitate exposure. The prosthesis is mounted on a holder and held by the assistant. The mattress sutures are passed through the annulus and then at similar distances through the prosthesis

■ **Fig. 24.22** An alternative technique to the everting or non-everting mattress sutures is the single suture or the twisting suture technique

■ **Fig. 24.23** Implantation of the prosthesis with the intermittent running suture technique. The suture starts underneath the commissure and continues till the next commissure, which is held under tension with a stay suture. So there are three running sutures, one each between the commissures

Especially the self-expanding devices need careful sizing after decalcification, and in general the aortotomy should be performed more distally than in conventional aortic valve replacement procedures. The first sutureless prosthetic valve was developed in the 1960s by George J. Magovern in cooperation with the engineer Harry W. Cromie (Magovern and Cromie 1963). The major problems with these prostheses at that time were the risk of valve thrombosis, the need for oral anticoagulation, and the risk of endocarditis. The Magovern-Cromie prostheses were implanted in the aortic as well as in the mitral position. Anecdotal reports of patients in whom this prosthesis was implanted have been recently published (Zlotnick et al. 2008).

Reduced ischemia and cardiopulmonary bypass times are major advantages for implantation of sutureless valve prosthesis. This may be of special importance for complex procedures or in patients with high-risk profiles. However, studies comparing outcome of sutureless prosthesis with conventional prostheses are still to be published. Another advantage of the sutureless prostheses may be the increased effective valve area that these type of prostheses offer, as they do not require a suturing ring which allows for larger inner opening diameters. Patients with heavily calcified aortic roots may especially benefit from implantation of a sutureless valve prosthesis.

The sutureless valves currently used, either in the clinical or in experimental setting, are the 3F-Enable Valve (3F ATS Medical, Minneapolis, MN, USA), the Perceval S (Sorin Biomedica, Saluggia, Italy), and the Intuity valve (Edwards Lifesciences, Irvine, CA, USA). The final judgment and acceptance of the sutureless valves will depend on the safety and simplicity of implantation, as well as on the durability in comparison to conventional biological valves.

24.5.4.3 Stentless Valves

The most frequently used stentless aortic valves are preserved and specially prepared porcine aortic roots. The durability of stentless prostheses does not seem to be superior to that of stented prostheses (Ali et al. 2006; Desai et al. 2004; Dellgren et al. 2002; Luciani et al. 2002); however, the major advantage of the stentless prostheses is their larger effective valve area at similar valve sizes, and thus in patients with small aortic roots these devices are preferred by some surgeons (Auriemma et al. 2006; Vrandecic et al. 2000, 2002) (■ Fig. 24.24).

■ Fig. 24.24 a–c Techniques for the implantation of stentless bioprostheses. a Subcoronary. b Root replacement. c The root inclusion technique

■ ■ Implantation technique

There are three main techniques for implantation of stentless valves: the subcoronary technique, the root replacement, and the cylinder inclusion technique.

In the *subcoronary technique* (■ Fig. 24.24a), the prosthesis is completely integrated in the native aortic root. This can be problematic in patients with very large or very small aortic roots and may mandate the use of additional reduction or enlargement techniques for the patient's valve annulus and/or root. The advantage of the subcoronary technique is the preservation of the native aortic wall and the physiological movement of the individual aortic root components. During the implantation, care must be taken to perform the aortotomy higher than usual (about 1 cm higher than the sinotubular junction) so that the commissures of the implanted prosthesis do not extend distal to the aortotomy. A transverse aortotomy or an aortotomy extending in then noncoronary sinus can also be performed. After excision of the native valve, decalcification, and sizing, the stentless valve is implanted using 4/0 basal single or interrupted sutures. These basal sutures are passed through the native aortic annulus and thereafter through the suturing ring of the prosthesis. Care should be taken to ensure a symmetry between the native aortic valve annulus and the prosthesis, to avoid malrotation of the prosthesis and obstruction of the coronaries, as well as to avoid injury to the conduction system (His bundle) which runs in the triangle between the right and noncoronary sinus. The prosthesis is then parachuted in place, and the sutures are tied down. Alternatively, the prosthesis can be sutured using multiple—two or three—running sutures (i.e., monofilament size 3/0, 4/0).

After the excision of the prosthesis's corresponding sinuses leaving a 3 mm rim, the sub-

coronary suture line is performed using running monofilament 5/0 or 4/0 sutures starting at the deepest point in the sinuses toward the commissures. The commissures are secured at the aortic wall using pledget U-sutures. The noncoronary sinus of the prosthesis can be preserved completely. For the closure of the aortotomy, the noncoronary sinus can be sutured at first using running sutures, and the prosthesis can be secured in this area using 4/0 monofilament U-sutures through the aortic wall, prior to the final closure of the aortotomy.

In the *root replacement technique* (■ Fig. 24.24b), the coronary ostia are excised with a small rim of aortic wall (coronary buttons), while the remainder of the aortic root is completely resected. The basal suture line for prosthetic valve implantation is performed in a similar fashion as in the subcoronary technique; however, when employing the single interrupted suture technique, the use of pledges or pericardium strips as reinforcement may be advantageous in terms of stability and hemostasis. After tying the basal suture line, the coronary buttons are reimplanted taking care to avoid any tension or distortion. Thereafter, the prosthesis is sutured to the proximal part of the ascending aorta using monofilament 4/0 sutures.

In the *cylinder- or root inclusion technique* (■ Fig. 24.24c), the basal suture line is performed similar to the previously mentioned techniques, and the coronary buttons are implanted on the prosthesis using monofilament running or single interrupted size 5/0 sutures. However, the wall of the aortic root stays in place. The prosthesis is then sutured to the native aortic wall with a 4/0 monofilament running suture, and the aortotomy is closed in a similar fashion.

The basal suture of the stentless prostheses should be deep enough in the aortic root (left ventricular outflow tract) to facilitate a tension and distortion-free reimplantation of the coronary buttons.

Other modifications of stentless valves are manufactured from pericardium and require tailored implantation procedures such as a basal suture and mere fixation of the commissures (Grubitsch et al. 2005) or a solitary basal suture (Beholz et al. 2006).

24.5.4.4 Homografts

Human donor valves (homografts) offer similar long-term results as biological prostheses; however, they do suffer from an accelerated degeneration rate when implanted in younger patients (Takkenberg et al. 2003; Talwar et al. 2005). They present an attractive choice of prosthesis in patients with extensive endocarditis, as they carry no foreign material. Homografts offer similar advantages as stentless prostheses (larger effective orifice area, no need for lifelong anticoagulation) and may be regarded as an alternative to a valved conduit in patients requiring combined aortic valve and aortic root replacement.

Implantation technique: The implantation technique of the homograft is similar to that of stentless valves. Because the homograft tissue is much more flexible and compliant than that of the stentless valves, during the subcoronary or root inclusion implantation, the homograft can be inverted inside the left ventricular outflow tract, and the basal suture can be performed with a running monofilament 3/0 or 4/0 suture (■ Figs. 24.25 and 24.26).

24.5.4.5 The Ross Operation

The Ross procedure was originally performed in 1967 by Donald Ross (Ross 1967). Its principle is to replace the diseased aortic valve with the patient's own native pulmonary valve. The latter then has to be replaced with a pulmonary homograft. The benefits of this procedure lie in the fact that vital tissue is being implanted in the aortic position that has the potential for growth, requires no anticoagulation, and has superior durability than aortic homografts in the aortic position. The reason behind the greater durability of the pulmonary homografts in the pulmonary positions than that of aortic homografts in the aortic position is the fact that in the Ross procedure the pulmonary homograft is implanted in a low-pressure system and thus they develop degenerative changes at a

lower rate than aortic homografts implanted in the aortic position (Alkog et al. 2000). The disadvantages of this procedure are its technical complexity and the fact that a Ross procedure converts a «one-valve problem» to a potential «two-valve disease.» Studies have shown that degeneration of the pulmonary homograft is responsible for a significant proportion of the reoperations observed in these patients in the long term (Carr-White et al. 2001). Data from registries show that in experienced centers, the Ross procedure is an attractive alternative to conventional aortic valve replacement in young patients (Böhm et al. 2003; Duebener et al. 2005; Pasquali et al. 2007; Schmidtke et al. 2001; Sievers 2002; Sievers et al. 2006, 2010a, b).

The implantation techniques for the pulmonary autograft in Ross procedure are similar to the implantation of stentless valves or homografts (see also ► Chapter «Anomalies of the Left Ventricular Outflow Tract», Sect. 16.2.6.3; Fig. 16.11a–c). Typically, subcoronary, root replacement, and root inclusion techniques are employed. Especially the subcoronary and the root inclusion technique seem to have superior long-term results, as the native aortic wall can provide support to the weaker pulmonary valve and artery tissue and thus better resist to dilatation (Schmidtke et al. 2001; Sievers et al. 2006, 2010a, b). The reinforced full root replacements also offer excellent long-term results (Charitos et al. 2009a). The pulmonary homograft that will replace the harvested autograft is implanted distally as well as proximally using running monofilament 4/0 or 5/0 sutures. Mild right ventricular outflow size mismatch can be corrected using either autologous glutaraldehyde fixated pericardium or a synthetic membrane. Of special importance for the durability of the Ross procedure is strict adherence to as low as possible blood pressure for 2 months after the procedure as well as lifelong endocarditis prophylaxis.

24.5.5 Combined Procedures

Many patients require combined surgery on the aortic valve and its surrounding structures, like coronary arteries or other parts of the thoracic aorta or on other valves, also. One should take into consideration that complex procedures in general increase the overall operative risk.

Prior to any procedure, a general operative strategy should be *planned well in advance*.

■ **Fig. 24.25** a–e Aortic valve replacement with a homograft. **a** The sinuses of the homograft are excised. **b** The valve is inverted. **c** The homograft is inverted into the left ventricular outflow tract, and the homograft basis is sutured to the native anulus using an atraumatic suture. **d** Thereafter, the homograft is everted again, and the commissures are pulled up into the aorta and sutured to the aortic wall using pericardial or Teflon pledgeted sutures. **e** The rim of the homograft sinuses is sutured to the aortic wall using running suture in between commissures

24.5.5.1 Aortic Valve Replacement and Coronary Artery Bypass Grafting

Isolated coronary artery bypass grafting as well as isolated aortic valve replacement are routine cardiac surgical interventions. The indications for combined aortic valve replacement and CABG procedure are the same as for isolated aortic valve replacement. As a mild aortic valve disease, however, can quickly progress to a severe form, concomitant aortic valve

replacement at the time of primary coronary bypass grafting should be performed also in the setting of mild or moderate aortic valve disease (Rosenhek et al. 2004; Smith et al. 2004). Intraoperative aortic valve inspection may help to determine the degree of valve degeneration and facilitate the decision.

During combined CABG and aortic valve replacement, on extracorporeal circulation, the aortic valve is excised to start with, in order to allow for manipulation of the heart during CABG without the

risk of dislocation of calcium plaques. Thereafter, the distal coronary bypass anastomoses are performed. This is followed by replacement of the aortic valve and closure of the aortotomy. Finally, the grafts are anastomosed proximally. With the distal anastomoses in place, it is possible to perfuse coronary arteries with cardioplegic solution distal to their obstruction until the end of the ischemic period.

24.5.5.2 Aortic Valve Replacement in Multiple Valve Disease

If more than one valve requires surgical attention, the calcified aortic valve is excised at first. Thereafter, interventions on the other valves are performed in the following sequence:

- Mitral valve
- Aortic valve
- Tricuspid valve
- Pulmonary valve

This sequence prevents embolization of calcified aortic valve and/or wall plaques. It also allows for tricuspid and pulmonary valve surgery to be performed after closure of the aortotomy and while the heart is already being reperfused.

Because of the anatomic proximity of the aortic and mitral valve anulus (■ Fig. 24.1), mitral valve replacement or mitral ring anuloplasty can lead to reduction of the aortic valve diameter. Therefore, mitral valve surgery should be performed before the aortic valve is replaced. The aortic valve anulus should be sized only after the mitral valve has been taken care of (replacement/reconstruction).

The techniques for mitral, tricuspid, or pulmonary valve replacement during concomitant aortic valve replacement are described in the corresponding sections of this book.

24.5.5.3 Concomitant Replacement of Aortic Valve and Ascending Aorta

During concomitant surgery on aortic valve and ascending aorta, the decision should be made whether the aortic valve can be repaired or not and whether only the tubular part of the ascending aorta or the complete aortic root should be replaced, also. The classic Bentall procedure (Bentall and De Bono 1968) with reimplantation of the coronary arteries for the complete replacement of the aortic root and the ascending aorta can be performed either with a composite mechanical valve-graft conduit or in combination with a stented biological valve («bio Bentall»).

Long-term results are excellent (Hagl et al. 2003). Alternatively, a combination of a Dacron prostheses and a stentless biological valve can be used (Urbanski et al. 2003). If the aortic root is not diseased, then a conventional aortic valve and ascending aorta replacement can be performed which significantly simplifies the operative procedure (Houel et al. 2002; Sioris et al. 2004). In cases of ascending aortic ectasia or mild dilatation, an aortoplasty can be performed using mattress sutures followed by running 3/0 monofilament sutures over two Teflon strips for reinforcement (Bail et al. 2007; Robicsek et al. 2004; Walker et al. 2007). In cases of aortic root dilatation with a macroscopically normal aortic valve, a valve-sparing David or Yacoub procedure is indicated.

24.5.5.4 Aortic Valve Replacement in Advanced Age

Calcified aortic valve stenosis is a disease characteristically seen with advanced age, senile aortic stenosis. The aging of the overall population has led to an increase in the mean age of patients referred for aortic valve replacement. Although the natural history for severe symptomatic aortic valve stenosis carries a significant mortality and morbidity burden, almost a third of the elderly patients than could potentially benefit from surgery are not referred for surgical evaluation. The main reasons for this seem to be increased age and reduced left ventricular function (Jung et al. 2005). However, many studies have shown that although aortic valve replacement in the elderly carries a somewhat increased operative risk as compared to younger patients, these patients do benefit from aortic valve replacement, also (Carabello 2004; Charlson et al. 2006; Chukwuemeka et al. 2006a; Langanay et al. 2006; Sundt et al. 2000; Varadarajan et al. 2006b). As the perioperative risk of such procedures is increased in an emergency setting, especially in this patient population, a planned referral for timely surgery should be sought (Kohl et al. 2007; Mistiaen et al. 2004). The increased perioperative risk in this patient population should be communicated with the patient during the informed consent process, as often many patients decline the procedure. High-risk patients should be offered a minimal invasive alternative (transfemoral or transapical aortic valve replacement; see ► Sect. 24.8 «Alternative Therapeutic Interventions» and Chapter «Minimally Invasive Cardiac Surgery», ► Sect. 26.3.4).

24.5.5.5 Aortic Valve Replacement and Dialysis

Patients with terminal renal insufficiency are prone to develop calcified aortic valve stenosis. Because of the reduced life expectancy of these patients and the need for regular vascular access for dialysis, the American Heart Association and American College of Cardiology guidelines recommend the implantation of biological valves in these patients (ACC/AHA Guidelines, Bonow et al. 2006). However, no significant survival difference could be shown between biological or mechanical valves in patients with terminal renal insufficiency requiring dialysis (Herzog et al. 2002). For these reasons, the decision between mechanical or biological aortic valve replacements should take into consideration the patient's age and life expectancy, the option of renal transplantation, as well as the patient's preferences.

24.5.5.6 Aortic Valve Replacement and Pregnancy

Mild or moderate aortic valve stenosis (aortic valve area $>1.0 \text{ cm}^2$) rarely causes complications during pregnancy (Hameed et al. 2001). Severe aortic valve stenosis can lead to increased maternal morbidity and fetal mortality. Maternal mortality is rare (Silversides et al. 2003). Usually these patients will require aortic valve replacement during the first months after delivery. When patients with severe aortic valve stenosis develop symptoms during pregnancy, this may lead to interruption of pregnancy. Therefore, a balloon dilatation prior to surgical intervention may be necessary. Important factors for the prognosis of the disease during pregnancy are left ventricular function, grade of the aortic valve stenosis, and history of previous left ventricular decompensation or thrombotic complications. Aortic valve insufficiency is usually good tolerated during pregnancy.

Pregnancy does not cause acceleration of biological valve degeneration. Mechanical prostheses however carry a certain thromboembolic risk as well as a risk for warfarin embryopathy. For these reasons in patients wishing to become pregnant, biological valves may be an alternative. Patients with mechanical prostheses who become pregnant should be switched to unfractionated heparin during the first trimester and after the 36th week of pregnancy in order to reduce the risk for warfarin embryopathy or bleeding. Perioperative anti-

biotic prophylaxis may be used in these patients (Elkayam and Bitar 2005; Hung and Rahimtoola 2007; Reimold and Rutherford 2003).

A detailed information for the pregnant patient or the patient in childbearing age about the risk during and after pregnancy as well as during delivery and a close collaboration of cardiologists, cardiac surgeons, and gynecologists is of great importance.

24.5.5.7 The «Small» Aortic Valve Anulus

The term «prosthesis-patient mismatch» (PPM) was first introduced by Rahimtoola in 1978 (Rahimtoola 1978) and describes the situation when the effective valve area of the prosthesis is smaller than that of the normal aortic valve for the given body size. The first who examined relevance and implications of PPM on the patient's functional status after aortic valve replacement was Pibarot (Pibarot et al. 1996). ■ Table 24.2 presents the grading criteria of PPM as described by Blais et al. (2003).

Although studies have shown that the presence of PPM can have a negative effect on the early postoperative course (Kulik et al. 2006; Tascia et al. 2006), this can be masked by many other factors. In special cases, the use of a smaller prosthesis may be justified. This is true for older patients with small aortic roots (Arata et al. 2002; Bortolotti et al. 2000). Important factors to facilitate the decision for the size of prosthesis are not only the left ventricular functional status but also the patient's daily level of activity. Small prostheses should be avoided in tall or active patients, in order to decrease the early postoperative risk, as well as to facilitate late recovery of the left ventricular function (David 2005). In these patients, aortic root enlargement procedures may allow for the implantation of a larger prosthesis without a significant increase in operative risk (Peterson et al. 2007).

■ Table 24.2 Defining the severity of «prosthesis-patient mismatch» by valve area indexed to body surface area (Blais et al. 2003)

Definition	Effective aortic valve area (cm^2/m^2)
Severe PPM	<0.65
Moderate PPM	$0.65\text{--}0.85$
No PPM	>0.85

24.6 Intra- and Postoperative Course

24.6.1 Patient Monitoring

Intraoperative monitoring of patients undergoing aortic valve replacement is not different to other routine cardiac surgery procedures. Apart from the central venous access as well as invasive arterial blood pressure monitoring, transesophageal echocardiography (TEE) plays nowadays a central role. TEE can evaluate the prosthesis or native valve function, the anatomy of the aortic root, the coronary ostia, ventricular function when weaning from extracorporeal circulation, as well as evaluate the de-airing of the heart. Especially during aortic valve reconstruction, TEE can evaluate and document the postoperative result.

24.6.2 Postoperative Management

The early postoperative management of patients after aortic valve interventions does not deviate significantly from that of patients undergoing other routine cardiac surgery procedures. The management of patients however with aortic valve stenosis and significant left ventricular hypertrophy can be challenging. During hypertensive phases, the risk of bleeding in these patients is increased as well as the myocardium oxygen needs. For these reasons, strict blood pressure monitoring in these patients is advised. Due to decreased myocardial compliance, these patients

may also require increased filling pressures to maintain adequate cardiac output, and thus invasive hemodynamic monitoring with a Swan-Ganz or left atrial pressure catheter is of benefit and can aid postoperative decision-making. Patients after aortic valve replacement may develop temporary atrial or ventricular arrhythmia, and thus, temporary pacemaker electrodes should not be prematurely removed.

All patients after aortic valve interventions should receive endocarditis prophylaxis as well as adequate anticoagulation as recommended in the guidelines of the American Heart Association (Bonow et al. 2006).

24.6.2.1 Anticoagulation

Patients with mechanical valves must receive life-long oral anticoagulation, whereas patients with biological valves may require anticoagulation only for the first months after the procedure, if at all. The degree of anticoagulation requirement can vary from patient to patient according to the type and model of the implanted prosthesis as well as depend on other comorbidities. ■ Table 24.3 presents an overview of the anticoagulation recommendations in patients after mechanical and biological aortic valve replacement (Bonow et al. 2006).

In patients already receiving warfarin, the addition of acetylsalicylic acid (ASA) is recommended. Risk factors requiring a higher anticoagulation target range are:

- Atrial fibrillation
- Reduced left ventricular function
- History of thromboembolic event
- Hypercoagulopathy

■ **Table 24.3** Recommendations of The American College of Cardiology and The American Heart Association for anticoagulation of patients with aortic valve prostheses (Bonow et al. 2006)

Risk stratification	Acetylsalicylic acid (75–100 mg)	Warfarin (INR: 2.0–3.0)	Warfarin (INR: 2.5–3.5)
Mechanical prostheses			
Low risk, <3 months	x	x	
Low risk, >3 months	x	x	
High risk	x		x
Biological prostheses			
Low risk, <3 months	x		
Low risk, >3 months	x		
High risk	x	x	

In contrast to the abovementioned guidelines, in many centers, patients with low thromboembolic risk after biological aortic valve replacement receive warfarin only for the first 3 months and are switched thereafter to ASA. Patients with homografts or after the Ross procedure should receive ASA only for the first postoperative months.

24.6.2.2 Endocarditis Prophylaxis

A detailed overview of the indications and recommendations for endocarditis prophylaxis in patients after aortic valve replacement can be found in the guidelines of the American Heart Association (Bonow et al. 2006).

24.6.3 Surgical Results and Complications

Postoperative results after routine aortic valve surgery are nowadays excellent, so that older (Kvidal et al. 2000a, b) as well as patients with reduced left ventricular function (Chukwuemeka et al. 2006a, b; Scognamiglio et al. 2005; Tarantini et al. 2003) or pulmonary hypertension (Pai et al. 2007) benefit from aortic valve replacement. Of major importance is the optimal timing for surgery, as elective procedures have a significantly lower mortality and morbidity than the same procedures performed under emergency condition. Aortic valve reconstruction should be performed in specialized centers to ensure a satisfactory long-term result (Rankin et al. 2006).

Individualized risk profiling is of major importance for the decision to undergo aortic valve interventions.

24.6.3.1 Intraoperative Complications

Intraoperative complications may emerge in the form of anulus or aortic wall perforation during decalcification and can be directly treated by closing the defect with a Teflon pledget or pericardium-reinforced suture, or even with a pericardial patch. This complication can often only be identified late during the procedure, after pressure loading of the aorta leads to an enlarging subepicardial hematoma. Attempts to close the defect on the beating heart from the outside of the aortic wall are rarely successful, as the precise localization of the defect may not be identified. In these cases, opening of the aortotomy and closure of the defect from the inside is highly recommended. Bleeding from the aortotomy suture line can easily be controlled with additional U stitches and should be done while still on

extracorporeal circulation with minimal pressure loading of the aorta. In some cases where calcified plaques are near the aortotomy area, an opening of the aortotomy, excision of the aortic wall plaques, and closing of the aortotomy with the use of pericardium or Dacron patch might be necessary.

Potential obstruction of the coronary arteries should be taken into consideration when choosing the appropriate prosthesis size. In cases of atypical origin or course of the coronary arteries, it might be necessary to perform additional CABG in order to ensure perfusion of the atypical coronary.

24.6.3.2 Postoperative Complications

Postoperative complications can occur in the immediate as well as in the later postoperative phase. In the early postoperative phase, the most frequent complications are heart rhythm disorders such as AV block and either surgical or diffuse bleeding due to coagulopathies leading to pericardial tamponade. Somewhat later are general complications such as wound healing disorders or instable sternum. Late postoperative complications often have to do with the implanted prostheses such as valve degeneration, valve thrombosis, valve malfunction, and prosthetic valve endocarditis.

■ ■ Valve thrombosis

The risk for valve thrombosis depends on the anatomic position of the prosthetic valve. The risk for thrombosis is greater in the tricuspid position followed by the mitral position, while in the aortic position the risk is less than 1% per year. Acute valve thrombosis often carries a high mortality. Due to the obstruction of the valve function, it often requires an emergency intervention. Systemic thrombolysis may be an alternative to valve exchange in patients with acute mechanical valve thrombosis late after the original surgery. Although surgical removal of the valve thrombus can alleviate the valve obstruction, a valve exchange is recommended once it is opted for surgery, as the thrombus development can be a consequence of damaged or defect valve coating, and thus the valve may be prone to recurrent valve thrombosis in the future. In cases of chronic valve thrombosis or pannus formation and valve obstruction, the prosthetic valve should be replaced, anyways.

■ ■ Prosthetic valve endocarditis

Prosthetic valve endocarditis after aortic valve replacement is a serious complication that can

■ **Fig. 24.26** Refixation of a partially detached, however intact, mechanical prosthesis (paravalvular detachment and paravalvular leak) without evidence of endocarditis. The refixation is performed with additional mattress sutures, reinforced with pericardial or Teflon felt pledgets. The sutures are passed from the outside, through the aortic wall and the prosthesis

lead to in hospital mortality of up to 30% (Moon et al. 2001). In combination with prolonged antibiotic therapy and healed focus, aortic valve replacement is most often the therapy of choice. In about half of these patients, the aortic root can be involved, also. In order to prevent reinfection, during reoperation of patients with prosthetic valve endocarditis, the use of prosthetic materials should be limited as far as possible. For this reason, the use of homografts can be recommended, especially in prosthetic endocarditis with anuli abscesses (Lytle et al. 2002; Sabik et al. 2002). However, it remains unclear which is the prosthesis of choice in these cases, as the decision of the replacement prosthesis depends on the complexity of the intervention and the additional interventions that may be required to remove all infected tissues from the aortic root (Hagl et al. 2002; Leyh et al. 2004; Moon et al. 2001).

■ ■ Paravalvular leak

A partial valve detachment with the consequence of a paravalvular leak presents with an incidence of about 1–2%. In most cases an acute or cured endocarditis can lead to valve detachment and paravalvular leak; however, inadequate valve fixation during the primary operation can also result to paravalvular leak development. Paravalvular leaks are preferential sites for the development of prosthetic endocarditis. Most often, inadequate

valve fixation can occur due to incomplete valve and anulus decalcification. The indications for reoperation for paravalvular leak depend on the patients' symptoms, the presence or absence of hemolysis, as well as the hemodynamic consequences of the leak. In cases of a localized partial detachment, this can be repaired with additional pledget or pericardium-reinforced, size 3/0 Seralene or Mersilene U-sutures (■ Fig. 24.26). In cases of multiple or extended detachment of the prosthetic valve, a new valve replacement is recommended.

24.7 Reoperations

Aortic valve reoperations become more and more part of the daily routine in cardiac surgery. This in most case is due to the degeneration of biological prostheses, but there are also complications of mechanical and biological prostheses. Although elective reoperations require some special surgical approaches, they are not associated with a significantly higher morbidity and mortality in experienced centers as long as they are limited to isolated aortic valve re-replacements (Davierwala et al. 2006; Potter et al. 2005; Vigt et al. 2000).

Indications. Indications for aortic valve reoperations follow the general guidelines and criteria for aortic valve surgery and depend on the

presence of symptoms, other comorbidities, hemodynamic parameters, as well as upon the need for other, concomitant, cardiac procedures.

24.8 Alternative Therapeutic Interventions

The techniques for percutaneous aortic valve balloon valvuloplasty were developed in the 1980s as an alternative to conventional valve replacement, in order to offer symptomatic, high-risk, patients with severe aortic valve stenosis a therapy option (Cribier et al. 1986). Initial results showed a high (~25%) periprocedural complication rate, mortality rates up to 8%, and increased incidence of early restenosis and rehospitalization (NHLBI Balloon Valvuloplasty Registry Participants 1991). Since then however, with the use of refined techniques, results have significantly improved, and balloon valvuloplasty has now been shown to improve early and midterm survival (Agarwal et al. 2005). Studies have shown that combination of valvuloplasty and radiation may improve restenosis rates. Nowadays however the interest in less invasive aortic valve interventions has shifted to minimal invasive aortic valve implantation via the transapical or transfemoral approach, see ► Chapter «Minimally Invasive Cardiac Surgery», Sect. 26.3.4.

24.9 Surgical Techniques for the Management of Aortic Valve Endocarditis

Bacterial aortic valve endocarditis can affect various parts of the aortic valve and can result in destruction of the valve mechanism resulting in aortic regurgitation. Additional destruction of the aortic root and surrounding structures may also carry the risk of septic embolism. Without intervention, this disease is often fatal. The aortic valve is involved in 25% of cases with bacterial endocarditis (mitral valve, 40%; tricuspid valve, 20%; pulmonary valve, 2%). In almost 50% of all patients with aortic valve endocarditis, a surgical intervention is indicated. Indications for surgery should be individualized, since early intervention does not always lead to improvement of early postoperative prognosis (Tleyjeh et al. 2007). Especially in the setting of large (>8 mm), mobile vegetations, surgical inter-

vention is absolutely indicated. In patients with septic cerebral embolization, the time point of surgical intervention is of great importance as the risk for recurrent embolization should be weighed against the risk of intracerebral bleeding during the procedure due to the systemic heparinization required for extracorporeal circulation. The emergency procedure in these cases should be performed either within the first 24 h or after 4–6 weeks when the initial cerebral insult has stabilized. As cerebral insult often lead to blood-brain barrier disorders, a computed tomography may be performed prior to intervention in patients with cerebral insult.

Risk factors for aortic valve endocarditis are:

- Bicuspid and degenerated calcified aortic valves
- Past rheumatic fever
- Diabetes mellitus
- Congenital valve disease
- Prior endocarditis

In about 8–20% of all cases, dental procedures or other invasive interventions, respectively, were the main suspects of the initial bacteremia leading to endocarditis.

Typical microorganisms causing endocarditis are (Bashore and Khandheria 2004):

- *Staphylococcus aureus* (32.4%)
- *Streptococcus viridans* (13.1%)
- *Enterococcus faecalis* (10.6%)

For the prevention of endocarditis, guidelines from the American Heart Association have been published (Wilson et al. 2007).

It is recommended that in complicated cases of aortic valve endocarditis, bicaval cannulation should be preferred. This should facilitate an extension of the procedure into the right heart chambers if deemed necessary later on during the procedure. Not infrequently, the extent of the procedure necessary can be only determined intraoperatively after careful inspection of the diseased tissues and findings such as:

- Supravalvular abscesses and aneurysms with or without fistulas to other heart chambers
- Subvalvular abscesses or aneurysms with aortoventricular dehiscence
- Destruction of other valves (mitral, tricuspid, or pulmonary)

All excised infected tissues should be sent for microbiological examination and identification of

the culprit microorganisms to determine appropriate antibiotic regimen.

In cases of aortic valve endocarditis, one should differentiate between those with isolated leaflet endocarditis and those cases with additional involvement of the surrounding structures. The principal aim of surgical intervention in cases of aortic valve endocarditis is the excision of all macroscopically infected tissue. The choice of valve prosthesis in cases of aortic valve endocarditis remains an open question. The use of homografts or the Ross procedure, with minimal foreign material implanted, offers at least a theoretical advantage in cases of acute infection (Lytel et al. 2002; Sabik et al. 2002; Birk et al. 2004). Many studies have failed to show an advantage of biological prostheses in comparison to mechanical prostheses in patients with aortic valve endocarditis (Hagl et al. 2002; Leyh et al. 2004; Moon et al. 2001).

Care should be taken to completely remove all macroscopically infected tissue, in order to avoid endocarditis recurrence or spread of the infection.

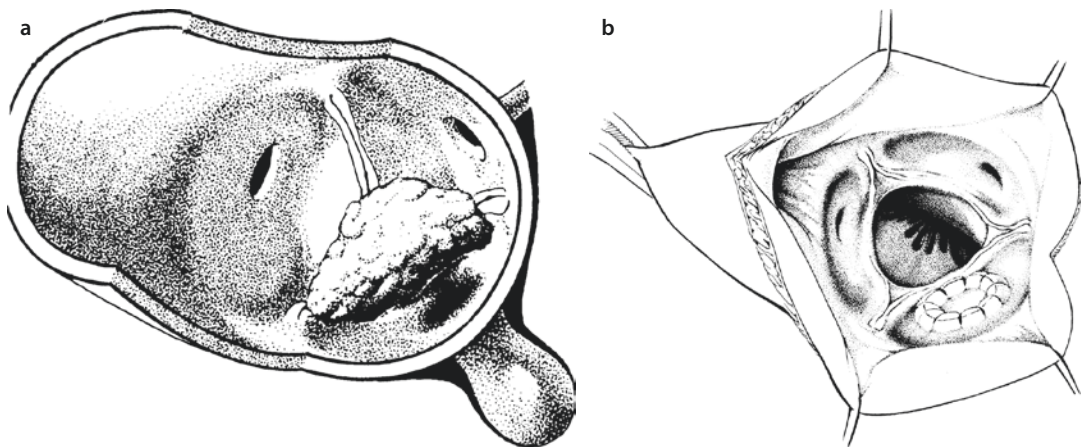

24.9.1 Aortic Root Abscess

In cases of aortic root abscess, the infectious tissues should be excised, and radical debridement of the abscess cavity should be performed. The abscess cavity should be sealed with native or glutaraldehyde-treated pericardial patch using running monofilament 4/0 or 5/0 suture (■ Fig. 24.27). In cases where subvalvular abscesses

were found, these may be directly closed after radical debridement using pericardium-reinforced, monofilament, 4/0 U-sutures or using a pericardium patch (■ Fig. 24.28). The same is true for abscess cavities extending in the ventricular or atrial tissues (■ Fig. 24.29). Experimental studies have shown that injection of a mixture of fibrin glue and antibiotics in the infected areas may have a beneficial effect in terms of endocarditis prophylaxis as well as for the treatment of endocarditis itself (Deyerling et al. 1984; Karck et al. 1990).

24.9.2 Multiple Valve Endocarditis

In cases of combined aortic and mitral valve endocarditis, a combined aortic and mitral valve replacement/repair should be performed. It is not rare that an infection of the aortic valve extends to the mitral valve and vice versa. In these cases, the Manouagian technique (Manouagian et al. 1979) for the enlargement of the aortomitral continuity through the noncoronary sinus and part of the aortic anulus should be performed in order to gain surgical access to the mitral valve. This technique allows for the radical excision of all infected tissue in this area and provides access in case additional interventions on the mitral valve are deemed necessary. For the reconstruction of the aortic basis and the aortomitral continuity, autologous or xenopericardium should be used. Similar techniques may be used in cases where the infection extends even toward the tricuspid valve.

■ Fig. 24.27 a Abscess of the noncoronary sinus penetrating toward the right atrium with destruction of the noncoronary cusp, also. b The aortic valve is excised, and the abscess cavity is closed with a pericardial patch

Fig. 24.28 **a** Of the aortomitral continuity. The attachment of the anterior mitral leaflet is completely detached from the aortic wall, and the left atrium may be seen. **b** Reattachment of the base of the aortic root to the anterior mitral leaflet using pericardium or pledget-reinforced U-sutures, only suggested in minor dehiscence. **c** To avoid tension on the sutures, the defect, especially when large, should be closed with a pericardial patch

Fig. 24.29 **a, b** Subvalvular abscess extending into the muscular ventricular septum. **a** The wall of the abscess is excised, and debridement of the abscess cavity is performed. **b** The cavity is closed with a pericardial patch using a running suture penetrating deep in the septal muscle

25.1 History of AV-Valve Surgery

The first successful mitral valve procedure in history was performed at the Peter Bent Brigham Hospital in Boston, Massachusetts, in 1923, by Elliot C. Cutler who used a teratomy knife placed from the apex of the left ventricle to open a stenotic mitral valve by commissurotomy (Cohn 1994). Two years later, in 1925, Souttar performed a mitral valvulotomy from the left atrium using his finger to fracture the commissures (Comas et al. 2006). The next step in the evolution of mitral valve surgery was depending on the development of cardiopulmonary bypass. Following Braunwald's research studies at the National Institute of Health in the 1950s, Starr and Edwards were the first to implant a mitral valve prosthesis at the University of Oregon in 1961. Despite a relatively high rate of thromboembolic complications, the Starr-Edwards caged-ball prosthesis presented the gold standard for mitral valve replacement for many years (Gao et al. 2004). The caged-ball prosthesis was replaced by tilting disc prostheses and later on by bileaflet prostheses in the 1980s. Another important development in heart valve surgery was the establishment of biological heart valve prostheses. In 1970, Hancock implanted the first stented porcine valve, and only 6 years later, the first generation of Carpentier-Edwards bovine pericardial valves was introduced (see also ► Chapter «The History of Cardiac Surgery», Sect. 1.9).

Following the establishment of heart valve prostheses for the treatment of mitral valve disease, reconstructive techniques such as open commissurotomy became less important. However, the negative side effects of prosthetic valve replacement, i.e., the need for lifelong anticoagulation and the risk of thromboembolic complications associated with mechanical valves and the high rate of degeneration of biological prostheses, led to a revival of reconstructive techniques particularly within the last two decades. One of the pioneers of mitral valve reconstruction is Alain Carpentier who applied a systematic and reproducible approach to reconstructive mitral valve surgery (Carpentier 1977).

With an aging patient population and a broader application of valve reconstruction or replacement, the rate of patients referred for redo mitral valve surgery is constantly increasing. Consequent long-term follow-up of patients undergoing mitral valve repair and improving imaging quality of echocardiographic assessment

reveals today the real quality and durability of repair techniques developed and applied in the early days of reconstructive valve surgery. However, meanwhile reoperative mitral valve surgery, accessed commonly via a median sternotomy but also via right and – less common – left lateral thoracotomy, has become a standardized and safe procedure in most cardiac tertiary care centers.

The proportion of tricuspid valve surgery compared to mitral valve procedures remains small, and the decrease of rheumatic diseases in industrial countries makes particularly tricuspid valve replacement a rare procedure today. However, tricuspid valve reconstruction, most commonly to treat tricuspid regurgitation due to pulmonary hypertension in patients with long-lasting mitral valve regurgitation becomes more important. Different techniques of tricuspid valve reconstruction are described at the end of this chapter.

25.2 Open Surgical Access

25.2.1 Median Sternotomy in Primary and Redo Surgery

Mitral valve surgery can be accessed by a median sternotomy (■ Fig. 25.1) or lateral thoracotomy from the right and less common from the left side. A right anterior thoracotomy is used for minimal-invasive approaches and usually limited to the AV valves and does not allow concomitant procedures such as CABG or aortic valve procedures. Particularly reoperative mitral valve surgery, which needs to be applied to an increasing proportion of patients, can be performed more safely via median sternotomy. However, redo sternotomy carries the risk to injure retrosternal structures such as the right ventricle or the right atrium, and therefore transection of the posterior proportion of the sternal bone and dissection of the pericardial tissue needs to be performed carefully to avoid severe bleeding complications. In redo cases, we strongly recommend a preoperative CT scan of the chest to measure the distance between the sternum and the cardiac structures. Sternotomy is performed with an oscillating saw while the respirator is disconnected in order to deflate the lungs and thus unload the right ventricle. Once the posterior layer of the sternal bone is cut, the parietal pleura and the pericardium are dissected. If the pericardium was not closed at the initial procedure, careful dissection between the parietal pleura and the right atrium/

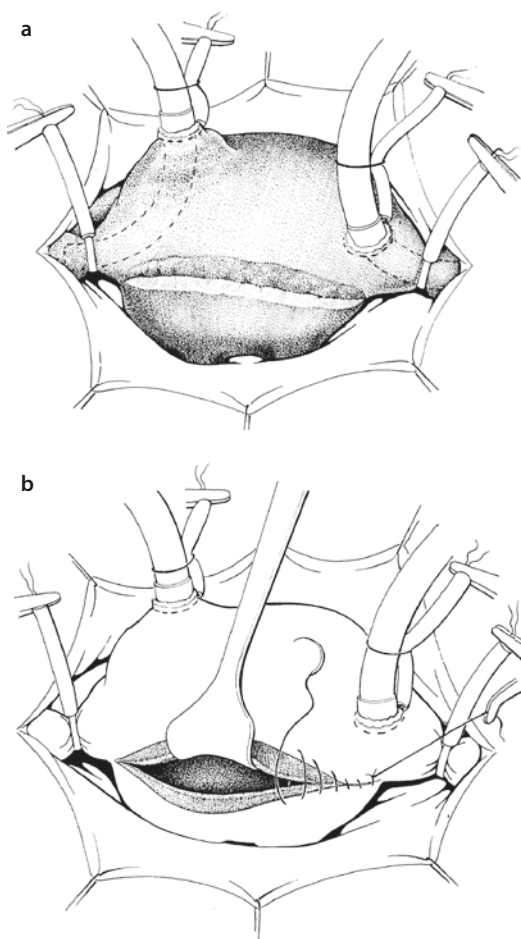

■ Fig. 25.1 Surgical approach to the mitral valve via median sternotomy, cranial-caudal view («anti-CT»)

ventricle is necessary. It is useful to open both pleural spaces right after sternotomy to avoid tension on structures such as the upper cava vein, the anomalous vein, the right ventricle, and the right atrium when the sternal retractor is placed. Once the upper and lower caval veins are dissected circularly and the ascending aorta is freed from adhesive tissue, cardiopulmonary bypass can be established in a standard fashion using bicaval venous cannulation. We only advocate cannulation of the femoral vessels for establishment of cardiopulmonary bypass before sternotomy in patients with severe obliteration of the retrosternal space and particularly in patients where the ascending aorta has broad contact to the posterior sternal layer. Once cardiopulmonary bypass is established, the heart should be completely freed from adhesions to allow a good exposure of the mitral valve, which sometimes requires rotation or elevation of the heart. In addition, complete dissection allows better application of topic cooling and deairing of the heart before releasing the cross-clamp.

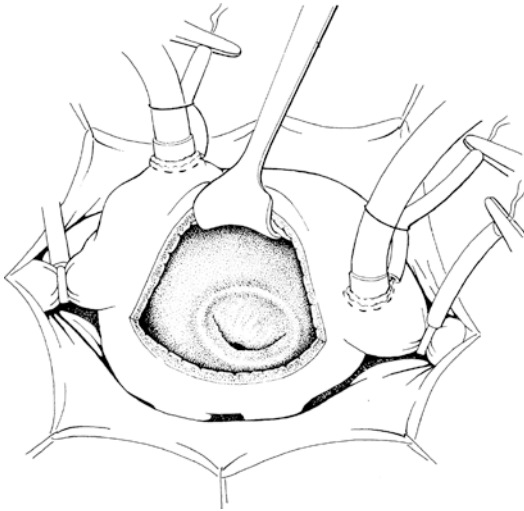

25.2.2 Atriotomy

The most common access to the mitral valve is an incision of the left atrium in the area of the interatrial groove (sulcus interatrialis, Sondergaard's groove) (■ Fig. 25.2) (Sondergaard et al. 1955). This can be achieved by dissection beginning from the upper left pulmonary vein while the assistant is pulling the right atrium towards a left and ventral direction. The epicardial fatty tissue in the interatrial groove can be dissected with scissors or a high-frequency electrocautery allowing separation of the left and right atrium 3–6 cm in length. The higher the incision is located towards the atrial septum, the better the

■ Fig. 25.2 a, b Opening of the left atrium in the interatrial groove. Epicardial fibrofatty tissue within the interatrial groove is dissected a and preserved to facilitate primary closure of the left atriotomy b

exposition of the mitral valve. While cardioplegic solution is applied in an antegrade or retrograde fashion, the left atrium is opened with a knife leaving an edge of 5 mm towards the septum. The incision is then extended caudally towards the lower cava and cranially into the roof of the left atrium carefully avoiding an opening of the right atrium. Using a special retractor with two to three hooks placed at the septal and caudal part of the incision usually allows for a good circumferential exposure of the mitral valve (■ Fig. 25.3). However, sometimes a sponge or gauze needs to be placed under the heart to lift up the subvalvular apparatus. If the visibility of the valve is not satisfactory, holding sutures in the area of the commissures of the mitral valve may improve the exposition. We routinely place a spiral wire-reinforced suction catheter in the left inferior

■ **Fig. 25.3** Exposure of the mitral valve after left atriotomy in the interatrial groove

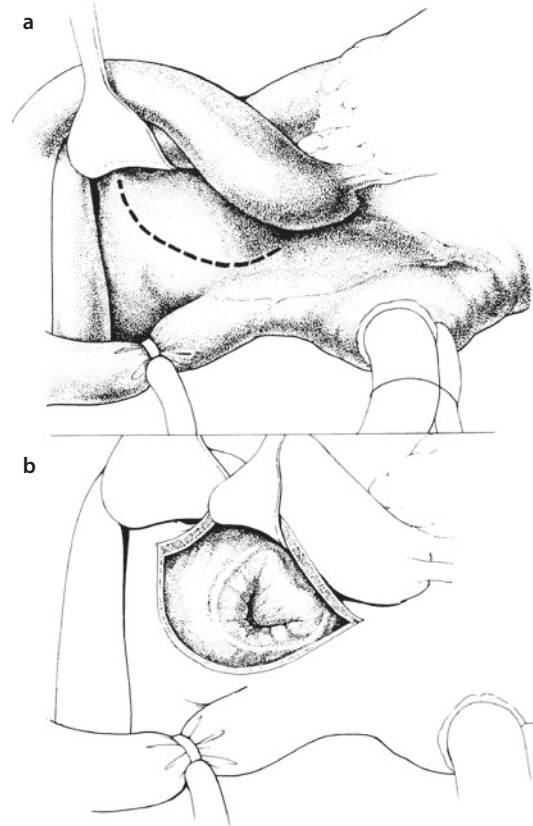

pulmonary vein, which is the deepest portion of the left atrium in this position to vent collateral pulmonary blood flow. In addition, we infuse carbon dioxide (CO_2) into the pericardium in all patients with the idea of minimizing the risk of air embolism.

Following mitral valve procedure, the left atriotomy is closed with two single polypropylene 3-0 sutures in an overcast fashion starting from cranial and caudal, respectively. Before the sutures are knotted in the middle of the atriotomy, saline is insufflated into the left atrium for de-airing purposes.

25.2.3 Opening of the Left Atrial Roof

Opening the left atrial roof between ascending aorta and superior vena cava (SVC) can be utilized as an alternative approach (■ Fig. 25.4). First, the ascending aorta is pulled ventrally with a hook and the left atrial roof is incised at least 1 cm behind the aortic root. The incision is then extended to the right towards the insertion of the SVC in the right atrium and to the left towards the insertion of the upper left pulmonary vein. With this technique, exposition of the mitral valve can be achieved almost without rotation of the heart. Sometimes temporary transverse dissection of the ascending aorta might become necessary for better exposition.

Pitfalls of this technique are accidental opening of the base of the left atrial appendage and an incision too close to the aortic root which may make closure of the atriotomy difficult. Atrial closure may

■ **Fig. 25.4** a, b Access through the roof of the left atrium. The incision starts at the interatrial septum ending at the origin of the upper left pulmonary vein with a distance of 1–2 cm to the aortic root anteriorly

be even more complicated when thin and fragile tissue is present, particularly in elderly patients, and therefore opening of the left atrial roof should be performed only by experienced surgeons.

An advantage of this atriotomy is seen in combination with a partial upper sternotomy. In this setting, usually a solitary «two-stage» venous cannula is used for drainage instead of bicaval cannulation. In addition, cardioplegic solution has to be administered in an antegrade fashion.

25.2.4 Trans Atrial/Trans Septal Approach

In some patients, particularly in those with small atrium, hypertrophic left ventricle and COPD patients with barrel-shaped thorax, the left atrial approach through the interatrial groove may not allow sufficient exposure of the mitral valve. In these patients, a trans-right atrial, transatrioseptal

■ **Fig. 25.5** **a** Trans-right atrial, transatrioseptal access to the left atrium. The *dotted line* represents the incision of the interatrial septum after right atriotomy. **b** Biatrial, transatrioseptal incision (the Dubost approach). Care has to be taken not to injure the atrioventricular junction, the tricuspid valve, the aortic root, or the His bundle

approach may be the better choice. First, the right atrium is opened with a hook-shaped incision followed by an incision of the interatrial septum in the fossa ovalis in a length of 3–5 cm between the origin of the upper cava vein and the caudal portion of the fossa ovalis. With this approach, a good exposition of both AV valves can be achieved without extensive rotation of the heart (■ Fig. 25.5a). However, this approach may have negative impact on the blood supply of the sinus node and may contribute to temporary or permanent sinus node dysfunction (Guiraudon et al. 1991). Both incisions are closed with 3-0 Prolene sutures in an overcast fashion.

25.2.5 Dubost Approach

The classic biatrial incision, as described by Dubost, allows a good exposition of both the mitral and tricuspid valves (Dubost et al. 1966). The incision starts at the right upper pulmonary vein and goes through the atrial septum as well as the ventral right atrial wall (■ Fig. 25.5b). A horizontal incision into the interatrial sulcus can be added to improve exposition (Brawley 1980; Deloche et al. 1990). However, there needs to be caution if the incision is extended, particularly in patients with small space between the pulmonary veins because uncontrolled tension by the retractor may enlarge the incision unintentionally into direction of the atrioventricular junction, the aortic root, or the His bundle (Deloche et al. 1990).

Closure of the Dubost incision needs to be performed carefully to ensure correct reapproximation

of the septum. Marking the different flaps of atrial tissue with stay sutures may help correct anatomic repositioning before closing the atriotomy.

However, the biatrial approach is associated with an increased rate of atrial conduction disturbances and should therefore, as recommended in the original publication by Deloche, only be used if the direct approaches are not suitable (Deloche et al. 1990).

25.2.6 Reoperation: Considerations

The rate of patients referred for reoperative mitral valve surgery is constantly increasing. In these patients, our standard approach is a median sternotomy. After dissection of the posterior portion of the sternum, either with an oscillating saw or with heavy scissors, the pericardium is carefully dissected from the chest wall. If the pericardium was not closed during the original procedure, then the right ventricle and right atrium may need to be dissected from the chest wall. To start with, we regularly open the pleural space to the right in order to avoid too much tension on structures like SVC, innominate vein, right atrium, and right ventricle when placing the retractor. Then the ascending aorta and the superior and inferior caval veins are dissected circumferentially in a step-by-step fashion. In case of severe adhesions between pericardial tissue and the right atrium, a more lateral transpericardial entry is chosen, while the ventral adhesions are left in place. In our opinion, an attempt to completely release the heart from adhesions should be made in every case to facilitate rotation of the heart

for better exposure of the mitral valve. This furthermore allows topical cooling of the heart during ischemia and facilitates better de-airing before releasing the cross-clamp at the end of the mitral procedure. An alternative approach for reoperative mitral valve surgery is a right anterolateral thoracotomy with or without transfemoral cannulation for the establishment of extracorporeal circulation.

25.2.7 Left or Right Lateral Approach

Under rare circumstances, a mitral procedure will be performed using a left lateral thoracotomy. In these cases, the left atrium will be opened by placing a diagonal incision between the base of the left atrial appendage and the insertion of the left pulmonary veins. However, venous cannulation remains an issue and is usually performed femoral \pm jugular veins. Right and left lateral thoracotomy approaches for minimally invasive, endoscopic, and robotic mitral surgery are described in more detail in ► Chapter «Minimally Invasive Cardiac Surgery», Sect. 26.3.5.

25.3 Closure of Left Atrial Appendage

The left atrial appendage can be closed from inside the left atrium during mitral valve surgery using a double 3-0 polypropylene suture. Alternatively, a 4-0 teflon pledgeted suture can be placed from outside to directly close the appendage. Another approach would be the resection of the appendage and direct closure with a running suture. There are also devices for epicardial exclusion of the left atrial appendage on the market. However, during mitral valve surgery direct closure under vision seems to be the most valuable approach. It has to be kept in mind that initially there is a risk for thromboembolism from the inner surface even if sinus rhythm is present.

25.4 Extracorporeal Circulation, Cannulation Technique, Myocardial Protection, De-airing

Establishment of extracorporeal circulation generally follows the same principles as of other cardiac surgery procedures. However, some aspects need to be discussed in more detail.

Following median sternotomy and resection of the thymus tissue, the pericardium is opened in an inverse t-shaped fashion. After systemic heparin application (400 IE/kg bodyweight) and placement of two 4-0 polypropylene stay stitches, a cannula is placed in the distal ascending aorta and secured with a tourniquet. Regarding venous cannulation, it is important to consider that the best exposition of the mitral valve is achieved by total cardiopulmonary bypass with bicaval cannulation. First, a 90° venous cannula is placed in the SVC and secured by tourniquet. Following initiation of partial extracorporeal circulation, another tourniquet suture is placed in the right atrium near the inferior cava (IVC) junction. A second 90° cannula is placed into the IVC and connected to the venous line using a y-connector. Using this bicaval cannulation technique allows for enlargement of the atriotomy in any direction for better exposure of the mitral valve if necessary. Furthermore, pulling the tourniquet of the IVC cannula moves the heart towards the surgeon also facilitating better exposure. Finally, tourniquets are placed around both caval veins to establish total cardiopulmonary bypass.

Placement of a catheter into the coronary sinus transatrially allows for the application of retrograde cardioplegia at every time point during the operation without changing exposure. The alternative route of antegrade cardioplegia administration via the aortic root most likely requires removal of the mitral retractors to allow a competent closure of the aortic valve during administration of cardioplegic solution. Usually, we administer 4 °C cold blood cardioplegia solution as described by Buckberg (initially 4 min followed by 2 min every 20–25 min of cardioplegic arrest). In addition, the patient's body temperature is lowered to 32 °C, and in most cases topic epicardial cooling is achieved by instillation of ice-cold saline solution.

A particular focus has to be directed to the complete de-airing of the heart before opening of the aortic cross-clamp following every mitral valve procedure because opening the left atrium results in air distribution into every structure of the left heart including the pulmonary veins. We feel two measures to be most important in order to minimize the risk of air embolism: insufflation of carbon dioxide into the pericardium and filling the left atrium with saline before definite closure of the atriotomy.

Before releasing the aortic cross-clamp, a de-airing maneuver is routinely applied in cooperation with anesthesia and perfusion. A cannula is placed in the ascending aorta just below the cross-clamp to allow evacuation of trapped air.

Alternatively, the entry site of an antegrade cardioplegia cannula can be used. While moving the table in a head-up position pulmonary backflow into the left atrium is increased by high-pressure ventilation hold by anesthesia and temporary volume shift by stopping venous drainage by perfusion. Careful manipulation of the ventricle and digital invagination of the left atrial appendage (if not closed or resected) helps to release trapped air in the trabecular structures of the left heart. Aortic cross-clamp is then removed in Trendelenburg position. However, manipulation, particularly elevation of the ventricle should be done carefully because the rigid structures of the valve prosthesis or anuloplasty rings may serve as a hypomochlion leading to rupture of the atrioventricular plane, which is a life-threatening complication on its own (Rodriguez et al. 2001).

Weaning off cardiopulmonary bypass is initiated once the patient is rewarmed. In patients with impaired left ventricular function, we routinely place a left atrial pressure measurement catheter to control left ventricular preload. In addition, all patients are under TEE surveillance, which allows control of mitral valve repair results as well as left ventricular function during weaning of cardiopulmonary bypass.

25.5 Mitral Valve Surgery

25.5.1 Functional Anatomy of the Mitral Valve

The mitral valve has a complex structure, and competent function is only achieved by interaction of leaflets, commissures, chordae, papillary muscles, and the left ventricle. Understanding these five anatomical structures helps defining the pathophysiologic basis of mitral valve disease and is crucial to achieve successful surgical repair (Adams et al. 2006).

The mitral valve has two leaflets. The anterior leaflet is of semilunar shape and comprises 40% of the annular circumference. There is continuity between the anterior leaflet of the mitral valve and the left and noncoronary cusp of the aortic valve. This area is referred to as the aortic-mitral curtain and is particularly fragile. The free edge of the anterior leaflet is slightly tented towards the cave of the left ventricle by primary chordae and is usually continuous without indentations. The lack of redundant tissue at the edge of the anterior leaflet is of importance in patients with anterior leaflet prolapse as only little amount of the leaflet can be resected

safely without leading to loss of coaptation. During the cardiac cycle, the motion of the anterior leaflet also defines an important boundary between the inflow (during diastole) and outflow (during systole) tracts of the left ventricle (David et al. 1997).

The posterior leaflet of the mitral valve has a quadrangular shape and comprises 60% of the annular circumference. Carpentier introduced a surgical classification of the mitral leaflets by dividing them into three segments. In opposite to the anterior leaflet, the posterior leaflet typically has two well-defined indentations at its free margin, which divide this leaflet into three scallops referred to as P1 (anterior or lateral scallop), P2 (middle scallop), and P3 (posterior or medial scallop). The three corresponding segments of the anterior leaflet are accordingly described as A1 (anterior segment), A2 (middle segment), and A3 (posterior segment) (Carpentier 1983). This nomenclature is particularly important for describing mitral valve pathology between echocardiographer and cardiac surgeon as well as for planning the operative strategy. In contrast to the anterior leaflet, the posterior leaflet comprises redundant tissue, particularly in the setting of prolapse due to excess tissue, and therefore tolerates more aggressive resection.

The commissures of the mitral valve define the region where anterior and posterior leaflet come together at their origin at the annulus. However, this area is not always well defined, and it is sometimes necessary to use the corresponding papillary muscles as landmarks to identify the commissures.

The zone of coaptation plays another important role for the function of the mitral valve which represents the area of contact between anterior and posterior leaflets during systole. There are two zones on the atrial surface of the leaflet, the peripheral smooth body zone and the central rough zone. From the surgical view (atrial view), the two zones are separated by a gently curved coaptation line. The rough zone represents the coaptation surface of the valve and is crucial for valve competency and the depth and length of coaptation is an important marker for the assessment of mitral valve function.

The mitral valve is an atrioventricular valve and therefore separates the left atrial chamber from the left ventricle. The annulus of the mitral valve represents the junction between the left atrium and the left ventricle and also serves as insertion site for the mitral leaflets. The mitral annulus is saddle shaped and changes its structure during the cardiac cycle. During systole, the commissures move towards the

apex of the ventricle while the annular circumference narrows. Both mechanisms support an optimal coaptation and may be impaired by annular dilatation or calcification. Furthermore, the mitral annulus is embedded into several important structures, such as the coronary portion of the aortic valve, the coronary sinus, the atrioventricular node, and the circumflex artery, which need to be taken into consideration during mitral valve surgery.

Finally, the chordae and the two papillary muscles need to be mentioned. The chordae are of importance for the end-systolic position of both leaflets. They have their origin at the papillary muscles and are classified according to their insertion sites at the leaflets. Primary chordae (marginal chordae) are attached to the free margin of the leaflet and prevent prolapse of the margin during systole. Secondary chordae (intermediate chordae) are attached to the ventricular surface of the leaflets and relieve excess tension from the leaflet tissue. Secondary chordae may also play a role in preserving ventricular shape and function (Rodriguez et al. 2004). Several studies, beginning with Lillehei, have shown that preservation of the posterior part of the subvalvular apparatus improves ventricular function following mitral valve replacement (Lillehei et al. 1964). Techniques of preservation of the subvalvular apparatus are described later in this chapter. Tertiary chordae (basal chordae) are only found at the posterior leaflet connecting the base of the leaflet and the mitral annulus to the papillary muscles. The kinetics of chordae and papillary muscles with their connection to the left ventricle directly interlinks mitral valve function with ventricular function.

The papillary muscles connect the mitral valve and its chordae to the left ventricle. The two papillary muscles have their origin in the area between the middle and apical third of the left ventricular wall. The anterior papillary muscle usually has one head, whereas the posterior papillary muscle regularly has two heads. Each papillary muscle serves as origin of chordae tendineae to both leaflets. The blood supply, particularly of the posterior papillary muscle is of great importance. The anterior papillary muscle is usually supplied by the left anterior descending and the diagonal or a marginal branch of the circumflex artery. The posterior papillary muscle is supplied by the left circumflex or the right coronary artery, depending on the dominance of the left or right coronary system. This single-vessel blood supply of the posterior papillary muscle leads to vulnerability against ischemic injury in case of myocardial infarction.

The complex structure of the mitral valve and its connection to the left ventricle is of great importance for left ventricular function. This fact is nowadays addressed by preservation of at least the posterior portion of the subvalvular apparatus during mitral valve replacement either with mechanical or biological prostheses, and long-term studies have shown an improvement of outcome compared to complete resection of the subvalvular apparatus (Chen et al. 2003; Yilmaz et al. 2005).

25.5.2 Mitral Valve Replacement

The marked decrease of rheumatic mitral stenosis in industrial countries, which represented the main indication for mitral surgery in the 1970s and 1980s, resulted in lower rates of mitral valve replacement compared to mitral valve repair. Today, the vast majority of patients undergoing mitral valve surgery suffer from mitral regurgitation due to degenerative or ischemic disease, which is more likely reparable than mitral stenosis. Nevertheless, mitral valve replacement is still a standard procedure in cardiac surgery and plays an important role in the armamentarium of every cardiac surgeon. Since the first successful prosthetic mitral valve replacement by Starr in 1961, many improvements were introduced into clinical practice, particularly regarding the type of prostheses. The burden of thromboembolic complications following prosthetic valve replacement is even more important in mitral position than after aortic valve replacement.

25.5.2.1 Choice of Prosthesis

During the recent decades, several prostheses for mitral valve replacement were introduced; however, only a few of them were further developed and are now established in clinical practice. The ideal mitral valve prosthesis unites optimal hemodynamic characteristics like low gradient, with long-term durability and low thrombogenicity. However, as the ideal prosthesis is not developed, yet the choice has to be made between durability (i.e., mechanical prostheses) and low thrombogenicity (i.e., biological prostheses). Given the fact that patients with mitral valve disease more often suffer from atrial fibrillation per se requiring anticoagulation therapy, one argument for biological prosthesis is diminished. It has, however, to be mentioned that patients with atrial fibrillation and a biological prosthesis require anticoagulation with a lower target international normalized ratio (INR)

compared to patients with a mechanical valve in mitral position. Nevertheless, the high rate of structural deterioration of tissue valves requiring reoperative valve replacement led to a decrease in the preference of tissue valves since the 1980s favoring mechanical prostheses particularly in younger patients. In our practice, we choose a biological prosthesis in all patients with a life expectancy not exceeding 10–15 years and those with contraindications for permanent anticoagulation.

Mitral replacement in children and young adolescents remains a problem, and therefore this patient population preferentially undergoes mitral repair even if the expected result is not ideal. Homograft replacement, which is a valuable option in aortic valve disease, has not been established in mitral valve disease due to suboptimal long-term results.

Most mechanical mitral valve prostheses used in clinical praxis today are bileaflet prostheses and have replaced the tilting disc prostheses. Modern bileaflet prostheses are made of polycarbon and are reliable with a very low rate of mechanical failure. They further have an acceptable low thrombogenicity but still require permanent anticoagulation. In our opinion, the best choice of a mechanical prosthesis in mitral valve position is a bileaflet prosthesis with a low profile and a broad suture ring (Wippermann et al. 2005). The low profile is important to avoid impairment of leaflet motion due to the subvalvular apparatus, which should be preserved in all cases. Generally, we attempt to implant large prostheses (29 mm). In cases with a small anulus and a small body surface area, a 27 mm prosthesis is also acceptable. We never noticed complications or problems in terms of too large prostheses. However, asymmetric or incomplete opening of bileaflet prostheses might occur due to slow flow across a very large prosthesis orifice particular in patients with atrial fibrillation potentially increasing the risk of thromboembolic complications.

25.5.2.2 Excision of the Native Valve

During the last decades, the question whether to excise or to preserve the subvalvular apparatus has been the subject of a long debate, and there is meanwhile clear evidence that preservation of at least a part of the subvalvular apparatus improves outcome. However, excision of the native mitral valve is determined by the underlying pathology of mitral valve disease and necessarily needs to be waged between «how many tissue needs to be resected?» and «which parts of the subvalvular apparatus can be preserved?»

In cases that require complete resection of the native valve, first the anterior leaflet is grasped and stabilized with a sharp clamp at its free margin. Alternatively, we place a 3-0 Prolene suture in the area of the A2 segment in order to pull the anterior leaflet towards the left atrium. Starting from a stitch incision in the A2 segment approximately 2–4 mm from the anulus, the anterior leaflet can be detached from the anulus towards both commissures using scissors or a scalpel. To excise the whole valve, the chordae are then cut at their origin at the papillary muscles, and the posterior leaflet is excised in the same fashion.

However, in our practice, we always try to preserve at least a part or if possible the whole subvalvular apparatus as several studies have shown improved outcome of patients with retained chordae tendineae after mitral replacement. Moreover, there is evidence that complete chordal-sparing mitral valve replacement is superior to partial chordal-sparing procedures (Yun et al. 2002; Chowdhury et al. 2005). We usually resect the anterior leaflet in the fashion described above preserving the posterior leaflet and the chordae to both papillary muscles (■ Fig. 25.6). In cases of severe calcification, the posterior leaflet can be decalcified using a rongeur leaving the fibrous parts of the leaflet as well as the chordae intact. This is important to avoid destruction of the posterior portion of the anulus with all its consequences such as injury of the circumflex artery or ventricular rupture at the atrioventricular junction (Casselman et al. 1999; Sasaki and Ihashi 2003).

In cases of severe mitral valve stenosis, small left ventricles, and particularly narrow annular diameter, a radial incision into the remaining leaflet towards both trigones and to the middle portion of the posterior leaflet between both groups of chordae creates enough space for the implantation of an adequately sized prosthesis.

Reoperative procedures following mitral valve replacement may become necessary due to deterioration of biological prostheses, endocarditis, thrombosis, or paravalvular leakage. In cases of mitral valve re-replacement, we prefer a transeptal or the classic interatrial approach to the left atrium, which allows the best exposure even if mobilization of the heart is limited (Murashita et al. 2004). Small noninfective paravalvular leaks can be closed by epianular U-sutures passed through the atrial wall, mitral anulus, and sewing ring of the prosthesis. Larger leaks require complete removal of the prosthesis in order to place the sutures for the new pros-

■ **Fig. 25.6** a, b Excision of the mitral valve preserving the posterior portion of the subvalvular apparatus. Following stitch incision in the A2 segment, the anterior leaflet is detached from the annulus towards both commissures, leaving approximately a 2–4 mm rim of leaflet tissue at the anterior annulus. The chordae of the anterior leaflet are cut at the top of the papillary muscle

thesis safely under direct vision. Particularly if a deteriorated prosthesis or valve thrombosis is present, the prosthesis is often healed in very firmly and covered by a fibrous layer. In these cases, we incise the fibrous layer circularly at the sewing ring close to the knots and cut all sutures separately. In most instances, the prosthesis can then be removed bluntly from the pannus. In case of severe adhesions, it might be easier to dissect the prosthesis out of the sewing ring, take the prosthesis out, and to remove the remaining outer layer of the sewing ring and the sutures hereafter. It is particularly important to completely remove all pannus to ensure that the new prosthesis can be sutured to the annulus.

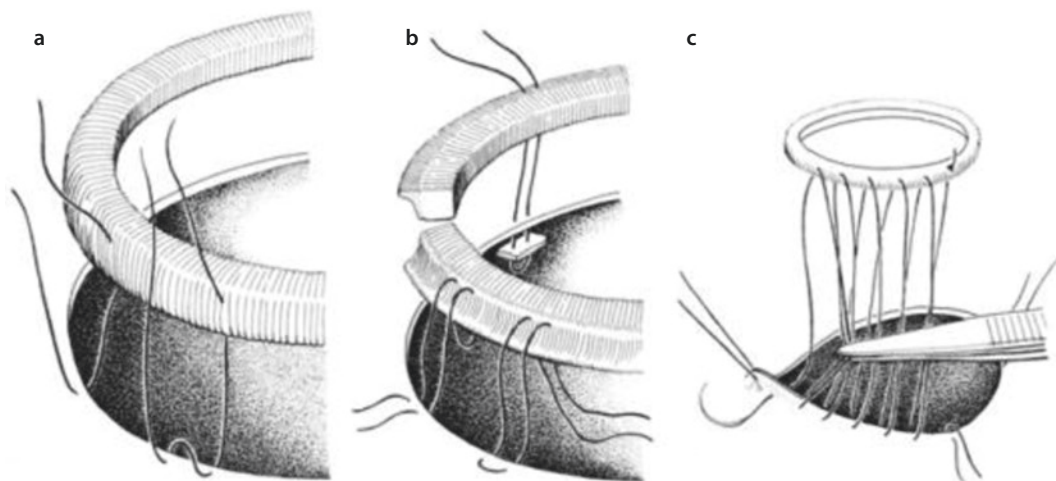

More problems are created by prosthetic valve endocarditis with involvement of the annulus requiring debridement of anular tissue. In this case, the remaining anular tissue may not be firm enough to sufficiently anchor the new U-sutures requiring deeper stitches and pericardium-supported sutures bearing a particular risk for compromising structures like the circumflex artery and the AV node.

The sutures for mitral valve replacement can be placed either from the ventricular side (for epi-/supraannular prosthesis placement) or from the atrial side (for intraannular placement) (■ Fig. 25.7). The epi-/supraannular technique results in lower stress for the anular tissue and has become the favorite technique. Commonly, 2-0 braided Teflon-pledgeted U-sutures are passed through the annulus from the ventricular side towards the left atrium. The utilization of small Teflon pledgets is particu-

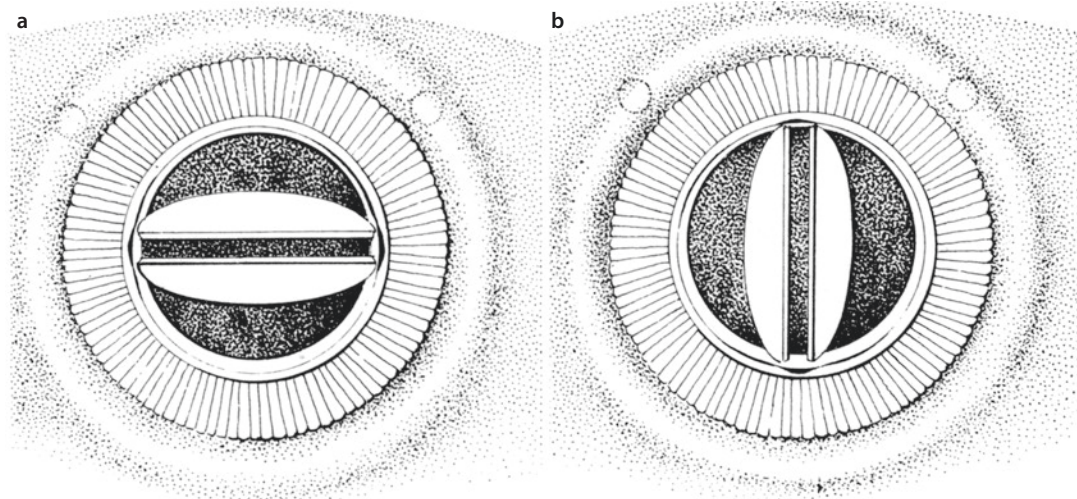

larly important in patients with thin and fragile anular tissue. Alternatively, for example, in patients with active endocarditis, autologous or glutaraldehyde-preserved bovine pericardium can be used. Usually, twelve to maximal 15 such U-sutures are placed depending on the valve size, ensuring that no gap remains between neighboring sutures. It is also important to avoid stitches covering a too large anular distance that may result in plication of the annulus bearing the risk of paravalvular leakage. Additional 4-0-polypropylene stitches can be placed from the atrial side to the sewing ring if there is suspicion of such plication.

The epianular technique provides a good adaptation of the subvalvular apparatus at the base of the prosthesis improving the functional ventriculo-anular connection and therefore leading to better long-term results. In patients with preservation of the posterior leaflet, the sutures can be placed from the anular insertion of the leaflet through the annulus leading to a horizontal plication that tightens the subvalvular apparatus. It is, however, particularly important to involve only a narrow portion of the leaflet because too much plication may lead to protrusion of the remaining leaflet tissue into the orifice of the prosthesis potentially impairing leaflet motion of mechanical prostheses. This plication technique can also be applied in patients with fragile anterior leaflet tissue.

In our practice, we usually do not place the U-stitches from the atrial side through the annulus, because this intraannular technique leads to an

■ Fig. 25.7 a–c Different suture techniques for mitral prosthesis implantation. a Single-stitch technique (left) and double U-stitch technique (right). b In counterclockwise direction: pledgeted epianular U-suture; intraannular suture from the atrium; intraannular suture from the ventricle. c Implantation of a mitral prosthesis with a running suture

■ Fig. 25.8 a, b Two common orientations of mechanical bileaflet prostheses in mitral position

eversion of the atrial tissue, which may become problematic in cases with extensive calcification of the atrial wall or the annulus itself.

Several techniques for reducing the size of the left atrium are described in the literature. Most techniques base on the plication of the posterior portion of the left atrial wall. An established approach consists of placing a 3-0 Prolene mattress suture starting from the origin of the pulmonary veins towards the right-sided margin of the incision in the interarterial groove, which leads to eversion of two-times 3–15 mm tissue depending on the stitching technique. An additional overcasting suture smoothens the endocardial atrial surface. Other techniques

such as resection of the left atrial tissue are described in the literature (Isomura et al. 1993).

25.5.2.3 Implantation of Mechanical Prostheses

Generally, the implantation of both biological or mechanical prostheses follows the suture techniques described above. However, some special considerations need to be discussed regarding the orientation of the recent generation of bileaflet mechanical valves. There are two ways of implantation: the axis of the leaflets can be directed horizontally or vertically to the intercommissural line (■ Fig. 25.8). The ques-

tion which position is best is not definitely solved yet; however, there is evidence that an antianatomic implantation less likely leads to a left ventricular outflow tract obstruction (Laub et al. 1992). Another issue may be the restriction of leaflet motion due to remaining tissue, particularly if the posterior leaflet with the subvalvular apparatus is preserved. However, in our own practice we have never observed such dysfunction. The design of some recent prostheses with a particular high anular cylinder reduces the risk of alteration of leaflet function from obstructing tissue. It is nevertheless important to ensure unimpaired leaflet motion once the valve is tied down and to make sure that no redundant tissue protrudes into the valve orifice. On the other hand, with ventricular relaxation during diastole subvalvular structures are moved laterally away from the prosthesis, and valve closure happens when the ventricle is maximally filled, and therefore impairment of prosthesis function is unlikely (Wipperman et al. 2005).

25.5.2.4 Implantation of Biological Prostheses

The commercially available biological prostheses for mitral replacement are made from porcine aortic valves or constructed with bovine pericardium and usually include a sewing ring and a stent with three struts. During implantation, two struts are directed towards both trigones, whereas the third strut is positioned in the middle of the posterior anulus (■ Fig. 25.9). This orientation keeps the struts away from the left ventricular outflow tract and thus avoids obstruction during systole (Chitwood 1998). Particular caution has to be directed towards the U-sutures, which can potentially get entangled with the struts leading to impaired function of the cusps of the prosthesis or even prosthesis destruction. Particularly bovine pericardial valves with their narrow struts are prone to this complication, which can be seen easily and becomes evident during echocardiography control after weaning from bypass. Therefore, most manufacturers deliver their prostheses with a temporary holding suture that connects the three struts and avoids this entanglement. This securing suture is removed eventually after the valve is tied down. In our practice, we routinely ensure unimpaired leaflet motion and regular coaptation using a small dentist mirror.

During valve implantation, it is sometimes useful to remove the handle of the prosthesis after tying down the three commissural sutures. This helps to avoid that one or more struts jam into the atrial wall or into the subvalvular apparatus while the prosthesis is tied down.

25.5.2.5 Technical Problems of Mitral Valve Replacement

Mitral valve replacement bears certain procedural risks, particularly during valve excision, anular debridement, and implantation of the prosthesis. Anular debridement during resection of the native valve should not be too aggressive in order to leave enough tissue for safely placing the valve sutures and neither damage the aortic valve, nor the conduction tissue, or the circumflex artery. Therefore, it is important to leave a margin of 3–5 mm leaflet tissue when excising the native valve whenever possible. This may, however, not be possible in cases of severe mitral stenosis with heavily calcified mitral leaflets and anulus where the left ventricular muscle is involved also (Iida et al. 2005).

Aggressive decalcification may not leave enough tissue as solid skewback for the valve sutures (■ Fig. 25.10), which results in a rare but particularly dangerous situation. Then, sutures for valve implantation sometimes need to be placed through the ventricular muscle, particularly in the posterior portion of the anulus. These sutures in face of an extensively thinned out anulus are prone to rupture or dissection of the posterior atrioventricular junction. This rupture may take place immediately with ventricular contraction resuming after opening cross-clamp but may also be delayed for several hours after the operative procedure when the sutures cut through the ventricular muscle. Other causes for ventricular rupture can be extensive tension on the anulus during valve excision, particularly during reoperation, and also inadequate pressure while pushing the prosthesis in place.

The most dangerous complication of mitral valve replacement is rupture of the posterior atrioventricular junction or the posterior left ventricular wall. This commonly is caused by too aggressive decalcification of the anular tissue and/or luxation of the heart after prosthesis implantation.

Fig. 25.9 a–d Orientation of biological prostheses. a Two of the three struts are directed towards the trigones (*right and left white point*); the third strut is placed at the middle of the posterior anulus (*middle posterior white point*). This orientation allows sufficient opening of the left ventricular outflow tract during systole. b Particular caution is required when tying the U-sutures to avoid entangling the struts. c Entangling a strut results in distortion of the neighboring leaflets which may be only discrete in bovine pericardial prostheses (*above*) and more obvious in porcine valves (*below*). d A dentist's mirror is a helpful tool to visualize correct implantation of the prosthesis after implantation

The only chance to treat atrioventricular disruption is to stabilize the atrioventricular junction with pledgeted (Teflon or pericardium) sutures placed from inside the ventricle after temporary removal of the prosthesis. It is further important to reestablish extracorporeal circulation immedi-

ately to unload the left ventricle. Attempts to control the disruption from outside should be avoided, because this inevitably involves luxation of the heart potentially worsening the life-threatening situation, which is per se associated with a mortality of 30–50% (David 1987). However, in some

■ **Fig. 25.10** In case of extensive resection of tissue and/or decalcification in the area of the posterior anulus, dissection of the AV sulcus may result (the *arrows* mark the channel of disruption). In these cases, reconstruction of the AV continuity can be achieved with pledged sutures

cases of atrioventricular disruption, successful pasting of a pericardial patch onto the ruptured area has been described. Preservation of the posterior leaflet minimizes the risk of atrioventricular disruption (Deniz et al. 2008).

Resection of papillary muscle under tension is also dangerous and bears the risk of ventricular rupture if the resection line is placed too deep at the base of the papillary muscle.

Another rare but typical complication of mitral valve replacement is rupture of the posterior ventricular wall caused by the prosthesis itself. This complication is seen in patients with small ventricles and in cases where the prosthesis reaches deep into the ventricular cavity. If the heart is displaced for de-airing purposes, the prosthesis may cause perforation of the ventricular wall. Likewise atrioventricular disruption, this

complication is serious and potentially life-threatening. Particularly biological prosthesis with their higher profile and the three struts of which one is located in the middle of the posterior anulus are associated with this complication, whereas it is rarely seen in patients receiving modern low-profile mechanical prostheses.

Generally, displacement of the heart should be avoided during mitral valve replacement once the prosthesis is in place.

25.5.3 Valve Sparring Procedures

The decreasing incidence of mitral stenosis due to rheumatic disease and the increasing proportion of patients presenting with mitral regurgitation due to degenerative or ischemic etiologies led to a

renaissance of valve-sparing procedures. Several concepts and techniques have been described to facilitate mitral valve repair. In this section, we will focus on techniques with broad application such as quadrangular resection with sliding plasty, chordal plasty, chordal shortening, and of course the implantation of anuloplasty devices. Minimal-invasive techniques and alternative approaches are described in ► Chapter «Minimally Invasive Cardiac Surgery», Sect. 26.3.5.

25.5.3.1 Open Commissurotomy

Open mitral valve commissurotomy was the most common reconstructive mitral valve procedure in the past and often effectively treated mitral stenosis. With the development of interventional percutaneous techniques, first of all catheter-based balloon valvuloplasty, open commissurotomy nowadays does not play an important role in the surgical armamentarium any more in acquired lesions.

Open commissurotomy works best in cases with commissural fusion, while the leaflets – particularly the anterior leaflet – are still mobile and allow competent systolic closure. In this case, even thickening of the leaflet margins does not affect success of reconstruction. However, commissurotomy is not a good option in patients with combined mitral disease with additional mitral regurgitation due to shrinking of the leaflets.

The technique of open commissurotomy includes identification of the fusion line between the leaflets in the commissural area and the assignment of the corresponding chordae to the anterior and posterior leaflet. This can be achieved by a small incision into the commissural line approximately 5 mm from the anulus and placement of a small right-angled clamp directing the tip of the clamp towards the mitral orifice dividing the chordae from the anterior and posterior leaflet, respectively (■ Fig. 25.11). If the

■ Fig. 25.11 a–c Technique of open mitral valve commissurotomy. a After exposure of the line of fusion a stitch incision is placed approximately 5 mm from the anulus within this line. b An angled clamp is then placed into the incision and opened towards the valve orifice. The commissure is then dissected sharply. c Finally, the commissurotomy is extended towards the central fibrous body

chordae are also conjoint, then sharp longitudinally separation is necessary. It should be avoided to extend the commissurotomy all the way to the anulus because the lack of tissue in this area will result in inadequate coaptation and thus mitral regurgitation. Some amount of superficial calcium may be carefully removed with a rongeur while keeping the continuity of the leaflet intact. In cases of heavily calcified leaflets, commissurotomy may not fix the problem, and valve replacement should be considered instead. Mitral replacement has also to be considered if a significant regurgitation is noticed following commissurotomy.

25.5.3.2 Mitral Valve Reconstruction (Leaflet and Anulus)

Mitral valve reconstruction requires a deep understanding of underlying pathology and involves all parts of the mitral apparatus. Carpentier's pathophysiologic triad describes the relationship between the cause of the disease (etiology), the result of the disease (lesion), and the functional impairment resulting from the lesion (leaflet dysfunction) (Carpentier 1983). Following Carpentier's principles, the vast majority of mitral pathologies –except heavily calcified lesions or extensively destroyed endocarditic valves – are potentially suitable for a reparative approach. However, it should be kept in mind that mitral replacement with modern prostheses results in acceptable long-term outcome, and therefore a critical assessment of long-term durability in patient with complex pathologies is required.

Following establishment of cardiopulmonary bypass and exposure of the mitral valve, the decision whether to repair or to replace the mitral valve has to be made by the surgeon. This judgment depends on three important factors:

- Experience of the surgeon in the application of different reconstructive techniques
 - Type and extension of mitral valve pathology
- Patient-related factors such as age, comorbidities, previous cardiac operations, contraindication against anticoagulation, and others

To date, repair rates up to 90% depending on pathology are feasible, particularly in tertiary centers with high caseload.

Feasibility of repair is first of all determined by the valve pathology and its extension. Most convenient are mitral valve pathologies with preserved leaflet mobility and enough leaflet tissue to allow remodeling a competent valve.

Every exploration of a diseased mitral valve should start with functional analysis. Saline is instilled into the left ventricle. The saline leakage through the valve helps in identifying the area and pathology of regurgitation. After saline testing, careful exploration of the valve using valve hooks is performed. Following Carpentier's anatomical classification, the height of coaptation of the corresponding segments of the anterior (A1, A2, A3) and posterior (P1, P2, P3) leaflets is analyzed (■ Fig. 25.12).

Carpentier's systematic classification of mitral valve regurgitation is generally based on leaflet motion (■ Fig. 25.13):

- *Type I, normal leaflet motion.* This type of mitral regurgitation is commonly caused by anular dilatation resulting in a loss of coaptation area while the leaflets retain their normal mobility. In this case, the left ventricle is usually dilated. Leaflet perforation is also referred to as type I mitral regurgitation. Isolated type I regurgitation is found in about 10% of cases.
- *Type II, extended leaflet motion.* Extended leaflet motion is commonly found in patients with degenerative mitral valve disease (Barlow's disease, fibroelastic deficiency). Barlow's disease is typically associated with excess leaflet tissue, chordal elongation, and anular dilatation leading to complex mitral regurgitation. Chordal rupture and papillary muscle rupture are also referred to as type II lesions. With 60% of cases, type II is the most common lesion in patients with mitral regurgitation.
- *Type III, restricted leaflet motion.* Restricted leaflet motion during systole and diastole (type IIIa) is caused by leaflet thickening and retraction, chordal thickening and shortening, and commissural fusion frequently observed in patients with rheumatic disease. The mechanism of type IIIb dysfunction is restricted leaflet motion during systole due to left ventricular enlargement and papillary muscle displacement as seen in patients with congestive heart failure and in ischemic mitral regurgitation.

The most common cause of mitral regurgitation in industrialized countries is degenerative disease with leaflet dysfunction type II (excess motion of the margin of the leaflet in relation to the anular plane) due to chordae elongation or rupture. Anular dilatation (type I) is almost always an associated finding.

■ **Fig. 25.12** a, b Principle of mitral valve reconstruction for mitral regurgitation. One goal of reconstruction is the restoration of a broad coaptation surface b. A small coaptation line a results in high tension on the chordae potentially leading to chordal rupture and leaflet prolapse

In clinical practice, there is a broad spectrum of degenerative disease ranging from fibroelastic deficiency (FED) to Barlow's disease. The most complex form, Barlow's disease, is characterized by excess leaflet tissue with large billowing, thickened leaflets, and anular dilatation. Chordal elongation is the most common cause of prolapse, and multiple leaflet segments are usually involved. It generally occurs in younger patients (aged <60 years), who have a long history of a heart murmur. In contrast, fibroelastic deficiency is a degenerative disease of older individuals (usually >60 years of age), with a shorter history of valve regurgitation. Rupture, often of a single chord, is the most common cause of leaflet dysfunction in fibroelastic deficiency, and in most cases the only abnormal leaflet tissue is found in the prolapsing segment. The other leaflet segments are often thin and translucent and of normal height. The posterior anulus may be dilated, but the size of the anterior leaflet and valve is most often normal. In

patients with longstanding prolapse, secondary changes may occur in the prolapsing segment, resulting in myxomatous leaflet thickening and expansion (FED+). *Forme fruste* defines an intermediate form of degenerative disease with excess tissue with myxomatous changes in usually more than one leaflet segment, but usually does not involve the whole valve, differentiating it from Barlow's disease (Adams et al. 2010). The underlying pathology defines the technical approach in reconstructive mitral valve surgery for degenerative mitral regurgitation.

Mitral valve reconstruction follows three general principles: preservation of leaflet motion, restoration of a large surface of leaflet coaptation, and remodeling of the anulus of the mitral valve (Carpentier et al. 1971). A large area of coaptation in early systole minimizes leaflet shear stress and the smaller the coaptation area, the higher the tension on the primary cords increasing the risk of chordal elongation or rupture (see ■ Fig. 25.12).

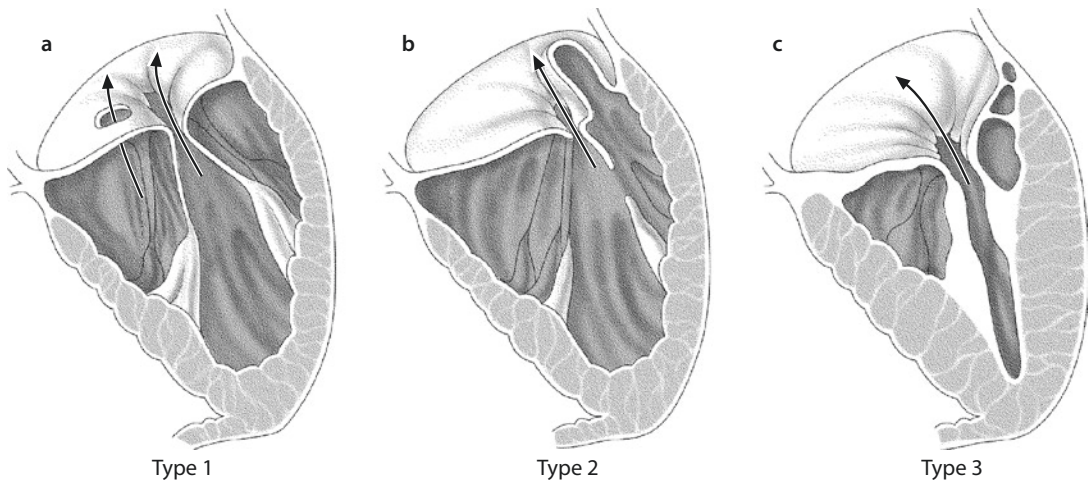

Fig. 25.13 a–c Carpentier’s classification of mitral valve regurgitation. **a** Type I dysfunction (normal leaflet motion) results from anular dilatation, leaflet perforation, or a combination of both. Leaflet perforations may be congenital (as part of a broad spectrum of anterior leaflet clefts with or without concomitant defects of the atrioventricular channel) or achieved following mitral valve endocarditis. **b** Type II dysfunction (excessive leaflet motion) is caused by elongation or rupture of the chordae tendineae or the papillary muscles. Papillary muscles pathology can be degenerative or ischemic. Type II dysfunction commonly affects the posterior leaflet but may also be found in the anterior leaflet or both leaflets. From the surgical view, degenerative type II lesions of the posterior leaflet can be repaired easily and with good long-term durability. **c** Type III dysfunction (restricted leaflet motion) affects the posterior as well as the anterior leaflet and is commonly associated with rheumatic heart disease. Due to the underlying pathology, rheumatic type III dysfunction is less likely to be repaired as compared to type II dysfunction. In patients with concomitant mitral valve stenosis, percutaneous valvulotomy has become a valuable approach. Open valvulotomy still plays a role; however, in most instances mitral valve replacement with preservation of the subvalvular apparatus provides good long-term results. Type III dysfunction may also be caused by ventricular dilatation in patients with dilated cardiomyopathy or by papillary muscle displacement in patients with ischemic cardiomyopathy

Enlargement of the coaptation area can usually be achieved by narrowing the mitral anulus using anuloplasty devices. Due to the relationship of the anterior portion of the anulus to the fibrous trigones of the heart, significant narrowing of the anulus can only be achieved at the posterior portion. The normal ratio between the septolateral and transverse diameter of the mitral anulus is approximately 3:4 during systole. A remodeling ring anuloplasty and basically also all historic remodeling techniques, as described by Paneth, Whooler, and others, attempt to restore this ratio. An anuloplasty ring prevents further anular dilatation, preserves leaflet mobility, and relieves tension to the leaflets (stabilizing the repair) by optimizing the coaptation area.

■ ■ Quadrangular resection of the posterior leaflet and sliding plasty

Posterior leaflet prolapse due to fibroelastic deficiency is usually caused by rupture of a single chord and therefore often affects an isolated portion of the leaflet. The ruptured chord is

identified during initial valve analysis in most cases, as the free prolapsing margin including the ruptured chord is flushed back into the left atrium (Carpentier 1983). In Barlow’s disease, not only the prolapsing segment is affected. In these patients, excess tissue is also seen in the neighboring valve segments and needs to be addressed to achieve successful repair. Our preferred approach for prolapsing posterior leaflet segments is a quadrangular resection with sliding plasty (■ Fig. 25.14). This technique together with mitral valve anuloplasty represents the most common reparative measure and has proven long-term durability. First, it is important to assess the extension of prolapsing segment (most likely involving the P2 segment) in order to define the amount of tissue that needs to be resected. We then identify the primary chordae of the prolapsing segment and mark them with a 5-0 Prolene suture. Depending on valve size, the length of the segment to be resected is 1–3 cm. Following the definition of the resection borders, it is recommended to

preserve a primary chord of this segment for potential correction of the corresponding segment of the anterior leaflet by chordal transfer. Prior to resection of the P2 segment, it is further recommended to place 2 marking sutures around the chordae of the P1 and P3 segments, which need to be preserved. The quadrangular resection is then carried out by two vertical inci-

sions from the margin of the leaflet towards the annulus with the marking sutures as orientation. The base of the quadrangular resection is also cut with a knife carefully respecting the annulus. It is recommended to leave an edge of 1–2 mm to preserve the integrity of the annulus (Gillinov and Cosgrove 2001). In many instances, it is useful to close the vertical gap between P1 and

Fig. 25.14 a–c Mitral valve reconstruction for degenerative mitral regurgitation due to chordal rupture in the P2 segment. **a** After careful functional and anatomic valve analysis, a quadrangular resection of the prolapsing segment of the posterior leaflet is performed. The excision lines are directed vertically to the annulus avoiding convex or concave orientation. For an additional sliding plasty, the incision can be extended parallel to the annulus towards the P1 and P3 segment. **b** Following the quadrangular resection, valve reconstruction is performed in two steps. The annulus is narrowed at the base of the resected segment by compression sutures placed in figures of 8 or as mattress sutures with or without pledgets at the atrial as well as the ventricular aspect of the annulus. **c** The remaining parts of the posterior leaflet are then readapted by a sliding plasty at the base. The remaining cleft between the P1 and P3 segment is then closed by single figure-of-eight sutures or by a running suture

P3 segments at the top with single Prolene 5-0 stitches. In cases of excess tissue as seen in Barlow's disease, following quadrangular resection of the prolapsing segment, a sliding leaflet plasty is performed to shorten the height of remaining leaflet segments. The residual P1 and P3 segments are detached from the anulus approximately one third in the direction to the corresponding commissures. The next steps attempt to gather the posterior portion of the anulus as much as possible. To achieve this, up to three compression stitches are placed tangentially through the posterior segment of the anulus. Finally, a «sliding plasty» of the residual P1 and P3 segments is performed and the gap between the residual leaflets is closed with sutures.

The reconstruction of the posterior leaflet should be already sufficient before the additional anuloplasty is performed. To test the result, saline is instilled into the left ventricle as described before. In case of residual regurgitation, additional adaptation stitches may be placed into the A1-P1 or A3-P3 to improve leaflet coaptation. The anuloplasty, which completes mitral valve reconstruction, stabilizes the repair but does usually not improve the leaflet reconstruction (Lim et al. 2002).

In some patients, particularly in the case of Barlow's disease, excessive posterior leaflet tissue is present, and it is necessary to reduce the height of the posterior leaflet sufficiently to avoid postoperative systolic anterior motion with resultant left ventricular outflow tract obstruction and mitral regurgitation. Systolic anterior leaflet motion can also be a result of too small anuloplasty ring sizes. Postrepair echocardiography is an important tool to detect this complication.

■ ■ Triangular resection of the anterior leaflet

As mentioned before, in contrast to the posterior leaflet, aggressive resection of the anterior leaflet is not possible due to anatomic limitations. Resection of large portions of the anterior leaflet (>10%) distorts leaflet geometry and reduces the coaptation area. Furthermore, extensive resection of the anterior leaflet compromises leaflet mobility and increases the risk of repair failure (Filsoufi and Carpentier 2007). Therefore, repair strategies for anterior leaflet prolapse are designed to correct prolapse without resection of significant areas of leaflet tissue. A limited prolapse of the anterior leaflet can be treated by

a triangular resection of the prolapsed part followed by direct closure with interrupted sutures (■ Fig. 25.15d, e). The triangular resection should be limited to the rough zone to avoid compromising the body of the leaflet (Adams et al. 2006).

■ ■ Anuloplasty

After addressing the prolapsing segments of the anterior and/or posterior leaflet, an anuloplasty should be performed. The use of anuloplasty devices in the setting of mitral valve repair has several reasons. Most important are the restoration of a normal anular shape and dimension. The normal ratio between the septolateral and transverse diameter of the mitral anulus is approximately 3:4 during systole. This ratio inverts in patients with chronic mitral regurgitation leading to a loss of leaflet coaptation area, even in nonprolapsing segments. A remodeling ring anuloplasty restores the physiologic ratio of the normal anulus during systole, restoring not only the size but also the shape of the anulus. An anuloplasty ring prevents further anular dilatation, preserves leaflet mobility, and relieves tension on the leaflets by optimizing the coaptation zone. There are several different anuloplasty devices available including flexible or semirigid rings and bands. In our practice, we preferably use semirigid closed anuloplasty rings in addition to every mitral valve repair in order to normalize the mitral geometry and furthermore to stabilize the reconstruction by relieving tension from the sutured leaflets.

First, appropriate ring sizing is performed following Carpentier's principles. The measurement is based on the intercommissural distance and also the surface area of the anterior leaflet. The height of the anterior leaflet is defined by pulling it downwards to the posterior leaflet and in comparison with the sizer's surface (■ Fig. 25.15a). The intercommissural distance is measured by the distance between the two corner points of each individual sizer.

The anuloplasty is then performed by first placing horizontal mattress stitches circumferentially through the anulus (■ Fig. 25.15b). In opposite to mitral valve replacement, we do not use Teflon-pledgeted sutures for mitral anuloplasty. In case of leaflet reconstruction, it is important to place the sutures outside the area of reconstruction. Particular attention needs to be addressed to the conduction system and the

course of the circumflex artery. The anular sutures are then equally spaced in the area between the two commissures and the corresponding segment of the prosthetic ring. In the remaining portion of the anulus, the spacing is set to conform the anulus to the shape and size of the prosthetic ring. When the ring sutures are tied, the ring reshapes the anulus to a normal systolic geometry (■ Fig. 25.15c).

25.5.3.3 Mitral Valve Reconstruction (Chordae)

Mitral regurgitation may be caused by isolated chordal pathologies, but more often chordal pathologies are accompanying lesions in patients with degenerative mitral disease. In this section, reconstruction techniques for mitral regurgitation due to chordal pathologies are described.

■ ■ Plication or resection of the posterior leaflet with or without chordal transfer

Chordal rupture is most commonly located at the posterior leaflet, particularly at the P2 segment, probably because the chordae of the P2 segment are prone to the highest tension in patients with loss of coaptation area. Chordal rupture is a typical complication of Barlow's syndrome which is characterized by excess leaflet tissue, chordal elongation, and anular enlargement. Chordal pathologies are also seen in patients with Marfan's syndrome.

An isolated rupture of a posterior leaflet chord can be treated by leaflet plication. Alternatively, particularly in the setting of anterior leaflet prolapse due to chordal rupture, a triangular resection of the prolapsing segment can be performed. The triangular resection technique equals the quadrangular resection without sliding plasty as described above. Herein, the leaflet plication will be described in detail.

The leaflet plication technique involves invagination of the portion of the leaflet the ruptured

chord belongs to. A continuous horizontal mattress suture is placed vertically to the anulus plicating the prolapsing segment and shortening the anular circumference by the length of the prolapsing segment. Consequently, the suture line needs to be extended into the atrial wall. An alternative approach would be the resection of the prolapsing segment in a quadrangular or triangular shape and direct readaptation of the remaining segments with intact chords. Chordal ruptures of the anterior leaflet chords, particularly of strut chords (principle chords), represent a special challenge and were deemed not repairable with satisfying long-term results and therefore led to valve replacement. However, a feasible approach in our practice is the utilization of the chordal transfer technique. A small segment of the corresponding posterior leaflet segment with its marginal chord in place is dissected and sutured to the ventricular surface of the anterior leaflet close to the insertion of the ruptured chord. The resulting defect in the posterior leaflet is closed by leaflet plication. The midterm results of this technique are promising; however, long-term data is required to determine the durability of this approach (Anyanwu and Adams 2007).

■ ■ Chordal plasty

Chordal plasty presents an alternative approach for the treatment of leaflet prolapse instead of leaflet resection (■ Fig. 25.16). In our practice, we utilize 4-0 or 5-0 polytetrafluoroethylene sutures (PTFE) as neo-chordae. The required length of the neo-chordae is determined by lowering the free margin of the anterior leaflet to the anulus and measuring the distance between the margin of the leaflet from this position and the head of the papillary muscle. This distance is usually 1.5–2 cm. Determining the correct length is particularly important – a too short neo-chord results in restricted leaflet motion where as a too long neo-chord does not effectively reduces the leaflet

◀ **Fig. 25.15** a–e Mitral valve anuloplasty. **a** Different anuloplasty rings are utilized for mitral valve reconstruction. Sizing is performed by measuring the height of the anterior leaflet and the intercommissural distance. This can be achieved by grasping the anterior leaflet with a hook. **b** Horizontal mattress sutures are placed circumferentially through the anulus and the corresponding segments of the prosthetic ring. **c** When the sutures are tied down, the anuloplasty ring reshapes the mitral anulus to a normal geometry. Usually, 10–12 sutures are required to sufficiently secure the ring. **d, e** In patients with anterior leaflet prolapse due to chordal rupture, a triangular resection of the prolapsing segment (here shown for segment A2) can be performed followed by direct closure of the defect with single sutures. **e** Note the triangular resection is not extended to the base of the anterior leaflet. A stabilizing ring anuloplasty should be added in any instance

prolapse (Sarsam 2002). The neo-chord is attached to the corresponding papillary muscle using pledgeted sutures stitched through the fibrous portion of the muscle. Meanwhile, there are also commercial sutures with integrated Teflon pledgets available. At the leaflet margin, the suture should be stitched twice to avoid tearing the often fragile and thin leaflet tissue (Risteski et al. 2007). To ensure the correct length before definitely tying the neo-chord, a clip can be used to fixate the neo-chord at the estimated length. If saline testing shows a sufficient result, the neo-chord can be tied down to its final length.

■ ■ Chordal shortening

If leaflet prolapse is caused by chordal elongation, shortening of the affected chord can be a valuable option. Following Carpentier, the relative amount of chordal elongation is estimated by pulling the free margins of the leaflets with two valve hooks. The body of the papillary muscle originating the elongated chordae is then spliced longitudinally. The portion with the insertion of the elongated chordae is then slid downwards and reattached to the remaining muscle (■ Fig. 25.17). Alternatively, the elongated chord can be folded downwards and tied to the base of the papillary muscle (■ Fig. 25.18). Both techniques result in a shortening of the elongated chord thus improving valve geometry. However, in our opinion, this technique may harm the papillary muscle, and therefore we prefer the utilization of artificial chordae. Another alternative is described by Kay (1992), who also folds the elongated chord but fixates the resulting loop at the fibrous head of the papillary muscle and not at the body.

Regardless of these techniques described, it needs to be taken into consideration that limited leaflet prolapse due to chordal elongation might be resolved by correcting the posterior annulus

with anuloplasty which creates a good area of coaptation and therefore limits the tension on the elongated chords. The valve is, moreover, molded towards a funnel shape which prevents prolapsing of the leaflet segment with elongated chords (Smedira et al. 1996).

25.5.3.4 Patch Reconstruction

The most common cause of leaflet perforation leading to type I regurgitation is mitral valve endocarditis. Surgical treatment with the intention to restore the native valve requires removal of all infective material while preserving intact leaflet margins. The resulting defect can be closed utilizing a patch of autologous pericardium or glutaraldehyde-treated bovine pericardium with a 5-0 running polypropylene suture. It is important to size the patch approximately 20% larger than the defect to avoid tension on the leaflet due to the suture line (Sternik et al. 2002; Zegdi et al. 2005).

25.5.3.5 Alfieri-Technique

The simplest maneuver for mitral valve repair of type I insufficiency with central regurgitation is the so-called Alfieri stitch (edge-to-edge repair) (■ Fig. 25.19). After exploration of the valve, the central margin of the A2 segment is identified and pulled towards the surgeon. Accordingly, the central margin of the P2 segment is grasped, and both segments are tied together with a pledgeted (Teflon or pericardium) 4-0 polypropylene mattress suture 3–5 mm from the free margin (Maisano et al. 1998).

The long-term results of this technique are controversial. Alfieri himself recommends always adding an anuloplasty device. With the advent of minimal-invasive and catheter-based procedures, the edge-to-edge repair has become more popular. These techniques are described in detail in ► Chapter «Minimally Invasive Cardiac Surgery», Sect. 26.3.5.1; Sect. 26.3.5.2.

◀

■ **Fig. 25.16** a–e Artificial chordoplasty. **a, b** The use of 5-0 Polytetrafluoroethylene (PTFE) sutures as artificial chords has replaced common techniques for chordal shortening and «flip-over» techniques in most instances of mitral valve reconstruction. The figures show an anterior leaflet prolapse with ruptured chordae. The remnants of the ruptured chordae are excised. In addition, secondary chordae may be released. **c, d** Double-armed 5-0 PTFE sutures are passed through the papillary muscle in a figure-of-eight manner approximately 1 cm from the tip. Both ends of the suture are then passed through the margin of the prolapsing leaflet segment. **e** A temporary holding suture is passed through the prolapsing leaflet and the corresponding nonprolapsing segment of the opposite leaflet. Pulling the holding suture allows determination of the correct height of the artificial chordae before tying the PTFE chord

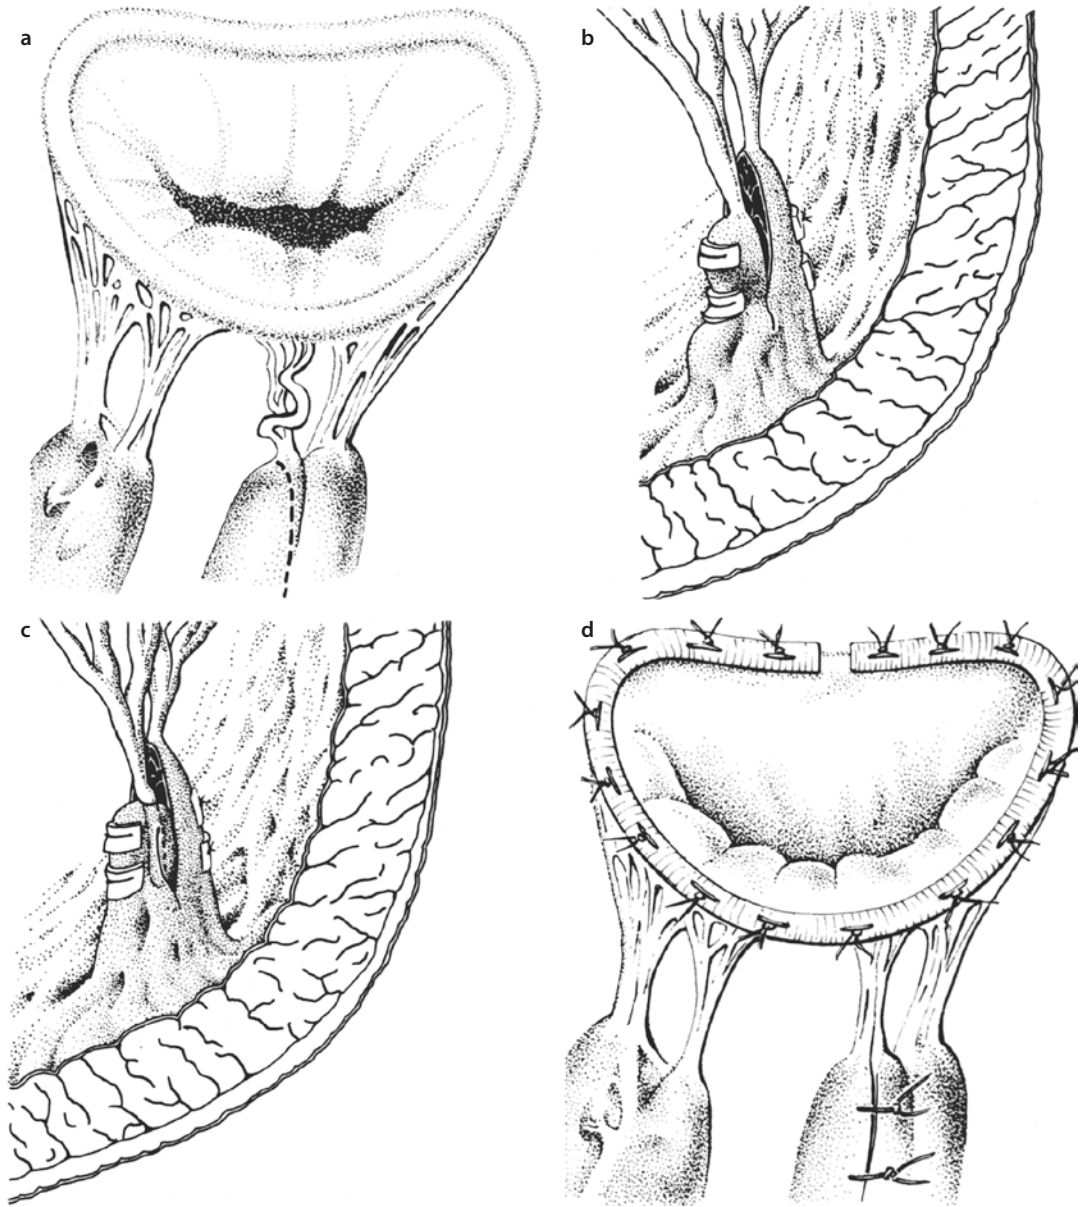

Fig. 25.17 a–d Carpentier's technique of chordal shortening for elongated chords. The corresponding papillary muscle can be incised longitudinally **a**, moved downwards by the length of elongation and reattached with pledget-armed sutures thus tightening the elongated chords **b**. An alternative technique consists of gathering the elongated chord and attaching it to the incised papillary muscle **c**. **d** The incision of papillary muscle is finally closed covering the gathered chord. An additional anuloplasty is strongly recommended to stabilize the repair

25.5.4 Ischemic Mitral Valve Regurgitation

Ischemic mitral regurgitation represents a serious complication in patients with coronary artery disease, and surgical treatment of this entity is associated with a significantly higher perioperative risk as

compared to degenerative mitral regurgitation (Filsoufi et al. 2006). Most commonly, ischemic mitral regurgitation is caused by remodeling processes of the left ventricle following myocardial infarction and develops chronically over time, whereas in some cases ischemic mitral regurgitation results from acute myocardial ischemia leading

■ **Fig. 25.18** a, b
Chordal fixation plasty for elongated chords. The chord is gathered to the optimal length and attached to the fibrous part of the papillary muscle

■ **Fig. 25.19** a, b «Edge-to-edge» repair for ischemic mitral regurgitation. a Pericardial sutures or pledget-armed horizontal mattress sutures are passed through the margins of the anterior and posterior leaflet and tied creating a double orifice. This fixation results in a better coaptation during systole thus reducing mitral regurgitation. b «Edge-to-edge» repair of an anterior leaflet prolapse in the area of A3 segment

to papillary muscle rupture. In the latter patient group, acute mitral regurgitation and accompanying pulmonary edema often require emergency surgery.

Surgical outcome of patients with acute ischemic mitral regurgitation often is inferior; however, immediate and consequent surgery remains the only option. In this setting, mitral valve replacement is usually preferred over reconstructive measures. However, some authors suggest refixating the rup-

tured papillary muscle with sutures. In cases of papillary muscle elongation due to fibrotic degeneration and elongation of papillary muscles following myocardial infarction, Teflon-pledgeted PTFE sutures are stitched through the base of the papillary muscle on one side and through the head of the papillary muscle on the other side in a U-fashion. This leads to a shortening of the elongated papillary muscle and avoids cutting through the muscle (Fasol et al. 2000). If this reconstructive approach does not significantly

reduce mitral regurgitation, mitral valve replacement has to be performed in the same session. In this patient population in particular, it is important to preserve as much of the subvalvular apparatus as possible to avoid further re(de-)modeling of the already altered ventricle (Jouan et al. 2004).

Chronic ischemic mitral regurgitation in patients with ischemic cardiomyopathy following myocardial infarction requires a more differentiated approach. In most instances, chronic ischemic mitral regurgitation develops following occlusion of a dominant right coronary artery or a concomitant occlusion of branches of the right and circumflex artery. This leads to several pathoanatomic and pathophysiologic changes affecting the components of mitral valve function. The left ventricle loses its elliptical shape and becomes more spherical which leads to displacement of the papillary muscles, especially the posteromedial papillary muscle. This papillary muscle displacement leads to a tethering of the mitral leaflets significantly reducing the coaptation area resulting in type III b mitral regurgitation (Filsoufi et al. 2006). This restricted leaflet motion is mainly seen after posterior infarction and affects the posteromedial scallop of the posterior leaflet (P3 segment) adjacent to the posterior commissure area.

Surgical treatment of chronic ischemic mitral regurgitation usually includes coronary artery revascularization, as most patients present with multivessel disease. However, coronary revascularization alone, either surgically or interventional, does not correct ischemic mitral regurgitation in most patients. Furthermore, several studies have shown a survival benefit of patients with ischemic cardiomyopathy and sufficient mitral valve function compared to those with untreated mitral regurgitation. Therefore, if more than mild mitral valve regurgitation is present, bypass surgery should be accompanied by mitral valve reconstruction. Mitral valve anuloplasty is the appropriate surgical procedure in most cases of ischemic mitral regurgitation. The goal is to restore a large coaptation area and to remodel the anulus while preserving leaflet mobility (Carpentier 1983). This can be achieved by downsizing the anulus using an undersized anuloplasty ring. This downsizing corrects the septolateral displacement and thus reduces restricted leaflet motion and restores leaflet coaptation. For this approach, several devices (rings and bands) have been utilized. However,

recurrence or residual mitral regurgitation has been observed, and the choice of the right device is still under debate. The trend goes to completely closed semirigid rings and some authors advocate disease-specific rings that help in addressing the asymmetric tenting and leaflet restriction seen in ischemic mitral regurgitation (Daimon et al. 2006). The inability to overcorrect the septolateral dimension and to address anterior or asymmetric anular dilatation are some major concerns current percutaneous approaches to correct ischemic mitral regurgitation are faced with (Anyanwu et al. 2006).

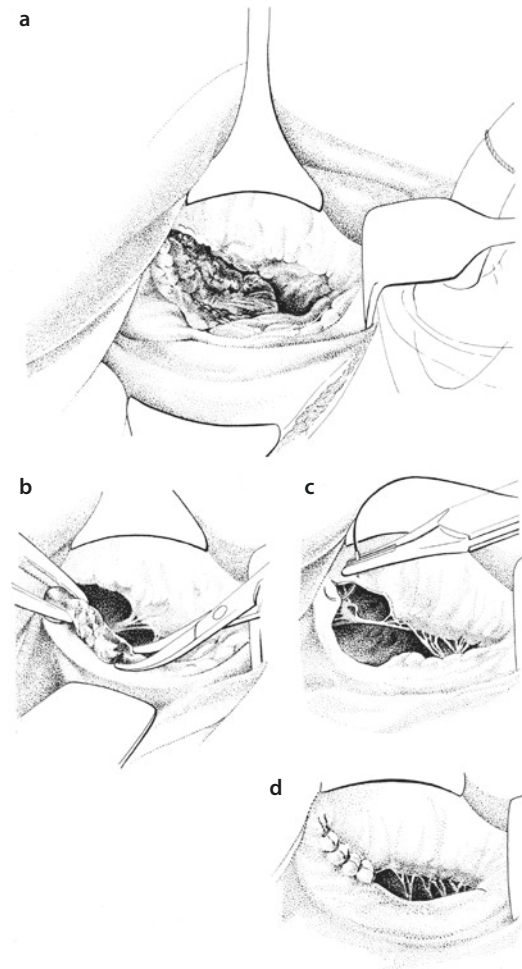

25.5.5 Mitral Valve Endocarditis

Infective endocarditis commonly includes the aortic valve while involvement of the mitral valve is seen less frequently. In many instances, mitral valve endocarditis occurs secondary to aortic valve endocarditis. Destruction of the infected aortic valve leads to aortic regurgitation and prolapse of the aortic cusps into the left ventricular outflow tract during diastole and can produce «jet lesions» of the mitral valve. These lesions are typically located in the central portion of the anterior leaflet and range between minimal vegetation and extended leaflet perforation (Piper et al. 2002). Primary mitral valve endocarditis is a rare entity and usually leads to chordal rupture and/or large vegetations. Mitral anular abscess formation is rare and presents a challenge for surgical treatment.

The surgical principle of repairing the valve is to completely remove all infected tissue (Alexiou et al. 2000; Mylonakis and Calderwood 2001) (■ Fig. 25.20). This often leads to resection of large parts of the mitral valve requiring mitral valve replacement. The technique of replacement follows the same principles as described above. We usually preserve the subvalvular apparatus – if not infected – and implant the prosthetic valve in an epianular position with Teflon-pledgeted U-sutures.

In some patients, resection of infected tissue is limited to smaller portions of the valve and allows native valve reconstruction. We particularly try to achieve preservation of the native valve in children, adolescents, and young adults to avoid negative side effects of prosthetic valve replacement even if mitral valve reconstruction results in mild to moderate mitral regurgitation. Reconstruction techniques depend on the localization of the

■ **Fig. 25.20** a–d Mitral valve reconstruction for infective endocarditis. In cases of local destruction **a** of the mitral valve, complete resection of the infected tissue may be possible while preserving enough tissue for sufficient reconstruction. In the case shown here, parts of the anterior and posterior leaflet in the area of the anterior commissure had to be resected **b**. The defect was closed by reattaching the remaining anterior and posterior leaflets at the commissure **c** resulting in a competent and nonstenotic mitral valve **d**

resulting defect. Smaller defects can be closed by direct sutures, whereas larger defects require readaptation similar to a commissuroplasty. This is only possible as long as the remaining valve orifice – measured with a sizer intraoperatively – is large enough. Even very large defects of the anterior leaflet can be handled with patches from autologous pericardium.

A surgical challenge is patients with abscess formations involving the mitral annulus or the neighboring myocardium. In these cases, resection of infected tissue involves an extended debridement of annular or ventricular wall tissue and leaves large defects requiring patch reconstruction. The patch, consisting of autologous pericardium, needs to be sutured carefully to the left ventricular wall and – passing the annulus – the left atrial wall (Alexiou et al. 2000) before a valve prosthesis can be implanted. Prognosis of the patients, however, remains poor, as the inflammatory processes lead

to a very fragile tissue in this area often not allowing a firm fixation of the prosthesis leading to para-valvular leakage or complete tear out of the prosthesis. Some authors have therefore suggested placing the prosthesis not in an annular position but above the annulus directly in the atrial wall (Dreyfus et al. 1990; de Kerchove et al. 2007).

25.5.6 Testing of Mitral Valve Reconstruction

Successful and reliable mitral valve repair requires intraoperative evaluation of mitral valve function. Several methods have been described (■ Fig. 25.21).

The easiest and most common method to test the repair utilizes a large syringe to inject saline into the left ventricular cavity. Once the ventricle is filled, the mitral leaflets are distended and

■ **Fig. 25.21** a, b Intraoperative testing of mitral valve repair by filling of the left ventricle with cardioplegic solution. a Following isolated mitral valve reconstruction a thin perfusion catheter (12 Ch) is passed through the aortic valve into the left ventricle using the cardioplegia insertion site at the ascending aorta. Cardioplegic solution is then administered under pressure control. Mitral valve closure and potential leakage can be visualized from the left atrium then. In cases of concomitant aortic valve replacement with complete excision of the aortic valve, a Foley catheter is placed into the aortic valve orifice b. After inflating the balloon, cardioplegic solution can be administered via the catheter in a similar fashion

mimic a systolic position. At this point, the valve should be competent along the whole coaptation line. According to Carpentier, the coaptation line looks like «a smiling mouth».

Hetzer has described a reliable and reproducible technique to test mitral valve competency by placing a small catheter (12 Ch) through the insertion of the antegrade cardioplegia line and through the aortic valve into the left ventricle. Cardioplegic solution is then administered into the ventricle with a maximum pressure of 40–50 mmHg to avoid distension of the myocardium. With this technique, valve closure and leaflet coaptation can be controlled easily. In cases of concomitant aortic valve replacement, this methodology has been modified by placing a urine catheter (Foley catheter) in the left ventricular outflow tract through the aortotomy and blocking the catheter at the level of the aortic anulus after excising the cusps. Saline can then be instilled into the left ventricle accordingly (Borst et al. 1991). These methods may work in most instances. In patients with functional mitral regurgitation such as restricted leaflets in ischemic cardiomyopathy, however, these

testing methods may fail because they are static and do not evaluate valve function during regular cardiac cycle.

Therefore, definitive testing of repair can only be achieved with a beating heart employing transesophageal echocardiography. This method, however, requires termination of cardioplegic arrest and rewarming of the patient to allow at least partial weaning off bypass. Nevertheless, echocardiography can be performed with the cannulas in place and allows immediate reassessment for further reconstruction or valve replacement in the absence of satisfactory repair. With consequent utilization of intraoperative echocardiography, we have not experienced relevant postoperative mitral regurgitation in our practice.

25.6 Tricuspid Valve Procedures

The tricuspid valve separates the right atrium from the right ventricle. As the tricuspid valve is only prone to low mechanical stress, isolated acquired diseases of the tricuspid valve are rela-

tively rare. Most surgical procedures of the tricuspid valve are necessary for secondary tricuspid valve regurgitation in the setting of chronic mitral valve disease and pulmonary hypertension. In these cases, the native tricuspid valve and its subvalvular apparatus are commonly intact, while the tricuspid annulus is severely dilated. After years of debate whether to address tricuspid valve regurgitation during mitral surgery or not, there is meanwhile clear evidence that simultaneous repair is beneficial for patients with combined mitral and tricuspid regurgitation (Dreyfus et al. 1990). As a rapid and relatively simple procedure, we liberally perform additional tricuspid anuloplasty in patients undergoing mitral valve surgery, when more than moderate tricuspid regurgitation or a dilated tricuspid annulus is present. This approach is based on the observation that tricuspid regurgitation does not recover even many years following successful mitral valve repair or replacement (Bianchi et al. 2009).

Nowadays, at least in industrialized countries, organic tricuspid valve stenosis or combined pathologies due to rheumatic disease have become a rare entity. However, reconstruction can often be achieved by commissurotomy or anuloplasty.

Infective endocarditis involving the tricuspid valve on the other hand is more common and increasingly seen in patients with immunosuppression and more important chronic i.v. drug abuse (Shatapathy et al. 2000).

25.6.1 Functional Anatomy

The tricuspid valve consists of three leaflets, the anterior, posterior, and septal leaflet. The anterior leaflet has the largest surface area, whereas the posterior leaflet is the smallest. The septal leaflet is attached to the fibrous part of the heart. The leaflets are separated by three commissures (anteroposterior, posteroseptal, anterosseptal). A large anterolateral papillary muscle originates from the free right ventricular wall and sends chordae to the anterior and posterior leaflets, whereas a smaller posteromedial papillary muscle originates from the septum and is attached to the septal leaflet. The septal leaflet has also chordae that are directly attached to the septal wall.

The triangle of Koch is an important anatomical landmark defined by the tendon of Todaro (a fibrous structure formed by the junc-

tion of the Eustachian valve and the Thebesian valve), the septal leaflet of the tricuspid valve, and the orifice of the coronary sinus. The AV nodal bundle is located near the apex of the triangle of Koch in the region of the membranous septum, and thus suture placement in this area should be avoided.

25.6.2 Tricuspid Valve Replacement

As mentioned before, organic tricuspid pathologies are rare, and therefore tricuspid valve replacement is rarely necessary. In cases of tricuspid stenosis due to rheumatic disease or infective endocarditis with valve destruction without repair option, we replace the tricuspid valve following the same principles as described for mitral valve replacement including preservation of the subvalvular apparatus. Even in cases of severe stenosis, mobilization of the subvalvular apparatus can be achieved by commissurotomy allowing implantation of a biological prosthesis or a low-profile mechanical valve.

It is important to mention that the U-sutures that are placed in the same manner than in mitral valve replacement in the area of the anterior and posterior portion of the annulus have to be placed through the base of the septal leaflet instead of the septal portion of the annulus to avoid impairment of the conduction system. When the leaflets need to be excised, at least a margin of the septal leaflet should stay in place. Nevertheless, complete AV block is frequently associated with tricuspid valve replacement.

If a mechanical prosthesis needs to be implanted, one should keep in mind that thereafter placement of a Swan-Ganz catheter or more important implantation of transvenous pacemaker electrodes is not possible. If a tissue valve is chosen, the prosthesis should be orientated in the way that the struts are not directed towards the anterior portion of the annulus because this may cause partial outflow tract occlusion. In our opinion and as advocated by other groups, in most cases tricuspid valve replacement is performed with a commercially available biological mitral valve prosthesis (Filsoufi et al. 2005). The lower mechanical burden in tricuspid position leads to a significantly lower rate and later onset of prosthetic biological valve degeneration compared to mitral or aortic position.

25.6.3 Treatment of Tricuspid Anular Dilation

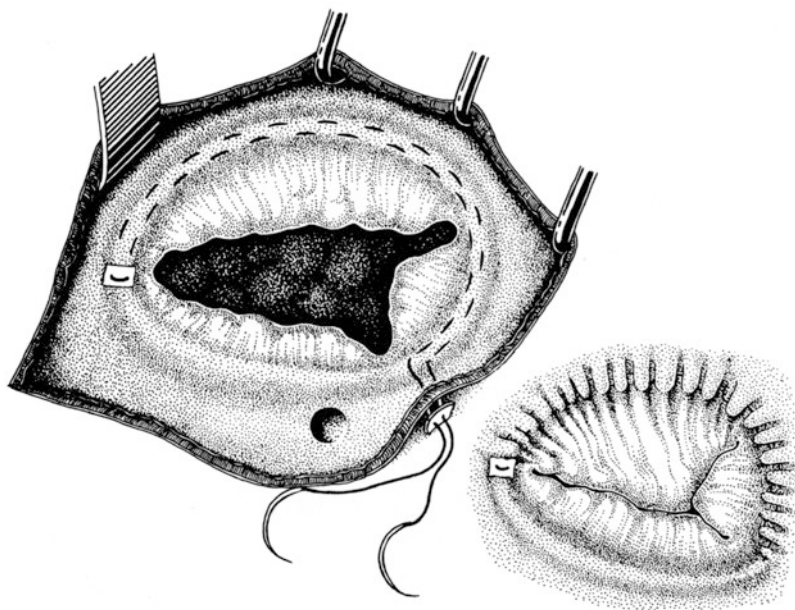

The different approaches for tricuspid valve repair follow the same rules described for mitral valve repair. The goal is to downsize the tricuspid anulus in the anterior and posterior portion while keeping the geometry of the septal part of the anulus intact to avoid compromise of the conduction system. The orifice area is commonly reduced to 3–4 cm².

25.6.3.1 De Vega Anulorrhaphy

The de Vega anuloplasty shortens the anular circumference at the base of the anterior and posterior leaflets (■ Fig. 25.22). We usually perform this technique with a double row of a Teflon-pledgeted semicircular 4-0 polypropylene suture beginning at the anterior trigone and running along the anulus of the base of the anterior and posterior leaflets. The two suture lines are placed parallel but in an alternative sequence to ensure homogeneous narrowing of the tricuspid anulus. In the area of the

posteroseptal commissure, the sutures are stitched through the outside of the atrial wall and secured with another Teflon pledget. When tying the sutures, the remaining orifice should allow for two of the surgeon's fingers to be introduced. A better estimation of the remaining orifice can be achieved with a valve sizer; a number 27 (mm) sizer of any manufacturer is recommended. With these measures, the anular diameter is reduced to a third, and the orifice is downsized to about 4 cm² (De Paulis et al. 1990). Alternatively, the atrium can be closed first. The suture lines are then tied from outside the atrium after weaning off cardiopulmonary bypass under echocardiographic control until the tricuspid regurgitation disappears.

One major drawback of this simple technique is the potential risk of a suture tear out due to high tension on the anulus. This can be avoided by stitching the second suture line in an overcast fashion with a supporting pericardial strip. Also the long-term results are not comparable to ring reduction plasties, as it was shown in the later years.

■ Fig. 25.22 Tricuspid valve anuloplasty for tricuspid regurgitation according to de Vega. The technique employs a double-lined suture in the anular segments of the anterior and posterior leaflet running from the posteroseptal commissure to the anteroseptal commissure and back with a pledget at the turning point at the anteroseptal commissure. The suture is then passed through a second pledget at the posteroseptal commissure. The suture is tightened, producing a purse-string effect resulting in a length reduction of the anterior and posterior anulus segments providing a broader leaflet coaptation. If the suture is passed through the atrial wall at the posteroseptal commissure, final tightening can be performed after closure of the atriotomy and weaning off bypass under digital and/or echocardiographic control

25.6.3.2 Tricuspid Anuloplasty

Today, the de Vega plasty has been replaced by ring anuloplasty in most cases. As for mitral anuloplasty, several rings and bands especially designed for the tricuspid valve are available. We prefer a three-dimensional ring that mimics the shape of the tricuspid annulus. Alternatively, conventional semirigid rings can be used. In these cases, we bend the septal portion slightly inward to create a three-dimensional shape which mimics the annular direction along the membranous septum. Sizing of the tricuspid valve is based on two measurements: the intercommissural distance of the septal leaflet and the surface area of the anterior and posterior leaflets. First the intercommissural (intertrigonal) distance of the septal leaflet is measured. Using a valve hook, primary chordae of the anterior and posterior leaflets arising from the anterior papillary muscle are secured at the margin of the leaflets and pulled down to expose the surface area of these two leaflets. The surface area of the anterior and posterior leaflet is measured using the plane of the sizer. If the intercommissural distance and surface area measurement result in different sizes, the ring size is chosen in favor of the measured surface area of the leaflets. In general, we

also tend to pick a smaller ring if a measurement was in between sizes available. Ring implantation is performed by placing a series of eight to ten simple 2-0 Polyester mattress sutures through the tricuspid annulus around the orifice. As previously mentioned, particular attention needs to be directed to avoid injury of the intracardiac conduction system. As described above, the atrioventricular node is located in the area of the membranous septum at the apex of the triangle of Koch. This area is marked by placing the first two sutures on either side of this area. The remaining sutures are then placed circumferentially around the annulus. The atrio-annular junction is identified by pulling down the anterior and posterior leaflets, respectively. The stitches are placed with wide bites in a 1 mm distance from this atrio-annular junction and directed towards the ventricle (■ Fig. 25.23). Overlapping of the sutures and smaller corresponding bites through the ring particularly at the posterior leaflet produces a measured annular plication in this region of maximal dilatation. Each arm of the sutures is then passed through the sewing ring of the prosthesis. Next, the ring is lowered into position and tied securely to the annulus. A final intraoperative test by injecting normal

■ Fig. 25.23 Tricuspid valve anuloplasty with an open ring. The ring is fixated with horizontal single mattress sutures avoiding injury of the bundle of His in the septal portion of the annulus

saline into the right ventricle should show a competent valve with a good amount of coaptation in between all three leaflets.

25.6.3.3 Bicuspidalization

The bicuspidalization technique as described by Kay et al. lowers the dimension of the posterior anulus by plicating the posterior leaflet towards the ventricle (Kay 1992). In our opinion, this technique should only be used occasionally in patients with mild tricuspid regurgitation or anular dilatation or in cases of endocarditis, when mainly the posterior leaflet is affected.

26.1 Introduction

The development of minimally invasive and alternative operative techniques has gained significant importance in modern cardiac surgery. The goal is not only to establish better tolerated and more effective surgical techniques but also more efficient management algorithms. Central aims in modern minimally invasive cardiac surgery are to minimize size of thoracic surgical access incisions, reduce immunologic trauma, prevent myocardial ischemia, and maintain pulsatile systemic blood flow (i.e., myocardial and cerebral). To achieve these aims, interdisciplinary communication and the development of common multidisciplinary therapeutic strategies are mandatory. This strategic approach represents an important part of modern cardiac surgery.

Fundamentally, the term minimally invasive cardiac surgery refers to the combined effort to reduce trauma, operative risk, and thereby morbidity and mortality of conventional cardiac surgical procedures. Overall, these patients should expect a quicker convalescence and rehabilitation. Factors which result in more efficient pre- and postoperative in patient and postoperative ambulatory care ultimately lead to a shorter hospital stay and reduce hospital costs, thereby achieving more optimal resource utilization. These are ancillary expectations of alternative operative strategies. While cosmetic outcomes may be considered in the planning of cardiac surgical procedures, they should come second to the central aims of minimal invasive cardiac surgery as outlined above. Due to more effective medical and interventional therapies, conventional cardiac surgery is being confronted by progressively increasing cardiovascular disease in an aging population. We must advance to meet these challenges.

In summary, today's demands on cardiac surgery relate to an increasing risk profile of the entire patient population. These demands are significantly determined by the following factors:

1. The age of the patients who are undergoing a primary or secondary cardiac operation is rising (2011, 13.4% of patients were older than 80 compared to 2010, 12.4%; 2006, 9.6%; and 2005, 8.4%) (Funkat et al. 2012; Gummert et al. 2007).
2. The severity of the basic cardiac illness is more complex, primarily because of comorbid illnesses, often due to age, and prior interventional procedures.
3. An increase in combined procedures (i.e., multivalve, CABG procedures, etc.).
4. The proportion of patients requiring a reoperation is rising dramatically.

The following chapter should provide an overview of minimally invasive and alternative operative methods and concepts, illustrate the advantages and disadvantages of different techniques, depict the use of video-assisted procedures, and finally present perspectives on telemanipulator-assisted surgery.

26.2 The Development of Minimally Invasive Procedures in Cardiac Surgery

26.2.1 Requirements, Problems, and Challenges

With the goal of optimal exposure, taking anatomical factors and pathological complexity into account, most cardiac surgical procedures are carried out through the conventional approach of complete median sternotomy.

To reduce the invasiveness of this procedure, various aspects of the conventional approach may be altered:

- *Minimize* the operative approach.
- *Reduce* the length of the incision.
- *Avoid* cardiopulmonary bypass and operate on the beating heart.
- *Combine* surgical and interventional strategies (hybrid procedures).

In order to do so, various strategies and techniques have been described:

- *Partial sternotomy* in different fashions
- *Parasternal* and *thoracoscopic* approaches
- *Lateral thoracotomy*
- *Mini-thoracotomy*
- *Subxiphoid* and *subdiaphragmatic* accesses

The combination of a limited surgical approach with catheter-based intervention (hybrid strategy) represents a valuable alternative option in highly selected patients and can lead to a significant further reduction in invasiveness (Shannon et al. 2012).

However, problems inherent to minimization of surgical access may occur in the presence of a rigid bony thorax leading to limited exposure. Or the necessity of multiple smaller incisions to place additional instruments may lead to an increase in postoperative pain.

Challenges in surgery on the beating heart, besides the moving target, include the hemodynamic imbalances resulting from manipulation and luxation of the blood-filled heart. As a result, an array of techniques and systems, such as video-assisted presentation, CO₂ insufflation, flexible mechanical stabilizers, mister-blowers, and coronary shunts, have been developed and represent part of the routine practice of minimally invasive cardiac surgery.

The first clinically relevant developments began in the early 1990s on the basis of laparoscopic techniques from general surgery. Therapeutic thoracoscopy or video-assisted thoracic surgery (VATS) became more commonplace (Mack et al. 1992). Currently, VATS is the preferred worldwide approach to a variety of surgical procedures, including more complex thoracic operations such as lobectomy and esophagectomy (Landreneau et al. 1992).

26.2.2 Fundamental Concepts of Minimally Invasive Cardiac Surgery

In the 1990s, three significant developments led to a significant reduction of invasiveness in cardiac surgery:

- *The HeartPort system*
- *Reduced size of the surgical approaches*
- *Beating heart surgery*

The HeartPort system, a cannulation and catheter system developed in Stanford, CA, was first applied to carry out a LIMA-LAD anastomosis during a coronary bypass operation after conventional sternotomy Woo et al. (2006). Using this system, cardioplegic arrest was achieved through inflation of an endovascular balloon (so-called endoclamp technique) in the ascending aorta with subsequent administration of cardioplegia into the aortic root. The balloon itself was inserted via the femoral artery and advanced into the ascending aorta just above the coronary arteries. As a further development, the LIMA-LAD operation,

including the endoclamp technique, was carried out using a left anterior mini-thoracotomy on the arrested heart (Reichenspurner et al. 1998a, b). However, for the correct positioning of the HeartPort system, a sufficient transesophageal echocardiography imaging is absolutely mandatory.

As a result of a variety of reported complications, this technique is used almost exclusively now in minimally invasive mitral valve surgery, telemanipulator-assisted coronary artery bypass surgery or in rare cases of conventional cardiac reoperations, or porcelain aorta (see ► Sect. 26.2.3, «HeartPort Technique»).

With the introduction of direct coronary artery revascularization through a *limited thoracotomy access* such as the left anterolateral thoracotomy or the subxiphoid approach using video-assisted IMA preparation on the beating heart and the deployment of specially developed stabilizers and instruments (Reichenspurner et al. 1998a, b), new operative techniques could be transferred into clinical practice. Furthermore, these techniques could be used in patients with high operative risk, either for single- or multivessel coronary artery disease in combination with interventional procedures as a hybrid procedure (Holzhey et al. 2012; Shannon et al. 2012).

Beating heart coronary artery revascularization via a complete or partial sternotomy or various thoracic surgical approaches can be carried out with (on-pump beating heart) or without extracorporeal circulation («*off-pump*»). This technique first became possible through the development of special instruments and heart stabilizers, which enabled an optimal exposure of the corresponding coronary vessels.

Different algorithms were developed to achieve coronary anastomoses, such as insertion of a shunt or application of a special blower. The introduction of distal and proximal anastomotic connectors facilitates these techniques.

Particularly with off-pump coronary bypass surgery, effective collaboration with cardiac anesthesia is indispensable. This is the only way stable hemodynamics and patient security can be guaranteed. This technique is presently applied to over 25% of all coronary artery bypass operations in the USA. The effectiveness and the superiority as compared to conventional coronary artery bypass surgery with respect to blood loss, renal failure, intensive care unit, and hospital length of stay

have already been demonstrated (Puskas et al. 2005). The proof of superior survival has not been shown. However, the recently published data coming from the GOPCABE study showed that there is no significant difference between on-pump versus off-pump CABG in the older population (age >75) with regard to death, stroke, myocardial infarction, or repeat vascularization up to 1 year after surgery (Diegeler et al. 2013).

A direct comparison to interventional strategies is presently the object of multiple clinical studies. The 10-year follow-up from our randomized study comparing bare-metal stenting with MIDCAB observed similar outcomes regarding composite clinical end points. Nonetheless, the MIDCAB procedure was associated with more incompleteness of coronary revascularization (Blazek et al. 2013).

In our own analyses for patients with reduced LV function and increased operative risks, the «beating-heart» technique is superior to conventional bypass surgery with extracorporeal circulation avoiding cross-clamping especially in emergency operations (Rastan et al. 2006).

26.2.3 HeartPort Technique

The HeartPort system, a cannulation and catheter system developed at Stanford University, CA, was designed to enable minimally invasive and endoscopic cardiac operations (CABG and mitral valve) by providing endoluminal occlusion of the ascending aorta (Stevens et al. 1996a, b; Pompili et al. 1996). The catheter system can be introduced percutaneously via the femoral vessels. The distal end consists of a balloon, which is advanced and placed into the ascending aorta, above the aortic valve and proximal to the brachiocephalic trunk. After the balloon is inflated with normal saline, a temporary endoluminal occlusion of the aorta is achieved. Finally, through the same catheter system, cardioplegia can be administered into the aortic root. Thereafter the same catheters may be used for drainage also. Through the jugular vein, an additional catheter can be placed into the pulmonary artery for drainage also. Furthermore a transvenous catheter can be placed into the coronary sinus for retrograde cardioplegia administration. To ensure secure placement and intraoperative steering of the catheter system, TEE and an additional invasive blood pressure

measurement of the right radial artery are essential for early recognition of balloon dislocation and other complications (Siegel et al. 1997). The HeartPort technique was initially used and evaluated for minimally invasive coronary artery bypass surgery (Grossi et al. 1999; Subramanian et al. 1997). Further applications have been described in aortic valve surgery (Wheatley et al. 2004), congenital heart surgery (De Mulder and Vanermen 2002; Yamada et al. 2000), reoperations, and minimally invasive mitral valve surgery (Mohr et al. 1998; Ricci et al. 2010; Meyer et al. 2009; Casselman et al. 2007a, b).

Due to various reported complications with this technique, indications have been severely restricted. Possible complications include injury to the iliac vessels, dissection of the femoral vessels, injuries to the ascending aorta and aortic root including type A acute aortic dissection, traumatic aortic insufficiency, incomplete cardioplegia administration through displacement of one or both coronary ostiae with resulting inadequate myocardial protection, migration of the catheter and occlusion of the brachiocephalic trunk with resulting cerebral ischemia, and incomplete deairing after opening the cardiac chambers (Muhs et al. 2005; Wimmer-Greinecker et al. 1999).

Exclusion criteria for the application of the HeartPort technique are advanced peripheral vascular disease, arteriosclerotic or aneurysmal changes of the thoracic aorta as well as aortic insufficiency, and mitral valve calcification.

The endoluminal clamp technique enables the performance of minimally invasive techniques, but has no significant advantages over the direct clamp technique developed by Chitwood for mitral valve surgery (Dogan et al. 2005; Reichenspurner et al. 2005). As a routine method for elective cases, this technique has not found broad clinical application. Several authors report on its use with TECAB (totally endoscopic coronary artery bypass) procedures (Subramanian et al. 2005; Bonatti et al. 2007) and during reoperations, but definitive data is lacking.

26.3 Current Clinical Concepts

26.3.1 General Principles

Median sternotomy allows for any type of surgery for all cardiac and great vessel pathologies where

surgical treatment is indicated. The excellent exposure of the thoracic anatomical structures comes at the expense of a major surgical trauma. This can lead to excessive mechanical strain and produce an injury of the bordering costochondral joints or thoracic musculature. Patients may experience pronounced postoperative pains. This sensitivity to pain can result in a limitation of breathing mechanics and limit postoperative mobilization. The incidence of postoperative infection and mediastinitis reported to be as high as 2–6% in the literature, with consequent additional surgical procedures and wound therapies, represents complications that should not be underestimated (Gummert et al. 2002; Gorlitzer et al. 2013).

In particular for patients with a high EuroSCORE (see also ► Chapter «Risk Scores in Cardiac Surgery», Sect. 2.2.2), diabetes mellitus, COPD, and an elevated body mass index (BMI), there is an increased risk of developing such wound complications.

Since the early days of cardiac surgery, lateral thoracotomy has been a routine procedure. This led to its use for mitral and tricuspid valve surgery, ASD closure or treatment of congenital descending aortic lesions. These full-thoracotomy procedures still represent a significant trauma and are often associated with rib injuries and significant acute and chronic postoperative pain. Isolated encapsulated pleural effusions and lung adhesions are not uncommon and complicate the use of the lateral thoracotomy. As a result, alternative surgical access and techniques have been evaluated, whereby each approach is concentrated to particular anatomic structures and a specific operative strategy.

Presently, four essential strategies have been established as routine approaches, with validation in an array of clinical studies:

1. A reduction of the size of the surgical access and a corresponding reduction in the surgical trauma are of major significance. From valvular surgery to repair of congenital defects like atrial septal defect, as well as in coronary artery bypass surgery, alternative approaches like the mini-sternotomy, the left or right anterior mini-thoracotomy, or the subxiphoidal thoracotomy have become established as possible minimally invasive surgical approaches (see ► Sect. 26.3.2.2, «Atrial Septal Defect Closure»; Sect. 26.3.4, «Minimally Invasive Aortic Valve Surgery»; Sect. 26.3.5, «Minimally Invasive Mitral and Tricuspid Valve Surgery»;
2. A second strategy is the reduction or elimination of extracorporeal circulation. Nowadays, many coronary surgical procedures can be carried out on the beating heart without the heart-lung machine (HLM). Despite a conventional sternotomy, one should still regard this approach as a minimally invasive procedure. Even operations such as valvular surgery or left ventricular reconstruction can be carried out with a beating heart technique on extracorporeal circulation, whereby the avoidance of cardiac ischemia leads to a reduction of cellular trauma. In addition, the miniaturization of the heart-lung machine in adults, as well as children, reduces the immunologic trauma. From a systemic view, adding a sternotomy to a procedure is rather less invasive than adding extracorporeal circulation. Therefore, employing sternotomy in order to avoid cardiopulmonary bypass is a way to minimize surgical trauma.
3. A third building block is arterial, especially aortic endografting. In increasing proportions, chronic, as well as acute, pathologies such as dissection and aneurysms (including ruptured aneurysms) of the thoracic and abdominal aorta are treated successfully with endoluminal stent graft implantation. Even dissections in the region of the aortic arch are being treated with stents that cover the supra-aortic

Sect. 26.3.6.1, «Alternative Incisions for Revascularization»).

As innovative techniques, endoscopic and telemanipulator-assisted methods have been evaluated in CABG, valve surgery, repair of congenital defects, and the therapy of atrial fibrillation. A radically new approach is beating heart percutaneous therapy of various native and prosthetic heart valve pathologies ranging from aortic, mitral, and pulmonary stenosis or regurgitation to prosthetic valve dysfunction. The development of new cannula systems enables safe and reliable connection for extracorporeal circulation via the femoral, axillary, and neck blood vessels. Furthermore, endoscopic harvest techniques for bypass conduits, in particular saphenous vein and radial artery, have become increasingly important. Alternative surgical access for the specific pathologies of the heart will be presented in more detail in the ensuing paragraphs.

2. A second strategy is the reduction or elimination of extracorporeal circulation. Nowadays, many coronary surgical procedures can be carried out on the beating heart without the heart-lung machine (HLM). Despite a conventional sternotomy, one should still regard this approach as a minimally invasive procedure. Even operations such as valvular surgery or left ventricular reconstruction can be carried out with a beating heart technique on extracorporeal circulation, whereby the avoidance of cardiac ischemia leads to a reduction of cellular trauma. In addition, the miniaturization of the heart-lung machine in adults, as well as children, reduces the immunologic trauma. From a systemic view, adding a sternotomy to a procedure is rather less invasive than adding extracorporeal circulation. Therefore, employing sternotomy in order to avoid cardiopulmonary bypass is a way to minimize surgical trauma.
3. A third building block is arterial, especially aortic endografting. In increasing proportions, chronic, as well as acute, pathologies such as dissection and aneurysms (including ruptured aneurysms) of the thoracic and abdominal aorta are treated successfully with endoluminal stent graft implantation. Even dissections in the region of the aortic arch are being treated with stents that cover the supra-aortic

vessels, and the supra-aortic vessels are treated with separate extra-anatomic bypass from the ascending aorta.

4. This concept leads to a fourth important strategy in minimally invasive cardiac surgery, one that represents a meaningful combination of surgical and interventional procedures, the *hybrid approach*. This technique places new demands on the entire team and requires a redefinition of the equipment and instrumentation found in the classic operating room with that of the requirements for a hybrid operating room. While this process is presently in widespread clinical evaluation, it has already become routine practice in many centers.

26.3.2 Congenital Diseases

26.3.2.1 Patent Ductus Arteriosus

At present, there are three different operative techniques for closure of a persistent patent ductus arteriosus (PDA).

Gross described in 1938 the first successful ligation of a PDA in a 7-year-old girl via a left fourth interspace posterolateral thoracotomy (Gross et al. 1939). After retraction of the lung, the vagus and phrenic nerves are exposed, and the pleura is incised longitudinally over the aortic isthmus. This procedure is associated with a pronounced surgical trauma, but offers an optimal exposure to all anatomic structures. General complications include recurrent laryngeal nerve injury and rarely phrenic paresis or chylothorax. Mortality is exceedingly rare.

A second approach, described in 1992 by Laborde, is the video-assisted thoracoscopic procedure, which has been in use for many years. Using a left chest approach, two 5-mm ports are placed into the thorax, and videoscopic instruments are used to dissect out the anatomic structures and place a titanium clip on the PDA to achieve surgical ligation. Laborde's 12-year experience ($n=743$ patients) shows no difference in efficacy compared to the standard open technique. There was no operative mortality, persistent damage of the recurrent laryngeal nerve was observed in 4.2% of patients, and the average hospital stay was 2 days. An important exclusion criteria for this approach was a PDA >8 mm (Laborde et al. 1993; Villa et al. 2004 and 2006).

Concurrently, many centers have advanced to a percutaneous catheter-based technique as the

preferred approach for PDA closure (Abu Hazeem et al. 2013). Interestingly, the technique was first successfully carried out in 1971 by Porstmann and colleagues (1971). Presently, different systems are available for clinical use, including a variety of coil systems or the Amplatzer occluder device. The efficacy and safety of this approach has been established in a large study not only in children but also in small infants and premature babies (Sungur et al. 2013). Importantly, this procedure is not limited utility in very small children and not limited for PDA closure in premature babies anymore (Abu Hazeem et al. 2013).

26.3.2.2 Atrial Septal Defect Closure

Both the first open-heart surgery by Lewis and his team in 1952 and Gibbon's first successful application of his heart-lung machine in 1953 were operative closures of a secundum atrial septal defect (ASD II) (Gibbon 1953) (see also ► chapter «Surgery for Congenital Heart Defects: A Historical Perspective», Sect. 11.2). Since then, various methods were employed for ASD closure: median sternotomy, right lateral thoracotomy (with central connections to the heart-lung machine), the right parasternal thoracotomy, the mini-sternotomy, the subxiphoidal access, and the right mini-thoracotomy (■ Fig. 26.1) with connections to the heart-lung machine via the femoral vessels, percutaneous endovascular occlusion techniques, hybrid techniques, and completely endoscopic procedures (Horvath et al. 1992; Doty et al. 1998; Doll et al. 2003; Hongxin et al. 2007; Bartakian et al. 2012; Kotowycz et al. 2013; Liu et al. 2013).

One requirement for surgical ASD closure is the heart-lung machine. With respect to cannulation, there are several choices. For one, the ascending aorta or the femoral artery may be cannulated. The venous drainage can be established via the superior and inferior vena cavae, the jugular vein and the inferior vena cava, or via the femoral vein. However, one requirement for transfemoral cannulation is a satisfactory vessel size, so this approach is dependent on the size and age of the patient. Even complex septal pathologies, including sinus venosus defect or a partial AV canal, can be surgically repaired using a lateral approach but require more experience.

For isolated ASD II, complete median sternotomy is rarely used. As a surgical standard, the right lateral mini-thoracotomy could be considered the standard approach (see ■ Fig. 26.1) (Gibbon 1953). Notwithstanding the very good

Fig. 26.1 Minimally invasive approach for atrial septal defect closure: **a** right lateral mini-thoracotomy and **b** subxiphoid approach

operative results, this approach involves a smaller skin incision, reduced trauma, reduction in postoperative pain, results in a quicker postoperative convalescence and, in particular for women, an excellent cosmetic result (Kotowycz et al. 2013).

With this technique, as with minimally invasive mitral and tricuspid valve surgery, an inframammary curvilinear skin incision is made, followed by a fourth intercostal space thoracotomy. All relevant anatomical structures can be nicely exposed. Finally, the pericardium is opened parallel and at least 2 cm superficial to the phrenic nerve. The HLM connections are made via the femoral vessels, and an additional venous cannula is placed via the jugular vein. The insertion of additional port systems (videoscopes, CO₂ insufflation), the cross clamping (Chitwood technique), and cardioplegia administration are similar to the approach for minimally invasive mitral and tricuspid valve surgery. The superior and inferior vena cavae are clamped or snared, and following cross clamping, and during cardioplegia administration, the right atrium may be opened, and the ASD may be closed directly.

As soon as the ASD is securely closed, the cross clamp may be released, and the right atrial incision can be closed while the heart is beating. With the parasternal minimally invasive thora-

cotomy (seldom used), the surgical access was via the third or fourth interspace. The HLM was via direct aortic and superior and inferior vena cava cannulation (Cremer et al. 1999).

Another operative method is the mini-sternotomy (hemisternotomy). It can be further subdivided into an upper or lower partial sternotomy or include subxiphoidal access (Barbero-Marcial et al. 1998). The advantage of a partial upper sternotomy in ASD closure seems to be difficult to understand, and a cosmetic advantage is rather questionable.

With these techniques, the HLM connections can be made via the femoral vessels, central or combined, and the venous drainage can be performed via the right atrial appendage and the inferior vena cava. Irrespective of which form of mini-sternotomy is used, authors report very good exposure, excellent operative results, and a high rate of patient acceptance. Which surgical approach will be preferred remains to be seen, but will likely remain variable from center to center.

In 1976, King and Mills reported the first possible interventional catheter-based closure of a secundum ASD (King et al. 1976). They laid the foundation for a rapid and exciting development in this area. Since the 1990s, percutaneous ASD closure using various occluder systems has been established as the first-line treatment in older children and adults. A randomized comparison of

right lateral mini-thoracotomy or other minimally invasive approaches is still required. In the single, nonrandomized study, catheter-based occlusion was compared with conventional sternotomy (Du et al. 2002). Initially, this technique was only used with uncomplicated ASD, but in the meantime, even large ASDs measuring up to 4 cm have been successfully closed with occluder systems.

As a result of dislocation, thrombosis, perforation, infection, and embolic complications, secondary surgical treatment after interventional ASD closure may be required (Divekar et al. 2005; Walther et al. 2007a).

A further minimally invasive approach is the combination of surgical and interventional techniques without the HLM. On a beating heart, using a right lateral mini-thoracotomy, the right atrium is exposed, and through its free wall, an occluder device is positioned under TEE guidance. First results of this technique have been reported (Hongxin et al. 2007).

Completely endoscopic procedures (telemanipulator-assisted techniques) with the da Vinci System (Intuitive Surgical, Sunnyvale, CA, USA) on the hypothermic fibrillating heart represent innovative measures, which are not widely used because the instrumentation may be cumbersome and expensive (Liu et al. 2013).

26.3.2.3 Results

The efficacy and safety of catheter-based ASD closure has been demonstrated in an array of clinical studies (Du et al. 2002; Hongxin et al. 2007; Bartakian et al. 2012; Kotowycz et al. 2013).

Divekar and colleagues analyzed 34,000 occluder implantations with respect to cardiac complications. Twenty-nine patients experienced cardiac complications, with five deaths and three neurologic events. Perforations were noted in the region of the anterosuperior right atrial wall in close proximity to the aorta. The authors did not offer an explanation for the localization of this complication, but we believe that this may arise from the abrasion of the implanted system with the smooth-walled portion of the right atrial wall. Overall, there was a higher incidence of secondary surgical revisions after interventional occluder implantation (Divekar et al. 2005).

In 2000, a nonrandomized, multicenter study compared 442 patients who underwent percutaneous ASD closure with 154 patients who underwent median sternotomy and direct ASD closure.

The success rate was significantly better in the surgical group (100% vs. 95.7%), with no mortality in either group. The early and long-term results (12 months) were similar. However, the periprocedural complications in the surgical group were significantly higher (24% vs. 7.2%), resulting in a prolonged hospital stay. Based on the higher complication rate, the authors concluded that interventional therapies represented a superior approach to surgical ASD closure (Du et al. 2002). However, there is no randomized comparison of minimally invasive surgical approaches with interventional therapies for ASD closure. A currently published nonrandomized single-center study with 718 ASD closures (383 surgical and 335 transcatheter procedures) showed that the long-term mortality of interventional procedure was not inferior to surgery (5-year mortality, 5.3% vs. 6.3%; $p=1.00$), and the secondary outcomes were similar in both groups. However, the reintervention rate was much higher in the transcatheter group than in the surgical group (Kotowycz et al. 2013).

The early and long-term results following surgical ASD closure are very good. Independent of the selected operative approach, there are no significant differences in mortality (<1%) or efficacy. Minimally invasive approaches reduce the surgical trauma and lead to a quicker convalescence (Bartakian et al. 2012; Kotowycz et al. 2013). In a randomized study, Luo and colleagues compared median sternotomy with a partial lower hemisternotomy. Both techniques had comparable safety and efficacy, but the minimally invasive approach resulted in less pain, less postoperative bleeding, a shorter hospital stay, and a better cosmetic result (Luo et al. 2001). In general, minimally invasive approaches are better accepted by patients, particularly in women, where the cosmetic aspect plays a larger role.

A further technique is the previously mentioned combination of a right lateral surgical approach and direct placement of an occluder through the right atrial wall on the beating heart under TEE guidance. Hongxin et al. evaluated this technique in a series of 100 patients (Hongxin et al. 2007). The size of the ASDs ranged from 5 to 37 mm. After 12 months, the authors reported no mortality and complete ASD occlusion in all patients. They concluded that this method is a feasible alternative to isolated endovascular and surgical techniques.

Moreover, the safety and efficacy of the catheter-based and combined approach for ASD closure has been demonstrated even in children less than 1 year of age.

26.3.2.4 Conclusion

The first-line treatment for ASD closure is percutaneous placement of an occluder, which can treat even large secundum ASDs up to 40 mm in size. If this modality fails or is complicated by infection, thrombosis, emboli, or complex anatomy, surgical treatment is indicated. The right lateral mini-thoracotomy with femoral vessel cannulation could be considered the standard approach, with feasible alternatives including telemanipulator-assisted (robotic) approaches or the various forms of mini-sternotomy. A significant aspect to consider is the HLM connection, which can be carried out via the femoral vessels, centrally or a combination thereof. In slim patients of all ages, suprainguinal cannulation of the iliac vessels is as easy as employing the femoral vessels, however, thereby avoiding any potential lymph leaks. Moreover, in rather young patients, the external iliac vessels are of larger and therefore more suitable size for cannulation than the femoral vessels. The role of hybrid approaches on the beating heart and completely endoscopic procedures is not yet determined; further study is required.

26.3.2.5 VSD Closure

A left anterior parasternal mini-thoracotomy has been described as a minimally invasive approach to the treatment of a subarterial or perimembranous VSD. Direct access is achieved via a third or fourth left intercostal space approach. Videoscopic assistance can be achieved directly or via insertion of port systems. Finally, the relevant anatomic structures can be exposed, to include the left phrenic nerve, and the pericardium can be longitudinally incised. The HLM is connected via the femoral vessels. Cross-clamping is not absolutely required. The operation can be carried out using mild hypothermia and ventricular fibrillation (Lin et al. 1998). Other approaches include the partial lower (fourth intercostal space to the xiphoid) or upper sternotomy (inverted T incision into the fourth intercostal spaces bilaterally) to treat subarterial, perimembranous, and muscular VSDs (Kadner et al. 2004; Murashita et al. 1999). Alternatively, percutaneous interventional procedures with the Amplatzer system are being applied.

Initial studies show good results, particularly with perimembranous VSDs (Pinto et al. 2006). In addition, hybrid procedure to cure VSDs is also of great clinical interest. The current published paper by Zhu and colleagues showed that the combination of transcatheter VSD closure and percutaneous coronary intervention for treating VSD in acute myocardial infarction is also safe and a promising alternative to open surgery (Zhu et al. 2013).

26.3.3 Pericardial Diseases

The first time pericardial diseases, acute and chronic pericarditis, were described was in 1669 by Lower (1669). The primary surgical approach, particularly with constrictive pericarditis, was carried out in most cases via a median sternotomy. In a study by Billa and colleagues, a left lateral approach was shown to be a safe operative approach for constrictive pericarditis, with similar postoperative and long-term results. In the sternotomy group, there were more wound infections and pulmonary complications (Tiruvoipati et al. 2003).

A further operative approach is the subxiphoidal access (Mills et al. 1989; Becit et al. 2005). Alternative procedures, in particular pericardial window for recurrent pericardial effusion, can be carried out via a right or left lateral mini-thoracotomy (Tiruvoipati et al. 2003). Video-assisted thoracoscopic surgery has taken an increasing role in most centers, with thoracoscopy requiring the use of a double-lumen endotracheal tube and special instrumentation (Georghiou et al. 2005; Noyes et al. 2003). Pericardial cysts and tumors can also be resected thoracoscopically. Rees and colleagues reported thoracoscopic partial pericardiectomy via a left-sided approach (Rees et al. 1993). Case reports of telemanipulator-assisted resection of pericardial cysts exist, but represent a significant increase in technical expertise that may not be widely available (Bacchetta et al. 2003).

26.3.4 Minimally Invasive Aortic Valve Surgery

The standard approach to surgically treat diseases of the aortic valve, ascending aorta, aortic arch, and bordering structures is the median sternotomy

with central connection for ECC. However, complete sternotomy is not absolutely required, because the anatomic structures can be exposed via a minimally invasive partial sternotomy or thoracotomy. This approach is sufficient to expose and cannulate the ascending aorta and the right atrium. The cardiac vent catheter can typically be placed into the right superior pulmonary vein, the pulmonary artery, or directly through the aortic valve. External defibrillation pads should be placed routinely prior to patient preparation.

A more recent completely new concept is the catheter-based aortic valve replacement. Presently, three different techniques—the transapical (via left anterior mini-thoracotomy), transaortic (via upper mini-sternotomy), and the percutaneous transfemoral or transaxillary approach are being intensively evaluated clinically.

Various forms and modifications of the partial sternotomy for aortic valve and ascending aorta operations include (■ Fig. 26.2): the J-forming upper sternotomy, the transverse sternotomy, the S-forming sternotomy, and the right-sided parasternal thoracotomy. With the J-forming partial upper sternotomy (see ■ Fig. 26.1c), the sternum is divided from the sternal notch caudally until the fourth or fifth intercostal space and curved into the respective intercostal space on the right side, taking care to preserve the right internal thoracic vessels (Konertz et al. 1996). Through this slightly right-dominant approach, the aortic valve, ascending aorta, and right atrium can be well exposed. The aortic cannula can be placed directly into the ascending aorta. In case of difficult anatomic exposure, the femoral vessels can be cannulated for the HLM. The venous cannula may be advanced into the right atrium under TEE guidance or may be placed directly into the right atrium but brought up through a subxiphoidal incision or a right chest incision.

The advantage of these latter approaches lies in a better exposure because the light tension on the cannula results in retraction of the right atrium away from the aortic root. Sternal closure is usually achieved with normal wires, taking care to achieve good bone approximation and stabilization of the entire sternal incision, including the portion into the right intercostal space. A transverse division of the sternum at the level of the third intercostal space (see ■ Fig. 26.2e) may also be utilized. The disadvantage of this method is that both internal mammary arteries are divided,

precluding their use for later coronary revascularization.

Cosgrove described a right-sided parasternal incision (see ■ Fig. 26.2d). This involves division of ribs from one or three to five from their sternal attachment. However, the resulting sternal instability resulted in this technique being abandoned by most surgeons (Cosgrove and Sabik 1996).

The S-forming partial sternotomy (see ■ Fig. 26.2f) enables, with preservation of both internal mammary arteries, a good exposure of the aortic valve region and the neighboring pulmonary artery (Autschbach et al. 1998). The advantage of this strategy lies in its preservation of the continuity of the shoulder girdle. Subsequent stabilization of the sternum with wires is challenging, and the technique is rarely used.

26.3.4.1 Results of Minimally Invasive Aortic Valve Surgery

Whether there is a clear advantage of partial upper sternotomy versus complete median sternotomy is heavily debated. It has been shown that mini-sternotomy leads to a reduction in blood loss, and shorter ICU and hospital length of stays (Bakir et al. 2006; Khoshbin et al. 2011). A significant advantage with respect to mortality has not been demonstrated. Alternatively, a median sternotomy can be performed using a small skin incision (limited skin, full sternotomy). Despite an array of alternatives, at most centers, the partial upper sternotomy or the classic median sternotomy remains the preferred approach for aortic valve surgery.

26.3.4.2 Transapical and Transfemoral Aortic Valve Replacement

The transapical access represents a new surgical concept (■ Fig. 26.3) (Dewey et al. 2006). With this approach, entry into the thorax is achieved through a small left anterolateral thoracotomy at the level of the fifth or sixth intercostal space. Via this limited access, the pericardium is opened and a purse-string suture is placed on the beating heart at the left ventricular apex. Simultaneously, a specially designed biological valve mounted on a stent is crimped onto a delivery catheter. Next, antegrade catheter-based implantation and expansion of this valve is performed under angiographic and echocardiographic guidance (Dewey et al. 2006). Additionally, during the mechanical expansion of the valve, an external pacemaker is used to stimulate

the heart to undergo rapid ventricular pacing to avoid valve dislodgment or embolization. Once the

valve is expanded and fixated by radial force, the ventricular pacing is terminated. The entire intervention is performed without ECC; however, additional cardiac unloading with ECC, when required, can be achieved via femoral cannulation. Multiple successful series with this surgical procedure have already been reported (Lichtenstein et al. 2006; Walther et al. 2007a, b; Pilgrim et al. 2012). Through the avoidance of a complete sternotomy, reduction of the surgical trauma, and avoidance of ECC, this technique is a valuable alternative for high-risk patients, i.e., those requiring cardiac reoperation or aortic valve reoperation as a «valve-in-valve» procedure (Walther et al. 2007a, b, c; Eggebrecht et al. 2011; Kempfert et al. 2013) or for patients with a porcelain aorta (Zahn et al. 2013).

A concurrent interventional procedure, which avoids a surgical incision, is the transfemoral retrograde aortic valve replacement and represents an alternative minimally invasive approach. First clinical experiences have been reported, but the

overall rate of stroke appears high and the procedure cannot be performed in those patients with small femoral vessels (Webb et al. 2007; Grube et al. 2007; Eggebrecht et al. 2012; Pereira et al. 2013; Franzoni et al. 2013).

Currently, direct «true» percutaneous approaches for aortic valve implantation are of great clinical interest and the focus of intensive clinical research. First clinical experience with the direct transaxillary transcatheter approach reported by the Hamburg group is promising (Schäfer et al. 2013). However, further results and technical developments are needed to minimize the surgical or interventional access.

Generally, all procedures require close collaboration (team approach) between cardiac surgeons, cardiologists, and cardiac anesthesiologists (Kappetein et al. 2013).

26.3.4.3 Conclusion

Minimally invasive aortic valve surgery is a safe, reproducible, and cosmetically accepted operative approach. However, there is no evidence for improved survival in comparison to median sternotomy, yet. The limited surgical approach enables good exposure of the relevant anatomy, with a reduced risk of sternum instability or infection. Concomitant bypass surgery is not possible using the partial upper sternotomy, with the exception of the proximal right coronary artery. Transapical and transfemoral aortic valve replacement are innovative, already clinically widely used, approaches and represent a significant advancement for multi-morbid, high-risk, or previously inoperable patients. In conclusion, the view that aortic valve replacement requires ECC and a big open exposure is no longer contemporary, and ECC can be avoided in selected cases with percutaneous aortic valve replacement.

26.3.5 Minimally Invasive Mitral and Tricuspid Valve Surgery

Historically, the first attempts to treat mitral valve stenosis in the early 1900s were minimally invasive approaches. In 1902 Sir Lauder Brunton carried out the first surgical procedures on the mitral valve (Brunton and Edin 1902). Cutler and Levine subsequently reported the first mitral valve dilation via a median sternotomy in 1923 (Cutler and Levine 1923). Souttar carried out the first

digital dilation of the mitral valve in 1925 (Souttar 1925). The first closed mitral commissurotomies were reported independently around the same time by Harken, Bailey, and Brock (Harken et al. 1948; Bailey 1949; Baker et al. 1950). These pioneering attempts antedated the development of cardiopulmonary bypass. With the introduction of extracorporeal circulation, Lillehei published the treatment of mitral valve insufficiency via a right-sided thoracotomy (Lillehei et al. 1957). In 1960, McGoon reported on the possibility of mitral valve reconstruction (McGoon 1960). A few years later, Starr and Edwards introduced prosthetic valves, enabling the first mitral valve replacement via sternotomy in 1961 (Starr and Edwards 1961).

Extracorporeal circulation and good exposure are essential to optimal surgical treatment of mitral valve disease. In most centers, median sternotomy and direct left atriotomy represent the preferred approach to mitral valve pathology. A good exposure of the mitral valve and the subvalvular apparatus is also achieved using the transverse biatrial incision described by Dubost and colleagues (1966). This can also be accomplished via a transseptal incision (Guiraudon et al. 1991). In 1996, Cosgrove and colleagues described a right-sided parasternal approach. This technique involved resection of a portion of the third and fourth ribs, as well as division of the right internal thoracic artery. Access to the mitral valve was then performed by opening the right atrium and the interatrial septum (Navia and Cosgrove 1996). Although, the parasternal approach has fallen out of favor, the transseptal approach still remains widely used. Various surgical access options are illustrated in ■ Fig. 26.4. The techniques (see ■ Fig. 26.4d) and instrumentation (■ Fig. 26.5) described by Carpentier and Chitwood which enable a minimization of the operative approach represent pioneering achievements in mitral valve surgery (Carpentier et al. 1996; Chitwood et al. 1997a, b). The endoluminal clamp technique played an important role in the development of mitral valve surgery. The advantages and disadvantages of this method have been discussed in ► Sect. 26.2.3, «HeartPort Technique».

At present, the safest, most effective, and durable nonsternotomy technique for mitral valve surgery is the right anterolateral mini-thoracotomy in the fourth intercostal space (see ■ Fig. 26.4d). Through the imaginary projection of the mitral

■ Fig. 26.4 Minimally invasive mitral valve surgery, surgical approaches: a, b right- and left-sided partial upper sternotomy, c left-sided C-shaped partial sternotomy, d right-sided anterolateral thoracotomy, e T-shaped upper sternotomy

■ Fig. 26.5 Chitwood clamp

valve plane in the direction of the right shoulder, isolated mitral or tricuspid as well as combined mitral and tricuspid valve pathology can be effectively exposed and surgically treated. Additional procedures like ablation for atrial fibrillation, closure of PFOs/ASDs, or removal of tumors (i.e., myxomas) can be performed concomitantly without difficulty (■ Fig. 26.6).

At the Leipzig Heart Center, this approach is used routinely for primary procedures. This

technique is a safe alternative for reoperations, also, in particular for high-risk patients (Seeburger et al. 2008; Garbade et al. 2013).

To perform the right anterolateral thoracotomy, the patient is placed in supine position, with the right chest elevated to around 30°. The right arm is lightly abducted and placed on a positioning board. External defibrillation pads should be applied primarily. The first surgical step is femoral vessel cannulation and connection to ECC circuit.

■ **Fig. 26.6** Positioning, surgical incision, and projection of the anatomic structures for the right-sided anterolateral approach for mitral and tricuspid valve surgery—Leipzig technique

Therefore classically the right femoral vessels are exposed. For elective procedures, it is of value to perform the necessary cardiac catheterization by avoiding the right femoral vessels, since such diagnostic measures may be associated with injuries and hematomas complicating cannulation. Following exposure of the femoral vessels, a 4-0 or 5-0 Prolene purse-string suture is placed on the anterior surface of the vessels. Next, using Seldinger technique, the vessels are cannulated, beginning with the femoral vein. It is advantageous to use TEE to determine the correct positioning of the venous cannula. If there is concomitant tricuspid valve pathology or the body weight is above 90 kg, an additional venous cannula can be placed percutaneously via the jugular vein.

Possible complications include vessel rupture, particularly of the retroperitoneal vasculature, and retrograde dissection. For this reason, at our center, simultaneous TEE examination is performed during femoral cannulation. If right femoral cannulation is not possible, either left femoral or axillary cannulation may be performed. Following cannulation, the lateral mini-thoracotomy is performed. The length of the skin incision is 4–6 cm and is carried out in a lightly convex course caudally to the inframammary fold. For especially obese patients and for women, prior skin marking and special positioning using an adhesive drape is helpful. After dissection of the subcutaneous layers and controlled division or displacement of the musculature, the thoracotomy is performed in the fourth intercostal space. Next, a special soft tissue-spreading retractor is used to spread the thoracotomy incision atraumatically. Additionally, three further incisions,

approximately 1 cm in size, are necessary. In an imaginary axis between the mitral valve and the right shoulder, a stab incision is made into the second intercostal space for introduction of a videoscopic camera. This is introduced via a special port system into the chest, which also allows for simultaneous CO₂ insufflation (4–6 l/min). We deem the CO₂ insufflation essential and perform it during the entire time of intracardiac manipulation. The videoscope can either be stabilized by a special holder arm or can be connected to a speech-responsive robotic arm (Computer Motion, USA).

A second incision in the second intercostal space at the anterior axillary line is necessary to place the Chitwood clamp (see ■ Fig. 26.5).

■ **Figure 26.6** gives an overview of the positioning and the necessary incisions for minimally invasive mitral valve surgery, as they are routinely used at the Leipzig Heart Center. After opening of the intercostal space, the pericardium is exposed. This is opened horizontally and parallel to the phrenic nerve, with care taken to maintain a suitable distance between the pericardial incision and the nerve (at least 2 cm).

After the ascending aorta is exposed under direct or indirect vision (videoscopic), cross-clamping of the aorta with the Chitwood clamp is performed as ECC flow is reduced. Care must be taken during preparation and cross-clamping of the aorta to avoid injury to adjacent structures, in particular of the pulmonary artery or the left atrial appendage. Injury to these structures usually requires sternotomy. Although aortic cross-clamping is preferred, endoluminal occlusion of the aorta using the HeartPort technique may be used alternatively. As previously discussed, due to a variety of complications, many surgeons have abandoned this technique (see ► Sect. 26.2.3, «HeartPort Technique»).

In order to optimally access the left atrium, a third small incision in the parasternal portion of the right fourth intercostal space (see ■ Fig. 26.6) is made, to place an atrial retractor and/or retraction stitches. If performed under direct visual control, injuries to the right internal mammary artery should be avoided.

Along with endoscopic performance of isolated steps of the operation, special instruments have been developed and are necessary (i.e., Chitwood clamp, HeartPort instruments). The surgeon's headlight, as well as the light source for

the videoscope, illuminates the surgical field. Using a connected documentation and video-scopic camera system, every individual step, the pathology, and the operative result can be digitized and recorded. An intelligent arrangement of the monitors allows the assistant(s) and anesthesia and nursing personnel to follow every step of the operation. Via the right anterolateral approach, direct access to the left and right atrium can be achieved easily. For isolated or concomitant tricuspid valve pathology, additional cannulation of the jugular vein is necessary to achieve complete caval occlusion. The placement of the jugular venous cannula can be performed in the induction room by the cardiac anesthesiologists. Both venous cannulae are then connected with a Y-connector for ECC. The superior and inferior vena cavae can be controlled with tourniquets or large, atraumatic clamps.

Using a special cannula, the cardioplegia is delivered into the aorta after aortic cross clamping. Finally, this cannula can be brought out through the incision for the atrial lift retractor and be used for later deairing (needle vent). Closure of this site is performed using the usual technique.

Particularly for reoperations, the procedure can be carried out on the beating or fibrillating heart. After reconstruction or replacement of the corresponding heart valve, closure of the atrium is performed with simultaneous deairing. Continuous CO₂ insufflation during the operation is useful. Following atrial closure, deairing, weaning from the HLM, and decannulation, hemostasis is performed. The ribs are adapted with Vicryl sutures, and the incision site for the video camera can be used for placement of a chest tube. Layered wound closure and administration of local anesthesia into the mini-thoracotomy incision helps reduce postoperative pain.

Multiple centers follow the concept of a completely endoscopic, telemanipulator-assisted surgery. In recent years, there is a growing body of literature on this topic demonstrating its safety, efficacy, and durability. However, widespread application of this technique is limited by the extensive team and technical training and expertise required (Woo et al. 2006; Casselman et al. 2007a, b; Arcidi et al. 2012; Nifong et al. 2012; Mihaljevic et al. 2013).

In summary, there are more data available on the use of telemanipulators for minimally invasive

valve surgery, with at least comparable results to other approaches. However, the technique may not gain universal acceptance primarily because of the resources required.

26.3.5.1 Results of Minimally Invasive Mitral and Tricuspid Valve Surgery

A current study from our group examined the short- and long-term results of minimally invasive right anterolateral thoracotomy (Seeburger et al. 2008). A total of 1,339 patients were analyzed. The average bypass time was 122 ± 41 min, and the cross clamp time was 70 ± 35 min. The 30-day and 1-year mortality for isolated mitral valve reconstruction were 2.4% and 5%, respectively and 3.7% and 11.2% for isolated mitral valve replacement, respectively. In seven patients, conversion to sternotomy was required; causes for conversion included uncontrollable bleeding, obscured anatomy, or dense adhesions. For 494 patients, additional procedures such as atrial fibrillation ablation ($n=305$), tricuspid valve repair ($n=94$), and closure of a PFO ($n=95$) were carried out. The average follow-up time was 28.4 ± 23.5 months, with a follow-up rate of 99% (Seeburger et al. 2008). In addition, a large single-center review of more than 3,000 minimally invasive mitral valve procedures showed the safety and the very low rate of conversion to complete sternotomy (Vollroth et al. 2012). However, there is an individual learning curve for minimally invasive mitral valve procedures providing the need for good monitoring, training, and mentoring not only in the initial phase for this kind of surgery (Holzhey et al. 2013).

In contrast to this work, a study from the Cleveland Clinic showed that the rate of mitral valve repair was lower after lateral thoracotomy than with median sternotomy, and the former was also associated with a higher risk of stroke. The authors concluded that in most cases, sternotomy remains the preferred method (Svensson et al. 2007). The results of this study were based on a small number of patients and therefore may not be generalized.

Completely endoscopic, telemanipulator-assisted procedures are presently the subject of intense clinical evaluation. Fifteen years experience from Chitwood's group, including reoperations, shows that there was a comparable 30-day mortality (2.2% vs. 1.0%) among 341 video-assisted and 100 completely telemanipulator-assisted procedures (da Vinci System). There were no conver-

sions to sternotomy or dissection. In both groups, complex mitral valve repairs were performed. However, the authors came to the conclusion that the times of cross-clamp, cardiopulmonary bypass, and overall operation were significantly longer in the da Vinci group (Arcidi et al. 2012). In a recent study from Vanermen et al., it was shown that for patients requiring cardiac reoperations, the video-assisted minimally invasive approach for mitral and tricuspid valve surgery is not only safe but also associated with a lower 4-year mortality than statistically expected (Casselman et al. 2007a, b).

26.3.5.2 Percutaneous Minimally Invasive Strategy

As with the aortic valve, the mitral valve is also the focus of intensive research efforts for the development of percutaneous strategies. Based on the cooperation of multiple professional societies (STS, AATS, SCAI, ACCF, AHA, EACTS), a position paper on percutaneous valve technology was produced (Thomas et al. 2005).

The goal of percutaneous techniques is to use a catheter-based approach to deliver a system that can treat mitral valve disease on the beating heart, thereby avoiding a sternotomy and ECC. Historically, percutaneous mitral balloon valvotomy represents an established approach for the treatment of mitral stenosis that is still widely performed. Limitations of this concept lie in its limited durability or efficacy of the balloon dilatation. However, it may be used for certain patients as a bridging therapy for later surgical valve replacement (Kim et al. 2007).

At present, two different percutaneous strategies have been evaluated: the edge-to-edge technique using a clip or suture (double-/triple-orifice technique) and the partial anuloplasty through implantation of stabilizing systems in the coronary sinus (CS) to reduce the circumference of the posterior mitral anulus.

The EVEREST trial (*Endovascular Valve Edge-to-Edge REpair STudies*) includes the first clinical results of this double-orifice concept (EVEREST Registry 2007). After implantation of the MitraClip device (Evalve Inc, Menlo Park, California), a significant reduction in mitral regurgitation could be demonstrated (Feldman et al. 2009, 2011; Glower et al. 2012).

Like the first technique, the partial anuloplasty also is limited by its ability to treat all relevant mitral valve pathologies, particularly severely cal-

cified valves or those with leaflet restriction (i.e., type IIIB dysfunction). The necessity for performing simultaneous procedures like atrial fibrillation ablation or reconstruction of a relevant tricuspid valve insufficiency also limits this technique. Potential problems include the anatomic relationships of the posterior mitral anulus, the CS, and the circumflex coronary artery (Tops et al. 2007). An important prerequisite for the safe and effective implantation of the partial anuloplasty is a parallel relationship between the anulus and the coronary sinus (CS), which is also a limiting factor. Additionally, the CS can no longer be used later for the administration of retrograde cardioplegia or cardiac resynchronization therapy. The first clinical results still reflect an experimental character and are not comparable with the present high standards and excellent results of the right anterolateral minimally invasive mitral valve surgery.

In addition to the interventional percutaneous mitral valve repair (MitraClip procedure), there is a new concept of transapical beating heart adjustable chordae replacement for mitral valve repair (NeoChord device) or transapical beating heart mitral valve replacement (Seeburger et al. 2010; Cheung et al. 2013). Both concepts are very promising, but further results and specifications are needed.

26.3.5.3 Conclusion

Short- and long-term results have demonstrated the safety, efficacy, and reproducibility of the right-sided anterolateral mini-thoracotomy as an alternative approach for the treatment of mitral and tricuspid valve disease. Additional surgical procedures like ablation of atrial fibrillation or closure of a PFO/ASD can be performed simultaneously. This technique also has broad applicability for cardiac reoperations and especially in high-risk patients. The partial opening of the pericardium represents an additional protective measure for possible later sternotomy. Based on present data, this technique can be regarded as a «gold standard» in mitral valve surgery.

Video-assisted endoscopic procedures are safe and effective, but require a constant learning process and intensive training. Completely endoscopic, telemanipulator-assisted procedures are presently limited to certain centers and represent interesting, albeit elaborate, alternatives. Percutaneous strategies are still evolving. Because of the

small number of clinical studies, in contrast to percutaneous aortic valve replacement, these methods still remain experimental.

26.3.6 Coronary Arterial Revascularization

The four major components in minimally invasive strategies for coronary revascularization are surgical access, use/avoidance of ECC, beating heart surgery (avoidance of ischemia), and the combination of surgery with interventional approaches (hybrid strategy).

The goal is to obtain adequate and safe exposure of the target vessels through a limited incision and reduce the immunologic and operative trauma by avoiding ECC. In achieving these goals, the minimally invasive approach should be at least as safe and effective as the conventional method. Furthermore, the use of hybrid procedures should reduce the operative risk even further. Prerequisites for this approach include not only the development of corresponding instruments but also an intelligent planning and performance of the operation.

- **OPCAB** (*off-pump coronary artery bypass*) refers to operations via a partial or complete sternotomy, in which coronary revascularization is carried out without ECC on the beating heart.
- **MIDCAB** (*minimally invasive direct coronary artery bypass*) refers to operations via a mini-thoracotomy, in which coronary revascularization is done without ECC, also on the beating heart.
- **TECAB** (*totally endoscopic coronary artery bypass*) represents an innovative approach that is still in its infancy. The principle of this technique is complete endoscopic and computer-assisted performance of the coronary bypass operation. In addition to perfect surgical technique, the operator must contend with the additional visuospatial and technical demands of performing the operation from a console. A detailed presentation of this technique is given in ► Sect. 26.4.2, «Endoscopic and Telemanipulator-Assisted Cardiac Surgery».

26.3.6.1 Alternative Incisions for Revascularization

The classical approach of complete median sternotomy is not always required. ■ Figure 26.7 illus-

trates surgical approaches for revascularization via a partial sternotomy.

In particular, for stenoses of the LAD, the technique of left-sided anterolateral mini-thoracotomy (MIDCAB), described by Kolessov in 1967 (Kolessov 1967), has been established as a standard technique in many centers (■ Fig. 26.8a).

An array of different surgical approaches and conduit harvest techniques, such as thoracoscopic LIMA preparation (Benetti et al. 1991, Benetti and Ballester 1995), the subxiphoidal (Subramanian 1997) or transabdominal approach (Subramanian and Patel 2000), the extended left anterior mini-thoracotomy (Calafiore et al. 1996), or the right parasternal thoracotomy (Stanbridge et al. 1997), have been described in the literature (■ Figs. 26.7 and 26.8).

With the development of special instruments like rib retractors and stabilizers, MIDCAB has become the procedure of choice for isolated LIMA-LAD revascularization, with excellent clinical long-term results (Thiele et al. 2005; Holzhey et al. 2012; Blazek et al. 2013; Etienne et al. 2013).

With this technique, the skin incision is inframammary, lightly curved over a length of approximately 6 cm. Additionally, anastomoses in the region of diagonal and obtuse marginal branches can be carried out, whereby an extension of the skin incision can be very helpful. For two-vessel coronary disease, a hybrid strategy can also be considered as an alternate approach (Repossini et al. 2013). Particularly for high-risk patients with multiple comorbidities, a hybrid strategy may be valuable to reduce operative risk. The hybrid strategy may involve either simultaneous or staged PCI of a second coronary vessel after LIMA-LAD revascularization.

A direct cross-clamping of the aorta or performance of a central anastomosis is generally not possible with this technique. However, in almost all cases, revascularization is performed on the beating heart. When use of ECC is required, femoral cannulation can be carried out.

The MIDCAB technique is also useful for revascularization of the right coronary artery (RCA). Via a right-sided anterolateral mini-thoracotomy (see ■ Fig. 26.8b), the right internal mammary artery (RIMA) can be exposed, prepared, and anastomosed to the RCA (Stanbridge et al. 1997).

Further alternate approaches include the partial lower sternotomy, the partial left-sided sternotomy, and a technique developed at the Heart Center in Dresden, Germany, the upper left-sided

■ **Fig. 26.7** Minimally invasive surgical approaches via an incomplete sternotomy for coronary artery bypass surgery: **a** left-sided C-shaped partial sternotomy, **b** lower left-sided L-shaped sternotomy, **c** lower T-shaped sternotomy, and **d** upper left-sided L-shaped sternotomy

anterolateral thoracotomy (see ■ Fig. 26.8c) (Gulielmos et al. 1999). With the latter technique, a left third interspace thoracotomy is performed, and rib division is often required to achieve sufficient exposure. The advantage of this method is a good exposure of the ascending aorta and right atrium, which enables central cannulation if the HLM is required and the ability to perform proxi-

mal anastomoses on the ascending aorta. The partial lower sternotomy offers the advantage of being able to harvest both internal mammary arteries and revascularize all coronary arteries (Walterbusch 1998).

The subxiphoid, transabdominal approach (see ■ Fig. 26.8d) described by Subramanian is useful for revascularization using both internal mammary

■ **Fig. 26.8** Minimally invasive surgical approaches via a thoracotomy for coronary artery bypass surgery: **a** left-sided anterolateral mini-thoracotomy, **b** right-sided anterolateral mini-thoracotomy, **c** extended left-sided anterolateral thoracotomy, and **d** subxiphoid and transabdominal approach

arteries and the gastroepiploic artery (Subramanian et al. 1997, Subramanian and Patel 2000).

With respect to quality assurance, it is useful to perform an assessment of the coronary bypass grafts. Transit-time Doppler flow measurement has become established as a routine approach and can also be used with minimally invasive approaches. Furthermore, intra- or postoperative angiography has also been used.

26.3.6.2 Results of Minimally Invasive Open Coronary Artery Bypass Surgery

Multiple reports indicate that minimally invasive direct revascularization has become a standard surgical approach that has a higher freedom from reintervention than catheter-based interventional approaches (Diegeler et al. 2002; Thiele et al. 2005;

Holzhey et al. 2012; Blazek et al. 2013; Etienne et al. 2013). In several studies, MIDCAB has also been shown to be superior in terms of freedom from angina and clinical symptoms (Thiele et al. 2005; Blazek et al. 2013).

When compared to sternotomy, this approach also resulted in fewer wound infections and less postoperative pain, which translated into a better convalescence and shorter hospital stay. The perioperative mortality is currently under 1%, with excellent long-term results (Boodhwani et al. 2006).

In one of our own studies (Holzhey et al. 2012), the early postoperative mortality among 1768 MIDCAB patients was 0.8% ($n=15$), and the perioperative stroke rate was 0.4% ($n=7$). A conversion to median sternotomy was necessary in 1.7% ($n=31$) because of severe pleural adhesions, intramyocardial course of the LAD, bypass failure, or bleeding. For 712 patients, a routine postoperative angiography was performed, with 95.5% of patients having a normal configuration of the bypass graft. In the early postoperative course, 11 patients required additional PCI, and 48 patients required an additional coronary bypass operation. The 5- and 10-year survival was 88.3% and 76.6%, respectively. Freedom from cardiac and neurologic complications (MACCE) at 5 and 10 years was 85.3% and 70.9%, respectively. The MIDCAB technique is also safe for coronary reoperations but challenging (Holzhey et al. 2012).

In a randomized study (MIDCAB vs. PCI) for isolated one-vessel coronary disease, Cremer's group in Kiel, Germany, showed no difference in mortality. However, again in this study, there was a significant difference in reintervention rate favoring MIDCAB. At a mean follow-up of 5 years, the reintervention rate in the PCI group was 24% (Fraund et al. 2005). In a meta-analysis of 1,110 patients, there was a significant advantage to surgical revascularization of the LAD when compared to PCI in terms of mortality, MACCE rate, and freedom from angina (Boodhwani et al. 2006).

In a study from our group, patients with isolated LAD stenoses were randomized to MIDCAB or PCI with bare-metal stent (BMS) implantation (Thiele et al. 2005). At 5 years, there was no difference in mortality or recurrent infarction rate, but the reintervention rate in the PCI group was significantly higher, and the MIDCAB patients had fewer clinical symptoms by CCS classification (Thiele et al. 2005).

Overall, the published data show that minimally invasive, direct coronary revascularization is safe and effective and can be considered a standard of care. The precise role of hybrid procedures remains to be seen. However, it clearly represents a valuable alternative that can reduce the operative risk of patients with multiple comorbidities.

26.3.6.3 Off-pump Coronary Revascularization Strategies

With the introduction of ECC, an innovation that launched cardiac surgery, a higher standard could be achieved in coronary bypass surgery, although the first coronary bypass operation by Kolessov was already carried out without ECC (Kolessov 1967).

However, cardiopulmonary bypass represents a significant operative and immunologic trauma. As a result of the manipulation of the great vessels, activation of the inflammatory cascade, and active modulation of the blood temperature and laminar flow, the use of the HLM is not without risk. Activation of the immune system results in release of multiple vasoactive substances and cytokines. This response results in increased capillary permeability with sequestration of neutrophils and increased microemboli. As a result, a vasoplegic syndrome is produced (Brasil et al. 1998; Gomes et al. 2003).

Avoidance of the HLM reduces cytokine release, in particular IL-8, which reduces the inflammatory response and the ensuing myocardial injury (Deng et al. 1996). In particular, the risk of HLM under emergency conditions and for patients with multiple comorbid illness is very high (Brasil et al. 1998; Rastan et al. 2006; Palmar et al. 2007; Ben-Gal et al. 2011; Lamy et al. 2012). Injuries to the ascending aorta, including aortic dissection or mobilization of plaque or calcific fragments, may also occur during cannulation or use of the HLM and lead to cerebrovascular complications.

The renaissance of beating heart coronary bypass surgery came primarily through the work of Benetti (1985) and Buffolo (1991) in the early 1980s. One of the most important developments in modern off-pump coronary artery bypass surgery was the technique propagated by Benetti and Calafiore in which the LIMA-LAD anastomosis was performed directly on the beating heart via a

left lateral mini-thoracotomy (Benetti et al. 1991; Calafiore et al. 1996).

Conditions for beating heart surgery include a good exposure and stabilization of the target vessel, a temporary interruption of coronary blood flow during the anastomosis without irreversible myocardial ischemia, maintenance of sufficient systemic circulation during the anastomosis, and a logical sequence of revascularization.

With the development of new instruments and surgical tools that lead to efficient immobilization and presentation of the target vessel, beating heart coronary bypass surgery without ECC can be performed with very high quality and has become standard in many centers. Important in this context is the close cooperation with a specialty group of cardiac anaesthesiologists.

In contrast to on-pump surgery, the sequence in which target vessels are revascularized is of great clinical significance. The surgical approach may be a classical median sternotomy, partial sternotomy, lateral left- or right-sided mini-thoracotomy, or subxiphoidal.

For optimal myocardial physiology during luxation and performance of the bypasses, a reduction of the dp/dt, heart rate, and afterload should be achieved. Ischemic or pharmacologic preconditioning can also be helpful. The Trendelenburg maneuver can be used to regulate volume status.

Performance of central aortic anastomoses is not absolutely necessary, especially in the setting of a calcified aorta. As an alternative, particularly for complete arterial revascularization, the use of T- and Y-anastomoses based on the left internal mammary artery can be conducted. Using this technique with the RIMA or the radial artery, all territories can be revascularized. If central anastomoses are required, a partial cross-clamp may be applied to the ascending aorta. Newer connector systems also offer the possibility to perform proximal aortic anastomoses using a clampless technique, thereby reducing operative trauma and neurologic events (Emmert et al. 2011).

26.3.6.4 Results

Only a brief discussion of results is presented here but discussed in greater detail in ► chapter «Coronary Artery Disease», Sect. 22.5. In Germany in 2011, 14.7% of CABG was performed using an off-pump technique, with an increasing tendency in recent years (Funkat et al. 2012). In multiple studies, the safety and efficacy of off-pump coro-

nary artery bypass surgery has been demonstrated, with beneficial effects on neurocognitive dysfunction, ventilation time, blood loss, and hospital stay as well as postoperative atrial fibrillation and renal insufficiency. All of these benefits have been associated with optimal resource utilization. However, with respect to mortality and bypass graft function, there has been increasing benefit for OPCAB when compared to conventional strategies (Rastan et al. 2006; Palmer et al. 2007; Keeling et al. 2012; Diegeler et al. 2013). On the other hand, a randomized study from 2007 showed that OPCAB had no advantage with respect to neurocognitive function or 5-year survival (van Dijk et al. 2007). Nevertheless, patients with an acute myocardial infarction benefit from this operative strategy (Rastan et al. 2006), as do older patients, high-risk patients, or patients with a calcified/porcelain aorta (Marui et al. 2012; Keeling et al. 2013). In experienced hands, OPCAB is also safe for coronary reoperations (Usta et al. 2013).

26.3.6.5 Conclusion

Despite the very good results of conventional coronary artery revascularization, it should be concluded that modern coronary revascularization is confronted with four demanding challenges for surgeons:

- Increasing comorbidity of the patients
- Increased demand for reoperations, due to an aging patient population
- Multiple previous interventions by cardiology
- A higher and more progressive/aggressive interventional standard

As a result, procedures that reduce operative trauma, such as beating heart revascularization with or without the ECC, minimization of the surgical approach (MIDCAB), and all-arterial revascularization should be standard procedures in modern CABG surgery.

26.3.7 Conduit Harvest

In recent years, endoscopically minimally invasive procedures for conduit harvest are increasingly used. The endoscopic harvesting of the greater saphenous vein, as well as the video-assisted harvest of the radial artery, are well-accepted and standard procedures in many centers (Connolly et al. 2002; Patel et al. 2004; Williams et al. 2012; Sastry

et al. 2013). In clinical studies, these techniques have been shown to preserve the histological structure and endothelial function of the vessels, although there is clearly a learning curve (Fabricius et al. 2000; Aziz et al. 2005). These techniques have been shown to reduce the wound infection rate, particularly in obese patients (Williams et al. 2012). For minimally invasive techniques of vein harvest, two different procedures have been described, either harvest under direct or under endoscopic vision (Sastry et al. 2013).

26.3.8 Cardiac Arrhythmia Surgery

Surgical therapy of atrial fibrillation has evolved dynamically through the evaluation of various energy sources, minimally invasive approaches, and completely endoscopic techniques. Based on the theory that existing electrical triggers for atrial fibrillation are located in the region of the pulmonary veins and the atria, the concept of surgical isolation of these foci was developed. With respect to atrial fibrillation, the MAZE procedure represents the most effective surgical technique but requires entry into both the left and right atria. Irrespective of the energy source used (monopolar or bipolar radiofrequency, microwave, cryoenergy, or ultrasound), a safe and effective therapy of isolated atrial fibrillation can be performed via a right lateral mini-thoracotomy with femoral cannulation. Commonly, the therapy can be combined with other cardiac surgical procedures (valve or CABG procedures). Pulmonary vein isolation can be carried out on the beating heart, even as an off-pump procedure, as long as no concomitant intracardiac surgery is required.

Various authors have reported successful ablation of atrial fibrillation on the beating heart via a minimally invasive or completely endoscopic approach (right- and left-sided miniMAZE) (Weimar et al. 2012). Surgical success rate seems to also be dependent on ganglionic plexus ablation (parasympathetic innervation) (Mehall et al. 2007; von Oppel et al. 2009; Pison et al. 2012).

Completely telemanipulator-assisted ablation techniques have been described (Weimar et al. 2012).

The interventional treatment of atrial fibrillation represents an alternate approach. This technique uses focused electrical isolation in the atria and pulmonary veins and has been generally

associated with very good clinical outcomes, with a low rate of complications (O'Neill et al. 2007).

Currently, the hybrid strategy of combined endocardial and thoracoscopic epicardial ablation is of great clinical interest to overcome the shortcomings of catheter-based ablation therapy (multiple procedures are often required and creating linear lines are challenging) and beating heart epicardial ablation (creating mitral isthmus line can be challenging). First results are very promising (Pison et al. 2012).

26.3.8.1 Results

Minimally invasive techniques are well established for the treatment of atrial fibrillation. Isolated atrial fibrillation can be treated surgically using a minimally invasive approach as for mitral valve surgery. Alternatively, bilateral video-assisted thoracoscopic pulmonary vein ablation can be performed using an off-pump technique. Concurrently, surgical and interventional results must be compared, but randomized trials are lacking (see ► chapter «Surgical Therapy for Atrial Fibrillation», Sect. 29.6.4).

26.3.9 Great Vessels

Since the ascending aorta and aortic arch are located in the upper mediastinum, replacement of these aortic segments can be performed via the various partial sternotomy approaches described earlier for aortic valve replacement. Often, aortic replacement for aneurysmal disease is performed concomitantly with aortic valve replacement, but may also be performed as an isolated procedure.

Cannulation may be performed centrally, via the right axillary artery or via femoral access as for mitral or tricuspid valve surgery. With increasing experience, partial or total aortic arch replacement and even various forms of aortic root replacement may be performed via a partial upper sternotomy. As with other minimally invasive procedures, the quality of the operation should not be compromised by the limited surgical approach.

In reoperative cases, or for patients with poor lung function, the use of the partial sternotomy may be beneficial to limit the amount of cardiac dissection required or reduce respiratory complications, respectively.

Off-pump debranching of the aortic arch vessels may also be performed via a partial upper

sternotomy, with either simultaneous or staged implantation of a stent graft to treat aortic arch pathology. For cases of acute type A aortic dissection, a novel approach has been recently described for inoperable patients, whereby a transapical approach has been used to deliver a stent graft into the ascending aorta without the HLM (Köbel et al. 2013; Ronchey et al. 2013). These are further examples of the use of minimally invasive and hybrid approaches (see ► Sect. 26.4.1 «Hybrid Strategy») to reduce the operative risk for cardiac surgical patients.

26.3.10 Heart Failure/Ventricular Assist Devices

26.3.10.1 Left Ventricular Assist Device

The incidence of heart failure worldwide continues to increase, so does the number of treatment options to prevent or delay the onset of end-stage heart failure. The last decade has seen fundamental advances in the medical and surgical therapy for patients with severe heart failure. While heart transplantation remains the gold standard for patients with end-stage heart failure, the rate of transplantation has remained relatively steady over the past 20 years (Stehlik et al. 2010; Francis et al. 2010). This has resulted in a major imbalance between supply and demand leading to 20% mortality for patients on a waiting list for heart transplantation. Giving the relative constant number of donor hearts available, with a continuously increasing number of heart failure patients requiring transplantation at some point, the waiting list mortality will increase dramatically. As a consequence of the persistent and relatively even increasing donor organ shortage, there has been growing interest for alternative strategies. These strategies are in particular left ventricular mechanical circulatory support or partial circulatory support not only as bridge to transplantation but also as a permanent solution: destination therapy (see also ► chapter «Cardiac Assist Devices and Total Artificial Heart» Sect. 38.4).

Recently, newer, more durable devices have been developed and have further advanced the mechanical circulatory support field (Lietz and

Miller 2009; Wilson et al. 2009; Aggarwal and Pagani 2010). Continuous-flow pumps appear to have an advantage over the larger, bulkier pulsatile-flow assist devices, both in survival and complication rates (Griffith et al. 2001; Gregoric et al. 2011). Thus, supporting the ongoing trend of further miniaturization of these devices and the insufficient supply of acceptable donor hearts have led to innovative thinking about less invasive mechanical strategies for long-term circulatory support.

The newly designed LV-sewing ring revolutionizes and facilitates the positioning of the inflow cannula to the left ventricle and makes this extremely versatile. The diaphragmatic approach to HVAD implantation is an alternative implantation technique that appears to be particularly suitable for patients with small lateral thoracic dimensions, e.g., pediatric patients, and/or an unusually enlarged heart (Cheung et al. 2011; Loforte et al. 2011). Implantation via thoracotomy with two small incisions and with or without cardiopulmonary bypass (cannulation via femoral vessels) avoiding the invasive sternotomy is being most recently being utilized and shows promising results (Slaughter et al. 2010; Strueber et al. 2011). Regarding the small design, the device can be placed after implantation either transapical, transmitral, intercostal, or subcostal.

Several centers have published on biventricular application of the HVAD pump. Hetzer and associates described biventricular implantation techniques and reported on five patients implanted simultaneously with an LVAD and RVAD and an additional three patients implanted with an RVAD after initial LVAD implantation. All five patients with simultaneous LVAD and RVAD implantation survived and were discharged home (Hetzer et al. 2010). Strueber and colleagues reported on one patient who received a right ventricular assist device (RVAD) after initial LVAD implantation (Strueber et al. 2010). The patient was awaiting transplantation at the time of publication. Loforte and colleagues described a new technique for biventricular assist device (BiVAD) implantation in a small (1.6 m²) patient (Loforte et al. 2010).

In summary, the message is clear: continuing to shrink the size of the pump and the concept of only partial circulatory support may minimize the surgical trauma, thus resulting in less adverse events, shorter recovery times, and enhanced quality of life.

26.4 New Clinical Concepts

26.4.1 Hybrid Strategy

The term hybrid strategy refers to the combination of surgical and interventional methods, either in a simultaneous or staged fashion that is used to treat a particular pathology. The goal is to combine minimally invasive surgical techniques and/or operative «partial solutions» with catheter-based interventional procedures to keep the risks to patients as low as possible. This new, controversial therapy has already found broad clinical applications in the realm of multivessel coronary, valve, and great vessel disease in adults, as well as in various pediatric cardiac surgical diseases. The hybrid approach requires close multidisciplinary collaboration among various specialties and a strategic planning of the procedures (Byrne et al. 2008).

In particular, in coronary artery disease (CAD), the combination of MIDCAB (mortality <1 %) and PCI is gaining increasing popularity, particularly for high-risk patients with 2+ vessel disease (Shen et al. 2013). Still unresolved is the question whether simultaneous or staged therapy is preferred. Simultaneous treatment has the advantage of achieving a complete revascularization, immediate assessment of the bypass graft, and a single operative setting for

the patient, which reduces the hospital stay. A prerequisite for this approach is the presence of an operating room that combines the requirements of the surgical and interventional team and is outfitted with a modern fluoroscopic system and the necessary software for online image processing and reconstruction, the so-called hybrid operating room (■ Fig. 26.9) (Jakob et al. 2011).

26.4.1.1 Results

First clinical experiences with the hybrid strategy were made in coronary revascularization (de Canniere et al. 2001; Davidavicius et al. 2005). In a multicenter study, the combination of MIDCAB with PCI for the treatment of multivessel CAD was evaluated. Wittwer and colleagues reported that the method was safe and effective to achieve a complete revascularization and that the approach is valuable for high-risk and older patients, as well as for patients requiring cardiac reoperation (Wittwer et al. 2000). The 2-year results from Davidavicius' group comparing hybrid and OPCAB surgery for two-vessel CAD showed that the hybrid method is safe and effective. Both groups had similar freedom from cardiac symptoms. The perioperative morbidity, requirement for blood products, pain control, and hospital stay were reduced in the hybrid group (Davidavicius et al. 2005).

■ Fig. 26.9 Hybrid operating room

Telesurgery-assisted coronary revascularization has also been successfully combined with PCI (hybrid procedure). A recent study published by Bonatti's group showed that at a mean follow-up of 5 years, there was a 5-year survival of 92.2%, and 5-year freedom from major adverse cardiac and cerebral events was 75.2%. At 5 years 2.7% of bypass grafts and 14.2% of stented target vessels needed reintervention (Bonatti et al. 2012).

The combination of minimally invasive valve operations with percutaneous revascularization, particularly for high-risk patients or patients requiring reoperations, is also the subject of intense clinical investigation (Umakanthan et al. 2009). Various pathologies in babies and small children are being treated with hybrid approaches (Bacha et al. 2005, 2007), and the most frequently used being the «Giessen procedure» for stage I palliation of hypoplastic left heart syndrome (Akintürk et al. 2002; Galantowicz et al. 2008).

A rapid development of this technique has also been seen in the treatment of aneurysms and dissections of the thoracoabdominal aorta and aortic arch. Many centers have reported success with a staged approach to complex aortic arch pathology. In some cases, treatment of a type A dissection has involved surgical replacement of the ascending aorta and arch, with simultaneous stenting of the descending thoracic aorta (Lin et al. 2007; Torsello et al. 2007; Tsagakis et al. 2013; Kang et al. 2013).

26.4.1.2 Conclusion

The hybrid approach has established new benchmarks not just in cardiac surgery, but in all areas of medicine. The introduction of this method is the logical result of the changing patient population and the increasing complexity of the pathologies. It requires an intensive collaboration of the individual specialties and has already become established in coronary revascularization and pediatric heart surgery. Interesting applications include the treatment of thoracoabdominal aneurysms and the combination of minimally invasive valve surgery with adjunctive PCI. However, a clear definition and characterization of the patients are yet to be determined. Further studies will be required to establish specific indications for the hybrid approach.

26.4.2 Endoscopic and Telesurgery-Assisted Cardiac Surgery

Telesurgery-assisted or robotic surgery finds its origins in open surgery by transferring open surgery dexterity to a minimally invasive environment, hence overcoming the limitations of classic laparoscopic surgery. The introduction of the endoluminal clamp technique (see ► Sect. 26.2.3, «HeartPort Technique») supported the development of telesurgery-assisted cardiac surgery (Stevens et al. 1996a, b; Pompili et al. 1996).

The basic idea of the telesurgery-assisted technology consists of mechanical translation of the surgeon's motor movements through a limited surgical approach, with simultaneous visual presentation and control of the operative site. The technique has been applied during IMA preparation, coronary revascularization (LIMA-LAD anastomosis) (Mohr et al. 1999; Argenziano et al. 2006; Bonaros et al. 2013, with simple and complex mitral valve pathologies (Falk et al. 1996, 1998; Chitwood et al. 1997a, b, 2003; Cosgrove et al. 1998; Nifong et al. 2005; Reade et al. 2005; Smith and Stein 2008; Mihaljevic et al. 2013), atrial fibrillation ablation (Akpınar et al. 2003; Cheema et al. 2009), left ventricular mapping, and placement of epicardial electrodes. Endoscopic and telesurgery-assisted systems have not only been used to support minimally invasive procedures with speech-directed holder and camera systems, but there have also entire operations been carried out (Falk et al. 1998; Bonatti et al. 2012).

The limitations of endoscopic surgery, such as limited movement of rigid insertion systems (only four degrees of freedom) and the limited flexibility of the distal instrument tips, result in increased technical demands on surgeons. The transmission of movement tremors over the endoscope should also not be underestimated. Telesurgery-assisted systems are in the position to reduce these limitations. Two different systems are available: systems which function primarily as passive tools and function as instrument or position holders. These systems enable a tremor-free transmission or fixation of the operative site. Instrument steering, i.e., *AESOP* (Automated Endoscopic System for Optimal Positioning; Intuitive Surgical, Sunnyvale, California, USA), can be controlled via speech or manually. The second group, telesurgery-assisted, enable a direct 3D-controlled, fine sur-

■ **Fig. 26.10** Telesystem. da Vinci System (Intuitive Surgical, Sunnyvale, California, USA): **a** steering console and **b** robotic console (©2015 Intuitive Surgical, Inc)

gical manipulation on the heart. Presently, the most commonly used system is the da Vinci system (Intuitive Surgical, ■ Fig. 26.10).

The da Vinci System consists of a surgeon console, a patient side cart holding the instruments, and a vision cart, so that the surgeon can flexibly position various arms (from surgeon console two or three instrument arms) with up to seven degrees of freedom axis for translations and orientations, achieving controlled movements within the operative site. The movements of the operator are sensed and converted into synchronous surgical movements through computer algorithms.

The simultaneous control of the endoscopic camera produces a high-definition 3D (1080i) picture, which is transmitted from the operative site to the console. The insertion of robotic arms is achieved through various ports through the body wall. Advantages of telesystem-assisted surgery, in comparison to endoscopic surgery, include increased degrees of freedom, no transmission of tremors, variable speed of movement transmission, indexing, linear maintenance of strength, and a direct hand-eye coordination (Falk et al. 1998).

In accordance with the technical complexity and the visual demands, implementation of this

approach can occur in a stepwise fashion (level I–III) (Falk et al. 1996, 1998; Chitwood et al. 1997a, b) until a complete, robot-assisted closed-chest operation can be achieved (level IV) (Falk et al. 1998).

26.4.2.1 Results

The AESOP systems are primarily used during minimally invasive mitral valve surgery as speech-guided stabilizers and instrument-holding systems. Studies have shown that these systems can be used safely and effectively (Nifong et al. 2005; O'Neill et al. 2007; Bonatti et al. 2012; Bonaros et al. 2013; Mihaljevic et al. 2013).

In 2013, a total of 523,000 procedures had been carried out worldwide with the da Vinci Robotic System. Essentially, four different pathologies were treated: coronary one-vessel disease (TECAB)—up to two-vessel disease, mitral valve repair (MVR), ASD closure, and atrial fibrillation ablation.

With the *TECAB* (totally endoscopic coronary artery bypass surgery) procedure, initially performed in 1998 in Paris and Leipzig (Loulmet et al. 1999; Mohr et al. 1999), the preparation of the left internal thoracic artery and the LIMA-LAD anastomosis were performed totally endoscopically on the arrested heart with a closed-chest

■ Fig. 26.11 Telemanipulator-assisted cardiac surgery. Operative setup (©2015 Intuitive Surgical, Inc)

approach (using the HeartPort technique). The positioning of the patient is supine, with the left hemithorax lightly elevated. Three ports are then placed, forming a triangle (■ Fig. 26.11). One port is in the fourth left intercostal space, medially and anteriorly. The cranial port is in the third intercostal space, lateral and more posteriorly located and the caudal port lies in the sixth or seventh intercostal space, lateral and more posteriorly located. For a better exposure and overview, CO₂ insufflation to achieve an intrathoracic pressure of 6–14 mmHg has also been shown to be helpful.

The results of the first prospective multicenter study with the da Vinci System showed no difference with respect to mortality and morbidity (Argenziano et al. 2006). The angiographic patency and reintervention rate were comparable to conventional operation. However, in this study, the construction of the LIMA-LAD anas-

tomosis was carried out using the HeartPort technique and not on the beating heart (Argenziano et al. 2006; Bonatti et al. 2007). For patients with two-vessel coronary artery disease, a hybrid approach can also be considered (Bonatti et al. 2012).

Telemanipulator-assisted mitral valve repair of complex pathologies has already been demonstrated in studies by Chitwood and colleagues (1997a, b, 2003). In an FDA study of the da Vinci System, various techniques such as quadrangular resection, sliding plasty, chordal transfer, chordal replacement, and implantation of anuloplasty bands were carried out (Chitwood et al. 2000). With the introduction of new instruments, suture techniques, neochordae and nitinol clips, mitral valve reconstruction, and implantation of anuloplasty bands are possible with good clinical results. Increased experience has resulted in a

reduction of operative, bypass, and cross clamp times (Reade et al. 2005; Mihaljevic et al. 2013).

With respect to atrial fibrillation ablation, the MAZE procedure represents one of the most effective surgical techniques, whereby the left and right atria must be opened. Independent of which energy source is used (radiofrequency or cryotherapy), a safe and effective therapy can be performed via a right lateral mini-thoracotomy with connection to ECC via the femoral vessels. Commonly, this procedure is performed in conjunction with mitral or tricuspid valve surgery (Seeburger et al. 2008; Akpınar et al. 2003). Totally endoscopic techniques for isolated pulmonary vein ablation on the beating heart (Saltman et al. 2003; Cheema et al. 2009), but also systems for ablation on the beating heart, have been described (Cheema et al. 2009).

Garrido reported successful use of the da Vinci System to treat atrial fibrillation (Garrido et al. 2004). Interventional therapy of atrial fibrillation represents an alternate therapeutic strategy. This approach involves focused electrical isolation in the right and left atria, and the pulmonary veins, and has been associated with very good clinical results but also serious complications (O'Neill et al. 2007) (see also ► chapter «Surgical Therapy for Atrial Fibrillation», Sect. 29.6.5).

26.4.2.2 Conclusion

The application of computer-assisted telemanipulation techniques represents a new level in cardiac surgery. As with each type of breakthrough, this technique also has its drawbacks and has not yet become routine practice worldwide. Meanwhile, in the USA this technique has become a routine approach for isolated MVR. However, in many centers, the combination of endoscopic techniques has become the standard for minimally invasive procedures, whether this is for coronary artery bypass conduit harvest or complex valve surgery. The rapid technical developments, the creation of new instruments, and the evolving areas of imaging and image processing make telemanipulator-assisted surgery one of the most interesting areas of minimally invasive cardiac surgery. However, there are significant associated material and time requirements that need to be considered. In addition, intensive training, simulation of potential operative situations, mastery of all tools and acceptance of a new perception of the operative field, as well as a technically accomplished and creative surgeon are required. Despite all the excitement, each technique should

be critically evaluated and compared to the existing high standards of modern cardiac surgery.

27.1 Introduction

The surgical options for treating diseases of the aorta have been extended in the past 15 years. This development was driven, in particular, by the search for means of reducing surgical trauma. For example, new techniques that were introduced for procedures at the aortic arch brought about considerable improvement in intraoperative neuroprotection (Hagl et al. 2003). Moreover, new methods are now available for various indications in classic «open» surgery; while they are not suited to *replace* the diseased aortic segment, these methods nonetheless enable us to treat affected aortal segments by implanting endovascular prostheses – so-called endografts (Baraki et al. 2007; Nienaber et al. 2007). Accordingly, a new chapter, «Endovascular Surgical Therapy of Thoracic and Thoracoabdominal Disease of the Aorta,» is added to this book (► Chap. 28).

The surgical treatment of diseases of the aorta, therefore, is increasingly being conducted at interdisciplinary treatment centers, which is sensible. The following account, however, is being given primarily from the perspective of classic aorta surgery and deals with the interventional procedures according to surgical indication.

27.1.1 Definitions and Outline

Aneurysms and dissections of the aorta result from a weakness in the viscoelastic «belt» of the vascular media that sustains the arterial pressure. This can be strictly localized – as in the case of rupture of the vascular wall due to trauma – or can involve extensive segments of the vessel – as in the case of primary medial degeneration and atherosclerotic aortopathy. The consequences are a progressive increase in the vessel radius as well as a thinning and – and according to Laplace's law – a disproportionate increase in wall tension, resulting in compression of neighboring organs and ultimately in rupture. Aortic dissection represents a special case, in which intima and the degenerated media rupture and split longitudinally from the adventitia, usually over long stretches of the vessel. If an individual does not die as a result of an acute rupture associated with cardiac tamponade, massive aortic insufficiency, or malperfusion of vital organs, the outermost

wall layer of a dissected aorta will go through the typical transformation process and evolve into an aneurysm. A dissection can also develop from a preexisting aneurysm. Owing to these relationships and also considering the similar type of surgical treatment, the procedures for proximal thoracic aneurysms and aorta dissection are presented together.

Operations for aneurysms and dissection of the descending thoracic aorta will be discussed with respect to the need to replace numerous aortic segments. The respective chapter also deals with interventional procedures for treating aortic disease involving the aortic arch and/or the thoracoabdominal aorta. In addition, the reader is referred to the corresponding ► Chap. 28 in this textbook. By definition, an *aneurysm of the ascending aorta* involves the segment between the aortic valve and the origin of the innominate artery, an *aortic arch aneurysm* when the aneurysm runs between the branches of the brachiocephalic trunk and left subclavian artery, and, finally, an *aneurysm of the descending aorta* if the thoracic aorta segments beyond this artery are affected.

Today, *dissection of the aorta* is divided into type A and type B (Miller et al. 1979), basically superseding the original classification by De Bakey et al. (1966). The two types only differ with regard to the segment affected – ascending or descending aorta – irrespective of the site of proximal «entry» and the peripheral extent of the dissection process. This view is thought to best satisfy the requirements for surgical management since a type A dissection is always accessed via a sternotomy, type B in contrast via a left-lateral thoracotomy. In our opinion, it is still sensible to apply DeBakey's type II terminology for dissections limited to the ascending aorta – in spite of their rarity – because they often engraft a preexisting anular ectasia, mainly associated with Marfan syndrome. In addition, they are usually easier to operate than dissections extending far distally.

More recent studies have shown that intramural hematomas and atherosclerotic ulcerations can be signs of a beginning aortic dissection. Thus, Swensson et al. (1999) suggested that pathomorphological criteria be used to distinguish them.

Lansman et al. (1999) recommended classifying aortic dissections with regard to the site of the intimal tear. In some cases, a type B dissection

extends retrogradely into the aortic arch and up to the aortic valve.

A dissection is defined as acute if surgery is undertaken within 14 days of onset, usually accompanied by tremendous suddenly occurring chest pain. It is called subacute if that pain event took place more than 2 weeks but less than 2 months previously, and it is chronic if a longer period has passed. From the surgeon's standpoint, it is largely irrelevant to distinguish between acute and subacute dissection as in both cases the walls of the aorta are delicate and fragile since stabilizing scar tissue only develops in the outermost wall layer later on.

27.1.2 Historical Remarks

Surgical strategies for treating the proximal thoracic segments of the aorta lagged behind those of the descending aorta due to initially unresolvable technical problems. These mainly involved intraoperative protections of vital organs and the availability of vascular prostheses that remained blood tight even in a patient fully heparinized. Up to the middle of the 1950s, therefore, surgeons were restricted to operate upon saccular and upon fusiform aneurysms by resecting the first and reducing the size of the latter (Cooley and De Bakey 1952). Cooley and De Bakey were the first to implant a tubular prosthesis in the ascending aorta under conditions of extracorporeal circulation in 1956. Later, the aortic root and the ascending aorta were either replaced separately (Wheat et al. 1964) or jointly (Bentall and De Bono 1968; Schulte and Birks 1971), with the latter technique largely becoming established. Today, hospital mortality of those procedures is comparable to that for a simple aortic valve replacement (Kouchoukos et al. 1986). The valve-sparing procedures introduced by Yacoub in 1983 and by David at the early 1990s extended the therapeutic options considerably (David and Feindel 1992; Yacoub et al. 1983).

For aortic arch replacement, surgeons initially used temporary or permanent extra-anatomic circulatory bypasses (Cooley and DeBakey 1956; Cooley et al. 1955; Creech et al. 1956; Muller et al. 1960) until De Bakey, Crawford, and Cooley successfully replaced the aortic arch on extracorporeal circulation for the first time in 1957 (De Bakey et al. 1957). Heberer et al. (1960) described

this development in detail. Indeed, arch procedures were considered high-risk operations for quite some time until Griep et al. (1975), Ott et al. (1978), Thevenet (1980), and particularly Crawford (Crawford and Saleh 1981; Crawford et al. 1979, 1984) picked up on an older suggestion made by Borst and colleagues to operate under conditions of circulatory arrest and deep hypothermia (Borst et al. 1964). After Bachet et al. (1991) and more so Kazui et al. (2007) introduced scientifically well-founded techniques for protecting the brain during surgery, excellent results can now be achieved for partial and total arch replacement. Long perfusion times and potentially severe coagulation disorders due to the extremely low body temperatures prompted a number of authors to compromise between moderate hypothermia and comparably short periods of circulatory arrest (Bachet and Guilmet 2002; Di Eusanio et al. 2002; Kamiya et al. 2006, 2007). Today, there is increasing evidence that neurological outcome after circulatory arrest of more than 30 min is improved when antegrade cerebral perfusion was used in comparison to deep hypothermia alone (Krüger et al. 2011).

Although true long-term follow-up data are still limited, endoluminal thoracic aortic prostheses have been widely introduced clinically as, in the meantime, this is considered to be at least as good an option as classic open surgery for several indications (Nienaber et al. 2007). This applies to diseases of the descending aorta and, as recently reported, also to those of the aortic arch (Schumacher et al. 2006; Kotelis et al. 2011). Here, however, the supra-aortic branches need to be extra anatomically transposed to the ascending aorta before implanting aortic endovascular prostheses.

27.1.3 Surgical Indications

The goal of surgical treatment of aneurysms and/or dissections of the thoracic and abdominal aorta is to prevent rupture; less often compression of neighboring organs has to be eliminated, also. In general, an increase in the diameter of an aneurysm to >5 cm in the ascending aorta and in the arch segment and to >6 cm in the descending aorta gives the indication for elective procedures. Symptoms of an impending rupture or a life-threatening compression of intrathoracic organs require a rapid line of action. For manifest

rupture and for acute type A dissection, emergency surgery is always needed in order to prevent cardiac tamponade and massive aortic insufficiency.

Further refinements concerning the indications for operative therapy in diverse subcohorts of patients with aortic aneurysms have been published recently and are displayed in updated guidelines and (Erbel et al. 2014; Hiratzka et al. 2010, 2016).

27.1.4 Prostheses, Sutures, and Stentgrafts (Endovascular Prostheses)

Today, prostheses fashioned from woven double-velour Dacron and pretreated with collagen are used almost exclusively. Mostly, simple tubular vascular prostheses are applied that, depending on where they will be implanted, are supplied with prefabricated side branches to facilitate an anastomosis to the large branches of the aorta (Spielvogel et al. 2003). For treating diseases involving both the aortic arch and the descending aorta, vascular prostheses are available that carry a stented and a nonstented segment (so-called hybrid prostheses; Karck et al. 2005). By using such prostheses that are designed like an endograft distally, a later second operation via a lateral access is often unnecessary.

In addition, a wide variety of vascular stents and prostheses has emerged for endovascular treatment of many aortic diseases (Chuter 2007; Greenberg et al. 2006; Melissano et al. 2007). For details, please see also ► Chapter «Endovascular Surgical Therapy of Thoracic and Thoracoabdominal Disease of the Aorta», Sect. 28.2.

Human aortic homografts are particularly well suited for repeat procedures of the thoracic aorta due to vascular prosthesis infection (Lesèche et al. 2001).

Sutures for aortic surgery have largely been standardized. We exclusively employ monofilament, usually double-armed size 3/0 suture material. Extra-long threads (monofilament polypropylene, 120 cm) are better for deep suturing, whereas lower-sized threads and needles are preferable for anastomosing aortic side branches and also for joining the coronary ostia to the aorta prosthesis. By choosing a special, hardened surgical needle, it is much easier to create an anastomosis if the target vessel is calcified.

27.2 Aneurysms of the Ascending Aorta

Aneurysms that extend from the aortic root to the branches of the innominate artery may be limited to one of the aortic sinuses or to the supracommissural segment. More often, however, they involve the entire aortic bulb and the actual ascending aorta, meaning an anuloaortic ectasia associated with aortic valve insufficiency caused by aortic ring dilatation. How radical the treatment must be depends largely on the degree of aneurysmal dilatation. The surgeon, however, will attempt to restrict the procedure to the proximal segment of the aorta.

For planning the procedure with the aim of possibly sparing the aortic valve, the surgeon must be aware about the type, extent, and prognosis of any concomitant valve malformations.

27.2.1 Access and Extracorporeal Circulation

For all proximal aneurysms, the heart and aorta are accessed in the same way, via a *median sternotomy*. If the pericardium is intact (first operation), the aneurysm is usually protected from sawing injury. Thus, sternotomy is performed in standard fashion. After opening the pericardium, the surgeon first determines whether the proximal aortic arch is suitable for arterial cannulation. If not, one of the two common femoral arteries or the right axillary artery can be used. In complicated situations, particularly reoperations, the procedures outlined in ► Sect. 27.5, «Reoperations», apply.

With large aneurysms, the aorta is inevitably elongated, and thus, the heart is frequently displaced to the left and caudally, which makes it difficult to access the right atrium. In this case, it may be easier to decompress the heart by first starting with *one* venous cannula and adding a second caval catheter later. More often, we insert a single two-staged cannula through the auricle of right atrium, while the assisting surgeon carefully holds the aneurysm to the side. Frequently, adhesions have developed between the aneurysm, the right

atrium, and the superior vena cava, which need to be detached first so that the aorta can be clamped and opened as soon as the extracorporeal circulation has been established and ventricular fibrillation has been commenced. It is also advisable to detach adhesions between the aneurysm and the pericardium, but the phrenic nerve must be preserved under all circumstances. We always insert a left ventricular suction catheter, either via the interatrial sulcus at the level of the upper right pulmonary vein and the mitral valve or – if access is awkward – directly through the apex of the left chamber. After clamping the aorta, cardioplegic solution is then injected into the ascending segment for aneurysms not associated with aortic insufficiency. Cardioplegia may be delivered in a retrograde fashion through the coronary sinus, also. In all other cases, the aorta has been opened prior to direct intubation of the coronary ostia if antegrade delivery of cardioplegia is planned. The technique for opening the ascending aorta including its base depends on the intraoperative findings.

27.2.2 Limited Ascending Aorta Replacement

Saccular aneurysms that develop – though rarely – in the aortic root, in a sinus of Valsalva, or supra-commissurally can be successfully treated with a patch or another valve-sparing procedure (see ► Sect. 27.2.4, «Ascending Aorta Replacement Associated with Aortic Valve Reconstruction»). After occluding the aorta and introducing cardioplegic arrest, the aneurysm should first be inspected to determine its dimensions and extension. Then, it is resected up to where the aortic wall appears to be healthy. Subsequently and in the simplest case, a pericardial or prosthetic patch is implanted to cover the aortic defect by oversewing with continuous running 3/0 sutures, possibly with the aid of Teflon- or pericardium-reinforced mattress sutures.

A supracommissural *fusiform aneurysm* is opened along its longitudinal axis so that the dilated segment of the aorta can subsequently be resected. A defective aortic valve associated with stenosis is replaced in the usual manner. A prosthetic tube graft that corresponds to the diameter of the aorta is inserted into the defect of the ascending aorta and proximally and distally (usually beveled) anastomosed end to end to the aortic

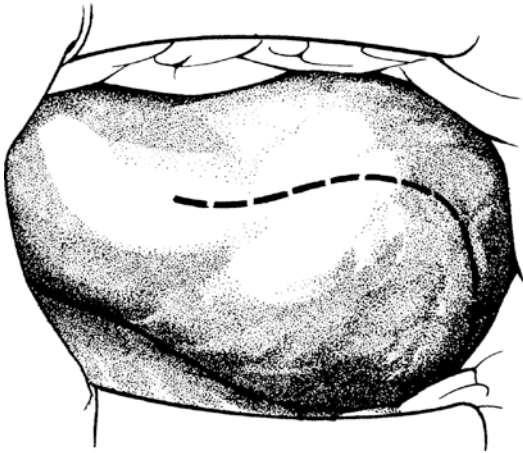

stumps by using continuous running sutures. In cases of valve insufficiency, a valve-sparing procedure can also be chosen and the aneurysmatic segment of the ascending aorta replaced with a vascular prosthesis at the same time.

Aortic root aneurysms that definitely involve the sinus of Valsalva are repeatedly and erroneously termed aneurysms of sinus of Valsalva. This term, however, is generally reserved for congenital saccular weakness of the ventricular-aortic junction that, over time, perforates most frequently into the right atrium or ventricle. Aneurysms of the sinus of Valsalva do not cause aortic or aortic root dilatation to the extent of an aortic root aneurysm.

27.2.3 Ascending Aorta and Aortic Valve Replacement

The entire proximal aorta including the aortic root and valve needs to be factored into surgical planning if the base of the aorta is dilated proximal to the actual ascending segment of the aorta in terms of an anuloaortic ectasia. If the valve cannot be spared, the ascending aorta can be replaced separately by using Wheat's technique (Wheat et al. 1964) or according to Bentall and De Bono (1968) by using a valved composite graft. If the first technique is chosen, the defective base of the aorta must be eliminated to the greatest extent possible in order to prevent an aneurysmatic dilatation of the residual base of the aorta from developing later. Indeed, as a result of their extensive experience, Kouchoukos et al. (1986) advise doing this. We employ this method in elderly patients with normal sinuses and preserved sinotubular junction. It also represents an option for a very narrow base of the aorta, for coronary ostia that lie extremely close to the anulus, or when a functioning aortic valve prosthesis is already in place.

Regardless of the technique chosen, the aorta is opened by making a «hockey stick»-like incision that initially ends at the level of the sinotubular junction before it enters the noncoronary sinus (► Fig. 27.1). Subsequently, we transect the aorta at this level in order to allow for a better view and mobility in the area of the aortic root.

■ **Fig. 27.1** Typical incision line for replacement of the ascending aorta

■ **Fig. 27.2** Separate replacement of aortic valve and ascending aorta. The valve prosthesis is implanted. The aortic prosthesis is anchored as deeply as possible in the sinus. Arch-shaped gaps corresponding to the coronary ostia are cut out of the proximal end of the prosthesis. The ostia are semi-circumferentially included into the suture line (the left ostium is illustrated here). In the noncoronary sector, the edge of the prosthesis can be joined directly with the suture ring of the artificial valve

27.2.3.1 Separate Replacement

Applying the Wheat technique (Markewitz et al. 1986; Wheat et al. 1964; Yun et al. 1997), the aortic valve is first replaced in the usual manner. Then, two small arch-shaped excisions are made in the proximal end of the ascending aorta prosthesis that correspond to the anatomical site of the coronary ostia; later, the prosthetic tube needs to be anchored as deeply as possible in the bulb here. Double-armed continuous anastomotic suturing begins at the level of the noncoronary sinus and proceeds in the direction of the left coronary ostium, which is semi-circumferentially included into the suture line. Sewing is continued in a clockwise direction until the right ostium is reached and can also be included into the anastomotic suture (■ Fig. 27.2). With the other end of the thread, the surgeon stitches deeply into the noncoronary sinus to the right, to ultimately reach the corresponding thread and tie the two ends together. It is important to exclude the noncoronary sinus as completely as possible as recurrences are especially likely to develop in this zone. It may be advantageous, therefore, to join the ascending aorta graft directly with the suture ring of the already implanted aortic valve prosthesis (for distal prosthesis-aorta anastomosing, see ► Sect. 27.2.3.3, «Distal Anastomosis»). This technique may be also employed in ascending aortic aneurysms secondary to earlier aortic valve replacement revealing a well-functioning valve prosthesis, usually a mechanical one.

27.2.3.2 Combined Replacement/ Composite Graft

Combined replacement of the ascending aorta and aortic valve constitutes a routine procedure for treating anuloaortic ectasia, irrespective of whether it is caused by aneurysm or dissection (Ehrlich et al. 2001; Gott et al. 1999; Mingke et al. 1998; Sioris et al. 2004). Following the original method of Bentall and De Bono (1968), the coronary ostia are not excised but reimplanted in the composite graft in continuity with the aortic wall.

In the modification described here, however, the coronary ostia are first excised out of the vessel wall with a trumpet-shaped aortic tissue cuff (button) for better mobilization. We prefer this method for both primary and redo procedures at the aortic root because it always allows reimplantation of the coronary ostia into the aortic prosthesis without producing any tension. Indeed, we have also largely departed from employing the original method because we occasionally observed recurrent aneurysms in the area of the coronary ostia anastomoses in patients who had previously undergone surgery. In particular Svensson et al. (1992) and Gott et al. (1995) gained experience using the modified technique already early on.

■ **Fig. 27.3** Combined replacement of the ascending aorta and aortic valve. The prosthesis is anchored along the right aspect of the base of the aorta using Teflon-pledgetted mattress sutures. The valve cusps are removed. The coronary ostia are excised out of the aortic wall and held aside by stay sutures

■ **Fig. 27.4** All sutures have been placed and the prosthesis can be inserted into the base of the aorta

Other variants are described in ► Sect. 27.2.3.6, «Alternative Methods of Proximal Aorta Replacement» (Bachet et al. 1996).

The size of the prosthesis for combined replacement of the aortic valve and the ascending aorta depends on the diameter of the aortic anulus. It is determined in the same way as for isolated aortic valve replacement after excising the cusps. After transverse aortotomy at the level of the sinotubular junction, the coronary ostia are readily accessible, and the surgeon has a good view for excising them in a «U shape» from the aortic wall and for subsequently placing stay sutures to hold them aside. Three additional stay sutures at the level of the valve commissures are lifted under light tension. In this way, the entire aortic root is lifted more into the surgical field of view, which facilitates the further procedure. The prosthesis is anchored into the base of the aorta, usually with Teflon felt-reinforced single mattress sutures that are placed from an aortal direction (■ Figs. 27.3 and 27.4).

As a time-saving alternative, the composite graft can be implanted by using three long, double-armed 2/0 polypropylene sutures and a continuous sewing technique. They proceed from the depth of each of the three sinuses to the corresponding commissure and then inserting and anchoring the prosthesis in the anulus («block-and-tackle» effect).

After fixating the composite graft in the base of the aorta, the coronary ostia are sutured to the respective sides of the vascular prosthesis. Our

preferred procedure is to sparingly fenestrate the tubular segment of the prosthesis precisely at the point at which the corresponding ostium can be anastomosed with the least possible amount of tension. To achieve this, the first assistant holds the ostium toward the vascular prosthesis before the surgeon places the window at the site that corresponds most favorably to the bottom of the ostium. For this, a battery-operated electrocauterizer is used. At the same time, a wide-enough remnant of prosthetic tissue must be left between the suture ring of the valve prosthesis and the respective ostium so that the anastomosis is not under any tension later. The holes in the prosthesis should be compatible with the size of the ostia unless the ostium is sclerosed such that one would need to leave a greater margin around the holes. When creating the anastomosis, the entire aortic wall including the adventitia needs to be passed by the needle. Depending on the condition of the surrounding aortic wall, a 5/0 or also a 4/0 suture is recommended. First the left ostium is anastomosed to the prosthesis (■ Fig. 27.5). For practical reasons, the lower part of the coronary anastomosis is sewn by inserting the needle through the prosthesis and capturing the lower margin of the ostium. For the rest of the anastomosis, the direction is less important. Nonetheless, it is easier to sew toward oneself and around the anastomosis. The right coronary ostium is attached to the prosthesis in the same way; the anastomosis is usually technically easier (■ Fig. 27.6).

It is wise to ensure that there is no leakage in any of the two coronary-prosthesis anastomoses before finishing the distal prosthesis-ascending aortic anastomosis (Borst 1981). To control for potential bleeding sites, the distal end of the composite graft

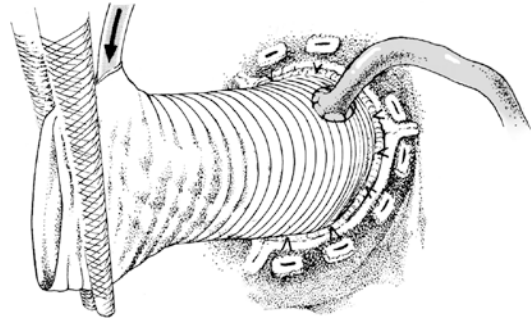

■ **Fig. 27.5** Anastomosing the left coronary ostium to the aortic prosthesis as a coronary button. By stitching through the prosthesis from inside to outside, the lower part of the periostial tissue is sutured first

■ **Fig. 27.6** Anastomosis of the right coronary ostium, which is done in the same way as for the left side

is clamped and put under pressure by administering cardioplegic solution via a separate arterial supply into the graft, at this time perfusing already the coronary arteries (■ Fig. 27.7). Any residual sources of bleeding can then be easily recognized and readily treated; this is considerably more difficult when

■ **Fig. 27.7** By infusing cardioplegic solution into the distally clamped prosthetic tube graft, any anastomotic leakage between the coronary ostia and the prosthesis can be detected

the distal prosthesis-aorta anastomosis has already been completed.

27.2.3.3 Distal Anastomosis

Independently of which method of proximal aortic reconstruction is used, the next step involves anastomosing the prosthesis to the distal ascending aorta. Usually this connection is established just upstream of the occlusion clamp. In contrast, for aneurysms that extend into the arch and occasionally also for dissections, anchoring must be more distal (see ► Sect. 27.2.3.6, «[Alternative Methods of Proximal Aorta Replacement](#)»). Two options are available for distal prosthesis-aortic anastomosis. It can proceed entirely from the lumen of the aorta by using transmural continuous sutures. Alternatively, the aorta can be transected about 12 mm from the occlusion clamp toward the heart so that an end-to-end anastomosis can be fabricated (■ Fig. 27.8). This variant has the advantage that any sources of bleeding discovered later can readily be inspected and easily managed. The aneurysmal flaps are not sewn in but rather left for later graft inclusion (see ► Sect. 27.2.3.4, «[Prosthesis Inclusion, Wrapping Technique](#)»). Prior to creating the prosthesis-aortic anastomosis, the closed occlusion clamp is carefully pulled down toward the heart and the heart itself is raised, as it often has shifted far caudally and to the left. Then the prosthesis is cut back to proper size, usually strongly beveled. The end-to-end anastomosis is fabricated by using double-armed 3/0 polypropylene thread, suturing by beginning at the backside of the prosthesis and toward the aorta. After completing the anastomosis at the front part of the aorta, a more or less large

■ **Fig. 27.8** Performing the distal prosthesis-aortic anastomosis with continuous everting sutures through the lumen. For this technique, it is advantageous to divide the aorta completely

prosthetic flap is sometimes left over that can be used for de-airing. Thereafter, the base of the flap is fastened with the anastomotic suture line and the residual flap is removed.

27.2.3.4 Prosthesis Inclusion, Wrapping Technique

The technique originally published by Bentall and De Bono in 1968 has made it possible to establish a complete inclusion of the entire ascending aorta prosthesis provided by the original aneurysm. After opening the aorta, the redundant aneurysmal flaps are cut back. Both proximally and distally, as well as left-laterally, large triangular shaped parts of the aneurysmal wall need to be removed also, in order to achieve a tight fit of the prosthesis within the custom tailored aneurysmal wall tissue. For this, continuous everting sutures are applied. Very thin aneurysmal wall tissue may require a continuous mattress suture and a second layer of interlocking sutures. The surgeon best starts the suture at the lowest point in the surgical field of view in the area of the noncoronary sinus and proceeds over the zenith of the ascending vessel. Distally the left and right residual aneurysmal flaps are joined with the adventitia of the aortic wall slightly downstream of the prosthesis-aortic anastomosis; they are joined with any Teflon felt strips that may have been used.

Reasoning for a complete inclusion of the graft implanted has been hemostasis and potential protection from infection, especially when mediasti-

nitis occurs. By modifying the original method of Bentall and De Bono in that we excise the coronary ostia, our preferred procedure, a complete hemostatic effect cannot be achieved in the area of the aortic root. This eliminates one important reason for establishing a prosthetic inclusion in the first place. Therefore we are increasingly abandoning the aim of accomplishing a graft inclusion. In addition, it has not been proven that an inclusion provides a real protective effect from infection of the prosthesis in mediastinitis.

27.2.3.5 Concomitant Coronary Revascularization

When aortic disease is associated with ischemic heart disease or – more rarely – when damage in the area of the coronary ostia (sclerosis, dissection) occurs during root replacement, coronary revascularization may be necessary simultaneously with ascending aorta replacement (with or without valve replacement). In coronary artery disease, the distal bypass anastomoses are performed as in any standard CABG procedure. If a coronary ostium had to be sacrificed for technical reasons, the distal venous bypass anastomosis is performed most proximal at the coronary artery involved in order to establish the shortest connection possible. If a coronary ostium needs to be closed, it is essential that retrograde leakage is prevented. This is most reliably achieved by placing a deep mattress suture that is always reinforced.

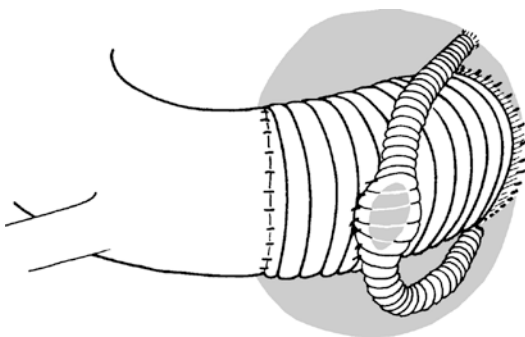

The proximal anastomosis of vein grafts can be problematic in these situations, particularly in patients with dissections.

Two variants of proximal anastomoses can be employed: the one we prefer involves anastomosing the bypass graft (s) to the innominate artery, which – if at all possible – is clamped off tangentially during surgery. The alternative remains in a direct coronary bypass graft anastomosis to the aortic prosthesis. We only select this latter possibility when the innominate artery is not suitable, such as for an extensive dissection or if sclerosis is palpable. In that case, a round pericardial patch with a diameter of about 1.5–2 cm is first sewn into the aortic prosthesis and the bypass anastomosis created in the center thereafter. This procedure is more laborious than a direct vein anastomosis into the prosthetic material; however, it prevents an anastomotic stenosis from developing as a result of intimal hyperplasia later postoperatively.

27.2.3.6 Alternative Methods of Proximal Aorta Replacement

Important alternatives to the procedures of Bentall and De Bono (1968) and the variants thereof emerge when a «biological» heart valve is chosen for replacement of the defective native valve. Here, an aortic homograft valve, the procedures of Ross (1967), implantation of a composite graft with a biological heart valve prosthesis (Etz et al. 2007), and recently also complete porcine aortic root grafts (Carrel et al. 2003) have to be mentioned. Employing a human aortic root graft (homograft) for replacing an infected composite graft may have advantages in presence of a pronounced aortic root abscess. If so, we frequently have chosen this option because an aortic homograft offers the possibility of reliable anchoring in the left ventricular outflow tract (Yankah et al. 2005). More recently, we prefer complete porcine aortic root grafts for this indication due to its availability in all sizes at any time.

Cabrol and colleagues (1986) performed another variant of the Bentall/Bono technique in a large number of patients. While replacement of aorta and aortic valve is performed in a standard fashion, they join the two coronary ostia first with an 8-mm Dacron tube and anastomose this inter-coronary graft side to side with the ascending aortic prosthesis (■ Fig. 27.9). We see an advantage of this procedure for those coronary ostia that have not or only minimally been displaced from the aortic anulus and therefore could not be easily joined to the prosthesis in the routine way. On the other hand, this method requires that another prosthesis be implanted, with the associated addi-

■ **Fig. 27.9** Combined replacement of the ascending aorta and aortic valve according to Cabrol. The two coronary ostia are joined by using an 8-mm tube graft. Subsequently, the inter coronary graft is anastomosed side to side with the aortic prosthesis

tional risks. It also prohibits a tight graft inclusion as otherwise the bypass graft would be compromised.

In the event of anastomotic bleeding into the graft inclusion space, Cabrol et al. (1981) recommend to anastomose the graft inclusion space, which developed around the prosthesis, with the right auricle (■ Fig. 27.10). Shunts created in this way thrombose over time; however, different surgeons have had different experiences like long-term heart failure due to a significant left-right shunt. Therefore, we have only used this technique in exceptional cases and would only employ it when everything else did already fail.

Reduction aortoplasty is another method suggested for the surgical treatment of proximal aortic aneurysms. While Senning's group (Egloff et al. 1982) mainly recommended it for repairing poststenotic dilatation, Robicsek (1982) also applied it for fusiform aneurysms of the ascend-

■ **Fig. 27.10** Relieving the tension on the periprosthetic graft inclusion by anastomosis with the right auricle according to Cabrol

ing aorta associated with aortic valve disease. The ascending aorta is initially mobilized in a circular fashion as far as possible and then opened lengthwise into the noncoronary sinus. The vessel caliber is reduced to normal size and the valve replaced. Then, two to three valve sutures are placed over the circumference of the aorta outward through the aortic wall at the noncoronary sinus. After closing the aorta by using continuous sutures, the vessel is enclosed by a synthetic prosthesis that has been beveled proximally and adjusted to the corresponding diameter. Thereafter, the prosthesis is fixed by sutures placed through the base of the aorta and then closed around the ascending aorta with running sutures under moderate tension. It is obvious that the diseased segment of an aorta reconstructed in this way would largely still be in place. Thus, we no longer use this technique and only perform reduction aortoplasty of the ascending aorta – if necessary – in very elderly patients in conjunction with aortic valve replacement surgery. More recent results with this technique, however, showed satisfactory 5-year results with regard to the fate of the diameter emphasizing the preserved Windkessel function of the ascending aorta (Bail et al. 2007; Walker et al. 2007).

27.2.4 Ascending Aorta Replacement Associated with Aortic Valve Reconstruction

Anuloaortic ectasia of the aortic root that develops from lateral displacement of the commissures may cause a central aortic valve insufficiency. This pathology can frequently be treated by valve-sparing reconstruction of the aortic root when the cusps are morphologically intact. Yacoub et al. (1983) developed a method of remodeling the aortic root in patients with aneurysm. The dilated ascending aorta is resected with the sinus of Valsalva sparing the aortic valve with its commissures. A narrow rim of aortic tissue is kept at the edge of the valve sinuses and commissures. The coronary ostia are excised from the aortic wall and mobilized. Then, the proximal end of a Dacron graft is fashioned such that three tongue-shaped extensions of the prosthesis can be anastomosed to the residual rims of the aorta. Subsequently, the excised coronary ostia are reimplanted into the

prothetic neosinuses of Valsalva. The base of the aorta needs to be reinforced at the level of the annulus with a ring of autologous pericardium to prevent anuloaortic dilatation from recurring.

For our procedures, we prefer the valve-sparing reimplantation method according to David (David and Feindel 1992) for replacement of the ascending aorta. With this technique, the diseased aortic tissue is resected to the same extent as for the Yacoub procedure; however, as the valve is reimplanted into a complete vascular tube graft, secondary dilatation of the aortic annulus and reconstructed root is prevented.

27.2.4.1 Indications for Applying the Reimplantation Method

An important advantage of aortic valve reconstruction lies in the fact that long-term anticoagulation is not required. The mid- and long-term follow-up results available so far are quite positive (David et al. 2012; Kallenbach et al. 2005; Shrestha et al. 2012). Whereas David described the reimplantation method in patients with aortic root aneurysms and aortic insufficiency with intact valve cusp morphology, today this technique is also employed to treat aortic insufficiency without pronounced aortic ectasia, acute type A aortic dissection, bicuspid aortic valves, mildly pronounced prolapse of one or more valve leaflets, and also in pediatric patient groups (David et al. 2001; Kallenbach et al. 2002, 2004; Karck and Haverich 2005; Vricella et al. 2005).

The long-term prognosis of valve-sparing surgical techniques in patients with Marfan syndrome and aortic root ectasia is still the subject of controversial discussion and requires further clarification (Benedetto et al. 2011; Kallenbach et al. 2007; Karck et al. 2004). Irrespective of whether Marfan syndrome is present, we apply the reimplantation method in all patients with structurally intact valve leaflets. Pronounced stress fenestration or very pronounced prolapse of one or more valve cusps in Marfan syndrome suggests progressive structural changes in the aortic valve. Therefore, a reconstruction procedure should not be performed here.

27.2.4.2 Reimplantation of the Aortic Valve

The aorta is opened transversely at the level of the sinotubular junction and completely transected there (Karck and Haverich 2005). Often, however,

this structure has not been preserved, particularly in patients with Marfan syndrome, and instead has evolved as aortic root ectasia, which is typical of that condition. In this case, the ascending aorta should be opened further distally in order to avoid injuring the coronary ostia, which occasionally drift surprisingly far downstream. The distal part of the aorta is kept out of the surgical field by a stay suture. After administering cardioplegic solution via the coronary ostia, the aortic valve is inspected.

The decision for or against reconstruction depends on whether the valve geometry can be repaired, the degree of sinus calcification, and whether the heart valve macroscopically appears to be structurally intact. At reconstruction the aortic root is externally mobilized as far proximally as possible until a virtual, almost horizontal plane has been achieved near the bottom of the sinus of Valsalva. Then the coronary ostia are excised from the aortic wall in a U shape and held aside with stay sutures before resecting the sinus of Valsalva up to a rim of 4–5 mm to the insertion line of the valve leaflets (■ Fig. 27.11).

To calculate the diameter of the vascular prosthesis needed for the aortic valve reimplantation, three double-armed stay sutures are first placed at the commissures. Under mild tension, they are lifted to be parallel so that coaptation of the valve cusps can be well visualized. The assistant holds a commercially available heart valve

prosthesis phantom or a Hegar dilator above the aortic root, whereby the diameter size is taken when the parallel commissural sutures touch the sizer. To that number 2–3 mm are to be added in order to determine the corresponding vascular prosthesis diameter because the vascular prosthesis encompasses the entire heart valve from the *outside*.

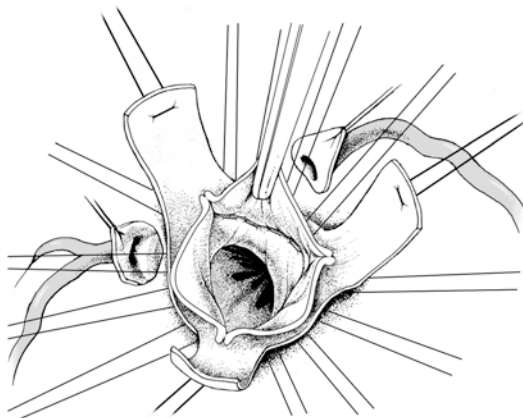

To anchor the vascular prosthesis, we use up to 12 double-armed polyester sutures to be placed transmurally in an outward direction from the horizontal subvalvular level of the left ventricle (■ Fig. 27.12). Other groups have used as few as three of these sutures, that is, one for each sinus (Tsang et al. 2011). The vascular prosthesis is then shortened to the appropriate length. Subsequently the positioning of the commissures is marked for later use on the outer side of the prosthesis with a sterile pencil by dividing the perimeter of the prosthesis into three equal segments. After the stay sutures at the commissures have been drawn through the lumen of the prosthesis and held aside by small clamps, the anchor sutures are placed at each corresponding position of the proximal end of the prosthesis. The prosthesis is anchored at the base of the aorta with ligatures to these sutures.

The ligatures should not be drawn too tightly as this would cause an undesired plication of the anulus.

■ Fig. 27.11 Reimplantation method according to David. The aortic wall was resected, leaving the commissures with a 4- to 5-mm wide margin of aortic wall. The commissures are suspended with stay sutures. The coronary ostia were excised from the aortic wall in a U shape and held aside with stay sutures

After this is completed, the stay sutures at the commissures are placed through the prosthesis and pulled gently. The tissue rims from the excised sinuses of Valsalva are then reimplanted into the vascular prosthesis by using continuous 4/0 thread. The surgeon starts at the bottom of the sinus and sutures toward the commissures (■ Fig. 27.13). The suture lines that meet up are tied together outside of the prosthesis above the commissures, likewise the stay sutures at the commissures. Now the patency of the valve can be checked by performing a «water test.» Subsequently the coronary ostia are reimplanted into the neocoronary sinus, in correspondence to the procedure for infracoronary ascending aorta replacement. Depending on the intraoperative findings, the distal part of the prosthesis is anastomosed to the distal aorta by using

■ **Fig. 27.12** To anchor the vascular prosthesis up to 12 double-armed polyester sutures are placed transmurally in an outward direction from the horizontal subvalvular level of the left ventricle

either a prothesio-aortic or prothesio-prosthetic technique. Before the patient is weaned from the extracorporeal circulation, valve function should be checked by transesophageal echocardiography.

27.2.4.3 Modifications of the Reimplantation Method

The aforementioned reimplantation method corresponds to the technique originally suggested by David (the so-called David-I method; David and Feindel 1992). Since then various modifications of the original method have been recommended, which should largely enable the surgeon to reconstruct the aortic root more physiologically. David himself uses a vascular prosthesis that exceeds the vessel dimensions by up to 5 mm, whereby a neosinus is created as a result of plication when it is being anchored to the base of the aorta (David et al. 2007). Miller generates neosinuses by creating multiple plications while implanting the vascular prosthesis (Demers and Miller 2004).

De Paulis developed a special vascular prosthesis with prefabricated neo-aortic bulb (De Paulis et al. 2000). Experimental and clinical studies have shown that, after reimplantation of the native valve into a prosthesis with a prefabricated neosinus, the physiological behavior of the valve is better than after using the David-I method (Aybek et al. 2005; De Paulis et al. 2002). To what extent this phenomenon is relevant for long-term function after aortic valve reimplantation as compared to the David-I method, however, remains to be seen.

■ **Fig. 27.13** The commissures are suspended in the prosthesis under mild tension of the stay sutures, and the rims of tissue from the excised sinuses of Valsalva are reimplanted in the vascular prosthesis

27.2.5 Complications

The most important complication of proximal aortic replacement is *hemorrhage* that cannot be controlled. While bleeding from a distal prothesio-aortic anastomosis can usually be taken care of without major problems by additional reinforced sutures, more extensive bleeding from a proximal anastomosis or from a coronary anastomosis can be fatal. If more extensive bleeding develops in these areas in spite of the aforementioned measures, it is best to open the ascending prosthesis longitudinally after re-clamping the aorta. In this way, sufficient access is gained to both the distant part of the aortic sutures and also to the coronary anastomoses.

Should intraoperative echocardiography show pronounced regurgitation after reconstruction, the aortic valve should be replaced. Upon renewed cross-clamping of the aorta, the prothesio-aortic anastomosis is opened, or in case of a longer ascending aorta prosthesis, the tube may be transected above the reimplanted commissures. To gain a better overview of the aortic root, another incision can be made into the vascular prosthesis toward the base of the noncoronary neosinus. During repeat cardioplegia, the valve cusps are resected and a heart valve prosthesis is anchored into the native anulus by using standard technique.

27.3 Dissection of the Ascending Aorta

27.3.1 Diagnosis and Indications

Combining 963 patients from six available natural history series for acute type A aortic dissection, mortality was 18% within 15 min, 22% within 6 h, and 38% at 24 h. After 48 h, 50% of these patients were dead. Another 20% died within the next 5 days, and after 2 weeks, survival was only 20% (Anagnostopoulos et al. 1972). Acute type A aortic dissection represents one of the most urgent indications for cardiovascular surgery. The still substantial perioperative mortality even in experienced hands (De Bakey et al. 1982) demonstrate, on the one hand, just how threatening acute dissection was and, on the other, that technical surgical problems still exist which have not been resolved even today (Bachet et al. 1999; Fann et al. 1995; Hagan et al. 2000; Kallenbach et al. 2004; Krüger et al. 2012; Safi et al. 1998a). Diagnosis can be confirmed both echocardiographically and with contrast-enhanced computed tomography (CT), identifying a dissection membrane in the ascending aorta. Moreover, CT can provide information concerning the extent of the dissection and the resulting malperfusion pathology. Magnetic resonance imaging (MRI) is not indicated for reasons of effort involved and the duration of the examination in an emergency situation such as this.

In our hands, only patients with signs of most severe cerebral damage are excluded from surgery, but operation is not contraindicated in those individuals with more discrete neurological deficits. Other ischemic complications at any site do not constitute a contraindication for emergency surgery, nor do continuing resuscitation measures as long as adequate circulation can be maintained until the patient can be connected to extracorporeal circulation. Chronic dissection is diagnosed like any aneurysm of the proximal aorta and includes, under elective conditions, MRI or high-resolution, contrast-enhanced CT. In elderly patients, the coronary status should be determined preoperatively, preferably by angiography. Goals of surgery include preventing aortic rupture, repairing aortic insufficiency, and – not rarely – resolving ischemic complications in peripheral organs and the heart (■ Fig. 27.14).

27.3.2 Access and Extracorporeal Circulation

Sternotomy, establishment of extracorporeal circulation, myocardial protection with cardioplegia, and drainage of the left ventricle comprise conventional treatment principles as outlined for aneurysm procedures (see ► Sect. 27.2.1, «Access and Extracorporeal Circulation»). To prevent embolism or malperfusion, we prefer a site for arterial cannulation that can be perfused antegradely. The right axillary artery is suitable for cannulation via an end-to-side vascular prosthetic anastomosis for vessels of a small diameter (Reuthebuch et al. 2004). The advantages of this technique lie in the option of using the usually nondissected innominate artery for perfusion. Later, antegrade cerebral perfusion can be facilitated via this access.

Alternatively the dissected ascending aorta or the proximal arch segment can be cannulated directly (Minatoya et al. 2003). Vessels should be punctured under echocardiographic control to ensure that the tip of the perfusion cannula is positioned in the true lumen.

For retrograde perfusion the femoral artery is cannulated, whereby in rare cases of a residual dissection at this level, intubation of the true lumen should be attempted.

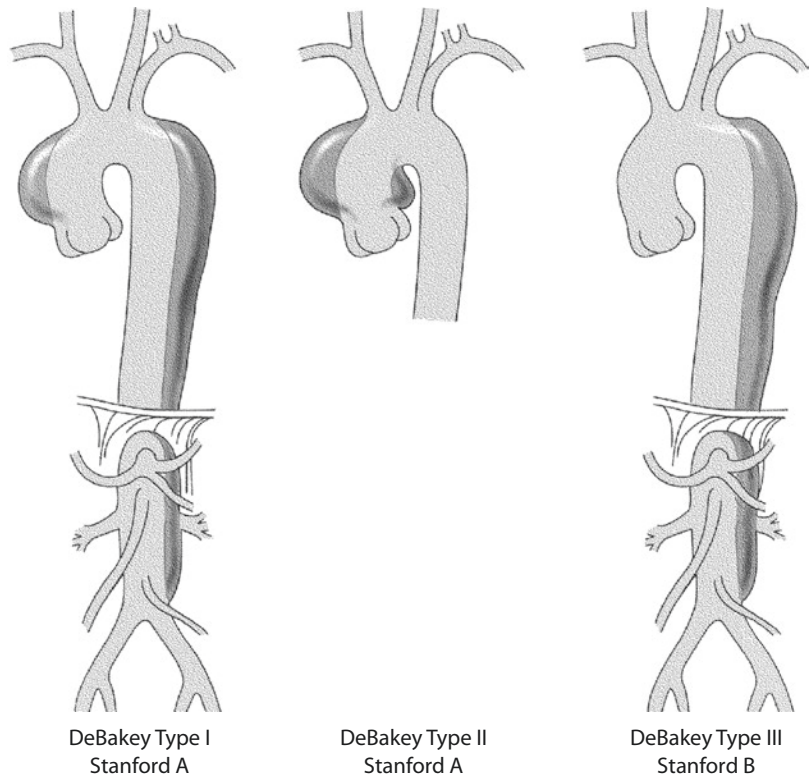

Various cannulation sites are available for acute aortic dissection type A, all associated with advantages and drawbacks (Tiwari et al. 2010). Primary goal of any cannulation must be safe perfusion of the true lumen.

For all types of cannulation, pressure must be measured in one femoral artery and in the right radial artery so that any deficient perfusion of the true aortic lumen is most probably detected in time (see ► Sect. 27.3.6, «Complications»).

Moreover, it has proven to be helpful to intraoperatively monitor cerebral oxygen saturation in both brain hemispheres, particularly during the phase of circulatory arrest with or without selective antegrade cerebral perfusion (Orihashi et al. 2004).

As soon as the extracorporeal bypass has completely taken over the patient's circulation, the aorta is mobilized at the level of the pericardial reflection

■ **Fig. 27.14** Classification of acute aortic dissection by DeBakey and by the Stanford classification

in order to enable clamping the vessel as rapidly and as high as possible when ventricular fibrillation during cooling ensues. By using wide clamps for gentle occlusion and careful closure of the branches, breakage of the damaged aortic wall can be avoided. To completely exclude this risk, the «no clamp technique» is recommended, particularly in cases of acute dissection. Here, the surgeon refrains altogether from cross-clamping the aorta. Instead, the patient's body temperature is cooled to a hypothermic level, and the aorta is only opened when circulatory arrest has been induced (Bavaria et al. 1996). In this case, it is essential that the left ventricle is sufficiently decompressed during cooling.

27.3.3 Selecting a Surgical Technique

Without pronounced anuloaortic ectasia present, the standard procedure for the ascending aorta is replacement associated with downstream resection or reconstruction of the dissected wall layers. The surgical method chosen for the area of the aortic root depends on whether the aortic valve

can be spared/repared or needs to be replaced. A stable result can be achieved for acute dissection and normal aortic sinus morphology by resuspending the commissures and gluing the dissection membrane in the base of the aorta. Then, the supracommissural ascending part of the vessel is replaced. However, reports of late postoperative redissection of the aortic root call the value of this procedure into question, particularly in younger patients (De Paulis et al. 2005; Fukunaga et al. 1999). Nowadays, we only perform this operation as an exceptional procedure in very elderly patients. Our routine approach is to resect the entire dissected aortic wall except for the commissural segment with the valve cusps attached. In most instances, the aortic valve may be preserved by using the technique described by David – irrespective of the diameter of the aortic root (Kallenbach et al. 2004).

The base of the aorta needs to be replaced with a composite graft if the aortic root is ectatic and the aortic valve shows pronounced pathological changes. For older patients, implants with a biological heart valve prosthesis are available. Individualized composite grafts can also be

crafted intraoperatively from a biological heart valve and a Dacron graft in relatively little time.

In patients with Marfan syndrome and in patients with anuloaortic ectasia typical for chronic dissection as well as in acute dissection occurring in an ectatic aorta, combined replacement of the ascending aorta and valve with a composite graft is *one* option. Here, too, valve-sparing reimplantation techniques, especially in younger patients with Marfan syndrome, lead to durable results (Karck et al. 2004).

We perform a revision of the arch (under circulatory arrest and moderate hypothermia with selective antegrade cerebral perfusion) in all aortic dissections of type Stanford A and in aneurysmatic aortic arch (Hagl et al. 2002; Kamiya et al. 2007). The extent of revision depends on the vessel diameter and the dissection pathology in the aortic arch. We only deviate from this procedure for those rare cases of DeBakey's type II aortic dissection if the dissection in the distal ascending segment can be resected completely without opening the aortic arch.

27.3.4 Acute Type A Dissection

On extracorporeal circulation with the aorta cross-clamped, the ascending aorta, actually the false lumen, is opened lengthwise via the thin-walled adventitia that has been separated from the two inner wall layers by the dissection. The whitish, thicker wall of the true lumen, the dissection membrane as seen in imaging, can then be recognized, which usually incorporates the proximal «entry» a few centimeters upstream of the aortic valve (■ Fig. 27.15). The presence of an abundant accumulation of thrombi in the proximal pocket of the dissection indicates a distal site of the proximal tear. The aorta is then completely transected through all layers of the wall about 5 mm downstream of the aortic valve commissures and resected up to a few millimeters of the aortic clamp. Aortic valve and coronary ostia can then be viewed well. Cardioplegia solution is infused, which according to the condition of the coronary ostia is administered antegradely via the ostia or retrogradely via the coronary sinus after inserting a perfusion catheter.

Subsequent assessment of the condition of the aortic root determines the further proce-

■ Fig. 27.15 Aortotomy for acute dissection. The ascending aorta was opened with a hockey stick-shaped incision. The proximal «entry» lies in the wall of the true lumen

The two coronary ostia must be examined carefully before intubation especially because the right coronary artery is occasionally involved in the dissection or even shows an «entry.»

dure. If the geometry and structure of the aortic sinuses speak for the reimplantation method, the aortic root is mobilized from outside in a proximal direction toward the base of the aorta (see ► Sect. 27.2.4.2, «Reimplantation of the Aortic Valve»). Should the dissection extend to that point, the adventitia is usually imbibed with blood. Nonetheless, it should remain intact during this preparation step if at all possible, as it is needed later to stabilize the line of sutures when reimplanting the aortic root into the vascular prosthesis. The two coronary ostia including the adventitia are then excised in trumpet shape from the aortic wall and held aside. The operation then proceeds like that for a nondissected aortic root, whereby in an acute dissection, the tissue is considerably more fragile.

If the surgeon has decided to reconstruct the dissected aortic root as a whole, it only needs to be dissected as necessary for further management – possibly sparing the adventitia entirely (■ Fig. 27.16). The goal of the reconstruction is to rejoin the dissected layers of the aortic wall. For

this, biocompatible glues (gelatin-resorcin-formaldehyde glue; Bioglue^R, Cryolife) can be applied or the aortic wall layers are merged together by continuous suturing and reinforcement with one or more Teflon^R felt strips.

If gelatin-resorcin-formaldehyde glue is used, the false lumen, which often can only be followed in the noncoronary sinus up to the base of the aorta, is sparingly filled with both glue components. Subsequently, the dissected wall layers are adapted under moderate pressure; here, special clamps should be employed (Borst fixation clamp, Aesculap, Art.-Nr. FB940R; **■** Fig. 27.17). Once the tissue-impregnating glue has hardened, the clamps are removed; the base of the aorta reconstructed in this way now has a leather-like consistency and can be anastomosed to a vascular prosthesis of the same diameter.

If Bioglue is used, the Borst fixation clamp should not be applied because its effect – which is different from that of the gelatin-resorcin-formaldehyde glue – is mediated merely by gluing the tissue without impregnating it. Before gluing was widely introduced into clinical use, a

different technique was commonly employed to reconstruct the aortic root. Starting in the posterior aspect of the aorta, the dissected layers at the level of the commissures were joined together by using continuous 3/0 mattress sutures. Here the vessel is reinforced on the outside with a Teflon felt strip and between the dissected layers with a second strip (**■** Fig. 27.18). If the dissected wall of the true lumen is fragile, it may be advantageous to reinforce the suture rejoining the aorta with a third Teflon^R felt strip inside the lumen. It is advisable to end mattress suturing at the zenith of the aorta. Before pulling the suture, an abundant amount of fibrin glue is inserted in the sinus pocket of the dissection in order to completely

■ Fig. 27.16 Reconstruction of the aortic valve and ascending aorta after acute dissection. The aorta is completely transected only a few millimeters downstream of the valve commissures

■ Fig. 27.17 Borst fixation clamp for adapting the dissected wall layers employing gelatin-resorcin-formaldehyde glue

■ Fig. 27.18 As an alternative to tissue gluing the dissected portions of the aortic wall are joined together distally and proximally by using continuous mattress sutures slightly distal to the valve commissures, whereby Teflon felt strips are used to reinforce the outer layer and between the wall layers of the aorta. The residual pericardial sinuses of the dissection can be obliterated by loading them with fibrin glue. The aortic valve commissures (usually the noncoronary sinus) that have been frayed from the dissection are resuspended by placing reinforced mattress sutures across the wall. The dissected layers of the wall are reapproximated distally in a similar fashion

obliterate it as it is very difficult to stop any bleeding that develops upstream from the reconstruction zone. Then the suture, which serves exclusively to join the wall layers together, is tied. It should not be pulled too tightly such that the aortic wall breaks or a purse-string effect is produced. For aortic valve reconstruction, the commissures that have now been raised into their normal position are each secured additionally with a transmural 4/0 mattress suture.

If the dissection involves the right or more rarely the left coronary ostium, the layers of the wall of the respective circumference of the ostium first need to be joined together by continuous everting 5/0 stitches. If one of the coronary arteries has been completely torn off its ostium and the vessel lumen is large enough, the surgeon should at least attempt a circular reapproximation by suturing out through the ostium using continuous 6/0 sutures, grasping the torn coronary artery together with the adventitia of the aorta and sewing them together (■ Fig. 27.19). If the ostium is small, a coronary bypass will likely be unavoidable (Kawahito et al. 2003; Neri et al. 2001). For this, the surgeon inserts a probe into the right coronary

artery in order to search for the vessel just outside the aorta and to ligate it proximally. The (venous) bypass is placed end to side with the coronary vessel just beyond the ligature. This type of procedure inevitably requires an ascending aorta replacement in order to gain a base for the bypass vessel unless a mammary artery bypass is employed.

The distal wall is reconstructed mostly in the same way as has been described for the base of the aorta. We only deviate from this procedure in selected patients who present with dilated descending aortas or malperfusion caused by compression of the true lumen. In these patients, it may be better to use the elephant trunk technique and its variations – also by employing novel implants with integrated vascular stents. This technique is dealt with in ► Sect. 27.4.5, «Total Aortic Arch Replacement Using the Elephant Trunk Prosthesis».

27.3.5 Chronic Type A Dissection

Repairing the base of the aorta for chronic dissection type A is only slightly different from ascend-

■ Fig. 27.19 a, b Reconstructing a dissected right coronary ostium. a The margin of the coronary artery that is partially or entirely torn out of the wall of the true lumen of the aorta is grasped by a 5/0 suture sewn from inside out and rejoined with the orifice in the aortic wall. b After the ostium has been reconstructed, the dissected portions of the wall are connected by sewing around the distant circumference of the ostium

ing aorta replacement in primary anuloaortic ectasia. Owing to the underlying degenerative aortic disease, we prefer in both situations to radically eliminate the aortic wall and sinus. If the aortic valve can be spared, we use a Dacron tube (David's method). If the valve has to be replaced, also, we rather use a composite graft than replacing the ascending aorta segment and the aortic valve separately. Surgical preparation for proximal implantation of the Dacron prosthesis or of the composite graft involves radically excising the floating parts of the wall of the false lumen and sparing a 10-mm-long cuff upstream of the aortic occlusion clamp.

If the aortic valve was previously damaged and the surgeon decides to replace the valve, the composite graft is first anchored in the aortic anulus. Then, the coronary ostia are implanted in the corresponding hole of the prosthetic ascending segment, as performed in conjunction with the procedure for true aneurysm ► Sect. 27.2.3.2, «Combined Replacement/Composite Graft». Only for tears of the inner aortic wall near the coronary ostia, the torn edges of the adventitia need to be fixated by using continuous 5/0 prolene sutures so that the affected ostium can be anastomosed. Reinforcing this suture line with Teflon felt strips is usually not necessary because of the scarred, consolidated outer vessel wall.

If surgical fenestration of the aorta is required, we explicitly advise against opening the aorta through the fragile wall of the false lumen. Closing the aortic wall at a dissected site is very difficult to manage successfully.

Distally, the dissected aortic wall layers are generally joined in the aortic arch segment, similarly to the procedure for acute dissection. However, tissue gluing here is not effective because the wall layers are frequently completely fibrotically remodeled. It is thus usually sufficient to place a continuous mattress suture to join the wall and reinforce it on the outside with Teflon felt strips. The distal prosthesis-aortic anastomosis is established by widely grasping the firm, opposing side that has been created in this way by using continuous everting 3/0 or 4/0 sutures.

27.3.6 Complications

Changes in the aortic blood stream primarily caused by the dissection or secondarily related to surgery can cause characteristic disorders that must be managed. If the dissection has caused regional compression of the true aortic lumen and/or large vessel branches, organ perfusion needs to be restored. Ischemia of the visceral tissues or lower extremities can spontaneously resolve if antegrade perfusion through the true lumen is restored proximally at dissection repair. For acute dissections, it may be helpful to inspect the abdominal cavity by extending the sternotomy somewhat to detect any persisting visceral malperfusion. If ischemia does persist, intervention – aortic fenestration – may be required immediately after diagnosis (e.g., anuria, no femoral pulse). This can be performed in an open surgical procedure or an intervention by introducing a transfemoral catheter. The catheter-guided technique is less traumatic and thus better. If this is not successful because the resulting window is not large enough, the surgeon can attempt to alleviate the malperfusion by implanting a stent or endovascular prosthesis in the true lumen of the descending aorta (Chavan et al. 2003).

If surgical treatment is decided upon for visceral or renal ischemia, the surgeon dissects the infrarenal aorta as far as needed via a left-lateral extraperitoneal access so that the aorta can be double clamped gently for a length of about 4 cm. A faster access would be the transabdominal route to the infrarenal aorta. Here, a nondissected strip of the aortic wall needs to be identified and incised along the available length of the vessel. The nondissected part of the aortic circumference is identified by its white color as opposed to the blue or even dark red-blue dissection. Then a window as large as possible is cut out of the membrane on the opposite side that separates the true and false lumen so that the lumina can communicate with each other. The aortotomy can usually be sutured with no difficulties, as the suture is in the nondissected part of the aortic wall.

For ischemia of the extremities, the surgeon can make a blind attempt to fenestrate the dissection membrane. However, an x-ray-guided transfemoral

Fogarty maneuver should be preferred. When withdrawing the catheter, the desired communication between the two lumina is established. If this attempt is not successful, fenestration can be achieved through the external iliac artery exposed retroperitoneally.

A dangerous complication associated with femoral arterial cannulation is compression of the true lumen of the aortic arch and/or its side branches. This may result in severe malperfusion of the brain. If this is not detected, permanent neurological deficits can develop, including decerebration. A typical sign of this complication is an acute drop in perfusion pressure, as measured in the right radial artery, while the values measured in the femoral artery at the onset of extracorporeal perfusion would be high. This is the reason why surgery for acute aortic dissection both the right radial and one femoral artery pressure has to be monitored continuously and simultaneously. Permanent intraoperative monitoring of cerebral oxygen saturation in both brain hemispheres also helps to identify this complication, by showing a rapid drop in saturation. If the cerebral oxygen saturation is constantly normal, an isolated temporary decrease in right radial arterial pressure can be ignored.

Immediate measures can involve reinstatement of spontaneous circulation in the patient, whereby normal pressure signals are restored in the arms and legs. Robicsek (1985) made some useful suggestions for resolving such an event.

Another option is to reduce the patient's body temperature first under partial extracorporeal circulation and when ventricular fibrillation ensues (also electrically induced) to cannulate the true lumen of the aortic arch by transapical cannulation with an additional arterial line. Under these perfusion conditions, the patient's body temperature is lowered to a nasopharyngeal temperature of $<20^{\circ}\text{C}$ to stop the circulation. In this phase, the first steps are undertaken to reconstruct or replace the base of the aorta. Under circulatory arrest, the proximal aortic arch is replaced. Subsequently, the distal prosthesis clamped toward the heart is cannulated with the arterial perfusion catheter so that subsequent surgery on the proximal aorta can be performed, while rewarming is initiated by orthograde circulation.

27.4 Aneurysms and Dissection of the Aortic Arch

Aortic arch aneurysms are those aneurysms between the takeoff of the innominate artery and the left subclavian artery. They may be either restricted to the proximal or the distal segment, or more often they affect the entire arch and also the neighboring ascending aorta, less often the descending aorta. The vessels supplying the head and arms can also be involved, especially in aortic dissection. To protect the brain and the heart, a considerable degree of practical planning and refined technique are required in repairing such aneurysms. As initially mentioned, the aortic arch is usually replaced in an orthotopic manner, under circulatory arrest in deep or moderate hypothermia with selective perfusion of at least one cerebral hemisphere. The variants of proximal, subtotal, and complete aortic arch replacement are presented in  Fig. 27.20. For distal aortic arch replacement, see also  Sect. 27.4.6, «Distal Aortic Arch Replacement», Fig. 27.30.

By applying new treatment strategies, the diseased aortic arch can be successfully excluded by both transposing the supra-aortic branches and implanting an endovascular prosthesis without using extracorporeal circulation (Kotelis et al. 2011; Schumacher et al. 2003). Whether perioperative risk and long-term surgical outcome are better for this extra-anatomical reconstruction procedure than for orthotopic techniques under extracorporeal circulation remains to be seen.

27.4.1 Access and Extracorporeal Circulation

A *median sternotomy* is always used to access the aorta for aneurysms and dissections that do not extend beyond the aortic arch. It allows for combined replacement of both ascending aorta and aortic arch. Usually either the distal ascending aorta or even the aortic arch can be cannulated so that antegrade perfusion can be initiated directly when starting extracorporeal circulation. If the ascending aorta is adherent to the sternum, which may occur after previous sternotomy, the surgeon should proceed as described in  Sect. 27.5, «Reoperations».

Fig. 27.20 a–c Variants for aortic arch replacement. **a** Proximal arch replacement, sparing the supra-aortic vessels beyond the distal prosthesis-aortic arch anastomosis. **b** Subtotal arch replacement, sparing the left subclavian artery beyond the prosthesis-aortic arch anastomosis. The right arch branches are implanted into a window at the zenith of the prosthesis. **c** Total arch replacement. The prosthesis-aortic anastomosis lies distal to the branch of the left subclavian artery, namely, distal to the arch. All arch branches are implanted in one window

Normally it is possible to insert a large-lumen two-stage venous cannula into the right auricle to completely drain the systemic venous return and fully bypass and take over the heart's function. In most cases, bicaval cannulation is not required for total extracorporeal circulation. For procedures involving the aortic root and in particular for aortic valve insufficiency, a left ventricular suction catheter should be inserted.

Aneurysms of the entire arch affecting the descending aorta also can be surgically treated via median sternotomy if a secure prosthesis-aortic anastomosis cranial to the left pulmonary hilus can be established, that is, if no more than the proximal 4 cm of the descending segment are to be replaced. Alternatively a vascular prosthesis reinforced with a stent on the distal end can be implanted into the descending aorta via the opened aortic arch for exclusion of the distal part of the aneurysm («frozen elephant trunk,» hybrid prosthesis; Karck et al. 2003; Orihashi et al. 2001).

Otherwise, a two-step procedure is recommended, whereby the size of the aneurysm and the relative risk of rupture determine which comes first. Combined replacement of the aortic arch and the descending aorta via sternotomy is difficult because of the great depth of the surgical field and the left pulmonary root that is in the way. If the surgeon still decides for this procedure, however, we recommend selecting a clamshell access (Kouchoukos et al. 2007). Alternatively, at least aneurysms of the

median and distal arch can be repaired together with the descending aorta via a left thoracotomy (see ► Sect. 27.4.6.1, «Surgical Access»).

Management of the extracorporeal circulation needs to be closely coordinated with the anesthesiologist, owing to the sometimes long duration of the cooling and warming phases during surgery and also especially in regard to intraoperative neuro-monitoring. For aortic insufficiency, the aorta is occluded when ventricular fibrillation ensues; otherwise, the decompressed heart is allowed to fibrillate until the target temperature has been reached. Circulatory arrest is induced after an at least 30-min cooling period to a hypothermia level of 26 °C temperature both in the urinary bladder and nasopharyngeal. The temperature of the heart is maintained at <15 °C by repeatedly infusing cardioplegic solution and pericardial cooling. An additional neuro-protective effect is achieved during circulatory arrest by applying external cool packs to the head, which should avoid rewarming by ambient temperature. After opening the aortic arch, we begin with selective perfusion of the brain. Here, 26 °C arterial-ized blood is infused into the innominate artery and the left carotid artery via a perfusion catheter and a roller pump (flow volume: 10 ml/kg body weight/min) (Bachet et al. 1991; Frist et al. 1986; Hagl et al. 2002; Strauch et al. 2003). The left subclavian artery is clamped or intubated with an occlusion catheter (► Fig. 27.21). For selective cerebral perfusion, we prefer employing self-occluding balloon catheters as

■ **Fig. 27.21** Selective perfusion of the brain during aortic arch replacement. In order to shorten the duration of total circulatory arrest, the innominate artery and the left carotid artery can be intubated from the arch lumen and perfused. The left subclavian artery is occluded here with a Fogarty catheter

used for retrograde administration of cardioplegic solution. We perform the entire arch procedure under these conditions – irrespective of the extent of the arch replacement – with the body under circulatory arrest but brain circulation maintained. In our experience and as a general rule, the entire aortic arch replacement procedure takes between 40 and 60 min, for proximal replacement only 15–25 min; thus, lowering the temperature during circulatory arrest to 26–28 °C suffices. If deep hypothermic circulatory arrest has to be instituted without selective cerebral perfusion for >15 min, nasopharyngeal temperatures of <20 °C, better 16–18 °C, are required.

During the rewarming phase, the perfusionist ensures that the water temperature in the heat exchanger does not exceed the arterial blood temperature by more than 6–8 °C so as to prevent gas bubbles from pearling from the oversaturated blood. The anesthesiologist compensates the omnipresent, more or less pronounced acidosis in a stepwise fashion. Administration of vasodilators facilitates homogenous rewarming of the body.

27.4.2 Ascending Aorta: Decision Making

After connecting the patient to extracorporeal circulation, the next step involves further mobilizing and then clamping the ascending aorta, which is

often adherent. The aortic arch is dissected free at its ventral aspect as far as needed, always remaining close to the aortic wall. Injury to phrenic, vagus, and laryngeal recurrent nerves must be avoided. During the cooling phase, the surgeon can begin with the ascending aorta and valve procedure, which later on can be completed during the more time-consuming rewarming phase. As soon as the desired target temperature has been reached, perfusion is stopped. During circulatory arrest, the patient should be kept in a moderate Trendelenburg position to reduce the risk of cerebral air embolism. The head lies below the level of the surgical field; in this way, a certain fluid level is maintained in the supra-aortic branches reaching the arch. The aortic arch is incised from the ascending segment as far as necessary for reconstruction, in extreme cases even beyond the arterial ligament.

At this point, active measures are taken to protect the brain; here we apply selective cerebral perfusion via the first two aortic arch branches (see ► Sect. 27.4.1, «Access and Extracorporeal Circulation»). It may be helpful to first loop these vessels because it is then easier to maintain the position of the perfusion catheter during lengthy procedures.

If extracorporeal circulation is established through arterial perfusion via the right axillary artery, the cerebrum can also be perfused via this route as an alternative, whereby the innominate artery is then clamped near the branch or blocked with an occlusion catheter. It is advisable under these conditions to intubate the left carotid artery separately in order to ensure that both brain hemispheres are supplied with blood.

If, however, the surgeon decides for retrograde cerebral perfusion, the venous drainage catheters in the superior vena cava should first be reconnected to the arterial line of the extracorporeal circulation. This technique requires bicaval cannulation for extracorporeal circulation.

Now, the surgeon needs to determine the kind and extent of aortic replacement. In principle, the line of the prosthesis-aortic anastomosis needs to lie far enough distally so that it can be sutured to an intact segment of aortic wall. For atherosclerotic aneurysms, this is often only possible after plaques and atheromas have been completely debrided. They must be removed by targeted suction and lavage of the arch including the origin of the supra-aortic vessels. For aneurysms, the distal prosthesis-aortic anastomosis is placed

There are four options for protecting the brain during circulatory arrest:

- Deep hypothermia (nasopharyngeal temperature of 16–18 °C)
- Deep hypothermia combined with retrograde cerebral perfusion
- Deep hypothermia with selective antegrade cerebral perfusion
- Moderate hypothermia of 26–28 °C (depending on the duration of circulatory arrest) with selective antegrade cerebral perfusion

Although the evidence is still questionable, we prefer selective antegrade cerebral perfusion under moderate hypothermia even for complete arch replacement up to 60 min and more. One great advantage of this technique lies in the shorter warming period and avoiding very low core body temperatures, which can promote clotting disorders and systemic inflammatory reactions. We also employ this technique for procedures at the proximal aortic arch, which usually require shorter periods of circulatory arrest. For this, we use the self-occluding balloon catheter for cerebral perfusion that was developed originally for retrograde cardioplegia (RSCP MR 20, 15F, Medtronic, Minneapolis, USA).

beyond the dilated segment of aorta where the intima is usually intact. The surgeon can often successfully create a beveled anastomosis in the arch so that the supra-aortic vessels do not need to be joined to the arch prosthesis separately. Notably, one should anastomose the bases of one, two, or all three vessels with one window that is created at the convexity of the arch prosthesis (subtotal or total arch replacement). As an alternative to this technique, special vascular prostheses with prefabricated side branches are available for attaching each individual supra-aortic vessel. Kazui and colleagues have gained substantial experience in using these implants, particularly in conjunction with selective antegrade cerebral perfusion (Kazui et al. 2007).

After finishing the arch replacement, the vascular prosthesis is cannulated with the arterial

When a core body temperature of 26 °C has been reached after a least 30 min of cooling (measured both in the urinary bladder and nasopharyngeally), the extracorporeal circulation is stopped and the aortic clamp opened; in addition, the supra-aortic vessels are exposed. After intubating the innominate artery and the left common carotid artery, the catheters are blocked carefully using balloons and shifted cranially out of the surgical field. Via a separate roller pump on the heart-lung machine, cold, oxygenated blood at 26 °C is infused at a rate of 10 ml/kg body weight/min, which should produce a perfusion pressure (measured in the right radial artery) of 40–60 mmHg. The perfusion cannulas are removed just before completing the aortic anastomosis. Then, extracorporeal circulation is reestablished, so that the brain has only been without selective perfusion for a few minutes during circulatory arrest. With this technique, the duration of circulatory arrest of >90 min can be tolerated without increasing the rate of neurological complications (Kazui et al. 2007).

perfusion catheter. Now perfusion is resumed, whereby the patient remains in Trendelenburg position. While the prosthesis is filling, any residual air is expelled from the supra-aortic vessels by careful digital or instrumental manipulation. Subsequently, the prosthesis is clamped proximally and the rewarming process is initiated. Any anastomotic bleeding is stopped by placing reinforced mattress sutures at the source.

27.4.3 Aortic Arch Replacement for Aneurysms

27.4.3.1 Proximal Replacement

A proximal, partial aortic arch replacement is recommended as a complementary step while repairing extensive ascending aorta aneurysms, particularly in patients with dissections (Ohtsubo et al. 2002). We always do this when the ascending aorta is dilated well beyond the level of the occlusion clamp that is always placed immediately proximal to the brachiocephalic trunk. After opening

the aortic arch and initiating selective antegrade cerebral perfusion, a prosthesis is selected whose diameter corresponds to that of the aortic lumen. The tube graft is trimmed and beveled such that the aneurysmatic part of the arch can be completely replaced upstream of the selected anastomotic line. Complete resection of the aneurysm often helps to create a primary, blood-tight suture line by anastomosing end to end for the entire length. The anastomosis is started at the deepest point of the surgical field in the concavity of the arch with a row of initially open stitches (3/0 sutures, continuous everting). The stitches are then placed along the dorsal and ventral circumference of the aorta until they meet up directly to the right of the innominate artery. If this vessel is also dilated due to aneurysm, we recommend anastomosing its distal segment to an 8-mm prosthesis end to end before initiating hypothermic circulatory arrest and joining this to the arch prosthesis later.

After expelling the air from the arch, the proximal anastomosis is created directly above the commissures. If the ascending aorta is being replaced at the same time, the prosthetic stumps are anastomosed in end-to-end fashion.

27.4.3.2 Subtotal and Total Replacement

After opening the arch and initiating antegrade cerebral perfusion, a prosthesis is selected whose diameter corresponds exactly to that of the aorta at the planned level of anastomosis. If possible, the connection should be established at the orifice of the descending aorta. Beginning at the deepest point of the planned line of anastomosis, the prosthesis and aorta are joined by placing several open turns of big bites using a running double-armed 3/0 sutures. Suturing is continued on both sides in the aortic lumen, pulling the threads at regular intervals, before ligating the sutures at the front. Please note that the suture line should run rather distal to the takeoff of the left subclavian artery, which facilitates the anastomosis to the arch prosthesis considerably. If the subclavian artery takeoff has a significant distance from the left carotid artery, it may sometimes be better to leave it outside the prosthetic graft, distal to the prosthesio-aortic anastomosis.

The next step involves excising an oval piece of prosthesis from the convexity of the arch graft that corresponds exactly with the branches of the vessels that will be anastomosed (■ Fig. 27.22). Their common base is then in turn anastomosed to the arch prosthesis with continuous and deep 3/0

sutures. Suturing begins directly distal of the branch of the artery that is farthest downstream and often involves the vessel itself. First, it is sewn dorsally from out of the prosthetic orifice, later continued at the front, and finally tied just this side of the innominate artery branch (■ Fig. 27.23).

During this procedure, it is sensible to insert a suction catheter into the descending aorta through

■ Fig. 27.22 Total arch replacement. Distal end of the prosthesis and orifice of the descending aorta have already been anastomosed end to end. The arch prosthesis is then sparingly fenestrated at its zenith across from the branches of the supra-aortic vessels. A sufficiently great distance between the distal prosthesio-aortic anastomosis and this window facilitates considerably anastomosing the island carrying the supra-aortic vessels with the window of the prosthesis

■ Fig. 27.23 Beginning at the distal point of the prosthetic window the dorsal margin of the island carrying the supra-aortic branches is anastomosed first

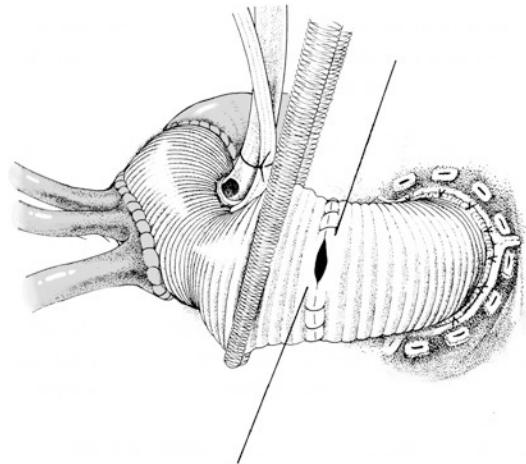

■ **Fig. 27.24** The anastomosis is completed. After de-airing the aorta and the supra-aortic vessels, the aortic prosthesis is clamped proximally. Any leakage can be identified and dealt with when the extracorporeal circulation is resumed

the prosthetic tube graft to keep the surgical field free of blood. After suturing is finished, the arch prosthesis is cannulated arterially, expelling air while initiating the extracorporeal circulation in a stepwise fashion, and then clamped proximal to the brachiocephalic trunk. At this point, the downstream parts of the body can be fully perfused and the rewarming process initiated (■ Fig. 27.24).

If the takeoff of the left subclavian artery lies very deep, we prefer excising the three aortic branch orifices from the aortic arch wall as tissue islands already at the outset. Thereafter, we dissect the descending aorta directly distal to the branch of the left subclavian artery over the entire circumference. By using this technique, we can establish the necessary mobility for being able to securely anastomose the vascular prosthesis to the descending aorta and then to the island carrying the supra-aortic branches.

Depending on the measures that need to be taken for repairing the ascending aorta, either the arch prosthesis is anastomosed to the supracommissural ascending aorta or to the remaining prosthetic reconstruction of the proximal segment of the aorta, here, too. In this case, upon lifting the heart and pulling the aortic clamp caudally, the

■ **Fig. 27.25** The proximal aorta has already been replaced. The arch and the proximal aortic prosthesis are anastomosed

two synthetic tube grafts are shortened considerably and beveled before joining together by using continuous sutures (■ Fig. 27.25). After de-airing the heart and releasing the cross-clamp from the aortic tube graft, there is enough time during the rewarming process to properly trim any remaining bits of the aneurysm and sew them tightly around the prosthesis, thereby supporting hemostasis.

27.4.4 Aortic Arch Replacement in Type A Dissection

Replacing the proximal and also the entire aortic arch in dissection follows the same principles that apply to the procedure for arch aneurysms in terms of access, extracorporeal circulation, and exposing the aorta. However, the procedure for *acute dissection* requires a far-reaching, technically difficult, and sometimes questionable reconstruction of the delicate and fragile vessel wall layers. If the dissection extends beyond the aortic occlusion clamp, then at least the proximal aortic arch needs to be replaced employing circulatory arrest. If upon inspection no «reentry» is visible in the aortic arch, and the wall of the aortic arch can be safely reconstructed by gluing the dissected layers or using a suitable suture technique alone, we only replace the proximal segment of the arch. In all other cases, the aortic arch needs to be replaced completely, possibly also including the proximal descending aorta, by using the («frozen») elephant trunk technique (Karck et al. 2003; Shiono et al. 2006).

The indications for arch replacement in *chronic dissection* correspond to those for aneurysms of other origins; however, even for arch segments of a normal caliber, an open revision procedure is required if the dissected intimal cylinder does not appear to be intact at the level of the aortic occlusion clamp.

■ ■ Surgical Technique

First extracorporeal circulation is initiated. For proximal arch replacement, the body temperature is cooled to 27–28 °C as measured both in the urinary bladder and nasopharyngeally; for total replacement, the body temperature is lowered to 26 °C. These target temperatures apply under the condition that the brain is still being protected by antegrade arterial perfusion during circulatory arrest. Without brain perfusion, the body temperature should be reduced to a deep hypothermic level first (16–18 °C nasopharyngeal or tympanic temperature). After ventricular fibrillation ensues, the distal ascending aorta is occluded by using a soft clamp, and the first steps are undertaken to replace the proximal aorta. Once the desired body temperature is reached, the aortic clamp is removed and the arch is opened – first only narrowly – by making an incision from the ascending aorta to determine the point at which the second (arch) prosthesis can be anastomosed. The aortic arch is then mobilized at least far enough beyond this point to create enough space to reinforce the site on the outside with Teflon felt strips where the anastomosis will later be established. Likewise, the proximal segments of the innominate artery and left carotid artery, possibly also of the left subclavian artery, are mobilized. The goal of reconstructing an acutely dissected aortic arch is to restore antegrade circulation of the true lumen of the arch, possibly also their branches, by joining the wall of the false lumen with that of the true lumen. For this, we use gelatin-resorcin-formaldehyde tissue glue, which is first allowed to harden after adapting the wall layers before the prosthesis-aortic anastomosis is established. Quite often additional reinforcement of the suture line with a Teflon felt strip is advisable (■ Fig. 27.26). It has proven useful in such situations to completely transect the aorta proximal to the innominate artery branch in order to then mobilize the arch and its vascular branches from the dorsal side. Alternatively and instead of gluing, the dissected layers of the aortic arch wall

■ Fig. 27.26 After applying the gelatin-resorcin-formaldehyde glue components into the false lumen, the resected wall layers are firmly adapted with Borst clamps

may be reconstructed by placing suture lines supported with one or more Teflon felt strips (Fleck et al. 2003; Sabik et al. 2000). Here, a vascular prosthesis that has been fashioned accordingly by beveling is anastomosed to the reconstructed aortic wall with continuous 3/0 everting sutures. In this case, the branches of the innominate artery, the left carotid artery, and the subclavian artery remain beyond this anastomosis. For total replacement of an acutely dissected aortic arch, the aortic wall layers must be stabilized enough to allow for a blood-tight anastomosis between the prosthesis and the distal aorta. First, we resect the dissected aortic arch in toto up to the descending aorta, sparing one tissue cuff that is bearing the supra-aortic branches. With regard to the stability of the anastomosis that will be created later, it is particularly important to entirely spare the adventitia of the descending aorta and the vascular cuff carrying the arch branches. Before establishing the prosthesis-aortic anastomosis, the dissected aortic wall downstream is joined by gluing the tissue or by using a reconstruction suture that is reinforced with felt strips. Alternatively, the prosthesis-aortic anastomosis can be established directly by using felt-armed sutures both on the outside and possibly also inside the aorta. Whenever possible, the aortic arch branches should be reconstructed with the aid of reinforced mattress sutures such that a common base is created for the subsequent anastomoses with the aortic arch prosthesis (■ Fig. 27.27). In contrast to acute arch dissection, in chronic dissection, it is usually not necessary and mostly not possible to rejoin the aortic wall layers because scar tissue has already formed on the adventitia of the aorta

■ **Fig. 27.27** The dissected aortic arch branches are reconstructed by suturing with the aid of Teflon felt strips

giving sufficient stabilization for direct suture. The floating segments of the dissection membrane are resected within the arch and, insofar as they can be viewed, into the descending aorta, also. If the dissection extends into the supra-aortic vessels, it is usually sufficient to join the wall layers of their orifices with non-reinforced, continuous everting sutures that are stitched from inside out of the arch lumen. Thereafter, their common base is anastomosed to the window in the convexity of the aortic arch prosthesis created for this purpose.

27.4.5 Total Aortic Arch Replacement Using the Elephant Trunk Prosthesis

For the successive replacement of the aortic arch and the descending aorta, Borst developed the so-called elephant trunk technique (Borst et al. 1983). In the course of a complete aortic arch replacement procedure via a median sternotomy, the distal end of a vascular prosthesis is pushed into the descending aorta, where it floats freely (■ Fig. 27.28a). In the second operation to repair the aneurysm of the descending aorta via a lateral thoracotomy, it is either anastomosed with native undiseased downstream aorta directly or to a second prosthesis, which, in the latter, allows com-

pletion of the repair far downstream. Crawford simplified the surgical procedure originally developed by Borst (Crawford et al. 1990): A segment of the distal end of the aortic arch prosthesis corresponding to the segment of the descending aorta that is to be replaced is invaginated. The free ends of the double-layered prosthesis thus created are pushed into the descending aorta. The distal aortic anastomosis is then completed between the folding edge of the prosthesis and the circumference of the descending aorta right distal of the origin of the left subclavian artery. Then the invaginated segment of the prosthesis, which was pushed into the descending aorta as an inner layer, is everted. In the past, the distal part of the trunk end that remained in the descending aorta was marked with metal clips. This is no longer necessary – and under certain circumstances even bothersome – thanks to today's advanced imaging techniques.

For patients with chronic dissection, it is important to excise or incise the floating wall far enough so that both lumina are perfused via the trunk prosthesis. In acute dissection, however, the elephant trunk prosthesis needs to be forwarded into the true lumen of the descending aorta only before sewing the circumferential anastomosis between all layers of the descending aorta and the invaginated prosthesis inside. The rest of the procedure at the aortic arch is performed using conventional aortic arch replacement technique (■ Fig. 27.28b).

In the meantime new types of vascular (hybrid) prostheses have become available, rendering a second procedure as required for the «elephant trunk technique» superfluous. A wire mesh is integrated in the distal segment of these prostheses to create a radial force within the vascular graft («frozen elephant trunk technique»). This variant enables alignment of the frozen elephant trunk segment to the inner wall of the descending aorta at a desired level thereby promoting thrombus formation within the perigraft space. The implant is inserted via the open aortic arch into the descending aorta by using a delivery system (■ Fig. 27.29). Further procedure is the same as for conventional «elephant trunk» technique (Karck et al. 2003). More recently, prostheses with sidearms were developed allowing for separately anastomosing the supra-aortic vessels to the frozen elephant trunk prosthesis. This strategy facilitates partial clamping of the aortic arch while the heart-lung machine is

■ **Fig. 27.28** a, b Preparation for descending aorta replacement while replacing the arch using the «elephant trunk technique.» a Already at the beginning of the arch replacement procedure the distal end of the aortic prosthesis is invaginated (according to Borst). The folding edge of the invaginated prosthesis is anastomosed with the proximal end of the descending aorta. Thereafter, the invaginated edge is pushed into the descending aorta with a long straight clamp. This trunk-shaped prosthesis now lies freely in the aneurysmatic descending aorta. b The supra-aortic vessels are then anastomosed to the arch prosthesis. The arterial perfusion cannula is finally transferred to the arch prosthesis

connected through a separate sidearm to the prosthesis, thus reducing the circulatory arrest time (Shrestha et al. 2016).

27.4.6 Distal Aortic Arch Replacement

27.4.6.1 Surgical Access

Acquired and congenital aneurysms can affect the distal aortic arch, usually in conjunction with the descending aorta. A type B dissection occasionally extends retrograde into the distal arch segment, only rarely as far as into the ascending aorta (Cipriano and Griep 1979). The goal of surgical treatment is to eliminate the affected aortic arch segment and segments of the descending or thoracoabdominal aorta via a left-lateral access. Typical variants of distal arch replacement are illustrated in ■ Fig. 27.30.

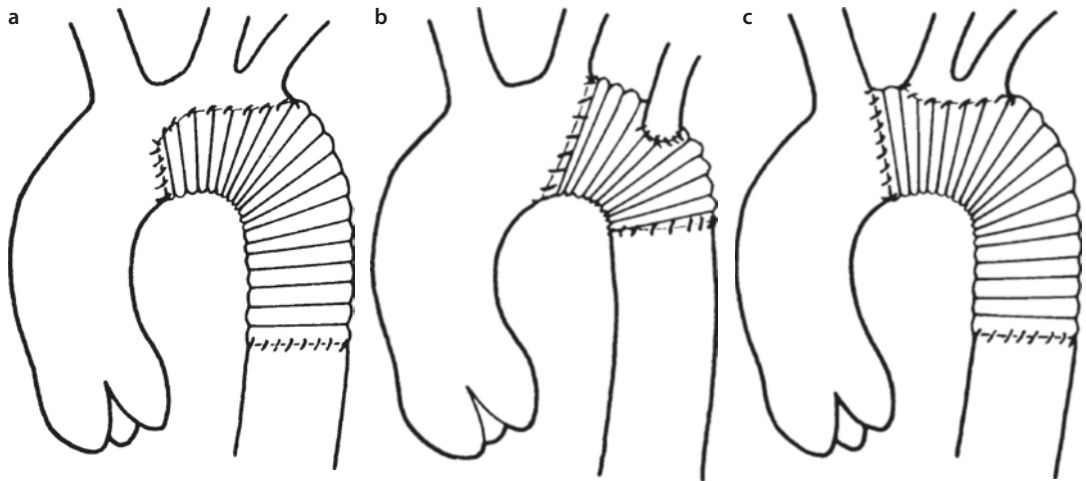

Normally, the chest is opened via a standard left posterolateral thoracotomy in the fourth intercostal space to gain unhindered access to the distal aortic arch, to the proximal descending aorta, and also to the heart. No compromises should be made concerning the height at which the chest is opened. For aortic aneurysms extending beyond the seventh intercostal space, it is advisable to perform a second thoracotomy below the seventh rib as well. The skin incision is planned to be correspondingly lower than for a solitary thoracotomy only. The second thoracotomy is undertaken out

■ **Fig. 27.29** The hybrid vascular prosthesis is inserted via the opened aortic arch into the descending aorta by using a delivery system. Further procedure for arch replacement remains unchanged

of the same skin incision before preparing the distal end point of the aortic repair. The anesthesiologist is responsible for ensuring that the left lung is collapsed for the entire duration of the procedure because the descending aorta can only be viewed without compressing the heart if the lungs are not in the way. The use of a «cell saver» is absolutely essential for these operations, which may involve a considerable amount of blood turnover and blood loss as well.

Crawford et al. (1987) proved it is possible to replace the entire aortic arch using a left-lateral

■ **Fig. 27.30** a–c Three variants of distal aortic arch replacement. **a** Beveled prosthesis-aortic anastomosis, which spares the arch vessels on the native aortic wall. **b** Prosthesis-aortic anastomosis directly distal to the branch of the left carotid artery; anastomosis of the left subclavian artery in the arch prosthesis. **c** Prosthesis-aortic anastomosis between the innominate artery and the left common carotid artery. Implantation of the common base of the common carotid and subclavian artery into a window of the arch prosthesis

access. More often, however, only the distal segment of the aortic arch with the branches of the left carotid artery and the left subclavian artery need to be replaced via this access (■ Fig. 27.30b, c).

27.4.6.2 Managing Intra- and Extracorporeal Circulation

After sufficiently exposing the aorta, the surgeon must decide whether to proceed under conditions of simple clamping of the aorta, under partial extracorporeal circulation (left ventricular bypass or femorofemoral bypass), or under deep hypothermia and circulatory arrest.

■ ■ Simple Aortic Clamping and Extracorporeal Circulation

In the past, individual authors emphatically propagated simple aortic clamping for distal aortic arch replacement, pointing to the advantages of not having to cannulate the aorta or to heparinize the patients. Indeed, the surgical mortality and risk of paraplegia did not seem to be significantly higher when compared to the use of extracorporeal circulation (Crawford et al. 1984; Hammerlijnk et al. 1989; Kay et al. 1986). Convincing evidence has been presented that perfusion of the distal descending and thoracoabdominal aorta through active circulatory bypass helps to minimize the risk of paraple-

gia – with the exception of emergency bleeding from a ruptured aneurysm (Girardi et al. 2005; Safi et al. 1998b; Schäfers et al. 1987; Schepens et al. 1999). Therefore, we perform these procedures with the patients completely heparinized and using the heart-lung machine for normothermic partial extracorporeal circulation. The perfusion cannulas can often be placed intrathoracically via the lateral access. Venous return may be accomplished by retrograde cannulation of the right ventricle via the pulmonary artery (solitary angulated catheter with a diameter of 14 mm) and arterial inflow by cannulating the distal descending aorta. Should intrathoracic cannulation be cumbersome because of pericardial adhesions or pronounced aortic sclerosis, we prefer to access the left femoral vessels. Usually pump flow volumes of 2.0 l/m² body surface area/minute are sufficient to achieve physiological pressure values in an adult patient proximally and distally to the clamped segments of the aorta. The anesthesiologist, the perfusionist, and the surgeon must work closely together under continuous monitoring to maintain an adequate equilibrium between the two circulation segments.

As an alternative to this regimen, an isolated left ventricular bypass is often employed. The means of connecting and operating the centrifugal pumps, which can be used under mild

heparinization (5,000 IU), have been described frequently (DeBois et al. 2000). After administering heparin, the left common femoral artery is cannulated. The pericardium is opened via a longitudinal incision dorsal to the course of the phrenic nerve and a purse-string suture is placed on the left lower or upper pulmonary vein. Then, the vessel is cannulated with an angulated perfusion catheter. If the lumen of the pulmonary veins is too narrow or they are not accessible for other reasons, the left auricle represents an alternative site for cannulation with a straight venous cannula. However, the catheter may not be put under any tension during perfusion as the auricular myocardium tears easily.

A heparin-free TDMAC shunt without a pump (Argyle, Fa. Shervood, St. Louis, USA) can be applied during distal aortic arch and descending aorta replacement procedures if the surgeon abstains from active circulatory support via a blood pump. In this case, however, the shunt should originate in the ascending aorta (Verdant et al. 1988). Another technique widely applied by some teams involves establishing a temporary vascular prosthetic bypass between the right subclavian artery and the left iliac artery (Kogel 2001).

If surgery must be performed under simple aortic clamping in an emergency setting, the anesthesiologist is primarily responsible for managing the patient, ensuring that the left ventricle is not overloaded in this phase and compensating for any ensuing metabolic acidosis continuously and effectively. The proximally measured arterial blood pressure is controlled by administering vasodilators such that baseline values are not exceeded to any significant degree. A Swan-Ganz catheter provides information about the preload of the left ventricle. Induced vasodilation is terminated right before removing the aortic clamp. Blood gas analysis is required at 10- to 15-min intervals. Metabolic acidosis has to be antagonized without delay before and especially after the aortic clamps have been removed. At this point, we recommend restoring left pulmonary ventilation to support hemostasis.

■ ■ Hypothermic Circulatory Arrest

Borst performed an operation of the aortic arch through a left-lateral access under deep hypothermia and circulatory arrest already in 1963

(Borst et al. 1964). In 1984, Crawford et al. (1984) again reported on the utility of this technique for complex procedures of the aortic arch via a left-lateral access. Today, such a procedure should mainly be considered when the arch cannot be controlled and clamped proximally from the dilated segment in large or even ruptured aneurysms. Here, starting with moderate hypothermia, one should proceed according to the protocol for circulatory arrest as outlined in ► Sect. 27.4.1, «Access and Extracorporeal Circulation». After arresting the circulation, the aneurysm is opened longitudinally from distal to proximal. The patient is positioned with the head lowered. The ostia of the left carotid artery and the innominate artery are then intubated with perfusion catheters and selective antegrade cerebral perfusion is commenced. Again, the left subclavian artery is either clamped or blocked with a Fogarty catheter. If the aortic valve is patent, we put the heart under isoelectric arrest by infusing cardioplegic solution into the aortic root via a blocked Foley catheter. Beforehand, the catheter is inserted retrogradely under digital control via the aortic arch into the ascending aorta. The prosthesis, which has a side arm, can now be anastomosed – possibly including one or more of the supra-aortic vessels – to the arch. Subsequently, the prosthesis is filled with blood, clamped distally, and the upper half of the body is perfused via the side arm, while the lower half of the body continues to be perfused via the original site of cannulation (femoral artery or distal descending aorta). The distal prosthesis-aortic anastomosis is created during the rewarming phase.

27.4.6.3 Procedure at the Aorta

As already mentioned, a standard incision in the bed of the fourth rib offers ideal access to the distal aortic arch and to the proximal segment of the ascending aorta. Any pleural adhesions present must be carefully detached in order to prevent any bleeding into the lung – particularly under heparinization. Adhesions of the lung with the aneurysm are only detached as far as needed to mobilize the aorta proximal and distal to the clamp. If a strip of aorta is free of adhesions dorsally, the vessel lumen can later be opened in this area without having to detach the lung. The phrenic nerve is identified, the vagus nerve is

protected with an elastic vessel loop, and the recurrent branches mobilized as far as possible. The left common carotid and left subclavian arteries are mobilized to enable later control. Depending on the proximal extent of the repair, the aorta is mobilized between the innominate artery and the left carotid artery or between that and the left subclavian artery. We recommend first dissecting the tissue between these vessels with scissors or electrocautery and then with the index finger until the front face of the trachea can be palpated. This is then followed in a caudal direction. The next step involves dissecting the arterial ligament just at the aorta followed by careful dissection into the concavity of the aortic arch until the level of tracheal bifurcation is reached. Any tissue fibers behind the aortic arch should be dissected under visual control, if possible. Subsequently, the surgeon can navigate around the distal arch using a curved clamp and digital guidance. After dissecting the parietal pleura, the readily visible intercostal arterial branches 1–4 should be closed with metal clips right away so that they do not need time-consuming sutures from inside, once the aneurysm is opened.

Irrespective of whether the surgeon is operating under conditions of simple aortic clamping or extracorporeal circulation, the proximal aorta, the supra-aortic branches distal from the occlu-

sion site, and the distal aorta are clamped. This may not be required under circulatory arrest. The aneurysm is then opened along the longitudinal axis. In the presence of a type B dissection, one first encounters the false lumen and often also the proximal «entry.» The free wall of the true lumen is excised immediately in order to gain an overview of any residual intercostal arterial bleeding; these vessels are then oversewn with heavy sutures. As soon as bleeding has ceased, the surgeon decides upon the subsequent procedure at the proximal and distal aorta.

■ ■ Proximal Anastomoses for Aneurysms

For distal arch aneurysms, the surgeon attempts to establish the proximal and distal anastomoses at the point where the diameter of the aorta approaches a normal size and where the conditions of the wall are suitable for the anastomotic sutures – as shown by an intact intima. For aneurysms, if possible, the proximal prosthesio-aortic anastomosis at the distal arch is created such that the supra-aortic vessels do not have to be joined to the prosthesis separately. The prosthesis is strongly beveled in order to sew it to the aortic wall at the lowest point, beginning in the concavity of the arch (■ Fig. 27.31a). Suturing is continued both at the back and the front in preferably healthy aortic wall tissue until the level of the supra-aortic ves-

■ Fig. 27.31 a, b The proximal prosthesio-aortic anastomosis is created in the lumen of the open distal arch. a The branch of the left subclavian artery remains downstream of the anastomosis line in this case. b The base of the subclavian artery is anastomosed with the prosthesis. The distal prosthesio-aortic anastomosis is completed

sels is reached. The leftover prosthetic flap is then sutured to the aortic wall first at the back and then at the front just before these vessels take off, whereby the ends of the thread are tied just left of the origin of the carotid artery or the subclavian artery. If for reasons of surgical technique these vessels need to remain downstream of the anastomosis just created, they can be anastomosed directly or via vascular bridges to the tubular prosthesis at a later point. Two surgical steps in creating a prosthesis-aortic anastomosis between the left common carotid artery and the subclavian artery and subsequent implantation of the latter vessel into the prosthesis are illustrated in **■ Fig. 27.31**. The sutures for the distal prosthesis-aortic anastomosis are either sewn end to end or beveled such that large intercostal arterial branches downstream of the seventh thoracic segment are spared in order to preserve spinal perfusion. If extensive aortic replacement is required, it is usually better to implant the intercostal arterial branches that come into question as an island into a window that has been created in the prosthesis and to anastomose the end of the prosthesis with the distal aorta. A prerequisite for preserving such vessels, however, is that aortic wall is still available at the base that can be used for suturing. According to more recent observations, all thoracic intercostal arterial branches can also be sacrificed under certain conditions without increasing the risk of spinal cord injury (Etz et al. 2006).

■ ■ Proximal Anastomosis for Dissection

Whenever possible, the proximal end of a type B dissection extending retrograde to the aortic arch should be selected as the site for anastomosis so that sutures can be placed in a firm vascular wall. If the proximal end of the dissection cannot be reached in acute dissections, the walling of the false and true lumen proximal to the dilatation of the aorta, which is always present and quite extensive, is joined so that the proximal prosthesis-aortic anastomosis can be established at this level. Gluing here is only possible in exceptional cases if enough wall tissue is available. Thus, the technique of applying reinforced Teflon felt-supported sutures to join the walls of a dissected aortic lumen is mostly utilized; this technique is described in **► Sect. 27.3.4**, «Acute Type A Dissection». For chronic retrograde type B dissections that have a firmer outer aortic wall as a result of scarring, we

recommend anastomosing the prosthesis there so that true and false lumens communicate.

For acute *retrograde dissections* extending to the ascending segment, a beveled prosthesis-aortic anastomosis should be avoided. Rather, the aortic arch should be circumferentially mobilized up to the selected line of anastomosis and transected there. If there is not enough space and too little tissue surface for gluing, the dissected wall layers are joined here, too, by placing Teflon felt strips on the outside and in between the layers using continuous mattress sutures so that there is a firm opposing point to anastomose the prosthesis. Normally, the left-lateral arch vessels, whose branches may need to be reconstructed, are anastomosed directly to the arch prosthesis.

■ ■ Distal Anastomosis

Distal anastomoses for the combined replacement of the aortic arch and the descending aorta are placed at that site where the vessel diameter approaches a normal size, if possible. Often, however, the aneurysmatic dilatation involves the entire downstream aorta so that a compromise must be made as regards which vessel segment should be replaced. Experience has shown that the aorta narrows when kinking toward the hiatus aorticus, where it can be anastomosed quite often. Removing the residual diseased aorta is then postponed to a second procedure, which may be prepared for using the distal elephant trunk technique (see **► Sect. 27.4.5**, «Total Aortic Arch Replacement Using the Elephant Trunk Prosthesis»). The distal prosthesis-aortic anastomosis must be made to the true lumen for *acute dissections*. This implies that the entire wall must be reconstructed by using Teflon felt-reinforced mattress sutures. For *chronic dissections*, the distal prosthesis-aortic anastomosis is always established with the scarred adventitia of the aorta. However, first the floating part dissection membrane should be excised so that both lumina remain perfused. For this purpose, it may be necessary to release the distal aortic cross-clamp briefly. By using this maneuver, the dissection membrane can be excised under direct vision over a length of 2–4 cm, and an additional incision of the membrane may even reach much farther.

We have made it our rule to sacrifice all intercostal arterial branches up to the level of the sixth thoracic segment, while larger vessels branching farther distally must be spared by using a beveled

prothesio-aortic anastomosis or implanting the relevant vessel-bearing islands of the aortic wall in the prosthetic tube graft. For the distal anastomosis itself, the aorta is incised to the right and left of the clamp as far as necessary so that a 3-cm strip of intact wall is preserved dorsally. First open stitches are made out of this strip; subsequently, the edge of the prosthesis and the cut edge of the aorta are anastomosed on both sides and the thread tied at the front. After carefully expelling the air from the aortic arch, the vessel branches, and the prosthesis, the clamps are removed with the patient in Trendelenburg position. The wall of the aneurysm is sewn closely around the prosthetic tube graft for graft inclusion.

The «elephant trunk» technique as described in ► Sect. 27.4.5 can also be employed for the distal anastomosis whenever it appears likely that further downstream repair will become necessary in the future (Carrel et al. 2001). The distal prothesio-aortic anastomosis is then not fashioned end to end in the standard way but rather the descending aorta prosthesis is invaginated for several centimeters in order to connect the thus created edge of the prosthesis and the descending aorta. Just before tightening the suture, the invaginate is manipulated into the distal aorta and the anastomosis then completed. The prosthetic stump that is suspended in the lumen of the downstream aorta serves to simplify the connection of the thoracoabdominal aortic prosthesis in a future operation.

27.4.7 Alternative Techniques for Aortic Arch Replacement

An imaginative suggestion for managing extensive aortic arch and descending aorta aneurysms, the «thrombo-occlusion» operation, was originated by Carpentier et al. (1981). This technique presumes that a normal aortic base and normal ascending aorta are present. The operation can be performed without using mechanical circulatory support. A longitudinal sternotomy and pericardiotomy are made to access the heart and large vessels. The first segments of the ascending aorta and the supra-aortic vessels are mobilized. The latter are anastomosed side to end with 8-mm prosthetic bridges during short-term occlusion or clamping. The authors recommend preparing bi- or trifurcational prostheses so that only a short

segment of the ascending aorta is needed to subsequently anastomose the prosthesis. By extending the sternotomy to the umbilicus and excising the hepatic ligament, the surgeon can advance to the aortic hiatus to mobilize the aorta. The vessel is either doubly occluded or tangentially clamped off. Then, a right-angled end-to-side anastomosis is created between the prosthesis, which is at least 14-mm in diameter, and the aorta. At this point, the patient is fully heparinized. An incision is then made in the diaphragm, and the prosthetic tube, from which the air has been expelled and then put under tension, is pulled along the right atrium to the ascending aorta in order to determine the length that is required. The graft is then tailored by strongly beveling and then anastomosing it to the right aspect of the clamped ascending aorta. In the next step, the common bases of the cerebral and brachial bridges are joined to the aortic graft end to side; after careful de-airing, these vessels can be unclamped. The branches of the supra-aortic vessels are ligated. Finally, the natural aortic blood stream is interrupted beyond the anastomosis, between the aortic prosthesis and the proximal arch, by using a specialized plastic clip developed by Carpentier et al. (1981). Alternatively the aorta can be dissected between the anastomoses, cut and oversewn by placing reinforced, continuous mattress sutures. The affected segments of the aorta will then thrombose up to the branches of the first vital arteries. Late outcome results of this complex procedure are not available.

The *hybrid technique* for aortic arch replacement is in part similar to the method Carpentier has described; however, it has only been used in relatively small numbers of patients to date. Circulatory aids are not required, and here, too, the aortic arch is first «debranched,» whereby the left subclavian artery is detached close to its branch and anastomosed end to side to the left carotid artery. After establishing an end-to-side anastomosis between the proximal branch of a Y-prosthesis and the distal ascending aorta, the left carotid artery is also detached close to its branch and anastomosed end to end with the right distal branch of the Y-prosthesis. Subsequently, this route can be unclamped and perfused while the left branch of the prosthesis is anastomosed end to side to the innominate artery, which can then also be unclamped centrally. In a second step, the entire aortic arch vessels can be excluded by transfemorally inserting an endograft

that has been selected to correspond to the patient's individual arch anatomy. Although the initially available early outcome data show a considerably higher mortality than for similar techniques performed under extracorporeal circulation, it is to be expected that with growing experience, this technique will also produce similarly good outcome as with «open» surgical treatment (Kotelis et al. 2011; Schumacher et al. 2006).

27.5 Reoperations

Even today reoperations after prior thoracic aortic aneurysm surgery are considered to be extraordinarily difficult, high-risk procedures that pose a great challenge to the surgical team's imagination and technical skill. It would be beyond the scope of this chapter to describe such multifaceted operations at the various segments of the thoracic aorta in detail. The reader is referred in this regard to the extensive experience as published by Crawford's group and others (Crawford et al. 1984; Yamashita et al. 1998; Lombardi et al. 2003). In our own experience from a more modest number of such reoperations, the technique used for the ascending aorta, the arch, and descending segments does not differ significantly from that for other difficult cardiovascular reoperations – except for the fact that great care must be taken if a second sternotomy is required. Essentially, therefore, we will discuss safe opening of the chest.

An overview of the site and extent of a possibly present contact zone of the aneurysm with the sternum is best gained by using contrast-enhanced computed tomography. If the aneurysm has intimate contact with the anterior chest wall or if even osseous destruction has developed from pulsating pressure, we first establish extracorporeal circulation via femorofemoral access. While continuously cooling on bypass, we separate the front blade of the sternum. Subsequently, the incision is then only completed in the inferior section, whereupon the diaphragmatic surface of the heart is detached as far as necessary so that a vent catheter can be inserted transapically or into the lower right pulmonary vein (interatrial groove) in the event that ventricular fibrillation develops in patients with aortic valve insufficiency. When reaching a body temperature of 25 °C, the extracorporeal circulation is stopped briefly and full sternotomy is completed (Karck et al. 1996).

As an alternative to this procedure, surgery can be started by performing a right anterolateral thoracotomy in the bed of the fourth rib. If the aneurysm can be dissected from the front part of the thorax with little difficulty, a longitudinal sternotomy is undertaken and the procedure conducted in the usual way. Otherwise, the right atrium (or one of the femoral veins) is cannulated with a large-lumen catheter and an arterial access is established for extracorporeal circulation via a peripheral artery. In presence of aortic valve regurgitation, the patient's core temperature is only cooled moderately to start with (30 °C) to avoid premature spontaneous atrial fibrillation. If there is no regurgitation, hypothermia can be deepened as needed. Then the sternum is opened by using an oscillating saw. Here, like with the previous technique, if the aneurysm is damaged, the aorta can be mobilized and clamped after short-term cessation of the extracorporeal perfusion and induced ventricular fibrillation.

Instead of using a right-lateral technique, control of an aneurysm can be achieved by applying a bilateral anterolateral thoracotomy in the bed of the fourth rib («clamshell thoracotomy»), whereby the thoracic segment that is in contact with the aneurysm is dissected horizontally. An access created in this way is excellent but considerably more traumatic than a longitudinal sternotomy.

27.6 Aneurysms and Dissections of the Descending Aorta

27.6.1 Treatment Strategies

The range of options for surgical treatment of diseases of the descending aorta has been extended by the interventional methods (see ► Chapter «Endovascular Surgical Therapy of Thoracic and Thoracoabdominal Disease of the Aorta», Sect. 28.6; Sect. 28.7). This group of extra-anatomical reconstruction procedures, including what is known as a «hybrid procedure», exclude the diseased sections of the aorta by implanting one or more vascular endografts. By taking an endovascular treatment approach, all forms of intraoperative circulatory support through extracorporeal circulation or temporary placement of extra-anatomical shunting can be avoided. These procedures differ distinctly from conventional «open» surgical procedures, in which the diseased segment of

the aorta is not excluded but rather replaced with a vascular prosthesis. In open procedures, circulatory support is needed in order to minimize the risk of organ damage as a consequence of inadequate perfusion as the aorta is cross-clamped while vascular areas distal to the aorta are being repaired.

27.6.2 Circulatory Support

In addition to the passive circulatory support techniques by temporarily placing shunts or an extra-anatomic vascular prosthetic bypass, active blood pumps with or without an integrated oxygenator are available. Some groups prefer repairing aneurysms not involving the arch by using a centrifugal pump as an isolated left ventricular bypass; this reduces the risk of perioperative bleeding as the patient does not require full heparinization (Coselli and LeMaire 1999; DeBois et al. 2000; Schepens et al. 1999). A disadvantage of this technique as compared to classic extracorporeal circulation, however, lies in the fact that hypothermia cannot be induced here. This is important for patients with proximal aneurysms of the terminal aortic arch just involving the descending aorta. Indeed, it is not rare that the surgeon can only decide during the procedure whether to open the arch in order to anastomose the vascular prosthesis with a healthy segment of the aorta. In such cases, extracorporeal circulation is used to induce a sufficiently deep level of hypothermia – in our hands, the core body temperature is cooled to 26 °C. After interrupting the extracorporeal circulation, we initiate selective antegrade cerebral perfusion for neuroprotection (see ► Sect. 27.4.6.2, «Managing Intra- and Extracorporeal Circulation»).

We also cool the body core temperature for surgeries in which circulatory arrest is not used, for reasons of organ protection mediated by hypothermia, but only by about 2–3 °C. In this regard, our own technique differs from the method of Kouchoukos, who performed procedures of the descending aorta under deep hypothermic cardiocirculatory arrest (Kouchoukos et al. 2002).

We consider the option of oxygenating the blood and being able to precisely regulate the blood volume distribution as additional advantages of using extracorporeal circulation for procedures on the descending aorta. Thus, our recent

experience is based on this form of intraoperative circulatory support.

27.6.3 Indications

The indications for surgical replacement of the descending aorta for aneurysms or dissections depend on the etiology, the maximum vessel diameter, the temporal dynamics of the developing vascular dilatation, and the patient's symptoms. For us, the indication to replace a diffuse, asymptomatic aneurysm of the descending aorta with or without dissection is given in a patient when the maximum vessel diameter exceeds 6 cm. If the number of risk factors increases, for example, confirmed deficiencies in various organ functions, then the decision to operate must be made on a very individual basis.

For clearly limited aneurysms that developed because of a plaque rupture, the surgical indication may already be given in smaller maximum vessel diameters even though the cutoff value has not been reached yet because here the three-layer aortic walling is affected and the vascular walls may already be dangerously thin. The same applies for suture line aneurysms that can develop after post childhood patch repair of an aortic coarctation. Here, too, owing to the lack of reliable data concerning the risk associated with the spontaneous course of rupture, the surgeon will likely decide for an early intervention (Aebert et al. 1993; Karck et al. 2002). Posttraumatic aneurysms of the descending aorta represent a special form for which no proven, maximum tolerable vascular diameter can be given. In these cases, the temporal dynamics for increasing diameter of the affected segment in the context of the individual surgical risk profile and age of the patient will speak for or against operative intervention.

27.6.4 Selecting a Technique

27.6.4.1 Thoracic Access

For proximal aneurysms of the descending aorta, patients are positioned on their right side with the left arm in abduction. The pelvis is rotated slightly in a dorsal direction as this facilitates better access to the left inguinal vessels needed for establishing the extracorporeal circulation.

To separately ventilate the right and left lung, a double-lumen endotracheal tube is required. For access to the proximal aneurysm of the descending aorta, we choose standard thoracotomy in the fourth intercostal space (see ► Sect. 27.4.6.1, «Surgical Access»). Via this access, the most proximally located diseased segments can be reached, and, moreover, it is possible to prepare for clamping the aortic arch between the left common carotid artery and the left subclavian artery. If the arch is definitely not involved and instead the entire descending aorta up to the passage into the diaphragm is to be replaced, it may be helpful to place the thoracotomy one intercostal space deeper, partially resect the fifth rib, or create an additional second access through the seventh intercostal space (see ► Sect. 27.4.6.1, «Surgical Access»).

27.6.4.2 Thoracic Aorta Replacement

The prophylactic effect of lumbar puncture in protecting patients from spinal injury is disputed; nonetheless, however, we preoperatively drain the cerebrospinal fluid before carrying out any extensive thoracic and thoracoabdominal aorta procedures (Coselli et al. 2002; Schepens et al. 2004). The catheter is inserted for this procedure on the day before surgery in order to exclude any acute, puncture-induced spinal bleeding before full heparinization for extracorporeal circulation is initiated.

At sites that have not been operated upon previously and when the distal descending aorta is not affected, extracorporeal circulation can be established via intrathoracic cannulation of the pulmonary artery trunk and the distal descending aorta (see ► Sect. 27.4.6.2, «Managing Intra- and Extracorporeal Circulation»). This form of cannulation spares exposing additional peripheral vessels like femoral artery and vein.

For aneurysms of the descending aorta that do not involve the arch, the aorta can usually be clamped directly behind the takeoff of the left subclavian artery. The phrenic and vagal nerves are mobilized by creating a tissue pedicle and held aside: these nerves should not be skeletonized. As for terminal aortic arch replacement, great care must be taken here, too, when exposing and mobilizing the recurrent nerve in order to protect it from injury caused by clamping or suturing.

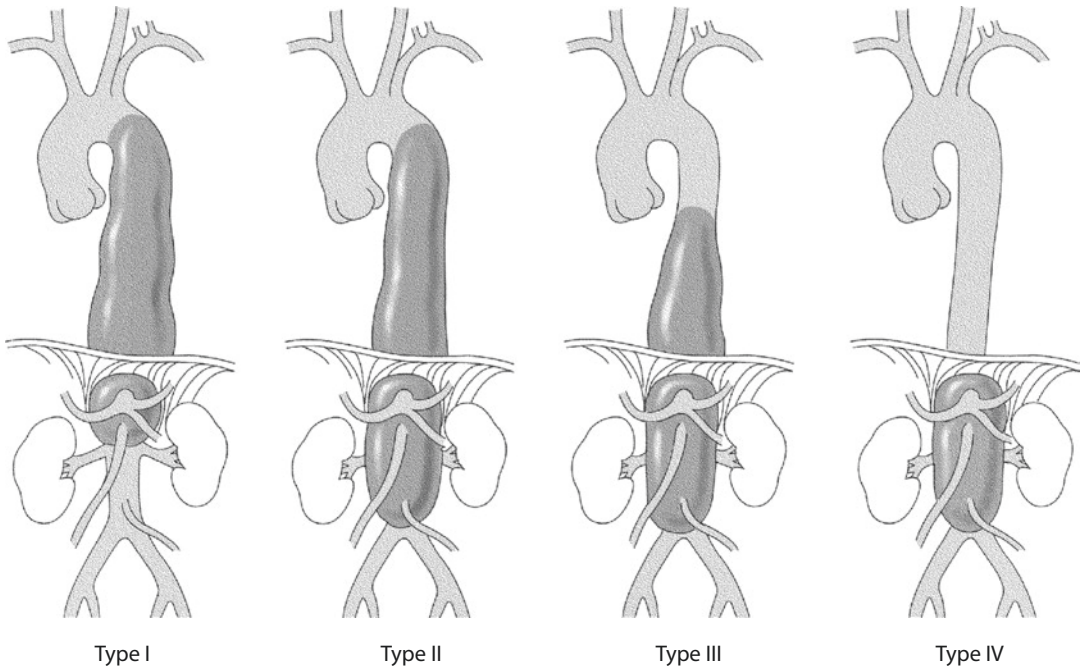

The second clamp is placed such that the proximal prosthesis-aortic anastomosis can be established under the best possible technical conditions.

For this purpose, the aorta needs to be mobilized for a short distance between the Th3 and Th5 segments, whereby it is occasionally necessary to detach one or two segmental arteries. In a medial direction, the esophagus, which is frequently adherent to the aneurysm, should be safely mobilized before clamping and kept out of the level of clamping.

The aorta is now double clamped, proximally at a healthy, more or less normal site where the proximal anastomosis with the vascular prosthesis is to be performed and distally at some distance, most often still within the diseased segment of the aorta. The vascular segment lying in-between these clamps is opened longitudinally and prepared for anastomosing. Any intercostal vessels that are still bleeding are oversewn. Thereafter, the aorta is cut subtotally or over the whole circumference, depending on which variant provides the most secure anastomosis, and leaving an approx. 1-cm-wide tissue cuff for anastomosis. Continuous suturing with a vascular prosthesis of equal diameter can now be performed in a routine fashion, adding Teflon felt strips to the suture line for fragile tissue. With the vascular prosthesis clamped, the proximal anastomosis then allowed to be perfused and tested for any blood leakage.

The next level for distal clamping is chosen as far downstream as needed to create the prosthesis-aortic anastomosis with a segment of the aorta that shows only slight pathological changes. For aneurysms that extend to the takeoff of the celiac trunk, an indentation needs to be made in the diaphragm before clamping the aortic hiatus. If clamping cannot be safely done at this site without damaging the branch of the celiac trunk, an occlusion catheter can be inserted into the distal aorta under visual control. For this, however, the extracorporeal circulation needs to be stopped for a few seconds in order to open the aorta.

The aorta is then incised longitudinally. For aortic dissections, the dissection membrane is resected at its origin in the aortic wall. Any intercostal vessels from the proximal aorta segment that are still bleeding are oversewn. Segmental arteries originating further distally can be reimplanted individually or in multiples with continuous sutures in a vascular prosthetic window corresponding to the vascular tissue island; this improves spinal cord perfusion. The criteria for selecting these vessels are still the subject of scientific controversy. As described in ► Sect. 27.4.6.3, «Procedures at the Aorta», we prefer ► liberally reimplant most

■ Fig. 27.32 Classification of thoracoabdominal aneurysms by Crawford et al. (1986)

large-lumen intercostal vessel branches that originate from the lower half of the thoracic aorta because the collateral supply of the middle and lower spinal cord is less well developed than in the more cranial segment (Biglioli et al. 2004; Minatoya et al. 2002).

Finally, the distal prosthesio-aortic anastomosis is created, depending on the wall conditions either by using an inlay technique or an end-to-end anastomosis.

Creating a «graft inclusion» from native aortic wall tissue can occasionally help to stop any bleeding caused by the suturing in the area of the intercostal artery anastomoses. Covering the vascular prosthesis with native tissue might also protect the site against infection and erosion.

27.6.4.3 Thoracoabdominal Access

For type I and II aneurysms of the thoracoabdominal aorta according to Crawford (■ Fig. 27.32; Svensson et al. 1993), we prefer performing thoracotomy in the sixth intercostal space and continuing the incision above the rib arch from pararectal in a caudal direction. For aneurysms that extend far upstream in the direction of the aortic arch, it may be necessary to choose a thoracotomy one or even two intercostal spaces farther cranial. In these less frequent cases, a second thoracotomy in

the seventh intercostal space needs to be performed using the same skin incision in order to gain safe access to the infradiaphragmatic aorta. In contrast, thoracotomy in the seventh intercostal space is sufficient to adequately expose the thoracic aorta segment that must be replaced for type III or IV aneurysms.

Independent of type of aneurysm, the left rib arch at the ventral end of the thoracotomy in the sixth or seventh intercostal space is dissected first. From here, the surgeon begins to mobilize the diaphragm in a circular pattern up to the aortic hiatus, whereby a rim of 3 cm is left at the point of insertion of the diaphragm at the thoracic wall. Compared to the alternative of radial mobilization of the diaphragm, this technique spares the phrenic nerve and facilitates later reconstruction. With progressing ventrodorsal mobilization of the diaphragm, the intact peritoneal sac can be mobilized carefully in a craniocaudal direction on Gerota's fascia and medial up to the aorta. In the next step, the left-lateral portion of the diaphragm can be sharply dissected from the aorta in the hiatus, whereby the branches of the celiac trunk and the superior mesenteric artery can be exposed at their origin from the aorta. The insertion at the aorta and the course of the left renal artery can now be identified from dorsal. Further distal and in the same preparation

step from the left, the infrarenal aorta is reached from dorsal, which can now be followed and controlled via this access up to the left iliac artery.

27.6.4.4 Thoracoabdominal Aorta Replacement

After exposing the diseased segment of the thoracoabdominal aorta, we begin with the vascular prosthetic replacement in craniocaudal order. In the same manner as described for thoracic aorta replacement, the aorta is cross-clamped proximal to the lesion as well as some distance downstream. In between these two clamps, the aorta is incised longitudinally. After completion of the proximal prosthesis-aortic anastomosis the next, farther distal level is selected for clamping. Depending on the extent of the aneurysm, this can lie proximal of the celiac trunk branch or infrarenally, yet down to the level of the iliac arteries.

If the first variant is chosen, a cross-clamped aorta at this site can represent a considerable obstacle for reimplanting deeply lying intercostal arteries into the vascular prosthesis. In this case, we prefer to clamp infrarenally to then open the entire length of the aorta. After intubating the orifices of the celiac trunk, the superior mesenteric artery, and the left and right renal arteries with perfusion catheters, organ perfusion with arterial blood is commenced via the extracorporeal circulation. Proceeding in this way prevents ischemia of the visceral organs after this segment of the aorta is opened and thus taken off the extracorporeal circulation. Moreover, it facilitates identification of the intercostal or lumbar vessels that will be selected for reimplantation in the prosthesis: retrograde blood can no longer reach the already quite deeply situated site of the aorta via the intubated ostia of the visceral arteries and obstruct the view. After reimplantation of one to three segmental arteries from the thoracolumbar transitional zone, the visceral arteries are anastomosed either separately or en bloc to the central vascular prosthesis. It is often possible here to reimplant en bloc the branches of the right renal artery, the superior mesenteric artery, and the celiac trunk together on a tissue island. Only the left renal artery, which branches somewhat further away, needs to be anastomosed separately.

As an alternative to this procedure, special vascular prostheses with anatomically adapted, prefabricated side branches can be used to separately create the anastomosis for each individual visceral

artery in an end-to-end fashion (Vascutek-Terumo, Gelweave R – thoracoabdominal prosthesis after Coselli).

Finally, perfusion of the visceral organs can be restored before completing the reconstruction by establishing the distal prosthesis-aortic anastomosis, depending on the aortic pathology. This anastomosis is created before, at, or behind the iliac artery bifurcation as a Y-prosthesis. Before weaning the patient from the extracorporeal circulation, not least for reasons of better spontaneous hemostasis, the body temperature should be normal. Like for replacement of thoracic aorta, the prosthesis should be enclosed by native aorta as graft inclusion.

28.1 Introduction

Open repair of aortic disease of the descending and thoracoabdominal aortic pathologies remains the gold standard for the treatment (Coselli et al. 2004; Dillavou and Makaroun 2008; Estrera et al. 2005; Khoynzhad et al. 2005; Kouchokos et al. 1995; Stone et al. 2006; Svensson et al. 1993). This approach can be associated with significant morbidity and mortality, with variable results throughout different centers. The application of endovascular techniques utilizing stent graft technology has evolved rapidly and changed the treatment paradigm of aortic diseases. Parodi and coworkers first demonstrated the feasibility of endovascular exclusion of abdominal aortic aneurysms in 1991 in a small clinical series that described the use of stent-anchored knitted Dacron grafts to treat abdominal aortic aneurysms (Parodi et al. 1991). The development and adoption of endovascular therapy for the treatment of descending thoracic aortic aneurysms soon followed the promising use of this revolutionary technology. Dake and coauthors reported the first series of endovascular treatment for descending thoracic aortic aneurysms in 1994 (Mitchell et al. 1996; Dake et al. 1994). Semba and colleagues published the first reports of the endovascular treatment of traumatic thoracic aortic injury in 1997 (Kato et al. 1997). White and coworkers performed the first thoracic endovascular aortic repair (TEVAR) for chronic type B aortic dissection in 1999 (Khoynzhad et al. 2009a).

In 2005, the US Food and Drug Administration (FDA) approved the first commercially available stent graft for thoracic endovascular aortic repair (TEVAR) for the treatment of descending thoracic aortic aneurysms (Gore TAG, Gore and Associates, Inc, Flagstaff, AZ) (Bavaria et al. 2007; Hughes et al. 2012; Makaroun et al. 2005). Two additional devices subsequently obtained FDA approval in 2008: Talent (Medtronic, Santa Rosa, CA) and TX2 (Cook, Inc, Bloomington, IN) (Fairman et al. 2008; Matsumura et al. 2008).

Since then, the feasibility and successful utilization of TEVAR have been established in selected patients for the treatment of various aortic pathologies including traumatic aortic injury, penetrating aortic ulcers, and aortic dissections. Potential advantages of TEVAR versus open surgery include shorter operative time, less blood loss, decreased need for general anesthesia, and shorter hospital

stays (Criado et al. 2005; Greenberg et al. 2005; Song et al. 2006). TEVAR avoids cardiopulmonary bypass with the need for aortic cross-clamping and deep hypothermic circulatory arrest.

28.2 Devices Approved for TEVAR

28.2.1 Gore TAG Device

The thoracic aneurysm graft (TAG) endoprosthesis (WL Gore and Associates, Flagstaff, AZ) received FDA approval in 2005 and was the first thoracic aortic device clinically approved for implantation in the United States (Makaroun et al. 2005) (■ Fig. 28.1). This is a modular endoprosthesis composed of an expanded polytetrafluoroethylene (ePTFE) tube with an external flexible nitinol exoskeleton and has covered flares with a sealing cuff present on both ends of the device. The exoskeleton is bonded to the graft material without sutures and is constrained by a PTFE sleeve. The device profile depends on the size of the graft and requires an 18–24-F sheath for delivery. The device deploys from the middle section outward by pulling on a deployment cord. The approved clinical indication is for descending thoracic aortic aneurysms with proximal and distal landing zones of 20 mm. The new conformable TAG (cTAG) was approved by the FDA in 2011 with an oversizing window ranging from 6 to 33%. This device conforms to the

■ Fig. 28.1 The Gore TAG device (From W.L.Gore & Associates; used with permission)

■ **Fig. 28.2** Valiant thoracic stent graft (From Medtronic; used with permission)

geometry of the aorta with better apposition along the inner curvature of the aortic arch. This device is available in diameters from 21 to 45 mm, with the intended treatment diameter of the noncritically diseased aorta ranging from 16 to 42 mm. Tapered device configurations are also available.

28.2.2 Medtronic Talent/Valiant

The Talent device (Medtronic, Inc, Santa Rosa, CA) was approved by the FDA in 2008 and is a modular device composed of a woven polyester graft sutured to a nitinol lattice with a proximal bare stent to improve fixation (Fairman et al. 2008). It is available in diameters of 22–46 mm, and the delivery system ranges from 22 to 25 Fr. Stent graft oversizing of 10–20% relative to the native aortic neck diameter is recommended to provide the necessary outward radial force to maintain apposition against the native aortic wall. The intended treatment diameter of the noncritically diseased aorta ranges from 18 to 42 mm, with 20 mm long proximal and distal landing zones required. In 2012 the Valiant (Medtronic, Inc, Santa Rosa, CA) stent graft was approved by the FDA, representing an improved overall design (■ Fig. 28.2). The Valiant stent graft differs from the Talent device in several ways including elimination of the longitudinal connecting bar between

the stents which allows for greater graft flexibility and conformability and increased number of proximal and distal uncovered stents (8-peak crown compared to 5-peak configuration of Talent) which distributes radial force across more points of contact and allows for better sealing characteristics. The Captivia delivery system allows for tip capture and for more controlled deployment.

28.2.3 Cook Zenith TX2 Device

The TX2 device was also approved in 2008 (Cook, Inc, Bloomington, IN) and is composed of woven Dacron fabric sutured to self-expanding stainless steel Z-stents (Greenberg et al. 2005; Matsumura et al. 2008). There are barbed covered top stents at the proximal end and an uncovered barbed stent at the distal end of the device. These barbed stents are intended to provide positive fixation at both ends of the device. It is available in diameters ranging from 28 to 42 mm with sheath sizes of 20–22 Fr. Recommended oversizing ranges from 10 to 25%, with 25 mm long proximal and distal landing zones of noncritically diseased aorta. Zenith TX2 with Proform was approved in 2011, designed to provide better apposition to the aortic wall in cases of tortuous anatomy (Melissano et al. 2010) (■ Fig. 28.3).

■ **Fig. 28.3** Zenith TX2 thoracic stent graft. Permission for use granted by Cook Medical Incorporated, Bloomington, Indiana

28.3 Preprocedural Considerations

28.3.1 Stent Graft Selection

Meticulous preoperative sizing and planning are critical for performing TEVAR with a successful outcome. Careful attention must be directed toward determining the diameter of the endograft, its length, and its relation to vital branch vessels. A minimum of 2 cm of noncritically diseased aorta free of significant amounts of thrombus or calcification is required both proximal and distal to the diseased segment of aorta to be excluded in order to achieve adequate graft fixation and prevent potential device migration (■ Table 28.1). Oversizing of more than 20% in the aortic arch in patients with a tight arch radius may be associated with catastrophic endograft collapse due to poor apposition of the endograft to the inner curve of the aorta. Conversely, inadequate oversizing may be associated with either

■ **Table 28.1** Anatomic requirements for successful TEVAR

Proximal/distal landing zones	Absence of circumferential calcification and significant thrombotic material greater than 20 mm length; diameter greater than 16 mm, less than 42 mm
Access vessels	Common/external iliac artery greater than 7 mm diameter
	Arterial angulation between common and external iliac artery less than 90°
	Absence of extreme tortuosity of access vessels and aorta

proximal (type Ia) or distal (type Ib) endoleaks. With regard to treatment of traumatic aortic injury and acute type B dissection, oversizing of up to 10% is recommended.

Proper pharmacotherapy during deployment is important for an accurate positioning of the stent graft, especially in the aortic arch and during subsequent balloon angioplasty to enhance the apposition of the stent graft to the aortic wall and to reduce the risk of type I endoleaks. Distal migration of the stent graft can occur during inflation of the balloon resulting in a technical failure or malpositioning of the device. Therefore, the use of intraoperative adjuncts including adenosine to induce a temporary cardiac arrest, anti-hypertensive medications such as a short-acting beta-blocker, or rapid right ventricular pacing to minimize the left ventricular output is very important during this procedure (Khojnejad et al. 2010) (■ Table 28.1).

28.3.2 Aortic Arch Landing Zones

The aortic arch is commonly divided into five landing zones that are demarcated by the origins of the branch vessels (Azizzadeh et al. 2009). Zone 0 is the distal ascending aorta including the innominate artery; zone 1 is distal to the innominate artery including the left common carotid artery; zone 2 is distal to the left common carotid artery including the left subclavian artery (LSA); zone 3 is from the left subclavian artery to a point 2 cm distal; and zone 4 is the descending thoracic aorta starting farther than 2 cm distal to the left subclavian artery (■ Fig. 28.4).

Fig. 28.4 a Distribution of landing zones for TEVAR. b, c Placement of a device in zones 3 or 4 does not require any revascularization. d Revascularization of covered LSA with a left carotid–subclavian bypass. e Revascularization of covered left carotid and subclavian arteries with a carotid–carotid and carotid subclavian bypass. f Complete revascularization of all aortic arch vessels with aorto-innominate and left carotid bypass as well as carotid–subclavian bypass (This figure was published in *Cirugía Cardiovascular*, Vol 17, Issue 1, Azizzadeh A, Valdés JA, Estrera AL, Charlton-Ouw KM, Safi HJ. Reparación endovascular torácica aórtica (TEVAR): un enfoque sobre complicaciones, Pages 11–23, Copyright © 2010 Sociedad Española de Cirugía Torácica-Cardiovascular. Published by Elsevier España S.L. All rights reserved. Published with permission of the author and the publisher)

Deployment of the endograft into zones 0 and 1 requires prior revascularization of the innominate and left common carotid arteries utilizing debranching techniques. This usually does not require shunting or extracorporeal circulation, unless there is a contralateral occlusion or high-grade stenosis of internal carotid artery. These debranching procedures include aorto-innominate and aorto-carotid or carotid–carotid bypass. Deployment in zone 2 with coverage of the left subclavian artery may require selective subclavian revascularization.

28.3.3 Left Subclavian Artery Coverage

The current management of preoperative left subclavian revascularization in cases with planned device coverage of the subclavian artery is not uniform as most of the data regarding morbidity with this is derived from various single institutional series. The Society of Vascular Surgery (SVS) recently formulated clinical practice guidelines based on a systematic review and meta-analysis of the current literature in order to address this issue

(Matsamura and Rizvi 2010). The meta-analysis revealed that coverage of the LSA without revascularization was associated with a much higher risk of arm and vertebral-basilar ischemia compared with patients who underwent preoperative LSA revascularization (Rizvi et al. 2009). There was also a trend toward an increased risk of paraplegia and anterior circulation stroke. A review of the European Collaborators on Stent/Graft Techniques for Aortic Aneurysm Repair (EUROSTAR) registry revealed that LSA coverage without revascularization resulted in a significantly higher incidence of spinal cord ischemia or stroke than in patients with prior LSA revascularization (8.4% vs. 0%; $p=0.49$) (Buth et al. 2007).

The SVS made the following GRADE 1 level C recommendations (Matsamura and Rizvi 2010) for preoperative LSA revascularization:

1. Presence of a patent left internal mammary to coronary artery bypass
2. Termination of the left vertebral artery into the posterior inferior cerebellar artery
3. Absent, atretic, or occluded right vertebral artery
4. Patent left arm arteriovenous shunt for dialysis
5. Prior infrarenal aortic operation with previously ligated lumbar and middle sacral arteries
6. Planned extensive (>20 cm) coverage of the descending thoracic aorta
7. Internal iliac artery occlusion
8. Presence of early aneurysmal disease where further therapy involving the distal thoracic aorta may become necessary

28.3.4 Cerebrospinal Fluid Drainage

The relationship between cerebrospinal fluid (CSF) pressure and the development of paraplegia after thoracic aortic surgery was first suggested by Sugie and colleagues in 1957 (Sugie et al. 1957). There have been various reports of the benefits of CSF drainage during open thoracic aortic repairs (Cina et al. 2004; Safi et al. 1994).

The incidence of paraplegia or spinal cord ischemia (SCI) in various large published series of TEVAR performed for primarily aneurysmal disease has been reported between 0.6% and 4.3% (Etezadi et al. 2012; Khojnejhad et al. 2007a; Ricco et al. 2006; Whateley et al. 2006). Possible mechanisms for immediate SCI after TEVAR are coverage of critical intercostal or other collateral arteries that provide segmental blood flow to the spinal cord

(Khojnejhad et al. 2007b). Perioperative hypotension may also lead to an inadequate spinal cord perfusion. SCI sequelae can range from monoparesis or paraparesis to paraplegia or quadriplegia and can occur immediately or in a delayed fashion.

The EUROSTAR registry (Buth et al. 2007) enrolled 606 patients from 2000 to 2006 undergoing TEVAR for aneurysm or dissection in the thoracic aorta. The incidence of paraplegia or paraparesis was 2.5%, and multivariate analysis revealed LSA coverage without revascularization, renal failure, concomitant abdominal aortic surgery, and the use of three or more stent grafts to be associated with spinal cord injury. Coverage and occlusion of the T10 level intercostal arteries were also more frequent in patients with SCI than in patients without neurologic symptoms.

The mechanism of SCI after TEVAR has not been well investigated. The lower 10 cm located proximal to the celiac axis is felt to be a critical area of stent graft coverage. This segment of the aorta is known to be the origin of the Adamkiewicz artery, which contributes significant collateral blood flow to the spinal cord (Hyodoh et al. 2005). In our experience with 184 TEVAR procedures performed between 1998 and 2005, aneurysmal pathology, use of an iliac conduit, and internal iliac artery coverage were highly associated with postoperative SCI after TEVAR (Khojnejhad et al. 2007a). It is likely that immediate SCI post-TEVAR may be related to acute ischemia of the spinal cord secondary to coverage of a large segment of intercostal vessels and/or other collaterals to the spinal cord blood supply.

For these reasons, placement of preoperative CSF drainage in patients undergoing TEVAR should be strongly considered when:

1. Prior infrarenal aortic repair is present
2. Extensive coverage of thoracic aorta (>20 cm) is planned
3. Coverage of the lower segments of thoracic aorta (T8–L2 vertebrae levels) is planned
4. Coverage of LSA without revascularization is planned
5. Use of iliac conduit or hypogastric artery coverage is planned

Estrera and associates described a protocol for CSF drain management based on their extensive TAAA surgical experience (Estrera et al. 2009). The authors reported a complication rate of 1.5% associated with CSF drain placement with no spinal hematomas being observed. The CSF drain is clamped

and removed on the first postoperative day if the patient remains neurologically intact. In patients who develop postoperative spinal cord ischemia, the CSF is drained to maintain a pressure <5 mmHg, oxygen delivery is optimized by achieving a cardiac index of >2.5 L/min/m² and blood transfusion to maintain target hemoglobin of >12 gm/dl, and a relatively high mean arterial pressure of >90 mmHg and spinal cord perfusion pressure of >80 mmHg are maintained to optimize spinal cord blood flow.

28.3.5 Neuromonitoring

The efficacy of neuromonitoring using both somatosensory-evoked potentials (SSEPs) and motor-evoked potentials (MEPs) during thoracic and thoracoabdominal aortic repair has been previously demonstrated by Safi and colleagues (Achouh et al. 2007; Keyhani et al. 2009). This is not a uniformly recognized intraoperative adjunct. However, Estrera and colleagues demonstrated that an alteration in surgical conduct with reimplantation of intercostal arteries in patients undergoing open TAAA repair and alterations in anesthesia management to optimize spinal cord perfusion in patients who lost neurologic signals resulted in a return of neuromonitoring signals (Estrera et al. 2010). This suggested a benefit of intercostal artery reimplantation and alteration in anesthesia conduct in order to maximize perfusion to the collateral network of the spinal cord.

Neuromonitoring in patients undergoing TEVAR may be a useful intraoperative adjunct as it may identify patients who are at risk of SCI following stent graft deployment and in whom intraoperative maneuvers may be performed to optimize spinal cord perfusion via the collateral network. These maneuvers as described by Estrera include:

1. Increasing proximal aortic mean pressure to >80 mmHg
2. Decreasing CSF pressure by gravity drainage
3. Increasing hemoglobin levels by transfusion
4. Perform LSA revascularization if necessary to improve collateral blood flow to the spinal cord

28.3.6 Vascular Access

The proper planning of vascular arterial access is critical in avoiding potential complications. The femoral artery must be of sufficient caliber to allow

passage of the delivery sheath or endograft, which can range from 18 to 25 F diameter. With open surgical access, either a vertical or oblique skin incision can be used. The advantage of a vertical incision is that it allows the ability to gain additional exposure of the common femoral artery if there is significant atherosclerotic disease that may require an endarterectomy or reconstruction. An oblique incision may minimize wound complications by keeping the skin incision above the femoral crease.

If the femoral or external iliac arteries are of insufficient caliber to allow passage of the device, then a conduit to the common iliac artery may be constructed (Abu-Ghaida et al. 2002). The iliac artery is exposed via a retroperitoneal exposure. A prosthetic conduit (10 mm Dacron or PTFE will accommodate the largest required sheath) is then used to perform an end-to-side anastomosis to the common iliac artery. The conduit is then tunneled percutaneously under the inguinal ligament through a femoral counter-incision and the distal segment of the conduit is then readily accessed. The utilization of iliac conduits was reported to be 15% in the Gore TAG trial, 9.4% in the Zenith TX2 trial, and 21% in the Medtronic VALOR trial (Fairman et al. 2008; Makaroun et al. 2005; Melissano et al. 2010). Alternative access sites, such as the subclavian/axillary and the carotid artery, have been used along with the infrarenal aorta, the ascending aorta, and the transapical approach.

28.3.7 Guidewires, Catheters and Sheaths

The physician performing TEVAR needs familiarity, experience, and expertise with a wide array of endovascular tools. This includes devices not frequently managed in most endovascular procedures, such as large-diameter occlusion balloons and endografts. However, perhaps the most important consideration in TEVAR lies in the use of common endovascular equipment to facilitate a remarkable solution to a life-threatening abnormality.

28.3.7.1 Initial Access and Lesion Crossing

In TEVAR, the suggested guidewire for initial arterial access using the Seldinger technique is a nonhydrophilic-coated Bentson-type wire (Bentson Starter, Boston Scientific Corp., Natick, MA, USA, or Bentson, Cook, Inc., Bloomington, IN, USA).

Traditionally, soft J-tipped wires (e.g., Safe T-J, Cook, Inc.) have been used for initial access because of their association with the lowest risk of dissection or other vessel injury (Andros et al. 2006; Ayerdi and Hodgson 2005). We find the Bentson Starter wire especially useful in that its straight floppy tip forms an atraumatic «functional J-tip» when advanced through a vessel, and yet the wire is able to cross tight stenoses because the «J» is not fixed. The primary access guidewire in TEVAR will also be used to cross the lesion in the thoracic aorta, in combination with a steerable selective catheter. The wire is later exchanged through this catheter for a stiff wire, to be used for intravascular ultrasound (IVUS) interrogation and/or device tracking.

The hydrophilic-coated Glidewire manufactured by Terumo (Terumo Medical Corporation, Somerset, NJ, USA) features a nitinol mandrel with a polyurethane outer coating instead of a metal coil. The polyurethane material contains tungsten for radiopacity, and this surface is further coated with a hydrophilic polymer (most manufacturers now offer similarly constructed wires). This wire is well known for its ability to track in tortuous areas and stenoses (Andros et al. 2006; Ayerdi and Hodgson 2005) and is our choice for gaining access to the abdominal aorta if the Starter wire fails. However, care must be taken when using this or any hydrophilic-coated wire, as there is a greater risk of dissection or perforation owing to the little resistance offered by these wires when advanced through vessels.

28.3.7.2 Guidewires

Exchange-length guidewires function to provide support and tracking ability to various catheters introduced over them, and their characteristics often reflect the task they are enlisted to help accomplish (■ Table 28.2). In TEVAR, a relatively stiff guidewire is needed to accommodate the IVUS catheter for inspection of the thoracic aorta. The guidewire also needs a soft tip so that when it is «anchored» by reflecting off the aortic valve, injury to the valve is avoided. For this purpose we prefer the Nitrex wire (ev3, Inc., Plymouth, MN, USA), Platinum Plus wire (Boston Scientific Corp.), or Meier wire (Boston Scientific Corp.). The Nitrex wire has become a favorite because it routinely reflects off the valve without any difficulty. These wires provide enough support to track most large catheters or devices; the Platinum Plus is often used for peripheral stent placement, and

the Meier wire is intended for TEVAR. However, a very stiff guidewire may be needed to further straighten vessel tortuosity and provide the tracking capability needed when delivering large devices such as thoracic aortic endograft systems (Andros et al. 2006; Deeb and Williams 2004; Ohki and Malas 2005; Schneider 2006). For this we choose either an Amplatz Super-Stiff wire (Boston Scientific Corp.) or a Lunderquist Extra-Stiff wire (Cook, Inc.). The Lunderquist wire is the stiffest guidewire in our supply and so the action is first attempted with the Amplatz Super-Stiff wire. The most flexible and safest guidewire that can accommodate the intended action should be used first. The Lunderquist and Amplatz stiff wires feature a short, straight tip; alternatively, a stiff guidewire with a preformed J-tip could be used, such as a Rosen wire (Cook, Inc.) (Chuter 2006). This wire is often employed for exchange of angioplasty catheters. ■ Table 28.2 lists various guidewires, both standard and exchange length, commonly used in TEVAR (Khoynezhad and Kruse 2009).

28.3.7.3 Catheters

Diagnostic catheters allow the practitioner to assess areas of the vascular system in order to evaluate for a possible intervention, but they also assist in performing the intervention. Often, this entails the delivery of radiographic contrast for opacification of the vessel lumen in radiographic studies. This can involve visualization of a specific branch vessel using a selective catheter or visualization of a significant portion of the arterial arborization using a nonselective catheter. Angiography in TEVAR is used to visualize the thoracic and thoracoabdominal aorta, as well as all branch vessels that may be affected by endograft placement. ■ Table 28.3 presents some useful catheter properties determined by catheter material.

Nonselective catheters are usually constructed of nylon and designed to rapidly infuse large volumes of contrast agent without injuring the vessel. To accomplish this, the distal portion of these catheters contains multiple side holes in addition to the standard end hole. This distal portion is preformed into a shape that assists in dispersion of the contrast, that is, Omniflush, Grollman pigtail, straight, tennis racket, and multipurpose (Ayerdi and Hodgson 2005; Dauterman et al. 2005; White and Silva 2007). Nonselective catheters are generally used only in large-diameter vessels such as the aorta or its primary branches. Aortography in TEVAR cases is

Table 28.2 Guidewires used in TEVAR

Device	Dimensions and materials	Company	Characteristics
Initial access and lesion crossing			
Bentson Starter	0.035" x 180 cm; stainless steel	Boston Scientific Corp. (Natick, MA, USA)	Preferred wire for initial access, TFE-coated medium rigid wire with straight floppy tip
Safe T-J	0.035" x 180 cm; stainless steel	Cook, Inc. (Bloomington, IL, USA)	TFE coated with soft J-tip
Wholey	0.035" x 145 cm; stainless steel with gold tip	Mallinckrodt, Inc. (St. Louis, MO, USA)	TFE-coated steerable wire with floppy tip
Glidewire	0.035" x 180 cm; nitinol core wire, polyurethane jacket with tungsten	Terumo Medical Corp. (Somerset, NJ, USA)	Hydrophilic coated, adept at traversing difficult anatomy, dissection risk

Teflon (poly)tetrafluoroethylene

normally done with a 5-F pigtail catheter inserted via retrograde femoral artery cannulation contralateral to the side of endograft device introduction.

Selective catheters, with a single end hole, are designed for the selective catheterization and contrast injection of specific branch vessels. An abundant selection of preformed distal ends is available to assist in catheterization of the various anatomic branch points of the vascular system. For primary aortic access in TEVAR from a retrograde femoral artery approach, we prefer a Berenstein-tipped catheter (Imager II Selective BERN, Boston Scientific Corp.), which is a shape similar to a hockey stick. When it is necessary to navigate tight stenoses, an alternate angled tip catheter that is hydrophilic coated may be useful (Glidecath, Terumo Medical Corp., or Slip-Cath, Cook, Inc.). For selective catheterization of aortic arch branches, common catheter shapes include Berenstein or vertebral, JR4, Vitek (Cook, Inc. Bloomington, IN), headhunter, and Simmons (Andros et al. 2006; Ayerdi and Hodgson 2005; Dauterman et al. 2005; White and Silva 2007). For catheterization of renal or mesenteric arteries, popular shapes are cobra, renal double curve, Judkins right, and shepherd hook (Simmons or Omni SOS). Although TEVAR can often be performed with only routine catheter types such as Berenstein and pigtail, familiarity with the range of available catheter shapes is needed in order to accommodate anatomic variations. Nonselective and selective catheters commonly used in TEVAR are shown in ■ Table 28.4.

28.3.7.4 Sheaths

Introducer sheaths currently provide the safest method of maintaining access to the vascular system during an endoluminal procedure. Use of sheaths is now recommended for nearly every endoluminal procedure, diagnostic or interventional. Large-diameter sheaths (18–24 F) are available for deployment of endografts in the treatment of aortic pathologies. Often, these sheaths are included into the endograft delivery systems. Sheath lengths range from 10 to 65 cm. However, a majority of sheaths used in our endograft cases are 10 cm in length. ■ Table 28.5 lists the commonly used sheaths in TEVAR procedures.

28.4 Imaging

28.4.1 Computed Tomographic (CT) Angiography

The pre-interventional contrast-enhanced CT angiography is the most common and precise imaging to delineate aortic pathology. If available, a fine-cut CT scan of the thoracic and abdominal aorta should be performed. Its noninvasive nature, the fast and extensive image receipt, the decreased amount of contrast needed, and the added value of visualization of structures in relation with the aorta are important aspects of this method. Nevertheless, the radiation exposure to the patient needs to be taken into account, especially in the occasional very young or in the rare pregnant patients.

Table 28.4 Catheters used in TEVAR			
Device	Dimensions and materials	Company	Characteristics
Selective			
Imager II selective	5 F × 100 cm (4 F with brachial access); Pebax composite with tungsten layering for radiopaque tip	Boston Scientific Corp.	Berenstein tip; preferred catheter for aortic access in combination with Bentson Starter wire; antifriction coating

Keller–Timmerman	18–24 F × 25–56 cm	Cook, Inc.	Large, valved sheath
Large and extra large, Check-Flo	10–24 F × 25–60 cm	Cook, Inc.	Tapered sheath with hemostatic valve

From Khoynzhad and Kruse (2009)

Accurate measurements using advanced imaging software that allow 3D reconstructions are of paramount importance (Criado 2011; Ferreira et al. 2008; Melissano et al. 2009; Setacci et al. 2012).

28.4.2 Magnetic Resonance Imaging (MRI)

MRI angiography is very helpful when CT angiography is contraindicated as in contrast intolerance or renal insufficiency. The dynamic contrast-enhanced MR angiography provides stable imaging within an acceptable speed. Alternatively «time-of-flight» noncontrast MRA can provide adequate imaging of the aorta. When dealing with aortic dissection, a second MR scan for the late enhancement may be helpful (Rousseau et al. 2009) (■ Table 28.5).

28.4.3 Intravascular Ultrasound

Intravascular ultrasound (IVUS) catheters constitute a valuable resource for the practitioner performing endoluminal procedures. The distal portion of the IVUS catheter incorporates a cylindrical ultrasound transducer that generates real-time cross-sectional images of vessels. This technology has numerous applications in TEVAR. IVUS is the most accurate modality in measuring the luminal diameter of vessels and can also be used to identify the position of branch vessels, inspect vessel wall morphology, evaluate for the presence of plaques or thrombi, and select appropriate landing zones for endografts (Khoynzhad et al. 2012a; Mauri and Kinlay 2007; White 2004, 2006). A particularly important

application of IVUS is the confirmation of the true vessel lumen in aortic dissection.

Adequate positioning of the endovascular graft has been cited as the major difficulty leading to technical failure (Fattori et al. 2003; Grabenwöger et al. 2000). The introduction of intravascular ultrasound has proved to be an important adjunct used during the endovascular procedure. It allows a more accurate length measurement of the proximal and distal landing zones, better evaluation of aortic side branch anatomy, and confirmation of the position of the wire in the true lumen in aortic dissections (Fernandez et al. 2008; Lee and White 2004a). After release of the endograft, IVUS permits confirmation of adequate stent graft deployment, complete apposition to the vessel, and evaluation for endoleaks and gives a good assessment of true and false lumen diameter and flow to the branch vessels (Lee and White 2004a). IVUS can significantly reduce the amount of contrast material used and fluoroscopy exposure to both the patient and the team of healthcare providers. For evaluation of the larger-diameter thoracic and thoracoabdominal aorta, a low-frequency catheter is needed (e.g., Visions PV 8.2 F; Volcano Corp., San Diego, CA, USA). Familiarity with the artifacts produced by guidewires and catheters in the arterial lumen is essential in using this technology (■ Tables 28.6 and 28.7).

28.4.4 Transesophageal Echocardiography (TEE)

The use of two-dimensional (2D) TEE has some advantages in early diagnosis of thoracic aortic pathologies. The TEE should be available in nearly all emergency rooms; it is semi-invasive and can be

performed without using contrast dye. The TEE allows imaging of the thoracic, ascending, and descending aorta including the supra-aortic vessels. At times, parts of the upper abdominal aorta can be visualized, too. By using color Doppler, the intimal tear or the blood disturbances in an aneurysm can be detected (Rousseau et al. 2009).

28.5 Adjunctive Pharmacology

In order to have a successful endovascular procedure, a series of adjunctive medications is used either during or after the procedure. In the following, the most frequently used pharmacologic agents

are described along with their clinical indications and limitations in today's endovascular practice.

28.5.1 Heparin

Anticoagulation with heparin is performed before the large-bore sheaths are introduced into the arteries. This serves to reduce thrombotic complications secondary to stagnant circulation of the ipsilateral extremity. The initial bolus dose of heparin is 80 U/kg and the activated clotting time (ACT) is checked after 3 min. The large sheath is introduced into the femoral and iliac arteries after successful systemic anticoagulation is confirmed. The therapeutic range of ACT is 200–300 s during the TEVAR procedure. The ACT is rechecked every 30–45 min and more heparin is given according to the ACT. At the end of the endovascular procedure, and once the presence of distal pulses has been confirmed, protamine can be given to reverse the heparin effects. The only exception to this practice is in patients with traumatic aortic transections, who frequently have trauma-related cerebral and abdominal bleeding that can be exacerbated by heparin bolus in the endovascular operating room. In these cases, based on the surgeon's judgment, either no heparin is given or a subtherapeutic bolus (2,000–4,000 U) is given to polytraumatized patients.

28.5.2 Vasopressin

In endovascular procedures, vasopressin or other vasoactive drugs (e.g., epinephrine, norepinephrine) are used to increase systemic blood pressure in patients who are at high risk of spinal cord ischemia. Unlike catecholamines, vasopressin does not cause

tachycardia, which can have deleterious effects on coronary perfusion and increase in myocardial contractility during stent graft deployment. The blood supply to the spinal cord arises from the intercostal arteries (most importantly from the T7 to L3 segmental arteries) and from branches of the subclavian and internal iliac arteries. When a significant portion of this network of vessels is affected by the stent graft, the possibility of spinal cord injury resulting in paraplegia or paraparesis is increased (Khoynzhad et al. 2005, 2007b; Khoynzhad and Donayre 2007a; Maeda et al. 2012; Safi et al. 2008). An increased blood pressure following the use of vasopressin increases the spinal cord perfusion pressure and therefore reduces the possibility of postprocedural spinal cord ischemia (Eggebrecht et al. 2006a; Khoynzhad et al. 2007a). The mean arterial pressure is kept between 85 and 95 mmHg using vasopressin or other hemodynamic stimulants.

28.5.3 Adenosine

Adenosine bolus is utilized during percutaneous intervention of the aorta to induce transient asystole so as to reduce the impulse of the cardiac output during stent graft deployment. The usual intravenous dose for TEVAR is 36 mg adenosine (followed by 18 mg for subsequent episodes), which will produce a cardiac asystole for a period of 4–6 s (Lippmann et al. 2007). This transient asystole reduces the maximum rate of pressure development in the left ventricle and the aorta and the force applied to the stent graft at the time of the deployment. The reduced «windsocking» effect allows for a more precise deployment of the stent graft and reduces the chance of malposition and inadvertent coverage of vital brachiocephalic arteries. The «windsocking» effect also applies to ballooning of the stent graft. This is performed to expand the stent graft to appose the aortic wall, thereby stopping type I endoleaks. Adenosine cardiac arrest is used at this time as well. Alternatives to adenosine include rapid right ventricular pacing which is also often used for transcatheter valve replacement.

28.5.4 Beta-Adrenergic Receptor Blockers

The American Heart Association has published guidelines recommending the use of beta-blockers

for the treatment of hypertension in patients with angina, prior myocardial infarction, or heart failure (Rosendorff et al. 2007). Their use in TEVAR is limited to temporary anti-impulsive/anti-hypertensive therapy during deployment and ballooning of the stent graft and is therefore not addressed by the American Heart Association guidelines.

Beta-blockers are competitive inhibitors of endogenous catecholamines at beta-adrenergic receptor sites, causing negative chronotropic and inotropic effects that are desired during certain portions of TEVAR procedure. For the same reasons, short-acting beta-blockers such as esmolol are preferred during TEVAR. The onset of action after intravenous administration is extremely rapid, with steady-state concentrations achieved within 5 min of a loading dose being given. Steady-state esmolol concentrations are proportional to the infusion rate. Following discontinuation, esmolol effects begin to decline in 1–2 min, with beta-antagonist activity completely reversed within approximately 20 min. Another beneficial side effect is the beta-1-selectivity. Cardioselective beta-blockers such as esmolol have less influence on bronchial and vascular beta-2 receptors and are safer for patients with chronic obstructive lung disease (Andrus and Loyed 2008).

28.5.5 Aspirin

Aspirin is an integral part of treatment during and after endovascular interventions, including intra-aortic and intracoronary stent implantation (Rodondi et al. 2005). Aspirin can also reduce the size of an embolic stroke by decreasing subsequent clot formation.

Most patients undergoing TEVAR are already on aspirin for the aforementioned reasons. However, some patients with aortic dissection, aortic transection, or aortic aneurysm might not be receiving an antiplatelet agent. To reduce the chance of clot formation in the proximity of the proximal and distal junctions of the stent graft and the aorta, these patients should be placed on low-dose aspirin initiated on the first postoperative day for a period of 3–6 months after original TEVAR. This will allow for pseudo-intimal coverage of the stent graft, including the critical segment of the aorta that may be prone to clot formation and distal embolization.

28.5.6 Clopidogrel

In order to reduce stroke and the thrombotic complications in proximity of the proximal and distal junctions of the stent graft and the aorta, patients undergoing TEVAR should receive an antiplatelet medication for 3–6 months after index TEVAR. Aspirin is the first-choice antiplatelet medication; however, a dual antiplatelet or sole clopidogrel therapy is indicated in a subset of patients, including those with aspirin sensitivity, allergy to aspirin, or aspirin resistance.

Although there is increased surgical or intervention associated bleeding with the preoperative use of clopidogrel, this is not clinically significant unless a retroperitoneal iliac artery exposure or sternotomy for vascular access is necessary. In these patients, the risks and complications associated with increased perioperative bleeding must be weighed against the benefits of starting clopidogrel preoperatively early in patients with coronary artery disease, especially with recent drug-eluting stents. Premature discontinuation of dual antiplatelet therapy prior to noncardiac surgery has been found to be associated with increased rate of stent thrombosis, myocardial infarction, and death (Vicenzi et al. 2006).

28.5.7 Preoperative Antibiotics

Prophylactic antibiotic administration is indicated before the skin incision is made for TEVAR to reduce surgical site and possible stent graft infection. Antibiotic administration should take place within 1 h of skin incision for vascular access. Redosing of intraoperative antibiotics is indicated for lengthy procedures of significant blood loss. Postoperative antibiotics are not necessary and might increase opportunistic infections.

28.5.8 Nephroprotective Adjuncts

There is controversy in the literature regarding the incidence of worsening renal function following repair of thoracic aortic pathologies with stent grafts resulting in a large spectrum of reported incidence ranging from 1.5 to 33% (Eggebrecht et al. 2006b; Fairman et al. 2008). This is partially the case because a standard definition for renal failure such as the one supported by National

Kidney Foundation is not reliably used (Levey et al. 2003). The etiology of increased post-TEVAR renal dysfunction is thought to be contrast nephropathy, although an atherosclerotic embolic component during TEVAR cannot be excluded (Eggebrecht et al. 2006a).

The principles of renal protection in the perioperative period include bicarbonate-based intravenous hydration, maintenance of adequate blood pressure, avoidance of nephrotoxic drugs, rapid treatment of malperfusion syndromes in patients with aortic dissections, the use of low-osmolar contrast medium, and reducing the amount of administered contrast medium (Maeder et al. 2004). The latter is arguably the most important in routine, uncomplicated TEVAR cases. A reduction in the amount of contrast material might be achieved by adjunctive use of intravascular ultrasound during the TEVAR and a feasible reduction in contrast bolus amount and concentration (Pisimisis et al. 2010). The use of N-acetylcysteine, originally a routine measure to protect the kidney, was found to be ineffective in avoiding contrast nephropathy in recent trials (Ferrario et al. 2009).

28.6 TEVAR for Thoracic Descending and Thoracic Abdominal Aneurysm

To date, there have not been any randomized trials comparing TEVAR to open surgical repair (OSR) for treatment of DTAAs. The published trials leading to the FDA approval of the three commercially available devices in the United States were nonrandomized, industry-sponsored studies comparing endovascular to open surgical repair of DTAAs (Fairman et al. 2008; Makaroun et al. 2005; Melissano et al. 2010).

In 2008, the 5-year results of the Gore TAG trial were published, comparing patients undergoing TEVAR ($n=140$) with standard open surgical controls ($n=94$) from 1999 to 2001 (Makaroun et al. 2008). Early data showed a significantly lower aneurysm-related mortality after endovascular repair compared to open surgery after 5 years (2.8% vs. 11.7%, $p<0.008$), but no difference in the all-cause mortality after 5 years (68% vs. 67%, $p=0.43$). During follow-up the TEVAR group was less likely to be subject to experience major adverse events (57.9% vs. 78.7%, $p<0.01$) or an additional secondary interventions (15.0% vs. 31.9%, $p<0.01$).

In the STARZ (Matsumura et al. 2008) (Study of Thoracic Aortic Aneurysm [TAA] Repair with the Zenith TX2 Thoracic TAA Endovascular Graft) multicenter study, 160 patients were treated with the Zenith TX2 TEVAR system and 70 patients underwent open surgical repair (OSR) from 2004 to 2006. The 30-day survival was non-inferior for the TEVAR group (TEVAR 98.1% vs. open group 94.3%, $p < 0.01$), and the cumulative major morbidity scores were significantly lower in the TEVAR group at 30 days compared with the open group (Matsumura et al. 2008). Reintervention rates were similar in both groups at 12 months (TEVAR 4.4%, OSR 5.7%). At 30 days, The TEVAR patients had fewer cardiovascular, pulmonary, and vascular adverse events compared to OSR, but no significant difference in neurologic events (TEVAR 8.1%, OSR 14.3%, $p 0.15$). There were no ruptures or conversions during the first year. At 12 months, aneurysm growth was identified in 7.1%.

The VALOR (*Medtronic Vascular Talent Thoracic Stent Graft System for the Treatment of Thoracic Aortic Aneurysms*) clinical trial enrolled 195 patients with DTAA undergoing TEVAR between 2003 and 2005 (Fairman et al. 2008). The results were compared to those obtained in 189 patients after OSR for DTAA. Patients received a mean number of 2.7 ± 1.3 stent graft components. In 33.5% of patients, the bare spring segment of the most proximally implanted device was in zone 1 or 2 of the aortic arch. Left subclavian revascularization was performed prior to TEVAR in 5.2%. The incidence of paraplegia was 1.5% and stroke 3.6%. The TEVAR group had better acute procedural outcomes compared to OSR ($p < 0.001$), decreased number of 30-day major adverse events (41% vs. 84.4%, $p < 0.001$), lower perioperative mortality (2% vs. 8%, $p < 0.001$), and decreased 12-month aneurysm-related mortality (3.1% vs. 11.6%, $p < 0.002$), respectively.

Lee et al. (2011a, b) reported a series of 400 consecutive patients receiving TEVAR from 2000 to 2009 for various pathologies including aneurysms (49%), dissections (25%), penetrating ulcers (14%), and traumatic transections (6%). The overall 30-day mortality was 6.5% (elective 2.6%, urgent 9.5%, emergent 20%), spinal cord ischemia occurred in 4.5% of patients, and stroke in 3%. Spinal drains were placed prophylactically in 32% of planned extended aortic coverage. The 3-year survival rate was 78%. Risk factors for mortality included stroke,

urgent/emergent repair, age ≥ 80 years, general anesthesia, and dissection pathology. Overall rates of mortality and neurological complications were relatively low, but there were a substantial number of late deaths that could be attributed to patient selection and treatment failures.

A meta-analysis of 42 nonrandomized studies involving 5,888 patients comparing TEVAR and OSR for treatment of DTAA performed by Cheng et al. was recently published (Cheng et al. 2010). TEVAR patients were significantly older, but there was no significant difference in baseline comorbidities between the two groups including coronary artery disease, diabetes, chronic obstructive pulmonary disease, smoking, hypertension, and renal insufficiency. At 30 days, all-cause mortality (5.8% TEVAR vs. 13.9% OSR), paraplegia, cardiac complications, transfusions, reoperation for bleeding, renal dysfunction, pneumonia, and length of stay were lower for TEVAR compared to OSR. However, there was no significant difference in stroke, myocardial infarction, aortic reintervention, and mortality beyond 1 year.

An observational study comparing all Medicare patients in the United States undergoing TEVAR and OSR for intact and ruptured DTAA from 1998 to 2007 was recently published (Goodney et al. 2011). Overall, 12,573 patients underwent OSR, and 2,732 patients underwent TEVAR. This review of «national, real-world practice» found that perioperative mortality was lower for patients undergoing TEVAR compared with OSR for both intact (6.1% vs. 7.1% $p = 0.07$) and ruptured (28% vs. 46%, $p < 0.0001$) DTAA. However, patients undergoing TEVAR for intact DTAA had significantly worse survival than those undergoing OSR at 1 year (TEVAR 82%, OSR 87%, $p = 0.001$) and at 5 years (TEVAR 62%, OSR 72%, $p = 0.001$). In adjusted and propensity-matched cohorts, patients undergoing TEVAR had worse 5-year survival than those undergoing OSR. The authors interpreted these findings to suggest that higher-risk patients are being offered TEVAR who previously may not have undergone OSR. However, since the propensity-matched analysis demonstrated worse long-term survival in patients undergoing TEVAR, these differences in survival could be explained by device-related complications occurring within the first 5 years of surgery.

These studies all demonstrate TEVAR to be a safe and effective alternative to OSR, with lower perioperative mortality and complications.

However, sustained benefits on long-term survival have not yet been proven (Cheng et al. 2010), and randomized trials will be needed to address this question.

28.6.1 Open Debranching and TEVAR (Hybrid Aortic Repair)

Generally, patients with «physiological constraints,» not being suitable candidates for open thoracoabdominal or aortic arch repair, are usually evaluated for TEVAR (including fenestrated and branched TEVAR), while patients with «anatomic constraints,» not having proper proximal and distal landing zones, are considered for open repair. There is a cohort of patients, who are poor candidates due to physiologic and anatomic constraints that may benefit from open debranching followed by TEVAR exclusion of the branched-aortic portion (■ Fig. 28.5a, b). Alternatively, for most patients in the United

States requiring TAAA repair, a complete endovascular solution is not commercially available. For these patients, hybrid aortic repair may be a reasonable option.

Hughes and colleagues reported a series of 47 patients from March 2005 to June 2011 undergoing extra-anatomic debranching of all visceral vessels followed by endovascular aneurysm exclusion (Hughes et al. 2012). The debranching and endovascular portions of the procedure were performed in a single operation in the initial 33 patients and as a staged procedure during a single hospitalization in the most recent 14 patients. The 30 day rates of death, stroke, and permanent paraparesis/paraplegia were 8.5%, 0%, and 4.3%, respectively, but were 0% in the 14 patients undergoing staged repair. Lin and colleagues also reported a lower rate of renal insufficiency in patients undergoing a staged approach versus a single operation (Lin et al. 2010).

Our midterm follow-up of debranching procedures in the TAAA and aortic arch has been

■ Fig. 28.5 Extra-anatomic bypass to celiac, superior mesenteric, and both renal arteries coming off the left common iliac artery using a custom quadrifurcated graft a. Completion angiogram reveals patency of all bypassed grafts and exclusion of the aneurysm. Same custom graft can be used for total aortic arch hybrid repair b

published (Khoynzhad et al. 2012b). From 342 patients between 2005 and 2011, 195 required a combined open and endovascular approach. From this group, 52 patients with multiple comorbidities had hybrid repair using the custom quadfurcated graft for TAAA (35%) or arch (65%) repair. Forty patients underwent simultaneous repair. There were 4% perioperative stroke, with no paraplegia/paraparesis, no endoleak, and no new-onset renal replacement therapy. Early mortality was 6%, with 4-year survival rate at 79%. All surgical grafts were patent; there was one endovascular reintervention and no aortic-related death in average 34 months follow-up. In our experience hybrid aortic repair is feasible, safe, and effective in this selected high-risk patient cohort. Furthermore, appropriate patient selection for hybrid debranching is critical for optimal outcomes, and with increased penetration of commercially available branched and fenestrated stent grafts, the role of hybrid debranching would be limited (Khoynzhad et al. 2012b).

28.6.2 Branched and Fenestrated Grafts for TEVAR

Conventional open surgical techniques to repair thoracoabdominal aortic aneurysms (TAAA) have achieved excellent results in the modern era with the addition of intraoperative adjuncts including distal aortic perfusion, cerebrospinal fluid drainage, and passive moderate hypothermia with the overall incidence of neurologic deficits decreasing to approximately 2% (Estrera et al. 2005; Safi et al. 2008). Due to the complexity of this procedure, endovascular techniques have been adopted for the treatment of TAAAs in patients who are at high risk for open surgical repair. If thoracic aneurysms require fixation or landing zones within the aortic arch or visceral segment of the aorta, endovascular repair requires either a hybrid two-staged operation with open surgical debranching followed by endovascular graft exclusion or a single-stage endovascular repair using either branched or fenestrated stent grafts. In the United States, these devices are currently available only as part of a physician-investigator-sponsored IDE (Investigational Device Exemption) study.

Open surgical aortic arch replacement requires cardiopulmonary bypass with deep hypothermic circulatory arrest. Hybrid aortic

arch debranching procedures combined with TEVAR for arch aneurysms involving zones 0 and 1 can be performed without the need for cardiopulmonary bypass in patients who are at significant risk with open surgical repair. Antoniou and colleagues performed an analysis in 2010 of all published series reporting on hybrid aortic arch repair with supra-aortic branch revascularization and thoracic stent graft deployment (Antoniou et al. 2010). A total of 18 series with 195 patients were analyzed (only series with greater than 5 patients were included in analysis). Complete arch repair was performed in 63%; perioperative mortality was 9%. The incidence of perioperative stroke was 7%, spinal cord ischemia 0.5%, and endoleak (type I or III) 9%.

Experience with branched and fenestrated devices has accumulated in a few specialized centers throughout the world during the past decade. Rodd et al. (2011) studied 70 consecutive patients with thoracic abdominal aortic aneurysms. Only 60% of the patients were identified as suitable for complete endovascular repair. In 1999, Inoue (Inoue et al. 1999) implanted surgeon-made stent grafts (one to three side branches) into 15 patients with thoracic aortic aneurysm with a primary success rate of 60%, a median follow-up of 12.6 months, and two late deaths. Uchida (Uchida et al. 2010) reported on a case of an ascending aortic rupture that was treated with endovascular therapy using a custom-made fenestrated stent graft introduced via the femoral artery. These examples demonstrate that experience with branched endovascular aortic repair and fenestrated endovascular aortic repair is still limited (Bungay et al. 2011; Murphy et al. 2012). Chuter and coauthors (2003) developed branched stent grafts with a simplified modular approach to make branched and fenestrated TEVAR technology ready for a more widespread use. Dijkstra, Greenberg, and colleagues reported on advances in imaging technologies with the ability to integrate a preoperative CT scan into the operative fluoroscopic image which allowed for more accurate positioning of the stent graft in relation to critical branches without the need for angiography and reduced radiation and contrast medium exposure in complex branched and fenestrated endovascular stent graft cases (Dijkstra et al. 2011).

Greenberg and colleagues reported a series of 406 patients with thoracoabdominal aneurysms

and 227 patients with juxtarenal aneurysms who underwent repair with branched endografts (Greenberg et al. 2010). Reinforced fenestrated branches coupled with balloon-expandable stent grafts, and sidearm branch designs were used in the study. When patients undergoing endovascular repair (ER) were matched with those undergoing surgical repair (SR) for anatomic extent of disease, mortality at 30 days (5.7% ER vs. 8.3% SR), mortality at 12 months (15.6% ER vs. 15.9% SR), and paraplegia risk (4.3% ER vs. 7.5% SR) were similar between the two groups. Reinforced fenestrated branch patency when coupled with balloon-expandable stent grafts was 97.8% with a mean follow-up of 15 months.

28.7 TEVAR for Acute Thoracic Aortic Dissection

28.7.1 Uncomplicated Type B Dissection

Acute descending thoracic aortic dissection (Stanford type B) is a dramatic and potentially catastrophic condition. The current treatment of type B dissection remains medical (Estrera et al. 2007), and the majority of patients with uncomplicated disease can be treated conservatively with anti-impulsive and antihypertensive therapy (Khoynezhad and Plestis 2006). Antihypertensive therapy should include β -blockers such as labetalol, esmolol, and metoprolol. This has two goals: reduction in blood pressure and prevention of a reflex tachycardia. Reflex tachycardia may increase the maximum left ventricular contraction force (dP/dt) and must be avoided in the acute phase of the disease (Khoynezhad et al. 2009b). If β -blockers cannot be used, calcium channel blockers may serve as equally efficacious alternative, without inducing reflex tachycardia. The target heart rate should be less than 60 bpm and the target systolic blood pressure less than 100 mmHg. An effective pain control regimen using morphine is recommended to tranquilize the patient and reduce stress-induced hypertension (Garbade et al. 2010; Gupta et al. 2009; Khoynezhad and Plestis 2006; Khoynezhad et al. 2010; Svensson et al. 2008). Hemodynamic stabilization in the acute setting is important to decrease the risk of secondary adverse events such as further dissection,

branch vessel malperfusion, and weakening of the aortic wall (Kodama et al. 2008; Svensson et al. 2008).

Estrera and colleagues reported a series of 159 patients with acute type B aortic dissection in which the mortality associated with uncomplicated dissection (85/159 patients) was 1.2% with medical management (Estrera et al. 2007). Nevertheless, long-term mortality rates remain high and successful management remains a clinical challenge. Data from the International Registry of Acute Aortic Dissection (IRAD) indicates that the 3-year survival of patients treated medically was only 77% and that independent predictors of mortality include female gender, history of prior aortic aneurysm, history of atherosclerosis, in-hospital renal failure, and in-hospital hypotension (Tsai et al. 2006).

Persistent patency of the false lumen has been implicated as a predictor of poor long-term outcomes. The European multicenter study showed that late outcome was better in patients with a thrombosed false lumen than in those with a patent false lumen (Erbel et al. 1993). In an analysis of 62 patients with chronic type B dissections undergoing regular follow-up CT scans, Sueyoshi et al. found that the presence of blood flow in the false lumen was the only significant risk factor for the increase in diameter. The patients with blood flow in the false lumen had significantly higher mean growth rate of the aorta (3.3 mm/year) than the patients without blood flow (-1.4 mm/year) (Sueyoshi et al. 2004).

The Investigation of Stent Grafts in Aortic Dissection (INSTEAD) trial was undertaken to determine if endovascular treatment might improve long-term outcome in patients with type B dissections (Nienaber et al. 2009). This was a randomized trial in which 140 patients in stable clinical condition at least 2 weeks after the index dissection underwent either elective TEVAR in addition to optimal medical therapy or optimal medical therapy alone. The investigators found no difference in all-cause mortality or aortic-related mortality between the two groups; the 2-year survival rate was 95.6% with optimal medical therapy versus 88.9% with TEVAR ($p=0.15$). Although there was no difference in midterm survival, aortic remodeling (defined as true lumen recovery and thoracic false lumen thrombosis) occurred with 91.3% of patients with TEVAR versus 19.4% of those with optimal medical therapy. The question of whether thrombosis of the false

lumen in the thoracic aorta has any impact on survival needs further reporting of long-term follow-up on these patients.

A randomized European trial comparing TEVAR with the GORE TAG device and best medical therapy to best medical therapy alone (ADSORB) in patients with uncomplicated acute type B dissections is currently ongoing (Brunkwall et al. 2012). The primary outcomes include false lumen thrombosis, aortic rupture, and aortic dilation. The results of this trial may help further define the role of TEVAR in the management of uncomplicated acute type B dissection.

28.7.2 Complicated Type B Dissection

Management of complicated type B dissection remains challenging, as open surgical repair performed under emergent conditions even in experienced centers of excellence is associated with significant morbidity and mortality (Crawford et al. 1988; Estrera et al. 2007). Estrera and colleagues reported a mortality of 17% in their series of patients with complicated type B dissection (Estrera et al. 2007). For this reason, TEVAR is gaining increasing acceptance as an initial treatment for patients with complicated type B dissection (Dake et al. 1999; Hansen et al. 2004; Nienaber et al. 1999). The goal of this therapy is to exclude the primary entry site, obliterate the false lumen, prevent aortic rupture, and relieve lower body malperfusion.

In 2009, we reported midterm results of 28 patients undergoing endovascular interventions for complicated acute type B aortic dissection (Khojenezhad et al. 2009a). Indications for emergency TEVAR were rupture in 14%, severe lower body malperfusion in 29%, visceral/renal malperfusion in 25%, persistent chest pain despite proper anti-impulsive therapy in 18%, uncontrollable hypertension in 4%, and acute dilation of false lumen with impending rupture in 11% of patients. Overall survival was 82% at 1 year and 78% at 5 years follow-up (mean follow-up 36 months with complete follow-up in 100%). The aorta-related mortality was 10% for the entire follow-up period. Complete thrombosis of the false lumen was observed in 85% of survivors, and partial thrombosis was observed in the remainder. Zeeshan, Bavaria, and colleagues reported a series of 45 patients with complicated

type B dissection undergoing TEVAR in whom the 30-day mortality was 4%, and the survival at 1, 3, and 5 years was 82%, 79%, and 79%, respectively (Zeeshan et al. 2010). Twenty patients undergoing open surgical repair with similar characteristics had 30-day mortality of 40% with 1-, 3-, and 5-year survival of 58%, 52%, and 44% ($p=0.008$).

The «PETTICOAT» (Provisional ExTension to Induce COmplete Attachment) procedure employing a covered Zenith TX2 stent graft placed over the proximal entry tear with self-expandable bare stents placed distally has been performed in patients undergoing TEVAR for complicated type B dissection (Lombardi et al. 2012; Melissano et al. 2012a). The STABLE (Study of Thoracic Aortic Type B Dissection Using Endoluminal Repair trial) investigators recently published their results of a prospective single-arm multicenter study with 40 patients using a composite TEVAR (Lombardi et al. 2012). The study reports 5% inhospital mortality and a 90% survival after 1 year. Morbidity within 30 days included stroke 7.5%, paraplegia 2.5%, retrograde progression of dissection 5%, and renal failure 12.5%. Favorable aortic remodeling was observed during follow-up, with complete thrombosis of the thoracic false lumen noted in 31% noted at 12 months.

TEVAR for complicated type B dissection is associated with superior early and midterm outcome compared to open surgical repair. A large trial with a multicenter registry is needed to substantiate these findings and establish long-term (>10 years) durability and safety of stent grafts in complicated acute type B aortic dissection.

An intramural hematoma (IMH) without intimal disruption occurs in approximately 5–20% of the patients with acute aortic syndromes and is most often located in the descending aorta (Evangelista et al. 2003; Ganaha et al. 2002; Nienaber and Eagle 2003; Shimizu et al. 2000; Svensson et al. 2008). Progression to aortic dissection occurs in 16–36% of patients, and symptomatic patients can be managed in similar fashion as patients with acute type B dissections (Evangelista et al. 2003; Maraj et al. 2000; Svensson et al. 2008). TEVAR is indicated in IMH associated with penetrating aortic ulcer (PAU) or secondary to vasa vasorum hemorrhage in the media, as progression of disease with enlargement of the aneurysm and ongoing dissection has to be expected

(Grabenwoger et al. 2003). PAU may appear as an «ulcerlike» projection into the media of the aorta and is often associated with extensive atherosclerosis, with or without IMH, as well as pseudoaneurysms (Chong et al. 2012; Ledbetter 2005; Svensson et al. 2008). The aortic pathology is regional with PAU, and therefore, endovascular repair may be the ideal therapy (Czerny et al. 2004; Demers et al. 2004; Neuhauser et al. 2004), although significant atherosclerotic burden may make suitable sheath access and passage of guidewires into the aortic arch challenging (Svensson et al. 2008).

28.7.3 TEVAR in Blunt Aortic Injury

Blunt traumatic aortic injury is the second leading cause of death from blunt trauma after head injury, though it accounts for less than 1% of trauma admissions (Clancy et al. 2001). Following traumatic aortic injury, approximately 85% of the patients die before being transferred to the hospital, and 30% of those reaching the hospital alive die within the next 6 h (Hoffer 2008; McGwin et al. 2002).

Endovascular repair is an effective treatment option in patients who may not be able to undergo open surgical repair safely and may decrease the risk of paraplegia. Early endovascular experience included the use of commercially available aortic cuffs to treat these injuries since there were no commercially available thoracic stent grafts suitable for this application (Sam et al. 2003). With the availability of smaller diameter thoracic stent grafts which conform better to the aortic arch in younger patients who are frequently the victims of traumatic aortic injury, TEVAR offers the potential for a durable aortic repair while avoiding the morbidity of a thoracotomy, aortic cross-clamping, and extracorporeal circulation. In 2012, the US FDA approved the first commercially available stent graft (Gore TAG, Gore and Associates, Inc., Flagstaff, AZ) for endovascular aortic repair for the treatment of traumatic aortic injury.

The Society of Vascular Surgery (SVS) commissioned a third party (Knowledge and Encounter Research Unit, Mayo Clinic, Rochester, MN) to perform a systematic review and meta-analysis of the available literature to address this issue, and published clinical practice guidelines based on the findings (Lee et al. 2011a, b). The

systematic review included 7,768 patients (mean age 39 years TEVAR, 36 years OSR). The mortality rate was significantly lower in patients undergoing TEVAR compared to OSR (9% vs. 19%, $p < 0.01$). There was no significant difference in stroke rate between the two groups, but the risk of spinal cord ischemia (SCI) and end-stage renal disease (ESRD) was higher with OSR compared with TEVAR (SCI 9% open vs. 3% TEVAR, $p = 0.01$; ESRD 8% open vs. 5% TEVAR, $p = 0.01$). The percentage of patients undergoing open surgical repair utilizing adjuncts including distal aortic perfusion is not stated. Open repair was associated with an increased risk of graft infection and systemic infections compared with TEVAR, but there was a trend toward increased risk of a secondary procedure in TEVAR compared with open repair ($p = 0.07$) with a median follow-up of 2 years.

A classification system for grading and treatment of traumatic aortic injury has been published by Azizzadeh et al. and adopted by the SVS for management of these injuries (Azizzadeh et al. 2009) (■ Fig. 28.6). The grading classification is as follows: grade I (intimal tear), grade II (intramural hematoma), grade III (pseudoaneurysm), and grade IV (rupture). Azizzadeh and associates recommend expectant management with serial imaging for grade I injuries, with repair recommended for grades II–IV.

Based on the findings of the commissioned party, the SVS published clinical practice guidelines for endovascular repair of traumatic aortic injury in 2011 (Lee et al. 2011a, b). All of the recommendations were categorized as grade 2, level C statements:

1. Endovascular repair to be performed preferentially over open surgical repair or nonoperative management, regardless of patients age if anatomically suitable
2. Regarding timing: urgent (<24 h) repair when feasible with respect to other potential life-threatening injuries and at the latest prior to hospital discharge
3. Expectant management with serial imaging for grade I injuries
4. Suggest selective revascularization of LSA
5. Routine heparinization but at a lower dose than in elective TEVAR
6. Do not suggest routine spinal drainage
7. Suggest general anesthesia
8. Suggest open femoral exposure

28.8 Complications After TEVAR

28.8.1 Endoleaks

Endoleaks were defined as reporting standards by Chaikof and coworkers (2002). Type I endoleaks communicate with the aneurysm sac from around the proximal (Ia) or distal (Ib) landing zone. Type II endoleaks are not connected or associated to the landing zones or the junction between various stent grafts. Type III endoleaks occur between the junctions of two or more stent graft components. Both type I and type III endoleaks are indicative of a technical failure. Type IV endoleaks are caused by graft wall porosity and mainly a problem of first-generation stent graft materials. Endotension refers to an endoleak characterized by an increase in aneurysm diameter by persisting pressure in the excluded sac without radiologic evidence of an endoleak (■ Fig. 28.7 a-d).

The incidence of endoleaks following TEVAR in a recent meta-analysis of reported studies is 12.1% (Cheng et al. 2010). However, this may not be an accurate estimate since many studies did not report data on endoleaks. Type I endoleaks have been identified as an independent risk factor of early mortality after TEVAR (Khojinezhad et al. 2008a). In the VALOR trial (Fairman et al. 2008), the overall incidence of endoleaks at 30 days post-operatively was 25.9% (4% type I; 4%, 15.5% type II; 1.7% type III; and indeterminate 4.6%). At 12 months, the incidence was 12.2% (4.9% type I, 4.9% type II, 2.4% indeterminate). In the Zenith TX2 (Matsumura et al. 2008) trial, the incidence of endoleaks was 12.6% at pre-discharge, 4.8% at 30 days, 2.6% at 6 months, and 3.9% at 12 months. Most endoleaks were type II. The reintervention rate was 4.4%, with most being due to type I or III endoleaks. No type II

Fig. 28.7 a-d Type I endoleaks communicate with the aneurysm sac from around the proximal (Ia) or distal (Ib) landing zone. **a** Type II endoleaks are not connected or associated to the landing zones or the junction between various stent grafts. **b** Type III endoleaks occur between the junctions of two or more stent graft components. **c** Type IV endoleaks are caused by graft wall porosity and mainly a problem of first-generation stent graft materials **d**

endoleaks required reintervention. In the TAG trial (14,78 Makaroun et al. 2005, 2008), the rates of observed endoleaks decreased from 8.1% at 1 month to 4.3% at 5 years. Endoleaks were not consistently observed in some patients at all times, and a total of 15% had an endoleak detected at some time during the first 2 years of follow-up. Most were of undetermined origin on CT scan.

A review of the etiology of endoleaks following TEVAR in 200 patients at the Cleveland Clinic reported an incidence of 19.5% (type I 7%, type II 8%, type III 3.5%) with mean follow-up of 30 months (Morales et al. 2008). The type I and III endoleaks were treated with either secondary endovascular intervention or conservatively. Of the type II endoleaks, glue embolization was used to treat those due to coverage of LSA, and the rest were observed. Factors associated with endoleaks were presence of a carotid-LSA bypass and longer aortic coverage by the stent graft. The authors concluded that secondary intervention is required for most type I and III endoleaks, and conservative treatment is adequate for most type II endoleaks.

28.8.2 Vascular Access Injury

Vascular access injury is a major issue in TEVAR with potentially fatal sequelae. Incidence of injury to access vessels occurs in 1–15% of patients (Dake et al. 2011; Lee et al. 2011a, b; Tonnessen

2011). Using large-caliber systems (18-F to 25-F), complications include arterial dissection, rupture, tear or thrombosis, hematoma, pseudoaneurysm, arteriovenous fistula, retroperitoneal bleeding, embolism, and wound infection. This underscores the importance of using iliac conduits whenever access vessels are of questionable caliber and the need to perform these procedures in an operating room where resources and equipment are readily available to facilitate treatment of any complications.

28.8.3 Neurologic Complications

Stroke is among the most feared and devastating complications of endovascular and open repairs of the thoracic aorta. Perioperative stroke has an incidence of 3.5–5.5% with a similar rate in both open and endovascular interventions (Ehlert et al. 2011; Go et al. 2007; Maeda et al. 2012). Perioperative stroke after TEVAR may be related to patient age and underlying cerebrovascular disease, etiology of the treated aortic pathology and proximal extent of disease, coverage involving the aortic arch vessels, systemic factors (hypotension, hypertension, anticoagulation), intracranial causes (hemorrhage, edema, CSF drainage), or emboli (air, atheroma, thrombus) (Matsamura and Rizvi 2010). Most strokes in the anterior circulation likely have an embolic etiology, and posterior circulation strokes are likely ischemic in origin. Over 60% of patients

have a dominant left vertebral artery with absent or hypoplastic right vertebral artery, and coverage of the LSA in these circumstances can be associated with significant risk (Matsamura and Rizvi 2010).

Embolization may be related to the use and advancement of wires, catheters, and devices into a diseased atheromatous aortic arch, with dislodgement of atherosclerotic plaque to the brain. As a result, patients with a significant atherosclerotic burden and those with aneurysms close to the aortic arch are inherently at higher risk. In a 2007 review of 171 patients undergoing TEVAR, Gutsche et al. reported a 5.8% incidence of stroke which was associated with a 33% inhospital mortality rate (Gutsche et al. 2007). Severe atheromatous disease involving the aortic arch (>5 mm protrusion into aortic lumen) was strongly associated with stroke ($P=0.0016$). Combining a history of prior stroke with extent A coverage (proximal descending thoracic aorta) carried a 60% stroke incidence, while extent C coverage (entire descending thoracic aorta) resulted in a 15% incidence. There were no perioperative strokes in patients undergoing extent B coverage (distal descending thoracic aorta). After reviewing these data, three risk factors for perioperative stroke were identified: (1) a history of preoperative stroke, (2) CT grade IV atheroma (>5 mm) in the aortic arch or proximal descending aorta, and (3) extent A or C.

In a 2007 prospective multicenter report from the EUROSTAR registry (*European Collaborators on Stent/Graft Techniques for Aortic Aneurysm Repair*) on 606 patients with endovascular repair of thoracic aorta pathologies (aneurysm, dissection, traumatic injury, anastomotic pseudoaneurysm, and infectious/nonspecified), Buth et al. found a 3.1% incidence of stroke (Buth et al. 2007). Using multivariate regression analysis, female sex and duration of procedure >160 min were associated with an increased risk for stroke. This is likely related to lengthy manipulation of catheter, wires, and devices within the aortic arch. The use of transcranial Doppler ultrasound may be helpful in selecting appropriate catheters, wires, and maneuvers to reduce significantly the embolization (Khoynzhad et al. 2008b).

In our 2007 review of 184 TEVARs for DTAA, type B aortic dissection, traumatic aortic injury, and penetrating aortic ulcer, we reported a stroke rate of 4.3% (Khoynzhad et al. 2007b). Using univariate analysis, risk factors associated with

stroke were obesity (body mass index >30 kg/m²), peripheral vascular embolization/thrombosis, and significant blood loss.

Feezor et al. reported on the risk factors for perioperative stroke during TEVAR for various aortic pathologies (Feezor et al. 2007). The study included 196 patients treated with TEVAR with a 4.6% incidence of stroke. Proximal extent of repair was significantly associated with a higher incidence of strokes (zones 0–2 vs. 3–4, $p=0.025$). Fifty-five percent of patients suffering a stroke had intraoperative hypotension (SBP <80 mmHg). Selective LSA revascularization based on preoperative cerebrovascular imaging demonstrating a dominant left vertebral artery or incomplete circle of Willis resulted in lower rates of stroke (6.4% vs. 2.3%, $p=0.30$) and posterior circulation infarcts (5.5% vs. 1.2%, $p=0.13$). The authors concluded that proximal extent of repair might serve as a surrogate marker for greater severity of degenerative disease in the aortic arch. Avoidance of hypotension and preservation of antegrade vertebral perfusion may be important in prevention of posterior circulation strokes (Canaud et al. 2010; Feezor et al. 2007). Furthermore, maintaining stable hemodynamics and therapeutic anticoagulation and performing the procedure expeditiously may further decrease the risk of stroke (Khoynzhad et al. 2009b; Maeda et al. 2012; Melissano et al. 2012b).

28.9 Technical Failures and Late Complications in TEVAR

28.9.1 Device Migration

Migration is defined as greater than 10 mm movement of the endograft or any movement of the device leading to symptoms or requiring intervention. Outside of clinical trials, there is little published data and it is likely to be underreported.

In the Gore TAG trial, there were three proximal migrations (4%) and four component migrations (6%) at 2 years follow-up without any associated clinical events (Makaroun et al. 2005). In the Cook TX2 trial, proximal or distal migration was noted in three stent grafts (2.8%) within 12 months, with two cases of caudal migration of the proximal graft and one case of cranial migration of the distal graft (Matsumura et al. 2008). None were associated with clinical

events or required a secondary intervention. All three patients had oversizing of the proximal neck diameter of less than 10%, and all had placement of the barbed stent in either an acutely angled segment or in an area of thrombus. In the Medtronic VALOR trial, four stent graft migrations (2.1%) were noted within 12 months (Fairman et al. 2008). Two migrations involved the proximal end of the graft moving distally, and two involved the distal end of the graft moving proximally. One patient required a secondary intervention related to device migration.

28.9.2 Retrograde Dissection

Retrograde type A dissection (RAAD) is a rare and catastrophic complication of TEVAR. It is defined as an intimal tear distal to the aortic arch which extends retrograde proximally into the ascending aorta. The incidence has been reported to be between 1.3% and 6.8% (Eggebrecht et al. 2006b, 2009a; Fattori et al. 2005; Neuhauser et al. 2005). RAAD has been attributed to several factors in these series: (1) trauma from the TEVAR procedure (caused by wire manipulation, sheaths/large-bore delivery systems, and stent graft balloon dilation); (2) device properties (semi-rigidity and proximal bare spring stent, excessive oversizing >20% causing increased radial force); (3) aortic wall friability (acute and chronic dissection); and (4) connective tissue disorders (Marfan syndrome, Ehlers–Danlos syndrome).

The European Registry on Endovascular Aortic Repair Complications reports an incidence of RAAD of 1.3% (Eggebrecht et al. 2009b) with a total of 63 cases being reported from 28 centers between 1995 and 2008. Of these, 81% underwent TEVAR for type B dissection (acute 54%, chronic 27%), and 83% had a bare proximal spring stent graft placed. RAAD occurred before the TEVAR procedure in 21%, during the procedure in 15%, and during follow-up after discharge in 65%. Management consisted of emergent surgical repair in 64%, elective repair in 13%, and nonoperative treatment with anti-impulse therapy in 23%. Overall mortality was 42%, which included 19% of patients who presented with sudden death. The mortality rates were similar for conservative management (33%), elective surgery (20%), and emergency

surgery (28%, $p=0.868$). Causes of RAAD included the stent graft in 60%, manipulation of guidewires and sheaths in 15%, and progression of underlying aortic disease in 15%. The majority of cases were associated with proximal bare spring stent grafts, with direct evidence of device-related injury noted at surgery or autopsy in one-half of the patients.

Dong et al. reported an incidence of RAAD of 2.5% in a series of 443 patients undergoing TEVAR for type B dissection (chronic 75%, acute 25%) (Dong et al. 2009). Three of 11 patients had Marfan syndrome. The perioperative mortality was 27.3%, and the site of new entry was identified at the tip of the bare spring of the stent graft in 81%.

28.9.3 Graft Infection

The reported incidence of graft infection ranges from 1 to 5% (Cernohorsky et al. 2011; Chiesa et al. 2010a; Heyer et al. 2009). Etiology includes perioperative contamination, hematogenous seeding, local bacterial translocation, and graft erosion into the aerodigestive tract (Chiesa et al. 2010b). The most commonly isolated organisms include *Staphylococcus*, *Streptococcus*, *Propionibacterium* species, *Enterobacter cloacae*, *Escherichia coli*, and *Pseudomonas aeruginosa* (Cernohorsky et al. 2011; Heyer et al. 2009). The median time elapsed from the TEVAR procedure to the diagnosis of infection ranges from 115 to 244 days (Cernohorsky et al. 2011; Heyer et al. 2009). Treatment requires surgical explantation of the infected endograft, in situ replacement with either homograft or antibiotic-impregnated Dacron graft with possible coverage of the new graft with an omental flap, and lifelong antibiotic therapy. The mortality from this complication ranges from 25 to 60% (Cernohorsky et al. 2011; Heyer et al. 2009).

28.9.4 Device Malfunction

Several factors including larger hemodynamic forces, more tortuous anatomy, and larger devices delivered over a longer distance increase the complexity of device delivery and deployment in the thoracic aorta relative to the abdominal aorta. Lee described the failure modes of thoracic stent

grafts and prevention and management strategies (Lee 2009). Intraoperative factors leading to maldeployment include inability to advance the delivery system, unintended device movement, and inability to conform to local tortuous anatomy (Lee et al. 2007a, 2009). A transbrachiofemoral wire (body floss) may be used to overcome severe aortic tortuosity by providing two points of wire fixation that can provide a stiff rail to facilitate device delivery (Lee 2009). Device infolding is related to excessive oversizing and/or lack of apposition of the device to the inner curve of the aortic arch, almost exclusively being associated with Gore TAG stent graft (Bandorski et al. 2010). The newer generation of Gore TAG has been designed to have greater conformability to the lesser curve of the aortic arch in patients who have a tight radius.

In the postoperative period, device failures can manifest as endograft collapse, component separations, and metallic fractures and fabric tears. Additional endografts and bare stents can be placed to increase the radial force of the stent graft and prevent proximal collapse of the device (Rodd et al. 2007; Steinbauer et al. 2006). A meta-analysis (Jonker et al. 2010) of all published cases of endograft collapse in 2010 identified 60 reported cases with a median time interval from TEVAR to diagnosis of endograft collapse of 15 days (range 1 day to 79 months). On average, the collapsed endografts were oversized by $26.7 \pm 12.0\%$. Excessive oversizing was reported as the primary cause of endograft collapse in 20%, and a small radius of curvature of the aortic arch was responsible for 48% of the cases. The 30-day mortality was 8.3%. Treatment entails either a redo-TEVAR with a high radial force device if feasible or a conversion to an open repair (Tadros et al. 2011). All devices are subject to material fatigue, which underscores the need for lifelong surveillance in all patients undergoing endovascular repair.

28.9.5 Aortobronchial or Aorto-esophageal Fistula

Erosion of the thoracic endograft into adjacent tissue can manifest as aortobronchial (ABF) or aorto-esophageal fistula (AEF). The incidence of ABF or AEF has been reported to be 1.7–2% (Chiesa et al. 2010a; Eggebrecht et al. 2009a). In a retrospective review of 1,113 TEVAR procedures performed over

10 years, increased risk of AEF/ABF was found to be associated with aortic pseudoaneurysm as an indication for TEVAR and emergent and complicated procedures (Chiesa et al. 2010b). Perioperative mortality of patients undergoing surgical treatment was 64%, and all patients treated nonoperatively died within 30 days. The overall survival was 16% at a mean follow-up of 17.7 months.

28.10 Trends and Future Directions in TEVAR

28.10.1 Total Percutaneous TEVAR

The total percutaneous TEVAR without the need of inguinal dissection is an important tool, minimizing postoperative complications, such as lymphocele or wound healing complications. Percutaneous closure devices are designed to place sutures into the arterial wall prior to large sheath introduction. After the procedure and removal of the large-bore deployment devices, the previously placed sutures can be approximated and the entry deficit of the arterial wall can be closed. The Perclose ProGlide (Abbott Vascular, Redwood City, California) device has a success rate ranging from 88 to 100%. Shorter overall procedural times and reduced complications, such as wound healing problems, have been achieved (Dosluoglu et al. 2007; Lee et al. 2007b; Ni et al. 2011; Shafique et al. 2009). However, the deployment of these devices should be done with caution. Known contraindications are obesity, especially morbid obesity, severe atherosclerosis, multiple previous procedures in the target area, and an anatomically high femoral bifurcation (Criado et al. 2009). The benefit of these devices with very low short- and mid-term complications is apparent in selected patients (Bent et al. 2009), but in the event problems with percutaneous closure occur, a conversion to open surgical access arterial repair is necessary to avoid late complications such as pseudoaneurysms or limb ischemia (Lee et al. 2011a, b).

28.10.2 Low Profile TEVAR Devices

Major limiting factors in TEVAR are compromised vascular access and arterial tortuosity. Commonly used delivery sheath sizes are 20–25-F with required vascular diameters from 7.3 to 9.2 mm.

Low-profile devices with increased flexibility will expand TEVAR availability to patients with suboptimal vascular access, as well (Pavčnik et al. 2001; Strecker et al. 2004). Future generation of thoracic stent grafts will focus on lower profile to reduce vascular injury in this patient cohort.

28.10.3 Devices for Ascending TEVAR

The various pathologies of the ascending aorta such as dissections, aneurysms, or pseudoaneurysms are treated with open ascending aortic replacement (see ► Chapter «Aneurysm and Dissection of the Thoracic and Thoracoabdominal Aorta», Sect. 27.1.1). Currently TEVAR for patients with ascending aortic pathology is not indicated in patients with acceptable surgical risk (Lin et al. 2007). The stent grafts that have been used for this purpose were commercially available descending thoracic aorta stent grafts. Taking the aortic pathology into account, antegrade access may offer better success to enter the true lumen. Retrograde deployment is more difficult and could put the entire supra-aortic trunk perfusion at risk or trigger a rupture of the false lumen.

Only a few case reports and small series have been published. Rayan et al. described in 2004 the endovascular repair of a mycotic ascending aortic pseudoaneurysm in a 54-year-old man using 28.5-mm × 3.3-cm Gore Excluder aortic cuff that was deployed via the left subclavian artery by cutdown (Rayan et al. 2004). Three years later, Lin et al. (2007) reported the same procedure in 78-year-old man suffering from an ascending aortic pseudoaneurysm after cannulation of the aorta for coronary artery bypass. Its dimension was 8 × 12 cm, located in the midsegment of the ascending aorta compressing the pulmonary arteries. Due to his comorbidities, the patient was not suitable for open surgery. Under general anesthesia, using fluoroscopy and TEE, a Zenith aortic cuff device (32 × 36-cm) was delivered via the left common carotid artery with transient cardiac arrest using intravenous adenosine. No complications occurred, and the 1-month follow-up CT scan identified a successful procedure without endoleak. Similar case reports support the feasibility

of ascending aortic stent grafting in selected patients.

In another series of 11 patients with ascending aortic intramural hematoma, floating thrombus after chronic type A aortic dissection, and penetrating aortic ulcer, Kolvenbach et al. (2011) reported their experience with endovascular treatment of these pathologies. Patients included were high risk according to the American Society of Anesthesiologists (ASA) classification ≥IV. Patients with acute type A aortic dissection were excluded due to a missing ethical board approval. The combined mortality and morbidity was 18%. Bavaria et al. (2010) treated 27 patients with distal arch aneurysms with a hybrid procedure consisting of debranching followed by ascending aortic stenting. They report a successful stent deployment rate of 100% and a 30-day mortality of 11%. These data support hybrid repair for ascending or arch aneurysms in selected high-risk patients.

In order to perform TEVAR for ascending aortic pathology such as type A aortic dissection, the available devices must be adapted accordingly with shorter distal tips and elimination of bare springs. Problems and technical pitfalls such as penetrating bare springs, risk of cerebral and myocardial emboli, a very short landing zone, and the risk of aortic rupture have to be considered during planning of the procedure.

Development of TEVAR specifically designed to address ascending aortic pathologies would be advantageous compared to the open surgery without the need for extracorporeal circulation, deep hypothermia, and circulatory arrest. Currently, all authors concur that ascending TEVAR should only be reserved for high-risk patients. But if the future brings a broad special device portfolio for ascending aortic EVAR, the number of treated patients will grow.

There are current attempts to use permeable multilayer stent grafts that can cover aortic side branches, maintain perfusion of branch vessels, and simultaneously decrease blood flow within the aneurysm sac. These stents are called multilayer aortic repair stents (MARS) (Carrafiello et al. 2011). Potential applications of this device include dissections or aneurysms involving aortic segments with multiple side branches, such as the arch or the abdominal aorta.

28.11 Conclusions

TEVAR is a promising alternative approach to open surgery in properly selected patients for treatment of acute aortic disease with lower early mortality and lower complication rates including paraplegia, especially in high-risk patients. The only FDA-approved indications at this time are DTAA and traumatic disruptions. Patient selection is important, and TEVAR should be offered to those patients who will benefit the most from this endovascular procedure. Long-term survival, durability, and cost-effectiveness remain to be determined. Appropriate recognition and management of TEVAR complications can improve long-term outcomes.

29.1 Epidemiology

Atrial fibrillation (AF) is the most common sustained arrhythmia affecting about 2% of the general population and almost 3 million people in the USA. The number of AF-related hospitalizations is increasing, with predictions to double by the year 2025. Its prevalence is highly correlated with age. It increases from 0.1% in persons younger than 50 years of age to 10–15% in persons older than 80 years. Overall, a person's lifetime risk to develop AF is estimated to approach 25% (Lloyd-Jones et al. 2004). This results in a costly public health issue. A study analyzing three federally funded databases of the USA in 2005 suggested a total annual cost of US \$ 6.65 billion for the treatment of AF. This included \$ 2.93 billion for hospitalizations with a principal discharge diagnosis of AF, US \$ 1.53 billion for outpatient treatment of AF, and US \$ 235 million for prescription drugs (Coyne et al. 2006). In all analyses, AF was a significant contributor to hospital cost.

Comorbidities that are recognized to be associated with AF include arterial hypertension, heart failure, and valvular or ischemic heart disease possibly resulting in interstitial fibrosis and atrial dilatation. However, 10–15% of patients present with lone AF without any underlying cardiac pathology.

Although AF itself is not considered life threatening, it is associated with significant morbidity secondary to hemodynamic compromise and tachycardia-induced cardiomyopathy in some patients. While palpitations frequently result in discomfort and anxiety, the loss of synchronous atrioventricular contractility may cause various degrees of ventricular dysfunction, exercise intolerance, or congestive heart failure. Furthermore, stasis of blood flow in the fibrillating left atrium increases the risk of thrombus formation. Thromboembolic events and stroke remain the most feared complications in these patients. AF accounts for about 25% of strokes in patients older than 80 years and increases a person's risk of stroke by five-fold with an average rate of stroke of about 5% per year in affected patients (Wolf et al. 1991). While the prevalence of stroke is low in patients under the age of 60 with less than 0.5%, it

approaches 30% for patients between 80 and 90 years. The intensity of anticoagulation required involves a fine balance between prevention of ischemic stroke and avoidance of hemorrhagic complications.

Overall, AF has been identified as an independent risk factor for mortality. Using the data from the Framingham study, the established risk factor adjusted odds ratio for death in men and women with AF was 1.5 and 1.9, respectively (Benjamin et al. 1998).

29.2 Electrophysiological Aspects of Atrial Fibrillation

There are four main components, which play an important role in the initiation and the sustention of AF:

1. A trigger, which can be a single premature beat or a run of focal ectopic depolarization
2. The effective atrial refractory period
3. The conduction velocity
4. The geometry or anatomy of the atrium

In general, as the refractory period is decreased, the conduction velocity is slowed, or the atrial size increases, and the probability of initiating and sustaining AF increases. If the underlying distribution of atrial refractory periods becomes more inhomogeneous, unidirectional block can occur. This is a necessary condition for the initiation of reentry. However, when unidirectional block occurs, reentrant arrhythmia will occur only if a critical mass of tissue is present.

Although the precise mechanisms that cause atrial fibrillation are incompletely understood, AF appears to require both an initiating event and a permissive atrial substrate. There is supportive data for multiple wavelets, mother waves, fixed or moving rotors, and macro-reentrant circuits playing a role in AF. In a given patient, multiple mechanisms may coexist at any given time.

29.2.1 Abnormal Impulse Formation

An increase in the slope of spontaneous diastolic depolarization in myocytes possessing pacemaker

activity can cause *enhanced automaticity*. Other causes are a lowered threshold of the action potential upstroke or a less negative maximal diastolic potential. *Triggered activity* arises from membrane oscillations following normal action potentials. If such oscillation reaches threshold of depolarizing currents, they can provoke new action potentials. Dependent on the time of occurrence, they can be differentiated in early or delayed after depolarizations. Under certain circumstances, such triggered responses can in turn elicit new action potentials, resulting in self-sustaining runs of triggered activity.

Once the role of pulmonary veins (PVs) in initiating AF was reported, most interventional treatment strategies focused on the isolation of triggers from these anatomic sources (Haïssaguerre et al. 1998). Indeed, the conduction velocity within the PVs is slower (0.3 m/s) compared to the surrounding atrial tissue (0.9 m/s). The complex fiber orientation spiraling perpendicularly around the vein with other fibers running parallel to the vein and the lack of Connexin40 in the veins, a major determinant of conduction velocity in the atria, probably contribute to this slower conduction. This arrangement creates heterogeneity of electrical conduction around the pulmonary veins, which is thought to promote reentry and sustain AF. While the PVs have the substrates needed to initiate and maintain AF in most patients, current mapping data suggest that up to 50% of patients have multiple potential drivers for AF that originate not exclusively from the PVs but also from the coronary sinus and the left or right posterior atrium.

29.2.2 Reentrant Activation

There are multiple theories for the mechanism of electrical reentry in the atrium:

Circus movement reentry is characterized by an activation that travels around a preformed anatomical structure or obstacle, i.e., the orifices of the pulmonary veins, the atrial appendage, or the atrioventricular annulus. Initiation of *circus movement reentry* requires unidirectional conduction block often occurring in regions with long refractory periods (■ Fig. 29.1). A short refractory period and a low conduction velocity make circus movement reentry more likely. The

■ Fig. 29.1 Circus movement reentrant

minimal path length for circus movement reentry can be calculated as the product of conduction velocity and refractory period called the wavelength. If the path of the circuit is longer than the wavelength, an «excitable gap» occurs.

In the *leading circle concept*, an unstable reentrant circuit that does neither require an anatomical obstacle nor a fully excitable gap propagates through relatively refractory tissue. The dynamics of reentry are determined by the smallest possible loop in which the impulse can continue to circulate.

In the *spiral wave theory*, the rotor rotates around an unexcited yet excitable core (■ Fig. 29.2). Along the wave front, there is a decline in conduction velocity until block occurs where the activation front and the repolarization tail meet, a point of undefined voltage state occurs that is usually referred to as the phase singularity. This results in a rotor.

Multiple unstable rotors resemble conduction patterns similar to that of the *multiple wavelet hypotheses*. According to Moe's computer simulation, wave fronts continuously undergo wave front-wave tail interactions resulting in wave breaks and generation of new wave fronts.

29.2.3 Atrial Remodeling

Alessie's group demonstrated that during rapid atrial pacing, action potential duration and atrial

■ Fig. 29.2 a Leading circle concept. b Spiral wave theory

refractory period both decreased (Wijffels et al. 1995). This electrical remodeling led to an increased susceptibility of AF («AF begets AF»). However, structural changes of the atrium contribute to this remodeling process as well. Age, arterial hypertension, congestive heart failure, or heart valve diseases are all strong predictors for the development of AF. The pathomechanism includes increasing atrial wall stress and some degree of atrial dilatation due to enhanced volume or pressure load. All these conditions can be the cause of the development of fibrosis and myocyte hypertrophy, both of which may result in slow conduction or even conduction block in some areas of the atrium.

29.3 The Development of Surgical Therapy of AF

29.3.1 The Maze Principle

Unlike other historical attempts to surgically address AF, such as the left atrial isolation procedure, His-bundle ablation, the corridor procedure, or the atrial transection procedure, the Maze procedure, introduced by Jim Cox in 1987, was designed to block the multiple macro-reentrant circuits which were believed to be the sole cause of AF at that time while successfully restoring both atrioventricular synchrony and sinus rhythm (Cox et al. 1991) (■ Fig. 29.3). The operation consisted of creating a myriad of surgical incisions in both the right and left atrium while allowing propagation of

the sinus impulse throughout both atria. Thus, most of the atrial myocardium could still be activated, resulting in preservation of atrial transport function in most patients. Although the possible underlying pathomechanism was not all known at that time, this principle accounted for all theories we consider to be possibly responsible for initiating and sustaining AF today: it isolated anatomical structures and obstacles and reduced the critical mass, thus isolating triggers and preventing or terminating reentrant circuits and rotors. In general, the atria are not capable to fibrillate anymore after a Cox-Maze procedure (CMP).

The final iteration of the Maze procedure, termed the Cox-Maze III procedure (CMP III), became the gold standard in the surgical treatment of AF with excellent long-term freedom from symptomatic AF of 95% with a median follow-up of 5.9 years and a low postoperative risk of stroke (Weimar et al. 2012a). There is no difference in success rates between patients undergoing a stand-alone CMP and those undergoing concomitant procedures, and it is also equally efficacious in paroxysmal and persistent or long-standing persistent AF (Prasad et al. 2003a; Weimar et al. 2012a, b).

Despite its proven efficacy, the CMP III was technically challenging and invasive, and it was not widely adopted in cardiac surgery. With the development of ablation technologies, the surgical incisions have been replaced with linear lines of ablation using a variety of different energy sources like radiofrequency (RF), cryotherapy, or high-intensity focused ultrasound (HIFU).

■ **Fig. 29.3** a Propagation of the sinus impulse throughout both atria in the original Cox-Maze procedure. b The original cut-and-sew Cox-Maze procedure III (From Cox et al. 1991; used with permission)

These ablation-assisted procedures have greatly expanded the field of AF surgery in the past decade. With present ablation technology, surgery can be performed with low mortality and morbidity as well as limited access incisions while preserving the high success rates of the original «cut-and-sew» procedure.

29.3.2 Ablation Technologies

Different alternative energy sources were introduced to simplify and shorten the procedure, reduce morbidity, and allow for a minimally invasive or endoscopic approach. The heterogenic morphology of the atria has to be kept in mind when using any ablation device. While the mean posterior left atrial wall ranges from 2.1 ± 0.9 mm to 2.5 ± 1.3 mm in patients with a history of AF, structures as the *Bachmann's bundle* as a preferential conduction pathway between the right and left atrium crossing across the roof of the atria in the transverse sinus might be much thicker with 4.6 ± 1.1 mm (range 1.7–9.3 mm). In general, patients with structural heart diseases reflect more closely patients referred for surgical ablation, who frequently present with a significant larger atrial wall thickness. Moreover, epicardial fat is a barrier to depth of penetration for most ablation technologies. Even in normal individuals, the fat layer at the posterior mitral anulus can be 10 mm thick. In addition, there are free running pectinate muscles in both the right and left atrium that are not continuous with the epicardial surface. This highly variable wall thickness and

anatomy provide a challenge to any unidirectional device attempting to achieve transmural lesions.

The chosen ablation technology and devices to efficaciously replace surgical incisions must meet three important criteria:

1. It must reliably produce bidirectional conduction block since this is the mechanism by which incisions either block macro- and micro-reentrant circuits or isolate trigger foci. Even small gaps as narrow as 1.5 mm within ablation lines can conduct fibrillatory impulses.
2. It must be safe. This requires a precise definition of dose-response curves to limit excessive or inadequate ablation. The surgeon must also have knowledge of the effects of the specific ablation technology on surrounding vital cardiac structures, such as the coronary sinus, coronary arteries, and valvular structures. The risk of collateral damage to surrounding extracardial structures like the esophagus or the phrenic nerve should be minimized.
3. It must be simple to use and allow for a minimally invasive or endoscopic approach.

This would require features such as rapid lesion formation, simplicity of use, adequate length and flexibility, and the ability to reliably create transmural lesions epicardially on the beating heart.

Currently, no device has perfectly met all of these criteria yet. It is imperative for surgeons to develop a complete understanding of the effects of each surgical ablation technology and carefully consider variations in atrial anatomy and electrophysiology. This will allow for more appropriate use of devices in the

operating room for each individual patient. While most of the devices have shown to be efficacious in the arrested heart, few have shown the capability of creating reliable transmural lesions on the beating heart. This has to be considered in the era of the development of endoscopic and hybrid approaches in an attempt to evoke less invasive surgical ablation techniques

Three different energy sources are currently available for the surgical endocardial or epicardial ablation of AF.

29.3.2.1 Cryo-energy

Cryoablation has an excellent safety profile and has been used for ablation of arrhythmia for more than three decades. As opposed to other alternative energy sources, cryoablation creates direct physical injury, cumulative sublethal cellular stress response, and molecular-based cell death by freezing instead of heating. The formation of intracellular and extracellular ice crystals disrupts the cell membrane and causes cell death. A homogenous surface contact is essential for good ablation performance. Any fluid or vapor trapped between the probe and the targeted tissue freezes to form ice balls. Ice has a low thermal conductivity coefficient and increases thermal resistance. Thus, ice ball formation within the valleys of a nonuniform surface-probe contact acts as an insulator, retarding heat loss. As heat is removed by various cryogens such as nitrous oxide, argon, or liquid oxygen; extracellular fluid freezes at -20°C , creating a hyperosmotic environment that causes cell shrinkage and ultimately cell death. Rapid freezing to -40°C induces expansion of intracellular ice formation that disrupts organelles and cell membranes even before osmotic imbalance occurs. A fast rate of cooling will increase cell death, while slowly thawing the tissue is also effective in prolonging the mechanisms of cell destruction (Mazur 1970). Currently, two commercially available sources of cryothermal energy are being used in cardiac surgery. One is manufactured by AtriCure (Cincinnati, Ohio) and uses a disposable malleable linear probe or reusable rigid probes with nitrous oxide as cooling agent. More recently, Medtronic (Minneapolis, Minnesota) has distributed a malleable linear probe and a clamp device based on argon. At 1 atmosphere of pressure, nitrous oxide is capable of cooling tissue to -89.5°C ,

while argon can reach temperature of -185.7°C . Cryoablation has a well-defined efficacy and safety profile and is generally safe except around the coronary arteries. The relatively long time period of 1–3 min required to reliably create transmural lesions is one potential disadvantage of cryoablation. There is also difficulty in creating lesions on the beating heart due to the «heat sink» of the circulating blood. Furthermore, if blood is frozen during epicardial ablation on the beating heart, it coagulates, creating a potential thromboembolic risk. However, it preserves fibrous tissue and collagen and can therefore safely be used close to valvular tissue or the fibrous skeleton of the heart with a low arrhythmogenic potential.

29.3.2.2 Radiofrequency Energy

Radiofrequency (RF) energy has been used in the electrophysiology laboratory for many years and was one of the first energy sources to be applied in the operating room. RF energy uses alternating current in the range of 100–1,000 kilohertz (kHz). This frequency is high enough to prevent rapid myocardial depolarization and the induction of ventricular fibrillation, yet low enough to prevent tissue vaporization and perforation. The lesion size created by thermal coagulation injury depends on electrode-tissue contact area, the interface temperature, the current and voltage (power), as well as the duration of delivery. On histologic examination of radiofrequency lesions, a focal coagulation necrosis predominates. This correlates with the irreversible nature of the injury, which occurs at temperatures $>50^{\circ}\text{C}$. There is destruction of the myocardial collagen matrix and replacement with fibrin and collagen. At high temperatures greater than 100°C , char formation predominates. Char presents as an impediment to heat transduction and has been associated with asymmetrical ablations. The depth of the lesion can be limited by char formation, epicardial fat, myocardial and endocavity blood flow, as well as tissue thickness.

RF energy can be delivered by either unipolar or bipolar electrodes.

■ ■ Unipolar RF

Numerous devices are currently on the market with popular devices distributed by Estech (San Ramon, California), nContact (Raleigh, NC), and Medtronic (Minneapolis, Minnesota). These

include both dry and irrigated devices as well as devices which incorporate suction to improve tissue surface contact. Resistive heating occurs only within a narrow rim of tissue in direct contact with the electrode, usually less than 1 mm. The deeper tissue heating occurs via passive conduction. To prevent char formation at the tissue-electrode interface, irrigated catheters were developed keeping temperatures cooler at the tissue-probe interface. While in animals, unipolar RF has been shown to create transmural lesions on the arrested heart with sufficiently long ablation times of 60–120 s, this has been more difficult in clinical use. After 2-min endocardial ablations during mitral valve surgery, only 20% of the *in vivo* lesions were transmural. Epicardial ablation has been even more difficult. Animal studies have consistently shown that unipolar RF is incapable of creating transmural lesions epicardially on the beating heart. A recent clinical study confirmed this problem. Epicardial RF ablation resulted in only 7% of lesions being transmural despite electrode temperatures of up to 90 °C. One main reason for failure has been felt to be the heat sink (Santiago et al. 2003). The complications of unipolar RF devices have been described after extensive clinical use and include coronary artery injuries, cerebrovascular accidents, and the devastating creation of esophageal perforation leading to atrial-esophageal fistula (Doll et al. 2003).

■ ■ Bipolar RF

This technology is either applied between electrodes embedded in the jaws of a clamp or between electrodes arranged in parallel in linear devices. By using a clamp, the electrodes are shielded from the circulating blood pool, which allows for faster ablation times and limits collateral injury to surrounding structures. Bipolar RF ablation clamps are the most reliable devices for creating transmural lesions on the beating heart both in animals and humans with short ablation times (Gaynor et al. 2004; Prasad et al. 2002, 2003b). The linear devices developed for epicardial ablation on the beating heart have not been as reliable and seem to be more affected by the heat sink affect and variable wall thickness. Three companies (AtriCure, West Chester, OH; Medtronic, Minneapolis, MN; and Estech, San Ramon, CA) currently market bipolar RF devices. Use of the bipolar RF clamp devices has elimi-

nated most of the collateral damage that occurred with the unipolar devices likely due to the focused delivery of energy within the jaws of the clamp. However, the devices with side-by-side bipolar electrodes have not been extensively evaluated for safety yet and could have the same potential problems as unipolar devices.

29.3.2.3 High-Intensity Focused Ultrasound

High-intensity focused ultrasound (HIFU) is an ablation energy marketed by St. Jude Medical (St. Paul, MN) and effectively ablates tissue via mechanical hyperthermia. It utilizes ultrasound beams in the frequency range of 1–5 megahertz (MHz) or higher causing compression, refraction, and particle movement and thus creating focused lesions by rapidly raising the temperature of the targeted tissue to above 80 °C. This translates into kinetic energy and coagulative tissue necrosis. HIFU produces rapid, high-concentration energy in a focused area and is reportedly able to create transmural epicardial lesions even through epicardial fat in a short time.

HIFU is unique in that it is able to create non-contact focal ablation in three-dimensional volume without affecting intervening and surrounding tissue. Its ability to focus the target of ablation at specific depths is an advantage over other energy modalities. Unlike all other energy sources that heat or cool tissue by thermal conduction, HIFU ablates tissue by directly heating the tissue in the acoustic focal volume and is therefore much less affected by the «heat sink» of the circulating endocardial blood pool. The clinical studies utilizing HIFU, however, have had mixed results (Ninet et al. 2005). There has been little independent experimental verification of the efficacy of HIFU devices to reliably create transmural lesions, and long-term efficacy seems to be rather disappointing. The fixed depth of penetration of these devices may be a major problem in the wide range of thickness of pathologically altered atrial tissue.

29.4 Preoperative Modalities

29.4.1 Classification of Atrial Fibrillation

As per recent guidelines, AF can be defined as follows (Calkins et al. 2012):

1. Paroxysmal AF: recurrent AF (≥ 2 episodes) that terminates spontaneously within 7 days or episodes of ≤ 48 h duration that are terminated by electrical or pharmacological cardioversion
2. Persistent AF: continuous AF that is sustained beyond 7 days or AF episodes ≥ 48 h of duration that are terminated by electrical or pharmacological cardioversion
3. Long-standing persistent AF: continuous AF of greater than 12 months' duration

The term «permanent AF» is felt to be not appropriate in the context of patients undergoing surgical ablation, as it refers to a group of patients for which a decision has been made not to restore sinus rhythm by any means.

With regard to treatment strategies, a differentiation between *paroxysmal* and *nonparoxysmal* AF might be more helpful. While the pulmonary veins have been identified to be the main source of triggers responsible for initiation of the arrhythmia in many patients with *paroxysmal* AF, isolation of the PVs (PVI) might be appropriate and sufficient in the majority of this patient group. However, patients with *nonparoxysmal* AF usually require and extend left-atrial or biatrial lesion set to additionally treat the substrate responsible for sustaining AF.

29.4.2 Indications for Surgical Ablation

In general, surgical ablation is reasonable for symptomatic patients undergoing cardiac surgery for other indications regardless of their type of AF (class IIa/level C, ■ Table 29.1). This is valid for patients who do not tolerate or are refractory to class 1 or 3 antiarrhythmic medication (see ■ Table 9.10) as well as for patients prior to initiation of antiarrhythmic drug therapy (Calkins et al. 2012).

Regardless of their type of AF, symptomatic patients who do not tolerate or are refractory to class 1 or 3 antiarrhythmic medication qualify for a stand-alone surgical ablation, if they either prefer a surgical approach or have failed one or more catheter ablations (class IIb/level C, ■ Table 29.2) (Calkins et al. 2012) (■ Table 29.2).

In addition to these recommendations, we feel that there are several more indications for surgery that were not included or clearly expressed in the consensus statement:

1. AF patients who develop a contraindication to long-term anticoagulation and have a high risk for stroke (CHADS2 score ≥ 2 , ■ Table 29.3) are excellent candidates for surgery. Surgery does not only eliminate AF in most of these patients but also amputates the left atrial appendage (LAA), which is known to be one of the main sources of atrial thrombus formation. The stroke rate following a CMP off anticoagulation has been remarkably low, even in patients with high CHADS2 scores.
2. Patients with long-standing AF who have suffered a cerebrovascular accident despite adequate anticoagulation are at high risk for repeat neurological events.
3. AF patients with a clot in the left atrial appendage are not candidates for catheter ablation and should be primarily considered for surgical ablation.

29.4.3 Preoperative Evaluations

Surgery is indicated in patients with recurrent symptomatic episodes of AF refractory to class I or III medical therapy in whom electrical or pharmacological cardioversion failed within 6 months prior surgery. Patients undergoing stand-alone procedures older than 60 years of age and younger patients with an existing cardiovascular risk profile should undergo preoperative coronary angiography or cardiac CT evaluating Ca⁺⁺ scores. To define the anatomical location of the circumflex coronary artery is important to safely create the left-atrial isthmus lesion and to perform the ablation of the coronary sinus. In patients who have failed catheter ablation, a chest CT is indicated to assess for pulmonary vein stenosis.

Besides documentation of the patient's heart rhythm, preoperative transthoracic and an intraoperative transesophageal echocardiogram should be performed to determine left-atrial diameter and to evaluate for the presence of a left-atrial thrombus. Left-atrial size is a significant predictor of failure and is important to define prior to surgery (Damiano et al. 2011). It is also important to determine the precise atrial tachyarrhythmia (ATA) in patients who have failed catheter ablation, which may require an electrophysiological study. Atrial tachycardia is

Table 29.1 Indications for concomitant surgical ablation of atrial fibrillation (AF) (Calkins et al. 2012)

	Class	Level
Symptomatic AF refractory or intolerant to at least one class 1 or 3 antiarrhythmic medication		
<i>Paroxysmal</i> : Surgical ablation is reasonable for patients undergoing surgery for other indications	Ila	C
<i>Persistent</i> : Surgical ablation is reasonable for patients undergoing surgery for other indications	Ila	C
<i>Long-standing persistent</i> : Surgical ablation is reasonable for patients undergoing surgery for other indications	Ila	C
Symptomatic AF prior to initiation of antiarrhythmic drug therapy with a class 1 or 3 antiarrhythmic agent		
<i>Paroxysmal</i> : Surgical ablation is reasonable for patients undergoing surgery for other indications	Ila	C
<i>Persistent</i> : Surgical ablation is reasonable for patients undergoing surgery for other indications	Ila	C
<i>Long-standing persistent</i> : Surgical ablation may be considered for patients undergoing surgery for other indications	IIb	C

usually not amenable to surgical ablation, and atypical atrial flutter usually necessitates a full biatrial Cox-Maze lesion set.

There are still conflicting data whether an extended left-atrial lesion set is sufficient to treat the underlying pathomechanism of AF. Future diagnostic tools to identify the patient subgroup benefiting from a biatrial ablation might further improve results. Electrocardiographic imaging (ECGI) can be used to compute epicardial potentials noninvasively and reconstruct a three-dimensional anatomical map of atrial electrical activity using multiple surface electrodes and anatomic data obtained through computerized tomography, thus potentially providing a map-directed approach in the future.

Table 29.2 Indications for stand-alone surgical ablation of atrial fibrillation (AF) (Calkins et al. 2012)

	Class	Level
Symptomatic AF refractory or intolerant to at least one class 1 or 3 antiarrhythmic medication		
<i>Paroxysmal</i> : Stand-alone surgical ablation may be considered for patients who have not failed catheter ablation but prefer a surgical approach	IIb	C
<i>Paroxysmal</i> : Stand-alone surgical ablation may be considered for patients who have failed one or more attempts at catheter ablation	IIb	C
<i>Persistent</i> : Stand-alone surgical ablation may be considered for patients who have not failed catheter ablation but prefer a surgical approach	IIb	C
<i>Persistent</i> : Stand-alone surgical ablation may be considered for patients who have failed one or more attempts at catheter ablation	IIb	C
<i>Long-standing persistent</i> : Stand-alone surgical ablation may be considered for patients who have not failed catheter ablation but prefer a surgical approach	IIb	C
<i>Long-standing persistent</i> : Stand-alone surgical ablation may be considered for patients who have failed one or more attempts at catheter ablation	IIb	C

Table 29.3 CHADS₂ score

	Condition	Points
C	Congestive heart failure	1
H	Hypertension: blood pressure consistently above 140/90 mmHg (or treated hypertension on medication)	1
A	Age ≥75 years	1
D	Diabetes mellitus	1
S ₂	Prior stroke or TIA or thromboembolism	2

29.5 Postoperative Management

Following rhythm surgery, patients are started on antiarrhythmic drugs. Amiodarone is the current drug of choice if postoperative atrial tachyarrhythmias (ATAs) occur. Over 40% of patients might experience ATAs including AF, atrial flutter, or atrial tachycardia during the first month. Electrical cardioversion might be performed as needed to restore sinus rhythm. Antiarrhythmics are discontinued within 3 months if the patient is in normal sinus rhythm as documented by ECG or prolonged monitoring.

Anticoagulation with warfarin should be started postoperatively with a targeted INR of 2.0–2.5. Anticoagulation is discontinued at 3 months, if prolonged monitoring shows no ATAs and echocardiography shows no atrial stasis or thrombus.

Postoperative sinus node dysfunction might occur in up to 5% of patients, many of whom have had a history of sick sinus syndrome, and therefore successful treatment of AF may have just unmasked it. In patients developing postoperative bradycardia or slow junctional rhythms, antiarrhythmic medication may be discontinued and pacemaker implantation should be considered after 5–7 days.

Follow-up should include prolonged electrocardiographic monitoring at 3, 6, and 12 months and annually thereafter. Success rates should be defined as freedom from ATAs and antiarrhythmic medication documented by prolonged monitoring of at least 24 h. A recurrence of any ATAs >30 s is considered a failure according to the recent consensus statement (Calkins et al. 2012). However, the implantation of an insertable cardiac monitoring device (Reveal® DX, Medtronic Inc., Minneapolis, MN) is strongly recommended to improve patient's compliance with follow-up protocols, to avoid an underestimation of recurrent ATAs and to gain a better understanding of the actual AF burden.

29.6 Surgical Techniques and Their Outcomes

There is a myriad of surgical procedures currently performed to ablate AF. They can be grouped into three broad categories:

1. The biatrial Cox-Maze procedure
2. Left-atrial lesion sets
3. Pulmonary vein isolation

Moreover, new approaches have been developed for the treatment of lone AF. Epicardial lesions performed on the beating heart including PVI and left-atrial lesion sets allow for an endoscopic approach without the need for cardiopulmonary bypass. Furthermore, a hybrid team approach with electrophysiologists applying endocardial catheter ablation techniques combines the promising success rates of epicardial surgical ablation with more sophisticated mapping to determine lesion integrity and evaluate results.

29.6.1 The Ablation-Assisted Cox-Maze Procedure (CMP IV)

This biatrial procedure can be performed concomitantly or as stand-alone procedure via a median sternotomy or a minimally invasive right lateral minithoracotomy using cardiopulmonary bypass. It can be performed using cryo-energy or a combination of cryo- and bipolar radiofrequency energy. It contains all lesions of the original CMP III except the interseptal lesion.

After initiating normothermic cardiopulmonary bypass, the right and left PVs are bluntly dissected. If the patient is in AF, amiodarone is administered, and the patient is electrically cardioverted after a left-atrial thrombus has been ruled out by intraoperative transesophageal echocardiography. Pacing thresholds are obtained from each PV. Using a bipolar RF ablation device, the PVs are isolated by ablating a cuff of surrounding atrial tissue. Proof of electrical isolation is confirmed by demonstrating exit and/or entrance block from each PV.

The right atrial lesion set is performed on the beating heart. A single incision is usually made in the right atrial free wall. All ablations are performed with the bipolar radiofrequency clamp except for two endocardial ablation lines to the tricuspid annulus. These are performed endocardially with a linear cryoprobe, which is cooled to $-60\text{ }^{\circ}\text{C}$ for 2–3 min (■ Fig. 29.4).

The left-sided lesion set is performed via a standard left atriotomy in the interatrial groove under cardioplegic arrest. Isolating the entire posterior left atrium with connecting ablation lines between the upper and lower pulmonary veins, termed the box lesion set, which resembles more closely the original CMP III lesion set, has resulted

Fig. 29.4 a Right atrial lesion set of the Cox-Maze procedure IV. b Left-atrial lesion set of the Cox-Maze procedure IV (From Damiano et al. 2011; used with permission)

in a significantly higher drug-free freedom from AF at 6 and 12 months. Cryoablation is used to connect the lesion to the mitral annulus and complete the left-atrial isthmus line. It is important to remember that the coronary sinus needs to be ablated epicardially in line with the endocardial ablation in order to create the left-atrial isthmus line. This is usually done with either the bipolar RF clamp or a linear cryoprobe placed epicardially over the coronary sinus. The left atrial appendage is amputated, and a final ablation is performed through the amputated left atrial appendage into one of the left pulmonary veins. In patients undergoing a right minithoracotomy, cryoablation is more extensively applied to complete the posterior left-atrial isolation, and the left atrial appendage is oversewn from the inside.

29.6.1.1 Outcomes

A propensity analysis has shown that there was no significant difference in the freedom from AF at 3, 6, or 12 months between the cut-and-sew Cox-Maze III and the ablation-assisted CMP IV (Lall et al. 2007). However, the CMP IV has significantly shortened operative time and lowered complication rates while maintaining the high success rate of the original Cox-Maze III procedure (Lall et al. 2007; Melby et al. 2006). A Kaplan-Meier estimate of freedom from symptomatic AF for the CMP (III+IV) was 85% at 10 years (Weimar et al. 2012a). In 100 patients undergoing a stand-alone CMP IV for lone AF (31% paroxysmal and 69% persistent or long-standing persistent AF), a freedom from AF of 90% and freedom from AF off

antiarrhythmic medication of 84% at 2 years with no intraoperative mortality and no postoperative strokes were reported (Weimar et al. 2011). Moreover, 84% of patients were free from anticoagulative therapy with warfarin. In CMP IV series including concomitant cardiac procedures, the freedom from AF was 89%, and the freedom from AF off antiarrhythmic drugs was 78% at one year (Damiano et al. 2011). There is no difference in success rates for patients with paroxysmal compared to persistent or long-standing persistent AF with this procedure (Damiano et al. 2011; Weimar et al. 2011). An enlarged left-atrial diameter, failure to isolate the entire posterior atrium by a complete box lesion set, and early atrial tachyarrhythmias are predictors identified for late AF recurrence (Damiano et al. 2011) (■ Figs. 29.5 and 29.6).

29.6.2 Left-Atrial Lesion Sets

Over the past decade, numerous new procedures have been introduced to surgically treat AF. Especially as a concomitant procedure to mitral valve surgery where the left atrium is opened already, this lesion set has gained popularity. These procedures generally involved subsets of the left-atrial lesion set of the Cox-Maze procedure. This concept is supported by the fact that the majority of paroxysmal AF appears to originate around the PVs and the posterior left atrium. A left-atrial lesion set typically involves pulmonary vein isolation with an isthmus lesion to the mitral annulus as well as removal of the left atrial appendage.

29.6.2.1 Outcomes

A myriad of ablation technologies has been used to create these left-atrial lesion sets with various degrees of success ranging from 20 to 90 % freedom from recurrent AF. There have been no randomized trials of biatrial versus left-atrial ablation for patients treated surgically. Because of this, the importance of the right atrial lesions of the traditional Cox-Maze procedure is difficult to determine. A meta-analysis of the published literature revealed that a biatrial lesion set resulted in a significantly higher late freedom from AF when compared to a left-atrial lesion set alone (87 % versus 73 %, $p = 0.05$) (Barnett and Ad 2006).

29.6.3 Pulmonary Vein Isolation

Pulmonary vein isolation is an attractive therapeutic strategy that may be considered in patients with paroxysmal AF undergoing concomitant cardiac procedures, because the procedure can be done on the beating heart before initiating cardioplegic arrest. Moreover, it can also be performed endoscopically or by minimal access incisions on the beating heart as a stand-alone procedure. Based on the original report of Haïssaguerre, it has been documented that the triggers for paroxysmal AF originate from the pulmonary veins in many patients with lone AF (Haïssaguerre et al. 1998). However, it is important to remember that up to 30 % of triggers may originate outside the pulmonary veins. This might be even more often the case in patients with structural heart disease. The pulmonary veins can be isolated separately or combined as a box lesion. Additionally, the left atrial appendage is resected. The most common technique which is described here utilizes an endoscopic, port-based approach to minimize incisional size and pain for the patient. At our institution, bipolar RF clamps are favored to isolate the pulmonary veins, but unipolar radiofrequency and HIFU devices have been used as well.

Patients are intubated with a double-lumen endotracheal tube and external defibrillator pads are placed. A camera port is placed at the right fifth intercostal space slightly above the anterior axillary line (■ Fig. 29.7). Under thoracoscopic vision, two working ports are placed in the fourth and sixth intercostal space at the midaxillary line. Under one-lung ventilation the pericardium is

opened anterior and parallel to the phrenic nerve from the superior vena cava to the diaphragm. The space above and below the right pulmonary veins is dissected to allow for insertion of an articulating dissector. The dissector and a guiding sheath are introduced and guided into the space between the PVs and the right pulmonary artery. After the dissector is removed, the sheath remains in place as a guide for the insertion of the bipolar RF clamp. At this point, the patient is cardioverted into sinus rhythm if needed so that pacing thresholds can be obtained from the right PVs. In addition, some surgeons also take advantage of the surgical exposure to detect and ablate ganglionated plexi at this time. High-frequency stimulation evokes a vagal response with bradycardia when applied to ganglionated plexi. The detected areas can be ablated until the vagal response diminishes. However, there is no strong evidence in the literature that ablating ganglionated plexi improves long-term success. After pacing maneuvers are completed, the guiding sheath is attached to the lower jaw of the radiofrequency clamp. The PVs are isolated by placing the jaws of the ablation device on the surrounding cuff of atrial tissue. Ablation is continued until bidirectional block can be documented from each PV. However, we recommend to repeat ablation runs at least in triplicate. The approach to the left chest is similar as described above. However, the ports are positioned more posteriorly. The pericardium is opened posterior to the course of the phrenic nerve. The ligament of Marshall is divided. The dissector and the guiding sheath were used to position the clamp around the left PVs. After isolation, bidirectional block is confirmed for the left PVs. The left atrial appendage (LAA) can be resected by stapling across the base with an endoscopic stapler device.

29.6.3.1 Outcomes

The results of PVI alone have been variable and have been dependent on patient selection. Encouraging results have been reported in patients with paroxysmal AF, suggesting a success rate between 80 and 89 % after PVI. However, success rates decrease remarkable in patients with persistent or long-standing persistent AF. Edgerton and colleagues reported only 56 % of patients with persistent AF being free from AF at 6 months after PVI, with merely 35 % being both free from AF and antiarrhythmic medication (Edgerton et al.

■ **Fig. 29.5** Kaplan-Meier (K-M) analysis of freedom from atrial fibrillation (AF) for the Cox-Maze procedure. *Pts* patients (From: Weimar et al. 2012a; used with permission)

■ **Fig. 29.6** Freedom from atrial tachyarrhythmias (ATAs) and freedom from ATA off antiarrhythmic drugs following a stand-alone Cox-Maze IV procedure (From Weimar et al. 2011; used with permission)

■ Fig. 29.7 Port positioning for thoracoscopic approach (From Weimar et al. 2012b; used with permission)

2008). With concomitant procedures, the success rate of PVI is even worse. This is not surprising because those patients present with different underlying mechanisms for AF, and a choice for PVI as treatment option just based on the type of AF seems to be insufficient in most of those patients.

29.6.4 Endoscopic Left-Atrial Lesion Set

There is wide consent that the goal of developing less invasive procedures should not be at the cost of success rates. To address the shortcomings of PVI alone in many patients, new ablation devices have been developed allowing for an extension of the applied lesion set that can be performed thoracoscopically. Using a new generation of bipolar and unipolar RF devices, it is possible to perform a more extensive left-atrial box lesion set epicardially via port access. In addition to the PVI technique described above, the transverse and oblique sinuses are dissected. This allows for a box lesion set to be performed isolating not just the PVs but the entire posterior left atrium. It is crucial that attention is paid to overlapping the lines of ablation from the right and the left side to avoid gaps and to complete a transmural roof lesion. An inferior line is created to connect the encircling ablation of the inferior right PV with that of the inferior left PV. Because it is impossible to perform a left-atrial isthmus line epicardially, it is recom-

mended to add a trigonal line of ablation from the isolated superior right PV to the aortic annulus. To confirm conduction block of the ablation lines, pacing should be performed from within the box (■ Fig. 29.8).

29.6.4.1 Outcomes

Early results with an extended left-atrial lesion set in addition to PVI have shown improved success especially in patients with persistent AF compared to PVI alone. Sirak and colleagues reported a success rate of 87% off antiarrhythmic drugs after 6 months in 32 patients with persistent AF. In a larger series of almost 90 patients, the authors reported success rates of about 90% freedom from AF and 85% freedom from AF off drugs at 12 and 24 months follow-up independently from the type of AF with no conversion to sternotomy (■ Fig. 29.9) (Weimar et al. 2012b). Moreover, quality of life improved significantly postoperatively (■ Fig. 29.10). A recently published randomized trial comparing endoscopic surgical ablation to catheter ablation revealed superior success rates of 66% vs. 37% at one year in favor of surgery (Boersma et al. 2012). However, it is important to point out that it is technically challenging and more time-consuming to perform these extended lesions thoracoscopically and that proof of conductance block is mandatory for the box lesion set as well. This necessity to prove lesion integrity is due to the fact that there are still no devices on the market that reliably create linear transmural lesion on the beating heart except for the bipolar clamps. Also it is important to note that acute demonstration of conduction delay or block does not guarantee a chronic block or transmural lesion. Moreover the demonstration of conduction delay can be difficult and may lead to misinterpretation even by experienced surgeons and electrophysiologists.

29.6.5 The Hybrid Approach

The goal of the hybrid procedure is to combine the benefits of epicardially performed surgical ablation and endocardially performed catheter ablation in a dual approach. While thoracoscopic surgery is effective in isolating the PVs, addressing the ligament of Marshall and managing the left atrial appendage, it has its limitations in

effectively ablating atrial tissue, particularly the right and left-atrial isthmus and the coronary sinus. Those areas can be addressed by catheter ablation if intraoperative mapping performed by the electrophysiologist shows gaps and conduction in one or more of this regions. Also the success of creating transmural ablation lines can be confirmed by instantaneous mapping and by demonstrating conduction block using pacing. Possible gaps can then be closed by endocardial catheter ablation in the same setting (see

■ **Fig. 29.8** Endoscopically performed extended left-atrial lesion set (From Weimar et al. 2012b; used with permission)

■ **Fig. 29.8**). Ideally, this procedure should be performed in a hybrid operating room. Because the underlying pathomechanism are more complex in patients with persistent AF, this team approach may allow for a more patient-tailored lesion set that more effectively prevents AF recurrence. A recent study from Allesie and colleagues has formed what they call the «Double-Layer Hypothesis», where narrow wavelets in the endocardial and epicardial layers of the heart constantly feed each other in persistent AF (Eckstein et al. 2011). Although this has to be confirmed by further studies, it could add further support as to why hybrid ablation might be a promising approach for persistent AF.

29.6.5.1 Outcomes

Only a few centers have reported on hybrid procedures. In many institutions it has been challenging to set up a team approach involving both electrophysiologists and surgeons. In a combined series of the University of Virginia and University of Maastricht, 12 patients with persistent AF received hybrid ablation. At 12 months of follow-up, 83% of patients were free from atrial fibrillation and off antiarrhythmic drugs (Edgerton et al. 2008). A larger series of 63 patients reported by La Meir's group revealed significant better success rates for a hybrid approach compared to sole endoscopic ablation (100% vs. 87.5%, $p=0.04$) (La Meir et al. 2012). However, it is too early to comment on the efficacy or safety of the hybrid approach. Scientifically conducted trials are needed to evaluate any advantage over other ablation strategies.

30.1 Introduction

In general, cardiac rhythm device implantation is a standardized and safe procedure. The overall number of complications decreased over the past years. Nevertheless, serious and life-threatening complications may still occur. The possible complications and their management are elucidated.

The last part of this chapter is dedicated to lead extractions, a part of CIED therapy reserved for advanced surgeons. The indications, techniques, and available extracting tools are summarized for both percutaneous and lead extractions via open-heart surgery.

The development of modern cardiac implantable electronic devices is based on more than 50 years of clinical research and experience. Nowadays, the treatment of heart rhythm disorders with cardiac implantable electronic devices represents a well-recognized standardized therapy with low-risk, low-morbidity, and reliable results.

30.1.1 Milestones of Rhythm Device History

- 1958 The first clinical implantation of a fully implantable pacemaker at the Karolinska Institute in Solna, Sweden, performed by Åke Senning via thoracotomy (Elmqvist and Senning 1960). The first patient, Arne Larsson, received 26 pacemakers during his lifetime. He died in 2001, at the age of 86.
- 1959 Temporary transvenous pacing with the catheter electrode inserted via the patient's basilic vein (Furman and Robinson 1959).
- 1962 Permanent transvenous pacing in conjunction with an implanted pacemaker (Parsonnet et al. 1962; Lagergren and Johansson 1963).
- 1964 Principle of demand-function (Castellanos et al. 1964).
- 1969 Principle of bifocal sequential stimulation (Berkovits et al. 1991).
- 1971 Introduction of lithium-iodide cell (Greatbatch et al. 1971).
- 1980 Implantation of the first implantable cardioverter/defibrillator (ICD) in human (Watkins et al. 1980).
- 1981 Programming of pacemaker via telemetry (Kirk 2001).
- 1999 Implantation of the first cardiac resynchronization therapy (CRT) device (Sutton et al. 2007). See also ► Chapter «The History of Cardiac Surgery», ► Sect. 1.11.

30.1.2 Nomenclature and Modes of Cardiac Pacing

The majority of pacing devices are versatile and capable of different pacing modes. In conduction disorders requiring temporary or permanent pacing, the most appropriate pacing mode for each patient must be selected to accommodate his specific clinical needs. In order to standardize and clearly arrange the terminology, an international ICHD code (ICHD, Intersociety Commission for Heart Disease Resources) was implemented and periodically updated.

At present, a five-letter position code is valid to describe pacemaker function based on the generic pacemaker code (NBG) of the North American Society of Pacing and Electrophysiology (NASPE) and British Pacing and Electrophysiology Group (BPEG). See ► Table 30.1.

According to established pacemaker code, ICD functions are also defined by the North American Society of Pacing and Electrophysiology (NASPE) and British Pacing and Electrophysiology Group (BPEG) in Generic Defibrillator (NBD) code (► Table 30.2).

The purpose of cardiac pacing is to treat patients who have AV conduction block, bradyarrhythmias, or tachyarrhythmias. Temporary pacing is utilized when arrhythmia is transient or as a temporary measure until definite long-term therapy can be initiated. Permanent pacing is absolutely indicated when long-term pacing is necessary to avoid or to prevent life-threatening arrhythmias, especially in higher-grade AV conduction block. For all other indications, the clinical condition and symptomatology of the patient are the decisive factors.

30.2 Indications for Pacing

30.2.1 Temporary Pacing

The first group of indications for temporary pacing includes pacing for a reversible condition. This may be a result of injury to the AV node or the His-Purkinje system after heart surgery. Empirically, it may improve over time, making permanent pacing unnecessary.

Intraoperative or perioperative overdrive pacing might be used to prevent atrial fibrillation and atrial flutter, although beta-blockers are usually the treatment of choice (Blommaert et al. 2000).

Table 30.1 North American Society of Pacing and Electrophysiology (NASPE)/British Pacing and Electrophysiology Group (BPEG) Generic Pacemaker Code (NBG)

First letter	Second letter	Third letter	Fourth letter	Fifth letter
Pacing chamber(s)	Sensing chamber(s)	Modus of pacemaker response to sensing	Programmable options	Antitachycardia function(s)
A = atrium	A = atrium	I = inhibited	R = rate modulation	0=none
V = ventricle; D = dual chamber (atrium and ventricle)	V= ventricle; D = dual chamber (atrium and ventricle)	T = triggered; D = inhibited and triggered	P = programmable	P=pacing
0 = none	0 = no detection of sensing	0 = no response	M = multiprogrammable C = communicating 0 = absence of rate response	S = shock D = dual (pacing and shock)

Table 30.2 North American Society of Pacing and Electrophysiology (NASPE)/British Pacing and Electrophysiology Group (BPEG) Generic Defibrillator Code (NBD)

First letter	Second letter	Third letter	Fourth letter
Shock chamber(s)	Antitachycardia pacing chamber(s)	Tachycardia detection	Antibradycardia pacing chamber(s)
A = atrium	A = atrium	E = electrogram	A = atrium
V = ventricle	V = ventricle	H = hemodynamic (not available yet)	V = ventricle
D = dual chamber (atrium and ventricle)	D = dual chamber (atrium and ventricle)		D = dual chamber (atrium and ventricle)
0 = none	0 = none		0 = none

Similarly, rapid burst pacing can terminate AV nodal and AV reentry and sustained monomorphic ventricular tachycardias. Some polymorphic ventricular tachyarrhythmias can be prevented by rapid pacing as well. In case of polymorphic ventricular tachycardia associated with prolongation of QT interval, like torsades de pointes, rapid pacing can prevent its initiation by shortening the QT interval and by preventing ventricular premature beats.

Prophylactic pacing prior to surgery is rarely indicated. However, temporary pacing might be a part of surgical or nonsurgical intervention like rapid pacing in a case of transcatheter aortic valve implantation (TAVI) or catheter ablation procedures in patients who undergo AV nodal modification to slow conduction in the AV node during rapid rates in atrial fibrillation.

Inflammatory entities like bacterial endocarditis or Lyme carditis may also harm the electrical conduction system of the heart. Toxic, metabolic, electrolyte (hyperkalemia), and drug-induced

causes for bradycardia (e.g., digoxin, beta-blocker, antiarrhythmic drug therapy, etc.) may require temporary pacing as well.

Temporary bradycardia may occur in the settings of acute myocardial infarction. Permanent pacing is mostly not required since bradycardia and conduction abnormalities usually will resolve. There may, however, be a need for temporary pacing like in case of asystole, unstable hemodynamics (hypotension, signs of hypoperfusion, congestive heart failure), and/or complete AV block with very slow ventricular rate.

Finally, temporary pacing is indicated in pacemaker-dependent patients when a lead revision or pacemaker generator change is necessary or if the permanent pacemaker needs to be explanted because of underlying infection.

If necessary, temporary pacing can be performed via endocardial leads, epicardial electrodes placed at the time of heart surgery, external thoracic patches, and an esophageal electrode.

30.2.2 Permanent Pacing

Permanent pacing is absolutely indicated in patients with life-threatening arrhythmias. Relative indications include preservation, restoration, or improvement of patients' clinical performance. Guidelines for permanent pacing have been established by a task force of the American College of Cardiology, the American Heart Association, and the Heart Rhythm Society (ACC/AHA/HRS) in cooperation with the American Association for Thoracic Surgery (AATS) and the Society of Thoracic Surgeons (Epstein et al. 2008). Concordant guidelines have also been established by the European Society of Cardiology (ESC) (Vardas et al. 2007).

Indications for permanent pacemaker implantation are as follows:

- Symptomatic sinus bradycardia
- Sinus node blockade/arrest
- AV block grade IIb/III and AV block IIa with complementary symptoms
- Trifascicular block
- Sick sinus syndrome
- Carotid sinus syndrome
- Bradyarrhythmia absoluta and bradyarrhythmia under indicated antiarrhythmic medication

For other indications, the clinical condition and presence of symptoms of the patient are the determining factors.

30.3 Pacing Device Implantation

The group of devices for permanent cardiac pacing includes pacemakers, implantable cardioverter-defibrillators with pacing function, and devices for cardiac resynchronization therapy. Besides the generator, the placement and flawless functioning of the leads are of utmost importance for the performance of pacemaker system.

Historically, epicardial leads were primarily used for permanent cardiac pacing. However, with advances in techniques, a fully transvenous approach has become the technique of choice for pacemaker lead implantation. Nowadays, almost all primary lead implantations in adults or older children are conducted using a transvenous approach; nevertheless, the epicardial leads regain importance in the past years again. Neonates, infants and small children in need for permanent pacemaker therapy still require epicardial leads.

30.3.1 Transvenous Leads

Since the introduction of transvenous leads into clinical practice in the early 1960s, lead technology and design have improved substantially. Bipolar leads mostly replaced the original unipolar leads. The current bipolar leads are preferred because of greater signal-to-noise ratio, less interference with external signals (e.g., skeletal myopotentials), better prevention of skeletal muscle stimulation seen at the pulse generator site, and less frequent cross talk between the atrial and ventricle electrodes. Another improvement in lead design is related to the improvement of lead fixation mechanisms. The leads utilize either passive fixation via tines or fins entanglement in the trabeculae of the ventricle and atrium (■ Fig. 30.1a) or active fixation via a grasping screw (■ Fig. 30.1b). Although both lead types reveal equally good performances, the screw-in leads are preferred because of more versatility in fixation site (not dependent on the presence of trabeculae). Especially the current technique of septal positioning of the ventricular lead would be almost impossible without an active fixation process. Another advantage of screw-in leads is their easier removal when needed.

Steroid-eluting leads represent one of the most important landmark developments in lead technology. Contemporary electrodes have a reservoir within the tip of the electrode that elutes steroids in order to decrease local reactive tissue fibrosis at the screw-in site.

■ Fig. 30.1 a transvenous lead with passive fixation (anchor lead), b transvenous screw-in lead

30.3.2 Implantation

Prerequisites of transvenous pacemaker implantation are informed consent and standard preoperative preparation of the patient. The required equipments for the intervention include ECG monitoring, external defibrillator, pacing system analyzer (PSA), blood pressure cuff, oxygen saturation probe, fluoroscopy, and sterile surgical instruments. The intervention could be performed either in a conventional operating theater, a hybrid OR, or in a cath lab, assuming that sterility is guaranteed and skilled staff is available.

Most of the pacemakers are implanted under local anesthesia either via surgically exposed cephalic vein or via puncture of the subclavian vein. Rarely, in case of not feasible subclavian access, external or internal jugular vein may serve as access site (■ Fig. 30.2).

After skin disinfection and infiltration with local anaesthetic, a 5–6 cm incision approximately 3–4 cm below and parallel to the lateral third of the clavicle can be performed. This incision allows easy-device-pocket fashioning and ensures good access to the subclavian vein but may cause few challenges for the dissection of the cephalic vein

for lead positioning. An alternative approach is an incision parallel to the deltopectoral groove. This scenario makes it easier to find and dissect the cephalic vein but may limit access to the subclavian vein and may hamper pocket preparation.

30.3.2.1 Cephalic Vein Access

The cephalic vein is located in the groove between the pectoralis major and deltoideus muscles at the dorsal border of pectoralis muscle. After the cephalic vein is dissected, two loops are placed around the vein. The distal loop (absorbable material) will be knotted and the vein incised proximally to the ligature. At times, insertion of the lead may be challenging due to the presence of a venous valve. In this case, a Seldinger wire should be introduced into the vein in order to open and pass the valve. The advancement of the lead via the T-junction of the subclavian vein and superior cava vein may represent another obstacle; however, usually after cautious back and forth movements or after guide wire preforming, this is easily overcome. The proximal loop from nonabsorbable material around the cephalic vein will be knotted at the end of the implantation procedure in order to fix the lead in an appropriate position.

■ Fig. 30.2 Cephalic vein anatomy

30.3.2.2 Subclavian Vein Access

The cephalic vein is often of insufficient diameter to incorporate two pacing leads. In this case, a direct puncture of the subclavian vein is a valid alternative. Although subclavian access carries a slightly higher complication potential, in the hands of skilled operators, it is very safe. Indeed, for many physicians, it is their first choice of access. The insertion of pacing leads by means of subclavian vein puncture is performed in a standard Seldinger technique. Briefly, after the puncture, a Seldinger wire and peel-away sheath are introduced into the subclavian vein. The forward push and the maneuverability of the lead with stylet are mostly satisfactory. Sometimes a stylet may be reshaped to allow its tip to be steered into a specific direction. In case that a direct passage through the tricuspid valve is not possible, a slight pullback of the stylet, thereby creating a lead loop, might be helpful (■ Fig. 30.3a, b). Similarly, reshaping of the stylet may help to pass the tricuspid valve. The optimal placement

of the right ventricular (RV) lead is a matter of debate. Traditionally, the RV leads have been positioned in the apex (■ Fig. 30.3c). However, in the past years, there is growing evidence that position on the septum or RV outflow tract might be advantageous. Once the lead is in optimal anatomical position, the pacing parameters need to be determined in order to obtain satisfactory and durable pacing characteristics. Therefore, the final lead position is dependent on the intraoperative measurement of sensing, impedance, and pacing threshold via pacing system analyzer (PSA).

The placement of the right atrial (RA) lead follows a similar protocol. Traditionally, the RA leads are placed in the RA appendage (■ Fig. 30.4a). In case of unsatisfactory pacing characteristics, the leads may be placed anywhere in the RA, most frequently at the lateral wall (■ Fig. 30.4b).

For both ventricular and atrial leads, it is important to avoid any tension on the lead in order to prevent lead dislocation. Therefore, a small loop

■ Fig. 30.3 a–c Right ventricular lead placing

■ Fig. 30.4 a, b Right atrial lead placing

■ Fig. 30.5 Intraoperative view on a right atrial placed epicardial suture-on lead (Medtronic CapSure Epi 4968)

should be left in the course of the lead in order to allow to follow heart movement without tension.

30.3.3 Epicardial Leads

In the early days of pacemaker therapy, epicardial leads were the only option to connect pacemaker with the myocardium. The first implantable pacemaker in 1958 stimulated the heart via an epicardial lead (Elmqvist and Senning 1960). Unfortunately, the initial epicardial leads which all had to be placed by means of open-chest cardiac surgery were quite unreliable, and they had to be frequently replaced. Transvenous leads for endocardial pacing became available during the late 1960s. Soon,

they became very popular not only because of easier and faster placement in a less-incriminating implantation procedure but also because of reliable and satisfactory function. In addition, further development of steroid-coated transvenous leads and ongoing miniaturization in the late 1980s increased its reliability and popularity (Sutton et al. 2007). Therefore, epicardial leads went out of fashion. Original epicardial leads were uncoated unipolar myocardial screw-in leads. They acquired a bad reputation because of frequent and steep increase of pacing threshold and therefore need for frequent replacement. Another breakthrough has been the introduction of suture-on epicardial leads containing steroids (Medtronic CapSure Epi 4965, 4968) into the clinical daily routine (■ Fig. 30.5).

■ **Fig. 30.6** Modern epicardial screw-in lead (St. Jude Medical 1084 T). Screw-in lead tip

The latest step has been the development of epicardial bipolar steroid-coated screw-in leads (e.g., St. Jude/1084 T) (■ Fig. 30.6). Except for reliability and excellent electrical performance, the reduction in size and development of introducer (implant tool) enabled their implantation via minimally invasive lateral thoracotomy or even by means of an endoscopic approach.

Current epicardial pacing leads gained nowadays again good standing due to their excellent electrical performance and durability as recently reported (Burger et al. 2012).

Indications for epicardial pacing lead implantation include:

1. Pacemaker/defibrillator infection, sepsis, or valve endocarditis in pacemaker-dependent patients
 1. Complete removal of the cardiac implantable electronic device (CIED) system in case of pacemaker lead infection in pacemaker-dependent patients
 2. Systemic infection or valve endocarditis requiring open-heart surgery and concomitant pacemaker indication
2. Impossible venous access
 1. Due to the rising number of patients requiring cardiac electronic devices or system upgrades, venous occlusion appears increasingly. Epicardial lead implantation represents an option for upgrades or new implantations if contralateral lead implantation or extraction of functional or nonfunctional leads to regain venous access fails.

3. Epicardial LV lead implantation for permanent CRT pacing
 1. Alternative if transvenous LV lead approach fails
 2. Chronic phrenic nerve stimulation or unacceptable pacing threshold of transvenous LV lead if alternative vein for transvenous lead positioning is missing
4. Simultaneous epicardial pacing lead implantation concomitant to open-heart surgery
 1. In patients undergoing CABG or valve surgery if additional CRT indication exists
5. Tricuspid valve prosthesis
 1. Mechanical tricuspid valve prosthesis represents a contraindication for transvenous RV lead implantation
 2. Biological valve prostheses depict a relative contraindication for transvenous RV leads
6. Pediatric heart surgery
 1. Small vessel size for transvenous access and children's growth make epicardial leads a useful solution.
 2. For ICD treatment in small children, a defibrillation coil can be placed in the pericardium or sinus transversus.

30.3.3.1 Surgical Approach

Standard access for epicardial LV lead implantation is left-sided anterolateral or lateral thoracotomy. Full-lateral approach allows better view and more comfortable manipulations, but the patient needs to be positioned on table in 60–80° right-sided position. Therefore, many surgeons prefer the anterolateral approach.

The implantation is performed under general anesthesia. Double-lumen intubation might be helpful for easier implantation but is not mandatory. Incision is preferentially performed in the fourth or fifth intercostal space, the subcutaneous tissue is divided, and the intercostal muscles are separated close to the upper side of the rib. It might be useful to infiltrate local anesthetics into the intercostal space and periosteum to prevent severe postoperative pain. After retractor placement, the pericardium will be directly visible (■ Fig. 30.7a). If present, pericardial fatty tissue can be carefully resected while paying attention to phrenic nerve. Pericardiectomy is performed via an L-incision. Pericardial stay sutures are placed and coronary arteries are identified. The

■ **Fig. 30.7** Implantation of epicardial lead via left-sided mini-thoracotomy **a** exposure of pericardium after thoracotomy, **b** exposure of targeted myocardium and implantation of screw-in lead after pericardiotomy

left ventricular epicardial lead should be placed dorsal to the first diagonal branch.

Electrical mapping before lead fixation is possible, especially by using suture-on leads. Mapping procedures while using screw-in lead implement high risk for bleeding complications with low risk/benefit ratio. Epicardial leads should be fixed directly on the myocardial tissue and areas of fatty tissue should be avoided. Suture-on leads are fixed with 5–0 Prolene suture (■ Fig. 30.7b).

The initial pacing threshold usually decreases after a few minutes and initial values about 1.5–2 V are acceptable. After lead fixation, an adequate lead loop should be left in the pericardium and might be fixed with a fine suture. The pericardium should be closed with single sutures. Afterward, the lead will be positioned across the intercostal space and then subcutaneously tunneled to the pocket and connected with device. The thoracotomy closure is performed in its anatomical layers.

Another option for epicardial lead implantation is the simultaneous approach during concomitant cardiac surgery (e.g., CABG, valve surgery, etc.). Both screw-in and suture-on leads can be implanted. They can be subsequently connected with device or alternatively temporarily be placed subcutaneously and connected in a subsequent second intervention.

In addition, anterior or subxiphoid thoracotomy can be performed for RV lead and occasional right-atrial-lead implantation, and right-sided thoracotomy might be useful for atrial epicardial lead implantation. For LV lead implantation, minithoracotomy approaches or thoracoscopic

approaches are also practicable, and even robotic-based implantations have been reported.

30.3.4 Generator Pocket

The implantation side does not matter. Some physicians prefer the right side to preserve the left side for a possible later defibrillator implantation; the others prefer the patient's nondominant side—mostly the left side. This would be our recommended access site as well.

With the size of current generators, the pocket for pacemaker is usually formed subcutaneously. After the skin incision, the subcutaneous tissue has to be divided until the pectoralis fascia appears. Once in the correct plane, using two fingers to gently spread the tissue creates the pocket. Alternatively, and especially in young patients with tight tissue, an electrocautery or sharp dissection might be used. Some surgeons prefer to place a sponge soaked in antibiotic solution into the pocket until final generator placement.

In patients with a very slim habitus and preferentially in all ICD patients, a submuscular (subpectoral) pocket should be the preferred approach. In order to create a submuscular pocket, the pectoralis major muscle is divided by blunt dissection parallel to the clavicle just down to the pectoralis minor. By doing so, some fatty tissue and vessel-nerve bundle running medially and laterally can be found. This bundle may be clipped to reach an adequate pocket size.

After the pocket was prepared, the leads are secured with nonabsorbable suture material and

connected with the device. The device will be placed in the pocket and the redundant length of the leads forming coils preferably placed behind the generator. The generator itself should be fixed with nonabsorbable suture in the pocket in order to avoid its migration. Wound drains might be placed in selected cases of diffuse bleeding or in patients with high bleeding risk. Afterward, the wound closure is usually performed with two layers of absorbable sutures and intracutaneous suture.

30.4 Cardiac Rhythm Device Therapy in Severe Heart Failure

30.4.1 Cardiac Resynchronization Therapy (CRT)

For almost 20 years now, cardiac resynchronization therapy (CRT) is a well-established and effective therapy in patients suffering advanced heart failure when optimal medical treatment fails (Auricchio et al. 1993; Auricchio and Abraham 2004). Especially, patients with severe heart failure based on abnormally prolonged ventricular activation (left bundle block), systolic ventricular dysfunction, prolonged QRS duration (>120 ms), New York Heart Association (NYHA) functional class III or IV symptoms, left ventricular ejection fraction less than 35%, and optional mitral valve insufficiency benefit from CRT therapy. The positive impact of biventricular pacing (CRT-P (pacemaker) and CRT-D (defibrillator)) on ventricular strength and clinical outcome, even in long-term follow-up, has been thoroughly investigated and

reported in several randomized multicenter clinical studies. According to them, a significant improvement in patient symptoms, quality of life, exercise tolerance, and reduction of hospitalizations was observed (Abraham et al. 2002; Bristow et al. 2004).

In the Cardiac Resynchronization-Heart Failure (CARE-HF) study (Cleland et al. 2005), a 52% reduction of heart insufficiency-based hospitalizations and a 39% reduction of severe cardiovascular event-dependent hospitalization in CRT-P patients were observed. Furthermore, a 36% reduction of mortality within a period of 29 months could be demonstrated. Consistent results have been observed in the Comparison of Medical Therapy, Pacing, and Defibrillation in Chronic Heart Failure (COMPANION) study (Bristow et al. 2004) with 36% reduction of mortality in CRT-D patient. The Multicenter InSync ICD Randomized Clinical Evaluation (MIRACLE-ICD) study (Abraham et al. 2002) pointed out advantages of using CRT-D in patients suffering NYHA class III/IV, LVEF $\leq 35\%$, QRS width ≥ 120 ms, and common ICD indication. In addition, several studies illustrated reduction of left ventricular end-diastolic diameters and an increase of left ventricular ejection fraction (EF) within six months, illustrating the effect of «reverse remodeling» in more than 70% of patients (Yu et al. 2005).

■ Tables 30.3, 30.4, 30.5, 30.6, 30.7, and 30.8 give an overview of current CRT indications according to the European Society of Cardiology (ESC) and German Society of Cardiology (DGK) guidelines (see current guidelines; Dickstein et al. 2010; Vardas et al. 2007; Vlay 2009; Zipes et al. 2006).

■ Table 30.3 Classes of recommendations

Classes of recommendations	Definition	Suggested wording to be used
Class I	Evidence and/or general agreement that a given treatment or procedure is beneficial, useful, effective	Is recommended/is indicated
Class II	Conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of the given treatment or procedure	Should be considered
Class IIa	Weight of evidence/opinion is in favor of usefulness/efficacy	May be considered
Class IIb	Usefulness/efficacy is less well established by evidence/opinion	
Class III	Evidence or general agreement that the given treatment or procedure is not useful/effective and in some cases may be harmful	Is not recommended

Table 30.4 Levels of evidence

Level of evidence A	Data derived from multiple randomized clinical trials or meta-analyses
Level of evidence B	Data derived from a single randomized clinical trials or large nonrandomized studies
Level of evidence C	Consensus of opinion of the experts and/or small studies, retrospective studies, registries

30.4.1.1 Implantation of Transvenous Left Ventricular (CRT-) Lead

For implantation of a transvenous left ventricular lead, we recommend to use a left-sided approach. This simplifies coronary sinus intubation because of the more homogeneously curved course of the lead as compared to a double-angled course on the right side when accessing via the subclavian vein.

It is reasonable to start the procedure by implanting a right ventricular lead. This gives the option for external pacing in case of acute AV block or even asystole, which is a possible complication when manipulating with firm guiding sheaths close to the tricuspid valve while trying to intubate the coronary sinus. Moreover, the presence of an RV lead indicates the position of the tricuspid valve by the course of the lead's loop and makes it easier to locate the ostium of the coronary sinus. An argument against this approach would be the possibility of RV lead dislocation and sometimes reduced space for the delivery catheters, especially when the right atrium is small. Our first choice, however, is to always start with the RV lead placement first.

The procedure begins usually with subclavian vein puncture and insertion of a peelable lead introducer valve sheath. Cephalic vein access can also be used but is surgically more challenging, and the vein caliber is mostly not suitable for insertion of three leads. Afterward, a delivery catheter is inserted. Good knowledge of coronary sinus anatomy and its variants is indispensable for the implanting physician and cannulation of the coronary sinus orifice,

and its course might be sometimes a very challenging procedure. For this purpose, many specific tools have been developed: different curved delivery sheaths, EP catheters, assessable EP catheters, inner sheath catheters, different guide wires, and the LV lead itself together with a special stylet are available.

Description of all variants of implantation techniques is beyond the scope, but the most common approach for LV lead implantation should be described herein: When reaching the right atrium with a delivery sheath, a little bulk of contrast agent can be injected close to the tricuspid valve in a dorsal direction in order to locate the coronary sinus ostium. Coronary sinus location can be hindered by the eustachian ridge, which is mostly prominent close to the inferior vena cava, or Thebesian valve located at an inferior boundary close to the coronary sinus ostium or a large valve flap occluding the ostium. Furthermore, other anatomic variants can seriously aggravate coronary sinus cannulation. If coronary sinus cannulation fails, one possibility might be to place the delivery sheath into the right ventricle, torque it dorsally, and pull the catheter carefully backward with simultaneous administration of contrast fluid. When passing the tricuspid valve, the catheter then quite often slips into the coronary sinus tube. Specific landmarks on the triangle of Koch are shown in **Fig. 30.8**.

After successful cannulation of the coronary sinus, a target vein for LV lead placement has to be identified. For this purpose, a venography can be useful (**Fig. 30.9**). Contrast agent may be

■ Fig. 30.8 Triangle of Koch

■ Fig. 30.9 Contrast agent fluoroscopy of the coronary sinus

injected directly through the delivery catheter or after temporarily blocking the coronary sinus with a single-lumen balloon catheter.

Some physicians disclaim venography and directly after CS-cannulation insert a coronary

guide wire in order to find an appropriate left lateral target vein. Another possibility is to abdicate the use of delivery catheter and contrast fluid and try to insert LV lead directly by the use of a bended stylet.

Lateral, posterolateral, or anterolateral cardiac veins can be targeted in order to obtain effective LV pacing. Transvenous leads in the anterior cardiac vein or the posterior interventricular vein will usually only stimulate the interventricular septum and thus do not lead to resynchronization of the ventricle.

In the next step, a coronary guide wire should be introduced into the target vein (■ Fig. 30.10a). Once the coronary guide wire is in target position, the LV lead can be introduced in an over-the-wire technique (■ Fig. 30.10b).

The projected position of LV lead should be verified by fluoroscopy in LAO projection. Pacing threshold, impedance, and sensing have to be determined. Moreover, no phrenic nerve stimulation should appear on maximal pacing output (e.g., 10 V). If intraoperatively measured parameters are not satisfactory or phrenic nerve stimulation occurs, alternative lead positions must be looked for. If measured values are acceptable, all guide wires and catheters should be taken off, and the lead

■ **Fig. 30.10** Guide wire introduced into anterolateral target vein **a** followed by LV lead positioning via over-the-wire technique **b**

should be fixed on the pectoralis muscle by the use of permanent suture and the lead sleeve provided.

Unfortunately, not every patient can be treated with a transvenous LV lead. In some cases, insurmountable anatomical variants, coronary sinus thrombosis, coronary sinus dissection, unacceptable thresholds, no LV target vessel available, or ongoing phrenic nerve stimulation represent major obstacles for successful transvenous LV lead placement. In some of these cases, a second attempt is reasonable (e.g., coronary sinus dissection); however sometimes, the only alternative for efficient LV pacing is transthoracic implantation of epicardial LV leads.

30.4.1.2 LV Lead Types

In consideration of the great variance of coronary venous system, various caliber and curvatures of target veins and many different LV leads are available. Besides unipolar and bipolar leads, multipolar leads have been developed offering numerous (up to fourteen) possible stimulating vectors. Furthermore, different lead sizes are available ranging from 6 French (Fr) down to 4 Fr size. The majority of intravenous LV leads are being passively fixed (curved lead tips, leads with little tines). Nevertheless, an active fixation in very large veins is also possible, although this may lead to difficulties whenever lead extraction should be required at a later stage.

30.4.2 Cardiac Contractility Modulation (CCM)

A novel device therapy for advanced heart failure represents the cardiac contractility modulation

(CCM). Several clinical trials could demonstrate the efficacy of CCM therapy in patients with severe heart failure, ejection fraction fewer than 30% but without left bundle block, and no prolonged QRS complex. This patient group is not indicated for and will not benefit from cardiac resynchronization therapy (CRT). Therefore, CCM seems to be an additional device therapy in the battle against advanced heart failure, offering also the possibility of left ventricular «reverse remodeling» in long-term therapy.

In contrast to CRT system, CCM does not initiate an action potential and causes myocardial contraction like cardiac pacing in order to resynchronize the failing ventricle. The biphasic CCM impulses are delivered during the absolute ventricular refractory period of the contractile cycle. This impulse, delivered 30 ms after QRS onset with high voltage of 5–7 V for duration of about 20 ms, can enhance ventricular inotropy in the failing myocardium (■ Fig. 30.11).

Several clinical trials have been performed in order to get knowledge about the regional and global, as well as the acute and long-term effects of CCM stimulation on myocardial interactions and functions (Winter et al. 2011). The rapid and acute positive inotropic effect on myocardial contraction appears only a few minutes after CCM stimulation gets started. It depends on the increase in phosphorylation of phospholamban. Phospholamban is a key protein that modulates the activity of sarcoplasmic reticulum calcium ATPase type 2a (SERCA2a) that modulates the sarcoplasmic reticulum calcium turnover (Imai et al. 2007). In chronic heart failure, it was found that SERCA2a expression

■ Fig. 30.11 CCM biphasic impulse

decreases and increases again by ongoing CCM stimulation. Moreover, it was observed that this effect in long-term CCM-stimulated hearts was not limited only close to the stimulation area SERCA2a expression increases even in remote regions. Therefore, two reasons may explain the global effect. First, the benefit is a secondary effect based on the benefits in global hemodynamics, and it is responsible for a change of gene expression in remote areas, and second, the change of gene expression in remote areas is a direct effect transmitted via gap junctions.

In summary, not all details are known, yet, but current literature could demonstrate that CCM impulse may have a direct impact on cellular physiology besides the acute effect on calcium turnover by increasing the intracellular calcium level. Signal can impact protein-protein interaction, modulate gene expression (including reversal of fetal gene program expressed in heart failure), and increase local and global myocardial contractility without the increase of myocardial oxygen consumption. Moreover, in long-term follow-up, CCM stimulation induces reverse ventricular remodeling similar to the observed ventricular remodeling after CRT system implantation (Zhang et al. 2013).

30.4.3 CCM Device Implantation

The device implantation procedure for CCM is similar to pacemaker implantation, and it is performed under local anesthesia, sometimes combined with moderate sedation. General anesthesia would influence the necessary measurements of acute CCM effects during the procedure and therefore is not recommended. In the beginning of CCM implantation, acute stimulation benefit has been monitored by the increase of dP/dt measured by Millar box. Therefore, additional Millar catheter

has been inserted into the left ventricle by femoral artery access and connected with a special monitoring system (Millar box). With increased experience nowadays, the use of Millar catheter is not required.

Most often, surgical implantation starts by right-sided skin incision in sulcus deltoideopectoralis. Afterward, a generator pocket must be prepared anterior to the pectoralis fascia. Because of substantial energy need, the CCM impulse generator (Optimizer IV[®], Impulse Dynamics Inc., Orangeburg, NY, USA) has to be recharged regularly. In order to guaranty a safe recharging contact, the device cannot be overlaid by tissue more than 2 cm thick and so a subpectoral device placement is not reasonable. It is also important that the recharging coil be placed toward an outside direction (■ Fig. 30.12).

■ Fig. 30.12 Optimizer IV[®] generator is about the size of a defibrillator

■ **Fig. 30.13** Target zone, right ventricular mid-septal position

■ **Fig. 30.14** CCM lead positions in combination with single-chamber defibrillator

The Optimizer IV[®] will be connected to the heart by two standard ventricular leads fixed in septal position of the right ventricle (■ Fig. 30.13). Lead implantation can be done via cephalic vein or via subclavian access (see ► Sect. 30.3.2.1, «Cephalic Vein Access»; ► Sect. 30.3.2.2, «Subclavian Vein Access»). For the necessary septal lead position, screw-in leads guaranteeing good and safe fixation should be used. The distance between both leads should be at least 2 cm. Importantly, these leads should be implanted with some distance to the often concomitantly implanted ICD leads to avoid any interference.

For a safe and proper CCM impulse timing, a right atrial lead has to be fixed in usual atrial locations in addition to the ventricular leads. The atrial lead is needed to enable the generator to detect ventricular arrhythmias by the intrinsic atrial signal. In this case, the CCM signal delivery will be suspended.

All leads have to be checked for proper position via PSA measurements of sensing, pacing threshold, and impedance. Also important is a high-voltage output test (10 V) to exclude sensations and phrenic nerve stimulation. When all leads are fixed well, a CCM delivery test is performed, and all leads are connected via sterile cable to optimize test device. When Millar box is used, a baseline dP/dt is set, and the changes after temporary CCM activation are observed. An increase of 5–10% in dP/dt after 10 min will indicate good lead function and successful therapy. If no dP/dt increase can be observed, locations of the ventricular leads have to be changed until, in new positions, an adequate response will be achieved.

When the test is passed successfully, lead sleeves have to be fixed by using permanent sutures, and the CCM device has to be connected. The device has to be fixed in the pocket by a non-absorbable suture. Afterward, wound closure is usually performed with two layers of absorbable sutures and intracutaneous suture.

After completion of the implantation (■ Fig. 30.14), any possible interference with a concomitantly implanted ICD system should be tested for.

30.5 Cardiac Implantable Electronic Device (CIED) Exchange

All patients with CIED (e.g., pacemaker, ICD, CRT, etc.) undergo regular check-up of the system. Besides pacing parameters, the capacity of battery is of major importance. An elective generator replacement is indicated when interrogation of device shows elective replacement interval (ERI). An urgent replacement is indicated when the term end of life (EOL) of the battery appears.

A complete system check-up, including lead parameters, is necessary before planning any device replacement. Moreover, the generator pocket should be critically examined, and the patient should be asked for any problems, paresthesia, or pain.

The replacement is usually performed in local anesthesia with or without additional intravenous sedation. After skin incision, with the removal of the old scar for better cosmetics, lead loops and generator should be palpated. Careful and gentle lead mobilization with electrocautery

or scissors is carefully performed paying attention not to damage the leads by stretching, pulling, or inadequate flexure. The pocket will be opened and the device pulled out. While device extraction ECG monitoring is mandatory, pacemaker-dependent patients with implanted or programmed unipolar leads will not be stimulated, once the device loses the contact with the patient's body. In this case, an external pacing via pacing system analyzer (PSA) is necessary. When the leads are connected to the external PSA threshold, impedance and intrinsic signal should be controlled and compared with previous measurements in order to attest the proper lead function. Moreover, all visible parts of the lead have to be inspected for potential insulation or lead damage. If insulation damage appears, you can try to seal it with special silicone pipes and silicone glue. In most of the cases, the damaged leads cannot be repaired and need to be replaced as well. In our experience, newer generation of active-fixed leads should be extractable up to 2 years, whereas passive-fixed leads up to half a year after implantation. The extractability can be checked by moderate lead traction under fluoroscopy control. If the leads cannot be removed, they should be isolated with plastic protection cap and left in situ. For detailed description, see ► Sect. 30.7, «Lead Extraction». The pocket has to be modified according to the new generator size and form. After connection of the leads with a new device, the generator should be fixed with nonabsorbable suture to avoid its later movement, and stepwise wound closure is performed.

30.6 Complications After Cardiac Rhythm Device Implantation

In general, cardiac rhythm device implantation is a standardized, straightforward, and very safe procedure. The overall number of complications decreased over the past years, and lethal complications are extremely rare. Serious and life-threatening complications are still possible, and therefore, pacemaker/ICD or CRT systems should be implanted only by a well-trained team in hospitals with an adequate surgical risk management (Trohman et al. 2004).

In general, complications can be divided into early/perioperative and late events. In the following, the most common complications are described.

30.6.1 Pneumothorax

Postoperative pneumothorax is mostly a consequence of venous puncture by implanting the leads via the subclavian vein. Its incidence is about 0.4–2.8% and depends on the skills and experience of the implanting physicians (Blommaert et al. 2002). A pneumothorax may occur immediately, but it also occurs with some time delay of hours or even 1–2 days after the intervention. Therefore, chest X-ray should be performed at least 2–4 h after the procedure, and in case of any suspicion, it has to be repeated. In case of a relevant pneumothorax, thoracic drainage should be placed, thus controlling the pneumothorax effectively. The essential drain time varies between 1 and 10 days.

30.6.2 Hematothorax and Pocket Hematoma

In general, bleeding complications after pacemaker/ICD interventions lead to an increase risk for infection, cause pain, and may boost the overall costs. Patients scheduled for pacemaker/ICD intervention who require oral anticoagulation therapy (e.g., after stent implantation, mechanical valve replacement), and particularly with dual platelet therapy, are assumed to have higher postoperative bleeding risk.

The incidence of relevant postoperative bleeding causing hematothorax, however, is very low. Nevertheless, once any hematothorax occurs, it has to be treated surgically. In the majority of cases, the patients' coagulation system needs to be normalized, and thorax drainage should be placed. Surgical intervention including thoracotomy is rarely necessary. The essential drain time varies between 1 and 10 days.

The incidence of relevant pocket hematoma in comparison with that of hematothorax is much higher (between 0.2 and 1.7%). Pocket bleedings can appear very fast and may reach large dimensions. Its expansion depends on the pocket

position (subfascial or subpectoral), and the hematoma can spread to the lateral thorax wall or to the caput humeri. Except for pain, it may compromise tissue perfusion, especially of the pectoralis muscle. In this case, the pocket has to be revised immediately and the bleeding should be stopped. A local small drainage is often helpful to deflect the secondary edema. Antibiotic prophylaxis is often performed in order to prevent infection.

30.6.3 Lead Dislocation or Dysfunction

Compromised lead function due to lead dislocation, exit block, loss of pacing threshold, sensing, or increase of impedance is generally described with an incidence of 1–7.7% in the German and Danish ICD and pacemaker registries as well as in the literature (Parsonnet et al. 1989, Parsonnet and Roelke 1999; Yamamura et al. 1999; Kiviniemi et al. 1999; Connolly et al. 2000; Karnatz et al. 2000; Trappe and Gummert 2011) (■ Fig. 30.15). In detail, oversensing (the detection of impulse noise) with 0.7%, undersensing (the failure to detect impulses) with 3.8%, electrode fractures with 3.8%, and isolation defects with 3.4% incidence are reported (Trappe and Gummert 2011). Regardless of the causality of lead dysfunction, the lead needs to be replaced.

A special case of lead dislocation is the Twiddler syndrome. It describes potential

device manipulation by patient. On purpose or unconsciously, the patient rotates the device in a circle and thereby extracts the leads (■ Fig. 30.16a–c).

■ Fig. 30.15 Right atrial lead dislocation. Arrow indicates position of lead tip

■ Fig. 30.16 Formation of Twiddler syndrome. Arrow indicates position of lead tip

30.6.4 Lead Perforation

Lead perforation represents a seldom but serious complication with a frequency up to 1% (Trappe and Gummert 2011). Perforations may occur perioperatively or several days thereafter. Powerful acting and the use of firm guide wires are the major causes of intraoperative lead perforation. The use of stiff anchor leads and forced maneuvers in the ventricular apex in order to passively immobilize these leads may increase the risk of lead perforation. Additionally, risk rises in older patients with conspicuously weak myocardium, dilated ventricles, very thin and tender atrial wall, or dilated coronary sinus. In these cases, it is safer to place the RV lead in the ventricular septum and to use a screw-in lead for the right atrium.

Indices for ventricular perforation:

- Acute loss of pacing capture
- Lead tip outside the heart on chest X-ray
- Changes of ECG
- Acute change of hemodynamic parameters
- Dyspnea
- Rising venous pressure

Late lead perforations after initial intraoperative correct lead positioning (■ Fig. 30.17a) are caused by different mechanisms. The screw of the atrial screw-in lead can accidentally also capture the pericardium outside of the atrium. The ongoing heartbeat or change of patient position can cause consistent tracking on the lead leading to a tear in the atrial wall with a consequent pericardial tamponade. Moreover, any RV lead can perforate the ventricle even days after implantation if the lead loop is too big and the atrial constriction pushed the lead repeatedly against the ventricular wall (■ Fig. 30.17b,c).

In case of early intraoperative perforation, the lead can be carefully pulled back and repositioned, and the perforation leak usually closes spontaneously in most cases. Small pericardial effusions (<200 ml) stay usually without consequences. Nevertheless, an echocardiography should be performed in order to exclude any increase in pericardial effusion and rule out the risk for tamponade. A pigtail catheter should be available for acute relief. Rarely, in case of fulminant pericardial bleeding, a thoracotomy may be necessary.

■ Fig. 30.17 Example of RV lead ventricular perforation within 10 days. Arrow indicates position of lead tip

30.6.5 Pericardial Tamponade During Lead Positioning

As described above, lead perforation or lead extraction may cause acute pericardial effusion leading to fulminant cardiac tamponade with a

■ **Fig. 30.18** Example for ventricular RV lead perforation causing acute pericardial tamponade. Arrow indicates position of lead tip

■ **Fig. 30.19** Subclavian lead crash. Arrow indicates site of wire crack and/or deinsulation of wires due to incorrect puncture technique far too medial. This results in an acute angle between coil and further wire course. Additionally, compression between clavicle and rib lead to wear and tear of the insulation sleeve (*insert*)

frequency of 0.1% (Markewitz 2008). Urgent transesophageal echocardiography may be helpful in order to verify the dimension and location of the tamponade. The treatment of choice is usually the insertion of a pigtail catheter. However, one must be aware of inadvertent malpuncture, e.g., to the liver. Alternatively, thoracotomy could be performed. In this case, the bleeding can be effectively stopped via direct suture; however, the infectious risk rises and reconvalescence is somewhat prolonged. ■ Figure 30.18 shows lead perforation during position, leading to pericardial tamponade as seen in fluoroscopy.

30.6.6 Broken Lead and Technical Dysfunction

Pacemaker and ICD leads are sensitive to mechanical pressure and rubbing. For example, too-tight fixation of the sleeves might cause lead damage.

Also, incorrect puncture technique of the subclavian vein may lead to lead damage. Any relatively medial puncture of the subclavian vein may result in compression of the lead between the clavicle and the first rib during arm movements which could lead to, later on, lead fractures («subclavian lead crash») (■ Fig. 30.19). Therefore,

the lead should be inserted into the subclavian vein at the level of the lateral third of the clavicle.

30.6.7 Venous Thrombosis, Vascular Stenosis After Lead Implantation, and Vena Cava Superior Syndrome

Subsequent venous thrombosis directly after lead implantation is rarely reported, but the incidence may be underestimated. Frequency increases by the number of implanted leads present, by lead insertion via subclavian vein puncture, and in the presence of less surgical experience. Historically, total venous occlusions after lead implantation were reported to occur as frequent as in 30–50 % of patients, mostly localized in the area of lead insertion (Da Costa et al. 2002) (■ Fig. 30.20). With the introduction of modern rather thin transvenous leads into clinical practice, the incidence of this complication decreases. Clinical signs and symptoms of venous thrombosis are pain, swelling of the subsequent extremity, and development of collateral circuits. Repeated vessel puncture, lead extraction, or vessel dissection can be causative for acute thrombosis. Chronic thrombosis resulted usually from «vascular overload» with leads or external vein compression.

Diagnostic tools for confirming the suspicion for venous thrombosis after lead implantations include venography, ultrasound or CT, and, in a case of an MRI compatible system, also MRI.

Very rarely, the superior vena cava can be completely obliterated by a thrombus (vena cava

superior syndrome). One positive predictor for complete cava thrombosis is a high number of implanted leads present. Fortunately, because of numerous collateral vessels, the blood flow is usually not perilously compromised, and patients in chronic state often are asymptomatic.

30.6.8 Pocket and Lead Track Irritation, Perforation, and Infection

The reasons for this group of complications are inadequate implant technique, device dislocation, patient habits (especially when certain kinds of sport are practiced), patient weight loss, and accidents with mechanical trauma of the pocket. Independent of causality, the pocket has to be surgically revised.

Device or lead perforation as well as chronic fistulae bears high risk of pocket infection. Moreover, under a worst-case scenario, a descending lead infection with consequent endocarditis may occur. In order to prevent these dramatic complications, once perforating the leads and the device have to be removed and pocket be surgically debrided. Similarly, also in a scenario of already manifested pocket infection (incidence about 1 %), surgical treatment is the therapy of choice (Parsonnet and Roelke 1999; Kiviniemi et al. 1999).

30.6.9 Cardiac Arrhythmia

Ventricular extrasystole, tachycardia, or ventricular fibrillation as well as acute AV block or atrial fibrillation can be triggered by mechanical manipulation during implant procedures. Ventricular arrhythmia usually terminates spontaneously after the lead is pulled out of the ventricle; however, occasionally, external defibrillation may become necessary.

Lead manipulation close to the tricuspid valve can provoke acute AV block. In this case, external pacing via RV or LV lead is indispensable. Fortunately, most of the higher-graded AV blocks occurring during implantation are only temporary.

In predisposed patients, manipulation in the right atrial appendage can cause atrial fibrillation.

■ Fig. 30.20 Subclavian vein stenosis. Lead tip (arrow)

Removing lead does not necessarily terminate arrhythmia. Antiarrhythmic drug treatment may be less effective in narcotized patients, thus requiring external cardioversion. One prerequisite for external electrical cardioversion is echocardiographic exclusion of the presence of intracardial thrombi.

30.6.10 Phrenic Nerve Stimulation

Phrenic nerve stimulation after pacemaker or ICD implantation may occur even if intraoperative testing with 10 V stimulation test was not able to provoke diaphragm contractions. The reason might be a different more caudal or slightly turned heart position after the patient gets up. Diaphragm contractions are in vast majority of cases caused by phrenic nerve stimulation via LV lead. Nevertheless, although relatively rare, RV and RA leads may also stimulate the phrenic nerve.

In some cases, phrenic nerve stimulation via LV lead can be suppressed by reprogramming the stimulation vector or different impulse widths. In this scenario, the multipolar LV leads have a clear advantage. If phrenic nerve stimulation cannot be solved via reprogramming, a temporary switch-off LV lead for a period up to 3 months may lead to desired effect. The possible mechanism is callus formation around the tip of the lead, causing slight electrical isolation. Failing of these alternatives makes lead replacement indispensable.

30.6.11 Pectoral Muscle Stimulation

Unipolar pacing can cause pectoral muscle stimulation, when the pacemaker contact surface is very small and direct muscle contact exists. Nowadays, preferentially, bipolar pacemaker leads are mostly used, making a simple solution of pacemaker stimulation vector switch to bipolar stimulation possible. If only unipolar lead is present, the generator pocket can be revised to perform a different device placement. However, pectoral muscle stimulation is in majority of cases caused by lead insulation defects. In these cases, the lead replacement, rather than insulation repair, represents the solution.

30.7 Lead Extraction

Infective endocarditis after pacemaker or ICD implantation represents the most severe complication with up to 33% mortality in CIED. In addition, the presence of lead vegetations with size >10 mm increases the potential hazard of pulmonary embolism substantially. Moreover, the tricuspid valve can be involved and therefore open-heart surgery might be necessary. Infected leads have to be removed completely, and simultaneous antibiotic therapy has to be initiated to avert the patient of lethal complication. In case of pocket infection, endocarditis, device or lead perforation, lead-dependent arrhythmia, or high number of implanted leads with lead dysfunction, lead extractions can become necessary or urgent. The majority of data for lead extractions in the current literature is based on extractions due to infection (54–73.4%) and lead dysfunction (20.3–40%) (Smith et al. 1994; Jones et al. 2008; Rusanov and Spotnitz 2010).

Lead extractions represent the most challenging operations within the framework of cardiac rhythm device interventions. Therefore, these high-risk operations at times should be conducted in special centers with adequate experience. According to published results, complete lead extraction success is more than 90% with increase in efficiency with modern coated leads. The mortality varies between 0.5 and 1% independently of the extraction method (Hemmer et al. 2002).

While there is no doubt about the necessity of lead extraction in case of infected system, extraction of old functionless leads was for a long time controversial. Traditionally, the functionless leads were shortened but left in situ. New leads are usually implanted from the same side, if impossible from the contralateral side. Therefore, some patients collected relevant number of leads over the years. With increasing number of leads, the risk for vascular stenosis/thrombosis also increases making any new lead implantation without extraction of the sometimes-very-old leads impossible. Moreover, it is known that the risk of incomplete lead extraction or extraction complication increase in parallel to lead age.

As a consequence of the dilemma and ongoing discussion, guidelines for transvenous lead

extraction have been renewed in May 2009 by the Heart Rhythm Society in collaboration with the American College of Cardiology (ACC) and the American Heart Association (AHA) (Wilkoff et al. 2009).

According to them, lead removal should be performed in patients if a CIED implantation would require more than four leads on one side or five leads through the superior vena cava (class IIa indication) are indicated.

The number of patients treated with implantable cardiac rhythm devices increases rapidly. Therefore, despite decreasing percentages of complications due to better implantation technique and material improvements, the absolute number of patients requiring lead extraction increases substantially. For this reason, lead extractions become an important part in some cardiac surgery centers. Some of the different approaches for lead extraction are described below in detail.

In general, two different approaches for lead extraction exist:

1. Percutaneous lead extraction

1. *Unproblematic percutaneous lead removal by moderate traction:* Transvenous screw-in leads may be relatively easily removed by moderate traction if implanted only 1 and up to 3 years ago. Anchor leads (passive fixation), however, tend to adhere substantially especially at the lead tip. Therefore, lead removal via moderate traction can even be impossible after 6 months.

2. *Percutaneous lead extraction by the use of extraction devices:* Old leads or leads with strong adhesions can be extracted by using various extraction devices. In different escalation steps, special lead locking devices (e.g., Liberator[®], Cook Medical or LLD[®], Spectranetics) can be used to lock the lead and raise traction power.

Moreover, mechanical dilating sheaths (e.g., Byrd Sheath[®], Cook Medical or VisiSheath[®], Spectranetics) can be threaded over the lead, followed by countertraction, rotation, and push forward to chip adhesions free the lead.

The next escalation step for strong adhesions is the use of active extraction devices. For this purpose, electrocautery systems (Perfecta[®], Cook Medical) mechanical rotating dilator sheaths (e.g.,

Evolution/Shortie[®], Cook Medical or TightRail/Mini[®], Spectranetics), or excimer laser devices (SLS II[®] or GlideLight[®], Spectranetics) are currently available. These devices can be used even in case of complete subclavian vein occlusion to extract the leads.

2. Lead extraction by open-heart surgery

In case of massive vegetation >30 mm, strongly scarred or calcified tissue surrounding the leads, in cases of endocarditis or when additional cardiac surgery is required anyways, an open-heart access is advisable. Depending on individual circumstances, a median thoracotomy with all cardiac surgical options or a minimally invasive right-sided thoracotomy with slightly limited options (no concomitant CABG possible) could be performed.

Before starting the extraction, some important questions need to be clarified:

- Reason for extraction
- Lead type: anchor or screw-in lead
- Lead position and number
- Pacemaker or ICD lead, single or dual coil
- Lead age
- Lead size
- Pacemaker-dependent patient (AV block)
- Echocardiography with information about lead vegetation and its dimension, potential lead adhesion to myocardium or tricuspid valve, tricuspid valve function, pericardial effusion, and ejection fraction
- Number of and reason for previous pocket or lead revision
- Previous cardiac surgery
- Optionally, venography to evaluate the subclavian and superior cava vein
- Other cardiac entities (e.g., coronary or valve diseases) and eventually the need for cardiac surgery (CABG, valve operations, etc.)

30.7.1 Selection of Extraction Method

Pacemaker screw-in leads within the first year and often up to 3 years after the implantation most often can be simply extracted by moderate traction.

Leads with passive fixation (e.g., anchor leads) tend to adhere tightly, especially at the lead tip. Therefore, lead removal via moderate traction can

even be impossible already after 3 months. Nevertheless, moderate traction is the method of first choice in these leads up to 3 years after the implantation.

For older leads or for patients with known adhesions or vein occlusions, alternative extraction methods using different extraction tools have to be applied.

Lead extractions in the presence of lead vegetations are controversially discussed in current literature. In general, very large vegetations should be extracted by open-chest cardiac surgery. Until now, no consensual clear cutoff exists in order to decide whether percutaneous or open-heart lead extraction should be performed. Most physicians make a cutoff at 20–30 mm vegetation size. The structure, form, and consistence of vegetations as estimated in TEE also are of utmost importance. Therefore, the decision whether percutaneous or open-heart lead extraction will be performed must be made individually. The advantage of open-heart surgery is the safe removal of all vegetations. On the other hand, bleeding risk and risk of infection are much higher, and convalescence is much longer when compared to any percutaneous approach. The disadvantage of percutaneous approach is the risk of pulmonary embolism, which increases with larger and with friable vegetations.

Selection of the extraction method is based on objective lead/patient characteristics, available devices, and last but not least, on personal experience. Extraction should be performed either directly in cardiac surgery or in institutions with cardiac surgery being readily available.

30.7.2 Percutaneous Lead Extraction

Lead extractions should be performed under general anesthesia, especially if the use of extraction devices is expected. According to estimated extraction risk dependent on lead age and expected adhesions or venous occlusion, transesophageal echocardiography should be simultaneously performed in order to evaluate the function of tricuspid valve and eventual pericardial effusion. In addition, extracorporeal circulation (ECC) should be available on standby for any emergency situations of potential hemodynamic instability or severe bleedings. In the case of leads implanted within 1 year, without vegetations and no expected adhesions, the removal can also be performed

under local anesthesia. However, it may limit escalation of extraction methods when needed.

The percutaneous lead extraction starts with the removal of the generator out of pocket followed by lead and sleeve mobilization. Thereafter, a purse string is placed around the lead close to the clavicle. A guide wire should be inserted into the lead to avoid lead damage by lead pulling. In a case of screw-in lead, the screw will be released. The lead is carefully pulled out by continuously increased traction under fluoroscopy. Because valvular leaflet adhesions to the lead may exist, special attention should be paid to tricuspid valve function as visualized by transesophageal echocardiography. In case of leaflet adhesions, further traction on the lead may cause massive tricuspid insufficiency through valve damage. In these cases, extraction method has to be changed and countertraction technique be performed. For this purpose, passive mechanical tissue dilating outer sheaths like Byrd Sheath[®] (Cook Medical, Bloomington, IN, USA) or SightRail[®]/VisiSheath[®] (Spectranetics, Colorado Springs, CO, USA) can be used. In case of massive adhesion more aggressive, active outer sheaths can become necessary like an electrosurgical dissection cautery sheath (Perfecta[®] Cook Medical), sharp rotating trephines like the stiff Evolution[®] (Cook Medical) or the flexible TightRail[®] (Spectranetics) or an excimer laser device (SLS II[®]/GlideLight[®], Spectranetics).

30.7.2.1 Lead Locking Devices

If more traction is needed, guide wire should be taken out and lead end be cut to remove the plug connector. The inner diameter of the lead should be determined by using gauging tool and corresponding locking stylet like LLD[®] (Spectranetics) or Liberator[®] (Cook Medical) inserted into the lead. It is recommendable to fix the lead at the end by robust suture or metal device like Bulldog[®] (Cook Medical) in order to redistribute part of the traction power on lead surface (■ Fig. 30.21).

30.7.2.2 Passive Mechanical Outer Sheath

After locking stylet is introduced into the lead, an outer sheath device can be threaded over the lead. The device should be oriented parallel to lead direction. Afterward, the dilator sheath can be rotated and pushed forward under fluoroscopy control in order to stepwise dissect the lead and reach the subclavian vein. In addition, a combina-

■ **Fig. 30.21** Example for unlocked (*above*) and locked/expanded (*below*) locking stylet. Liberator[®] (Cook Medical) and LLD[®] (Spectranetics)

tion of two telescopic sloped dilation devices can be advantageous in dissecting the lead by shear movements. After reaching the subclavian vein, an intravascular device should be carefully introduced in the same manner. The leads are often not adherent for substantial part of their intravascular course, and therefore, the dilator can be easily pushed forward. Strong adhesions have to be expected usually close to the innominate vein and the SVC as well as at the distal end of lead. Countertraction and opposite device rotation are often effective in order to finally free the lead. The lead can be pulled out and the purse string will be tightened to prevent bleeding.

30.7.2.3 Active Outer Sheath Systems

Regrettably, very old leads often have solid adhesions, which cannot be separated by use of passive mechanical dilator devices or contraction devices. Moreover, extraction of the leads under these circumstances represents relatively high risk of tricuspid valve or vascular damage. Therefore, active outer sheath systems should be applied to escalate extraction method after passive extraction devices failed. Exemplary tools are electrosurgical dissection cautery sheaths, mechanic rotating trephine dilator sheaths, or excimer laser sheaths.

If an active device-based lead extraction is planned, the patients should be evaluated according to expected complication risk. General anesthesia, ECG and arterial pressure monitoring unit, simultaneous transesophageal echocardiography (TEE), and essential instruments for pacing and defibrillation and emergency cardiac surgical support including an ECC on standby should be assured. In case of pacemaker dependency, either a temporary pacing lead has to be inserted or, as

the first procedural step, a new transvenous or epicardial lead must be implanted and connected before the old leads could be extracted.

The first part of the operation is performed in analogy to the procedure using mechanical outer sheaths (lead mobilization, locking stylet, purse string). Fluoroscopy (in order to visualize the working area) and transesophageal echocardiography (in order to assess tricuspid valve function, presence of lead or valve vegetations, and pericardial effusion control) are mandatory.

30.7.2.4 Advanced Extraction Tools

■ ■ Electrosurgical dissection cautery sheath

Electrosurgical dissection cautery sheath (Perfecta[®], Cook Medical) represents the weakest of all advanced extraction tools. This device has to be connected by special adapter to an electrosurgical cautery generator (e.g., Valleylab[®], Covidien Surgical Solutions Group, CO, USA). Lead adhesions or scarred tissue will be dissected by radiofrequency (RF) energy applied between bipolar electrodes at sheath top. In order to dissect the lead, the device should be carefully pushed forward, while the lead is pulled out by tension to the locking device. Although effective in many cases, heavy calcified tissue mostly cannot be dissected when using this tool.

■ ■ Mechanical rotating trephine dilator sheath

Mechanical rotating dilator sheaths like the stiff Evolution[®] (Cook Medical) or the flexible TightRail[®] (Spectranetics) represent powerful non-electrical extraction tools. In principle, these trephine sheaths distinguish by the kind of its drill bit, the character of its tubular shank and its length. The short versions (Shortie[®], Cook Medical and TightRail Mini[®], Spectranetics) are offered to reopen the first pathway and to perform constriction from lead entrance to the subclavian vein passing the clavicle and first rib. Especially the Shortie[®] device mills more side-wise, and therefore, it can even dissect a very tight lead adhesions close to the bone or ligamentum costoclaviculare (usually as a consequence of very median subclavian vein puncture followed by inadequate lead insertion). The longer devices Evolution[®] and TightRail[®] can thoroughly mobilize adhesions all throughout intravascular lead course. Evolution[®] seems to be more aggressive and its blades forces mostly forward even in case

of heavy calcification. TightRail® also includes a powerful drill bit which remains shielded in the shaft until activated and therefore may course less complication. Its greatest advantage supposed to be the flexible tubular shank that allows easily to trail lead's course.

■ ■ Excimer laser sheath.

Excimer laser system (SLS II®/GlideLight®, Spectranetics) represents another powerful extraction tool. In analogy to devices described above, the locked lead is threaded into the inner lumen of the laser sheath. To begin with, the laser sheath should be pressed gently into the obstructing tissue, followed by moderate pressure on the laser sheath while laser is working forward. The device can advance into the tissue with approximately 1 mm per second. Continuous homogenous traction on the lead must be assured (■ Fig. 30.22).

Older laser generations have sometimes been insufficient to deal with massive calcification. Therefore, the new enhanced laser system (GlideLight®) offers now 80 Hz instead of the earlier 40 Hz (SLS II®). This new enhanced laser system noticeably increases the dissecting speed and theoretically also the possibility to release calcified tissue without an increase in risk for vascular perforations. In case of strong calcified tissue, the laser sheath should be a little oversized. A sloped outer sheath can also be slid over the laser sheath and additional mechanical dissection maneuvers are possible. The laser should not be used anymore when the lead tip is closer than 1 cm. The tip of the lead should be released by countertraction using the outer sheath and the traction device.

30.7.3 Lead Extraction by Open-Heart Surgery

Nowadays, open-heart surgery for lead extraction has become rare because of high efficacy of percutaneous lead extraction devices. But, nevertheless, in case of incomplete lead removal, large vegetations on the leads and/or tricuspid valve, or need of additional heart surgery anyways, it still plays an important role in absolutely indicated lead extractions.

30.7.4 Lead Extraction Via Median Sternotomy

Lead extraction via median sternotomy is performed in standard approach, bicaval cannulation, and total cardiopulmonary bypass. After right atriotomy, all leads and vegetations can be removed under excellent exposure (■ Fig. 30.23).

If necessary, tricuspid valve repair or replacement and/or additional surgery like mitral valve repair/replacement or CABG might be simultaneously performed.

30.7.5 Lead Extraction via Right-Sided Minimal Access Thoracotomy

Median sternotomy represents the gold standard in cardiac surgery for lead extraction in case of additional cardiac surgery. If there are no addi-

■ Fig. 30.23 Intraoperative view of lead vegetations of the septal tricuspid valve cusp (median sternotomy)

■ **Fig. 30.24** Tricuspid valve reconstruction after explantation of infected lead

tional reasons for median sternotomy (e.g., concomitant CABG), a minimally access approach might be the treatment of choice.

After right-sided 6 cm skin incision, a minithoracotomy in fourth intercostal space is performed. Video port is inserted in second intercostal space. For cardiopulmonary bypass, cannulation of the femoral artery and femoral vein or a combination of the femoral artery and femoral vein and right jugular vein is performed. Besides lead explantation, this approach even allows combination with tricuspid or mitral valve repair or replacement (■ Fig. 30.24). Implantation of epicardial right ventricular and atrial leads is also possible. Moreover, this approach seems to be superior to conventional sternotomy in terms of pain and bleeding reduction, reduced ICU and hospital stay, and improved cosmetics. Nowadays, it represents not only as an alternative but rather a first-choice procedure when performed in experienced hands.

31.1 Cardiac Tumors

31.1.1 Preliminary Remarks

Cardiac tumors are rare and have been found in large autopsy statistics with an incidence of 0.17–0.19 %, which is about 1 in 500 cases (Strauss and Merliss 1945). This includes primary benign and malignant cardiac tumors, as well as cardiac metastases.

Seventy-five percent of primary cardiac tumors are benign (Mc Allister and Fenoglio 1978).

Myxomas account for 50 % of primary benign cardiac tumors followed by rhabdomyomas with 20 % and several nonmyxomatous cardiac tumors with 30 % (Silverman 1980). Primary malignant tumors are dominated by sarcomas with 75 % of cases; however, in many instances, an exact histological classification is impossible (Mc Allister and Fenoglio 1978). The most frequent sarcomas are angiosarcomas, rhabdomyosarcomas, malignant mesotheliomas, and fibrosarcomas (Mc Allister and Fenoglio 1978). Secondary malignant cardiac tumors, namely, cardiac metastases are also very uncommon, but they can be found in about 10–20 % of patients dying of disseminated cancer (Fine 1968; Silverman 1980).

31.1.2 Surgical Anatomy

31.1.2.1 Myxomas

Myxomas are mesenchymal tumors of the heart, which can develop at any age. Their incidence is highest between the third and sixth decades of life, with females being affected two to three times more often than the males (Bulkley and Hutchins 1979). On average, myxomas are 5–6 cm large and have a weight of about 50–60 g, but myxomas with a diameter exceeding 15 cm have been reported (Reynen 1995; Wold and Lie 1980). While 75 % of myxoma cases are localized in the left atrium, 20 % are in the right atrium. One ventricle, either right or left in the same frequency, is involved in only 5 % of cases. Multiple myxomas in different heart chambers have been described, most often in both

atria (Reynen 1995). However, 94 % of tumors are solitary (Carney 1985). Myxomas are usually pedunculated. They rarely sit on a broad base. They typically arise from the interatrial septum at the cranial border of the fossa ovalis, but they may develop at any place of the endocardium, including heart valves and even caval veins. It has been assumed that the reason for the preferred localization at the fossa ovalis is due to the late development of the atrial septum from fetal mesenchymal cells, and the content of immature tissue.

The length of the tumor pedicle determines tumor mobility. Surgically, it is interesting that the tumor growth inside the stalk only rarely reaches beyond the endocardial layer.

Macroscopically, two-thirds of tumors present as an ovoid or ball-shaped structure with a smooth or slightly lobulated surface. These myxomas are rather solid. Less often (one-third of cases), a polyploid villus-type tumor pattern is seen, which is fragile, and tends to fragmentation and embolization. It has been assumed that myxomas develop from pluripotent, subendothelial mesenchymal cells (Ferrans and Robert 1973).

There are few reports to support the hypothesis that myxomas may develop malignancy. Local aggressive tumor growth as well as distant metastases including vessel wall infiltration has been observed (Read et al. 1974; Seo et al. 1980).

31.1.2.2 Other Benign Tumors

The term nonmyxomatous cardiac tumor summarizes rhabdomyomas, fibromas, and lipomas, or any type of mesenchymal tissue described as main component of a heart tumor (Mc Allister and Fenoglio 1978). In contrast to the pedunculated, usually solitary endoluminal growth of myxomas, nonmyxomatous cardiac tumors present with intramyocardial growth even in both ventricles at multiple sites. This renders surgical therapy difficult and radical resection in most cases impossible (Reece et al. 1984). At the surface of heart valves, papillary fibroelastomas may develop, which can obstruct coronary ostia and cause emboli by fragmentation, also.

Rhabdomyomas account for 20 % of all benign cardiac tumors. They are the most frequent cardiac tumors found in childhood (Bigelow et al. 1954). Eighty-five percent of rhabdomyoma patients are younger than 15 years. In >90 % of cases, rhabdomyomas simultaneously develop at

multiple sites, mostly affecting the ventricles. Pathoanatomically, rhabdomyomas are hamartomas. Therefore, half of the children further demonstrate symptoms of tuberous sclerosis.

Fibromas of the heart also are typical for childhood cardiac tumors with more than 80% occurring in children, especially in infants and toddlers. In contrast to other tumors, they are more often solitary and exclusively found in the ventricles. There is no association with other diseases or any known hereditary trait.

Lipomas can develop anywhere in the heart and at any age. They are well encapsulated and can reach a considerable size before clinical symptom may develop. A nonencapsulated fat deposition in the interatrial septum is termed «lipomatous hypertrophy» and can be found predominantly in obese elderly patients.

Papillary fibroelastomas account for about 7% of all cardiac tumors. They arise characteristically at aortic or mitral valve leaflets, less frequently at tricuspid valve leaflets, or at the ventricular septum.

31.1.2.3 Primary Malignant Cardiac Tumors

Primary malignant tumors account for about 25% of all primary cardiac tumors (Mc Allister and Fenoglio 1978). Almost all of them are sarcomas. They do usually not appear clinically before adulthood and there is equal distribution for gender. The preferred localization is the right heart, mainly the right atrium. Histologically, different mesenchymal tissues are involved. Most common is the angiosarcoma, whereas rhabdomyosarcomas, myosarcomas, and other soft tissue sarcomas are much less frequent. Highly malignant and undifferentiated tumors, however, often cannot be classified histologically. Sarcomas arise from the endocardium or pericardium and rapidly infiltrate the myocardial wall, grow into adjacent mediastinal structures, and metastasize early into the liver, lung, and brain (Bjerregard and Baandrup 1979). At the time of diagnosis, 80% of patients already suffer from metastases in both lungs. Another growth pattern exhibits a more intramyocardial, horizontal expansion, where the endocardium and pericardium remain intact for quite a while. Finally, sarcomas sometimes demonstrate an exophytic growth into the heart chambers.

An extremely rare primary malignant heart tumor is the *hemangioendothelioma* (Lisy et al. 2007).

31.1.2.4 Secondary Malignant Tumors (Metastases)

At autopsy, myocardial or pericardial metastases of extracardiac malignant tumors are much more often found than primary malignant cardiac tumors. However, they are usually not clinically evident because of the limitations related to the underlying disease (Fine 1968). It has been estimated that 10% of metastasizing tumors finally reach the heart and pericardium, either hematogenously, via lymphatics, or direct ingrowth. Such metastases are common for malignant melanoma, bronchial carcinoma, and breast cancer, and they mainly involve the ventricles and the pericardium. A peculiar variant is the endoluminally growing hypernephroma, which reaches the heart via the inferior caval vein. It can almost completely occlude the right atrium and ventricle with a cone-like tumor mass (Paul et al. 1975).

31.1.3 Clinical Presentation

Myxomas are typically sporadic and isolated, which means they are not associated with other anomalies. Only about 5% of myxoma patients show a hereditary familial clustering with an autosomal dominant transmission. The latter are younger, without a gender preference, and present more often with multisite tumors. One out of five myxoma patients suffers from additional neoplasms (adrenocortical nodular hyperplasia, Sertoli cell tumor, pituitary gland tumor, multiple myxoid fibroadenomas of the breast, cutaneous myomas, and pigment alterations). This is why this clinical entity has also been termed «*complex myxoma*» (Carney 1985).

The clinical presentation of the myxomas is primarily determined by their localization and texture. A characteristic feature of all cardiac tumors is a (variable) symptom-free interval until diagnosis is established (Larrieu et al. 1982). Most commonly, a local complication such as obstruction of the left ventricular outflow tract or a syncope as sign of an intermittent LV inflow obstruction initiates first symptoms and ultimately leads to diagnosis.

Myxomas of the left atrium reaching a certain size may impair left ventricular filling and mimic mitral stenosis. If myxomas grow into the mitral ostium or prolapse into the left ventricle, the

clinical picture of mitral incompetence occasionally may evolve, also. A short and acute medical history is characteristic and contrasts with the long-standing symptoms in patients with post-inflammatory mitral valve disease. Ultimately, the pedunculated myxomas lead to dyspnea due to lung congestion, particularly when the patients lie in on their back and the tumor prolapses into the mitral valve.

It is a distinctive feature in cardiac myxomas that heart failure builds up suddenly and may be associated with supraventricular rhythm disorders, which do not respond to digitalis and diuretics. Furthermore, syncopes (extremely rare in acquired mitral stenosis) and seizures can be triggered by hypotensive episodes. Myxomas adherent to the atrial wall provoke intermittent dyspnea which increases with tumor growth. Peripheral and central emboli due to detached tumor fragments are noted in 30–40% of cases (Silverman 1980). Pathohistology of suspicious embolic debris removed from peripheral arteries can occasionally be the first diagnostic tool for cardiac myxoma (Bulkley and Hutchins 1979). The incidence of cerebral emboli is high and has been reported in several investigations to be as high as 50% (Sandok et al. 1980). Neurological symptoms associated with atrial myxomas have to be seen as a consequence of cerebral tumor embolism.

Myxomas of the right atrium can lead to tricuspid valve dysfunction, which resembles the clinical presentation of tricuspid stenosis, chronic right heart failure, or constrictive pericarditis. Recurrent tumor embolization into the pulmonary vasculature can cause pulmonary hypertension. Rarely, paradoxical tumor embolism of a right atrial myxoma through a patent foramen ovale occurs. Right atrial myxomas not infrequently lead to a «myxoma disease,» which includes fever, arthralgias, polymyositis, weight loss, and hypergammaglobulinemia (Fitzpatrick et al. 1986). A rather common misdiagnosis is rheumatoid disease and long-term cortisone therapy for that with secondary osteoporosis has been published (Reynen 1995).

Ventricular myxomas and other tumors become symptomatic only at a very late stage. Only the progressive expansion of the tumor leads to an obstruction of the inflow or outflow tract, or an extracardial tumor growth finally compromises adjacent structures such as the phrenic nerve.

The symptoms of *malignant tumors* depend on their growth pattern. The clinical picture is domi-

nated by a rapidly progressive, myocardial failure with cardiomegaly not responding to medical therapy. Intramyocardially growing tumors may lead to conduction disturbance. The suspected diagnosis is usually cardiomyopathy. Some patients complain about thoracic pain, fever, and weight loss, suspicious of a pulmonary disease. Not infrequently, patients are referred on an emergency basis because of hemorrhagic pericardial effusion and symptoms of tamponade. There also may be severe venous congestion of the upper half of the body.

In patients with an extracardial malignant disease, a secondary involvement of the heart has to be thought of, if intractable bradycardia or tachycardia, cardiomegaly, hemorrhagic pericardial effusion, or obstruction of a caval vein without a visible mediastinal neoplasm is present.

The detection of malignant cells of the primary tumor after pericardial puncture may establish diagnosis of cardiac metastases. Massive hemopericardium may lead to hospital admission on an emergency basis like in cases with primary malignant cardiac tumors; however, an acute outflow tract obstruction is more often responsible for referral.

31.1.4 Diagnosis and Indication for Surgery

The clinical examination is unspecific and hardly productive except in cases which manifest heart failure. The chest x-ray is usually normal, but cardiac enlargement, pulmonary congestion, and sometimes an intracardiac calcification can give a hint. The ECG is also of little help, even if rhythm disturbances are present. The diagnosis of an atrial myxoma is established by echocardiography. It also may be an incidental finding following peripheral tumor embolism (DePace et al. 1981). Both the transthoracic and even better the transesophageal technique allow for exact visualization of the tumor location and size. Alternative diagnostic methods are cardiac computed tomography and magnetic resonance imaging. Cardiac catheterization is not necessary to establish indication for surgery but may be necessary to rule

out concomitant coronary artery disease in elderly patients. Indication for surgery is always given as the natural course of the disease cannot be predicted. The important differential diagnosis of a thrombus has to be always considered.

The diagnosis of the other benign and malignant tumors is ascertained by computed tomography and magnetic resonance imaging, if the patients present with heart failure, unspecific chest pain, and/or weight loss. Echocardiography can establish the diagnosis of a malignant cardiac tumor, too. Abnormal ventricular wall motion or displacement of coronary vessels in ventriculography may be suspicious of intramural cardiac tumor, but an exact topographic diagnosis is not possible by catheterization. Sometimes, primary malignant cardiac tumors are only recognized during an emergency explorative thoracotomy.

An indication for surgery is given in all patients when distant metastases have been excluded with an adequate staging procedures and when complete resectability of the tumor seems to be likely.

31.1.5 Operative Techniques

Although myxomas are operated upon in a rather typical fashion, a so-called gold standard technique has not been defined, yet. Basically, simple myxomas are only excised out of their endocardial basis, whereas familial myxomas may also be treated more aggressively. All other cardiac tumors are resected as radical as possible to lower the rate of local recurrence and clinical importance. The limits of resectability are determined by the remaining functionality of the heart.

Usually, complete tumor resection is only possible with the use of extracorporeal circulation (Dein et al. 1987). Closed techniques for resection of an atrial myxoma are obsolete as tumor fragments or adherent thrombi can be dislodged. The standard approach for extirpation of a cardiac tumor/atrial myxoma is the median sternotomy. Extracorporeal circulation is connected with bicaval cannulation, where direct cannulation of both caval veins offers the best access to the atria. If the tumor reaches the orifice of a caval vein, one caval and additional cannulation of a femoral vein or the right jugular vein respectively can be more

favorable. During institution of extracorporeal circulation, manipulation at the heart should be reduced to a minimum to prevent tumor embolization. For the same reason, it is reasonable to encircle the caval veins not before initiation of cardiopulmonary bypass and cross-clamping the aorta. Myocardial protection is achieved with standard aortic root cardioplegia and mild hypothermia.

31.1.5.1 Access to the Left Atrium

A left atrial myxoma can be approached directly through the left atrium via the interatrial groove (Waterston's groove) similar to a mitral access. At the arrested heart, the tumor size can be analyzed, and the tumor pedicle can be completely excised. It is recommended to excise the pedicle with a 5 mm surrounding of healthy tissue in a subendocardial layer or even better a local full-thickness resection of the interatrial septum. There are advantages and disadvantages of a direct left atrial access. In face of a large tumor, retrieval in one piece and the excision of the pedicle may be difficult. Moreover, closure of the septal defect after tumor resection may become difficult with this access.

We prefer a transeptal access coming through the right atrium. The right atriotomy is followed by an incision of the interatrial septum along the upper (or lower) edge of the fossa ovalis. The septal incision is further directed toward the right upper pulmonary vein or superior caval vein (or to the left atrial roof if necessary) (■ Fig. 31.1a). Thereafter, the tumor pedicle—usually attached to the atrial septum at the cranial part of the fossa ovalis—is exposed caudad to the incision (■ Fig. 31.1b). The pedicle is then excised out of the septum with a piece of full-thickness septum. The septum is further incised as much as necessary until the entire tumor can be seen and completely removed (■ Fig. 31.1c). After tumor resection and removal, the left atrium, the pulmonary lung orifices, and the left ventricular cavity have to be meticulously inspected for tumor fragments, and they have to be intensively rinsed. If part of the pedicle of the tumor/myxoma or other tumor remnants are found, further resection with an appropriate healthy surrounding is necessary to prevent recurrent disease. This is usually true when the tumor arose not from the atrial septum but the free left atrial wall and when the tumor tears off. Whether a subendocardial resection is sufficient or an aggressive transmural resection is necessary has not been adequately clarified yet. The resulting

■ **Fig. 31.1** **a** Access to the left atrium through the atrial septum. The right atrium is longitudinally incised; the *dashed line* shows the incision in the atrial septum. **b** The opened atrial septum gives exposure to the tumor pedicle. The pedicle is resected around its insertion. **c** The left atrial tumor is removed through the extended septal incision

■ **Fig. 31.2** Biatrial access. An additional incision in the left atrium below the interatrial groove facilitates the localization of the myxoma. *RV* right ventricle, *RA* right atrium

atrial wall defects can be closed by direct suture or insertion of a pericardial or PTFE (polytetrafluoroethylene) patch according to size and localization. After atrial closure and deairing of the heart, the aortic cross-clamp is released and extracorporeal circulation terminated in any routine fashion.

A *biatrial approach* with an additional left atrial incision is another option, which facilitates exposure and localization of the myxoma, especially when a large tumor mass is present and/or the localization of the site of adhesion is still not known (■ Fig. 31.2). A vertical incision is also possible, particularly in small anatomical dimensions. The incision starts at the basis of the right auricle, crosses the interatrial groove, and reaches the left

atrial free wall between the right pulmonary veins—corresponding to the Dubost access to the mitral valve (DuBost et al. 1966). Following two stay stitches, the tumor can be well exposed. After tumor resection, the atrial septum and the biatrial incisions are closed with a simple running suture.

31.1.5.2 Access to the Right Atrium

After bicaval cannulation, there are multiple ways to enter the right atrium. Most commonly, an oblique incision from the tip of the right auricle in direction to the right lower pulmonary vein is favored. When the tumor is found, it is carefully exposed and its attachment(s) identified. Thereafter, the tumor and its pedicle or basis can be completely excised as described above. As right atrial tumors frequently originate from the septum, a septal defect has to be closed after resection—like with left atrial tumors—with a pericardial or PTFE patch. Prior to closure of the septal defect, the left atrium should be inspected for additional tumors, also (Marvasti et al. 1984).

31.1.5.3 Access to the Ventricles

The site of cardiac access for a ventricular tumor depends on its localization and the size/extension and presumed type of neoplasm. Removal of a myxoma out of one of the ventricles usually does not require transmural resection since the tumor has an endocardial origin (see ► Sect. 31.1.2.1, «Myxomas») and recurrent disease has not been reported with the respective surgical approach. Therefore, the standard access for ventricular myxomas is transatrially, also, i.e., through the corresponding atrium and atrioventricular valve. Only in exceptional cases, the access is via the great arteries and their semilunar

valves or via a ventriculotomy. Moreover, especially in these cases, both atria should be explored as well to rule out additional atrial tumors. In very rare cases, in which the tumor pedicle originates from the AV valve or if AV valve function is compromised by tumor prolapse or compression, the valvular function should be analyzed on the arrested heart and surgically restored if necessary.

The other benign tumors, especially those with transmural growth, are treated like malignant tumors. Most important is the preservation of cardiac function or the release of an obstruction, i.e., a radical resection is not obligatory. The free left ventricular wall allows only limited tumor resection, as a ventricular wall replacement by a PTFE or Dacron patch is associated with a more or less considerable loss of contractility. The interventricular septum is surgically not well accessible. In contrast, the right ventricle as well as the tricuspid valve can be totally resected, unless pulmonary hypertension prevails. With normal pulmonary resistance, the blood from the caval veins can drain passively into the lung like after a Fontan operation in congenital heart surgery.

31.1.5.4 Extended Accesses and Autotransplantation

An extensive tumor growth, especially with infiltration of the basis of the left atrium and its adjacent structures, cannot be sufficiently approached with the standard surgical accesses. However, all large vessels which are connected with the heart can be divided step by step until complete or curative tumor resection is possible. In a simple case, separation of the superior caval vein or aorta and pulmonary artery may suffice. The extreme variant is the autotransplantation, in which the heart is excised according to the technique of Lower and Shumway or its bicaval modification after hypothermic conservation and later reimplanted again (see ► Chapter «Heart and Heart-Lung Transplantation», ► Sect. 37.1.5.1; ► Sect. 37.1.5.2). The advantage of the autotransplantation is an ex situ operation with an access to all structures of the heart in a bloodless field. The tumor can be completely exposed. The best possible resection and reconstruction of the ensuing structural defects may be simpler ex situ (Hoffmeier et al. 2004).

31.1.6 Complications and Prognosis

After a limited local tumor resection and clearance of an intracardiac obstruction, the postoperative

course is usually uncomplicated. Cerebral and peripheral deficits following intraoperative tumor embolization have become a rare complication with the introduction of extracorporeal circulation and the tumor removal under direct sight. Postoperative supraventricular tachycardias are frequent, but can be well treated medically (Dein et al. 1987).

The complete resection of a myxoma is curative. In case of a complex myxoma (myxoma disease/syndrome), the decline of clinical symptoms and inflammatory markers indicates the surgical success. The risk of a *recurrent myxoma* has been reported in several cases. Assumed underlying reasons were inadequate resection, intraoperative tumor spread, as well as multilocalized disease to start with (Read et al. 1974).

Yearly echocardiographic controls are advised to timely recognize recurrent disease.

In malignant tumors, a widespread infiltration of cardiac structures or neighboring organs and early distant metastases limit radical and curative surgical therapy. Occasionally, partial ventricular wall resection, valve replacement, and aortocoronary bypass surgery are necessary to relieve a life-threatening tumor obstruction (Poule et al. 1983). After radical surgical tumor resection, polychemotherapy and radiotherapy are frequently added to lower the incidence of early relapse. The prognosis of a primary malignant cardiac tumor is very unfavorable; only few rare cases have been reported with a survival beyond 1 year and cure of the disease in a few cases only (Sortie et al. 1984). The best prognoses supposedly have solitary metastases, which have been seen in some cases years after primary surgery (Bigelow et al. 1954). In many cases, only palliative treatment measures like drainage of recurrent pericardial effusion by fenestration of the pericardium into the pleura or the relief of a right ventricular obstruction can be anticipated.

31.2 Pericardial Diseases

31.2.1 Preliminary Remarks

The pericardium holds the heart in its position and prevents excessive distension of the heart in case of sudden systemic volume overload. It is composed of a collagen-enriched stable tissue

(parietal layer), which is covered with a thin mesothelium (visceral layer) at its inner side. This fibroelastic sac contains about 20 cc of serous fluid, which maintains a low frictional resistance of the moving heart against the surrounding structures (pleura, mediastinum, diaphragm) (Schollmayer 1982). The pericardial fluid also represents a barrier against inflammation following contamination or infection of the surrounding tissues.

The clinically most important diseases of the pericardium are a pericardial effusion and a tamponade as well as constrictive pericarditis. Pericardial cysts and primary pericardial tumors are extremely rare.

31.2.2 Pericardial Effusion

An acute or chronic inflammation of the pericardium may lead to an increase and/or an alteration of the composition of the pericardial fluid and compromise cardiac function. A rapid (acute) increase of the pericardial fluid by 150–200 mL can already lead to a pericardial tamponade, whereas in chronic processes up to 3 l can be accumulated without a significant restriction of the hemodynamic situation.

With regard to the etiology, serous, serofibrinous, putride, and hemorrhagic forms of pericardial effusion are differentiated. Serous and serofibrinous effusions dominate in case of heart failure, idiopathic pericarditis, chronic renal insufficiency, rheumatic and metabolic diseases, and in metastatic tumor diseases. In cardiac surgery, the postcardiotomy syndrome is relevant (Dressler-Syndrome; Dressler 1956). Putride effusions develop after perforating, purulent, or neoplastic processes in the abdomen or anterior or posterior mediastinum. A hemorrhagic pericardial effusion can be seen in unspecific inflammatory diseases. However, most commonly, it is a consequence of a trauma, a myocardial injury after diagnostic or therapeutic interventions (insertion of a central venous line, angiography, cardiac catheterization, and/or intervention as well as pacemaker implantation), or a penetrating or dissecting aortic aneurysm.

31.2.2.1 Diagnosis and Indication for Pericardiocentesis

Suspicion for a *pericardial effusion* arises with an increase of the cardiac silhouette in the chest x-ray. The diagnosis is then confirmed by echo-

cardiography. Typical findings during echocardiography are a diastolic collapse of the right atrium and ventricle and the free floating heart within the effusion («swinging heart»). Computed tomography and magnetic resonance imaging may serve as alternative tools, as both diagnostic techniques have a high diagnostic value, also with regard to the composition of the pericardial fluid.

A *pericardial tamponade* is a critical increase of the amount of pericardial fluid/effusion to the point of circulatory compromise. It can be assumed in case of a decreased systemic blood pressure, an increased central venous pressure, and tachycardia in combination with an according medical history. Diagnosis is confirmed again with the abovementioned imaging techniques.

The indication for a pericardiocentesis is based on the compromised hemodynamics and not on the amount of pericardial effusion. With known pericardial effusions, pericardiocentesis should always be accomplished before a tamponade develops.

The aim of pericardial relief is the instantaneous reduction of the intrapericardial pressure to relieve the compression of the heart and to prevent a circulatory low output failure. In an acute situation, either a pericardial puncture or a surgical (inferior) pericardiotomy can be performed. Chronic effusions are best treated with a pericardial fenestration or a pericardiectomy.

31.2.2.2 Pericardial Puncture

The idea to perform a pericardial puncture and descriptions of technical details about how to do it are well known from the literature for 300 years (Kleinschmidt 1945). Nowadays, the subxiphoid approach is preferred. According to Larrey, the needle is inserted in the triangular space between the left-sided base of the xiphoid and the united extremities of the seventh and eighth ribs (Rehn 1913; Sauerbruch 1925). Formerly, patients were put into an almost upright position (elevated 30–45°) to reach the lowest part of the pericardium and to lessen the risk of a ventricular laceration. Nowadays, more often pericardial puncture is performed in a supine position controlled by echocardiography or fluoroscopy in a cath lab.

The puncture area is cleaned, sterilized, and infiltrated with a local anesthetic. The puncture may be performed directly or is accomplished using Seldinger's technique. The long puncture needle attached to a syringe via a three-way stopcock is advanced between the xiphoid process and the left costal margin toward the left shoulder. The penetration of the pericardium is recognized with the drop of resistance and the instantaneous aspiration of fluid. A guidewire is inserted through the cannula and the latter is removed. Over the guidewire, a flexible atraumatic catheter, usually a pigtail catheter with side holes, is forwarded and the pericardial effusion aspirated (■ Fig. 31.3a, b).

If the subxiphoid approach is not possible, the apical and the parasternal puncture may serve as alternatives. The apical puncture is performed at the assumed cardiac apex in the fourth or fifth intercostal space at the anterior or midaxillary line. A parasternal puncture is possible on the fourth intercostal space and is considered as last resort.

The most frequent complication is an accidental puncture of the ventricle. It can be recognized when a pulsating blood steam is pouring through the needle which rapidly clots (old blood from the pericardium does not clot!). The catheter is then pulled back into the pericardial sac and left there. The laceration of the myocardial wall normally seals with time, usually pretty rapidly; till then the blood can drain over the catheter. Therefore, a surgical intervention rarely is necessary.

31.2.2.3 Subxiphoid Pericardiectomy

The subxiphoid pericardiectomy is a simple and efficient surgical procedure which can be well applied in critical and difficult patients. The access is provided by a longitudinal or transverse subxiphoidal incision. The pericardiectomy today is employed after open heart surgery, where due to the open pericardium it rather is a mediastinotomy, and occasionally, it is done in case of infected effusion. It guarantees an ongoing drain-

■ Fig. 31.3 a, b
Pericardiocentesis with Seldinger's technique. **a** A guidewire is forwarded into the pericardium through the needle. **b** The needle has been removed. A smooth catheter is inserted into the pericardium over the guidewire so that the effusion can be aspirated

age and also allows local rinsing as well the instillation of drugs.

Under local or general anesthesia, a 4–6 cm median incision starting at the base of the xiphoid caudally is followed by division of the former and the rectus abdominis muscle. A spreader is put into place, and with elevation of the lower sternum and detaching the diaphragm from the sternum, the pericardium can be identified. A separation of the diaphragm is seldom required. The pericardium is transversely incised over a length of 2–3 cm at the lower border, and a smooth drainage is placed after aspiration of the pericardial effusion (■ Fig. 31.4).

31.2.2.4 Pericardial Window

In patients with chronically recurrent serous pericardial effusions, a simple subxiphoid pericardiectomy is inadequate since the drains would have to stay in situ rather long until the healing process has finished which would add a considerable increase in the risk of infection. In these cases, a

persistent fenestration of the pericardium as an internal drainage into the pleura (Efler and Proudfit 1957) or a pericardial resection is recommended (Levitsky et al. 1976).

A thoracoscopy requires a lateral position of the patient which sometimes is not well tolerated. It also requires a double-lumen endotracheal tube intubation and a pleural cavity without dense adhesions. In selected patients, it may be an elegant alternative to open surgery.

After endotracheal anesthesia and thoracotomy, the pericardium is incised ventrally to the phrenic nerve, and by pericardial resection, a window of about 4×6 cm is created, carefully avoiding a prolapse of the heart. The pericardial effusion is aspirated, and a drainage is placed into the pericardium as well as into the pleura prior to closure of the wound. This pericardial drainage is deemed to be important by some to keep the window open as long as the intrapericardial secretion maintains. A different opinion is espe-

■ Fig. 31.4 Subxiphoid pericardiectomy. After a median skin incision along the xiphoid process, the abdominal wall layers are divided and the pericardium is opened. A smooth pericardial drainage is placed which is then exited over the skin incision or separately

cially not to employ a pericardial drain but only a pleural drain. The idea is that, with a pericardial drain placed, the window created may lose its function prematurely being not necessary as long as the pericardial drain is in place. Obviously, both ways work in most of the patients.

The surgical technique of the pericardial resection is similar to the pericardiectomy in constrictive pericarditis (see below).

31.2.3 Constrictive Pericarditis

In the second half of the last century, the incidence of constrictive pericarditis has steadily decreased and finally was reported to account for 0.2–0.5% of all cardiac diseases (Hermann et al. 1983; McCaughan et al. 1985; Wood 1961). Whereas formerly previous tuberculosis had been responsible in most cases for this disease, a tuberculous etiology is now encountered in <3% of constrictive pericarditis (Hamelmann 1962; McCaughan et al. 1985). Nowadays, the underlying etiology is quite variable. Each pericarditis—of unspecific, viral, bacterial, or fungal origin—can finally result in a constriction of the heart. Increasingly important are a mediastinal radiation, a postcardiotomy inflammation, and a trauma (Bubenheimer et al. 1985; Pick et al. 1984; Rice et al. 1981).

The embrace and constriction of the heart by the scarred pericardium, and sometimes also calcified shells, with a thickness of up to 1 cm, leads to an increasing impediment of atrial and consecutively ventricular filling. When the superior or inferior caval veins are strangulated, the venous return is additionally impaired. The constrictive pericarditis also compromises myocardial contraction and ultimately leads to muscular atrophy. Cardiac ejection fraction drops and the body is underperfused. Already in NYHA II, end-organ dysfunction of lung, liver, and kidney evolves (Hermann et al. 1983). Clinically, dyspnea on exertion, abdominal complaints with hepatomegaly and ascites, and peripheral edema dominate.

31.2.3.1 Diagnosis and Indication for Pericardiectomy

The diagnosis of constrictive pericarditis can be established with evaluation of hemodynamic/functional parameters and/or with imaging techniques. A chest x-ray only rarely demonstrates an increased silhouette of the heart, but in 40% of

cases, a calcified shell corresponding to the pericardial sac is visible. More suitable for diagnosis are computed tomography and magnetic resonance imaging, as they also allow visualization of the pericardial thickness, cardiac size (atrial dilatation, ventricular constriction), and the delineation of the myocardial and pericardial layers (Soulen et al. 1985; Sutton et al. 1985). Moreover, an infiltration of the pericardial calcification into the myocardium which increases the operative risk due to myocardial lacerations can be verified. Echocardiography is less suitable to diagnose a constrictive pericarditis; however, the restriction of diastolic filling with a simultaneously preserved systolic contractile function can be well demonstrated.

The hemodynamic proof of a constriction is obtained by a right heart catheterization. When measuring the pressure course in the right ventricle, a characteristic *dip and plateau phenomenon* is noted, which comprises an undisturbed early diastolic filling («dip») and an abrupt stop of the ventricular filling («plateau»). Additionally, an equalization of the right atrial and right ventricular pressure is visible. This phenomenon is typical for a restrictive disease, but does not differentiate between restrictive cardiomyopathy and constrictive pericarditis.

A pathological electrocardiogram and unspecific ST segment and T wave alterations are common, but barely specific. A low voltage of the QRS complex or atrial fibrillation is noted in one-third of patients (McCaughan et al. 1985).

The indication for a pericardiectomy is established with the typical clinical and diagnostic findings.

31.2.3.2 Pericardiectomy

A pericardiectomy is an elective surgical procedure.

The perioperative management requires monitoring of the systemic arterial and both systemic and pulmonary venous pressures (right and left atrium), since the filling pressures can rapidly alter after release of the pericardial constraint and the pump function worsens due to the lessened wall tension. Moreover, this online monitoring allows an immediate online control of the surgical result.

■ **Fig. 31.5** The pericardium is incised with a #11 blade and detached from the myocardium bluntly or with the knife. The phrenic nerve has to be identified before and taken care of

During the procedure, the patient should be provided with external defibrillation electrodes to be able to rapidly terminate ventricular fibrillation once occurred when induced during surgical preparation.

The best surgical access is a median sternotomy, since all four chambers can be approached, although the historical off pump approach always has been via a left lateral thoracotomy. The median sternotomy also allows an extracorporeal circulation that can be easily instituted in case of complications (hemodynamic instability, bleeding) (Shumaker and Roshe 1960). The classic approach allowed only limited access to the right ventricle and the caval veins, which, however, are the main targets in this therapeutic approach.

After sternotomy, the thickened pericardium is inspected, and areas of less thickened and less calcified pericardium are identified. Frequently, these areas are best to start preparation at, since the pericardium can be detached there more easily. If there is a homogeneous scar, it is least dangerous to start preparation caudally close to the diaphragm. When a suitable layer between the heart and the pericardium is found, the pericardium is carefully detached from the whole anterior and lateral epicardium as far as possible,

similar to a preparation in cardiac reoperation. The backside of the heart can be only partially pericardiectomized. At the lateral sides, the pericardium should be resected down to the phrenic nerve; the latter is identified after opening of the pleura (■ Fig. 31.5). Kocher clamps are fixed to the detached pericardial scar and gentle traction is applied, while the surgeon carefully holds the myocardium in the opposite direction with a humid gauze swab. With this technique, the cut surface is gently but well exposed. A laceration of the myocardium, however, cannot always be prevented even with the gentlest approach.

If the calcifications of the pericardium penetrate into the myocardium, its detachment can cause trouble, especially when the calcific spikes are in closest proximity to coronary arteries. An adequate preparation, i.e., separation of the correct layers, is most important here as a blunt extraction of the calcified shells can ensue myocardial lacerations with severe bleeding. Deep intramyocardial calcified fragments were cut short and left in situ, i.e., small remaining calcified islands can be left in place if their detachment seems to be hazardous. Larger calcified plaques, which cannot be removed in total but may hinder myocardial contraction, should be divided. Nevertheless, one should strive to achieve a complete decortication of the heart (Robertson and Mulder 1984). Special attention should be paid when dissecting close to the coronary vessels, especially the left anterior descending artery and its branches. It is recommended that the unsoldered pericardial flap is not immediately resected but held up with hemostat clamps or sutures. When lacerations or significant bleeding occurs, the prepared pericardial flap can be pushed back on the epicardial surface. Minor bleedings can be controlled with careful compression or few stitches (fine needle and suture). In some instances, fibrin glue is helpful. Not infrequently, a dense or calcified scar across the right ventricular outflow tract is present; its removal or division is important to avoid a post-operative functional pulmonary stenosis with consecutive right ventricular hypertension (Portal et al. 1966). The resection of the calcified plaques in the atrioventricular groove is hazardous as there are coronary vessels. Yet, at least a partial resection (1–2 cm) should be asked for (Paul et al. 1948). Decortication of the atria and the orifices of the caval veins is only indicated if

hemodynamically relevant stenoses are present. It may be necessary to weigh the operative risk against the expected result.

After removal of the pericardial shell which acted like a corset, the heart tends to dilate and ventricular function may deteriorate. Therefore, it is helpful to treat the patients after surgery with digitalis and catecholamines (e.g., epinephrine) even prophylactically.

31.2.4 Pericardial Cysts and Tumors

Pericardial tumors are extremely rare. The benign tumors most commonly are cysts, filled with serous fluid and originating from the diaphragmatic site of the pericardium. Their wall is thin and endothelialized. Acquired cysts are a consequence of pericardial inflammation and contain a murky fluid and a thickened wall. The differential diagnosis of cysts includes diverticula which can also be inborn or acquired and are not easy to distinguish. Further benign pericardial tumors are teratomas, angiomas, lipomas, and fibromas. These tumors are usually discovered by chance as they rarely cause symptoms. Only occasionally, their growth may cause dyspnea, difficulties in swallowing, or arrhythmias.

Once diagnosis is established, the indication for surgery is widely accepted. The removal of benign pericardial tumors is technically simple. The surgical access is dependent on the tumor localization which is verified by computed tomography or magnetic resonance imaging. A small pericardial defect after cyst or tumor resection is harmless. Care has to be given when larger defects, especially on the left side, may allow for luxation of the heart (when the patient's position changes). In such a situation, it is recommended to close the pericardial defect with an artificial membrane (e.g., PTFE) or with a surgical (resorbable) mesh.

Malignant tumors originating from the pericardium are very uncommon. The histological analysis differentiates between sarcomas, primary carcinomas, and endotheliomas. More often a malignant neighboring tumor like a bronchial

carcinoma infiltrates the adjacent pericardium. Sometimes, metastases of a distant tumor settle in the pericardium. A curative resection is hardly possible. Frequently, only a tumor reduction is achievable, which though should be as extensive as possible to prevent a later constriction of the heart by a tumor relapse.

32.1 Introduction

The first successful repair of a penetrating cardiac injury was performed on a beating heart by Ludwig Rehn in 1896 (Rehn 1897) ► Chapter «The History of Cardiac Surgery», Sect. 1.1. Since then, relatively little has changed in regard to the technique in the treatment of such injuries, although there have been significant advances in the instruments used, such as heart-lung machines for extracorporeal circulation (ECC) to unload the heart, modern suture material with atraumatic needles and materials such as xenopericardium, prosthetic patches and biological glues.

The blunt cardiac injury has to be distinguished from penetrating trauma caused by stab or gunshot wounds. In addition, the development of endovascular and endocardiac techniques has led to an increase in iatrogenic injuries to structures such as the atrium, myocardium, valves or coronary arteries as a result of interventional or diagnostic catheter procedures, positioning or removing pacemakers or defibrillator probes and after myocardial biopsy. The most common accompanying symptom of a penetrating cardiac injury is pericardial tamponade caused by hemopericardium, which also occurs relatively frequently following blunt cardiac injuries. However, hemopericardium may not be seen in patients with prior cardiac surgery or after pericarditis, because of adhesions between the pericardium and the epicardial surface of the heart. In these cases, the degree of the injury may be hidden or a hemothorax may appear as a symptom.

32.2 Penetrating Cardiac Injury

A penetrating cardiac injury normally presents in association with mediastinal penetrating trauma. Due to the mechanism of the trauma (stab, knife and gunshot), the direction of penetration is more frequently anterior-posterior less often lateral and most rarely posterior-anterior or caudocranial, resulting in various concomitant injuries to organs in the anterior, middle and posterior mediastinum as well as the lungs or abdominal organs. The causes of penetrating mediastinal injuries are mainly gunshot wounds and stab wounds; less common causes are impalements and other traumatic injuries.

Three significant *risk factors for early mortality in penetrating cardiac injury* are (American College of Surgeons Subcommittee on Trauma 2004; Demetriades et al. 2004):

- Extensive thoracic injury
- Severe concomitant neurological injury
- Systolic blood pressure of <90 mmHg at admission

If the systolic blood pressure is over 100 mmHg with no obvious bleeding, a comprehensive diagnostic investigation can be carried out (Burack et al. 2007; Renz et al. 2000). The patient's clinical status dictates the most appropriate diagnostic and/or therapeutic course of action. Circulatory instability requires immediate surgical exploration, while stable circulation should prompt further investigation with exact localisation of any bleeding followed by a more focused therapy. After localization, the bleeding site can either be treated surgically or possibly via percutaneous intervention using coil embolization or, for instance, by implantation of an endovascular covered coronary stent graft if injury to a single coronary artery is the only site that requires intervention (Romaguera and Waksman 2011).

32.2.1 Pathophysiology

A penetrating injury in the mid-thoracic area, which extends into the pericardium, usually also damages the heart and/or the adjacent large vessels. These patients should therefore be immediately admitted into a hospital with an experienced cardiac surgery team.

The prognosis for a stab wound is more favorable than that for a gunshot wound because the latter causes more internal tissue trauma, heavier bleeding, and tends to lead more rapidly to death. Projectiles that enter the chest and further the pericardium usually pass completely through the heart and/or chest, although they can also graze the heart or become lodged. This depends on several factors relating to the projectile, e.g. size, material shape and velocity. In

patients in whom a projectile pierces the mediastinum and injures a thoracic vessel, approximately 50% suffer hemodynamic instability. This results in a rather high operative mortality rate of 20–40% (Burack et al. 2007; Degiannis et al. 2000; Renz et al. 2000; Richardson et al. 1981). For penetrating cardiac injuries, a survival rate of >40–50% is considered excellent and is only possible with immediate surgical treatment (Asensio et al. 1998).

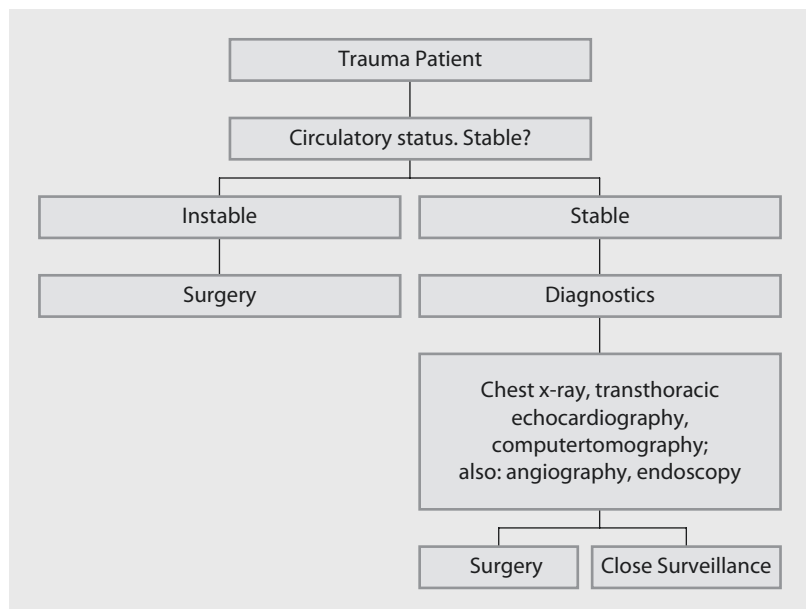

32.2.2 Clinical Presentation

Due to severe loss of blood, patients with penetrating cardiac injury usually present *hypovolemic shock*. Tachycardia with collapsed jugular veins is the most frequent clinical sign. Superior vena cava syndrome with a distended jugular vein indicates pericardial tamponade. With stab wounds, the superficial wound is not always recognizable on initial inspection and does not always provide information regarding the extent of the internal injury; this is particularly the case for penetrating injuries. Damage to the myocardium, as well as lesions of the coronary arteries, may be present. ECG changes, supraventricular or ventricular arrhythmia and chronic arteriovenous fistulas are possible in these cases. Heart valves may also be injured.

32.2.3 Treatment

The initial management of penetrating cardiac injuries in an ideal case would begin at the site of the accident and depends on the patient's circulatory status. However it rather begins later, most often in an emergency room (Nagy et al. 2002). The most important immediate goal is to stabilize the cardiopulmonary system by endotracheal intubation, pressure-regulated infusion of warm crystalloid solution and blood products as well as insertion of a chest tube in the case of a hemothorax or pneumothorax. The circulatory state can be determined by hemodynamic parameters such as heart rate, blood pressure and transcutaneous pulse oximetry (Lu et al. 2006). Objects lodged in the chest are initially left in situ and should be removed only when surgical control of the injury in an operating room environment is possible. The vital parameters will be further stabilized in the emergency center, if this had not been the case in the first place of treatment, anyway. Stable patients receive a chest X-ray and transthoracic echocardiography. A CT scan to determine intrathoracic and intra-abdominal organ damage is reserved for patients with a stable circulation. Inconclusive results can be followed up with further examination, e.g. endoscopy (Burack et al. 2007; ■ Fig. 32.1). In case of pericardial effusion, subxiphoid drainage

■ Fig. 32.1 Algorithm for treatment of a patient with penetrating mediastinal trauma

is performed. Any posttraumatic hemopericardium represents an indication for surgery. Unstable patients are treated in the emergency room by left anterolateral thoracotomy. Stable patients are treated, when necessary, in the operating room by median sternotomy or left thoracotomy, depending on the site of injury (Asensio et al. 1998). A stab wound to the right side of the sternum is rather approached via a sternotomy; a stab wound to the left chest via a left anterior thoracotomy (Kaljusto and Tønnessen 2012; Sanchez et al. 2010; Mitchell et al. 1993).

32.3 Stab Wounds and Gunshot Wounds

Patients who are admitted to hospital with a stab wound to the heart but do not require resuscitation have a relatively good chance of surviving the injury if they receive adequate treatment. This is in contrast to patients who require resuscitation or have borderline hemodynamics, as is often the case with gunshot wounds. In a hospital with a cardiac surgery unit, a median sternotomy is the preferred option to approach the chest, because this approach usually allows maximal control of the major cardiac injuries and facilitates the use of extracorporeal circulation if needed. However, ECC use is also possible through femoro-femoral cannulation if thoracotomy has been chosen as the surgical approach. However, cardiac injuries originating parasternally from the right should only be treated via median sternotomy. If possible, foreign objects should only be removed after opening of the pericardium and the placement of sutures to control bleeding. Bleeding wounds at the atrium, the aorta or the vena cava are best controlled with partial clamping when possible; a localized ventricular myocardial injury is best controlled digitally. After the source of bleeding has been verified, sutures can be placed.

Atrial perforations are closed with polypropylene 4/0 or 5/0. For larger injuries, an autologous or xenopericardial patch may be used. Large sutures in the ventricle are best reinforced with Teflon felt or xenopericardium to prevent further tearing of the tissue. Biological glues can provide additional strengthening of the closure (Jones et al. 2012). When the heart is severely injured

and has to be treated with a patch, the injured ventricle generally requires unloading with the help of the extracorporeal circulation. If there is no cardiopulmonary bypass circuit available, a short period (preferably less than 3–5 min) of bicaval inflow occlusion (clamping of the superior vena cava and the inferior vena cava) may be performed following hyperventilation and maximal oxygen delivery. The ventricles will be empty after a few heartbeats and the aorta can also be clamped. The cardiac injury can be treated in the remaining 2–3 min, after which the circulation can be re-established (if necessary with manual cardiac massage to start).

With less extensive injuries, the heart can be temporarily and repeatedly stopped using intravenous administration of adenosine in order to suture the myocardium (Kokotsakis et al. 2007). Stabilizers used in «off-pump» bypass surgery can help local immobilization of the heart. In addition to the pericardium, both pleural cavities should be opened via median sternotomy in order to eliminate or treat further sources of bleeding from intercostal or mammary arteries, as well as hilar vessels and lung parenchyma. In cases in which there is a transdiaphragmatic stab wound directed towards the heart, the upper abdomen (stomach, liver) also must be evaluated.

A significant rate of postdischarge complications is associated with penetrating cardiac injuries. In a retrospective trauma registry review from a level I trauma center, (Tang et al. 2011) reviewed 406 patients who sustained a penetrating cardiac injury during a 10-year period. Besides observations on the in-hospital stay, outpatient follow-up, echocardiogram results and outcomes were analyzed. One hundred nine (26.9%) survived to hospital discharge. A significant rate of cardiac complications was observed, and follow-up echocardiographic evaluation was found to be necessary prior to discharge.

Cardiac chambers involved were the right ventricle (45.9%), left ventricle (40.3%), right atrium (10.1%), left atrium (0.9%) and combined (2.8%). Abnormal echocardiograms demonstrated pericardial effusion, abnormal wall motion, decreased ejection fraction (<45%), intramural thrombus and valve injury as the most frequently observed complications following penetrating cardiac trauma. Following discharge, the 1-year and 9-year survival rates were 97% and 88%, respectively.

32.4 Blunt Cardiac Trauma

Blunt cardiac trauma and blunt trauma to the large vessels frequently occur in association with multiple injuries, mainly in road traffic accidents (deceleration trauma), but also in falls, explosions, combat actions or dangerous sports. The steering wheel injury was once the most common cause, but this has been significantly reduced with the advent of seat belts and airbags.

The presentation of blunt, posttraumatic cardiac injuries ranges from a total lack of symptoms to impaired myocardial function, although this rarely leads to symptoms of cardiogenic shock. Blunt trauma can result in the following damages to the heart:

- Myocardial contusion
- Injury to the pericardium, the atrial free wall, the endocardium, the interventricular septum, the valves and the coronary arteries

Cardiac trauma may be present without any visible external chest injury. Electrocardiogram is commonly normal. Fractures to the sternum, ribs (in particular parasternal fractures) and mediastinal enlargement as well as an atypical mediastinal shape are always suspicious. The most important diagnostic feature is a widened mediastinum, which can be observed on an anterior-posterior chest X-ray. Immediate surgery with the use of cardiopulmonary bypass is only appropriate in patients with significant injuries rehomolog valve repair or replacement or reconstruction of another initial structure. The decision to operate under full heparinization (as required for cardiopulmonary bypass) must be weighed against the risks of a life-threatening hemorrhage in other organ systems (e.g. brain), especially in cases of associated cranial and pelvic fractures or other sites of frank bleeding. The management also involves continuous ECG monitoring (arrhythmias, signs of myocardial infarction) and echocardiography. If allowed by the hemodynamic status, coronary angiography as well as radiological MRI may be indicated in the presence of elevated serum parameters for significant myocardial ischemia.

While commotio cordis simply describes a functional disorder of the heart, cardiac contusion involves a pathological change to the myocardium caused by trauma and can range from small, localized endo-, intra- or epicardial bleeding to transmural necrosis (Berg et al. 2012). A cardiac contusion is not always immediately symptomatic,

sometimes only becoming so after hours or days, potentially leading to heart failure (Asensio et al. 1998). In this case, other injuries such as traumatic ventricular septal defect or traumatic valvular defect must be excluded first. Delayed or long-term effects may include pericardial tamponade, rupture of the injured endocardium and formation of a ventricular aneurysm in the contusion area, which are treated either surgically, endovascularly or using hybrid procedure (Kadner et al. 2007).

The treatment of myocardial contusion is generally conservative. Antiarrhythmic medication and, if necessary, catecholamines are initiated; if cardiac instability persists, invasive monitoring including a Swan-Ganz catheter is advisable. In cases of severe ventricular dysfunction, an intra-aortic balloon pump or other cardiac support systems like peripheral ECMO may be used until the heart shows signs of recovery. Pericardial effusion, as long as not hemorrhagic in origin, is treated with drainage or occasionally by repeated puncture.

32.5 Heart Valve Injury

The appropriate surgical method for managing an injury to a heart valve is selected based on the character of the heart valve injury, e.g. direct sutures for small tears, refixation for partial avulsion or other reconstructive procedures. Large valve defects occasionally necessitate valve replacement (Hashmi et al. 2010). AV valve ruptures caused by tearing of the valve leaflets or by rupture of the chordae or papillary muscles occasionally occur, in particular following accidents leading to rudder new are increase in the chest. Regarding AV valves, the more ventrally positioned tricuspid valve is more often affected than the mitral valve (Thekkudan et al. 2012); however, tricuspid valve insufficiency usually becomes symptomatic only in a chronic state. Acute mitral valve insufficiency can be followed by pulmonary hypertension with concomitant acute pulmonary edema. The insufficient mitral valve must usually be operated on immediately. Rupture of the aortic valve occurs less frequently than of the AV valves. If the patient survives the acute trauma, a new murmur and signs of decompensation may later appear. Depending on the severity of the injury, this can occur immediately, but may also appear later. Posttraumatic heart failure carved by a valve injury that cannot be controlled conservatively must be treated surgically in a timely fashion.

32.6 Coronary Artery Injury

Coronary artery injury is characterized by a high mortality rate (Asensio et al. 1998). In general, coronary artery injury leads to pericardial tamponade. Assuming it can be promptly recognized by a thoracotomy, the acute treatment of small vessel lesions is best performed by ligation of the appropriate segment. Larger vessels (>1.5 mm) should be bypassed (aortocoronary venous bypass or left internal thoracic artery bypass (see also ► Chapter «Coronary Artery Disease», Sect. 22.4.1). Arteriovenous coronary fistulas and arterial fistulas to the heart cavities are rare complications and have to be closed surgically exceptionally by transcatheter method, if the shunt volume is large. Occasionally, catheter-guided interventional treatment using coils or other occlusion devices may be necessary. The most frequent cause of coronary artery injury is catheter intervention. More recently, coronary injuries have been described following interventional antiarrhythmic ablation procedures (Wong et al. 2011).

32.7 Pericardial Injury

The most common cardiac injury involves the pericardium. If this results in persistent bleeding from the pericardium, hemopericardium or hemothorax may develop. Small bleeding varices are not acutely life-threatening and may sometimes only be recognized by a pericardial friction murmur. Even small amounts of pericardial fluid (100–200 ml) can cause typical signs and symptoms of a tamponade with jugular venous distension with or without a drop of the arterial pressure.

Early signs of cardiogenic shock in combination with a decline of the diuresis, an enlarged cardiac silhouette in the chest X-ray or a direct sign of a pericardial effusion in echocardiography or CT scan require immediate pericardial puncture or subxiphoid drainage (Adams et al. 2012).

Pericardial puncture may be performed under echocardiographic control to prevent additional injury to the heart. Using the Seldinger method, a

pigtail catheter should be inserted above the puncture needle in order to provide further drainage. Should the bleeding be severe or persistent, a large subxiphoid chest tube must be inserted (Thorson et al. 2012). A complete tear of the pericardium with cardiac herniation into the pleural space with circulatory collapse due to kinking of the heart is extremely rare.

32.8 Myocardial Injury

Injury to the myocardium after blunt and penetrating trauma usually involves the right atrium, although other locations are possible. A complete rupture is usually first identified at necropsy. If the patient does reach the clinic, a suspected myocardial rupture should be immediately treated in the operating theater (Kumar et al. 2012). Myocardial rupture can appear immediately or after an asymptomatic interval of several days and without clinical warnings.

32.9 Traumatic Ventricular Septal Defect

A traumatic ventricular septal defect usually appears shortly after the accident and can be suspected by evidence of a murmur and the clinical situation and verified by echocardiography. A small ventricular septal defect with no hemodynamic impairment can initially be treated conservatively. Immediate surgical intervention is only required for large ventricular septal defects with acute pulmonary hypertension (Sugiyama et al. 2011; Ryan et al. 2012). As with muscular defects, they are closed using conventional suture technique with patches. In case of thermodynamic stability, prosthetic or xenopericardial traumatic defects are ideally closed after 4–12 weeks once the borders have become fibrotic (Schaffer et al. 1999). In certain situations, an interventional percutaneous defect closure may be considered.

32.10 Iatrogenic Cardiac Injury

In theory, an iatrogenic cardiac injury can happen during any diagnostic or therapeutic catheter insertion. A serious, but rare, complication of percutaneous coronary angiography and therapy is coronary artery perforation, which can either be

treated conservatively (after insertion of pericardial drainage in case of pericardial tamponade), directly with catheter techniques, or surgically by coronary bypass (Romaguera et al. 2011). A special form is the development of subepicardial tamponade after coronary laceration and after electrophysiology ablation treatment (Verna et al. 1992; Nagamine et al. 2011; Wong et al. 2011). Furthermore, cardiac perforations can be caused during placement or removal of pacemakers, insertion of thoracic or pericardial drainage or insertion of central venous catheters through the superior vena cava, the latter occurring more commonly in newborns and children than in adults.

More recently, new injuries have been observed during transcatheter (retrograde transfemoral or antegrade transapical) aortic valve implantation, such as rupture of the aortic anulus during balloon valvuloplasty or deployment of the stented valve, aortic dissection or rupture due to excessive manipulation with catheter and the introducing devices (Ong et al. 2011; Gerber et al. 2012; Hayashida et al. 2013; Pasic et al. 2012; Lee et al. 2014; Aminian et al. 2011) and after use of left ventricular assist devices crossing the aortic valve (Chandola et al. 2012).

33.1 Introduction

Most procedures in cardiac surgery, namely, coronary artery and aortic valve surgery, are caused by sequelae of atherosclerosis. Being a systemic disease, atherosclerosis frequently is present in other branches of the vascular tree at the time of cardiac surgery. Thus the question may arise regarding synchronous or staged treatment of atherosclerotic disease in different parts of the vascular tree.

A well-known scenario is coronary artery disease with concomitant carotid stenosis. Apart from atherosclerosis of the ascending aorta, carotid stenosis is one of the most significant risk factors for perioperative stroke in cardiac surgery. In Germany, there are 4000–6000 patients per year who present with coronary artery disease and concomitant carotid disease. In the USA, this figure has exceeded 20,000 patients per year. While there is agreement in symptomatic carotid stenosis about the indication for carotid endarterectomy before or during coronary artery bypass grafting (CABG) surgery, there is controversy about what to do with significant, but asymptomatic, carotid stenosis at the time of CABG. The literature does not provide clear recommendations for such cases. Therefore, this situation always presents an individual challenge when planning CABG. In simultaneous procedures combining CABG with carotid endarterectomy (CEA), the primary objective is to prevent the increased risk of perioperative stroke arising from carotid stenosis and less so the long-term risk of stroke. Presently there is no high-level evidence favoring routine combined surgery (either synchronous or staged). Neither is there any evidence backing the «conservative» approach of isolated CABG while leaving the severe carotid stenosis untouched. This open issue can only be settled by a randomized controlled trial. Since statistics demand a large number of patients and therefore a large number of trial sites as well, for a long time, such a trial was regarded as not feasible. When a multicenter coronary artery bypass graft surgery in patients with asymptomatic carotid stenosis (CABACS) trial was starting to enroll patients from December 2010 to December 2014, there was hope to receive answers to this important question (Knipp et al. 2012). Unfortunately, the trial was stopped early by the funder because of slow recruitment (Weimar et al. 2016).

Other combined cardiac and vascular procedures are rather rare. There are a notable number of publications on combined cardiac surgery and abdominal aortic aneurysm repair. In particular, the option of off-pump heart surgery has instigated numerous new publications on this subject. Heart surgery combined with procedures of the peripheral vascular tree has elicited less interest. In the past, such combined surgery has always been in small numbers, and with the advent of interventional vascular procedures, these numbers will decrease even further.

Although smoking is among the major risk factors for both atherosclerosis and lung cancer, concomitant lesions of the heart and lung are uncommon, but when present they pose a therapeutic challenge (Rao et al. 1996). In fact, such cancers are usually seen as incidental findings in the course of preoperative diagnostic workup for CABG. Combined synchronous cardiac surgery and lung resection may facilitate the treatment of two major problems with one intervention, improving outcome and providing economic benefit. However, the use of cardiopulmonary bypass (CPB) may adversely affect the natural history of pulmonary malignancies, while off-pump surgery eliminates organ dysfunction and suppression of immune system related to extracorporeal circulation. In the few retrospective case series of combined coronary bypass surgery and lung resection available in the literature, each comprising no more than 30 cases, the procedures can be performed without increased early or late mortality and/or morbidity (Rao et al. 1996; Danton et al. 1998; Dyszkiewicz et al. 2004, 2008). Long-term results are primarily determined by histological diagnosis and tumor stage. Thus, in selected patients, the combined procedure may be an alternative to the two-stage approach.

33.2 CABG and Carotid Endarterectomy

Stroke and its sequelae are the third most common cause of death in industrial nations. In addition, stroke-induced impairments not only represent a major psychosocial problem by reducing quality of life significantly but also represent an economic problem. There is speculation that stenosis of the extracranial internal carotid artery

accounts for up to 20% of all strokes (Lloyd-Jones et al. 2009). The prevalence of carotid stenosis is difficult to estimate since asymptomatic stenoses are usually found incidentally, and broad-based screening investigations do not exist. Carotid duplex scanning demonstrated carotid stenosis >50% in about 2–8% of adults (Moussa et al. 2007). The prevalence is clearly dependent on age with carotid stenosis >50% found in 6–8% of patients aged 65 years and up to 15% of patients above 70 years (Hillen et al. 2000). Stroke during cardiac surgery is far more common than in any other type of surgery. The overall incidence of this complication after CABG is about 2%, but rises to almost 9% in patients aged 75 years and older (Tarakji et al. 2011). In patients undergoing valve procedures or those with concomitant cerebrovascular disease, this rate increases to almost 16% (Ricotta et al. 1995; Roach et al. 1996). Since more and more elderly patients, often suffering from concomitant disorders predisposing to stroke, undergo cardiac surgery, it has to be assumed that the impact of stroke on patient outcome will continue to be significant. Numerous studies have identified a number of factors which may increase the risk of stroke during cardiac surgery and which also may be useful in risk assessment. Apart from ascending aorta and aortic arch atherosclerosis and previous cerebrovascular events, carotid stenosis is regarded as the strongest predictor of stroke (Hogue et al. 1999; Tarakji et al. 2011). Diagnosis of carotid artery atherosclerosis is important in order to detect increased cardiovascular risk and to prevent stroke by appropriate surgery or endovascular intervention.

Michael E. DeBakey established carotid endarterectomy as the standard procedure for carotid stenosis (DeBakey et al. 1965). It was Victor Bernhard in 1972 who opened the discussion whether carotid surgery may help lower the risk of stroke during CABG by successfully performing synchronous combined procedures on the heart and carotid artery (Bernhard et al. 1972). Since then, hundreds of papers have been published with evidence in favor of or against prophylactic intervention on the carotid artery, but no consensus has been reached as yet. In order to lower the increased rate of perioperative and long-term stroke, some heart and vascular surgeons favor combined CABG and CEA. The publications on combined surgery for coronary artery

disease and carotid stenosis are primarily retrospective single-center reports (Das et al. 2000; Naylor 2009). While some centers perform this type of surgery with good success, the overall combined complication rate in the literature of 10–12% for stroke, myocardial infarction, and/or death is relatively high (Naylor 2009). On the other hand, the evidence for isolated CABG, the least invasive and most cost-effective strategy, is limited to a small series of patients from individual centers only (Ghosh et al. 2005; Schoof et al. 2007; Mahmoudi et al. 2011). These series report different endpoints, and they have no control groups. In the absence of prospective randomized controlled trials, there is no evidence that combined CABG and CEA (synchronous or staged CEA-CABG or reverse staged CABG-CEA) in asymptomatic carotid stenosis and symptomatic coronary artery disease provide any benefit compared with isolated CABG. Conversely, it remains to be seen if the risk observed for synchronous surgery is justified in asymptomatic patients with severe carotid stenosis. The CABACS trial is the first prospective randomized controlled trial worldwide comparing the safety and efficacy of synchronous CABG with and without CEA (Knipp et al. 2012). Since December 2010, both strategies are being compared at more than 30 trial sites in 2 countries; perioperative morbidity and mortality (cumulative rate of stroke or death within 30 days after randomization) are the primary endpoint, and the follow-up for each patient is 5 years. It is expected that the trial will provide the basis for defining an evidence-based standard. In addition, this will also make it possible to develop and assess improvements in surgical technique and strategy, therefore having a significant impact on the treatment of this disease entity. As long as the results of this trial are not available, it is impossible to define clear-cut recommendations, and it becomes necessary for each heart surgery center to take into account its expertise and competence when developing individual concepts and solutions for each case. Due to the quality assurance modules for CABG as well as CEA, which are mandatory in many health-care systems, it is possible to compare the results of one's own institution with those in publications, thereby implementing a continuous improvement process and approaching optimal results.

33.2.1 Prevalence of Coronary Artery Disease and Carotid Stenosis

The synchronicity of carotid stenosis and coronary artery disease is well known. The data on the prevalence of >50% stenosis of the extracranial internal carotid artery in patients scheduled for CABG vary quite widely and range from 3 to 22% (Naylor et al. 2003a; Ricotta and Wall 2003; van der Heyden et al. 2007). On the other hand, surgically relevant coronary artery disease was also seen in up to 28% of the patients scheduled for CEA.

In 1997 and 1998, the New York State Cardiac Surgery Reporting System recorded 0.48% synchronous operations (Ricotta et al. 2005). A similar percentage of 0.51% in 132,762 CABG procedures was seen in Canada over a 10-year period (Hill et al. 2005). A review comparing several states in the USA cited an increase in combined CABG and CEA ranging from 1.1% in 1993 to 1.58% in 2002 (Dubinsky and Lai 2007). An analysis of Medicare patients in the USA yielded a rate of 2.1% (Brown et al. 2003).

The varying rate of synchronous operations may be due to the fact that many surgeons will only perform synchronous procedures if there is symptomatic carotid stenosis. The publication in 1995 of the trials on surgery of asymptomatic carotid stenosis probably sparked the fleeting enthusiasm for synchronous procedures (Executive Committee for the Asymptomatic Carotid Atherosclerosis Study 1995). On the other hand, the advent of carotid stenting by interventionists in angiology, radiology, and cardiology and their reluctance toward synchronous surgery promoted a tendency in the other direction (Byrne et al. 2006). Furthermore, there is no consensus on routine carotid screening before heart surgery. Diagnostic carotid duplex screening should be carried out in patients aged 65 years and older, with peripheral arterial occlusive disease, stenosis of the left main coronary artery, previous cerebrovascular events, hypertension, and in smokers. These patient populations are characterized by an up to 30% higher rate of high-grade carotid stenosis and warrant particular care possibly involv-

ing additional treatment of the carotid stenosis (Ascher et al. 2001; Durand et al. 2004; Sheiman and d'Othee 2007).

33.2.2 Stroke in CABG

Stroke is defined as an acute focal or global neurological deficit. The diagnostic criteria also comprise: (a) the deficit lasts for more than 24 h, or neuroimaging demonstrates acute bleeding or ischemia; (b) there are no other directly identifiable non-stroke causes for the symptoms (e.g., brain tumor, infection, trauma, hypoglycemia, pharmacological effects); (c) the diagnosis is confirmed by a neurologist or by neuroimaging (Daneault et al. 2011). The subsequent degree of disability resulting from the stroke may be classified further according to the Rankin Scale (■ Table 33.1), where a Rankin score ≥ 3 must be regarded as disabling stroke (Rankin 1957; Barnett et al. 1998).

Published retrospective analyses list a median rate of 1.4% for cerebrovascular incidents in CABG, while prospective studies yield a rate of 2.0% (Naylor et al. 2003b; Tarakji et al. 2011). In 23% of the cases, stroke is the immediate cause of death. Between 33 and 45% of strokes manifest within the first 24 h after surgery. However, the majority of neurological deficits become evident 1–7 days after surgery (McKhann et al. 2006).

■ Table 33.1 Modified Rankin scale

0—No symptoms at all
1—No significant disability despite symptoms. Able to carry out all usual duties and activities
2—Slight disability: unable to carry out all previous activities but able to look after own affairs without assistance
3—Moderate disability: requiring some help, but able to walk without assistance
4—Moderately severe disability: unable to walk without assistance and unable to attend to own bodily needs without assistance
5—Severe disability: bedridden, incontinent, and requiring constant nursing care and attention

From: van Swieten et al. (1988); used with permission

The incidence of stroke very much depends on patient age. In those patients aged 50 years and younger, it is <0.5% and increases to 8% or 9% in patients aged 80 years and older. The following risk factors predispose to postoperative stroke: advanced age, previous cerebrovascular accident, atherosclerosis of the ascending aorta, high-grade carotid stenosis, peripheral arterial occlusive disease, hypertension, prolonged on-pump period, and atrial fibrillation (Tarakji et al. 2011). The rate of cerebrovascular accidents increases with the severity of the carotid obstruction. While a stenosis of <50% correlates with a 1.9% stroke rate (Tarakji et al. 2011), this rate increases to 6.7% for 50–99% stenosis and to 11.7% for unilateral carotid occlusion. Significant bilateral lesions increase the risk even further. Patients with bilateral occlusion of the internal carotid arteries are at the highest risk (Naylor and Bell 2002).

Half of the patients with stroke do not have any obstruction of the extracranial carotid arteries. According to radiological pattern criteria in cerebral infarction, embolism is the underlying cause in 62% of these cases. Watershed stroke, probably due to obstruction of the carotid artery, is only seen in 9% of cases (Likosky et al. 2003). Atherosclerosis of the aorta probably is the most common cause of embolization. It is seen in half of the patients with carotid stenosis and coronary artery disease. Presumably the microemboli spilling forth from broken carotid plaques are more important than the hemodynamics of the carotid stenosis. The delayed manifestation of stroke may also be caused by embolism due to fresh postoperative atrial fibrillation, discontinuation of anticoagulants, and the surgical trauma induced by activation of the hemostasis system with subsequent hypercoagulability (Selim 2007).

33.2.3 The Role of CEA in Stroke Prevention

In the late 1980s and early 1990s, several large-scale prospective randomized trials were able to demonstrate the benefits of CEA in symptomatic as well as asymptomatic isolated carotid stenosis. In 1987, the North American Symptomatic Carotid Endarterectomy Trial (NASCET) studied the benefits of carotid surgery in a total of 2226 patients with >50% carotid stenosis (North American Symptomatic Carotid Endarterectomy

Trial Collaborators 1991). Two years after the start of the trial, CEA in the subgroup of patients with >70% high-grade symptomatic stenosis (stroke without severe disability [Rankin score <3], amaurosis fugax, transient ischemic attack [TIA]) resulted in a statistically highly significant absolute risk reduction of 17% (9% post-CEA stroke rate versus 26% in the control arm). The number of patients needed to treat (NNT = 1/absolute risk reduction [ARR]) over a period of 2 years in order to prevent one stroke was 5.9. Apart from the NASCET trial, the European Carotid Surgery Trial (ECST) also studied the effect of carotid endarterectomy on secondary prevention in patients with symptomatic stenosis (European Carotid Surgery Trialists' Collaborative Group 1998). In patients with >80% stenosis, the initially higher risk of surgery was more than compensated 3 years after surgery, since the surgery arm of the trial showed a significantly lower rate of stroke (14.9% vs. 26.5%; $p < 0.001$). The recommendation for CEA in patients with symptomatic carotid stenosis and a perioperative mortality and risk of stroke of <6% was based on the results of these two trials. The earlier the patients underwent surgery after the onset of symptoms, the more marked the reduction in the risk of stroke (NASCET 1991; European Carotid Surgery Trialists' Collaborative Group 1998). With the advent of carotid intervention by carotid artery angioplasty and stenting (CAS), a number of trials comparing CEA with CAS in symptomatic carotid stenosis have been conducted. In the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST), there was a greater incidence of stroke in the CAS arm, but this was offset by a greater occurrence of myocardial infarction in the CEA arm (Brott et al. 2010; Hill et al. 2012;). Likewise, in the International Carotid Stenting Study (ICSS) a higher occurrence of minor stroke in the CAS arm was balanced by a higher occurrence of cranial nerve palsy in the CEA arm (ICSS Investigators 2010).

Apart from demonstrating the benefits of CEA with its effect of secondary prevention, a number of trials have also studied the benefits of surgery in those patients with severe carotid stenosis who had been asymptomatic until the time of surgery. In the Asymptomatic Carotid Atherosclerosis Study (ACAS) from 1987 to 1993, 1662 patients with >60% stenosis were randomized in the CEA plus

■ **Fig. 33.1** Kaplan-Meier curves for stroke-free survival in the Asymptomatic Carotid Surgery Trial (ACST). In this trial, CEA resulted in a 5.35% ARR over 5 years. As you can see from the curves, the stroke rate in the conservative group remained constant over time (s. ACST Halliday et al. 2004)

acetylsalicylic acid arm or the acetylsalicylic acid monotherapy arm (controls) (Executive Committee for the Asymptomatic Carotid Atherosclerosis Study 1995). Despite a perioperative complication rate of 2.3%, the rate of ipsilateral stroke after 5 years was significantly lower in the surgery group compared with the controls (5.1% vs. 11%; relative risk reduction 54%; NNT 16.9; $p < 0.004$) (Rothwell 2004). Between 1993 and 2003, a total of 3120 patients with $>60\%$ stenosis from 30 countries were randomized in 126 trial sites as part of the subsequent large-scale European Asymptomatic Carotid Surgery Trial (ACST) (Halliday et al. 2004). After the expected increased initial risk, the Kaplan-Meier graphs of both groups already intersected 2 years after randomization, and 5 years later, the rate of stroke was significantly lower for the surgery arm (6.4% vs. 11.8%; $p < 0.0001$) (■ Fig. 33.1). While meta-analysis of both trials shows a benefit with CEA, this benefit is far less pronounced than in symptomatic patients. Even 10 years after randomization, the benefits of successful carotid surgery still persist with a combined risk of stroke and death (perioperative and over the course) of 13.4% ver-

sus 17.9% (ARR 4.6%) (Halliday et al. 2010) (■ Figs. 33.2 and 33.3).

The benefits of surgery for isolated carotid disease still strongly depend on the severity of the carotid stenosis. Most often it is expressed as percentage reduction of the lumen. Although the results obtained very much depend on the actual method of measurement, quite often, the latter is not stated. The angiographic measurements of the US trials (NASCET) do not coincide with those of the European studies (ECST), and only rarely are these measurements checked against duplex scans and calculations, which are increasingly becoming a routine modality. In the case of 70% stenosis determined by the NASCET method, it has to be realized that this really corresponds to an extremely severe case of stenosis with as much as 95% reduction in lumen.

33.2.4 Surgical and Interventional Options

For patients requiring coronary surgery who also present with significant carotid atherosclerosis, various combinations regarding sequence of

■ **Fig. 33.2** The prospective randomized US and European trials on carotid surgery (North American Symptomatic Carotid Endarterectomy Trial [NASCET] and European Carotid Surgery Trial [ECST]) rely on different reference values for determining the degree of stenosis. The NASCET trial established a relationship between the stenosis and the diameter of the internal carotid artery downstream of the stenosis where the vessel runs in parallel again, whereas the ECST trial refers the diameter of the stenosis to a virtual diameter of the vessel not revealed by contrast medium at the level of the stenosis. Graphical representation of the conversion of various methods for determining the degree of stenosis (reduction in lumen determined by duplex scanning; values in percent) (NASCET = $(1 - md/C) \times 100\%$ and ECST = $(1 - md)/B \times 100\%$), carotid index: C/A

procedures, type of anesthesia, and type of surgical technique are available. Carotid endarterectomy may either be performed synchronously at the time of CABG, before CABG («staged»), or after CABG («reverse staged»). CABG itself may be on-pump or off-pump. Isolated CABG, leaving the carotid stenosis as it is, may also be a treatment option (Ghosh et al. 2005; Schoof et al. 2007; Mahmoudi et al. 2011). The increasing implementation and

■ **Fig. 33.3** This carotid angiogram illustrates a subjectively perceived high degree of stenosis which, however, corresponds to an actual reduction in lumen of less than 70% and therefore does not warrant surgery

continued development of interventional procedures have created new treatment strategies for hybrid revascularization; for example, the carotid artery is revascularized by angioplasty and stenting (CAS) which is followed by CABG. This can be synchronous, in the same session (hybrid OR), or staged with CABG following CAS a few days or up to 4–5 weeks later (Versaci et al. 2007, 2009). To date, no prospective trials comparing the various methods have been performed.

Systematic reviews of 97 observational studies comprising more than 9000 patients have shown that combined synchronous surgery is favored by far compared to other strategies (Naylor et al. 2003a; Naylor 2009). A combined complication rate of 8.7% for stroke and death was seen in those patients undergoing synchronous surgery; however, this group of patients included in particular those with severely impaired pump function, stenosis of the left main coronary artery, and urgent indication for surgery. The stroke rate varied from commendably low value of <2% in «synchronous

CEA + off-pump CABG» to 2.7% in «staged CEA-CABG,» 4.2% in «staged CAS-CABG,» 4.6% in «synchronous CEA + on-pump CABG,» and 6.3% in «reverse staged CABG-CEA» (Naylor et al. 2003a, 2009). The relative low stroke rate in the «staged CEA +CABG» arm was partially offset by the highest rate of myocardial infarction (6.5%). In «reverse staged surgery,» where CABG was performed first followed by CEA, the rate of myocardial infarction was lowest (0.9%); on the other hand, this group displayed the highest risk of stroke. Somewhat unexpectedly, «staged CAS-CABG» was associated with the highest procedural mortality rate of 5.5%. The cumulative 30-day rate of stroke, myocardial infarction, and death was comparable in all groups at 10–12%, while other analyses showed rates of up to 17.7% (Roffi 2007). A large-scale nationwide hospital database analysis in the USA for the period 1998–2007 compared patients who underwent CEA before or after CABG during the same hospital stay, but not on the same day, with patients who underwent synchronous CEA + CABG. Mortality (4.2% vs. 4.5%) and stroke rate (3.5% vs. 3.9%) in the 6153 patients of the «staged» arm were similar to that in the 16,639 patients of the synchronous arm ($p > 0.7$ for both) (Gopaldas et al. 2011). However, morbidity was slightly higher in the «staged» group (48.4% vs. 42.6%; OR 1.8; 95% confidence interval [CI] 1.5–2.2; $p < 0.001$). These results imply the necessity for prospective comparison trials studying sequential or synchronous combined treatment and also stand-alone conservative treatment without touching the carotid stenosis.

In synchronous surgery, the carotid procedure is usually carried out before CABG. Quite often, it is performed by separate teams of vascular and heart surgeons. In synchronous surgery, sometimes the carotid procedure is performed under regional anesthesia.

Carotid revascularization is performed either as conventional thromboendarterectomy (TEA) with dissection of the intima cylinder and patch graft or as eversion endarterectomy (EEA) with transverse

amputation of the internal carotid artery (ICA) and subsequent anastomosis with the common carotid artery (CCA). The latter technique is particularly useful when the internal carotid artery is elongated. After the oblique skin incision along the anterior margin of the sternocleidomastoid muscle, dissection is carried out first through the subcutaneous tissue, then the platysma, and finally the neurovascular bundle; both the hypoglossal nerve and the vagus nerve must be treated with meticulous respect. A transverse facial vein is transected between ligatures. Once the carotid vessels have been exposed, vessel loops are placed around the arteries, and the vessels are then clamped. The CCA is opened and longitudinal arteriotomy extended beyond the stenosis into the ICA. The stenosing calcified cylinder is separated from the wall with a dissector and extracted under direct vision of its distal end. Care must be taken not to leave any intimal flap. In case of severe contralateral carotid stenosis or if there is no neuromonitoring (e.g., SSEP, NIRS, transcranial duplex scanning), shunting is recommended, and the TEA should be performed as an open procedure. Usually, the arteriotomy is closed with a patch plasty fashioned from autologous saphenous vein, a procedure which lends itself in case of synchronous CABG; patches tailored from xenogenic bovine or Vascu-Guard pericardium or Dacron may also be employed. In case of a large-diameter artery (>8 mm), the arteriotomy may be closed directly. Due to intraoperative heparinization, the wound should only be closed after completion of the CABG and heparin reversal. In order to avoid hyperperfusion while the patient is on-pump, it is desirable to leave the autoregulation of the brain intact. Thus, the theoretical advantages of alpha-stat blood gas management strategy should be employed to avoid hypercapnia which may otherwise affect autoregulation (Schoof et al. 2007; Selim 2007).

33.2.4.1 Isolated CABG or CABG Followed by CEA (Reverse Staged)

The estimated prevalence of significant carotid stenosis (i.e., $\geq 50\%$) in patients undergoing CABG is 6–8%, but the rate of synchronous combined surgery is about 2% in administrative data banks on CABG (Naylor and Bell 2002). This suggests that quite a substantial number of cardiac operations are performed without actively addressing concomitant carotid stenosis. Despite this common practice, there are only few data available

If surgery is performed under general anesthesia without routine intraluminal shunting, cerebral monitoring (e.g., somatosensory evoked potentials [SSEP], near-infrared spectroscopy [NIRS]) is recommended.

examining the correlation between untreated severe asymptomatic carotid stenosis and the rate of stroke during and after cardiac surgery. A single-center case series of 50 patients with >70% carotid stenosis did not demonstrate an increased rate of stroke compared with a patient population without carotid stenosis (Ghosh et al. 2005). In a larger retrospective study of 878 patients with documented preoperative carotid duplex scans who underwent isolated CABG between 2003 and 2009, the group of 117 patients with carotid stenosis >75% did not suffer from an increased rate of in-hospital stroke (3.4% vs. 3.6%) or death (3.4% vs. 4.2%) when compared to patients without (severe) carotid stenosis (Mahmoudi et al. 2011). In contrast, the only prospective observational trial in patients with (symptomatic and asymptomatic) carotid stenosis comparing isolated CABG with combined CABG followed by CEA («reverse staged CABG-CEA») found a higher rate of stroke, but a lower mortality and a lower rate of myocardial infarction (Hertzer et al. 1989).

Irrespective of the impact on the immediate perioperative rate of stroke once the carotid stenosis has been eliminated as part of the combined CABG and CEA procedure, it is also necessary to consider the effect of CEA in the long-term prevention of stroke. While previous trials on asymptomatic carotid stenosis (ACAS, ACST) have demonstrated a slight benefit for primary preventive CEA (Executive Committee for the Asymptomatic Carotid Atherosclerosis Study 1995; Halliday et al. 2004), this is being reexamined by several ongoing trials, the nonsurgical regimen of which has been improved as compared with the past, in particular with regard to consistent administration of cholesterol synthesis inhibitors (i.e., statins), acetylsalicylic acid, and close control of blood pressure (e.g., angiotensin-converting enzyme inhibitors, AT1 receptor blockers) (Transatlantic Asymptomatic Carotid Intervention Trial [TACIT], Stent-Protected Angioplasty vs. Carotid Endarterectomy-2 [SPACE-2] in asymptomatic carotid stenosis, Asymptomatic Carotid Trial [ACT]). The CABACS trial will also contribute to this.

33.2.4.2 Staged CEA Followed by CABG

If CABG is strictly indicated only in highly symptomatic patients or is performed as a preventive measure in patients with a stenotic left main coronary artery and coronary three-vessel disease

with impaired ventricular function, the percentage of patients where staged CEA is indicated should be low. The percentage of patients eligible for this procedure is estimated at less than 10% (Hertzer et al. 1997).

In the overwhelming majority of cases with concomitant carotid artery stenosis and coronary artery disease, it is not justified to risk myocardial infarction by performing isolated CEA.

Once interventional treatment of carotid stenosis became more prevalent, the benefits of dilating and stenting the carotid stenosis before CABG were also studied. So far, experience with this regimen is still limited. Prospective trials with a small number of patients have concluded that changing the surgical sequence in favor of intervening on the carotid artery before cardiac surgery is not justified (Randall et al. 2006; Versaci et al. 2009). Analysis of several trials including 760 patients with carotid angioplasty and stenting before CABG found a combined risk of stroke, myocardial infarction, and death in 9.4% of the cases over a 30-day period after CABG; however, the 5.5% rate of death was higher than in any other treatment series (van der Heyden et al. 2007, 2008). After carotid angioplasty and stenting, it is highly recommended to initiate antiplatelet therapy with acetylsalicylic acid and clopidogrel for 4 weeks, which in turn will delay cardiac surgery due to the increased risk of bleeding. Since a waiting period of 5–7 days is also required after termination of clopidogrel, this mandates a waiting period of at least 5 weeks before cardiac surgery can be performed. Whether this is acceptable must be assessed for each patient individually. In order to avoid such waiting periods, some study groups perform carotid angioplasty and stenting under acetylsalicylic acid and full heparinization 24 h before or on the same day as CABG, whereas clopidogrel is started after heart surgery (Versaci et al. 2007, 2009). Due to the low number of cases and a lack of comparison trials, for the time being, this hybrid revascularization cannot be deemed superior. With the growing interest of cardiologists in interventional carotid procedures and its enthusiastic acceptance by the patients, an unbiased evaluation of this treatment option is warranted.

33.2.4.3 Synchronous CEA plus CABG

In synchronous combined surgery for cardiac and carotid disease, the sequence of events is not uniform; most often, first, CEA is performed, usually under general anesthesia but sometimes under regional anesthesia. Some centers prefer to revascularize the carotid artery once extracorporeal circulation is initiated, still delaying cardiac surgery. With this protocol, the moderate hypothermia on cardiopulmonary bypass may serve as a brain-protecting measure (Minami et al. 2000). One risk, however, is the rather prolonged on-pump period using extracorporeal circulation. A trial comparing both protocols was unable to demonstrate the presumed benefits of CEA performed on bypass (Bonacchi et al. 2002).

Systematic meta-analysis of a large number of single-center observational studies, comprising a total of 7753 patients undergoing synchronous CEA + CABG, demonstrated a 4.6% rate of stroke for the 30-day period following the surgery (Naylor et al. 2003a; Naylor 2009). The cumulative rate of stroke or death was 8.2% (95% CI 7.1–9.3%). Taking also into account the significance of preventing perioperative myocardial infarction, a complication often neglected in the context of preventive CEA, the 30-day risk of death, stroke, or myocardial infarction increased to 11.5% (95% CI 10.1–13.1%). A nationwide US register trial comprising 26,197 patients who underwent surgery between 2000 and 2004, not including the systematic reviews cited above, found an 8.6% risk of stroke or death after synchronous CABG and CEA (Timaran et al. 2008). One alternative to traditional synchronous CEA and on-pump CABG is the combination of CEA and off-pump CABG. Pooled data from trials on synchronous CEA and off-pump CABG in 324 patients showed a relatively low risk of stroke at 1.1% and a 30-day risk of death, stroke, or myocardial infarction of only 3.6% (95% CI 1.6–5.5%) (Beauford et al. 2003; Garcia-Rinaldi and Cruz 2004; Mishra et al. 2004; Fareed et al. 2009). Although this might be due to statistical error (e.g., small series, publication bias, etc.), another important explanation could be the simple fact that off-pump CABG avoids manipulation and cannulation of the aorta as well as extracorporeal circulation. Thus, more detailed research into this protocol is warranted. Therefore, the risk of syn-

chronous surgery seems to be higher than the simple addition of the known complication rates for each procedure alone.

The question as to whether additional carotid surgery actually increases the complication rate as such or if a less favorable risk profile of the patients undergoing synchronous procedures is responsible for this result yields conflicting answers. A comparison of patients registered in the New York State Cardiac Surgery Database who underwent combined surgery with a group of patients having the same risk according to the propensity score did not demonstrate any difference in the complication rate. This implies that the additional CEA does not add to the increased complication rate (Ricotta et al. 2005). However, a study comparing patients undergoing isolated CABG with a risk-adjusted group of patients undergoing synchronous surgery demonstrated a complication rate which was higher by 38% (Dubinsky and Lai 2007). The authors of this study blamed it on the combined surgery.

33.2.5 Treatment Rationale in Coronary Artery Disease and Concomitant Carotid Stenosis

There are no clear-cut recommendations in the current literature or guidelines regarding the treatment rationale in patients requiring coronary surgery and also exhibiting high-grade asymptomatic carotid stenosis. Therefore, optimum treatment strategy for this disease entity still is open for debate. The higher complication rates in (staged or synchronous) combined surgery compared with isolated CABG (leaving the asymptomatic carotid stenosis untouched) demand that the need for combined surgery must be assessed in detail for each patient. Appropriate strategies would involve assessment of each disease on its own in terms of the urgency of its treatment. To this end, data are available at the highest evidence level, together with guidelines derived from these data. Priority should be given to treatment of the symptomatic disease. Recurrent transient ischemic attacks, particularly within a period of 14 days after onset, underline the urgency of treating the carotid stenosis. On the other hand, unstable angina or

stenosis of the left main coronary artery is an indication for urgent treatment of the coronary artery disease. Should both coronary disease and carotid disease be symptomatic, this situation would necessitate synchronous surgery.

If there are no symptoms or if angina is only triggered at high levels of physical exertion, the decision must be based on objective findings. Filiform stenosis of important coronary arteries should not be put at the risk of occlusion prior to CEA, while moderate stenosis of the left main coronary artery should allow synchronous surgery or even isolated CABG leaving the carotid stenosis untouched.

Asymptomatic carotid stenosis requires a very precise assessment of the severity of the stenosis, primarily through diagnostic angiography as well as carotid duplex scanning. It should be ensured that the degree of stenosis is >70% according to the NASCET method or >80% according to the ECST protocol. Here, too, there are no verified data on the necessity of synchronous surgery, and the results of perspective randomized trials need to be awaited. An asymptomatic significant carotid stenosis according to the above measurements, with concomitant occlusion of the contralateral carotid artery, however, would support the decision for synchronous surgery. Furthermore, the decision should also be based on the results of prospective trials on isolated surgery of asymptomatic carotid stenosis since long-term prevention of stroke is to be expected (SPACE-2, TACIT). When it comes to surgical techniques and sequence of treatment for coexisting carotid and coronary disease, there are insights into which treatment method may be superior. To date, the expectations for interventional treatment of carotid stenosis before CABG have fallen short. The results of on-pump CEA under the protection of hypothermia also did not yield any benefits when compared with the other protocols.

There were hopes to get further insights into the best treatment strategy for concomitant coronary and carotid arteriosclerotic disease with reliable data, from the CABACS trial (A Randomised Comparison of Synchronous CABG and Carotid Endarterectomy Vs. Isolated CABG in Patients with High-Grade Carotid Stenosis), starting in December 2010. These hopes were blasted, when the trial was stopped early by the funder because of slow recruitment (Weimar et al. 2016).

33.3 Other Combined Cardiac and Vascular Procedures

33.3.1 Combined Cardiac and Abdominal Aortic Aneurysm Surgery

Of all patients requiring abdominal aortic aneurysm (AAA) repair, 27–46% also presented with coronary artery disease (Kioka et al. 2002; Garofalo et al. 2005). Coronary artery disease and its sequelae are the main causes for perioperative complications and mortality in AAA repair. For this reason, special emphasis is placed on presurgical diagnostics of coronary heart disease, in particular, when prophylactic surgery of asymptomatic abdominal aortic aneurysms is planned. Several trials, including one with a prospective randomized design, however, could not demonstrate an overall advantage of preventive coronary revascularization preceding major vascular procedures (McFalls et al. 2004). Only patients with symptomatic angina pectoris at low exercise levels (Canadian Cardiovascular Society [CCS] classes III and IV), unstable angina, or acute coronary syndrome should not undergo elective vascular surgery without prior coronary revascularization. There are no data on the risks of elective vascular procedures in patients with morphological findings relevant for the prognosis of long-term survival such as left main coronary stenosis or left main equivalent coronary disease or three-vessel coronary disease with impaired left ventricular function. It has to be assumed, however, that these conditions will increase the surgical risk. In coronary heart disease, AAA does not represent a complication-prone concomitant disorder. Although asymptomatic AAA with a diameter >5 cm is not infrequent in patients with coronary disease (incidence 1–5.2%), AAA rupture during heart surgery appears to be extremely rare (Durham et al. 1991; Bergersen et al. 1998; Monney et al. 2004).

The risk of aneurysm rupture increases exponentially with its diameter, and for aneurysms with a diameter >7 cm, the risk of rupture within a year is 32.5% (Lederle et al. 2002). Aneurysms of this size should be repaired at an early stage—approx. 2 weeks after cardiac surgery—or, at the latest, when they are 8 cm in diameter and simultaneously

with cardiac surgery (Blackbourne et al. 1994). Simultaneous surgery should preferably also be performed on symptomatic aneurysms (Onwudike et al. 2000). The coincidence of coronary artery disease and AAA, both urgently requiring surgery, appears to be rare.

In terms of surgical technique, the AAA is best exposed through full-length median sternotomy and laparotomy. This extensive access offers an exceptionally good view for both procedures. Current publications describe the benefits and, in part, better results of off-pump CABG surgery (Ascione et al. 2001; Wolff et al. 2006). The perceived benefits of the on-pump technique, however, include a decreased load on the heart during the aortic clamping period and the possibility of autotransfusion during extracorporeal circulation.

In exceptionally rare cases, it may be advisable to perform simultaneous carotid surgery, CABG, and AAA repair.

33.3.2 Cardiac Surgery and Peripheral Vascular Procedures

Although many patients with coronary artery disease reveal peripheral arterial occlusive disease also, synchronous surgery is rarely required. Only when peripheral artery disease with pain at rest or already at the stage of necrosis is inaccessible by interventional techniques, synchronous surgery may be indicated. In order to keep the surgical trauma as limited as possible, less invasive surgical techniques for the peripheral vascular part are preferred, even if this may mean a limited long-term outcome. Therefore, despite the poorer long-term outcome, occlusive disease of the abdominal aorta would be treated by extra-anatomical axillofemoral bypass, since this will avoid having to enter both the thoracic and abdominal cavities, or a unilateral retroperitoneal procedure would be performed on the iliac axis, focusing on the extremity with the most severely impaired blood flow at rest. Quite often, pain at rest without necrosis due to involvement of the femoral arteries can be treated by isolated revascularization at the level of the femoral bifurcation, e.g., by endarterectomy of the common femoral artery and usually combined with patch grafting of the deep artery of the thigh. Even if there is extensive occlusion of the super-

ficial femoral artery, these procedures are particularly promising if there is angiographic evidence of collateral vessels connecting to a popliteal artery which is still patent. If this is missing completely up to the level of the trifurcation in the lower leg and if there is also gangrene, bypass revascularization, with its known risks, of one of the arteries in the lower leg cannot be avoided. It is recommended that this procedure be performed after successfully completed CABG surgery and carried out in a cardiovascular context which can be predicted to be as stable as possible. The bypass material available and the quality of the target vessels should offer a reasonable expectation of successful revascularization as the need for revision surgery during the post-operative period can thus be kept as low as possible. In any case of peripheral vascular occlusive disease, the respective extremity should be spared from vein harvesting. With significant peripheral vascular occlusive disease present at the time of cardiac surgery, the patient must always be informed in detail about the possibility of severe limb ischemia.

34.1 Introduction

Cardiac surgery and thoracic surgery developed contemporaneously during the 1940s and 1950s after the foundation for intrathoracic surgery was established during the two previous decades (see also ► Chapter «The History of Cardiac Surgery», Sect. 1.2; Sect. 1.6). Development of cardiac surgery required the ability to arrest blood flow through the heart, devices for valve replacement, blood vessel substitutes, and mechanisms for pacing the heart. Successful thoracic surgery required an understanding of risk assessment for lung resection based on pulmonary function testing, facility in single lung ventilation, and better knowledge of staging and long-term outcomes for cancers of the lung and esophagus. The development of both required improved anesthetic management, advances in blood component therapy, and the ability to manage temporary organ dysfunction.

It is not surprising that combined operations for synchronous problems separately affecting the heart and thoracic organs have been performed since heart and lung surgery became commonplace. Lung cancer, coronary artery disease, and esophageal cancer often share the same underlying etiology (tobacco use and other environmental exposures) and affect similar age groups of patients. The fact that surgeons treating cardiac problems are usually trained in thoracic surgery made this combined approach almost intuitive: the advantages of a single anesthetic, a single incision, and a single recovery period seemed obvious. However, outcomes of such operations have been reported only sporadically, and it remains unclear whether they are comparable to outcomes of the component operations done separately. This chapter focuses on issues surrounding combined heart and lung surgery and the outcomes of such operations.

34.2 Concerns

A number of concerns have been raised during the past two decades regarding whether eliminating an additional anesthetic and an additional incision, both of which are required for staged cardiac and lung operations, is sufficient to overcome the potential adverse effects of a combined operation (► Table 34.1). These issues may have limited the number of combined operations performed for patients with cardiac problems and lung cancer.

► **Table 34.1** Potential concerns regarding combined cardiac surgery and lung surgery for cancer

Immunosuppression induced by cardiopulmonary bypass
Acute organ dysfunction related to cardiopulmonary bypass
Passage of circulating cancer cells through the cardiopulmonary bypass circuit
Unfavorable access to performing
Parenchymal-sparing anatomic resections
Complete regional nodal dissections
Limited ability to administer postoperative adjuvant therapy when indicated

34.2.1 Immunosuppression

Immunosuppression is one of the mechanisms thought to be responsible for the permissive development of metastases in patients undergoing cancer surgery and can be facilitated by the trauma of surgery, anesthetic agents, analgesics, transfusion, alterations in body temperature, pain, and psychological stress (Vallejo et al. 2003). Immunosuppression is thus common after any major operation. Its underlying mechanisms are related in part to a shift in adrenocortical responses, causing a decline in cell-mediated immunity, especially through a decrease in natural killer (NK) cell activity. In addition to this ubiquitous postoperative process, the use of cardiopulmonary bypass (CPB) for cardiac operations results in a marked systemic inflammatory response (Pintar and Collard 2003) that can only be partially abrogated pharmacologically and that likely also interferes with natural immune processes designed to limit cancer spread (Ng and Wang 2012).

34.2.2 Organ Dysfunction

Organ dysfunction is common after cardiopulmonary bypass and is related to the systemic inflammatory response that results in part from CPB as well as other factors such as hypoperfusion and hypoxemia. Subclinical organ dysfunction is common and becomes clinically manifest in patients with limited reserve or who have an

exaggerated inflammatory response to CPB. The incidence of major organ dysfunction after isolated coronary artery bypass grafting (CABG) is appreciable, including renal failure in 3.6%, respiratory failure in 9.6%, cerebrovascular accident in 1.4%, and composite adverse outcomes in 14.4% (Shahian et al. 2009). Such perturbations in organ function adversely affect a lung resection patient's ability to recover from surgery. Impaired cognition reduces a patient's ability to cooperate with postoperative pulmonary toilet exercises and other physical therapies; renal dysfunction may precipitate fluid overload and contribute to problems with respiratory gas exchange; cardiac dysfunction may also contribute to pulmonary edema. Ventilation is severely impaired during the first 24–48 h after major lung resection, resulting in a 60–70% decrease in forced vital capacity; other contributions to pulmonary dysfunction related to concomitant cardiac surgery may further test pulmonary reserve during this critical period.

34.2.3 Oncologic Issues

Circulating tumor cells can be identified in the peripheral blood of a moderate number of lung cancer patients and in a large percentage of pulmonary venous blood in such patients (Okumura et al. 2009). The percentages vary somewhat with the staining techniques used for identifying the cells. Such circulating cells are found in 20% of patients with stage I lung cancer (Chen et al. 2013). The importance of these cells is not entirely clear, although they have been shown to have prognostic value, in addition to histology and stage, for survival. They have also been purported to serve as a means for identifying tumor makers and for monitoring response to systemic therapy (O'Flaherty et al. 2012; Young et al. 2012). While the lung tumor is the source of circulating tumor cells in patients with early stage lung cancer, the lung also serves as a filter removing such cells from the peripheral circulation. Placing patients on cardiopulmonary bypass circulates the blood past this natural filter directly into the systemic circulation, potentially exposing the peripheral circulation to a higher concentration of circulating cells. Although one study demonstrated that most circulating tumor cells are trapped on the internal surface of arterial filters (Akchurin et al.

1997), at least one case report of systemic tumor dissemination during such surgery has been published (Hasegawa et al. 2002). The systemic inflammatory response that follows CPB may increase the ability of such cells to adhere to the vascular endothelium, diapedese through the capillary wall, and develop into micrometastases. The mechanism for this may be an increase in circulating adhesion molecules which has been reported after CPB, whereas no such change was identified during lung resection operations (Boldt et al. 1998). Interestingly, one study reported improved long-term survival in lung cancer patients in whom the cancer was removed prior to institution of CPB (Brutel de la Reviere et al. 1995). Whether this was related to elimination of most circulating tumor cells prior to the onset of bypass and the systemic inflammatory response is unknown.

One of the primary concerns about the adequacy of major lung resection at the time of a cardiac operation is surgical exposure and access to the hilum and mediastinum. In general, the surgical approach is chosen to favor exposure for the cardiac operation, while exposure for lung resection is a secondary or sometimes a tertiary consideration. Most often the cardiac and thoracic procedures are performed through a sternotomy. Although it is technically feasible to do most standard lobectomies or pneumonectomies using this approach, a sternotomy is rarely the incision of choice for a major lung resection. In addition, access to performing a left lower lobectomy can be challenging, particularly in patients with cardiomegaly. More technically demanding operations, such as segmental resections, bronchoplasty or arterioplasty, and sleeve resections, can be quite difficult to accomplish through the exposure offered by a standard sternotomy. If combined surgery is necessary, it is optimal to perform the more technically demanding pulmonary resections through a separate incision at the time of the cardiac operation.

Of perhaps more importance is access to the mediastinum for performing systematic lymph node sampling or mediastinal nodal dissection, which is a standard of care for lung cancer resection (Lardinois et al. 2006; De Leyn et al. 2007). The regions that are most difficult to access through a sternotomy include the pulmonary ligament (level 9), paraesophageal (level 8), and subcarinal (level 7) nodes. Lack of adequate

sampling/dissection is associated with decreased survival, likely because of inaccurate pathologic staging and the resultant failure to provide appropriate postoperative adjuvant therapy. Lymphadenectomy also has the chance of reducing local recurrence (Nwogu et al. 2012; D'Andrilli et al. 2012).

There is general agreement that patients with clinical stages I and II non-small cell lung cancer should undergo local therapy as their initial treatment, which typically is anatomic lung resection for the majority of patients. Those who are identified as having hilar or mediastinal nodal involvement undergo postoperative adjuvant therapy consisting of chemotherapy and often hilar and mediastinal radiation therapy. The ability of patients to withstand a full course of postoperative adjuvant chemoradiotherapy, whether administered concomitantly or sequentially, is somewhat limited after major lung resection. It is very likely that even fewer patients would tolerate an entire course of postoperative adjuvant therapy if they have undergone combined cardiac and pulmonary surgery. Failure to complete a full course of adjuvant therapy likely would have an adverse effect on cancer-specific long-term survival.

34.3 Indications and Contraindications

The primary indications for combined cardiac surgery and pulmonary surgery fall into two main categories. Some patients are identified as having cardiac disease for which corrective surgery is indicated and during evaluation are found to have a suspicious lung nodule/mass that also requires evaluation and treatment. In one series of over 3,300 coronary bypass operations, 5% of patients were found to have pulmonary lesions, 80% of which were benign on the basis of calcifications (Johnson et al. 1996). The overall prevalence of malignancy was 7.8%; nodules >2 cm in maximum diameter had a substantially increased risk of malignancy (37%).

Other patients are identified initially as having a confirmed or suspected lung cancer amenable to resection but are found to have underlying cardiac disease that would not permit lung resection unless it is corrected. In the second instance, most patients' disease is managed via percutaneous

intervention; only a minority of patients require cardiac surgery to enable them to subsequently undergo lung resection.

In both situations, the suspected/proven lung cancer should be of clinical early stage (ideally stage I) and technically resectable through a sternotomy. A standard pulmonary evaluation should be performed, including spirometry and assessment of diffusing capacity. In patients who are at increased risk based on these tests, normally peak oxygen consumption during exercise is assessed as a final measure of operative risk. Patients with substantial underlying cardiovascular disease are not candidates for such testing, leaving the difficult decision of whether to proceed with lung resection up to the surgeon's experience and judgment.

Relative contraindications to combined surgery include regionally advanced cancer, including mediastinal nodal involvement and chest wall involvement (T3 status). Tumors that invade vital structures (T4) that require CPB for resection have unfavorable cancer-related survival, and this should be considered a relative contraindication to resection. In one report, 75% of patients undergoing resection of T4 tumors on CPB died of cancer recurrence with a median survival of just over 1 year (Kauffmann et al. 2013).

34.4 Operative Management

34.4.1 Incisions

The choice of incisions is typically based on needs for the cardiac portion of the operation. No series of minimally invasive combined operations has been described to date. The most common approach is via a partial or complete sternotomy. For patients undergoing initial or redo heart surgery through a left or right anterior thoracotomy, access for ipsilateral lung resection is enhanced compared to sternotomy, whereas there is no access for contralateral lung resection. Occasional reports have described the use of a posterolateral thoracotomy for lung resection and concomitant grafting; one included a single graft to a dominant circumflex lesion performed off pump (Ahmed and Sarsam 2001). Of course, the combined operations could also be performed through two incisions, as has been reported (Voets et al. 1997), optimizing the exposure for each but causing additional pain and trauma. This was associated

with increased operative mortality compared to sternotomy alone (27.2% vs 2.9%) in at least one study (Brutel de la Reviere et al. 1995).

34.4.2 Sequence of Procedures

A variety of methods are used to manage the sequence of intraoperative events, which are related to heparinization (related to bleeding), decompression of the heart (related to access), and patient hemodynamic stability (governing whether it is feasible to perform the lung resection prior to heparinization while off bypass). There are few reliable data that inform us about the relative advantages and disadvantages of these choices. Some surgeons perform the lung resection first, followed by heparinization, institution of CPB, and cardiac surgery. For patients who are at high risk from a cardiac perspective, it is more often the case that the cardiac operation is performed initially. The lung resection may then be accomplished while on bypass, with the heart decompressed for improved exposure. Alternatively, performing the lung resection after discontinuation of CPB and heparin reversal helps identify sites where bleeding may be a concern postoperatively. However, exposure can be challenging, and manipulation of the heart in a patient who has just been weaned from CPB often results in myocardial impairment and cardiac output or rhythm disturbances. One additional concern regarding exposure for the lung resection relates to the use of internal mammary vessels for coronary revascularization. Access to the pleural space may be compromised, and retraction of the heart away from that pleural space could put tension on the coronary anastomosis.

One method of mitigating some of the issues surrounding CPB and heparinization is to perform off-pump surgery with concomitant lung resection. This eliminates the increased bleeding risk and abrogates much of the systemic inflammatory response. Successful performance of such operations has been reported sporadically (Ahmed and Sarsam 2001; Koksai et al. 2002), and has been associated with decreased blood loss and ventilation requirements (Danton et al. 1998). Off-pump bypass also has been shown to decrease postoperative pulmonary complications compared to on-pump bypass (Schoenmakers et al. 2007).

34.4.3 Perioperative Management

Perioperative management presents challenges in patients undergoing combined cardiac and pulmonary surgery. During and after isolated lung resection, great care is taken to limit intravenous fluid administration to help prevent pulmonary edema and compromise of gas exchange. In contrast, fluid administration and fluid shifts during and after cardiac surgery, especially when CPB is used, are substantial and detrimental to gas exchange. Lung resection sometimes results in a residual pleural space, which is routinely drained by thoracostomy tubes and rarely is complicated by hemothorax. In contrast, blood loss after a cardiac operation, particularly those performed on CPB, is not uncommon. Such postoperative bleeding is normally easily managed with mediastinal drains. However, ongoing bleeding in a patient with a common pleural and mediastinal cavity, in whom a residual pleural space exists, is at increased risk for the development of a retained hemothorax. It is not unusual to keep patients intubated and ventilated for a period of time after cardiac surgery, whereas lung resection patients are best extubated in the operating room to permit them to begin vigorous pulmonary toilet exercises as soon as possible.

Pleural space management problems are a particular concern in patients undergoing combined cardiac surgery and pneumonectomy through the same incision. There is no soft tissue to tamponade even modest bleeding into the pleural space. Vigorous drainage of the pleural space after pneumonectomy, in an effort to prevent hemothorax, is associated with pulmonary dysfunction related to volotrauma, and this may be exacerbated by the systemic inflammatory response associated with CPB.

34.5 Outcomes

Clinical outcomes for combined cardiac and pulmonary operations have been reported sporadically (■ Table 34.2) (Brutel de la Reviere et al. 1995; Johnson et al. 1996; Voets et al. 1997; Danton et al. 1998; Schoenmakers et al. 2007; Ulicny et al. 1992; Yokoyama et al. 1993; Rosalion et al. 1993; Miller et al. 1994; La Francesca et al. 1995; Rao et al. 1996; Patane et al. 2002; Dyszkiewicz et al. 2008; Cathenis et al. 2009). No randomized trials

Table 34.2 Outcomes of combined cardiacsurgery and major pulmonary resection in series reporting ten or more patients

Author	Year	Patients	Lung cancer	Cardiac operations	Operative mortality	Major morbidity
Ulincy et al.	1992	10	5	CABG (7), AVR (1), CABG + MVR (2)	1 (10%)	8 (80%)
Yokoyama et al.	1993	10	10	CABG	0	0

Miller et al.	1994	23	23	Primarily CABG	2 (8.7%)	–
La Francesca et al.	1995	19	19	Primarily CABG	0	1 (5%)
Brutel de la Riviere et al.	1995	79	79	CABG (72), AVR (5), CABG + AVR (2)	5 (6.3%)	12 (15%)
Rao et al.	1996	11	11	Primarily CABG	2 (18.1%)	7 (64%)
Johnson et al.	1996	18	11	CABG	1 (5.5%)	–
Danton et al.	1997	13	10	CABG (12), AVR (1)	0	6 (46%)
Voets et al.	1998	24	24	CABG	5 (20.8%)	6 (25%)
Patane et al.	2002	11	9	CABG (6), AVR (2), MVR (1), AVR + MVR (1), myxoma resection (1)	0	0
Schoenmakers et al.	2007	43	43	CABG	3 (7%)	20 (47%)
Dyszkiewicz et al.	2008	21	21	CABG	0	6 (28%)
Cathenis et al.	2009	27	27	CABG 922), valve (2), valve + CABG (3)	0	16 (59%)

evaluating the potential benefit or harm have been performed. It is likely that such combined operations represent much less than 5% of all major lung resections for cancer. There is a trend toward somewhat increased operative mortality for combined operations compared to cardiac surgical procedures alone. It is not possible to reliably determine whether long-term cancer-specific survival is related to whether the lung resection was performed in a staged or synchronous manner. Survival data for combined operations are scarce and are not reported according to clinical stage, so direct comparisons are not possible. One retrospective observational study reported no difference in long-term survival for staged procedures compared to combined procedures (Voets et al. 1997), whereas another study from the same time period reported significantly better 5-year survival for pathologic stage I patients who had a staged resection compared to those who underwent combined resection, 100% vs 36.5% (Miller et al. 1994).

It is unclear from the literature whether, when a combined approach is used, a subspecialist in thoracic surgery performs the lung resection or whether this is done by the cardiothoracic surgeon who is also performing the cardiac operation. Recent findings suggest that subspecialist thoracic surgeons perform a more oncologically appropriate operation for lung cancer when performed as an isolated operation compared to general and cardiac surgeons (Farjah et al. 2009; Ellis et al. 2011). Morbidity and mortality for major lung resection are lower for thoracic surgeons than for cardiac surgeons and general surgeons (Schipper et al. 2009). Survival after lung cancer resection is also better when surgery is performed by a thoracic surgeon than a cardiothoracic or general surgeon (Farjah et al. 2009). How these findings apply to a combined cardiac and pulmonary operation is unclear.

Despite the theoretical risk that extracorporeal circulation will increase metastatic potential, this has not been borne out reliably in the literature. In fact, one retrospective observational study demonstrated improved long-term all-cause survival in patients undergoing combined coronary revascularization on CPB and lung cancer resection compared to those undergoing revascularization without CPB (Schoenmakers et al. 2007). However, the off-pump group in this study was significantly older and had somewhat

more advanced lung cancer at the time of treatment. Therefore, the conclusions from this isolated study need confirmation in larger clinical experiences.

34.6 Conclusions

Combined cardiac and pulmonary operations are uncommon. A number of theoretical concerns exist regarding the adverse effects of combining the operations, but the data regarding these concerns are limited and few clear conclusions can be drawn. No general agreement exists as to which portion of the operation should be done first, whether the lung resection should be performed on or off bypass, whether performing the cardiac operation off pump is advantageous and whether performing the lung resection through a separate incision provides any advantage. There appears to be an increase in both operative mortality and surgical morbidity for combined operations compared to isolated cardiac and thoracic operations. Staged, rather than combined, surgery may provide a cancer-specific survival benefit.

35.1 Pulmonary Embolectomy for Acute Pulmonary Embolism

35.1.1 Clinical Presentation

Massive pulmonary embolism carries a mortality rate of >30%, and its acute clinical presentation may be life threatening. Immediate therapeutic action is mandatory. Two thirds of deaths occur within the first hours (Stulz et al. 1994). Autopsy statistics have shown pulmonary embolism to be the major cause of death among patients without a clinically diagnosed cause (Morgenthaler and Ryu 1995; Morpurgo and Schmid 1995). In up to 90% of cases, pulmonary embolism is caused by venous thrombi mainly originating from the lower limbs. Only seldom may fatty tissue, bone fragments, amnion fluid, air, tumor tissue, bacteria, parasites, or foreign bodies embolize. In approximately 10–20% of cases, emboli arise from the area of the superior vena cava, and its incidence has increased with the more frequent invasive diagnostic and therapeutic procedures in the current era. In a study by Sandler and Martin (1989), deep venous thrombosis of the lower extremities was found at autopsy in more than 80% of patients who died from pulmonary embolism. In only a quarter of those, 19% of the whole group had been diagnosed already clinically ante mortem. Furthermore, Moser et al. (1994) revealed asymptomatic pulmonary emboli by scintigraphy in 40% of patients with deep venous thrombosis.

The Virchow triad—vascular wall lesion, blood stasis, and hypercoagulation—is considered to be the underlying pathological mechanisms of venous thrombosis formation.

The recognized risk factors are:

- Advanced age
- Surgery (depending upon procedure and duration of anesthesia; hip and knee procedures in particular)
- Thrombophilic diathesis
- Antithrombin III deficiency
- Protein C or S deficiency
- Resistance against activated protein V
- Malignant disease
- Previous venous thromboembolism
- Immobilization
- Trauma to the lower limbs
- Internal diseases requiring prolonged bed rest (such as cardiac insufficiency)

- Oral contraceptive and postmenopausal hormone substitution
- Puerperal period
- Obesity
- Long (flight) travels

The multiple facets in clinical appearance of pulmonary embolism make a timely and correct diagnosis difficult. There are on one hand the clinical symptoms, which depend not only upon the severity of the embolism but also on the patient's underlying condition. On the other hand, none of the symptoms or symptom complexes are highly specific (■ Table 35.1). Therefore, correct diagnosis is missed in more than 50% of cases (Moser 1997).

Clinical severity, mainly hemodynamic consequences of the thromboembolic event, dictates treatment of acute pulmonary embolism and determines the patient's course and outcome. The historic grading into four severities of pulmonary embolism is based upon the pathophysiologic changes and clinical manifestation (Grosser 1980). Today, for therapeutic decision-making, we only differentiate between hemodynamic non-effectual pulmonary embolism, i.e., without right heart strain (equates Grosser grade I–II) and a hemodynamic effectual embolic event (Grosser

■ **Table 35.1** Symptoms and signs in patients with confirmed pulmonary embolism

Symptoms	
Dyspnea	80 %
Chest pain (pleuritic)	52 %
Chest pain (retrosternal)	12 %
Cough	20 %
Hemoptysis	11 %
Syncope	19 %
Signs	
Tachypnea	20 %
Tachycardia (>100 bpm)	26 %
Signs of DVT	15 %
Fever (>38.5 °C)	7 %
Cyanosis	11 %

grade III–IV). While a hemodynamic non-effectual embolism may be also coined nonmassive embolism, a submassive embolism causes right ventricular dysfunction, and a massive embolism leads to systemic hypotension or even a shock.

Right heart strain is considered a decisive factor for the short-term prognosis in acute pulmonary embolism.

The aggressiveness of diagnostic and therapeutic procedures ensues the degree of right ventricular dysfunction (Konstantinides et al. 1997; Lualdi and Goldhaber 1995).

35.1.2 Diagnostics

Baseline diagnostics include plain chest x-ray examination, a standard 12-lead electrocardiogram, an arterial blood gas analysis, and determination of serum *D-dimer concentration*. Chest x-ray and ECG are often inconclusive, arterial blood gases (Brau et al. 1981), and D-dimer may point toward early diagnosis but are also of limited value and often inconclusive. Although moderate in severity, hypoxemia and associated hypocapnia are present in approximately 95% of patients with confirmed acute pulmonary embolism. Right–left shunting may aggravate hypoxemia.

D-dimer is elevated in >90% of patients with pulmonary embolism and deep vein thrombosis; a normal D-dimer value rules out the diagnosis of acute pulmonary embolism (Bounameaux et al. 1991). On the other hand, D-dimer may also be elevated in a wide variety of conditions, i.e., inflammation, infection, aortic dissection, and cancer, and therefore, the positive predictive value of D-dimer is low. Elevation of cardiac troponines and pro-BNP are markers for the degree of right ventricular dysfunction and damage (Konstantinides et al. 2002).

The critical consequence of a pulmonary thromboembolic episode is hemodynamic deterioration secondary to right heart failure. Evaluation of right ventricular function by echocardiography and radiologic pulmonary vascular bed imaging are the two pillars upon which the decision for invasive therapy is founded. Ventilation–perfusion scintigraphy (*V/Q scan*) is very sensitive and

specific. While a normal perfusion scan reliably rules out pulmonary embolism, mismatch in ventilation–perfusion has a high probability for the diagnosis of pulmonary embolism in the clinical setting being suspicious for it. However, scintigraphy is not available in all institutions and has lost its stand to more modern radiologic CT methods. Although the investigation is safe and radiation exposure low, the method is time consuming and may be unsuitable for patients in critical condition as further radiological imaging tests may be required to establish the pathway of treatment.

Echocardiography in experienced hands is an extremely useful diagnostic tool. Its noninvasive and mobile applicability allows for quick assessment of the patient's hemodynamic condition. It can ascertain imminent deterioration, help determine the intensity of monitoring required, and guide the treatment plan. It's highly effective for differential diagnosis of acute dyspnea, chest pain, circulatory instability, and other clinical situations when acute pulmonary embolism may be suspected. However, the method is subjective and observer dependant and has only limited value in differentiating causes of right heart strain. The assessment of important right heart parameters—such as right atrial and ventricular size, contractility of the free wall, movement of the ventricular septum, degree of tricuspid valve insufficiency, and calculation of pulmonary artery pressure—does, however, suffice for initiation of aggressive treatment when the patient's condition is critical. At the same time, echocardiography evaluates left ventricular function and may also differentiate between acute and chronic pulmonary hypertension. In acute pulmonary embolism, a previous normal right ventricle will not maintain a systolic pressure above 40 mmHg. Moreover, in massive pulmonary embolism, pulmonary pressure may decrease as a result of right heart and secondary circulatory failure. In these cases interpretation of pulmonary artery pressure must be evaluated in the clinical context (Wacker et al. 2003). Transesophageal echocardiography may even confirm diagnosis by detection of thromboemboli in the central pulmonary arteries. Also right heart thrombi, which are detected by transthoracic echocardiography in up to 20% of patients, justify aggressive treatment. Simultaneously, venous ultrasound may be performed to substantiate diagnosis and allows for risk stratification of therapy. The sensitivity for detection of deep vein thrombosis by ultrasound color

flow imaging (CFI, also: color flow Doppler imaging - CD sonography) is concordant with the result of CT venography (van Belle et al. 2006).

Multi-detector computed tomography has replaced conventional angiography as «gold standard» of radiologic imaging of the pulmonary vasculature in routine clinical practice. The visualization of the pulmonary arteries is adequate up to the segmental level, and the detection of thrombi suffices as evidence of pulmonary embolism. The large PIOPED II (Prospective Investigation of Pulmonary Embolism Diagnosis) study observed a sensitivity of 83 % and a specificity of 96 % (van Belle et al. 2006). Additionally, evaluation of right ventricular size and strain is feasible, and a CT venogram decides the status of deep vein thrombosis (Goldhaber 2005; Loud et al. 2005; Perrier et al. 2005; Stein et al. 2004). However, due to the relatively high overall examination radiation, the value of CT venography is debated in spite of diagnostic accuracy and should be used selectively (Torbicki et al. 2008).

Magnetic resonance imaging is noninvasive and provides reliable diagnostic data. The method is time consuming, expensive, and not always available. Especially for unstable patients with high-risk status, this diagnostic option is not suited (Madini and Jamieson 2003).

In patients with suspected high-risk pulmonary embolism, i.e., presenting with shock or hypotension, diagnostic measures must be kept at a minimum, either after echocardiography alone, or, if allowed for by stabilized hemodynamics, after a pulmonary CT, immediate therapeutic action (thrombolysis or surgical embolectomy) is imperative.

35.1.3 Medical Treatment and Surgical Therapy

All patients with suspected significant pulmonary embolism should immediately be transferred to the ICU. Acute right ventricular failure and subsequent shock, which is the leading cause of mortality, may be imminent, and rapid diagnosis followed by supportive therapy is imperative. About 40–50 % of patients with acute pulmonary embolism have right heart strain. If this leads to circulatory instability, mortality is exorbitantly

high (up to 90%). *Hemodynamic and respiratory support* is required when hypotension or even shock are present. Aggressive volume expansion may further impair right ventricular function by causing additional mechanic overstretch, tricuspid regurgitation, and further loss of contractility. Modest fluid support, however, may improve cardiac index. Positive inotropic drugs should be administered to improve contractility and maintain adequate coronary perfusion. No clinical data are available on noradrenaline (norepinephrine) in pulmonary embolism; dobutamine improves cardiac index but may cause systemic vasodilation and hypotension. Adrenaline (epinephrine) combines the beneficial properties of drugs mentioned and exerts beneficial effects in shock patients (Torbicki et al. 2008). Systemic administration of vasodilators may be detrimental due to systemic hypotension, but may be beneficial when inhaled. For respiratory support by mechanical ventilation, it is important to avoid excessive increase in intrathoracic pressure as it may further compromise right ventricular function. Therefore, high end-inspiratory pressures and PEEP are avoided.

Occasionally, extracorporeal membrane oxygenation (see ► Chapter «[Extracorporeal Circulation and Myocardial Protection in Adult Cardiac Surgery](#)», Sect. 6.3) may be necessary at times extended to mechanical circulatory support (► Chapter «[Cardiac Assist Devices and Total Artificial Heart](#)», Sect. 38.4.3), followed by thrombolysis or surgery.

Anticoagulant therapy is mandatory in patients with pulmonary embolism, and immediate full heparin administration should even be considered before definite diagnosis of pulmonary embolism is confirmed. Unfractionated heparin given intravenously and low molecular weight heparin and fondaparinux (Factor XA Inhibitor) administered subcutaneously are all equally effective and approved for treatment of low-risk pulmonary embolism and the latter two generally preferred due the easier application modus (Konstantinides 2006; Kucher and Goldhaber 2005). Unfractionated heparin is applied in patients with high risk of bleeding, in renal failure, and/or in high-risk pulmonary embolism.

35.1.3.1 Thrombolytic Therapy

Thrombolysis is the treatment of choice in high-risk patients with cardiogenic shock and persistent hypotension due to massive pulmonary embolism (Jerjes-Sanchez et al. 1995).

Table 35.2 Contraindications to thrombolytic therapy

Absolute:
Hemorrhagic stroke at any time
Ischemic stroke within preceding 6 months
Central nervous system damage or neoplasm
Recent major trauma/surgery/head injury within preceding 3 weeks
Gastrointestinal bleeding within preceding 1 month
Active bleeding
Relative:
TIA in preceding 6 months
Oral anticoagulant therapy
Pregnancy or within 1 week postpartum
Non-compressible punctures
Traumatic resuscitation
Refractory hypertension (syst. >180 mmHg)
Advanced liver disease
Infective endocarditis
Active peptic ulcer
From: Torbicki et al. (2008); used with permission

Active lysis rapidly resolves the thromboembolus within a few hours, thereby restoring the vascular lumen and reducing right ventricular afterload. Studies have demonstrated a 30% reduction in mean pulmonary arterial pressure, 15% increase in cardiac index, and reduction of right ventricular size (Dalla-Volta et al. 1992; Goldhaber et al. 1993). The greatest benefit is observed when treatment is begun within the first two days, but substantial effect can be observed up to 2 weeks after onset of symptoms. The hemodynamic effect of therapy is vastly confined to the first 2 days of therapy with >90% of patients responding. In randomized trials, the major risk of thrombolytic therapy is bleeding with a cumulative rate of major bleeding in 13% and intracranial/fatal hemorrhage in 1.8% (Torbicki et al. 2008). Absolute and relative contraindications are few (Table 35.2) and may become inconsiderable in the face of a life-threatening situation.

Three agents (Table 35.3) are approved for thrombolytic therapy of pulmonary embolism. Of

Table 35.3 Thrombolytic regimens for pulmonary embolism

Streptokinase	250,000 IU bolus over 30 min, followed by 100,000 IU/kg/h over 12–24 h
	Accelerated regimen: 1.5 mill IU over 2 h
Urokinase	4,400 IU/kg bolus over 10 min, followed by 4,400 IU/kg/h over 12–24 h
	Accelerated regimen: 3 mill IU over 2 h
rtPA	100 mg over 2 h
	alt. 0.6 mg/kg over 15 min (maximum dose 50 mg)
Heparin is infused concurrently with rtPA administration only, with urokinase and streptokinase afterward	
From: Torbicki et al. (2008); used with permission	

the three, rtPA (recombinant tissue plasminogen activator), a short-term lytic agent infused over two hours, seems to offer faster hemodynamic improvement compared to either urokinase or streptokinase and is therefore recommended. Data from other thrombolytic agents (reteplase and tenecteplase) seem to provide equally good hemodynamic and efficient results (Tebbe et al. 1999; Melzer et al. 2004). Direct local infusion in the pulmonary artery offers no advantage over systemic intravenous administration (Verstraete et al. 1988).

In patients with stable hemodynamics but right heart dysfunction, the usefulness of thrombolytic therapy is not proven, yet, but intensely debated. This group, accounting for 40–50% of patients presenting with acute pulmonary embolism, has a higher mortality than the group without RV strain (Goldhaber et al. 1999). In larger studies thrombolysis in patients without right heart dysfunction showed no advantage in terms of endpoint mortality (Goldhaber et al. 1999; Wan et al. 2004). It is suggested that after rapid risk stratification, selected high-risk patients without hypotension and with low bleeding risk should receive thrombolytic therapy (ACCP recommendation grade IIB; Kearon et al. 2008). Patients without right heart dysfunction and stable hemodynamics have an excellent long-term prognosis following therapy with heparin only.

Analyses of mortality (approximately 4–6%) between unselected patient groups receiving

thrombolytic therapy versus heparin only revealed no significant difference in outcome (Konstantinides et al. 2002; Wan et al. 2004; Dong et al. 2006), but Konstantinides found a significant higher degree of clinical deterioration requiring secondary (rescue) thrombolysis in the heparin-only group. In patients with massive pulmonary embolism and hemodynamic instability, thrombolysis is associated with lower mortality rates than the heparin group (6.2% vs. 12.7%) but without statistical significance (Wan et al. 2004). It is accepted that randomized studies cannot be obtained. Therefore, although not verified, thrombolytic treatment has become a guideline-based standard of care. Whether thrombolytic therapy is effective for chronic thromboembolic pulmonary hypertension or for preventing its occurrence after acute pulmonary embolism remains unclear (Meneveau et al. 2003).

Interventional percutaneous techniques to reopen the central pulmonary arteries can be applied either in adjunct to ongoing thrombolysis or as an alternative to lytic therapy or surgical embolectomy when these measures are absolutely contraindicated. Various techniques are applied either for removal (i.e., Greenfield suction catheter) or fragmentation and dispersion of thromboemboli utilizing conventional or specially designed catheters. By fragmentation a greater contact area for the lytic agent is achieved (Uflacker et al. 1996, Uflacker 2004). Its application should be limited to the central arteries to avoid perforation and terminated as soon as hemodynamic improvement is attained. Hemodynamic improvement can be substantial and lifesaving, and various good results have been described, but definite evaluations in larger trials are pending (Greenfield et al. 1969; Kucher et al. 2005; Brady et al. 1991; Chamsuddin et al. 2008).

35.1.3.2 Indication for Pulmonary Embolectomy

Thrombolytic therapy is feasible in most hospitals and in every intensive care unit and has proven highly effective as an emergency treatment in patients with acute significant pulmonary embolism. Thus the role of surgery has long been modified to be offered to patients with absolute contraindications for thrombolytic therapy or, moreover, when no hemodynamic improvement in spite of is achieved. Thus surgical intervention is indicated for patients with massive or fulminant pulmonary embolism in the presence of:

- Massive right ventricular failure and absolute contraindication to thrombolytic therapy
- Hemodynamic instability and imminent circulatory failure in spite of ongoing thrombolytic treatment

Furthermore, patients with floating (transit) intracardial thrombi and/or patent foramen ovale should primarily be considered for surgical removal. In this group mortality is particularly high, 80–100% when left untreated. With thrombolytic therapy, mortality is still beyond 20% as the intracardiac thrombus does not always dissolve in situ, but may disperse and migrate to the pulmonary vascular bed (Chartier et al. 1999; Torbicki et al. 2003). However, aggressive interventionists see no contraindication in this constellation and have reported good results with low mortality (Rose et al. 2002). In the presence of a patent foramen ovale, hospital mortality is significantly higher (33% vs. 14%). Atrial shunts may be easily detected during the primary diagnostic procedures and the finding must be considered in the decision-making of therapy; especially in event of «paradoxical» emboli, morbidity and mortality are increased (Chartier et al. 1999; Konstantinides et al. 1998; Rose et al. 2002). Patients with subacute pulmonary embolism (older than 5–7 days), in whom the thromboembolic debris has migrated into the segmental arteries and systemic organization and break down of clot has begun, are poor candidates for embolectomy, as the removal of clot may be incomplete or impossible. Likewise, patients with recurrent pulmonary embolism superimposed on long-standing history of dyspnea and pulmonary hypertension should not undergo pulmonary embolectomy, but should be evaluated for pulmonary thromboendarterectomy.

In life-threatening situations, ongoing thrombolysis is no contraindication for surgical embolectomy. Likewise, immediate thrombolysis must be initiated in patients with apparent indication for embolectomy when surgery is delayed for logistic reasons.

35.1.3.3 Techniques of Pulmonary Embolectomy

Pulmonary embolectomy is performed via a median sternotomy. Rapid cannulation and institution of normothermic cardiopulmonary bypass

provide immediate restoration of systemic blood flow and oxygen supply to the tissues. It also provides excellent resuscitation in cardiogenic shock. Single atrial cannulation may be used, but separate caval cannulation with snares for total bypass may be necessary for exploration of intracardiac chambers (i.e., thrombi, patent foramen ovale) or when performing the Trendelenburg maneuver. Bicaval cannulation also avoids air block of the venous line after pulmonary artery incision. Cardiopulmonary bypass or extracorporeal membrane oxygenation systems may also be inserted via the femoral vessels either by surgical cutdown or percutaneously in patients under ongoing resuscitation. This may be instituted in the cath lab, in the intensive care unit, or at the outside hospital before transfer to the cardiac surgery unit. In certain patients—considered poor candidates for sternotomy and embolectomy—temporary use of peripheral cardiopulmonary bypass may maintain circulation and oxygenation under thrombolytic therapy (also bridge to recovery).

Aortic cross-clamping should be avoided to allow for restoration of right ventricular function. A 4 cm longitudinal main pulmonary arteriotomy is performed (■ Fig. 35.1). If required it may be extended into the concavity of the left pulmonary artery after blunt dissection of the pericardial flexion toward the hilum. In such cases one must be cautious not to incise upper lobe or lingular artery branches. Larger intraluminal embolic material is removed with broad forceps or a bile duct clamp, and peripheral smaller emboli may be removed by suction. Often the emboli are localized further distally blocking the orifices of the segmental arteries. They may be either disseminated smaller thromboemboli or just migrated distally through the pressure wave. The inspection of the peripheral vessels may be facilitated by routine use of loupes and headlight.

An additional incision may be required in the right pulmonary artery for better peripheral exposure of the right pulmonary vessels. This incision is placed in the right pulmonary artery reaching into the lung hilum after mobilization of the superior vena cava (see ► Sect. 35.2.4.2, «Operative Techniques», ■ Fig. 35.2). The removal of embolic material at the (sub)segmental level is usually not required, but can, if necessary, be accomplished with a fine coronary sucker or suction dissector. Inflating the lungs is helpful to mobilize peripheral thromboemboli. The original alternative approach to mobilize peripheral

emboli by manual compression and massage of lung tissue after opening the pleural space has been described, but is not advocated. This maneuver may be damaging to the lung tissue, entail atelectases, and provoke or aggravate a potential pulmonary reperfusion edema (Couves et al. 1973; Mahfood et al. 1988; Makey et al. 1971; Timby et al. 1990; Ward and Pearse 1989). The pulmonary incisions are closed with a double row of running polypropylene sutures (4/0–6/0 and small needles depending upon the thickness and consistence of the vessel wall). The right heart cavities are then explored via a small right atrial incision. If present, transit emboli are removed and a patent foramen ovale closed. Jakob et al. (1995) recommends compressing and milking out the lower limbs with an Esmarch wrap and subsequently compressing the abdomen with the inferior cava open and cannula temporarily removed. Thus, further venous thrombi are mobilized and recurrent embolization intraoperatively or early postoperative prevented. For these procedures obviously, bicaval cannulation is necessary.

Postoperatively a Doppler—or CT—examination of the venous system should be performed to identify potential thromboembolic threats and help decide whether the insertion of a filter device is indicated. The routine insertion of a cava filter postsurgery is debated but probably indicated. Under all circumstances, early heparin therapy is indicated after surgery with an overlapping start of oral anticoagulant treatment. This treatment can be discontinued after 3 months in patients with a first episode of pulmonary embolism and an identified reversible risk factor and after 6 months if venous thromboembolism is idiopathic. In patients with recurrent VTE or continuing risk factors, anticoagulation should be rather indefinite (Torbicki et al. 2008).

35.1.3.4 Results

Results of surgical embolectomy are poor. In an earlier analysis of pooled data from various reports, the mean operative mortality was 36% in 356 patients, varying between 20 and 44% (Iversen 1997). Most evidently, patients requiring resuscitation before surgery carry the highest risk with a reported mortality ranging from 47 to 74%. Patients with stable or stabilized circulation at time of surgery have significantly better chance of survival. If embolectomy was performed in patients with massive pulmonary embolism but

■ **Fig. 35.1** Longitudinal incision of the pulmonary artery in the main stem. Grasping and extraction of a large thromboembolus with a bile duct clamp. *Insert:* removal of peripheral embolic material by suction

absence of shock, mortality varied between 6 and 8% (Aklog et al. 2002; Leacche et al. 2005; Meneveau et al. 2006). Furthermore, patient age, duration of symptoms, and number of episodes of pulmonary embolism influence results. The wide range of mortality rates reported reflects the inhomogeneity of the investigated patients with the diagnosis massive or fulminant pulmonary embolism. It also reflects that the indication for pulmo-

nary embolectomy is set at different levels in different institutions. The primary goal of the operative procedure performed in an emergency situation on moribund patients is to prevent acute death from circulatory collapse. Any conventional statistical analysis of results does not apply in these situations. If the patient is already in shock, mortality will be high. Working against long odds, each single success will corroborate the method.

35.2 Chronic Thromboembolic Pulmonary Hypertension and Pulmonary Thromboendarterectomy

35.2.1 Clinical Presentation

Chronic pulmonary hypertension caused by pulmonary embolism is a rare disease. Approximately 4% of patients experiencing a pulmonary embolism develop pulmonary artery hypertension within 2 years after the embolic event (Pengo et al. 2004; Tapson and Humbert 2006).

It has been estimated that only 0.1% of all pulmonary embolism patients require surgery for chronic thromboembolic hypertension (Fedullo et al. 2000). Left untreated, the prognosis in these patients is poor and correlates with the degree of elevation in right ventricular afterload and pulmonary pressures. An older analysis showed that the 5-year survival rate was 30% when the mean pulmonary artery pressure exceeded 30 mmHg, and merely 10% at mean pressures was measured beyond 50 mmHg. On the contrary, if mean pulmonary artery pressures were found below 30 mmHg, the survival rate was nearly 90% (Riedel et al. 1982).

In general, pulmonary artery hypertension of various etiologies remains a chronic disease without definite cure. In spite of recent advances, medical treatment is at large a palliative therapeutic option (Bresser et al. 2006; Galiè et al. 2004; Ghofrani et al. 2003). The mortality of patients treated medically—dependent upon the degree of pulmonary artery pressure elevation—amounted to 31.5% at 18 months at the beginning of this century (Lewczuk et al. 2001). But modern drug therapy—today approximately ten different drugs are in use alone and in combinations—has managed to reduce mortality by 43% (Galiè et al. 2009).

Pulmonary thromboendarterectomy is a surgical desobliteration of the obstructed pulmonary artery vessels that has been established for pulmonary hypertension caused by chronic persistent or recurrent pulmonary embolism (Archibald et al. 1999; Daily et al. 1999; D'Armini et al. 2000; Iversen 1994; Jamieson et al. 2003). Thus, chronic thromboembolic pulmonary hypertension has become a surgically manageable form of pulmonary hypertension with the potential of curative treatment.

Symptoms in patients with pulmonary hypertension are mostly nonspecific, and the early course of the disease is insidious and correct diagnosis is often missed in the early stage. The most ostensible symptom is progressive dyspnea upon exertion—in advanced stages, signs of right heart failure, arterial hypoxemia, and cyanosis become evident. Up to two-third of patients with chronic thromboembolic pulmonary hypertension have no evident history of acute pulmonary embolism (Lang 2004). In the daily practice, there is much uncertainty, lack of knowledge, and controversial opinions in regard to indication for surgery, patient selection, and timing of surgery. Much too often, patients are referred to surgery in advanced stages as a last resort after years of misdiagnoses and/or palliative medical treatment (Auger et al. 1999; Riedel 2003; Thistlethwaite et al. 2002).

35.2.2 Pathophysiology

In acute pulmonary embolism, the intraluminal obstruction of the pulmonary vessels by fresh thromboemboli can be easily mobilized. In chronic pulmonary embolism, the thromboembolic mass has become organized, i.e., incorporated into the vascular intimal layer, altered into fibrous and elastic tissue, and endothelialized. The pulmonary arteries reveal characteristic features of intimal thickening, membranous occlusions, intraluminal webs and bands, and stenoses (Wagenvoort and Wagenvoort 1977). The central arteries may—but not obligatory—be filled with intraluminal appositional thrombi of various ages. Fundamental for the *progression* of pulmonary hypertension once established is the development of a *precapillary vasculopathy* mainly in the still perfused vascular bed. By mechanisms not yet clearly understood, probably by relative hyperperfusion, the small vessels restrict, undergo a media hypertrophy, and become sclerotic. In the end, the vascular pathology of chronic thromboembolic pulmonary hypertension presents as a mixed picture of mechanically obstruction at the stem, lobar, and (sub)segmental level which may be surgically removed and in the end stage an irreversible vasculopathy in the primarily nonobstructed vessels. The degree of small vessel vasculopathy significantly determines the surgical outcome (Galiè and Kim 2006; Moser and Bloor 1993; Timby et al. 1990; Yi et al. 2000). The degree of vascular

obstruction and the level of precapillary vasculopathy are individual, highly variable, and time dependent. Thus, the degree of pulmonary hypertension, the course of the disease, the patient's condition at time of diagnosis, and the angiographic findings are different in each case. The progression of vascular changes leads to a gradual increase of right ventricular afterload which at first is compensated by right ventricular hypertrophy, and cardiac output remains normal. With time, however, right ventricular dysfunction and failure become evident. The clinical condition worsens with parallel progressive hypoxemia due to reduced pulmonary gas exchange and decreased low cardiac output leading to global cardiopulmonary failure.

35.2.3 Diagnostics

All diagnostic procedures aim at establishing the correct diagnosis of thromboembolic pulmonary hypertension and stage of the disease, differentiating from other forms of pulmonary hypertension, and above all evaluating the possibility of and indication for surgical intervention.

35.2.3.1 Basic Diagnostic Procedures

The general diagnostic work-up in patients presenting with dyspnea on exertion must consider all differential diagnoses. ECG, chest x-ray examination, arterial blood gas analysis, and pulmonary function tests will help rule out other causes of dyspnea and focus on pulmonary hypertension. ECG may show right heart strain through axis deviation, a p-pulmonale, and specific changes of the QRST segment. X-ray findings in chronic thromboembolic pulmonary hypertension may be absent or discrete, but full and large pulmonary hili, right heart enlargement, and sparse, irregular, pulmonary, vascular markings with clear lung fields are suggestive. Signs of peripheral scarring from previous infarction may be seen. The arterial blood gas analysis may be normal or show a mild hypocapnia at normal oxygen value also in significant pulmonary hypertension. Hypercapnia is generally associated with obstructive or interstitial lung disease. A decline in oxygen level at rest occurs in advanced stages of pulmonary hypertension or becomes unmasked with exertion. Pulmonary function tests must be performed to rule out severe obstructive or fibrotic lung disease. The alveolar-arterial diffu-

sion capacity (diffusion lung capacity for carbon monoxide (DLCO)) is commonly found decreased, and 20% of the patients present with reduction of vital capacity below 80% due to parenchymal scarring. The pulmonary function is otherwise normal in the majority of patients (Fischer et al. 1995; Moser et al. 1990).

35.2.3.2 Cardiac Diagnostic

Transthoracic echocardiography will document right ventricular strain with hypertrophy and dilatation and the presence of pulmonary hypertension at rest. Ventricular contractility as well as valvular function of both cardiac chambers may be determined and rule out left ventricular dysfunction as a cause of pulmonary hypertension. There will be a variable degree of right atrial and ventricular dilation, tricuspid regurgitation, and a leftward shift of the interventricular septum. A progressive right and in later stages, also left ventricular dysfunction may be diagnosed. A pericardial effusion may be seen, and in many instances high right atrial pressures may reopen a previously closed interatrial communication and a patent foramen ovale may be demonstrated by contrast or color echocardiography (Menzel et al. 2000).

Invasive cardiac evaluation and coronary angiography are generally required in patients with chronic thromboembolic pulmonary hypertension, especially if the patient is more than 40 years old or in the presence of risk factors. Response to vasodilator therapy such as sildenafil or nitric oxide inhalation may be tested. Right heart catheterization is mandatory and must include recording of all right-sided pressures, determination of right and left side oxygen saturations, as well as cardiac output and calculation of pulmonary vascular resistance to assess the hemodynamic impairment. The correct measurement of pulmonary wedge pressure may be difficult to achieve if measured in a thrombotic obstructed vessel. Thus, repeated measurements at different sites or inclusion of LV end diastolic pressures may be necessary to correctly obtain pulmonary vascular resistance. Left ventricular catheterization and coronary angiography provide evidence of valvular and/or coronary heart disease and indicate whether concomitant surgery at time of pulmonary endarterectomy will be required.

Radioisotope ventilation and perfusion scan is helpful to establish the diagnosis of chronic thromboembolic pulmonary hypertension. The

typical mismatch found with a normal ventilation scan demonstrates segmental perfusion defects with high sensitivity and specificity, but may also highly underestimate its extent and localization of obstructions and therefore play only a minor role when assessing operability.

35.2.3.3 Radiologic Imaging

Pulmonary angiography in the form of digital subtraction angiography *combined* with multi-slice CT scan remains the «gold standard» for imaging of the pulmonary arteries and definition of the pathomorphologic anatomy. It will differentiate the chronic thromboembolic pulmonary hypertension from that of other etiologies, help determine the location of obstructions, and assess the surgical accessibility and thus technical operability.

Pulmonary angiography should be performed biplane with the advantage of a lateral view and with separate contrast injections of the left and right side. The investigation is safe also in patients with severe pulmonary hypertension when performed in an experienced setting. Characteristic angiographic findings may include various filling defects, abrupt vessel narrowing or cutoff, intimal irregularities with pouching, or intraluminal webs and bands, or the vessels will be completely thrombosed with total occlusion at the segmental level or of the larger branches (Auger et al. 1992).

Contrast-enhanced multi-slice chest CT is often used primarily in the imaging of patients presented for surgical evaluation. The fast acquisition of images in a single-breath technique is less invasive, advantageous, and safe in this often very sick patient group. CT findings consist of chronic thromboembolic material within the pulmonary arteries often lining the vessels eccentrically, enlargement of the central arteries, as well as variability in the distribution and size of peripheral pulmonary branches. Typically, in the parenchymal «window,» a mosaic pattern reflecting the inhomogeneous perfusion (along with underperfused areas with low attenuation) is seen. Chest CT scan will also reveal parenchymal defects from prior infarctions, concomitant fibrous or emphysematous lung disease, obstructing tumors, or mediastinal fibrosis. Contrast-enhanced thoracic CT alone will determine thromboembolic pulmonary hypertension in all patients and predict technical operability with a specificity of 77% and sensitivity of 100% (Bergin et al. 1996, 2000; Castañer et al. 2009;

Schwickert et al. 1994). The investigation is less precise at the segmental level and the diagnostic value limited (Auger et al. 1999; Bergin et al. 1997; Pitton et al. 2002).

The immaculate imaging of both central and distal pulmonary vasculatures is a *conditio sine qua non* because the exact location of chronic thromboembolic vascular changes and the prediction of possibility for surgical removal of obstructions and consecutive reduction of right ventricular afterload are crucial. Profound knowledge of the pathomorphologic changes of the pulmonary vasculature in chronic thromboembolic pulmonary hypertension is important to understand and correctly interprets the radiologic findings. Extensive thromboembolic masses and vascular changes centrally in the major pulmonary arteries are characterized mainly by a mechanical obstruction with sparse antegrade perfusion. The secondary small vessel disease and reactive hypertension may be expected to be less pronounced and the prospect of surgical success auspicious. Solely distally located thromboembolic obstructions are associated with a significantly higher operative mortality (Auger et al. 1999; McGoon et al. 2004; Oikonomou et al. 2004). Moreover, distal occlusions with time and in advanced stages of the disease coincide with a higher degree of secondary reactive vascular changes and progressive pulmonary hypertension. In cases with long-standing thromboembolic pulmonary hypertension over many years, the angiographic findings of thromboembolic obstruction may become discrete and do not correlate with the advanced elevation of pulmonary vascular resistance. With excessively elevated pulmonary vascular resistance and the presence of frank right heart failure, the operative risk will be very high and the patients finally become inoperable.

35.2.4 Surgical Indications and Operative Techniques

35.2.4.1 Indications and Patient Selection

Prerequisite for successful surgery is careful patient selection. All patients with the diagnosis of thromboembolic pulmonary hypertension should primarily be considered surgical candidates.

Pulmonary endarterectomy is indicated if *pulmonary vascular resistance* at rest exceeds 300 dyn·s·cm⁻⁵ (Daily et al. 1999; Iversen et al. 1992;

Jamieson et al. 1993, 2003; more recent literature does not add to current knowledge). A few patients may present with less elevated pulmonary vascular resistance although they have a complete central, but only one-sided, occlusion. They suffer from significant dyspnea upon exertion due to death space ventilation and also should be considered surgical candidates. Another subgroup of patients in the early course of the disease will reveal pathologically elevated pressures only during physical stress. Considering the chronic course with progression of pulmonary hypertension due to reactive vasculopathy, it seems expedient to offer early surgery to these patients in the absence of contraindications. A complete *restitutio ad integrum* is only possible with removal of the thromboembolic obstructions in the early stages of the disease. In advanced stages, however, pulmonary thromboendarterectomy may be too late because the progressive increase of pulmonary resistance is associated with a decrease of cardiac output. This condition has proven significant for both the surgical risk and the long-term success of the procedure (Iversen et al. 1992; Jamieson et al. 2003; Darteville et al. 2004; Corsico et al. 2008). Decision for surgical treatment is based upon the vascular obstructions deemed accessible for removal and a significant (i.e., >50%) reduction of right ventricular afterload predicted. The decision-making depends upon the accuracy of diagnostics and its interpretation and is strongly influenced by the experience of the surgical team (Bergin et al. 1996, 2000; Daily et al. 1989, 1999; Iversen et al. 1993; Jamieson et al. 1993, 2003; Darteville et al. 2004). In patients in whom the thromboembolic obstructions are mainly located in the central pulmonary vessels, surgery should always be performed, because a significant reduction in pulmonary vascular resistance can be expected. In turn, the solely peripheral manifestation of vascular changes combined with year-long-standing pulmonary hypertension and the presence of frank right heart failure are associated with high operative risk and deficient right ventricular afterload reduction. Between these two extremes, the variety in clinical stages and pathological findings is broad, and ultimately, the individual surgeon's expertise will determine when to operate which patient. In young patients, in particular, in whom the long-term prognosis with any alternate therapy already is highly limited, should

surgery—*in dubio pro operatione*—be offered after extensive and detailed patient information. More recently, excellent results were reported for distal chronic thromboembolic pulmonary hypertension patients also (D'Armini et al. 2014).

The presence of parenchymal lung disease is a strong *contraindication* for surgery, as this condition is associated with an increased postoperative morbidity and mortality due to respiratory failure.

Perivascular inflammatory reactions which may complicate or frankly render thromboembolism impossible must be expected after septic pulmonary emboli. In patients with subacute pulmonary embolism, surgery should be postponed for at least 3 months to allow for completion of the organization process of the thromboembolic material. Concomitant heart procedures such as myocardial revascularization or valve interventions can be performed simultaneously.

Pulmonary thromboendarterectomy is technically possible if thromboembolic vascular wall changes are identified at or proximal to the lobar arteries. With this criterion fulfilled, further peripherally located vascular changes are irrelevant. As a prerequisite of technical operability, the *surgical intimal dissection* must start centrally, but will then extend into the subsegmental arteries. Solely peripheral, i.e., at the (sub)segmental level located, thromboembolic vascular lesions are only marginally or non-accessible to desobliteration. Surgery limited to these segments carries the hazard of incomplete removal, inadequate decrease in pulmonary vascular resistance, and consecutive right heart failure postoperatively.

35.2.4.2 Operative Techniques

The desobliteration of pulmonary arteries in chronic thromboembolism is a true endarterectomy different from the techniques applied during embolectomy for acute pulmonary embolism. *The pathological intima must be extracted along with the intraluminal obstructions; the removal of intraluminal thrombi alone will not clear the underlying vascular obstructions.* The operative techniques developed by Pat O. Daily have only been slightly modified over the last 20 years (Daily et al. 1989; Iversen et al. 1993; Jamieson et al. 1993).

The surgical approach is via a median sternotomy with the use of extracorporeal circulation in deep hypothermia and periods of circulatory arrest. The heart is arrested with cardioplegia

before the first period of circulatory arrest. Some basic principles and tricks applied during the preparation of the procedure differ from the standard heart operation and will facilitate the exposure of the pulmonary arteries in the dorsal pericardium. The pleural cavities remain closed during the procedure. The pericardium is incised in a wing-door fashion by mobilizing the pericardial flexion around the great vessels and the rims fixed to the presternal tissue. The valves of the sternal retractor are placed underneath to span and elevate the pericardial sac. The superior caval vein is mobilized entirely up to the confluence of the hemiazygos vein hereby dissecting the adhesions between the right atrium and right pulmonary artery. This is followed by an incision of the pericardial flexion posterior and parallel to the phrenic nerve over the upper right pulmonary vein and the loose surrounding connecting tissue divided. Hence, the ventral aspect of the truncus, and anterior, main, and intermediate stem of the right pulmonary artery is exposed. It is recommended to perform this dissection before heparin administration; often dilated bronchial vessels, lymph channels and engorged veins embedded in fatty tissue are encountered, which demand subtle dissection and hemostasis. It is important to leave the adventitia of the pulmonary arteries intact and not dissect it, as the dilated artery wall will become quite thin and fragile after the endarterectomy. For the same reason, subsequently only the adventitial tissue but never the artery wall or rims of incision is grasped transmurally with forceps to avoid lesions and bleeding. Following administration of heparin, the arterial cannulation is carried out high in the ascending aorta or even in the arch to improve pulmonary artery exposure. Bicaaval cannulation with tape snares around both veins is obligatory for total venous return. Because of the often massive collateral blood flow in the pulmonary vessels via the bronchial arteries, vent catheters are placed both in the left ventricle over the left atrium and in the pulmonary artery trunk. Cooling of the patient is initiated immediately to a core temperature of 18 °C with temperatures measured both for core (rectal or vesical) and the brain (nasopharyngeal or tympanal). Cerebral protection is carried out under EEG monitoring and includes administration of barbiturates and prednisolone as well as additional topical cooling (ice-packs or cooling helmet). The endarterectomy is begun in the right pulmonary artery already

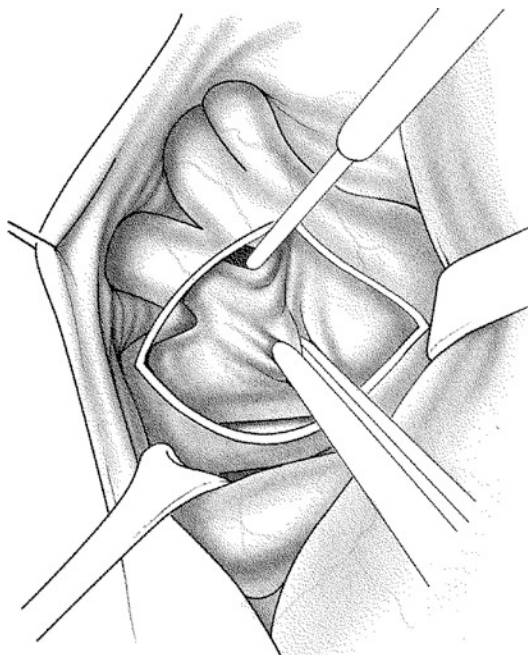

during cooling to save operative time because, from experience, most thrombotic material is found on the right side and the proximal sequence of endarterectomy may here be performed without the need of circulatory arrest. For this part of the procedure, it is advantageous for the surgeon to change to the left side of the table. The right pulmonary artery is exposed either lateral or medial to the superior vena cava by placing a small (blunt) self-retaining retractor (e.g., type cone); vision is facilitated using loupes and headlight. The incision is begun proximal to the truncus anterior and extended into the intermediate stem carefully avoiding the orifice of the middle lobar artery. Distally, the exposure may be improved by elevating the overlying upper pulmonary vein with a fine malleable (e.g., type «Marberger») vein retractor. After identification of the correct plane within the pulmonary wall (i.e., *lamina elastica interna*), the dissection is at first carried out circumferentially in the central pulmonary artery and then continued peripherally (■ Fig. 35.2). The intimal cast of each segmental branch is mobilized and extracted, and the successful endarterectomy extends to the subsegmental level beyond the obstructions where the intimal layer is thin and

■ Fig. 35.2 Anatomic view via median sternotomy: the adventitia and the media layer of the right pulmonary artery are incised from the level of the truncus anterior into the intermediate stem at a length of 5 cm without opening the intima. The intimal cast is circumferentially mobilized before the dissection is continued peripherally

nonobstructive (■ Fig. 35.3). This subtle anatomical dissection is considerably facilitated using specially constructed, slim suction dissectors (Daily et al. 1992).

In spite of these measures, accurate vision and precise endarterectomy are hindered by the presence of severe collateral blood flow via the bronchial arteries, and therefore, the peripheral desobliteration is best achieved in periods of either reduced flow of extracorporeal circulation or complete exsanguination of the pulmonary vessels in deep hypothermic circulatory arrest. After initiation of circulatory arrest, the lungs are repeatedly hyperinflated by the anesthetist and the patient's blood drained into the reservoir via the venous and vent lines. With increased surgical experience, circulatory arrest times exceeding 20 min for each lung side are rarely required. When longer arrest times are necessary, intermittent whole body reperfusion is recommended. If required, an additional incision may be made in the truncus anterior of the upper lobe when the obstructions are located peripherally and cannot be removed via the right pulmonary artery stem.

■ Fig. 35.3 The endarterectomy process continues circumferentially into each one of the segmental branches using a suction dissector. At this, the intimal cast is grabbed with vascular forceps and gently extracted. The reopening of a segmental area is characterized by brisk back bleeding of arterIALIZED collateral blood

Circulatory arrest and exsanguination are rarely required for desobliteration of the upper lobe segmental vessels. The incisions are closed with a double row of 6/0 Prolene running suture starting distally. It's advisable to use sutures with a small (CV) needle to minimize suture hole bleeding, and in the event of extreme fragile remnant pulmonary wall after endarterectomy, the area may be patched using autologous pericardium to relieve strain from the suture row.

The left pulmonary artery is then exposed by sharp and blunt dissection of the pericardial flexion and mobilization of the crossing left upper pulmonary vein. The preparation is carried out close to the vessels to avoid lesion to the phrenic nerve. The arteriotomy is made in the ventral aspect of the concavity into the pars basalis, avoiding the take-off of the lingual artery (■ Fig. 35.4). The incision extends to the level of the crossing upper lobe bronchus, with the intraluminal exposure being facilitated by stay sutures on both sides of the incision and by retraction of the pulmonary vein (e.g., Zenker retractor). The thromboembolic accretion and intimal changes on the left side are generally less distinct and often located in the lingual and lower lobe artery. Centrally the intima may appear normal, but may be elevated with the use of sharp intimal dissector. Endarterectomy is

■ Fig. 35.4 After mobilization of the pericardial flexion, the concavity of the left pulmonary artery is opened and the incision retracted with two stay sutures. The incision extends to the crossing upper lobe bronchus. The ostia of the upper lobe segmental arteries are visualized. Endarterectomy is begun by elevating the intimal layer with a sharp dissector

carried out as described and further distally intimal thickening and scarring become apparent. The specimen obtained after successful endarterectomy resembles a cast of the pulmonary vasculature with intimal layer thickened and scarred and the inner lumen membranous occluded or maybe with thrombotic debris in various stages of organization.

Rewarming of the patient is started during closing of the pulmonary incision as described above. During reperfusion a patent foramen ovale, present in 10–15% of the patients, is closed, the right heart chambers are inspected for thromboembolic material, and a severe tricuspid regurgitation is corrected (Daily et al. 1989). Even though the tricuspid regurgitation has been shown to alleviate after decrease of right ventricular afterload (Dittrich et al. 1989; Mayer et al. 1996; Menzel et al. 2000) and surgical correction thus seems superfluous, the often unstable hemodynamic situation in the early postoperative period is favorably enhanced by the competent valve function. In the presence of pure annular dilation, we prefer a fast and simple reduction anuloplasty (Kay et al. 1965; DeVega 1972; see ► Chapter «Surgery for Acquired AV-Valve Disease», Sect. 25.6.3) over the posterior leaflet, which adds no extension to the surgical procedure. The implantation of a ring prosthesis is hardly ever required.

35.2.5 Postoperative Treatment

The treatment of the patient in the ICU generally complies with the guidelines of postoperative cardiac surgical care. Patient monitoring, therapy for cardiac arrhythmias and cardiac low output, and management of coagulopathies and bleeding disorders follow the standardized regimens of heart surgery. There are certain specifics that need attention to secure the surgical result. *The main goals of ICU treatment are optimized right ventricular afterload and maintenance of adequate circulation, oxygenation, and diuresis.* In most patients, the reduction of right ventricular afterload after removal of pulmonary artery obstruction is associated with an immediate decrease of pulmonary artery pressure, an increase of cardiac output, and improved gas exchange and diuresis. However, residual pulmonary hypertension, postoperative pulmonary vasoconstriction, and development of reperfusion edema in the endarterectomized

areas of the lung caused by increased permeability, shift of perfusion pattern in the vascular regions, and hyperperfusion may entail right ventricular and/or pulmonary dysfunction and pose significant challenges. Thus, some patient will present with circulatory instability, metabolic disorders, and respiratory dysfunction immediately postsurgery.

35.2.5.1 Ventilator Therapy

Initially, the mechanical ventilation parameters are set at higher than normal minute volume to abolish metabolic acidosis after deep hypothermia, circulatory arrest, and prolonged extracorporeal circulation. A high tidal volume (at least 12 ml/kg BW) is chosen with a PEEP of 5–7 mmHg. Respiratory rate is adjusted to achieve an arterial pCO₂ in the low to mid thirties. *Hypercapnia is to be avoided.* This will counteract pulmonary fluid overload, atelectasis, intrapulmonary shunting, and pulmonary vasoconstriction. Besides securing oxygenation, it will also help improve the ventilation–perfusion ratio and thus pulmonary vascular resistance. Other potential negative effects of hypercapnia in these patients are the intracerebral vasodilation with increased intracranial pressure and cerebral edema, reduced myocardial contractility, and increased myocardial excitability with arrhythmia. Maximal inspiratory pressures on ventilation exceeding 30 mmHg should be avoided. The time on respiration is 24–36 h for the most patients, but is largely dependent upon the patient's fluid status. At times, prolonged ventilation is advisable until a significant fluid overload has been eliminated especially with significant residual pulmonary hypertension. It also may be required when outright pulmonary reperfusion edema is present.

35.2.5.2 Fluid Balance and Diuresis

Dependent upon the level of chronic right heart failure and congestion preoperatively as well as the unpredictable intraoperative fluid balance in patients undergoing circulatory arrest and prolonged bypass time, the danger of postoperative fluid overload is imminent. Accordingly, *subtle fluid monitoring and balancing along with securing diuresis are mandatory.* Fluid administration is restricted to a minimum. In most cases the postoperative hourly urine output is adequate due to the improved hemodynamics after reduction of pulmonary vascular resistance. Systemic hypotension

is well tolerated when cardiac output is increased, but aggressive diuresis should be sustained by maintaining a mean arterial pressure beyond 70 mmHg. Additional administration of furosemide is suggested to achieve an early negative fluid balance. Hematocrit is kept at values $>30\%$ also to improve oxygen transport capacity. These measures serve to obviate the development of pulmonary reperfusion edema. Total negative fluid balance before extubation must consider the preoperative status of the patient as well as the intraoperative balance and not solely depend upon postoperative fluid management, arterial blood gas analyses, and chest x-ray examination under mechanical ventilation.

35.2.5.3 Anticoagulation and Cava Filter

Patients undergoing pulmonary thromboendarterectomy remain on *lifelong anticoagulation regimen* to prevent recurrent pulmonary embolism or thrombus formation due to remnant obstructions in the pulmonary vessels. In the absence of bleeding, continuous intravenous heparin administration is begun 6 h postoperatively (initially in «low» dose—normal prothrombin time) and increased to therapeutic dose (PTT doubled to 60–80 s) on the first postoperative day. After mobilization on the normal ward, the overlapping therapy with oral anticoagulants is affected. Although debated in the literature, as hard data are difficult to obtain in this patient group, an inferior vena cava filter device is inserted before discharge, if it not had been placed preoperatively already. As various degrees of unresolved pulmonary artery hypertension will remain in some of the patients, the additional filter protection against recurrent embolism is prudent even in the absence of thrombophlebitis residue in the lower body. At the most, the exception would be the definite origin of thromboembolus in the upper body (e.g., pacemakers, port access devices, etc.) after exclusion of hereditary or acquired coagulopathies.

35.2.6 Results

The effectiveness of pulmonary thromboendarterectomy correlates with the degree of pulmonary vessel recanalization and presents with *an immediate decrease in pulmonary vascular resistance*. The immediate reduction of pulmonary artery pressures may be only moderate as long as

the reactive increase in cardiac output prevails, but it will further decline over time with regression of right ventricular hypertrophy (D'Armini et al. 2000; Iversen et al. 1992; Madini and Jamieson 2003; Mayer et al. 1996; Moser et al. 1987). In own material a reduction of pulmonary vascular resistance $>80\%$ (from mean 1045 to 194 dyn·s·cm⁻⁵) was found (Iversen et al. 1992). This complies with data reported from others (Daily et al. 1999; Moser et al. 1987; Tscholl et al. 2001; Mayer et al. 2011). The early relieve of right ventricular strain may also be confirmed by echocardiography (Dittrich et al. 1989). Normalization of right ventricular volume, decline in tricuspid regurgitation, and paradoxical septal movement can be seen already in the first postoperative days.

In the early postoperative period, the *pulmonary gas exchange remains impaired* and lags behind the hemodynamic convalescence. The arterial blood gas analysis may even show worse values compared to preoperative values and prolonged continuous oxygen supplement be necessary. However, oxygenation and gas exchange enhance with improvement of ventilation–perfusion ratio after absorption of pulmonary edema, resolution of pulmonary infiltrates, and normalization of pulmonary microcirculation (Kapitan et al. 1990). Accordingly, further decrease of pulmonary vascular resistance can be expected in the late postoperative course (Fadel et al. 2004; Hirsch et al. 1996; Iversen 1994; Moser et al. 1987). Final statements concerning the degree of circulatory and respiratory improvement after pulmonary thromboendarterectomy can thus not be made until 6–12 months postoperatively.

The attained operative results are generally sustained. *Long-term follow-up* reports reveal 6 years survival rate $>75\%$. The majority of the patients are classified into NYHA stage I or II (Archibald et al. 1999; D'Armini et al. 2000; Mayer et al. 1996). The procedure may be curative in individual patients, dependent upon the preoperative status, whereas in cases with incomplete surgical removal of peripherally located obstructions residual pulmonary hypertension, persistence of symptoms and compromised long-term prognosis may be expected in survivors. Also, a relapse in the clinical condition and progression of pulmonary hypertension after temporarily postoperative improvement are occasionally observed. Reasons may be rethrombosis in the pulmonary arteries due to inadequate anticoagulation or presence of severe coagulopathy, but in particular

due to progression of secondary vasculopathy in patients who presented to surgery at an advanced stage of the clinical course.

Repeat pulmonary thromboendarterectomy may be possible in highly selected patients. In our experience also corresponding with literature (Mo et al. 1999), reoperations are nearly exclusively limited to patients in whom the primary intervention was inadequate and incomplete. Such patients should better be reinvestigated and evaluated in an experienced high-volume center, and the indication for surgery is set on a case-to-case basis.

Albeit it's potential success, pulmonary thromboendarterectomy is associated with a high operative mortality. Main causes of death are respiratory failure due to reperfusion edema, cardiac failure as a result of persistent pulmonary hypertension, or a combination of these two complications. Perioperative morbidity is also high. In an international registry (Mayer et al. 2011), nearly every second patient suffered from one or more complications—e.g., pulmonary and other infections, persistent pulmonary hypertension, reperfusion edema, neurologic and bleeding complications, and pericardial effusion. Yet, operative risk has decreased significantly over the past 20 years due to increased experience in patient selection, operative techniques, and perioperative management. Published results from various centers indicate an operative mortality between 4.5 and 23.5% (D'Armini et al. 2000; Doyle et al. 2004; Hartz et al. 1996; Iversen 1994; Jamieson et al. 2003; Tscholl et al. 2001)—in the international registry, overall mortality amounted to 4.7% (Mayer et al. 2011). This wide range in results reflects not only the variable experience but rather also the diverse criteria in patient selection. Analyses of results reveal patient age, level, and duration of pulmonary hypertension at time of diagnosis as independent risk factors. There is a nearly linear relation between preoperative pulmonary vascular resistance and in-hospital mortality (Mayer et al. 2011). Thus, the operative risk will reach levels of 40% and above when patients in NYHA class IV and manifest right heart failure are accepted for surgery (Hartz et al. 1996; Iversen 1994; Tscholl et al. 2001).

35.2.7 Persistent Pulmonary Hypertension

The insufficient relief of pulmonary vascular resistance after pulmonary thromboendarterectomy is

a major and independent risk factor for in-hospital and 1-year mortality, and therefore the indication for surgery in patients with peripheral disease and high pulmonary vascular resistance remains controversial. Some authors propagate that all patients are operable but they show some reluctance in the presence of risk factors (Jamieson et al. 2003; Thistlethwaite et al. 2002). The definitely high operative risk in this patient subgroup must be evaluated in the light of limited alternative treatment modalities and life expectancy without attempted thromboendarterectomy. Surely, high pulmonary vascular resistance (exceeding 1500 dyn.s.cm⁻⁵) alone should not pose a contraindication to surgery, but the individual patient's findings rather be evaluated to predict outcome (accessibility, duration of pulmonary hypertension, and thus potential operative reduction of right ventricular afterload). For inoperable patients, bilateral lung transplantation may be an option when medical therapy fails. Due to limited donor organ availability, waiting-list pre-transplant mortality is as high as 30%. Posttransplant survival at 3 months and 1 year is merely 76% and 50%, respectively, in patients operated for idiopathic pulmonary hypertension. For patients surviving the first year, half-life survival is 9.5 years (Long et al. 2011; Christie et al. 2011). Thus, transplantation remains a palliative measure limited to inoperable patients, and no alternative to potentially curative pulmonary thromboendarterectomy.

36.1 Introduction

Lung transplantation is the established therapeutic option for all nonmalignant end stage lung diseases. The surgical technique is standardized and advances in perioperative and long-term patient management lead to improved results in long-term survival and quality of life. According to the International Society for Heart and Lung Transplantation (ISHLT) registry, there is a continuous increase in the number of procedures performed worldwide with meanwhile almost 4000 procedures reported annually (■ Fig. 36.1). This increase is due to a constant rise in bilateral lung transplants, whereas the number of single lung transplants shows a steady state. The number of combined heart-lung transplants is decreasing. This chapter mainly deals with the surgical and perioperative aspects of lung transplantation, whereas medical issues which are usually handled by pulmonary transplant physicians are only briefly mentioned.

36.2 Indications for Lung Transplantation

Virtually all non-malignant end stage lung diseases causing mono-organ failure are potential indications for lung transplantation (■ Table 36.1). A general prerequisite is a limited life expectancy due to the end stage lung disease, the failure of all other conservative and surgical treatment options and a continuous progression of the disease (De Meester et al. 2001).

A specific indication is the retransplantation due to acute or chronic graft failure which will be discussed separately.

The most frequent indication for lung transplantation still is chronic obstructive pulmonary disease (COPD) followed by idiopathic pulmonary fibrosis (IPF) and cystic fibrosis (CF). Other parenchymal and vascular lung diseases account for smaller percentages of transplantations performed worldwide. Lung transplantation for advanced lung cancer of a bronchioloalveolar growth pattern is not accepted by most centers due to the high recurrence rate (Machuca and

Cystic fibrosis	
Bronchiectasis	

Keshavjee 2012; de Perrot et al. 2004). However, incidental nodules or even verified early stage non-small cell lung cancer stage I do not necessarily pose a contraindication for lung transplantation and good outcome has been reported in carefully selected patients. Since the introduction of the lung allocation score (LAS), which prioritizes patients with a higher risk for mortality on the waiting list, a significant shift in the indication spectrum occurred with a steady increase in the number of procedures performed for IPF et al. (Pierson et al. 2000).

The decision for referral and listing for transplantation is not only based on functional criteria alone, but also takes the prognosis of the specific disease, the anticipated waiting list time and quality of life into account.

The functional parameters indicating the necessity for lung transplantation are as follows:
 COPD: FEV₁ <25 % predicted, pCO₂ >55 mmHg with or without subsequent pulmonary hypertension.

CF: FEV₁ <30 % predicted, increasing hospitalization time, cachexia, pO₂ <55 mmHg, pCO₂ >50 mmHg

IPF: Forced vital capacity (FVC) or Diffusing capacity of the lung for carbon monoxide (DLCO) <50 % predicted

Pulmonary hypertension: WHO functional class III or IV, cardiac index <2 l/min/m², right atrial

pressure >15 mmHg, mean pulmonary arterial pressure >55 mmHg (Orens et al. 2006).

The most commonly used age limit for lung transplantation is 65; however, the biological age rather than the actual age should guide the decision for waiting list acceptance.

36.3 Contraindications for Lung Transplantation

There are only few absolute contraindications for lung transplantation; however, a number of relative contraindications exist, which might vary from center to center according to different individual experiences and differences in the availability of donor organs. Absolute contraindications are: significant systemic diseases, severe extrapulmonary organ dysfunctions, recent malignancies, HIV infection, Hepatitis B or C, pan-resistant MRSA or *Burkholderia cepacia*, active nicotine, alcohol or drug abuse.

The large number of relative contraindications must be individually judged from case to case: osteoporosis, muscular or skeletal diseases, extreme cachexy or obesity, long time corticosteroid therapy, infection with mycobacteria, coronary disease or left ventricular dysfunction, significant peripheral vascular disease, renal insufficiency, mechanical ventilation, severe chest wall deformity and psychosocial instability.

36.4 Recipient Evaluation

Prior to accepting a patient on the waiting list, a complete medical workup is required. A list which might serve as an example for required examinations is shown in **Table 36.2**. Apart from these objective findings, the patient's clinical appearance and quality of life are major factors for the decision. If the patient is put on the waiting list, a physiotherapeutic training program is strongly recommended (Schwaiblmair et al. 1999).

The decision whether to list a patient for single (SLTX) or bilateral lung transplantation (BLTX) depends on various factors. In infectious diseases such as CF or bronchiectasis, bilateral transplantation is required to avoid cross infection of the transplanted organ. In COPD and IPF, single lung transplantation is possible; however, most available data report on favorable outcome for bilateral procedures. In pulmonary hypertension various approaches exist. Due to the shortage of donor organs, unilateral transplantation was suggested, which, however, has the significant disadvantage that almost the entire cardiac output is directed in the transplanted lung. This can be overcome by

Table 36.2 Recipient evaluation

Medical history and physical examination
Blood tests: routine laboratory examinations
Blood group
TSH, T4, T3, PTH, calcitonin, osteocalcin, Vit. D
HLA—typing, panel reactive antibodies (PRA)—lymphocytotoxic antibodies
Tuberculin test, virus serology: CMV (IgG/IgM), EBV, HIV, Hepatitis A, B, C
Chest X-ray, chest CT, lung function test, ventilation/perfusion scan
Sputum culture
ECG, echocardiography
Bone densitometry
Abdominal sonography
Disease specific: sinus x-ray, right cardiac catheter, coronary angiography, sonography of the carotid and vertebral arteries
Age >40 years: tumor markers, gynecologic examination, mammography, urologic examination
Additional examinations according to patient specific considerations

bilateral transplantation which is the standard approach for pulmonary vascular disease. Combined heart-lung transplantation is reserved for complex cardiac defect with Eisenmenger's syndrome. In simple atrial or ventricular septal defects, intraoperative repair during double lung transplantation on cardiopulmonary bypass (CPB) can usually be performed (Pielsticker 2001).

The necessity of a ventilator support or extracorporeal bridging device has long been considered a contraindication for lung transplantation. However, with refinements in the management and the introduction of new allocation algorithms, such as the lung allocation score (LAS), significantly improved outcome has been reported in the group of patients. The current strategy in patients requiring invasive support is to try to avoid intubation and keep the patient ambulatory with early implantation of an extracorporeal bridging device (Lang et al. 2012). By using this strategy the patient can be kept awake and in some cases even maintain physiotherapy to minimize amyotrophy. There are several bridging modalities available for different indications. The arteriovenous Novalung[®] is used for CO₂ removal (Camboni et al. 2009; Schmid et al. 2008; Strueber et al. 2009). Veno-venous extracorporeal membrane oxygenation (ECMO), which can be inserted with two separate cannulas or via a single double-lumen cannula (Avalon[®], iLA active[®]), offers additional oxygenation (Hayes et al. 2012; Garcia et al. 2011), although its main function remains CO₂ removal as first described by Gattinoni in 1980 as ECCO₂-R (Extracorporeal CO₂ removal, Gattinoni et al. 1980, 1986). Hemodynamic support with reduction of pulmonary arterial pressure is only provided by veno-arterial ECMO, which is the standard bridging tool in patients with pulmonary hypertension (Fuehner et al. 2012).

36.5 Legal Situation of Organ Donation

There are different legal regulations of organ donation. Three main forms of legislation can be described:

Presumed consent (e.g. Austria, Belgium, Luxemburg, Slovenia): Everyone diagnosed brain dead is a potential organ donor, unless registration in an opting-out register has been performed during lifetime.

Informed consent (e.g. Germany, Netherlands):

To be a potential organ donor, an informed consent has to be signed during their lifetime. Additionally there is the possibility for the relatives to give permission at the time of death, usually in the knowledge that the potential donor had expressed a wish to become a donor.

Required request (e.g. USA): The physician in charge of potential donors is required to ensure that someone speaks to the relatives about organ donation.

donors are categorized according to the Maastricht criteria in the controlled and uncontrolled. The majority of centers are using Maastricht category III controlled donors with result comparable to brain dead donors. One Spanish center has accumulated a substantial experience with uncontrolled DCD. The rate of primary graft dysfunction is higher than in other donor groups; however, long-term results are encouraging. With the development of ex vivo lung perfusion (EVLP), a powerful tool to evaluate DCD lungs has been introduced.

36.6 Donor Selection

36.6.1 Brain Dead Organ Donors

The lung is especially susceptible to bacterial infection or aspiration before brain death and organ procurement and is furthermore exposed to the trauma of mechanical ventilation; therefore potential donors have to be carefully evaluated.

When mechanically ventilated with a FiO_2 of 1.0 and positive end-expiratory pressure of 5 cm H_2O , a suitable allograft is characterized by a pO_2 of at least 300 mmHg. When ventilated with a FiO_2 of 0.4, pO_2 has to be above 120 mmHg. Concerning the acceptable donor age, different guidelines exist, though donors above 65 years are generally not accepted. The smoking history should be <20 pack-years. Chest radiography should be without any pathologic intrapulmonary findings. A chest trauma or in certain cases an infiltrate, if unilateral, does not preclude the donation of the unimpaired lung. Bronchoscopy is performed routinely prior to harvesting.

Besides those specific criteria the general preclusion criteria like malignant tumors, generalized infections, HIV infection and, in most cases, Hepatitis B and C apply.

The definite decision whether the organ is suitable for transplantation or not is made after retrieval and after inspection of the parenchyma and hilar structures.

36.6.2 Donation After Circulatory Death (DCD)

Donation after circulatory death has led to a significant increase in the available donor pool. DCD

36.6.3 Living Donation

Living lung donation was initially reported in 1994 and has been primarily used in pediatric CF recipients to overcome donor shortage (Cohen and Starnes 2001). Results are comparable and in some series even superior to brain dead donor grafts. Two adults, either the parents or close relatives serve as donor, each donating one lower lobe and a bilateral lobar transplantation is performed via clamshell incision using ECMO support. Access for harvesting the lobe is gained by anterolateral thoracotomy. No donor mortality has been described and 85% of the donors report about no difference in their health status since donation.

36.6.4 Ex Vivo Lung Perfusion (EVLP)

EVLP has emerged as a new option to increase the donor organ pool for lung transplantation. The first experience with EVLP was reported by the group in Lund, who used a blood-based perfusion solution for evaluation of a DCD lung. Thereafter EVLP was applied to repair and improve lungs which were not suitable for transplantation by conventional functional criteria. Several technical refinements have been made during the development process of EVLP with a complete paradigm shift from cold to normothermic perfusion. The first extended experience with EVLP was reported by the Toronto group, who used acellular Steen solution ([®]XVIVO, Gothenberg, Sweden) for prolonged perfusion periods of up to 12 h. From the same group derives the currently largest clinical experience, published in the NEJM in April 2011 with 23 EVLPs resulting in 20 transplantations during a 17-months observation period (Cypel

et al. 2011). We evaluated EVLP in a prospective clinical trial at 13 occasions resulting in nine transplantations with excellent short term results (Aigner et al. 2012). According to the current experience, EVLP is a valuable tool for evaluation and functional improvement of borderline donor lungs. However, it remains undetermined how far the limits for acceptance can be pushed by the use of EVLP. Furthermore, the potential of EVLP to recondition damaged lungs by counteracting the functional impairments caused by brain death has to be evaluated. Also still undetermined is whether the quality of procurement in standard donor lungs may be improved by routine EVLP.

36.7 Organ Procurement

Retrieval of the donor lungs is performed via a median sternotomy. The pericardium and both pleurae are opened and a first palpation and visual inspection of the lungs is performed. Compliance is checked by temporarily disconnecting the ventilator which should result in immediate collapse of the lungs. The superior and inferior caval veins are encircled and a suture around the superior vena cava is placed for later ligation. The aorta is separated from the pulmonary artery to allow aortic cross clamping. The donor is heparinized with 300 IE/kg intravenously. The pulmonary artery is cannulated and 500 mcg PGE1 is administered either intravenously or directly in the pulmonary artery. After the aorta is cross-clamped, the lungs are perfused with 6 l of perfusion solution via a cannula placed in the pulmonary artery. An extracellular high molecular dextran-based solution is the most widely used perfusion solution. After explantation of the donor heart, both lungs are retrieved en bloc while fully inflated. The lungs are separated at the backtable. After inspection of the hilar structures and the parenchyma, the lungs are stored in perfusion solution at an average temperature of +4–6 °C. An ischemic time of at least 6–8 h is usually tolerated.

36.8 Operative Techniques

36.8.1 Surgical Approach

The surgical approach for single lung transplantation is an anterolateral thoracotomy in either the

fourth or fifth intercostal space depending on the individual anatomical situation (■ Fig. 36.2). For double lung transplantation, access is gained either by bilateral transsternal anterior thoracotomy (■ Fig. 36.3), the so-called ‘clamshell incision’ (■ Fig. 36.4) or by two separate anterolateral

■ Fig. 36.2 Anterolateral thoracotomy

■ Fig. 36.3 Bilateral anterolateral thoracotomies

■ Fig. 36.4 Clamshell incision

■ Fig. 36.5 Positioning for bilateral transplantation

thoracotomies (■ Fig. 36.5). Sequential implantation of the lungs is the standard technique used worldwide in bilateral procedures.

Depending on the underlying disease and the patient's individual condition, the operation is performed with or without extracorporeal circulation. Cardiopulmonary bypass (CPB) is the most widespread device; however, extracorporeal membrane oxygenation (ECMO) can fully replace CPB and has distinct advantages such as avoiding full heparinization and the possibility to prolong the device directly in the postoperative period. Intraoperatively ECMO just does not directly accept blood suctioned from the surgical field. It is crucial that the entire team is familiar with all details in the management of the device in use to achieve satisfying outcome. The details are discussed in the ► Chapter «[Extracorporeal Circulation and Myocardial Protection in Adult Cardiac Surgery](#)», Sects. 6.1 and 6.3.

36.8.2 Standard Technique

The recipient pneumonectomy is begun after contralateral single lung ventilation is installed and the lung is collapsed. The hilar structures are prepared with attention to the conservation of the phrenic and vagus nerve, the pulmonary artery and veins are clamped and transected and the main bronchus is cut with a scalpel in an open fashion (■ Fig. 36.6).

Stay sutures are placed on the recipient's main bronchus to avoid retraction into the mediastinum. The left atrium and the pulmonary artery are prepared intrapericardially. The donor bronchus should be kept short with careful protection

■ Fig. 36.6 Right hilum after preparation for implantation

■ Fig. 36.7 Right donor lung prior to implantation

of the peribronchial tissue. For bronchial anastomoses the standard techniques are either a single running suture technique or a running suture on the membranous wall and single stitches on the anterior cartilaginous part. Thereafter the left atrium and the pulmonary artery are anastomosed with running suture technique. Occasionally a donor pericardial flap is interposed between the bronchus and the pulmonary artery. Now the air tightness of the bronchial anastomosis is checked. Endovascular de-airing is performed by retro- and antegrade flushing of the pulmonary vessels. Thereafter, the lungs are perfused in a controlled manner by partial manual compression of the pulmonary artery for 10 min to lower the risk of reperfusion edema if the procedure is performed without extracorporeal support. Finally, the chest is adequately drained and closed (■ Fig. 36.7).

In the case of double lung transplantation, the lungs are implanted sequentially.

36.8.3 Extracorporeal Support

Both single lung transplantation and bilateral lung transplantation can be performed without the use of any extracorporeal support in hemodynamically stable patients without significant pulmonary hypertension who tolerate single lung ventilation (Sherdan 1998). In bilateral transplantation the first implanted lung is consequently exposed to the entire cardiac output during implantation of the second lung, potentially leading to increased reperfusion injury. Therefore, some centers routinely employ CPB in BLTX (Szeto 2002). One paper even described a survival benefit for the use of CPB in emphysema patients with two Human leucocyte antigen-DR (HLA-DR) mismatches due to immunosuppressive effects (de Boer 2002). Due to the lack of prospective studies, no definite recommendations on the use of CPB are possible.

An established alternative to CPB is the use of ECMO. While CPB allows to save blood from the operating field, ECMO consists of a closed circuit without a reservoir and no recirculation of suctioned blood. The use of ECMO for bridging has already been discussed. The application in postoperative graft dysfunction is widespread as well (Meyers 2000; Nguyen 2000). The intraoperative use has been repeatedly described and it has been demonstrated that the veno-arterial ECMO can replace CPB intraoperatively with at least comparable results (Ko 2001; Aigner 2007). A distinct advantage of ECMO is the use of a low dose anticoagulation due to heparin bound cannulas which avoids full heparinization. Thus the blood turnover can be minimized while stable hemodynamics and oxygenation are provided during the implantation. A significant amount of the cardiac output is bypassed by the lung to allow optimal controlled reperfusion with the additional benefits of non-aggressive ventilation. The flow rate has to be set in a way to ensure a pulsatile pulmonary blood flow which can be monitored by the pulmonary artery pressure curve and the end-tidal CO₂. If the flow is too high the entire cardiac output is bypassed by the lung which then suffers from a warm ischemia. Intraoperative extracorporeal support can be provided either by central

or peripheral cannulation. Additionally the ECMO support can be directly prolonged into the postoperative period via femorofemoral cannulation providing controlled reperfusion with low perfusion pressures and the possibility for protective ventilation (Pereszlenyi 2002).

Generally patients with vascular lung diseases are always operated with the use of an extracorporeal support device to provide adequate hemodynamic support. Pediatric recipients and patient undergoing lobar transplantation are also transplanted on a veno-arterial device due to the reduced vascular bed to avoid an overflow of the first implanted lung. In other recipients the decision on the use of an extracorporeal device is based on clinical necessity.

36.9 Advanced Operative Techniques

36.9.1 Size-Reduced Lung Transplantation

Due to donor organ shortage it can be difficult to find suitable donor organs in due time especially for pediatric and small adult recipients. Therefore, options to downsize donor organs have been developed in order to allow for accepting oversized donors for these recipients. In cases of moderate size mismatch between donor and recipient, downsizing of the donor lung can be achieved by simple wedge resection. Especially middle lobe and lingula are preferred targets for this type of resection. In order to overcome more pronounced size discrepancies, lobar transplantation is an option. Basically any combination of lobes can be transplanted; however, a bronchial stump is at high risk of dehiscence, thus the combination of right upper and middle lobe should be avoided. Lobar transplantation can also be used for unexpected localized pathologies found during harvesting. The organ retrieval is performed in a standard fashion with the preparations of the lobes performed immediately prior to implantation (Aigner 2004).

Another technically challenging procedure which is performed only in few centers is the so-called 'split lung transplantation'. A left donor lung is separated in the upper and lower lobe and used for a bilateral procedure in a recipient with approximately 50% of the donor Total lung capacity

■ **Fig. 36.8** a Technique of split lung transplantation and b typical postoperative chest X-ray (From Marta et al. 2005. Used with permission)

(TLC). The lower lobe is implanted on the left side and the upper lobe is rotated 180° along the longitudinal axis and implanted on the right side (Couetil 1997). The technique is demonstrated in ■ Fig. 36.8. On the right side, the upper lobe bronchus is stapled and the intermediate bronchus is used for the anastomosis to allow sufficient length and improve size match. The atrial cuff is divided in the upper and lower lobe vein. The left donor pulmonary artery is stapled and the fissural aspect of the artery is splitted and used for the anastomosis.

36.9.2 Retransplantation

Retransplantation has been used for the treatment of acute and chronic graft failure refractory to other treatment options (Novick et al. 1992, 1998). Results of early retransplantation for primary graft dysfunction are disappointing and do not justify the use of donor organs for this indication. However, with retransplantation for patients with chronic lung allograft dysfunction without relevant comorbidity, results close to those of primary transplantation can be achieved (Aigner et al. 2008; Strueber 2006).

36.10 Peri- and Postoperative Management

After uneventful transplantation, early weaning and extubation should be favored, though extubation should not be rushed in patients transplanted for vascular lung disease. In order to avoid fluid

overload, infusions should be minimized and intravenous drips concentrated. Blood pressure is to be supported by catecholamines at low doses rather than by volume loading.

Physiotherapy is important for secretion clearance and should be started as early postoperatively as possible. Once the patient is extubated, early mobilization is crucial.

Routine bronchoscopies are performed immediately before extubation, usually on the first postoperative day. Surveillance bronchoscopies start 1 week postoperatively. Additional bronchoscopies are performed upon clinical necessity.

Usually patients can be discharged from the ICU 1 or 2 days after successful extubation.

Since wound healing is decelerated due to the high corticosteroid doses required, skin sutures and staples must not be removed before the 12th postoperative day. A lung function test and a computed tomography of the chest are performed before discharge of the patient.

After uneventful postoperative course, patients can usually be discharged 3 weeks postoperatively and will subsequently spend 4 weeks in a rehabilitation facility.

36.11 Immunosuppression

36.11.1 Introduction

Changes in immunosuppression and development of new drugs did substantially improve the results of lung transplantation. Data from the

ISHLT registry indicate that about 60 % patients after lung transplantation receive some type of induction therapy (20 % polyclonal anti-lymphocyte preparations, 40 % anti-IL2-antibodies, 4 % OKT3, 10 % Alemtuzumab). The induction therapy is used in the early postoperative period, when the risk of rejection is the highest. The aim is to decrease the incidence of acute rejections, which in lung transplantation is one of the highest among the solid organ transplantations.

For maintenance therapy most centers currently use a triple drug protocol consisting of either cyclosporine A or tacrolimus, corticosteroids and either azathioprine or mycophenolat mofetil. Additionally a number of new agents like sirolimus and the IL-2 receptor antagonists basiliximab and daclizumab have recently been developed and are tested in clinical trials. When obliterative bronchiolitis or bronchiolitis obliterans syndrome is diagnosed, augmentation and changes of maintenance immunosuppression are usually used in an attempt to slow the progression of the disease.

36.11.2 Cyclosporin A

Cyclosporine A (CSA): Was introduced into clinical practice in 1979 and is a specific inhibitor of IL-2 production in CD4+ cells. Oral bioavailability, which is highly bile-dependent, ranges from 10 % to 90 % and thus has to be monitored exactly. Most centers use through level monitoring. Drug interactions are described with various agents, e.g. rifampicin or phenytoin will cause a decrease in CSA level, while macrolide antibiotics, some calcium channel blockers, azole antifungals and grapefruit juice will increase blood levels. Initial dose, if renal function is unimpaired, is 2 mg/kg/24 h IV and adjusted to achieve a through level of 350–400 ng/ml in the beginning. The target level is gradually decreased, being 250 ng/ml after 1 year postoperative.

36.11.3 Tacrolimus

Tacrolimus (former FK 506): Was approved for clinical use in 1994 and is used as an alternative for CSA in double and triple drug regimen. The mechanism of action is similar to that of CSA,

though Tacrolimus is 10–100 times more potent than CSA. Oral bioavailability is poor (20–25 %), but completely independent of bile. Therapeutic drug monitoring is performed by through concentration measurement. Starting dosage is 0.01–0.03 mg/kg/24 h IV. Target level is 18–21 ng/ml initially and then gradually decreased, being 8–12 ng/ml after 1 year.

36.11.4 Mycophenolat Mofetil

Mycophenolat Mofetil (MMF): Inhibits both T and B cell proliferation by reversely and competitively inhibiting inosine monophosphate dehydrogenase. Bone marrow suppression occurs to a lesser extent than with azathioprine. Therapeutic drug monitoring is not routinely performed.

36.11.5 Prednisone

Prednisone: Corticosteroids were the first immunosuppressive drugs used in solid organ transplantation. They are non-specific anti-inflammatory agents that inhibit both humoral and cell-mediated immunity. Thus they are useful for prevention and treatment of rejection. There are various regimens to which corticosteroids are applied.

36.11.6 Sirolimus, Everolimus

Sirolimus and Everolimus: Were approved for clinical use in 1999. They reveal their properties by binding to the same FK—binding protein like tacrolimus. Sirolimus can be used in combination with both CSA and tacrolimus. The latter was discussed since both are binding to the same binding protein, but studies have demonstrated that these are ubiquitous available in vivo and thus competition for the receptor is unlikely. Oral bioavailability is poor (~15 %). Therapeutic levels are about 10–20 ng/ml when used with either CSA or tacrolimus. Because of the variability in bioavailability, therapeutic drug monitoring is required. These drugs are frequently used in case of compromised renal function. Their administration allows a reduction of calcineurin inhibitor levels which leads to reduced nephrotoxicity. Additionally a potent antiviral activity has been described.

36.11.7 Antithymocyte Globulins

Antithymocyte Globulins (*Thymoglobulin*[®] (rabbit ATG, Genzyme), *Atgam*[®] (equine ATG, Pfizer)): Is used as induction therapy as well as for treatment of steroid resistant acute rejection and to stabilize or delay bronchiolitis obliterans. Recommended dosage is 1,5 mg/kg/day for thymoglobulin[®] and 10–20 mg/kg/day for Atgam[®] for 3 up to 14 days.

36.11.8 Interleukin-2 Receptor Antagonists

Interleukin (IL-2) Receptor Antagonists (*Basiliximab*, *Daclizumab*): These are murine-human monoclonal antibody preparations. They are used for induction therapy and have improved side effect profiles and a lower incidence of immunogenicity compared to OKT3 (Muromonab-CD3). Longtime follow-up experience is still limited with these agents, though favorable short time results have been reported.

36.11.9 Alemtuzumab

More recently Alemtuzumab (Campath-1H; Berlex, Montville, NJ), a humanized rat monoclonal anti-CD52 antibody, has been used off label for induction therapy (Morris and Russell 2006; Shyu et al. 2011; van Loenhout et al. 2010). Even with one dose of 30 mg, prolonged lymphocyte depletion can be reached. CD52 is expressed on 95% of peripheral blood lymphocytes, natural killer cells, monocytes, macrophages and thymocytes. Monocytes and B cell recovery can be seen after 3 and 12 months, respectively, while T cells recover only to 50% after 36 months. It is a powerful cytolytic agent and has been used therapeutically in bone marrow transplantation, several autoimmune diseases and organ transplantation. Although it first had been used in organ transplantation in 1998 to prevent rejection, it is now being used with increasing frequency as induction therapy in many institutions. With the profound and prolonged lymphocyte depletion achieved with Alemtuzumab, most of these studies have utilized Alemtuzumab induction to facilitate a reduction in maintenance immunosuppression either with or without calcineurin inhibitors.

36.12 Management of Complications

36.12.1 Airway Complications

Postoperative airway complications are nowadays very rare due to improved anastomotic surgical techniques and preservation strategies. Problems could either be dehiscence, hardly seen in experienced centers, or bronchial stenosis, which typically occurs 2–6 months postoperatively due to granulation tissue ingrowth at the anastomotic site. Therapy of choice for the latter is balloon dilatation or insertion of a stent via rigid bronchoscopy. Granulation tissue can be removed via surgical or laser ablation (Colt et al. 1992).

36.12.2 Hyperacute Rejection

Due to careful evaluation, prior to transplantation and crossmatching between donor and recipient, hyperacute rejection is extremely rare. The most important differential diagnosis is post-ischemia-reperfusion injury. Preformed antibodies against HLA or ABO blood group donor antigens may cause a fulminant humoral reaction against the donor vascular endothelium minutes to hours after implantation of the graft. Subsequent thrombosis of blood vessels causes graft failure. Hyperacute rejection has an unfavorable prognosis concerning recipient survival.

36.12.3 Acute Rejection

Patients are most prone to acute rejection during the first six postoperative months. Acute rejection has a broad spectrum of clinical presentations—from completely asymptomatic patients to severe dyspnea, cough, fever or anorexia. Functional indicators are a decline in peak flow of 10–15% and a decrease in FEV₁ as well as in vital capacity, both having a high sensitivity. Specificity, however, is low since etiology can hardly be derived from functional impairment. Radiography is not infrequently unrevealing, though pleural effusions and perihilar or interstitial infiltrates may be indicators. Diagnosis is usually established by bronchoscopically gained transbronchial biopsy.

Severity of rejection is classified into four grades (A0–A4) according to the International Society for Heart and Lung Transplantation. Frequently acute rejection and infection occur together, so that an infection should be excluded or adequate therapy initiated before augmentation of immunosuppression. Main agent for the treatment of acute rejection is a 3-day course of high dose corticosteroids (7–15 mg/kg/day). If symptoms persist cytolytic therapy with antithymocyte globulins should be considered.

36.12.4 Chronic Rejection

Long-term survival after lung transplantation is still limited, mainly due to development of obliterative bronchiolitis. Its exact etiology remains unclear and many hypotheses exist for the pathophysiological genesis. While histological diagnosis is difficult, a clinical grading scale is used to determine the severity of bronchiolitis obliterans syndrome (BOS). After the most recent revision, the clinical severity is divided in five grades depending on the extent of airflow limitation (Estenne et al. 2002). Grades BOS 0 to BOS 3 are listed in ■ Table 36.3, where baseline is defined as the average of the two highest measurements—not necessarily consecutive—obtained at least 3 weeks apart. Incidence is as high as 40% of patients after 2 years (Radley-Smith et al. 1995) and 60–70% after 5 years (Heng et al. 1998). Recently the term «chronic lung allograft dysfunction» (CLAD) has been suggested since this incorporates also the restrictive form of lung allograft dysfunction which is observed in some patients (Verleden et al. 2011; Sato et al. 2011).

■ Table 36.3 Classification of bronchiolitis obliterans syndrome

BOS 0	FEV ₁ >90% of baseline and FEV _{25–75} >75% of baseline
BOS 0-p	FEV ₁ 81–90% of baseline and/or FEV _{25–75} <75% of baseline
BOS 1	FEV ₁ 66–80% of baseline
BOS 2	FEV ₁ 51–65% of baseline
BOS 3	FEV ₁ <50% of baseline

Risk factors include prior acute rejection episodes, especially late recurrent or refractory rejection, lymphocytic bronchitis or bronchiolitis, cytomegalovirus infections, insufficient immunosuppression, HLA mismatches and eventually airway ischemia. Symptoms are non-specific: patients usually report insidious dry or productive cough and dyspnea. Many different strategies are used for treatment including augmentation of immunosuppression, switching from CSA to tacrolimus or sirolimus, cytolytic therapy and photopheresis. Treatment usually slows but does not terminate functional decline (Sarahrudi et al. 2002). Another therapeutic option is retransplantation, which also might be performed for acute graft failure. While early results showed increased morbidity and mortality in comparison to initial transplantation (Novick et al. 1995), more recent data suggest that retransplantation outcomes are similar to those of primary transplantation (Strueber et al. 2006; Aigner et al. 2007).

36.12.5 Infection

As a side effect of immunosuppressive therapy, defense mechanisms are diminished and therefore infections are more likely to occur. Especially lung transplant recipients are prone to infections due to permanent exposure of the transplanted organ to the outside environment. In addition, impairment of both the cough reflex and mucociliary clearance facilitates susceptibility to infections.

Bacterial infections are the most common infections in the first two postoperative months. As prophylaxis all of our patients receive oral tazobactam 4.5 g three times daily and 800 mg/160 mg trimethoprim/sulfametrol orally three times a week initiated 2 weeks postoperatively. Additional antibiotics are given as necessary according to culture and sensitivity data. Fortunately less frequent but nevertheless important are mycobacterial infections, which are predisposed by chronic lung disease and immunosuppression, also. *Mycobacterium avium* complex is the most common in these infections.

Viral infections are almost exclusively caused by herpes group viruses, with cytomegalovirus (CMV) being the predominant source of infection. Infections may occur due to reactivation of the

virus or as primary infections mainly in the constellation of a CMV negative recipient who receives a graft from a CMV-positive donor. Symptoms are non-specific and are not infrequently accompanied by leukemia. Treatment of choice is currently ganciclovir or valganciclovir. Additionally patients may receive CMV hyperimmunoglobulin (IgM) 100 mg IV weekly for the first 4 weeks. All patients are routinely screened for CMV infection at every outpatient follow-up appointment.

Fungal infections occur mainly during the first 2 months after transplantation with *Aspergillus* species and *Candida* species being the predominant pathogens. Treatment of manifest infection is performed by administration of IV antifungal agents, according to the underlying subtype.

Protozoan infections, especially with *Pneumocystis carinii* or *Toxoplasma gondii* are usually prevented by lifelong administration of trimethoprim/sulfametrol (3 days per week).

36.12.6 Post-transplantation Malignancy

Due to immunosuppression the incidence of some neoplasms is higher in transplant patients than usual. Non Hodgkin lymphomas may appear 3–12 months after transplantation. Post-transplant lymphoproliferative disorder (PTLD) is associated with Epstein–Barr virus (EBV), with EBV-negative recipients being at higher risk. PTLD is commonly found in extranodal sites like the lungs, intestine or central nervous system. Therapy consists of a decrease in immunosuppression with additional chemotherapy or radiotherapy. Apart from PTLD the incidence of squamous cell cancer of the skin and lip, carcinoma of vulva and perineum, as well as the kidney and hepatobiliary tumors, are elevated.

36.13 Results

36.13.1 Mortality

Mortality on the waiting list varies widely from country to country depending on the individual legal situation. Eurotransplant reports about an overall mortality of 25% on the waiting list. In the USA the average waiting time differs depend-

ing on the size of the transplant center and has been significantly reduced since the introduction of the lung allocation score (LAS). Calculation of the LAS is based on formulas that take into account the statistical probability of a patient's survival in the next year without a transplant, how long that survival would be, the probability of survival following a transplant and the projected length of survival post-transplant. A raw allocation score based on these values is calculated and normalized to obtain the actual LAS, which has a range from 0 to 100. Recipients under 12 years of age automatically receive priority in organ allocation.

Survival statistics provided by the International Society for Heart and Lung Transplantation (ISHLT) report: 1-year, 3-year and 5-year survival rates of about 79%, 63% and 52%, respectively; however, there has been a significant rise in survival rates recently as shown in  Fig. 36.9. There is a difference in the survival rates in favor of double lung recipients versus single lung recipients, which diverges between the third and fourth year postoperatively. The survival benefit of transplantation versus medical therapy differs depending on the underlying disease.

36.13.2 Functional Outcome

After successful transplantation most patients experience a major improvement in functional capacity and report by the end of the first year about no restriction in activity. Six-minute walking tests are at least twice the preoperative value (Castleberry et al. 2015). A progressive rise in total lung capacity, FEV₁ and vital capacity is observed. Work capacity, tidal volumes and peak minute ventilation are not statistically different between single and double lung recipients (Schwaiblmair et al. 1998).

Quality of life is markedly improved after lung transplantation. Independence from oxygen insufflation with diminished dyspnea, improved sleep, improved mobility and energy to accomplish activities of everyday life all collude for improved quality of life. Three years after transplantation according to ISHLT, more than 40% of the patients are full- or part-time employed. Thereafter, with the development of bronchiolitis obliterans syndrome, this trend reverses, though most patients remain active for quite some time, despite the development of obliterative bronchiol-

■ **Fig. 36.9** Survival rates international (From: Yusen et al. (2014) ISHLT; used with permission)

itis. Another problem restricting long-term quality of life is the side effects of immunosuppressive medication.

36.14 Future Perspectives

Lung transplantation is now an established therapy option for advanced lung disease. Restricting factors are the limited availability of donor organs and limited long time survival after transplantation. Options for an increase of available donor organs are living related donations, especially for pediatric recipients and split lung transplantations, which are already performed in increasing numbers. Donation after circulatory death already had an impact on the number of available lung donors, and ex vivo lung perfusion holds a great potential for a further increase in the donation rates.

Refinements in organ procurement, lung preservation and immunosuppression will hopefully contribute to increased long-term survival rates. Research on induction of graft tolerance without

systemic immunosuppression is carried out and might hold potential for the future.

37.1 Heart Transplantation in Adults

37.1.1 History and State of the Art

The basic surgical technique behind the transplantation of organs, the suturing of blood vessels, was developed by Alexis Carrel, a French surgeon, at the beginning of the twentieth century. Together with Charles Guthrie, he described the first heterotopic heart transplant in ‘The Transplantation of Veins and Organs’ (Carrel and Guthrie 1905). In 1912 Carrel received the Nobel Prize in Medicine and Physiology for his groundbreaking research.

The next surgeon to experiment extensively with heart transplantation was Vladimir Demikhov, a Russian. By the 1940s, he had already developed an artificial heart and transplanted ‘piggyback’ hearts and heart–lungs in dogs. His most far-reaching achievement was a series of experiments in which canine hearts were successfully transplanted orthotopically, at a time when hypothermia had not been used and the equipment for successful extracorporeal circulation had not been invented.

In the 1950s, Norman Shumway and Richard Lower, heart surgeons at Stanford University, began publishing their experiments. It proved to be the beginning of a long list of important achievements. Key to their success was the use of topical hypothermia, which allowed the interruption of blood flow and adequate time to operate on the hearts. In 1960, they described their studies with orthotopic homotransplantations of canine hearts (Lower and Shumway 1960). In the following years, they improved and optimized their technique and management for orthotopic allotransplantation (Lower et al. 1962). The ‘Shumway technique’ is today still the preferred method for cardiac replacement (Lower et al. 1965).

On December 3, 1967, Christiaan Barnard used this technique to transplant the first human donor heart at the Groote Schuur Hospital in Cape Town, South Africa. The patient died of pneumonia on the eighteenth postoperative day (Barnard 1967). Three days after Barnard, surgeons at the Maimonides Medical Center in Brooklyn undertook the second human heart transplantation. Recipient was a 3-month-old infant who died the same day. One month later, Norman Shumway and his team undertook their

first human heart transplant. Within 2 years, more than 60 teams had transplanted hearts in some 150 patients (see also ► Chapter «The History of Cardiac Surgery», Sect. 1.12).

The leading European pioneer in this field was Christian Cabrol at the Pitié-Salpêtrière Hospital in Paris. He performed in 1968 the first heart transplantation in Europe.

At that time, the missing experience with the post-transplant immune reaction and the very limited variety of immunosuppressant drugs available (methylprednisolone, azathioprine, antilymphocyte globulin) resulted in 80 % 1-year mortality. The results were discouraging, and the number of heart transplants worldwide went down to 18 in 1970 (DiBardino 1999).

One of the few groups who continued was Norman Shumway’s group at Stanford University. His team developed techniques to determine and quantify rejection allowing them to tailor immunosuppression and to achieve 65 % 1-year survival. In 1980, they were the first to test cyclosporin A clinically and to incorporate its use into clinical practice after heart transplantation.

In the following decade, the improved outcome resulted in a second boom, reaching a peak in the mid-1990s with about 4,700 heart transplants per year. Subsequently, mainly due to the limited availability of donor hearts, the annual number began to level off and has reached in the last few years a steady state of about 4,000 to 4,500 cases (Lund et al. 2015).

37.1.2 Indication, Management of Candidates, Listing

Indication for cardiac transplantation is the significant, irreversible functional impairment of the heart despite maximal medical therapy.

The most common causes are either idiopathic dilated cardiomyopathy or ischemic cardiomyopathy caused by coronary artery disease. Less common are congenital heart disease, valvular heart disease or damage of the myocardium by conditions like amyloidosis or sarcoidosis. ■ Figure 37.1 gives the distribution of the current indications for heart transplantation worldwide between 2005 and 2010 (Lund et al. 2015).

An optimal management of potential cardiac transplant candidates is mandatory. It includes pharmacological and non-pharmacological

■ Fig. 37.1 Indications for heart transplantation in adults between 2009 and 2014 (Lund et al. 2015)

measures: The retention of body fluids results in peripheral edema and ascites which should be controlled by the application of diuretics. Chronic heart failure activates the neuroendocrine system of the body as a reaction to the malperfusion of the vital organs. The sympathetic nervous system, the renin–angiotensin–aldosterone system is activated. Vasopressin, cytokines and endothelin are released. Therefore, neurohormonal antagonists like ACE (angiotensin-converting enzyme) or ARB (angiotensin receptor blockers) should be used. Furthermore, β -blockers or aldosterone antagonists can be added (Jessup et al. 2006).

These pharmacologic measures should be accompanied by restriction of salt and fluid intake and regular exercises. Periodical examinations by a medical team experienced in heart failure treatment should be conducted, including semi-annual right heart catheterization to access pulmonary vascular resistance and to adjust medical treatment (Jessup et al. 2006).

If cardiac function further deteriorates, intravenous vasodilators are first choice options in medical management; in cases of hypoperfusion short term inotropic therapy can be used (Hübner et al. 2015; von Scheidt et al. 2016) If patients with cardiac failure of class NYHA (New York Heart Association) III or IV are refractory to medical treatment, urgent indication for heart transplantation is given. In

these cases, the temporary implantation of a mechanical circulatory assist device should be considered in order to prevent further deterioration of the clinical status and to improve renal and liver function. In cases of intermittently disabling tachycardia or cardiac dyssynchrony, cardiac re-synchronization therapy with an implantable cardioverter defibrillator should be used (Moss et al. 2002; Bardy et al. 2005; Gronda et al. 2006).

Elective transplant listing should be guided by evaluation of several parameters: Indication for transplantation is given if the maximal cardiopulmonary exercise test results in a peak oxygen consumption (Vo_2) <10 ml/kg/min; a peak Vo_2 between 10 and 14 ml/kg/min in combination with a major limitation to the activities of daily life can also be considered. In addition, the Heart Failure Survival Score (HFSS) may be used. The score is a predictive model calculated from seven prognostic variables including peak Vo_2 , left ventricular ejection fraction, serum sodium, mean blood pressure, heart rate at rest, non-specific intraventricular conduction delay and ischemic heart failure etiology. After calculation of the score, it can be grouped in risk strata: Low-risk strata are considered ≥ 8.10 , medium-risk strata 7.20–8.09 and high-risk strata <7.20 (Aaronson et al. 1997; Mehra et al. 2006).

Before listing for transplantation, patients should undergo a psychosocial assessment.

Evaluation should include their ability to comply with instructions, including drug therapy.

Possible co-morbidities must be carefully evaluated. Age over 70, pre-transplant body mass index (BMI) $>30 \text{ kg/m}^2$ and pre-existing neoplasms with a high risk of tumor recurrence are associated with poor outcome after transplantation. Diabetes with end-organ damage, irreversible renal dysfunction and severe symptomatic cerebrovascular disease should also be considered as relative contraindications for transplantation (Mehra et al. 2006).

Serial evaluations are essential for patients placed on the transplant waiting list. Assessment of heart failure stability should include echocardiogram and electrocardiogram as well as routine laboratory testing to evaluate multi-organ function. Right heart catheterization should be used to examine pulmonary pressures. Pulmonary hypertension should be challenged by vasodilators to determine whether it is fixed or reversible. Irreversible pulmonary artery hypertension is a relative contraindication to cardiac transplantation when the pulmonary vascular resistance (PVR) is >5 Wood units, the pulmonary vascular resistance index (PVRI) is >6 or the transpulmonary gradient (TPG) exceeds 16–20 mmHg (Mehra et al. 2006).

37.1.3 Organ Donation, Evaluation and Allocation

Organ donation rates vary significantly between the countries in Western Europe. While the Eurotransplant members Croatia, Austria and Belgium as well as Spain achieve donor rates per million inhabitants far above 20, Germany only reaches an annual quota of about 10–15 per million. Besides organizational variations, the major difference is how consent is regulated by law. Most countries have implemented donation rules based on presumed consent while Germany still relies on informed consent. The new German transplantation law, however, introduced several measures to improve donation rates (e.g. in house coordinators and regular education and information of the population) but did not alter the underlying informed consent (which is now called decisional consent) system.

In the United States, organ donation is also based on informed consent. Similar to other

countries with that type of legislation, the rate of consent for organ donation by next of kin is rather low. No more than 50% of those US families from whom donation is requested agree to donate. Nevertheless, the United States still achieve annually around 25 donors per million inhabitants.

The organ donation process itself is country specific organized by national organ procurement organizations. In Germany, this duty is contracted to the German Foundation Organ Transplantation (Deutsche Stiftung Organtransplantation, DSO). In the United States, more than 50 organ procurement organizations (OPOs) provide this service for the close to 300 transplant centers. The majority of these OPOs are private, nonprofit organizations, only a few are hospital based. Each OPO has a contiguous geographical service area designated by the Federal Government for recovering organs in all hospitals in that region (Nathan et al. 2003).

Even in countries with high donation rates, the shortage of post-mortem organ donors in general and especially of donors for thoracic organs represents the biggest challenge and limitation for heart transplantation. In addition to the lack of donors, the mean donor age is steadily increasing, further reducing the acceptance of potential heart grafts. Therefore, optimal donor management and improved evaluation and utilization of cardiac grafts are mandatory.

The care of brain-dead donors should involve cardiologists, pulmonologists, intensive care specialists and surgeons. Their goal should be optimization of the hemodynamic management, maintaining a neutral acid-base balance and correcting hormonal perturbations. Treatment with insulin, corticosteroids, triiodothyronine and arginine vasopressin as well as blood transfusions in cases of severe anemia might improve cardiac function (Novitzky et al. 1984; Zaroff et al. 2002).

Older donors (>55 years of age) can be used particularly for higher-risk or older recipients if other risk factors (left ventricular hypertrophy, ischemic time) are not significant. In donors aged 46–55 years, coronary angiography is recommended; older donors should have it routinely. Minor coronary plaques in angiography or elevated cardiac enzymes without the presence of other donor risk factors do not justify nonuse of a donor heart (Zaroff et al. 2002).

Heart grafts should be declined if there is echocardiographic and ECG evidence of substantial left ventricular hypertrophy, severe valvular or

congenital cardiac abnormality or if the expected cold ischemic time exceeds 6 h. The value of echocardiography to determine the physiological suitability of a donor heart is limited. Particularly younger hearts with left ventricular dysfunction can recover normal function over time (Zaroff et al. 2002).

A growing number of recipients are pre-sensitized mainly due to former blood transfusions or a previous transplantation. The pre-existing antibodies might result in antibody mediated rejection, either hyperacute or chronic, associated with hemodynamic compromise, increased graft loss and cardiac allograft vasculopathy. Solid-phase assays to determine antibody presence in the recipient have allowed for the development of a calculated panel-reactive antibody to avoid donors harboring the corresponding unacceptable antigens (Kobashigawa et al. 2011; Chang et al. 2012). Recently a portable warm blood perfusion system for donor hearts (organ care system) has been introduced. The machine maintains the heart in a functioning status outside of the body. The technology might allow to increase the time between explantation and implantation (allowing longer transport or recipient preparation times), to assess the function more thoroughly and to improve function or to enable resuscitation of the organ. Another perfusion system developed in Lund, Sweden, also revealed promising results (Steen et al. 2016). Further evaluation of the benefit of the systems, also considering the substantial costs for its use, is necessary.

In Germany as well as in currently six other European states, donor organs are allocated by the Eurotransplant International Foundation in Leiden, the Netherlands. Allocation guidelines are being continuously further developed by national authorities. In Germany, the German Medical Association determines the rules based on an organ-specific common waiting list and a patient-specific allocation system. While allocation regulations should consider urgency and success according to the German transplantation law, heart allocation is currently predominantly attributed to urgency. The vast majority of patients transplanted in Germany are therefore belonging to the so-called high-urgency status group.

In the United States, the United Network for Organ Sharing (UNOS), based in Richmond, VA, administers the national Organ Procurement and Transplantation Network (OPTN), in which each OPO is a member. The rules for organ allocation

are set by OPTN/UNOS. All patients waiting for an organ from a deceased donor are required to be placed in the common waiting list database; a computer algorithm for allocation of each type of organ matches donor and recipient. The current allocation algorithm prioritizes matching patients in the local OPO service area, followed by regional and then national candidates.

37.1.4 The Donor Operation

37.1.4.1 Donor Operation for Orthotopic Heart Transplantation Using Atrial Anastomoses (Lower et al. 1965)

Before starting the surgery to explant the donor heart, the matching blood groups of donor respectively recipient should be checked similar to procedures before blood transfusions. Due to the immaturity of the immune system of newborns and infants, ABO-incompatible transplantation may be an option in that age group. Low isohemagglutinin levels are a prerequisite (West et al. 2001).

After median sternotomy the pericardium opened. The heart is carefully inspected, particularly for possible signs of coronary artery disease. Contractility of both the right and the left ventricle is assessed. After the final decision to explant the organ is made, preparations begin: First, the ascending aorta is separated from the pulmonary trunk. The superior vena cava (SVC) is exposed all the way up to its junction with the azygos vein and the inferior vena cava (IVC) down into the diaphragm. The course of both the right and the left pulmonary veins is noted. Heparin (2.5–3.0 mg/kg i.v.) is administered. Next, the SCV is divided between two ligatures. The vessel should be divided up high, as close as possible to the azygos vein (■ Fig. 37.2). This minimizes possible damage to the sinus node. The ascending aorta is cross clamped proximal to the brachiocephalic trunk, after which the cardio-protective solution is inserted into the aortic root. The IVC is clamped directly at the diaphragmatic level and incised proximally in order to empty the right heart. An incision into one of the pulmonary veins empties the left heart. During infusion of cold cardioplegic solution, further cooling is achieved by filling the pericardium with ice-cold, normal saline solution.

■ **Fig. 37.2** Excision of the donor heart for orthotopic transplantation: The superior caval vein is separated between two ligatures; an aortic clamp is placed. The inferior caval vein is divided just above the diaphragm, the aorta distally to the cardioplegia site. Both pulmonary arteries and the pulmonary veins are cut directly at their pericardial entry site. The *dashed line* at the right atrial appendage displays the extended incision done prior to implantation

After the desired quantity of cardioplegic solution has been administered, the excision of the donor heart commences from caudal to cranial: First, the IVC is divided, followed by the left and the right pulmonary veins, a high transection of the ascending aorta and the pulmonary artery trunk near the bifurcation. The heart is then submerged in a bowl filled with ice-cold normal saline and prepared for final implantation: An incision is made in the right atrium in the direction of the right atrial appendage, starting at the IVC.

The interatrial septum is inspected. If a foramen ovale is discovered, it must be closed, in order to prevent right to left shunting early post-operatively. The left atrium is incised along a line connecting the orifices of the four pulmonary veins to each other. Finally, the ligature at the SVC is additionally secured by suture.

For long-distance transportation, the heart is packed into three plastic bags, each of which is filled with cold saline solution.

37.1.4.2 Donor Operation for Orthotopic Heart Transplantation Using Bicaaval Anastomoses (Dreyfus et al. 1991)

For bicaaval anastomoses, explantation of the donor heart has to be slightly modified. The harvesting must include segments of the superior and inferior vena cava as well as the four pulmonary veins. The tissue bridge between the superior and inferior pulmonary veins is then resected to create single left and right orifices.

■ **Fig. 37.3** Heterotopic heart transplantation: For preparation of implantation of the donor organ, inferior caval vein as well as the right pulmonary veins are closed with running sutures. The azygos vein and the superior caval vein are ligated. The incision of the right atrium is performed posterior in cranio-caudal direction

37.1.4.3 Donor Preparation for Heterotopic Transplantation

For heterotopic procedures the full length SVC is necessary. The azygos vein is therefore divided between two ligatures.

The final preparation again takes place while the explanted donor heart is kept in 4 °C normal saline: The two openings in the right pulmonary veins are closed by continuous 5–0 polypropylene sutures the same technique is applied to the IVC. Then the muscle bridge between the left upper and the left lower pulmonary vein is divided. This newly created opening in the left atrium should have the same diameter as the mitral valve orifice. Finally, the lateral wall of the SVC and the right atrium are incised; the ligated azygos vein serves as a reference point. The approximately 5-cm long incision should be placed in such a way that about half of its length includes the right atrial wall (■ Fig. 37.3).

37.1.4.4 Heart Preservation

The average ischemic time for donor hearts steadily increased over the last decade. The permissible maximum ischemic time of hearts is, however, much more limited than that of kidneys or livers. Therefore, adequate allograft preservation techniques are absolutely mandatory.

Preservation of cardiac allograft is based on a static cold flush with a crystalloid solution, suppressing metabolism and catabolic enzymes. Both intracellular and extracellular types (sodium content greater than or equal to 70 mmol/l) can be used. All commonly selected preservation solutions contain scavengers, energy substrates, buffers and substances to maintain osmotic pressure and prevent edema (Jacobs et al. 2010).

The University of Wisconsin (UW) solution was originally developed by Belzer and Southard in 1987 for preservation of the pancreas (Belzer and Southard 1988). The solution contains osmotic agents like lactobionate and raffinose as well as high potassium (120 mmol/l), resulting in a rapid cardiac arrest. While the solution seems to be superior for longer ischemic times, the potassium concentration might cause endothelial damage resulting in a higher incidence of graft vasculopathy (Kajihara et al. 2006).

An extracellular solution (sodium 100 mmol/l) is Celsior, which was developed in 1994 for hearts but is today the preferred solution for lungs (Menasche et al. 1994). The solution combines the buffer concept of HTK with the osmotic agents of UW (Maathius et al. 2007).

The only solution approved for preservation of donor hearts in Germany is the histidine–tryptophan–ketoglutarate (HTK) solution, which was developed by Bretschneider and coworkers in the 1970s. It is a low-potassium/high-volume solution (Bretschneider et al. 1975; Hölscher and Groenewoud 1991). In the United States, however, a variety of proprietary plegia solutions are utilized, of which the UW and Celsior are the most common.

37.1.5 Recipient Operation

37.1.5.1 Orthotopic Implantation of the Heart According to Lower and Shumway (1960)

A median sternotomy is done and the pericardium opened longitudinally. After administration of 2.5–3.0 mg/kg of heparin, tapes are passed around the SVC and IVC (■ Fig. 37.4). The ascending aorta is cannulated as close to the arch as possible. Venous return is achieved via two separate large cannulas which are inserted directly into both venae cavae.

■ Fig. 37.4 Excision of the recipient heart: The right atrium is excised at the crista terminalis. Beginning at the right atrial appendage, the incision is started cranially in direction of the aortic basis and caudally to the coronary sinus. The atrial septum is opened (*dashed line*), and the incision is again extended towards the aortic base and the coronary sinus. After transection of the aorta and the main pulmonary artery adjacent to their valves, the resection of the recipient's heart is continued along the wall of the left atrium, staying below the coronary sinus and the left atrial appendage

Cardiopulmonary bypass is commenced and the nasopharyngeal temperature lowered to 30 °C. Explantation of the recipient's own heart follows occlusion of tourniquets placed around the SVC and IVC: The ascending aorta is clamped proximally to the arterial cannula. The resection of the right atrium starts at the crista terminalis. The fossa ovalis is incised, emptying blood from the left atrium and ventricle. The resection of the recipient's heart is continued along the wall of the left atrium while keeping below the coronary sinus. The ascending aorta and the pulmonary artery trunk are divided midway.

The donor heart, with the right atrium facing anteriorly, is then placed in the recipient's pericardium to the left of the atrial remnants. Suturing begins at the level of the left upper pulmonary vein (■ Fig. 37.5). The anastomosis is continued clockwise and counterclockwise, using a single continuous technique with a double-armed 4–0 polypropylene suture. The stitches are kept tight and placed deeply. Both halves of the suture meet in the center of the atrial septum remnants and are then tied. A second suture commences at this

■ **Fig. 37.5** Implantation of the donor heart: The transplantation begins with the anastomosis of both left atria starting at the recipient's left upper pulmonary vein. The direction of the suture line is caudal and cranial and ends at the midpoint of the recipient's atrial septum

■ **Fig. 37.6** Both right atria are anastomosed with running sutures in a similar way as in ■ Fig. 37.5

point and is brought around the right atrium in a similar fashion (■ Fig. 37.6); de-airing of the right heart, after brief loosening of the IVC tourniquet, followed by tying.

Implantation of the heart is now completed by suturing the pulmonary artery and the aortic stumps (■ Fig. 37.7). For de-airing, the tourniquet around the IVC is loosened again briefly before tying the aortic suture line. The pump flow of the extracorporeal circulation is then reduced. At the same time the anesthetist inflates both lungs. By doing so, most of the remaining air within the

■ **Fig. 37.7** After adequate length adjustment, recipient and donor aortae are anastomosed end to end. Before the suture is finished, the heart is carefully de-aired through the aorta. Before, the main pulmonary arteries were also anastomosed to each other in the same fashion

pulmonary veins, left atrium and left ventricle will be removed, and the aortic suture line is tied. The left ventricular apex may be punctured for additional de-airing using a thick needle. It is however more important to allow for continuous de-airing at the site of the ascending aorta where continuous needle suction may be employed. The ascending aorta may be partially clamped distal to the de-airing needle.

Spontaneous ventricular rhythm usually resumes, but direct electrical shock may be required if ventricular fibrillation persists. 500-mg methylprednisolone is administered intravenously and rewarming to 35–37 °C commences. Temporary pacemaker wires are placed in the right atrial (on the donor side of the atrial anastomosis) and ventricular myocardium.

After approximately 30 min of reperfusion, extracorporeal circulation is slowly discontinued and the venous cannulas are removed. Protamine sulfate is administered in a quantity of 1.25 times greater than the amount of heparin previously given.

After circulatory stability has been achieved, the arterial cannula may also be removed. Before the chest is closed, drains are placed, one inferior to the heart in the pericardium and one posterior to the sternum in the anterior mediastinum.

Primary graft failure is a highly dangerous complication. It may be caused by persistent pulmonary hypertension; its treatment consists of intravenous prostaglandins. If biventricular failure persists in spite of adequate doses of catecholamines, the intraaortic balloon pump is introduced; thereafter heart function should improve within half an hour.

If one is still not able to discontinue the heart–lung machine support—and if the anesthetist has to increase the amount of catecholamines, especially adrenaline—the quick decision for the insertion of an extracorporeal membrane oxygenation system is life-saving, in our experience in about half of the cases. The circulation cannulas are then connected to the right atrium and the ascending aorta; heparin-coated lines should be used. The chest is then enclosed with a plastic patch which is attached to the skin using running suture.

37.1.5.2 Bicaval Anastomoses: Orthotopic Heart Transplantation (Dreyfus et al. 1991)

Bicaval anastomoses might generate an undisturbed flow within the right atrium, when compared with the original Lower and Shumway technique; bicaval connections are essential in patients with certain congenital cardiovascular lesions and their corrections. The Paris group described in their paper not only the end-to-end anastomosis of SVC respectively IVC but also the separate implantation of the left and the right pulmonary vein pairs—like for solitary lung transplantations.

Sarsam and coworkers modified in 1993 this original Dreyfus technique by leaving the pulmonary vein within the remnants of the left atrium as in classic orthotopic heart transplantation (Sarsam et al. 1993).

37.1.5.3 Heterotopic Implantation of the Heart

Nowadays, heterotopic techniques seem only rarely be indicated, like in patients with fixed pulmonary resistance of 6–8 Wood units. In these cases, the recipient's right heart is 'conditioned' and thereby supports the donor right side in the early postoperative course. Barnard and Losman introduced heterotopic heart transplantation in the 1970s in Cape Town, a technique which suited the South African circumstances in those days: long distances with only propeller-driven aircrafts available and therefore long ischemic times (Losman et al. 1977; Novitzky et al. 1985).

The operation begins in the same way as previously described for orthotopic heart transplantation (with the exception that the SVC cannula might be advanced via the right atrial appendage). A right-sided pericardial flap is then created by making two incisions at the

level of the SVC respectively IVC extended to a point approximately 2 cm anterior to the right phrenic nerve. This pericardial flap is laid over the hilum of the right lung and serves as a cradle for the donor heart. The transplanted organ will be located within the right chest and partially compresses the right middle and lower lobe of the lung.

After commencing extracorporeal circulation, the body temperature is cooled to 30 °C, the ascending aorta is cross clamped and the cardioplegic solution is infused into the recipient's heart. In addition ice-cold physiologic saline solution is applied topically. The donor heart is now placed in the right chest, the opening within the left atrium facing anteriorly (■ Fig. 37.8). This is followed by a longitudinal incision into the recipient's left atrium through the interatrial groove, as of for mitral valve surgery. Both left atria are connected to each other by a continuous suture line of double-armed 4–0 polypropylene. One half of the suture is laid clockwise, the other half counterclockwise, and finally tied at

■ Fig. 37.8 Heterotopic heart transplantation: On total cardiopulmonary bypass the recipient's left atrium is opened along the interatrial groove as for mitral valve surgery. With a running suture line, a broad anastomosis is performed with a combined opening of both the left pulmonary veins of the donor. The dashed line at the right atrium displays the incision for the right atrial anastomosis

the midpoint of the interatrial groove. As this anastomosis will be almost inaccessible later, absolute care must be taken that it is completely hemostatic.

Next, the two right atria are anastomosed. An incision in the lower lateral part of the recipient SCV and atrium is already made earlier in the procedure, before the left atrial anastomosis is done. The first stitch, with a 4–0 double-armed polypropylene suture, is directed from outside to inside at the most proximal part of the right atrial incision of the donor; it is then directed towards the mid-portion of a corresponding incision made in the recipient's SVC and atrium (■ Fig. 37.9). After tying, the anastomosis is continued in both directions until the two ends of the suture meet at a point directly opposite in front.

The right atrial diamond-shaped anastomosis as just described follows the original recommendation of Barnard. A modification suggests an even larger anastomotic area: The donor SVC is left open; an incision leads from its orifice into the

atrial appendage avoiding, however, the sinus node region. The two right atria are then combined.

The implantation continues with the aortic end-to-side anastomosis. It is important to leave the donor aorta as short as possible, in order to exert traction in an anterior and superior direction and facilitate a wide opening of the right and left atria. An adequate longitudinal incision into the recipient's ascending aorta is performed. It may be made in the most convenient area and should ideally be situated slightly to the right of the midline.

Finally, the two main pulmonary arteries are joined with the help of an adequate interposition Dacron graft (■ Fig. 37.10). The end-to-side anastomosis on the recipient side is performed first, proximal to the bifurcation. Then, an end-to-end anastomosis is constructed, joining the donor's main pulmonary artery to the Dacron tube. Occasionally, a Dacron graft can be avoided by anastomosing the donor's right pulmonary artery directly to the pulmonary artery of the recipient. Then the orifice of the donor's left pulmonary artery must be closed using a running suture.

Before both hearts are allowed to eject, air must be removed from both organs. This is done in the manner already described for orthotopic heart transplantation.

Extracorporeal circulation is discontinued and protamine given. After careful hemostasis has been achieved, three drains (one additional into

■ Fig. 37.9 The right atrial anastomosis is performed with a running suture starting at the midpoint of the recipient incision as shown in Fig. 37.8. The diamond-shaped anastomosis is then finished in a circular way like for the left atrium

■ Fig. 37.10 The donor aorta is anastomosed end to side to the ascending aorta of the recipient. The main pulmonary artery of the donor is then extended with a vascular prosthesis which is finally anastomosed end to side to the recipient's main pulmonary artery

the right chest) are inserted. It is also recommended that pairs of temporary epicardial pacing wires are placed onto each heart. Then, the chest is closed in a routine fashion.

The right-sided donor heart within the right pleural cavity impedes expansion of the middle and lower right lung lobes—a situation which is usually well tolerated. After heterotopic procedures, patients need heparin immediately followed by long-term coumadin in order to prevent thrombus formation within the left ventricular cavity of the recipient heart.

37.1.5.4 Transplantation in Patients with Mechanical Circulatory Support Devices

After implantation of a mechanical circulatory support device, severe adhesions must be expected. The adhesions are the result of foreign surfaces, in permanent non-physiological mode, with heat generation and chronic inflammations/infections. It is therefore safe to connect the patient to extracorporeal circulation first, utilizing the groin vessels; a long venous cannula may be advanced into the IVC. Later on, when the recipient heart and the great vessels are dissected out, only the SVC must be accessed for full venous return; venous tourniquets are snared.

If extremely severe adhesions are encountered, the SVC cannula may be introduced percutaneously via the right jugular vein.

The ascending aorta will then be cross clamped, allowing the surgeon to work on an open and empty heart, a step which greatly facilitates further dissections. Once the in- and outflow tubes of the assist system and the device itself are removed, this may take 2–3 h, the actual heart transplantation can begin.

At the end of the operation and with good control of bleeding sites, the remaining cavities of the previous assist system are also drained. In cases of local infections, irrigation lines are advisable as well as i.v. antibiotics according to bacterial cultures and their resistance profile.

37.1.5.5 Cardiac Re-transplantation

Acute or chronic rejection crises may necessitate re-transplantations. After orthotopic implantation of the heart, this operation differs little from other reoperations that form part of a cardiac surgeon's routine. However, following heterotopic operations, greater difficulties are encountered. Lung

adhesions, which have formed between the donor heart and the right lower lobe, present a great challenge. Multiple lung leaks are, therefore, not infrequent and pose a source of infection in an area of blood clots and extensive dissection. In order to make these procedures easier and safer, orthotopic replacement of the recipient's old heart is recommended, leaving the heterotopic donor heart untouched. As a result, the patient is left with two different donor hearts—a situation which is well tolerated. The two other possibilities—replacement of the rejected heterotopic heart or its removal followed by orthotopic transplantation—are not favored because of severe bleeding complications and a high risk of infection. The latter technique, changing from a heterotopic to an orthotopic situation, is especially unfortunate, since it creates an empty space previously filled by the donor heart. Decortication of the right lung would then be necessary (Novitzky et al. 1987).

37.2 Heart Transplantation in Neonates and Infants

37.2.1 Indications and Outcome

Terminal heart diseases necessitating transplantations at a younger age may be caused by systolic pump failure, most probably due to hereditary dilated cardiomyopathies or in the follow-up of valvular malformations at the aortic or atrioventricular level (Dipchard et al. 2015). Cases of myocarditis are a primary indication for left or biventricular assist devices; transplants seem to be only indicated after irreversible cardiac damage in spite of a lengthy treatment period. Bland–White–Garland syndrome or Kawasaki syndrome causing myocardial infarctions are rare. Patients with corrected transposition of the great vessels or those after atrial switch operations (Senning or Mustard procedure) have two ventricular chambers (see ► chapter «Congenitally Corrected Transposition and D-transposition of the Great Arteries», Sect. 19.2.5.1); the systemic ventricle is, however, the anatomical right one—and as such not suited for lifelong function to generate systemic pressures; severe systemic heart failure may be the result.

Morbus Ebstein and Uhl's disease (right ventricular dysplasia) are rare causes of isolated terminal right ventricular failure.

Endocardial fibroelastosis and diffuse, hypertrophic cardiomyopathy cause terminal diastolic pump disorders.

Different types of univentricular circulations may necessitate transplantations mostly during adolescence. This very complex group of congenital cardiac diseases comprises many lesions and includes tricuspid atresia, double inlet left ventricle, mitral/aortic atresia, respectively, hypoplasia (see ► Chapter «[Definite Palliation of Functional Single Ventricle](#)», Sect. 13.3).

The majority of patients just mentioned present after previous thoracic surgery, like bilateral Glenn anastomosis, various modifications of Fontan procedures including multistage palliations like Norwood operations (see ► chapter «[Surgery for Aortic Atresia, Hypoplastic Left Heart Syndrome, and Hypoplastic Left Heart Complex](#)», Sect. 17.6.2).

Transplant vasculopathy is also a limiting factor in pediatric cases, with an incidence of 2, 9 and 17% (after 1, 3 and 5 years), numbers which are much lower when compared with adult transplantation patients; new-onset terminal heart failure was seen in 1, 4 and 9% after 1, 5 and 9 years (Pahl et al. 2005). Re-transplantations are possible; their long-term results are, however, inferior, if compared with primary interventions (Chin et al. 2006).

This brief overview, which by far is not a complete compilation of possible indications (Rosenthal et al. 2004), proves that the rare pediatric cardiac transplantation should be reserved for those few centers who have experience in both cardiothoracic transplantation and surgical correction of congenital heart disease and their follow-up. Under these circumstances, follow-up results of pediatric cardiac transplantations are good and surpass those of adults (Groetzner et al. 2005; Ross et al. 2006).

37.2.2 Primary Orthotopic Heart Transplantation Technique Used for Hypoplastic Left Heart Syndrome (HLHS)

In 1985, L. Bailey and coworkers from Loma Linda performed the first transplants in neonates with hypoplastic left heart syndrome (Bailey et al. 1986).

A sternotomy is performed and the pericardium opened longitudinally. The thymus is almost completely removed. Thereafter, the aortic arch

branches are isolated and loosely taped. Heparin is given and the venous cannula inserted into the right atrium.

The arterial cannula is inserted via the distal main pulmonary artery through the patent ductus into the descending aorta and extracorporeal circulation is commenced immediately. A loose tape placed around the patent ductus is tightened after full bypass.

The recipient is now cooled to 18 °C. Bags of crushed ice around the head are additionally used to protect the brain. Deep hypothermic circulatory arrest is instituted and the patient's blood drained into the reservoir, both cannulas are removed. Before that, the supraaortic vessels were snared.

The excision of the heart commences at the level of the left and right atria, just above the AV valves. The main pulmonary artery is transected at the bifurcation, the patent ductus close to the descending aorta. On the side of the pulmonary artery, the ductus is ligated or suture closed. The diminutive ascending aorta is cut. The concavity of the aortic arch is incised, from the level of the brachiocephalic trunk to a point distal of the transected ductus.

The donor heart is removed as for routine harvest, with the exception that the full ascending aorta and the arch are retained. All aortic arch vessels are tied off, except for the brachiocephalic trunk through which cardioplegic solution is infused. The donor main pulmonary artery branches are transected separately, and one large opening is created by cutting the tissue bridge at the bifurcation.

Implantation of the donor heart is carried out with continuous 6 or 7–0 polypropylene sutures, beginning with the left and right atria, the original Shumway technique. The pulmonary artery anastomosis is facilitated by the relatively large donor vessel circumference created by joining the right and left main branches. The donor aorta is cut obliquely behind the brachiocephalic trunk in order to match the incision made in the aortic arch and isthmus of the recipient. After finishing the aortic anastomoses, extracorporeal circulation is reinstated by reinserting a venous cannula into the atrium; an aortic cannula is placed into the arch via the open brachiocephalic trunk. After air is evacuated, rewarming to 37 °C starts. Thereafter, bypass is discontinued and protamine given. Hemostasis is achieved, pacing wires and drains are inserted and the chest is closed.

While in the 1980s and early 1990s, neonatal cardiac transplantation was a viable alternative to

Norwood-type palliations for HLHS, nowadays primary choice for HLHS patients, is conventional Norwood surgery. It can be expected, however, that some of the Fontan children ('Stage III Norwood') will need transplantations in the future due to the fact that the univentricular (right) ventricle has to support the systemic circulation and may fail in addition to the shortcomings of a Fontan circulation.

37.2.3 Techniques of Heart Transplantation After Fontan Surgery for Single Ventricle

The ascending aorta or the femoral artery serve as arterial access, IVC (or extracardiac tunnel) and SVC (or innominate vein) as venous return. After commencing extracorporeal circulation, the ascending aorta is cross clamped and the venous return snared with tourniquets. The recipient heart and the great vessels are freed from adhesions which are usually severe due to multiple previous interventions (it would therefore be important to always reconstruct the precardial pericardium with a PTFE membrane (Gore-Tex®) at the end of each complex pediatric intervention before closing the chest—to facilitate future interventions).

A Glenn-anastomosis, atrio-pulmonary connections, respectively an extracardiac tunnel, both cranial and caudal of the right pulmonary artery branch, are taken down and their openings closed, preferably utilizing autologous pericardium. An extracardiac tunnel will be removed and the IVC transected.

The implantation follows the modified orthotopic technique by Sarsam and coworkers (1993) as described in ► Sect. 37.1.5.2, «Bicaval Anastomoses: Orthotopic Heart Transplantation (Dreyfus et al. 1991)». It is advisable to keep the SVC long (to a point where the anonymous vein merges).

Two additional vascular anomalies, may be worthwhile mentioning: A persistent left-sided SVC (without anonymous vein connection to the right side) and the transposition of the great arteries (TGA).

If the presence of a left-sided SVC is known in advance, the innominate (donor) vein may be dissected and left attached to the SVC; the innominate (donor) vein will later be anastomosed end to end to the (recipient) left superior caval vein.

Hemodynamically significant left-sided SVCs need an extra venous cannula for drainage.

In cases of TGA, the (donor) pulmonary artery trunk must be anastomosed to the left (recipient) pulmonary artery branch, the anastomosis augmented with an incised (autologous preferable) pericardial patch.

An unrestricted venous return is difficult to achieve in patients with situs inversus. The description of a case may serve as an example: dextrocardia with a univentricular heart (with hypoplastic left ventricle, ASD, VSD and mitral atresia) and TGA; during the previous Fontan intervention, the left-sided right atrial auricle was connected to the left pulmonary artery. An azygos drainage of the IVC complicated the situs inversus position of the SVC; hepatic veins drained into the atrium directly on the left.

The femoral artery served as arterial access; the lower part of the body was drained with a long cannula which was advanced from the femoral into the azygos vein. The anonymous and hepatic veins were further drained by two separate cannulas.

Cross clamping of the ascending aorta was followed by the removal of the dissected heart. The implantation started at the left atrial level, after rotating the donor organ counterclockwise by 30–45°; by doing so, an end-to-end anastomosis of the donor IVC and the connecting vessel of the hepatic veins became possible. Both recipient pulmonary artery branches were enlarged with an adequately trimmed (and partially incised) autologous pericardial patch, which was then connected with the donor pulmonary artery trunk. After the end-to-end anastomosis of both ascending aortic stumps, the confluence of the azygos drainage with the SVC was connected to the right atrium directly using a large-sized ring-stabilized Gore-Tex® prosthesis; alternatively a pulmonary or aortic homograft may have been chosen. The orifice of the donor SVC was finally oversown.

37.3 Heart–Lung Transplantation

37.3.1 History and State of the Art

The first attempts of combined heart and lung transplantation were reported by Cooley 1968 and Lillehei in 1969, respectively. In those times immunosuppressive therapy was crude, consisted of only corticosteroids and azathioprine, and therefore the results were disappointing. It was decided that

heart–lung transplantation techniques render no long-term results and have therefore no future. A decade later, however, Bruce Reitz from Stanford University proved in non-human primates the opposite, using cyclosporine A as primary immunosuppressive agent (Reitz et al. 1980). In 1981, he performed the first successful human heart–lung transplantation, and the 45-year-old female patient survived more than 4 years.

In 2014, according to the ISHLT statistics, less than 100 heart–lung transplantations were done worldwide. Congenital cardiac lesions with severe pulmonary hypertension were the main indication (Yusen et al. 2015; Goldfarb et al. 2015). In our own experience with 36 patients receiving combined heart and lung transplantations at the University of Munich Medical Center after 1996, 71 and 63% survived 1 and 10 years, compared with 50 and 28% of those treated between 1983 and 1996. Patients with congenital cardiac lesions were younger and lived longer: of those who were under 18 years of age at the time of the operation, 82 and 71% survived 1 and 10 years.

37.3.2 Indications

During the last decade, combined heart and lung procedures were indicated in fewer and fewer patients—this was due to the success of bilateral lung transplantations even in patients with moderate to severe primary pulmonary hypertension. Bilateral lung transplants were even successfully performed in patients with congenital cardiac malformations (and Eisenmenger reaction). Under these preconditions concomitant corrections of the heart lesions are necessary—a lengthy operation not without risks. In straightforward cases without previous interventions, it may therefore still be simpler and safer to decide for a combined transplant of both lungs and the heart.

In combined heart and lung transplantations in primary pulmonary hypertension patients, one may consider the ‘domino heart’ strategy whereby the non-malformed (right sided) hypertrophied (recipient) heart is transplanted into another person with somewhat elevated pulmonary artery pressure but otherwise acceptable pulmonary function (Yacoub et al. 1990).

Heart–lung transplants are indicated in NYHA class III–IV and IV patients with terminal double organ failure, mostly due to congeni-

tal heart diseases (and originally unrestricted pulmonary artery flow) causing Eisenmenger syndrome (extreme cases of pulmonary atresia without distal vessels are another, however, rare indication).

Under these circumstances the pulmonary artery pressure is at systemic level or above; concomitant severe tricuspid incompetence is present.

Echocardiography, x-ray, computer tomography, and magnet resonance techniques verify the diagnoses. Lung function tests reveal restrictive and obstructive lesions.

37.3.3 Evaluation of Donors for Combined Heart and Lung Transplantation

The cardiac function should be checked as described in paragraph ► Sect. 37.1.3, «[Organ Donation, Evaluation and Allocation](#)».

Special considerations include freedom from any pulmonary impairment or serious lung contusion. Careful attention is directed toward clearing pulmonary secretions with regular gentle aspiration via the endotracheal tube; retrieved aspirate is sent for culture and direct examination. The tracheal aspirate should not show gross contamination, particularly with candida. A bronchoscopy is always indicated to rule out severe (sometimes hidden) bronchial infection.

A size match is more important in combined heart–lung than in lung transplantation only. In order to match for size, measurements of the maximal thoracic diameters and the heights of the thoracic cavities are compared (■ Fig. 37.11). Ideally, the donor chest should be slightly smaller than that of the recipient to avoid postoperative atelectasis that would inevitably follow the inability of larger lungs to expand within a smaller chest cavity. Mismatches of up to 10% may be accepted. Too big lungs may produce severe impairment of cardiac function, once the chest will be closed. The only solution would then be an atypical lung resection or the removal of the left lower lobe.

Functional parameters include a peak inflation pressure on the respirator being less than 30-cm H₂O with a minute ventilation of 15 cc/kg at eight breaths per minute. Adequate gas exchange is mandatory, with an arterial oxygen tension of more than 100 mmHg on a FiO₂ of 0.4.

■ **Fig. 37.11** Thoracic diameters allowing a comparison between donor and recipient measures: 1 sternal length (jugulum to xiphoid), 2 thoracic aperture, 3 jugulum to acromion, 4 thoracic diameter at the height of the mammillae, 5 thoracic diameter at the height of the thoracic aperture

In a trial with the FiO_2 being increased to 1.0, the PO_2 should rise to more than 300 mmHg. Positive end-expiratory pressure of 3–5-cm H₂O is maintained to prevent atelectasis.

In recent years these just-describe ‘classic’ principles of pulmonary harvesting were successfully extended following the lead of Patterson and Cooper (1988) and Aigner et al. (2005). A history of smoking is no more important as are small lung damages, which can be excluded using stapler devices. The donor age is being increased continuously.

37.3.4 Donor Operation

After median sternotomy, the pericardium is cut longitudinally and resected on both sides down as far as the pulmonary veins, while both phrenic nerves are divided and the thymus gland is removed.

Heparin is now administered intravenously. The SVC and IVC are exposed, as well as the azygos vein; the latter vessel is doubly ligated and transected. Umbilical tape, passed around the ascending aorta, is used to pull the aorta away from the pulmonary trunk. Then the bifurcation, the right and the left pulmonary artery branches

are dissected; the arterial ligament is transected; on the right, the ascending aorta and SVC are freed of pulmonary artery tissue. Care must be taken not to damage the upper lobe pulmonary artery. Anterior traction on the aorta and the brachiocephalic trunk facilitates the exposure of the trachea which is located just distal to, and slightly to the right of the vessels. The trachea is freed, with care being taken to leave the peritracheal connective tissue intact as far as possible, especially 2 cm above the carina.

The SVC is then divided in between two ligatures. A straight vascular clamp is used to occlude the IVC which is then divided proximally. Once the right heart is decompressed, the ascending aorta is cross clamped as distal as possible. Ice-cold cardioplegia is given (see ► Sect. 37.1.3, «Organ Donation, Evaluation and Allocation»); the pulmonary protection with 4,000 ml LPD solution (Perfadex®; Müller et al. 1999) is started with added Tris buffer (0.5 ml/l).

It is recommended that 500-mg epoprostenol (Flolan®) is administered before infusing the Perfadex solution in order to dilate the pulmonary arterioles. The tip of the left atrial appendage is cut to decompress the left ventricle. A few liters of ice-cold saline solution are used for continuous external cooling.

Finally, the ascending aorta is divided immediately proximal to the brachiocephalic trunk. The lungs are inflated to about one third when the trachea is clamped 4 cm above the carina. With the clamp in place, the trachea is divided proximally. The clamp is pulled gently anterior by the assistant. The back walls of the trachea and of the main bronchi are dissected off the esophagus in a cranial to caudal direction. The remainder of the pericardium and the pleura are divided, as well as the right and the left pulmonary ligaments.

For transportation, the trachea is closed with a stapling device and the clamp removed. Thereafter the block of organs is secured in three plastic bags filled with ice-cold saline solution.

37.3.5 Organ Implantation in Combined Heart–Lung Transplantation (Reitz et al. 1980)

The operation commences with a median sternotomy. Then the whole frontal part of the pericardium is removed; right and left pleural cavities are opened widely. If pulmonary adhesions are present, it is advisable to divide them before heparinization. However, if significant cardiomegaly is present, it may not always be possible to reach all portions of the pulmonary surface, particularly at the apex and posteriorly. In cases with anticipation of severe pleural adhesions, instead of a median sternotomy, a transverse bilateral thoracotomy (within the fourth intercostal space) may therefore be extremely helpful; both mammary arteries will then be divided, the sternum split transversely.

Cannulation takes place as for orthotopic cardiac transplantation. With full flow on extracorporeal circulation, the venae cavae are snared and the ascending aorta is cross clamped. The heart is then excised at the atrial level. Attention is now turned to the left chest: A horizontal incision is made in the pericardium immediately anterior to the left pulmonary veins, posterior to the phrenic nerve, leaving as much distance from the left phrenic nerve as possible. This has the effect of preserving the phrenic nerve upon a pedicle of pericardium (■ Fig. 37.12).

A left-sided pneumonectomy is now performed (■ Fig. 37.13). In order to minimize bleeding from

■ Fig. 37.12 Left- and right-sided pericardial pedicle incorporating the left and right phrenic nerves. After the excision of the recipient's heart, the dorsal portions of the left and right atrial structures are exposed. Aorta and main pulmonary artery are transected. The excision of both lungs starts at the dorsal wall of the left atrium which is split in between the left respectively the right pulmonary pair of veins.

■ Fig. 37.13 The left lung is completely removed after dividing the main bronchus between two stapler lines and transecting the pulmonary artery

dissected areas, electrocautery is used wherever possible. The right and left pulmonary vein pairs are separated with a vertical incision through to the oblique sinus. Two mosquito clamps, attached to the posterior part of the veins, are gently pulled laterally, and this facilitates separation of the pulmonary veins from the tissue of the posterior mediastinum. Care must be taken not to damage both vagus nerves which follow the esophagus. The pulmonary arteries are divided. A cuff of the vessel

is left in the area of the arterial ligament, in order to avoid injury to the left recurrent laryngeal nerve. After division of the pulmonary ligament and dissection of the posterior pleural reflection, the left lung remains attached only by the left main bronchus. It is our practice to staple the bronchus proximally to reduce the possibility of contamination of the chest. The left lung is now lifted out of its pleural cavity.

The left-sided pneumonectomy may be complicated if a hemodynamically significant left persistent SVC is present. Whenever that structure drains into the coronary sinus, it should be separated from both the left atrium and ventricle. The left SVC is then cannulated separately. Connection to the right donor atrium is made simple if one leaves the donor innominate vein long; reconstitution of the venous drainage is then achieved by end-to-end anastomosis.

Attention is now turned to the right lung. Here also, the pericardium is incised above the right-sided pulmonary veins. Extra care must be taken as the right phrenic nerve lies closer to the hilum of the lung than on the left. An incision is now made in the left atrium from the right side, in the interatrial groove, as for mitral valve replacement. This has the effect of separating the right pulmonary veins from the right atrium. The main pulmonary artery is separated from the ascending aorta and the SVC, in order to allow it to be pulled into the right pleural cavity. The right main bronchus is dissected and divided, as described for the left side, and the right lung is removed.

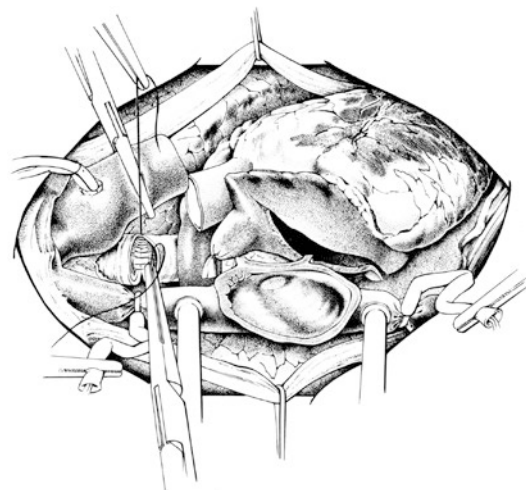

Finally, the trachea and the carina are exposed to the right of the ascending aorta (■ Fig. 37.14). As much peritracheal connective tissue as possible should be preserved to avoid interruption of the vascular supply. The trachea is then transected at the level of the carina and left open; the remnants of the distal carina and of the right and left bronchial stumps are removed.

Prior to the implantation of the donor organ block, the mediastinal structures are again inspected thoroughly for bleeding; it is difficult to approach these areas at a later stage.

After removal of the tracheal stapler line, the donor organs are placed in the recipient thorax (■ Fig. 37.15). The left lung is gently squeezed through the left-sided pericardial window and underneath the left phrenic nerve. The right lung is pushed underneath the right atrium and both cavae and pulled through into the right chest.

■ Fig. 37.14 Situs after complete removal of the recipient's heart and lungs. The trachea is seen below the ascending aorta, and it is cut just above the carina

■ Fig. 37.15 Insertion of the donor organ block into the chest: The left lung is pushed behind the phrenic pedicle into the left thoracic cavity. The right lung is pushed behind the right atrium and both cavae into the right chest. The implantation starts with the end-to-end tracheal anastomosis, and the dorsal part of the anastomosis is displayed

Suturing commences: First, the donor trachea is connected end to end to the recipient trachea by a single continuous suture of 4-0 polypropylene. The recipient trachea is commonly larger than the donor counterpart; the lumina are matched along the pars membranacea.

When the anastomosis is complete, it is checked under water for air tightness. Biological glue may be applied additionally as an unproven safety feature. Finally, the area is covered with surrounding connective tissue.

■ **Fig. 37.16** Start of the right atrial suture line: The incision within the right donor atrium was performed according to the orthotopic cardiac transplantation technique. Both aortic ends are displayed open. The aortic anastomosis is the last of the three anastomoses in heart and lung transplantation. The open left atrial appendix is suture closed

Now right atrial and aortic anastomoses follow, as in orthotopic transplantation. The open left atrial appendix is suture closed (■ Fig. 37.16). After de-airing via the left ventricular apex and the ascending aorta, the aortic clamp is released and the coronaries are perfused again. Secure hemostasis is achieved. This may be a long and tedious task, especially after previous thoracic surgeries. Pacemaker leads are implanted. Two drains are placed in each pleural cavity—one in the phrenicocostal sinus, one in the apex. The chest is then closed in a routine fashion.

37.3.6 Reoperation After Heart–Lung Transplantation

Chronic obliterative bronchiolitis may necessitate repeat transplantation. Isolated right-sided pulmonary transplantation is a reasonable option, under these conditions—especially if there is good cardiac function.

37.4 Postoperative Care

37.4.1 Rejection

Hyperacute allograft rejection by preformed recipient antibodies occurs within minutes after graft

reperfusion but is only observed in very rare cases. *Acute* cellular rejection is, however, more common, particularly in the first 6 months after heart transplantation. *Antibody-mediated* rejection, also known as *vascular humoral* rejection, might be found in conjunction with acute cellular rejection in patients with hemodynamic instability.

As introduced by Caves, the standard for detection of cardiac rejection in adult patients is periodic endomyocardial biopsy (Caves et al. 1974), at least during the first postoperative year. The myocardial tissue samples are stained and histologically classified according to the heart allograft rejection grading system (Stewart et al. 2005), which was developed based on the pioneering work of Margaret Billingham (1981). For detection of antibody-mediated rejection, evaluation by immunofluorescence for deposits of immunoglobulins and complement should be performed.

Noninvasive monitoring using electrocardiogram, echocardiography and magnetic resonance imaging as well as biochemical and inflammatory markers like B-type natriuretic peptide, troponin I or T or CRP are not very reliable as the primary methods for acute heart rejection surveillance (Taylor et al. 2012).

Recently, the predictive value of gene expression profiling (Allomap) has been assessed in several trials. So far, it only proved to be useful for ruling out higher-grade acute cellular rejection episodes in low-risk patients 6 months after transplantation (Taylor et al. 2012). After heart-lung transplantation, acute lung rejection may commence earlier (fifth post-operative day) than acute heart rejection (seventh post-operative day). For diagnostic tools see ► chapter «Lung Transplantation», Sect. 36.12.3.

The first-line therapy for higher-grade and/or symptomatic acute cellular rejection is methylprednisolone, 1,000 mg daily given for three consecutive days. If the clinical situation does not improve, control biopsy does not show resolution of histological changes or if hemodynamic compromise is present, antithymocyte antibodies should be administered additionally (Taylor et al. 2012). Furthermore, maintenance immunosuppression might need adjustment.

37.4.2 Immunosuppression

With the routine use of *cyclosporine A* in the mid-1980s, immunosuppression after heart

transplantation followed a standard protocol: a triple drug regimen consisting of cyclosporine, azathioprine and steroids with or without antibody induction therapy. In the meantime intensive pharmacological research has produced a number of new agents with a variety of immunosuppressive actions.

37.4.2.1 Induction Therapy

The benefits of antibody induction therapy in the initial phase after heart- and heart-lung transplantation are discussed controversially. The application of mono- or polyclonal antibodies enables a gentler, less nephrotoxic initiation of calcineurin inhibitor therapy and prevents rejection in the early postoperative period. This, however, may lead to short- and long-term adverse effects possibly associated with induction therapy and therefore may be over all disadvantageous.

To date, roughly 50% of centers use initial antibody induction therapy (Lund et al. 2015), and the variety of therapy schedules used has been steadily increasing with the number of antibody preparations available.

The traditionally used polyclonal antithymocyte globulin preparations (ATG Fresenius[®], ATGAM[®]) induce dose-dependent T-cell depletion in blood and peripheral lymphoid tissues. While their use seems to decrease rejection incidence when compared to no induction (Carrier et al. 1999), they have the disadvantage of being generated in animals (rabbit, horse), causing a subsequent anti-antibody response by the human recipient.

In order to avoid drug clearance and serum sickness, a chimeric (30% murine and 70% human protein) monoclonal anti-interleukin-2 (IL-2) antibody preparation has been developed. Basiliximab[®] has been studied in several heart transplant trials. Comparison of the IL-2 receptor antagonist either with no induction or with thymoglobulin induction did not reveal significant rejection or survival benefit (Aliabadi et al. 2011).

In summary, the question whether induction therapy is beneficial for patients after heart transplantation has not been solved, yet. There is, however, evidence that specific patient groups, particularly sensitized patients with circulating preformed antibodies (Kobashigawa et al. 2009) and patients with severe renal dysfunction pre- and perioperatively (Cantarovich et al. 2004), seem to benefit from thymoglobulin induction.

37.4.2.2 Maintenance Immunosuppression

Long-term immunosuppression after heart transplantation is still based on the use of calcineurin inhibitors. The introduction of cyclosporine A (CyA) at the beginning of the 1980s represented a milestone in cardiac transplantation (Oyer et al. 1983). Improvement of the original compound (Sandimmune[®]) by a microemulsion formulation (Neoral[®]) resulted in a more consistent pharmacokinetics and better bioavailability (Cooney et al. 1998). In the meantime, there are several generics of CyA available.

Monitoring of CyA is based on the standardized measurement of 12-h trough concentrations. Further research into improving CyA administration revealed that concentrations measured 2 h after administration (C₂) gave more information about CyA exposure than measurements just before drug intake (C₀). In most centers, this proved to be not practical for daily clinical routine but might be useful in selected patients in whom a pharmacokinetic profile of CyA is desired (Taylor et al. 2012).

Tacrolimus, like CyA a calcineurin phosphatase inhibitor, revealed superior immunosuppressive activity in the first single (Pham et al. 1996) and multicenter (Reichart et al. 1998) trials comparing the two compounds after cardiac transplantation. This finding was confirmed by subsequent evaluations (Meiser et al. 1998; Taylor et al. 1999). While both calcineurin inhibitors cause renal impairment, tacrolimus is associated with a smaller incidence of hypertension, gingival hyperplasia and dyslipidemia but more often with diabetes when compared to CyA (Taylor et al. 2012). Meanwhile, the majority of the centers worldwide use a tacrolimus-based immunosuppression after heart transplantation (Lund et al. 2015).

Morning pre-dose level monitoring of tacrolimus is in most cases sufficient for drug exposure estimate. While there are in the meantime several tacrolimus generics available, the original manufacturer has introduced an extended release once-daily product which should be taken in the morning for pharmacokinetic reasons.

In adjunction to a calcineurin inhibitor, most maintenance immunosuppressive protocols add an antimetabolite agent. In the early days, azathioprine used to be the antimetabolite of choice. Meanwhile, mycophenolate mofetil and

mycophenolate sodium preparations proved to be more efficacious for the prevention of rejection (Kobashigawa et al. 1998). Their active metabolic form, mycophenolic acid, is a reversible blocker of inosine monophosphate dehydrogenase, an enzyme which inhibits de novo purine guanosine synthesis. The compound is not nephrotoxic; most common side effects are leukopenia and gastrointestinal toxicities.

Mycophenolate is generally administered as a fixed-dose regimen. While routine therapeutic drug monitoring of mycophenolic acid levels to adjust doses is not generally recommended (Taylor et al. 2012), there are reports of a correlation between pre-dose levels and rejection incidence (Meiser et al. 1999). At least in children, and in adult patients with a high rejection rate, monitoring might be helpful to improve outcome.

Another class of immunosuppressants, sirolimus and everolimus, are proliferation signal or mammalian target of rapamycin inhibitors. While the initial immunosuppressive property of rapamycin (Morris and Meiser 1989) was discovered around the same time tacrolimus was evaluated, the regulatory approval took much longer. The compound acts later in the cell cycle and inhibits IL-2-dependent T-cell proliferation via arrest in the G1 to S phase. Sirolimus and everolimus have proven to be very efficacious for prevention of rejection either in combination with CyA (Lehmkuhl et al. 2009) or tacrolimus (Meiser et al. 2007).

Proliferation signal inhibitors are given once daily, usually in between calcineurin inhibitor intake because of drug interactions; therapeutic drug monitoring using trough concentration levels is recommended (Taylor et al. 2012). The compounds are not nephrotoxic, but they potentiate the nephrotoxic effects of calcineurin inhibitors. The most common toxicities include hyperlipidemia, oral ulcerations, lower extremity edema, bone marrow suppression, postsurgical wound-healing complications and pleural and pericardial effusions.

Either mycophenolic acid or a proliferation signal inhibitor should be included into the long-term immunosuppressive regimen because these drugs have been shown to reduce both, onset and progression of cardiac allograft vasculopathy (Taylor et al. 2012).

Besides the development of graft vessel disease, a major problem in long-term heart trans-

plant recipients remains the renal impairment caused by chronic calcineurin inhibitor intake. In selected patients, a calcineurin inhibitor-free immunosuppression using a combination of mycophenolic acid and a proliferation signal inhibitor is an acceptable therapeutic approach which might improve renal function and avoid further deterioration (Groetzner et al. 2009; Meiser et al. 2011). In general, complications caused by immunosuppressive drugs underscore the need for individualization of immunosuppression according to the characteristics and risks of the individual recipient (Taylor et al. 2012).

37.4.3 Additional Medication

Besides treatment of the underlying disease, additional medication is mostly needed due to the complications/side effects of chronic immunosuppressive drugs. As mentioned already, in cases of renal impairment, an alternative immunosuppressive regimen in combination with a minimization or withdrawal of calcineurin inhibitors should be considered. Similarly, the development of post-transplant diabetes might be counteracted by introduction of a calcineurin inhibitor-sparing regimen in combination with avoidance of additional risk factors. Arterial hypertension in transplanted patients should be treated with the same medications and goals as used by the general population (Hunt et al. 2012).

Allograft vasculopathy should be assessed annually by conventional angiography only or in cases of progression in combination with intracoronary ultrasound. Baseline should be an examination 4–6 weeks after transplantation. In order to prevent the development of the disease as much as possible, control of cardiovascular risk factors (hypertension, diabetes, hyperlipidemia, smoking, obesity) in combination with statin therapy is advised (Hunt et al. 2012).

In adults, the early use of HMG–CoA reductase inhibitors or statins after transplantation is recommended regardless of cholesterol levels (Taylor et al. 2012). Statins have both immunosuppressive and lipid-lowering properties. Treatment results in significantly lower allograft vasculopathy incidence (Wenke et al. 1997), particularly when initiated early after transplantation. The most serious adverse effect of statins is

rhabdomyolysis, mostly when used in higher doses.

Chronic immunosuppression is also a risk factor for the development of malignancies. Since the most common tumor after transplantation is skin cancer, transplanted patients should undergo frequent dermatologic surveillance. In cases of lymphomas adjuvant therapy should be minimization of immunosuppression as much as possible (Hunt et al. 2012).

38.1 Introduction

Heart failure is a disorder with a high incidence and an increasing prevalence among the Western population. In severe forms, namely end-stage heart failure (NYHA stage III–IV/AHA/ACC stage D), the mortality rate is up to 30–40% per year. Observational studies revealed the incidence and prevalence rising with age, being at 2–5% for age 65–70 years and an estimated 10% for the population 70 years and older (Hoppe et al. 2001). For this reason, in the context of the ongoing demographic change with the aging population, heart failure already has significant medical and socioeconomic implications.

Orthotopic heart transplantation is still the gold standard for the treatment of end-stage heart failure. The progress in medical/pharmacological management of cardiovascular disease as well as interventional treatment has led to more and more patients experiencing end-stage heart failure. While this creates a rising demand for cardiac transplantation, the number of suitable allografts is not increasing. *Mechanical circulatory support (MCS)* therefore is an alternative therapy with a growing importance. There has been remarkable technical progress over the last 30 years, both in the propulsion design and size of the assist devices. Current assist devices are miniaturized and therefore fully implantable resulting in high patient comfort and significantly improved quality of life. The durability of the devices has also increased due to implementation of magnetic and hydrodynamic bearing technology. The REMATCH trial (*Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure*) showed superior survival for patients with mechanical circulatory support when compared to optimal medical treatment (Rose et al. 1999, 2001). Today it seems reasonable to expand the indication for MCS beyond short-term bridge to recovery and medium-term bridge to transplantation and aim for long-term destination therapy.

In cases with extended myocardial damage, biventricular support is indicated. In our experience, carefully selected patients with structural damage to the heart due to myocardial infarction (LV-aneurysm), thrombi, intracardiac shunts, or patients with congenital heart defects may benefit from the implantation of a *Total Artificial Heart (TAH)*.

Considering the shortage of allografts for cardiac transplantation, mechanical circulatory support could be the major treatment option for end-stage heart failure. It still has to prove, however, to be close or equivalent to the effectiveness of orthotopic heart transplantation.

38.2 History of Mechanical Circulatory Support

The rationale for mechanical circulatory support originates in the event of *post-cardiotomy cardiogenic shock* observed after open heart surgery employing cardiopulmonary bypass and has been of great interest since the advent of cardiac surgery in the early 1950s.

In a patient suffering from post-cardiotomy cardiogenic shock after double-valve surgery, Michael DeBakey was the first to implant a pneumatically driven pump in 1966. The 37-year-old female patient was successfully weaned off support 10 days later and was discharged from the hospital (DeBakey 1971). Two similar patients could also be successfully managed with a temporary left ventricular pump as a *bridge to recovery* in 1971 (Campbell et al. 1988).

As it was not technically feasible to replace the native heart artificially in the late 1970s and early 1980s, orthotopic heart transplantation (oHTx) was established as the standard procedure for the surgical treatment of end-stage heart failure. Mechanical circulatory support, however, was implemented as a *bridge to transplantation* in the face of acute organ donor shortage. In 1984, Portner et al. reported the first case of a successful orthotopic heart transplantation following mechanical circulatory support with a Novacor left ventricular assist device (Portner et al. 1985). Frazier et al. 1992 reported the first successful bridge to transplantation case with a HeartMate XVE (Thoratec Inc., Pleasantville, NJ, USA) left ventricular assist device in 1992. The HeartMate XVE assist device received FDA approval for its use in the bridge to transplantation setting in 1994 and later on for *destination therapy* (2003).

The first successful bridge to transplantation case in our experience at Bad Oeynhausen dates back to 1989. The first pediatric case was performed at the German Heart Center Berlin in 1990.

With the development of small, portable drivers in the early 1990s, it became possible to

discharge patients from hospital with mechanical circulatory support for their waiting time before cardiac transplantation. Loisanche et al. were the first to use a portable Novacor driver in 1993 (Loisanche et al. 1994). We started doing this in Bad Oeynhausen in 1994.

In contrast to the first-generation assist devices which operated as displacement pumps and generated pulsatile flow, the miniaturized second- and third-generation devices are continuous flow systems. The first time a second-generation axial flow device (Micromed DeBakey) was implanted was in 1998 in the German Heart Center Berlin (Noon et al. 2001). The only second-generation axial flow pump device currently approved by the FDA for *destination therapy* in the USA is the HeartMate II (Thoratec Inc., Pleasantville, NJ, USA).

In third-generation assist devices, the rotor is magnetically suspended. This suspension significantly decreases the degree of hemolysis and the rate of thromboembolic complications (Gazzoli et al. 2007; Nishinaka et al. 2006). We started implanting the CorAide (Arrow Inc., Reading, USA) in 2001 and the DuraHeart assist devices (Terumo Heart Inc., Ann Arbor, USA) in 2004 in Bad Oeynhausen. Both have been first implantations worldwide. The DuraHeart is the only third-generation assist device so far to receive CE approval (CE: Conformité Européenne), the certificate to allow for widespread use in Europe.

The Arrow LionHeart LVD 2000 (Arrow International) was the first fully implantable left ventricular assist system specifically designed for *destination therapy*. All components including the pump with the inlet and outlet cannulae, the motor controller, the transcutaneous energy transmission systems and the compliance chamber were implanted in a preperitoneal pocket, the subcutaneous and the right pleural space, respectively. The system was first implanted by our group in 1999 at Bad Oeynhausen (El-Banayosy et al. 2003; Mehta et al. 2001). Unfortunately, due to logistical reasons, the LionHeart is currently not available.

The pioneering research of Kolff, Olsen and Jarvik in the field of TAH aimed to develop a device capable of permanently replacing the native heart. In the early 1980s, in four patients with end-stage heart failure, the Jarvik 7 TAH was implanted. Two of these patients suffered a stroke. Ultimately, all four patients died due to sepsis. The first successful bridge to transplantation case with

the Jarvik 7 TAH was performed in 1985 by the same group. The patient was discharged and was finally able to return to work.

In 1991 the Jarvik 7 TAH was renamed the CardioWest (SynCardia Cardiosystems, Tucson, USA). To date, more than 1,100 implants have been performed with 79% of all patients having been successfully bridged to transplant (Copeland et al. 2004, 2006; Leprince et al. 2003). A modified BerlinHeart EXCOR mobile driver which makes the discharge of the patients possible has been available since 2004. CE certification for the mobile driver was issued on the basis of the results of a clinical trial carried out by our group in Bad Oeynhausen.

The Abiocror (Abiomed, Danvers, Massachusetts, USA) is a completely implantable TAH developed by the Texas Heart Institute and Abiomed. The first implant took place in 2001 at the Jewish Hospital in Louisville, Kentucky. In a first clinical trial, the Abiocror was implanted in patients not eligible for transplantation and with a life expectancy of <30 days. Results have not been satisfying so far. The Abiocror is still under further development (Copeland et al. 2006).

38.3 Definition of Mechanical Circulatory Support

The term mechanical circulatory support (MCS) is used when a mechanical pump sustains systemic and/or pulmonary circulation over a variable period of time. A distinction between univentricular (left or right sided ventricle) and biventricular support is made. Almost always the native heart remains in situ.

When *left ventricular support* is introduced, blood flow is directed either from the left atrium or the left ventricle through the pump into the aorta. For reliable unloading of the left ventricle, the inflow cannula is typically placed in the left ventricle via the apex than in the left atrium. In *right ventricular support*, blood flow is from the right atrium or the right ventricle through the pump and then into the main pulmonary artery.

In order to employ a *total artificial heart* (TAH), both ventricles have to be excised at the atrioventricular level. The inflow cuffs of the TAH are sutured to the remaining native atria, and the artificial ventricles are connected to the aorta and pulmonary artery via vascular outflow prostheses, respectively. The two TAH systems which are currently available are the CardioWest (SynCardia

Systems Inc., Tucson, USA) and the Abiocor (Abiomed Inc., Danvers, USA). The Carmat TAH has been developed by Alain Carpentier and Matra Défense. The first in-man implant is scheduled for 2012. The ReinHeart TAH is being developed by our institution and the Department of Applied Medical Engineering in Aachen, Germany and is currently being tested in acute and chronic animal models.

38.4 Indications for Mechanical Circulatory Support

38.4.1 General

Mechanical circulatory support is indicated in cases of an *end-stage heart failure* (@@NYHA-class III–IV, AHA/ACC stage D) or in acute *cardiogenic shock* once conservative therapy options have been exhausted and conventional reparative surgery is not possible/indicated.

Intentions to treat include the following:

- Bridge to transplantation (BTT)
- Bridge to recovery (BTR)
- Bridge to bridge (BTB)
- Destination therapy (DT)/alternative to transplantation (ATT)

The indication for MCS and the intention to treat takes the anticipated *duration of support* into account:

- Short-term support: up to 30 days
- Medium-term support: 30–360 days
- Long-term support: more than 360 days

38.4.2 Bridge to Transplantation (BTT)

Mechanical circulatory support as a bridge to transplantation is an established therapy for end-stage heart failure in chronic patients with *dilated or ischemic cardiomyopathy* demonstrating clinical deterioration with an imminent risk of death despite maximal inotropic support while being on the waiting list for transplantation. The aim is to secure survival and to prevent multiple organ failure before cardiac transplantation can be performed.

Furthermore, bridge to transplantation may be considered as a therapeutic option in patients with an end-stage heart failure resulting from:

- Valvular cardiomyopathy

- Myocarditis (frequently giant cell myocarditis)
- Acute myocardial infarction
- Congenital heart defects
- Post-cardiotomy cardiogenic shock

In chronic patients, the decision to employ MCS is rather based on the deteriorating clinical state (NYHA stage IV, AHA/ACC stage D) and the left ventricular ejection fraction, estimated by echocardiography (<20%), than on the invasive hemodynamic parameters (Cardiac Index <2.2 l/qm/min, systolic blood pressure <90 mmHg, pulmonary wedge pressure >20 mmHg and maximal oxygen uptake <12 ml/kg/min).

38.4.3 Bridge to Recovery (BTR)

As volume and pressure overload trigger pathologic remodeling of the heart, mechanical unloading by means of MCS may well reverse or at least ameliorate the effects observed, resulting in recovery of the myocardium and restoration of ventricular function.

Mechanical circulatory support in a bridge to recovery setting is conceivable for the following situations:

- Post-cardiotomy cardiogenic shock
- Acute, fulminant myocarditis (giant cell myocarditis exempted)
- Acute myocardial infarction
- Primary allograft failure
- Acute allograft rejection
- Right ventricular failure following orthotopic heart transplantation
- Right ventricular failure following fulminant pulmonary thromboembolism
- Toxic cardiomyopathy
- Postpartum cardiomyopathy

Although it is known that in *dilated cardiomyopathy* assisted circulation may contribute to reverse remodeling, it is still unclear in which subsets of patients this reverse remodeling once taking place on the cellular level actually does translate to myocardial recovery and restoration of the basic cardiac functions. Successful weaning and long-term cardiac stability has been reported so far in less than 10% of patients following the implantation of a left ventricular assist device for dilated cardiomyopathy. It has been hypothesized that the myocyte atrophy resulting from long-term ventricular unloading may impair successful weaning

from assisted circulation despite the potentially beneficial reverse remodeling. Clenbuterol, a selective β_2 -agonist, initially approved for the treatment of bronchial asthma, has been reported to have beneficial effects on remodeling and protective effects against cellular apoptosis (Birks et al. 2006; Dandel et al. 2005; Mancini et al. 1998; Mann and Willerson 1998; Simon et al. 2005).

In post-cardiotomy cardiogenic shock, recovery of the ventricular function should be expected within 7–14 days. In acute allograft rejection, primary allograft failure or isolated right ventricular failure after heart transplantation recovery should be within 14 days, also, while in chronically dilated cardiomyopathy recovery may take as long as 6 months.

38.4.4 Bridge to Bridge (BTB)

Bridge to Bridge support mostly is considered in patients in whom at the initiation of MCS the potential duration of support required was quite unclear. Most of these patients had been in acute *cardiogenic shock* and were under resuscitation before and during MCS initiation. The neurological state and the extent of end-organ failure are initially unclear. Extracorporeal life support systems allow a short-term support of up to 1 month. If there are no further contraindications for heart transplantation, long-term support systems can be implanted during that time frame.

Common causes of cardiogenic shock are the following:

- Acute myocarditis
- Acute myocardial infarction
- Toxic cardiomyopathy
- Post-cardiotomy circulatory failure
- Acute heart failure
- Postpartum cardiomyopathy

Although in most of these cases after initial life-saving short-term circulatory support the next step is a BTT therapy, it also may end in a bridge to recovery. However, a secondary device employed for BTT or BTR may require a further step, a change to a device compatible with destination therapy.

38.4.5 Destination Therapy (DT)

Destination therapy is the long-term MCS as an alternative to cardiac transplantation for those

patients with contraindications for cardiac transplantation.

According to the current recommendations of the US Centers for Medicare and Medicaid Services, destination therapy is covered for patients who have chronic end-stage heart failure for at least 90 days with a life expectancy of less than 2 years, who are not candidates for heart transplantation and meet the following conditions:

- The patient's Class IV heart failure symptoms have failed to respond to optimal medical management, including dietary salt restriction, diuretics, digitalis, beta-blockers and ACE inhibitors (if tolerated) for at least 60 of the last 90 days.
- The patient has a left ventricular ejection fraction (LVEF) $<25\%$.
- The patient has demonstrated functional limitation with a peak oxygen consumption <12 ml/kg/min; or the patient has a continued need for intravenous inotropic therapy owing to symptomatic hypotension, decreasing renal function, or worsening pulmonary congestion.
- The patient has the appropriate body size (≥ 1.5 m²) to support the VAD implantation.

The REMATCH trial has been the landmark study for the destination therapy concept. Long-term mechanical circulatory support resulted in a significant risk reduction for death of any cause of up to 48% in NYHA IV patients when compared to optimal medical therapy (Rose et al. 1999, 2001).

The INTERMACS registry (*Interagency Registry for Mechanical Assisted Circulatory Support*) has the aim to define those patients who are eligible for mechanical circulatory support and to optimize the clinical outcomes (Kirklin and Naftel 2008). Seven patient profiles ('levels') have been defined according to the clinical symptoms:

1. Persistent cardiogenic shock despite an escalating inotropic support.
2. Progressive decline despite inotropic support.
3. Patient is stable under moderate inotropic support.
4. Recurrent advanced heart failure susceptible to medical treatment.
5. Comfortable at rest but intolerant to light exercise.
6. Comfortable at rest but limited to light exercise.
7. Comfortable at rest but limited to mild exercise.

Destination therapy is currently recommended in those patients who are clinically stable and in whom implantation can be performed electively (levels 3–6). For these patients the results of the third-generation assist devices are indeed encouraging. The 1-year survival is at 86% and is comparable to orthotopic heart transplantation. Destination therapy could therefore become a safe alternative to heart transplantation, especially for elderly people (Lietz and Miller 2005; Pennington et al. 1999; Stevenson and Rose 2003).

38.5 Indications for Left Ventricular and Biventricular Support

38.5.1 Left Ventricular Support

Prior to the implantation of a left ventricular assist device, it is essential to exclude the presence of an intracardiac shunt and of any left ventricular thrombus by means of 2D echocardiography.

It is furthermore important to identify the patients who are at *high risk of developing right ventricular failure* while on left ventricular support. According to our experience, the presence of the following:

- Central venous pressure (CVP) >16 mmHg
- Cardiac index (CI) <2.0 l/m²/min
- Systemic vascular resistance >1,400 dyn/s/cm⁵
- Pulmonary vascular resistance >250 dyn/s/cm⁵

Suggests that the patient is at high risk of developing right ventricular failure. Female gender and an emergency procedure are additional risk factors for right ventricular failure. A reduced right ventricular stroke index is most likely to indicate the need for prolonged therapy with i.v. inotropes during the post-operative course, but it does not indicate the need for right ventricular mechanical support.

38.5.2 Biventricular Support

Since mandatory guidelines are not available, the indication for biventricular support is mainly based upon clinical criteria. Hemodynamic parameters (CI <2.2 l/qm/min, CVP >18 mmHg, pulmonary vascular resistance >500 dyn/s/cm⁵, low pulmonary artery pressure) in addition are helpful.

According to our experience, biventricular support is indicated in the presence of the following:

- Biventricular heart failure refractory to medical treatment
- Including high-dose i.v. inotropic therapy
- Imminent multi-organ failure (renal failure requiring hemodialysis and hepatic failure resulting in an increase of bilirubin >5 mg/dl and an increase of GOT and GPT three times the standard value)
- Malignant arrhythmias

38.5.3 Total Artificial Heart (TAH)

Implantation of a total artificial heart (TAH) is indicated in the presence of end-stage biventricular heart failure and:

- Imminent multi-organ failure
- Complex congenital heart disease
- Intracardiac thrombi
- Intracardiac shunts
- Cardiac neoplasms
- Acute, fulminant myocarditis or a giant cell myocarditis
- Malignant arrhythmias
- Extended myocardial infarction with massive left ventricular impairment

38.6 Contraindications for Mechanical Circulatory Support

Absolute contraindications for mechanical circulatory support include:

- Sepsis (only short-term resuscitative measure MCL support indicated)
- Decreased life expectancy due to severe comorbidities (HIV, irreversible cerebral damage, aggressive neoplasms)
- Anatomical limitations
- Severe psychiatric disorders
- Severe abuse of alcohol or recreational drugs
- Non-compliance
- Irreversible end-organ failure
- Severe coagulation disorders

Relative contraindications for mechanical circulatory support include:

- Aortic valve regurgitation > I°
- Mechanical prosthesis in the aortic position
- Fixed pulmonary hypertension >6 Woods units

38.7 Adverse Events During Mechanical Circulatory Support

38.7.1 Bleeding

Bleeding is a frequent perioperative complication observed in MCS patients. The reasons are coagulopathies either due to liver dysfunction or due to previous oral anticoagulation therapy which is prevalent in many end-stage heart failure patients.

Furthermore, interactions at the blood–device interface may result in a *disseminated intravascular coagulation* disorder (DIC).

As the myocardium of the failed heart is extremely vulnerable, it is essential to take care that no surgical bleeding persists. This includes implementation of atraumatic surgical technique and meticulous hemostasis. Coagulation should be optimized by substituting platelets, fresh frozen plasma, factor VII and optionally Vitamin K. Heparin must be completely reversed by protamine, but not overdone.

We strongly recommend avoiding any systemic anticoagulation therapy with heparin during the first 24 h following the implantation procedure. Once the coagulation status is normal and the bleeding from the chest tubes has stopped, systemic heparin therapy can be carefully initiated.

The incidence of bleeding complications is still high and is about 40% (Mc Bride et al. 1999). In our institution bleeding complications were observed in 22–35% of all patients with first-generation assist devices (Novacor, Thoratec PVAD, HeartMate XVE) (El-Banayosy et al. 2001) but only in 15% of all patients with a third-generation assist device (DuraHeart). This could be due to the smaller artificial surface area and the absence of biological membranes in the new generation continuous flow devices.

38.7.2 Air Embolism

The major causes of air embolism are trapped air, either in the native ventricles or in the pump.

Also, free air could be sucked through a porous inflow graft due to the negative pressure inside the pump. It is therefore essential to completely deair the pump and the native heart and to preclot a porous inflow graft before activating the device. Transesophageal echocardiography can reveal trapped air. Events of air embolism are relatively rare. However, incidence and prevalence of air embolism in MCS has not been examined in a systematic fashion, yet.

38.7.3 Thromboembolic and Major Neurological Events

Thromboembolic complications (major neurological events, renal infarction, occlusion of peripheral vessels) are a major concern. The common cause of perioperative events can be traced back to the embolization of preformed thrombi located in the native ventricles and the atria. It is therefore essential to perform transesophageal echocardiography and to directly inspect the ventricles and atria during the procedure. Once detected, thrombi have to be removed or even excised prior to the implantation of the device.

The interactions at the blood–device interface stimulate local thrombus formation. This may lead to neurological events such as stroke, transient ischemic attacks and intracerebral bleeding even during the late post-operative course. The incidence varies depending on the device implanted between 5 and 37% (Copeland et al. 2001; El-Banayosy et al. 2000; Goldstein 2003; Pae et al. 2007b; Rose et al. 2001; Thomas et al. 2001). In our institution, the incidence of thromboembolic events in patients managed with first-generation assist devices was about 20% (El-Banayosy et al. 2001).

According to the results of the REMATCH trial, 76% of all patients treated with a left ventricular assist device had been free of any neurological complications, although oral anticoagulation therapy (other than aspirin) was not used routinely (Rose et al. 1999, 2001). A major neurologic event (stroke) was observed in 10% of all cases of which 47% had complete resolution of the clinical symptoms.

In the year 2000, the clinical outcome of the first-generation pulsatile pumps (Novacor, BerlinHeart EXCOR) was compared with axial flow pumps (Micromed DeBakey, BerlinHeart

INCOR). Fifteen percent of patients with a first-generation pulsatile pump experienced a major neurological event and 17.5% any additional thromboembolic event. In patients treated with an axial flow pump, intra-pump thrombus formation could be detected in 37% and any thromboembolic complications were reported in 25% (Koster et al. 2000).

In our experience, the incidence of thromboembolic complications in patients treated with a third-generation pump (CorAide, Ventracor, DuraHeart) is less than 3%, although the anticoagulation therapy regimen we implement is rather moderate.

In order to prevent thromboembolic and neurological events, it is mandatory to follow a strict anticoagulation therapy regimen consisting of warfarin and, depending on the device, additional use of aspirin and clopidogrel. Patients have to be properly trained in oral anticoagulation self-management.

38.7.4 Hemolysis

Hemolysis is defined as the constant increase of free hemoglobin plasma levels >50 mg/dl for over 5 h.

The degree of hemolysis is mainly dependent on the pump design, the degree of shear stress and the severity of turbulence red blood cells are exposed to during the downstream passage through the pump and the inflow and outflow cannulae. Theoretically, kinking of the cannulae or an acute regurgitation through the valves can also cause hemolysis.

The plasma levels of lactate dehydrogenase, a marker of hemolysis, depend on the design of the system. Plasma levels of lactate dehydrogenase are significantly higher with pulsatile (on average 600 U/l) than with continuous flow pumps (on average 200 U/l). In our institution, hemolysis was documented in 6% of the Thoratec BIVAD and 7% of the CardioWest patients. A multicenter trial investigating the results of the HeartMate II system reported hemolysis in 3% (Miller et al. 2007).

Plasma levels of lactate dehydrogenase (LDH) and free hemoglobin have to be measured on a regular basis. The reasons for hemolysis have to be identified and treated accordingly.

38.7.5 Right Heart Failure

Reasons for acute right heart failure during left ventricular support in the *early post-operative (LVAD implantation) course* are as follows:

- The inability of a dysfunctional right ventricle to cope with the increased venous return
- The increase of pulmonary vascular resistance resulting from extracorporeal circulation and mass transfusion

In order to ameliorate end-organ failure resulting from an increased central venous pressure, it is essential to decrease the pulmonary vascular resistance and the right ventricular afterload by the use of the following:

- Phosphodiesterase III inhibitors
- Levosimendan
- Prostaglandin derivatives
- Nitric oxide ventilation

Frequent causes for right heart failure *late after LVAD implantation* are as follows:

- A deviation of the interventricular septum to the left due to unloading of the left ventricle
- Air embolism

The diagnostic method of choice is transesophageal echocardiography.

In our experience, right heart failure occurs in 5–20% of patients with a left ventricular assist device (LVAD), of which only 3% require an ‘upgrade’ to biventricular support.

An emergency procedure proved to be an independent risk factor for a right heart failure in 25% of Novacor, 19% of Thoratec and 26% of HeartMate patients treated at our institution (El-Banayosy et al. 2001). During the DuraHeart registration trial, right heart failure occurred in 37% of patients of whom 78% could be medically treated. Biventricular support was not necessary in any of these patients.

38.7.6 Infection

With an incidence rate of 0.39 per patient year, according to the REMATCH trial (Rose et al. 2001), infection events at the driveline site and the pump pocket are the most frequent complications. Multi-organ failure and cerebral embolism resulting from sepsis (Gordon et al. 2006) occur

mostly during the early post-operative course in patients being already multimorbid to start with (Holman et al. 2003).

Risk factors for infection are as follows:

- A long driveline
- A large pump pocket
- Reduced general and nutritional status
- Long-term support

In the early days of MCS, driveline infections were observed in 24 % of Novacor patients and pump pocket infections in 30 % of HeartMate XVE patients. Since we observed that the rate of driveline infections was directly associated to the length of the driveline, we routinely tunnel the driveline to the right upper abdominal quadrant since 1998. The friction between the pump body and the pocket walls contributes to pocket infections. We therefore cover the upper surface of the pump with a collagen-impregnated Dacron patch (Hemashield) in order to stimulate tissue ingrowth. We additionally fix the body of the pump with four stitches.

Endocarditis due to an infected inflow or outflow conduit was observed in 3–4 % of all Novacor and HeartMate XVE patients in our experience (El-Banayosy et al. 2001).

The miniaturized third-generation continuous flow pumps require a small pocket, if any at all. Therefore, the rate of infection in this group is low and limited to the driveline. Fifteen percent of all our DuraHeart patients developed infections associated with the pump, of which three had been located at the driveline, one at the pump pocket and one at the driveline and the pump pocket. Local infections were documented in none of our CorAide patients.

Lietz et al. (2007) reported that perioperative mortality due to sepsis and multi-organ failure was high in patients with a reduced general and nutritional status at the time of implantation.

Zierer et al. (2007) reported a possible relation between the duration of mechanical support and the incidence of late infections. Especially in Novacor and HeartMate patients, infections were difficult to treat, and they were associated with a high mortality rate.

Post-operative infection precautions include antibiotic prophylaxis with cephalosporins until the chest tubes can be removed. It is essential to ensure asepsis while changing of the driveline dressing.

38.7.7 Ventricular Arrhythmias

Any forms of ventricular arrhythmias are observed in up to 20 % of all MCS patients. In the majority they are not relevant, they can be treated medically. They may finally resolve due to the progressive unloading of the ventricle.

It is difficult to predict the effects of ventricular tachycardia or ventricular fibrillation on the output of the pump. An implantable cardioverter-defibrillator is indicated in the presence of recurrent, therapy-refractory malignant arrhythmias.

Until now, less than 6 % of our patients with any type of assist device have developed severe, medically refractory ventricular arrhythmias.

38.7.8 Technical Disorders

Second to systemic infections, a *device failure*, the most severe technical disorder, proved to be a common cause of death in the REMATCH trial (HeartMate XVE), contributing to a 2-year survival rate of only 23 % (Rose et al. 2001).

The current second- and third-generation devices are more durable. According to our experience, there have been, so far, no cases of device failure among the HeartMate II, DuraHeart and CorAide patients. Nevertheless in 3–7 % of all HeartMate II patients, the pump had to be exchanged due to pump thrombosis or technical problems associated with the implantation procedure, such as kinking of the inflow cannula. Similarly, the DuraHeart assist device had to be exchanged in two known cases due to flow disorders.

The *extracorporeal system components* are prone to *wear and tear*. Driveline fractures, filter blocks and failure of the external batteries are common and usually easy to repair.

Wear and tear of the *intracorporeal system components* is rare but even more serious. The artificial valves which are integrated in the inflow and outflow parts of the first-generation as well as in the pneumatically driven assist devices facilitate unidirectional blood flow. These devices become dysfunctional over time due to their exposure to distinct flow and pressure. For the same reason, the flexible polyurethane diaphragms of the artificial ventricles of a CardioWest TAH can rupture. This has been observed as a rare event in two of our patients. The first could be successfully transplanted while the second patient died.

38.7.9 Psychological Disorders

Psychological disorders, such as a severe reactive depression to the point of suicidal thoughts, are frequent, especially among patients with a long-term circulatory assistance. Until now, these events have not been systematically examined. According to our experience, a reliable social environment and a permanent out-of-hospital team providing aftercare are essential in order to identify and successfully treat psychological disorders. Depending on the severity of symptoms, a low-dose anti-depressive monotherapy proved to be sufficient in most of our patients.

The guidelines which have been elaborated by the STS deal with the ethical, and in a broader context, psychosocial problems emerging from long-term mechanical circulatory support, such

as advanced care planning and deactivation of the assist device (Dudzinski 2006).

38.8 Assist Devices

38.8.1 Extracorporeal Assist Devices

In extracorporeal assist devices, the circulation may be cannulated peripherally or centrally. The pump may be even outside the bed, or extracorporeal/paracorporeal.

38.8.1.1 Centrimag LVAD

The CentriMag LVAD (Levitronix/Pharos, Zurich, Switzerland; ■ Fig. 38.1) is a *magnetically levitated centrifugal pump* which has been designed for short-term circulatory support, especially for cases of post-cardiotomy heart

■ Fig. 38.1 CentriMag

failure. The CentriMag LVAD is ideal as an 'extracorporeal life support system'. The pump rotates at speeds between 1,500 and 5,500 rpm and generates a flow of up to 9 L/min. Since the pump is magnetically levitated without any bearings or seals included, the degree of hemolysis is remarkably low.

Similar systems are the Rotaflow (Maquet Cardiopulmonary AG, Rastatt, Germany) and the TandemHeart (CardiacAssist Inc., Pittsburgh, PA, USA).

38.8.1.2 Biomedicus Centrifugal Pump

The Biomedicus centrifugal pump (Medtronic, Eden Prairie, MN, USA) is frequently used as a short-term circulatory support in patients with post-cardiotomy heart failure or in any form of cardiogenic shock. It may be employed as a femoro-femoral or standard central cardiopulmonary bypass as part of an extracorporeal membrane oxygenation (ECMO) system. It is possible to either support one or both ventricles.

First-generation extracorporeal systems have been associated with a high rate of adverse events, including hemolysis, excessive bleeding and thromboembolism. For these reasons, we currently prefer the CentriMag pump.

38.8.2 Paracorporeal Assist Devices (PAVD)

During paracorporeal assist the pump is placed outside but close to the body. Inflow and outflow grafts are used to connect the heart via atrium or ventricle and also the great vessels.

38.8.2.1 Thoratec PVAD

The Thoratec PVAD (Thoratec Inc., Pleasanton, CA, USA) is designed for uni- and biventricular support. It was developed in the early 1980s by William Pierce and James Donachy at Pennsylvania State University. In 1984 Donald Hill reported the first successful BTT case with a

Thoratec PVAD. Meanwhile, more than 7,000 patients have been treated with this device.

The pump consists of a rigid polysulfone case and a soft and flexible Thoralon pumping sack. The Thoralon material provides a low thrombogenicity and high endurance of the pump regarding wear and tear. Mechanical valves within the inflow and outflow conduits facilitate unidirectional blood flow.

The filling state of the pump is controlled by a sensor which triggers blood ejection. The pump can generate a stroke volume of up to 65 ml at a stroke rate between 20 and 110/min. The resulting cardiac output ranges from 1.3–7.2 l/min.

In the LVAD position, the inflow graft/cannula gets blood from the left atrium or the native LV. The outflow cannula is connected to the ascending aorta. In order to prevent kinking, the ventricular and the arterial cannulas are wire reinforced. A velvet coat minimizes the risk of ascending percutaneous mediastinitis via the tubes.

Electrical and pneumatic leads connect the pump to the dual driver. The operating pump rate, the vacuum level and the pressure of the system can be adjusted. In biventricular support these adjustments can be made for each pump separately. There are two modes of operation: a fixed rate mode and a volume mode. The volume mode is beneficial, since the pump can respond to an increased demand on stroke volume during exercise.

Due to the paracorporeal placement of the pumps, the Thoratec PVAD can also be used in small patients down to a body surface area of 0.73 m².

38.8.2.2 BerlinHeart EXCOR

The BerlinHeart EXCOR (BerlinHeart AG, Berlin, Germany) is a pneumatically driven system for uni- or biventricular support. Since different sizes of the pumps are available (10–80 ml), it can be used not only in adults with a small body surface area but also in children. The three leaflet valves in the inflow and outflow conduits are made of polyurethane. The system is operated by a portable dual driver. Like the Thoratec PVAD, the BerlinHeart EXCOR is mainly used in the bridge to transplantation setting.

38.8.3 Partially Implantable Assist Devices

In partially implantable assist devices, part of the device, namely, the pump, is implanted, while the driver and controller are placed paracorporeally.

38.8.3.1 Implantable Ventricular Assist Device (IVAD)

The implantable ventricular assist device (Thoratec Inc., Pleasanton, CA, USA) consists of a pneumatically driven displacement pump within a titanium housing, one inflow and one outflow conduit with a mechanical valve and a driveline which connects the pump with the external driver. The pump weighs 339 g and is placed in the left upper abdominal quadrant. The pump can generate a stroke volume of up to 65 ml. The IVAD can be implanted in patients with a body surface area $>1.3 \text{ m}^2$ and can be used for uni- and biventricular support as a bridge to transplantation system.

38.8.3.2 Axial Flow Pumps

The operation of axial flow pumps is based on the principle of the Archimedes screw: an impeller rotates at a very high speed and propels the blood forward. Axial flow pumps therefore do not generate a pulsatile, but a rather continuous blood flow.

The advantages of axial flow pumps are the following:

- Small size
- Absence of mechanical or biological valves in the inflow and outflow conduits
- Absence of compliance chambers
- Low power consumption
- Quiet operation
- Less mechanical components which are prone to wear and tear, therefore longer durability
- Easy to implant

■ ■ HeartMate II LVAD

The HeartMate II LVAD (Thoratec Inc., Pleasanton, CA, USA; ■ Fig. 38.2) was implanted for the first time by R. Kormos in Israel (Lietz et al. 2007) and shortly thereafter by us in Bad Oeynhausen. Due to a high incidence of thrombosis, the pump had to be redesigned and was reintroduced in 2003. Since then, the HeartMate II has been implanted in more than 7,000 patients.

■ Fig. 38.2 HeartMate II

The HeartMate II LVAD is an electromechanically driven axial flow pump with a weight of 350 g. The pump consists of an impeller in a titanium case (length 6 cm) which rotates at a speed between 6,000 and 15,000 rpm and generates a flow of up to 10 l/min, depending on the rotational speed and the pressure gradient between the inflow and the outflow conduit.

The inflow conduit is anastomosed to the left ventricular apex and the outflow conduit to the ascending aorta. The pump is positioned in the left upper abdominal quadrant. The driveline is tunneled in the right upper abdominal quadrant and connects the pump to the external driver. The pump blood flow is calculated by the power of the motor and the rotational speed of the pump. The external batteries have to be recharged every 7–10 h.

Based on the results of a prospective, randomized clinical trial, the Food and Drug Administration approved the HeartMate II as a permanent treatment for advanced heart failure in the USA for 2010 (Slaughter et al. 2009).

The main indication for left ventricular support with the HeartMate II LVAD is still bridge to transplantation (BTT). According to the results of the bridge to transplantation pivotal trial, the combined survival rate for recovery, ongoing support or transplantation was 79% at 18 months. The incidence of major complications such as neurological events and infections was remarkably low (Pagani et al. 2009). In the post-approval bridge to transplantation study, combined survival at 6 and 12 months was 90% and 85%, respectively (Starling et al. 2011).

■ ■ Jarvik 2000

The Jarvik 2000 (Jarvik Heart Inc., New York, NY, USA, ■ Fig. 38.3) is an electrically driven axial flow pump with an impeller which can generate a blood flow of up to 6 l/min at a rotational speed between 8,000 and 12,000 rpm. The device, including the pump and the titanium housing only weighs 85 g, is 5.5 cm long and has a diameter of 2.5 cm.

The system consists of pump, Dacron outflow graft (16 mm), external driver and batteries. All blood-contact surfaces of the pump are made of smooth titanium. The impeller is made of a neodymium-iron-boron magnet and titanium blades and is held in position by ceramic bearings. The driver and the batteries only weigh 1 kg. The batteries have to be recharged every 7 h.

In order to avoid blood stasis in the aortic root, a speed controller automatically decreases the pump speed to 6,000 rpm every minute, allowing the aortic valve to potentially open.

The pump is implanted through a left-sided thoracotomy (5th or 6th intercostal space) under femoro-femoral bypass. The outflow graft is anastomosed to the descending aorta, the driveline is tunneled in the right anterior abdominal quadrant and the pump is finally positioned into the left ventricle through the left ventricular apex.

Until now, the Jarvik 2000 has been implanted in more than 200 patients of whom 75% have received the device as a bridge to transplantation. The main adverse event has been pump thrombosis. The longest duration of support has been 7.5 years.

■ ■ BerlinHeart INCOR

The BerlinHeart INCOR LVAD (BerlinHeart GmbH, Berlin, Germany) is the only axial flow pump with a fully magnetically suspended impeller. The pump weighs 200 g, is 12 cm long and has a diameter of 3 cm. The pump generates a flow of up to 7 l/min at a rotational speed of 5,000–12,000 rpm. Blood flows from the left ventricle (silicone inflow cannula at the left ventricular apex) into a rigid cone in which it is rotated through the impeller. Before exiting the pump, blood flows into a streamer which ameliorates the rotation of the blood, builds up an additional pressure and drives the blood into the outflow cannula (silicone outflow cannula at the ascending aorta). The pump is positioned completely into the pericardial space. In order to avoid thrombus formation, all blood-contact surfaces consist of titanium which is coated with heparin (carmeda coating). However, according to our experience, an aggressive anticoagulation regimen is still necessary.

The BerlinHeart INCOR was implanted for the first time in 2002 and received CE approval in 2003. Since then, over 500 patients have been treated and the longest duration of support has been 6 years so far.

■ Fig. 38.3 Jarvik 2000

The clinical experience with the first-generation partially implantable and paracorporeal assist devices demonstrated that it is possible to effectively treat patients with end-stage heart failure in absence of any other therapy option. Furthermore, it became obvious that it is necessary to develop and implement innovative technological concepts in order to minimize the incidence of adverse events.

■ ■ HeartWare MVAD

The HeartWare MVAD (HeartWare Inc., Miramar, Fla, USA) is a miniaturized axial flow pump with a displacement volume of only 15 cc designed to be implanted in small and pediatric patients. The pump body consists of a wide-bladed rotor in a titanium housing which can generate a flow of up to 10 l/min at a rotational speed of 16,000–28,000 rpm. The rotor is suspended by passive magnetical and hydrodynamic forces. Real-time flow measurements of the pump flow are facilitated by an ultrasonic probe attached to the out-flow graft. The HeartWare MVAD is still an investigational device.

38.8.3.3 Miniaturized Centrifugal Pumps

■ ■ HeartWare HVAD

The HeartWare HVAD (HeartWare Inc., Miramar, Fla, USA) is currently the smallest left ventricular assist device available in the market. It weighs 160 g, has a short inflow cannula integrated in the pump body and a displacement volume of only 55 cc, thereby diminishing the need for a pump pocket. The system consists of the centrifugal pump with an impeller which is suspended by passive magnetic and hydrodynamic forces and can generate a flow of up to 10 l/min at a rotational speed of 2,400–3,200 rpm, a thin (4.2 mm thick) driveline, an external controller and a battery pack with 8 lithium-ion cells. A first prospective, non-randomized international BTT trial was performed between 2006 and 2008. Survival to 180 days on the device or to transplantation was 91 %. One year and 2 years survival was 85 % and 79 %, respectively. CE mark was granted at 2009.

The prospective, multicenter, non-randomized ADVANCE trial was initiated at 2010 and compared clinical outcomes to the INTERMACS registry cohort. Survival at 180 days was 91 % and at 2 years 84 %. Following adjustment of the anticoagulation protocol and sintering of the pump on the outer surface of the inflow in order to promote tissue ingrowth, ischemic stroke rate declined from previously 6.3 to 4.7 %. Similarly, the rate of thrombosis-associated pump failure was 4.2 % significantly lower than in the past (Aaranson et al. 2012).

■ Fig. 38.4 ReinVAD

■ ■ ReinVAD

The ReinVAD (■ Fig. 38.4) is a miniaturized device, which is currently being developed by our new institution and the Department of Applied Medical Engineering of the Helmholtz Institute in Aachen, Germany. The pump consists of a centrifugal impeller within a titanium housing. The impeller is suspended both magnetically and hydrodynamically. The main design features are as follows:

- The ‘wearless’ bearing system incorporates a journal bearing for radial/tilt support and a spiral groove thrust bearing for additional tilt and axial support.
- Passive magnets are used to reduce the load on the hydrodynamic bearings.
- Reducing hydraulic and magnetic forces acting on the impeller increases the suspension capacity with higher clearance gaps.
- The axial ‘slotless’ motor configuration incorporates a thin back iron yoke and is designed to be highly efficient (maximal power consumption of 5 W at a support level of 5 l/min at 80 mmHg).
- The 38-mm impeller is designed to produce full physiological support (5 l/min@100 mmHg) at a speed of 2,600 rpm.

In vitro testing in a pulsatile mock circulation loop confirmed the ability of the device to restore pathological hemodynamic conditions to normal in a pulsatile flow environment.

A first experimental proof of concept in vivo was established by six acute trials in a sheep model. The animals could be supported successfully for up to 4 h.

38.9 Past Assist Devices

The following devices are currently not available for clinical use. They are mentioned either due to historical reasons or due to specific technical features which are still of great interest in the clinical setting.

38.9.1 Extracorporeal Assist Devices

38.9.1.1 Abiomed BVS 5000

The Abiomed BVS 5000 (Abiomed Inc., Danvers, MA, USA) was a pneumatically driven pump designed for short-term uni- or biventricular circulatory support. It consisted of two polyurethane chambers placed extracorporeally. The atrial chamber was filled passively by gravity and the ventricular chamber pumped the blood pneumatically into the patient's circulation. A flow of up to 5 l/min could be generated.

38.9.2 Paracorporeal Assist Devices (PAVD)

38.9.2.1 Medos VAD

The paracorporeal Medos system (Medos AG, Stolberg, Germany) was designed for short- and midterm uni- and biventricular support. The system consisted of the following components: a displacement pump, wire-reinforced inflow and outflow cannulae and a pneumatic mobile dual driver. The pump sizes varied between 9 and 80 ml; the system could therefore be applied not only in adults with large and small body surface area but also in children.

38.9.3 Partially Implantable Assist Devices

38.9.3.1 HeartMate XVE LVAD

The HeartMate XVE LVAD (Thoratec Inc., Pleasanton, CA, USA; ■ Fig. 38.5) was developed by Thermo Cardiosystems and the Texas Heart Institute in the early 1990s. The XVE was an electromechanically driven displacement pump with a rigid titanium housing. A flexible diaphragm separated the air from the blood chamber. The pump could generate a stroke volume of up to

■ Fig. 38.5 HeartMate XVE

83 ml and a cardiac output of up to 10 l/min. The inflow cannula (diameter: 25 mm) was anastomosed to the left ventricular apex and the outflow conduit (diameter: 20 mm) to the ascending aorta. Biological valves within the inflow and outflow conduits facilitated unidirectional blood flow. The pump was placed in the left upper abdominal quadrant. The driveline connected the pump with the external controller. The pump weighed 1,200 g and the controller 300 g. An advantage of the HeartMate XVE was that the inner surface of the pump consisted of titanium microspheres which promoted the formation of pseudoneointima and minimized the risk of thrombus formation. Due to the positive results of the REMATCH trial, the HeartMate XVE was the first left ventricular assist device to receive Food and Drug Administration approval for destination therapy in the USA.

38.9.4 Axial Flow Pumps

38.9.4.1 HeartAssist 5

The HeartAssist 5 (Micromed Cardiovascular, Houston, TX, USA) is an electromagnetically driven axial flow pump which was introduced in 2009. With a weight of only 92 g, the HeartAssist 5 was one of the smallest pumps ever available. Due to its small size, it was implantable in patients with a body surface area of less than 0.7 m². The HeartAssist 5 was therefore approved by the FDA

as a Humanitarian Device Exemption for use in pediatric patients in the USA.

Like its predecessor, the Micromed DeBakey pump, the HeartAssist 5 pump consisted of an impeller surrounded by a titanium casing and was magnetically suspended. Pump speed varied between 7,500 and 12,000 rpm. A flow between 2 and 10 l/min could be generated. Due to its small size, the pump could be positioned in the pericardial space. The inflow graft was anastomosed to the left ventricular apex and the outflow graft to the ascending aorta. The driveline was tunneled in the right upper abdominal quadrant and was connected to the external driver.

While in all other currently available left ventricular assist devices, blood flow is calculated by the power of the motor and the rotational speed of the pump, HeartAssist 5 had an ultrasonic flow probe attached to the outflow graft which delivered real-time measurements of the blood flow. This is of great importance for the management of critical hemodynamic situations like acute right heart failure which we could observe and successfully treat in one of our patients.

A further feature of this device was that all relevant data, such as blood flow, power consumption and alarms, could be transmitted online to the transplant center (remote home monitoring).

The HeartAssist 5 was withdrawn from market in the year 2011 due to a number of cases of pump stop caused by default rear bearings.

38.9.5 Miniaturized Centrifugal Pumps

38.9.5.1 CorAide LVAD

The CorAide LVAD (Arrow International Inc., Reading, PA, USA) was the first third-generation assist device to implement the principle of magnetic and hydrodynamic suspension of the rotor. Due to severe hemolysis, the pump was redesigned. The first multicenter trial began in February 2005.

CorAide was an electromechanically driven pump. The pump worked either in a fixed speed mode or an automatic mode in which the rotational speed of the pump was adjusted to the systemic pressure and the heart rate. The pump weighed 303 g and consisted of titanium. The external batteries and the external controller weighed 1,350 g.

In order to avoid thrombus formation, all blood-contact surfaces were coated with fluorinated ethylene propylene (FEP). The pump generated a flow between 1.5 and 8 l/min at a rotational speed of 2,000–3,000 rpm.

The implantable parts of the system were the pump with the inflow cannula and at a right angle to the pump the outflow cannula. The pump was positioned into the pericardial space.

The results of the first multicenter trial (20 patients) showed a low infection rate and a low rate of thromboembolism. However, the magnetic suspension of the rotor proved to be unstable, resulting in severe hemolysis.

38.9.5.2 DuraHeart LVAD

The DuraHeart LVAD (Terumo Heart Inc., Ann Arbor, MN, USA; ■ Fig. 38.6) was the first centrifugal pump with a fully magnetically levitated impeller. The pump weighed 540 g, had a diameter of 72 mm, was 45 mm thick and generated a flow of up to 8 l/min at a rotational speed between 1,200 and 2,000 rpm. The pump flow could be adjusted to the patient's pre- and afterload. The system consisted of the pump within a titanium housing a titanium inflow conduit, a Vascutek GelWeave outflow conduit, the driveline, an external controller, external batteries (rechargeable every 6 h) and an external console. The DuraHeart LVAD was implanted for the first time in the year 2004 at our center in Bad Oeynhausen. We conducted a multicenter trial which included 33 patients with an average duration of support of 231 ± 194 days. The implantation was successful in 79% of cases. The 2-year survival rate was 77%. Infection rate, incidence of thromboembolism and hemolysis were low.

38.9.5.3 VentrAssist LVAD

The VentrAssist LVAD (Ventracor, Australia; ■ Fig. 38.7) was a pump with a hydrodynamically suspended rotor. The pump weighed 298 g and had a diameter of 67 mm. The pump consisted of titanium. In order to avoid thromboembolism the rotor was cone-shaped and was driven by four blades. Furthermore, all blood-contact surfaces were coated with a carbon layer. The pump generated a flow of up to 10 l/min. The pump could be placed in the pericardial space. The system consisted of the pump, silicone inflow cannula, a gelatine-coated outflow cannula (Vascutek Ltd.,

■ Fig. 38.6 DuraHeart

■ Fig. 38.7 VentrAssist

Renfrewshire, Scotland, UK), driveline, external controller and the external batteries.

The VentrAssist LVAD was implanted for the first time in the year 2003 and was CE certified. The medical device maker collapsed in 2009.

38.9.6 Fully Implantable, Pulsatile LVAD LionHeart

The LionHeart LVAD 2000 (Arrow LionHeart LVAD, Arrow International, Reading, PA, USA) was the only fully implantable left ventricular assist device. It was developed by The Pennsylvania State University (Penn State) in the USA as an alternative to transplantation (destination therapy). It was implanted for the first time in 1999 by our group in Bad Oeynhausen. It was tested in the CUBS trial (Clinical Utility Baseline Study (Pae et al. 2007a)). Although initial clinical results have been satisfying, currently, the LionHeart is not available for clinical implantation due to high development costs.

38.10 Total Artificial Hearts

Carefully selected patients with intracardiac shunts or thrombi, structural damage to the heart due to an extended myocardial infarction or with end-stage congenital heart disease may benefit from implantation of a *total artificial heart (TAH)*.

38.10.1 SynCardia CardioWest TAH

The SynCardia CardioWest TAH (SynCardia Systems Inc., Tucson, AZ, USA; ■ Fig. 38.8) is still

■ Fig. 38.8 CardioWest TAH

the most reliable and therefore the most frequently implanted TAH. The system received FDA approval as a bridge to transplantation therapy device in patients with end-stage heart failure and has been already implanted more than 1,100 times. Recently it received additional approval as a Humanitarian Use Device designation to be used for destination therapy. Due to the large dimensions of the artificial ventricles (70 cc), the SynCardia CardioWest TAH can be currently used only in patients with a body surface area of more than 1.7 m². A smaller, 50 cc system, which is designed for patients with a body surface area between 1.2 and 1.7 m², is currently being developed.

Technical description: The SynCardia CardioWest TAH is a pneumatically driven, biventricular system used for the orthotopic replacement of the native ventricles. The pump consists of four flexible polyurethane diaphragms housed in a semi-rigid polyurethane sack. By displacement the diaphragms generate a stroke volume of up to 70 ml and a pump flow of up to 10 l/min. Two mechanical valves, which are mounted in the inflow (Medtronic Hall 27 mm) and the outflow (Medtronic Hall 25 mm) conduits facilitate unidirectional blood flow. Two wire-reinforced, Dacron-coated drivelines connect the artificial ventricles to the external console.

The external console consists of two pneumatic drivers (of which one serves as a backup), batteries, air reserve tanks, an alarm panel and a computer system which monitors the operation of the TAH. There are two different drivers available. The Companion 2 hospital driver was approved by the FDA in the year 2012. During the initial recovery stage, the driver is docked in the hospital cart and after leaving the bed in the companion caddy which enables greater mobility during hospital stay. Prior to discharge the patients are switched over to the Freedom 2 portable driver. This weighs 6 kg, is worn in the backpack or a shoulder bag and is powered by two lithium-ion batteries. The Freedom portable driver received CE mark at the year 2010 and is currently undergoing an investigational device exemption clinical study in the USA.

In order to prevent end-organ failure and in order to minimize thrombus formation on the blood-contact surfaces, it is essential to provide a pump flow of 7–8 l/min at a systemic pressure of 70–90 mmHg and a perfusion pressure of 55–80 mmHg. For this reason:

■ Fig. 38.9 CardioWest TAH system components

- It is important to overcome the systemic and the pulmonary artery pressure by adjusting the drive pressure at the right side 30 mmHg over the systolic pulmonary artery pressure and the drive pressure at the left side 60 mmHg over the systemic systolic artery pressure.
- The TAH beat rate should range between 100 and 130/min, and the systolic duration should be between 50 and 60 % of the complete cardiac cycle length.
- The negative force, the vacuum in the artificial ventricles, should range between -10 and -15 mmHg.

Implantation procedure: the system consists of the following components (■ Fig. 38.9):

- Two artificial ventricles
- Two atrial cuffs
- Two outflow grafts
- One driveline
- Tools for leakage testing

Prior to median sternotomy, the outflow conduits are precoated with CoSeal Surgical Sealant (Baxter, Deerfield, IL, USA) and then cut to a length of 4–5 cm for the aortic and 5–6 cm for the pulmonary outflow. On total cardiopulmonary bypass, the native ventricles are excised at the atrioventricular level while care is taken to spare the mitral and

the tricuspid valve and a 1–2-cm wide rim of ventricular muscle. The ascending aorta and the main pulmonary artery are then excised immediately above the valvular level. The trimmed cuffs are anastomosed to the native atria and the outflow grafts to the aorta and the pulmonary artery. The driveline is tunneled, and the artificial ventricles are connected to the native atria and the outflow grafts. The ventricles are deaired by inflating the lungs and gradually declamping the great vessels.

38.10.2 AbioCor TAH

The AbioCor (Abiomed Inc., Danvers, MA, USA) is the first totally implantable, electrically driven TAH, designed as an alternative to cardiac transplantation in patients:

- With end-stage biventricular heart failure
- Who are not eligible for transplantation
- Who cannot be weaned from inotropic therapy
- Who cannot be weaned from a biventricular mechanical circulatory support
- Who are younger than 75 years of age

The internal part of the system consists of a centrifugal pump, which can generate a flow of up to 8 l/min at a rotational speed of 4,000–8,000 rpm, a controller, a rechargeable battery and a coil for

■ **Fig. 38.10** ReinHeart TAH pump unit: (1) linear motor, (2) left pusher plate, (3) right pusher plate, (4) linear bearing, (5) left artificial ventricle, (6) right artificial ventricle, (7) mechanical valve (From Pelletier et al. (2014))

energy transmission (TET). The external part consists of a coil, a TET monitor, a controller and batteries, which have to be recharged every 4 h.

In 2006 the FDA approved the Abioco under the *Humanitarian Device Exemption* program (HDE) for its use in patients with end-stage biventricular heart failure who are not eligible for transplantation and cannot be weaned from inotropic or biventricular mechanical device support.

38.10.3 ReinHeart TAH

The ReinHeart (■ Fig. 38.10) is an electrically driven TAH currently being developed by our new Institution and the Department of Applied Medical Engineering of the Helmholtz Institute, Aachen, Germany. The ReinHeart TAH is designed as an alternative to heart transplantation, aiming to support patients for at least 5 years. Anatomical and virtual fit studies demonstrated that the system can be implanted in patients with a minimum body surface area of 1.63 m^2 .

The application of a linear motor concept diminishes the need for wear-prone ball bearings, gears and lubricants. This increases the potential durability and the reliability and promises an extended lifetime of the system for more than 5 years. The linear motor is directly connected to a left and a right pusher plate, guided by a single

■ **Fig. 38.11** ReinHeart TAH system components: (1) pump unit, (2) electronic controller, (3) TET coil, (4) external batteries, (5) compliance chamber (From Pelletier et al. (2014))

linear bearing. The pusher plates are actuated in an alternating way, pumping the blood out of the chambers in a physiological sinusoidal way. Depending on the operational frequency, a chamber output between 4.5 and 7 l/min can be generated. Four mechanical valves embedded in the inlets and outlets of the pump chambers facilitate unidirectional blood flow.

The system consists of pump, electronic controller and a transcutaneous energy transmission system (TET). This system consists of two coils and a TET monitor, external batteries and a compliance chamber, which prevents suction events (■ Fig. 38.11).

The ReinHeart concept is currently being successfully tested in the chronic animal model.

38.11 Post-operative Care

38.11.1 Coagulation Management

In order to avoid an excessive bleeding during the first 24 post-operative hours:

- Avoid any routine intravenous anticoagulation medication

- Keep the International Normalized Ratio (INR) higher than 1.5
- Keep the platelet count above 100,000 ul
- Keep the partial thromboplastin time (PTT) around 50–60 s

Quality of life depends highly on the physical state (Pennington et al. 1999).

Systemic anticoagulation has to be initiated carefully. Partial thromboplastin time should not exceed 60 s. The small-molecule, direct thrombin inhibitor, Argatroban, is a safe alternative to heparin in the presence of a heparin-induced thrombocytopenia (HIT).

Oral anticoagulation with warfarin (INR 2.5–3.5) can be initiated only in the absence of any end-organ failure and after all chest tubes have been removed. Depending on the device, aspirin (1 mg/kg) or clopidogrel can be added to the oral anticoagulation.

We use to train the patients in oral anticoagulation self-management prior to their discharge from hospital.

38.11.2 Circulatory Management

The following hemodynamic parameters have to be monitored during the perioperative course:

- Arterial pressure
- Central venous pressure
- Pulmonary artery pressure
- Pulmonary wedge pressure
- Systemic vascular resistance
- Cardiac output

The hemodynamic data should be always correlated to the data displayed by the pump controller.

38.11.3 Physical Therapy

We always seek to wean the patients from mechanical ventilation as early as possible. This is possible in 80% of our MCS patients. Physical therapy can therefore be started already on the first post-operative day. Manual therapy techniques and therapeutic exercise

aim for increasing the endurance and the functional independence of the patient. The final target is to gradually reintegrate the patient in his social and working environment.

38.11.4 Nutritional Management

Malnutrition and even cachexia are common among patients with end-stage heart failure. It is therefore essential to substitute amino acids, lipids, minerals, vitamins and trace elements either parenterally or better via the enteral pathway. Since serum albumin maintains the oncotic pressure and regulates the intravascular volume, its levels must be routinely controlled and substituted if necessary

38.11.5 Medical Therapy

38.11.5.1 Inotropic Therapy

- Phosphodiesterase III inhibitors, levosimendan and prostaglandin derivatives are useful for the treatment of a right heart failure.
- Vasoactive substances (noradrenaline): since the pump flow depends on afterload, it is essential to maintain a normal systemic vascular resistance.

38.11.5.2 Antibiotics

- All patients receive antibiotic prophylaxis with cephalosporins (3 × 2 g/day) for the time until the chest tubes can be removed.
- A calculated antibiotic therapy is indicated in the presence of an infection.
- Patients who have already been treated with antibiotics preoperatively should receive a combination of vancomycin and piperacillin tazobactam for at least 4 weeks.

38.11.5.3 Heart Failure Medication

- The standard heart failure medication must be continued according to the recommendations of the ACCF/AHA (Jessup et al. 2009). The diastolic arterial pressure should not exceed 90 mmHg.

38.11.5.4 Antiarrhythmic Medication

- Since arrhythmias are a common event, a pre-existent antiarrhythmic therapy must be continued even after the implantation of an assist device.

38.11.6 Wound Management

A meticulous aseptic wound management is crucial in order to prevent driveline and pump pocket infections. The relatives of the patient have to be trained to appropriately change the driveline dressings.

38.11.7 Ambulatory Care

Ambulatory care is possible when:

- The patient has fully recovered and is in NYHA stage I–II.
- There are no signs for an end-organ failure.
- There are no signs for a systemic infection.
- The patient and his relatives are familiar with the handling of the device and the oral-coagulation self-management.
- The patient and his relatives are familiar with the management of the driveline dressings.
- Social and familial support is granted.
- A contact person from the hospital (VAD coordinator) is available at any time.

A follow-up is performed regularly (every 8 weeks) and includes:

- A physical examination
- An ECG examination
- An echocardiographic examination
- A laboratory examination
- An inspection of the driveline

38.12 Summary and Perspectives

Mechanical circulatory support is a well-established option for the treatment of end-stage heart failure. The clinical experience and the results of several multicenter trials demonstrate that it is possible to maintain survival and at the same time provide comfort for these critically ill patients.

The REMATCH trial is considered to be the landmark study in the field of mechanical circulatory support. The results, which were published in 2001 (Rose et al. 2001), demonstrated a significantly higher 1-year survival in those patients, who were treated with the pulsatile HeartMate XVE LVAD when compared to medically treated patients (52% vs. 25%, respectively). MCS patients also experienced a superior quality of life. However, adverse events, such as infections, bleeding disorders and technical or mechanical

problems, were frequent. Our own experience with positive displacement pumps, such as the HeartMate XVE, confirmed these results. The incidence of bleeding complications was 54%, the incidence of thromboembolism 7.4%. Driveline infections were documented in 21% of all cases and a pump failure in 11%. Fifty percent of all MCS patients underwent a heart transplantation (El-Banayosy et al. 2000, 2001).

The REMATCH trial has been important for two reasons: it proved that a long-time support is possible, and it outlined the necessity to develop assist devices, which would be associated with less adverse events.

Magnetically suspended pumps have several advantages: (1) they are small and can therefore be used even in pediatric patients, (2) adverse events such as excessive hemolysis, thromboembolism and bleeding disorders are less frequent and finally they are longer durable than other pump principles.

Due to bleeding complications associated with an aggressive anticoagulation management, 1-year survival rate in patients treated with the DuraHeart third-generation assist device was initially only 70%. Following adjustment of the anticoagulation management, employing self-management also, 1-year survival rate went up to 90%. An infection was documented in 15% and an acute right heart failure in 31% of all DuraHeart patients. Right heart failure was always treated medically and all patients recovered fully. Major neurological events in this group were documented in 27% of patients. There were no cases of pump failure, excessive hemolysis or pump thrombosis. In two cases the pump had to be replaced due to a temporary flow interruption. This resulted from a distortion of the motor back electromotive force waveform which led to a temporary interruption of the rotation of the motor.

The results of the HeartMate II second-generation axial flow pump are similar to those obtained with the DuraHeart. Bleeding complications were reported in 31%, driveline infections in 14%, medically treatable right heart failure in 13%, excessive hemolysis in 3% and major neurological events in 8% of HeartMate II patients. There had been no cases of a pump failure. However, the pump had to be replaced in five cases (3.7%). This was due to pump thrombosis or complications associated with the operative procedure. There had been three device-associated

deaths: two patients died due to technical problems of the external batteries and one due to kinking of the inflow conduit (Miller et al. 2007).

Patients treated with a continuous flow pump have significantly improved event-free survival rates as compared with pulsatile flow pumps. Two-year survival, free from device-related reoperation and stroke, was reported in 46 and 11% of patients treated with the HeartMate II and the HeartMate XVE pumps, respectively. Similarly, adverse events such as infections, bleeding complications, right heart failure and end-organ failure were less frequent in the HeartMate II cases. The result was an improved survival at 1 (68% vs. 58%) and 2 years (55% vs. 24%) and a significant reduction in the rate of rehospitalization (Slaughter et al. 2009).

The results of the DuraHeart and the HeartMate II trials show that a long-time support is feasible, with an acceptable rate of adverse events. The HeartMate II has been approved by the FDA for destination therapy.

The field of mechanical circulatory support is still evolving. The current results demonstrate that a long-term duration of support and a high quality of life can be achieved. Miniaturized systems, which are currently under development, may turn out to be a safe alternative and even an equal choice to orthotopic heart transplantation.

39.1 Introduction

The *median sternotomy*, developed at the end of the nineteenth century, is currently employed for access to the heart in >90% of all procedures in cardiac surgery. It is technically simple to perform and offers an excellent view of all structures relevant to the cardiac surgeon for any procedure. The sternal closure as the final step in a trans-sternal cardiac surgical procedure is technically *straight-forward* and usually well tolerated by the patient. However, with the increasing number of *elderly and more complex patients undergoing cardiac surgery*, sternal complications may pose *greater* challenges to cardiac and plastic surgeons in greater numbers than ever before.

In the literature, the overall incidence of sternal complications after cardiac surgery is reported to be between 0.2 and 10%; however, clear-cut definitions of a sternal complication are lacking. In Germany the reported range is smaller at 1–4%. There is a large spectrum from mild to life-threatening complications ending in septic circulatory shock. Comprehensive classifications of septic sternal complications have been suggested by El Oakley and Wright (1996; ■ Table 39.1) as well as from the US Centers for Disease Control and Prevention (CDC; Mangram et al. 1999), but these are rarely applied *clinically*. Commonly, a more or less

detailed description of sternal instability and infection is given; usually, soft tissue damage, involvement of the bone structure, and the mediastinum are analyzed, as well as *sepsis* may be reported.

Definition of the mediastinitis according to the Centers for Disease Control and Prevention (CDC; Mangram et al. 1999):

- Cultural evidence of pathogen from mediastinal tissue or fluid
- Clinical picture of a mediastinitis during surgical revision
- Chest pain or sternal instability or fever (>38 °C) *plus* secretion of pus
- Cultural evidence of pathogens from the blood or drainage fluid

At least one of the situations has to be given.

The *pathogenesis* of sternal complications in general is not completely understood and awaits further elucidation.

Primary aseptic sternal instability is *typically* a mechanical problem. Increased *lateral force* at the *sternal edges* and *failure of the closure technique* may lead to this problem.

In infected sternal instability, the pathogenesis is discussed rather controversially. On the one hand, it is presumed that sternal instability promotes wound infection; on the other hand, a sternal dehiscence may also develop secondarily as a consequence of a local osteomyelitis. Another hypothesis is based on inadequate drainage of the mediastinum with retrosternal accumulation of retained *fluid* (El Oakley and Wright 1996).

The following *risk factors* have been demonstrated in numerous studies:

- Obesity
- Diabetes mellitus
- Osteoporosis
- Chronic-obstructive lung disease
- Prolonged ventilation time
- Bilateral use of the internal mammary artery during coronary bypass surgery

Interestingly, the risk factors had additive effects (Eagle et al. 2004; El Oakley and Wright 1996). *The use of bilateral internal mammary arteries* is discussed quite controversially, as the sternal perfusion is reduced by >90%. Accordingly, the *potential* benefit of the arterial revascularization is opposed by an increased risk for sternal complications (Seyfer et al. 1988). Whether the application of bone wax *promotes* sternal instability

■ **Table 39.1** Classification of the mediastinitis after surgery with a heart-lung machine according to El Oakley and Wright (1996)

Type	Finding
I	Mediastinitis presenting within 2 weeks after the operation in the absence of risk factors
II	Mediastinitis presenting at 2–6 weeks after the operation in the absence of risk factors
IIIA	Mediastinitis type I in the presence of one or more risk factors
IIIB	Mediastinitis type II in the presence of one or more risk factors

V	Mediastinitis presenting for the first time more than 6 weeks after the operation

ity is also *unclear* (Nelson et al. 1990; Prziborowski et al. 2008).

The *mortality* of infectious sternal complications has decreased due to the effectiveness of currently available broad-spectrum antibiotics and the experience with various treatment options. There is still a high percentage of significant comorbidity, and mortality still ranges between 5 and 50% (Domkowski et al. 2003). *Another important* issue with sternal complications is the significantly prolonged hospital stay; costs are increased and *long-term survival may be* reduced (Sjogren et al. 2006).

39.2 Diagnostics

39.2.1 Sternal Instability

Isolated sternal instability is *nonunion of the sternal edges* without an associated infection. In contrast to infected sternal instability, noninfected instability is less frequent and may occur very early, almost immediately after surgery. The patients present with a macroscopically unremarkable wound and complain about ongoing or recurrent pain and/or crepitation. The laboratory *evaluation is unremarkable*. In obvious cases, diagnosis can be established by palpation, but a thoracic computed tomography *scan is helpful in confirming the diagnosis*. In the latter, a significant gap, i.e., dehiscence, is visible in the sternum, which can be localized. It often affects the whole length of the sternum. *Loosened* sternal wires can be recognized as an underlying cause, quite often combined with a *fractured sternum in one or multiple sites*.

39.2.2 Wound Healing Disorder

Wound healing disorders after sternotomy are usually the consequence of a soft tissue infection. Obese and diabetic patients are at increased risk for wound healing disorders. Perioperatively administered antibiotics may not fully *penetrate the adipose tissue*, and thick skin folds *may be difficult to prepare for surgery*. In *diabetic* patients, it *has been clearly* demonstrated that strict control of the blood glucose level *postoperatively* reduces the incidence of sternal infections (Zerr et al. 1997). Poorly healing soft tissue wounds *may develop following reoperative surgeries* or after multiple sur-

gical revisions via the same *site* which lead to considerable soft tissue trauma and *ischemia* (The Parisian Mediastinitis Study Group 1996).

A visual diagnosis can be made in 70–90% of wound infections by identifying *an erythematous, often wet, and discharging wound*, in most cases 9–11 days after surgery (Wouters et al. 1994). Painful induration and fluctuating abscess/edema are not uncommon. Laboratory serum parameters and blood cultures can *support the diagnosis*, but not exclude it.

A chest X-ray is of little help. Depending on the depth of infection, superficial and deep sternal wound disorders *can be distinguished*. Superficial wound disorders involve only the subcutaneous *tissues*, whereas deep infections also affect the sternal bone. The predominant microorganisms are *Staphylococcus aureus* and *Staphylococcus epidermidis* which usually respond well to intravenous and/or local antibiotics. Less often involved are enterococci, *E. coli*, *Klebsiella oxytoca*, *Propionibacterium acnes*, and others.

39.2.3 Infected Sternal Instability

The combination of sternal instability and sternal wound infection is much more frequent than an isolated, aseptic sternal *dehiscence*. The order of the underlying pathological mechanisms is unclear (see ► Sect. 39.1, “Introduction”). The risk factors are similar to those of any sternal wound healing disorders:

- Significant obesity (frequently associated with an osteoporotic sternum)
- Prolonged stay in the intensive care unit
- Obstructive airway disease
- Poor patient compliance *regarding sternal precautions* during mobilization
- Advanced age
- Impaired renal function
- Emergent operation

These risk factors have been outlined in the guidelines for mediastinitis after aortocoronary bypass surgery by the American College of Cardiology (ACC) and the American Heart Association (AHA) (Eagle et al. 2004). The need for dialysis and diabetes mellitus was considered to be of less importance.

Diagnosis is generally simple to establish. The patients complain about local or diffuse chest pain

and sternal crepitation. Deep in the wound, the sternal bone and/or wires can be reached with a small probe, while pus or suspicious fluid may be expressed. There may be signs of systemic infection and the overall clinical condition of the patient can rapidly decline. If the diagnosis remains uncertain, a computed tomography scan of the chest may provide confirmation. In any case, wound swabs for microbiology culture should always be taken to determine the involved microorganisms, preferably before any therapy with antibiotics is initiated.

39.3 Indication for Surgery

A limited local instability, with an otherwise stable sternum, can be managed conservatively, particularly when asymptomatic. Instability involving the majority or the whole sternum and complete sternal dehiscence are a clear-cut indication for surgical revision. Nonsurgical therapy is only employed when patients suffer no or minimal discomfort, and redo surgery is considered a very high-risk procedure.

Any wound drainage almost always requires surgical intervention and intravenous antibiotic treatment after material for cultures has been taken. Intravenous antibiotic treatment alone is not sufficient. Nevertheless, it is important to determine the underlying organism as well as antibiotic sensitivities to be able to successfully treat difficult microorganisms like the methicillin-resistant *Staphylococcus aureus* (MRSA). For superficial infections, reopening and debridement of the wound and conservative treatment modalities can be an effective approach. However, abscess formation, fluid retention, and necrosis always mandate surgical intervention.

39.4 Surgical Therapy

39.4.1 Sternal Instability

During surgical revision the sternal wound is reentered. If the sternal wires are only loosened without an evident infection, they can be simply retightened. Wires that have dehisced must be removed and the sternal edges prepared for reapproximation. Even if the sternum is only partially dehisced, it is favorable to reopen the

■ Fig. 39.1 Robicsek technique for rewiring of an unstable sternum

In any case it is important to keep attention not to lacerate mediastinal structures (e.g., coronary bypass graft) when preparing the sternal edges for reclosure.

sternum completely so new wires can be placed accurately.

Restabilization of the sternum can be achieved with different surgical techniques as no gold standard has yet been defined.

39.4.1.1 Rewiring

The sternal edges are approximated using single wires as with primary sternal closures or with two additional wires weaved through the intercostal spaces parasternally (■ Fig. 39.1) (Robicsek et al. 1977). The consolidated sternal edges are then reapproximated with sternal wires in various configurations (simple wires, wire loops, figure of eight) or with peristernal bands (e.g., Parham).

39.4.1.2 Plate Fixation

There are two possibilities for plate fixation of the sternum:

- A large 0.5 mm thick malleable titanium alloy plate with lateral perforations for suturing which is available in different sizes and shapes

can be placed onto the sternum, the Astudillo-Ley prosthesis (Astudillo et al. 2001). The sternal fragments are fixed to the plate with wires and sutures which renders the reconstructed sternum stable enough for careful rehabilitation.

- Alternatively, angle-stable titanium plates, as used in trauma surgery, can be transversely screwed to the ribs across the sternum (■ Fig. 39.2). The advantage of this technique is that excellent stability is achieved, even in the case of extensive sternal destruction. However, the surgical expenditure and complexity are much larger as compared to the other techniques. There are also newer fixation systems using titanium plates which are primarily intended for prophylaxis during primary procedures of high-risk patients. *A significant reduction in postoperative sternal wound infections was achieved using rigid plate fixation in a high-risk patient population as compared to simple closure with wires* (Song et al. 2004). *High-risk patients closed with wires had a 14.8% incidence of mediastinitis (n = 207) as compared to 0% in the plating group (n = 45).*

If *extensive fragmentation* of the sternum is present which is commonly also associated with significant osseous defects, immediate sternal restabilization can be *difficult*. Bone sequesters require extensive debridement to remove all destroyed and potentially infected sternal tissue. Small osseous defects can be covered with unilateral or bilateral pectoralis muscle flaps (Jurkiewicz et al. 1980). *This becomes much more complex if*

the whole sternum has to be resected. If there is no formation of granulation tissue within the mediastinum, reconstructive coverage of the defect by a plastic surgeon becomes necessary. Therefore, it is *advantageous* to preserve as much of the sternum as possible, especially if that *segment* provides local stability. For thoracic stability the manubrium is the most important and at times sufficient to allow for definitive treatment.

39.4.2 Wound Healing Disorders

A successful therapy of a sternal wound infection requires not only adequate antibiotic treatment but also mechanical elimination of the infection site to start with. *Infected superficial wounds* can be cleaned by excision of necrotic tissue and extensive rinsing with H₂O₂ (is controversially discussed for cell toxicity), polyvinylpyrrolidone-iodine, or other disinfecting solutions and thereafter closed again. Simple interrupted sutures are most suitable for that since a wound can be partially reopened in the case of a local reinfection. Also Penrose drains can be placed beforehand for 24–48 h.

Deep wound infections are more difficult to treat, since continuation of the infection directly into the sternum or via the sternal wires cannot be visually judged for sure. As in superficial cases of infection, the soft tissue must be radically and completely cleaned by necrosectomy and rinsing. Once this is done, a larger soft tissue defect remains which may be still closed directly, employing small wound drains if deemed necessary or possible. Tension at the wound edges can be relieved by mobilization of the pectoral muscles. In the presence of a large defect and extensive infection with uncertain spread, the negative-pressure wound therapy (NPWT), also called vacuum-assisted closure (VAC), has become a very popular therapy: the whole wound or the infected part of the wound remains open and it is filled out with an open-cell foam dressing or gauze. A drainage is placed over the foam and the wound is finally sealed with an occlusive film drape. With applied intermittent or continuous vacuum pressure to the drain (about 100 mmHg), the wound bed is cleaned, the wound edges are retracted, and granulation is stimulated. With sufficient granulation the wound can be closed at a second stage or further be treated conservatively.

■ Fig. 39.2 Sternal plating

Cowan could demonstrate that the need for surgical interventions is less and the hospital stays are shorter with vacuum therapy (Cowan et al. 2005).

39.4.3 Infected Sternal Instability

A wound *infection* with associated sternal instability poses the greatest challenge to the surgeon and to the patient. There are no standardized treatment concepts, but in all cases *complete eradication* of the infection in any tissue is the most important.

The first step is to open the infected wound and *debride* all necrotic tissue. All wires or other closure materials are *removed* and the sternum is separated. The mediastinum is inspected for evidence of *infection*. If there is suspicion of a mediastinitis, the mediastinum is rinsed with several liters of sodium chloride or Ringer's solution. H₂O₂ (see above for caution ► Sect. 39.4.2, "Wound Healing Disorders") and polyvinylpyrrolidone-iodine can be used as well.

In the case of extensive infection, implantation of a *closed chest tube drainage with irrigation system* is commonly utilized, with the irrigation tube being placed behind the manubrium and the drains placed subxiphoid (Shumaker and Mandelbaum 1963). *This approach provides a single-stage closure and has a low failure rate* (Merrill et al. 2004). Another option, especially used in recurrent mediastinal infection or in patients after cardiac transplantation, is to mobilize the greater omentum which can be prepared as a pedicled flap to cover the mediastinum. However, this technique requires a combined thoracic and abdominal *approach* which was associated with a significantly higher risk in elderly patients when *first described* (Lee et al. 1976).

Prior to *closure* the sternal edges are trimmed with curettes, Volkman's spoon, or a sternal saw. The pectoral muscle is mobilized (Jurkiewicz et al. 1980). Stabilization techniques are similar to those described for aseptic sternal dehiscence (see ► Sect. 39.4.1, "Sternal Instability"), but it seems advantageous to minimize the use of implants. Nevertheless, *rigid fixation* of the sternal edges is the prerequisite for uncomplicated wound healing. Depending on the soft tissue conditions, it is decided whether the wound can be closed primarily or has to be *left* partially or totally open. If

In conclusion, there are several options to stabilize an unstable sternum at present. Infected sternal wounds are reopened and aggressively cleaned. An infected sternal instability can be treated in two ways, with a closed chest drainage and irrigation system with primary closure of the wound or with a vacuum therapy and a secondary sternal closure.

primarily left open, definite closure follows once the bottom of the wound is clean and fresh granulation tissue *is formed*. For the latter circumstance, the vacuum-assisted closure (VAC) technique can be used since they are highly efficient, easy to care, and comfortable for the patient. This has become more commonly used for complex open soft tissue wounds following sternal closure with excellent results (Sjogren et al. 2006).
