Preface

The majority of the various comprehensive textbooks available cover either cardiac surgery in adults, mostly synonymous for acquired heart disease, or pediatric cardiac surgery, synonymous for congenital heart defects. This separation of the spectrum of cardiac surgery is not appropriate anymore, especially as the majority of children operated for congenital heart disease reach adulthood, potentially needing further surgical attention. On the other hand, although a rare phenomenon in the Western world, cardiac surgeons have to deal with acquired heart disease in children as well.

Surgery and catheter interventions, competing therapeutic strategies in the beginning, have become complementary: interventional valve implantation may be performed by cardiac surgeons, and aortic stent implantation is well established in the thoracic domain. This development also blurred the boundaries of involved specialties, necessitating close cooperation not only between cardiologists and cardiac surgeons, but also involving vascular surgeons, radiologists, and others. Furthermore, hybrid procedures performed in parallel or in sequence with open surgery and catheter intervention in the same setting by different groups of specialists (e.g., surgeons and catheter interventionalists) have changed the traditional field of surgery.

Only a few textbooks cover such a broad spectrum of cardiac surgery. Our predecessors as editors, Hans Georg Borst, Werner Klinner, and Åke Senning, started this endeavor, when they published the first and only German textbook on cardiac surgery, “Herz + herznahe GefäÙe” 1978 [1], the year, in which both of us (G.Z. and A.H.) just finished medical school.

For the second edition, published in 1991, now named “Herzchirurgie” [2], edited by Hans Borst, Werner Klinner, and Hellmut Oelert, we could contribute as junior faculty in our primary fields of interest. This led us to become editors of

the third and latest edition of this German textbook in 2010 [3].

In the spirit of our German teacher Hans Borst’s honored guest’s address at the 65th Annual Meeting of the American Association for Thoracic Surgery in New Orleans 1985: *Hands across the ocean, German-American relations in thoracic surgery* [4], we expanded the project of our German textbook and planned for an updated English language edition.

Among the authors and co-authors contributing to the latest German edition (mainly from Germany, Austria, and Switzerland), many had received at least part of their specialty and subspecialty training in clinical cardiac surgery or research in English-speaking countries, most of them in North America, but also in the United Kingdom, Australia, and South Africa.

This our first English language edition entitled *Cardiac Surgery: Operations on the Heart and Great Vessels in Adults and Children* comprises the view of 71 authors not only from 30 German, Austrian, Swiss, French, and Luxembourgian Cardiac Units, but also from Boston, MA; Chicago, IL; Greenville, NC; Houston, TX; Los Angeles, CA; Miami, FL; Milwaukee, WI; St. Petersburg, FL; Toronto, ON; and Washington, DC.

Starting rather traditionally, with a chapter on the history of cardiac surgery, we continue with risk scores and principles of quality assurance, followed by quality control in cardiac surgery in the United States, and an overview of databases in cardiac surgery.

This introduction is completed with a section of chapters on technical prerequisites for cardiac surgery in which we focus separately on postoperative critical care for adults and children. There also is a chapter on tissue engineering in cardiac surgery.

The major part of this book is divided into sections on congenital anomalies and those for acquired diseases, also addressing minimally invasive cardiac surgery as well as endovascular treatment of aortic diseases.

The publication of this book was significantly delayed due to the sudden death of our highly valued German Illustrator Reinhold Henkel, who had been responsible for our anatomical figures before. In memory of him and his longstanding contribution, we had to complete this edition without being able to use his artwork throughout.

We thank Claus-Dieter Bachem for serving as our project coordinator and Ellen Blasig and Gabriele Schroeder from Springer as publishing editors.

At the University of Chicago, we had native speaker editing support from Liz Johnson, Grace Macek, and Melanie Sojka.

Our hope is that this comprehensive but still concise textbook is suitable not only for cardiac surgical residents in training, but may also serve as reference for all surgeons, physicians, nurses, and technicians caring for patients with heart disease of any type, at any age.

1.1 From the Beginning

September 9, 1896, is generally agreed upon as the date of birth for clinical cardiac surgery. This was the day when in Frankfurt/Main, Germany, Ludwig Rehn (1849–1930) decided to operate on a 22-year-old gardener who suffered from a stab wound to his chest. He had been treated for 1 day conservatively with icepacks and camphor injections. When the patient's clinical condition rapidly deteriorated, Rehn performed a left thoracotomy and opened the pericardium. He found a 1.5 cm stab wound in the right ventricle, which he closed with three single stitches. The postoperative course was complicated by fever and frank pus draining from the thoracotomy wound; however, the patient eventually recovered and was discharged from hospital. When Rehn presented this case at the 26th Meeting of the German Society for Surgery in 1897, he concluded: «From now on, there should not be any more doubt about the feasibility of a heart suture.» He hoped his successful case would encourage others to continue the work in the field of heart surgery (Rehn 1897).

Rehn's pioneering effort was not an ingenious, spontaneous flash of inspiration. In 1868 Georg Fisher from Hannover, Germany, had published an analysis of medical discharge summaries of 452 patients with heart wounds (Fisher 1868). He found the recovery rate to be 10%. This meant not all patients died immediately from wound to the heart, which at least for some should allow for surgical intervention. Reports on successful experimental and unsuccessful clinical cases of stab wounds to the heart had been presented by Block from Gdansk (then Germany) and also by Norwegian and Italian surgeons (Bircks 2002; Block 1882).

The first surgery for a stab wound to the heart in the United States was performed in Montgomery, Alabama, by Luther Hill on September 14, 1902, on a 13-year-old boy, who had suffered numerous stab wounds to his chest. Surgery was performed under chloroform anesthesia. One single stitch had to be done on the myocardium, and the patient survived surgery without complications (Westaby 1997). In 1903, Ricketts from Cincinnati, Ohio, reported on 56 cases of cardiac sutures, with success in 20 (Ricketts 1903).

There has been controversy about a notion attributed to Theodor Billroth (1829–1894), «The surgeon who will try to suture a wound of the

heart can be sure to be definitively discredited by his colleagues.» This quotation is found in K.H. Bauer's *Aphorismen und Zitate in der Chirurgie* [*Aphorisms and Citations in Surgery*] (Bauer 1972). Karl-Ludwig Schober, in his work on early history of surgery of the thorax and its organs, has his doubts about this being a proper citation of what Billroth actually said. He rather thinks that this notion is a misquotation, originating from hearsay or from primary mistakes in citation (Schober 1981, 1993).

Among crucial points for the early years of cardiac surgery, Rehn's experience (Rehn 1913) is repeatedly quoted by Herrmann Küttner, who wrote the chapter «Cardiac Surgery» for the first 6 editions of the *Textbook of Surgery* edited by Bier, Braun, and Kümmel, first edition 1912 (Schober 1993):

» It is important not to take shallow bites on both wound edges, as the sutures need to be tied without cutting through the fragile tissue of the heart muscle.

Referring to the issue of continuous versus interrupted single sutures, Rehn clearly pleaded for interrupted single sutures.

» If the heart shows signs of fatigue and starts working in an irregular fashion while the suturing is performed, give it a rest to recover. Therefore one should put the heart back into its original, normal position and refrain from any manipulation for some time.

Most of this advice is still up to date!

Ludwig Rehn was a self-made man who had not been trained at any of the leading centers for surgery at that time. However, he was a thoroughbred surgeon who caught the momentum and acted accordingly. He became not only the first to successfully perform cardiac surgery, he also was the first cardiac surgeon, who developed and controlled his surgical techniques in animal experiments. This made him the founder of academic cardiac surgery (Mueller 2007; Schmieden 1931).

Three other surgeons became the leaders of experimental cardiac surgery before World War I and provided the base for its further clinical application (Schober 1993; Vaubel 1980; Westaby 1997):

- Alexis Carrel (1873–1944)
- Ernst Jeger (1884–1915)
- Rudolf Haecker (1878–1957)

Alexis Carrel was born in Lyons, France. After graduating in medicine from the University of Lyons, he left France for Montreal, Canada, but joined shortly afterward the Department of Physiology at the University of Chicago, where he mainly worked with Charles Guthrie (1880–1963). They perfected the technique of vascular anastomosis. The triangle method for vascular anastomosis developed by Carrel in 1902 is still a standard today. They also reimplanted limbs and performed autotransplantations of kidneys, ovaries, and thyroid glands.

In 1906 they separated; Charles Guthrie went to Washington University in St. Louis, Missouri, and Alexis Carrel joined the Department of Experimental Surgery at the Rockefeller Institute in New York City. There he replaced segments of the descending thoracic aorta with caval vein grafts, being already aware of the risk of paraplegia in this type of surgery. He did experiments on techniques of mitral commissurotomy and cardiac aneurysmectomy, and he also did research on coronary artery bypass surgery.

Another one of his areas of interest was heart transplantations. He transplanted hearts from little animals to the neck vessels of bigger animals (Carrel and Guthrie 1905). In 1912 Carrel was named the Nobel Laureate for Physiology and Medicine. After the World War I, he continued his research on organ preservation and worked with Charles Lindbergh on a mechanical pump which should support the circulation when the heart needed to be stopped for surgical procedures (Edwards and Edwards 1974; Westaby 1997).

Ernst Jeger (1884–1915) was born in Vienna, Austria. There he received his training in surgery from Professor Eiselsberg and Professor Zuckerkandl. A short time after that, he went to the Physiological Institute in London, England, and then to Berlin, Germany, to Professor Bickel in the Department of Experimental Biology at the Charité. In between, he spent 6 months studying with Carrel in New York City. In June 1913 he started working as a volunteer in the Department of Surgery at the University of Breslau with Hermann Küttner. Being a foreigner from Austria, taking this unpaid position was his only chance to work there without having to pass a new medical examination for the German Reich. When World War I began, he had to join the Austrian army and had to defend the Przemyśl fortress against the Russians (Schober 1993). Just before he could publish his overview

«The Current State of Blood Vessel Surgery» (Jeger 1914b), Jeger died in 1915 of typhus as a prisoner of war in Russia (Schober 1993).

Ernst Jeger's main interest was experimental cardiovascular surgery. In 1913 he reported on reimplantation of the renal vein into the inferior vena cava (Jeger and Israel 1913). In Breslau he succeeded in bridging resected aortal segments by end-to-side anastomoses of vein grafts (Jeger 1913). For treatment of portal hypertension, he proposed the mesenteric-caval shunt (Jeger 1914a). While in war, he took care of vascular injuries and was successful in six out of eight cases (Jeger 1914b).

In 1913, as part of a lecture at the 42nd Congress of the German Society of Surgery, he anticipated the later Blalock-Taussig shunt as a way to arterialize the pulmonary circulation, without having any idea about the clinical significance at that time (Jeger 1914a). Ernst Jeger's early death was not only a personal tragedy but also a step back for the development of the European cardiac surgery.

Rudolf Haecker is the third surgeon who has to be mentioned here. As an assistant to Paul Leopold Friedrich in the Department of Surgery at the University in Greifswald, Germany, he published on experimental cardiac pathology and surgery (Haecker 1907). His experiments on caval inflow occlusion in normothermia showed that dogs survived this for no more than 3 min without cerebral damage. Therefore, normothermic caval inflow occlusion was defined as a method to be used only for a very short period of time when treating wounds of the heart. This was confirmed by Ferdinand Sauerbruch and Ludwig Rehn (Rehn 1913; Sauerbruch 1907).

The next steps in the development of cardiac surgery included success in closed-heart surgery; the heart was operated from the outer surface, «trying not to disturb and certainly not interrupt the heart's pump function».

1.2 Operations on the Pericardium

At the beginning of the twentieth century, it was not possible to treat inflammatory pericardial disease in the state of purulent, especially tuberculous pericarditis; the consequence often was a severely contracting pericarditis leading to the end stage of *constrictive pericarditis*. In 1902 Ludolf Brauer inaugurated what he called cardi-olysis: resection of the ventral parts of the calcified

pericardium together with segments of the thoracic wall (Brauer 1903). The heart was indirectly unwrapped. The first successful pericardectomies were performed in 1912, again by Ludwig Rehn in Frankfurt/Main, and in 1913, by Ferdinand Sauerbruch in Zurich, Switzerland. Later, the technique of pericardectomy was mastered by Viktor Schmieden (1874–1945) in Halle/Saale and later in Frankfurt/Main, where he had become Rehn's successor in 1919. There he later continued to work with the internist Franz Volhard (1872–1950), who came to Frankfurt in 1927 after having been professor in Halle/Saale (Bircks 2002; Schober 1993). The first pericardectomy in the United States was performed in 1928 by Edward D. Churchill in Boston on an 18-year-old girl (Churchill 1929). In Cleveland, Ohio, Claude Beck worked experimentally on the clinical symptoms and the surgical therapy of constrictive pericarditis (Westaby 1997).

1.3 Trendelenburg's Pulmonary Thromboembolotomy

In his classical work about surgical pulmonary artery thromboembolotomy in 1908, Friedrich Trendelenburg (1844–1924), surgeon-in-chief at the University of Leipzig, Germany, precisely described and meticulously specified his technique of surgery (Trendelenburg 1908). With forceps and a suction cannula, the thrombotic material was extracted from the pulmonary arteries after the pulmonary trunk was opened with a transverse incision. He argued that patients often survived 10–15 min even after fulminant lung embolism. Therefore, a well-trained team should succeed in saving a patient with an intervention, which in those days only meant surgery. External cardiac massage would also help. Unfortunately, Trendelenburg had no successful clinical cases of his own in Leipzig. In Jena, Germany, F. Krüger (1878–1954) had a patient who, in 1909, survived the Trendelenburg operation for 5 days (Krüger 1909; Schober 1993). Dagobert Schumacher, chief resident with Ferdinand Sauerbruch in Zurich, Switzerland, summarized nine unsuccessful pulmonary embolotomies from the literature and added three new unsuccessful cases from their group (Schumacher 1913). It was not until 1924 that the first successful embolotomy was performed by Martin Kirschner (1879–1942) in: Königsberg,

East Prussia/Germany (Kirschner 1924). Thereafter, successful Trendelenburg operations were reported by Arthur W. Meyer (1885–1933) from Berlin, Germany (Meyer 1928, 1931) and by Clarence Crafoord and G. Nystrom from Sweden (Crafoord 1929; Nystrom 1930).

1.4 Resection of a Right Ventricular Aneurysm by Sauerbruch (1931)

With the diagnosis of a mediastinal tumor, the big mass was punctured intraoperatively. When bleeding occurred, the tissue had to be clamped; however, it continued tearing and bleeding even more. It eventually could be controlled by compression with a finger. Sutures were laid over the compressing finger in situ and tied. Histopathology revealed an aneurysm of the wall of the right ventricle (Sauerbruch 1931).

1.5 The First Successful Ligatures of a Patent Arterial Duct by Robert Edward Gross (1905–1988) in the United States and by Emil Karl Frey (1888–1977) in Germany

Frey was working at the University of Duesseldorf, Germany, before World War II (Bircks 2002; Frey 1978). In his book *Rueckschau und Umschau* (retrospective look around), he writes:

» In 1939 Edens, the internist in Duesseldorf sent a 14 year old boy to us, in whom loud sibilating sounds were heard through the chest, that made me think of an arteriovenous aneurysm. In surgery, we found a patent ductus Botalli. The loud sound immediately disappeared, when I compressed the small communication between pulmonary artery and aorta. As this did not show unfavorable sequelae, I ligated the short passage twice with the assistance of Karl Vosschulte. I did not report this operation immediately, as we hoped we could soon treat another patient in the same way, so that more accurate data from preoperative examinations and exact reports about changes after surgery could be presented. This did not happen,

World War II came. I was told somewhat later, that Gross in the United States already had written about the ligation of a patent ductus Botalli. He had the primacy of this surgery (Frey 1978).

In fact, Robert Gross had already ligated an open ductus Botalli on August 26, 1938 at Boston Children's Hospital (■ Fig. 1.1). With this, he started the era of pediatric cardiac surgery (Gross and Hubbard 1939). While Frey described his surgery as rather unplanned, Gross had planned to perform a ductus closure well ahead by working out a surgical approach with his pediatrician partner John Hubbard in the laboratory and autopsy room (Moore and Folkman 1995). The first suitable patient, a 7-year-old girl showed up when Gross was still chief resident, and his chief William Ladd like many Bostonians was out of town taking summer vacation. With the permission of the acting chief, Thomas Lanman, he went ahead. Apparently, so the story goes, Ladd encountered Gross shortly after the successful operation at some sporting event. When asked how things were at the hospital, the laconic answer of Gross was that nothing unusual had happened (Castaneda 1981).

Doubts about Gross's primacy in successfully closing a persistent ductus arteriosus are not substantiated, although published peer reviewed (Kaemmerer et al. 2004).

In his biographical memoir (Moore and Folkman 1995) Dr. Gross is cited to never again have ligated a ductus after the 12th pediatric patient, a 14-year-old girl, died while dancing with her friends at a party for her 2 weeks after surgery. Autopsy showed a cut through ligature permitting massive hemorrhage. According to Dr. Gross's original surgery case logbook 1937–1972 (provided by Bob Replogle, see ■ Fig. 1.1), this must have been his 14th pediatric ligation patient (of total 20), a 16 year old girl (■ Fig. 1.2). Thereafter he performed two ductus divisions before he returned to ligation only for another 14 months up to patient number 42. Thereafter ductus ligation became a rarity in his and his associates' practice (■ Fig. 1.3). Almost all further ductus patients until his last one, number 1610, in March 1972, underwent ductus division with suture closure of the ends (Moore and Folkman 1995).

Date	Patient Name	Age	Procedure
7/8/38	William Skid	22574	Supra-pubic cystostomy
7/10/38	Baby Guy Nash	22578	Incision umbilicus of ileum, lateral anastomosis, gastrostomy
7/12/38	Jonathan Black	22588	Incision caecum - ascending colon
7/12/38	Donald Cross	22589	Cystostomy, gastrostomy
7/11/38	Bobby Gordon	17767	Incision of drainage at leg
7/12/38	Baby Girl Tachest	225018	Abd. Expl. with freeing of adhesions of jejunum - distalities of jejunum
7/15/38	Eduin Minor	C.H.	Excision - intussusception
7/21/38	Margaret Cassius	225717	Excision upper jejunum
7/22/38	Richard Sack	22582	Excision tendon - left hand
8/11/38	Baby Girl Cecae	22580	Freeing adhesions - duodenojejunostomy
8/16/38	Clarence Sherr	22587	Proctoscopy
8/16/38	Bobby Gordon	15747	Free dressing
8/18/38	James Sherr	22587	Proctoscopy or subcutaneous to pelvis
8/22/38	Lorraine Tachest	224018	Freeing duodenal adhesions
8/25/38	Bobby Gordon	225078	Left thoracotomy
8/26/38	Lorraine Sweeney	220100	Ligation - patent ductus arteriosus
8/27/38	Arthur Tachest	22582	Excision - appendectomy
8/29/38	Elizabeth Mandy	21726	Appendectomy with drainage
8/31/38	Bobby Gordon	22760	Excision - gastrostomy
9/1/38	John Dent	22974	Excision - without structure
9/11/38	William Cross	22577	Proctoscopy - excision of polyp
9/12/38	Tracy Cook	16557	Ligation - patent ductus arteriosus

■ Fig. 1.3 After September 1942, ductus ligation became a rarity, almost exclusively replaced by ductus division (Dr. Goss's surgery case logbook #1, «Patent Ductus» list, pp.174/5, Sept. 1944 – Oct. 1945) (Courtesy Dr. Robert and Carol Replogle)

1.6 Blocked Developments and Missed Opportunities

1.6.1 Endotracheal Intubation

Friedrich Trendelenburg (1844–1924), at that time still at the University of Rostock, Germany, used tracheal intubation in a patient for the first time in 1869. The rationale was to avoid aspiration of blood and secretions during oral surgery (Trendelenburg 1871). At the end of the nineteenth century, other surgeons reported successful narcosis employing tracheal intubation, like Karel Maydl (1853–1903) in Prague, Bohemia (Maydl 1892); Viktor Eisenmenger (1864–1932) in Vienna, Austria (Eisenmenger 1893); and Theodore Tuffier in Paris, France (Schober 1993). A cuffed rubber tube, which also had a pilot balloon, was already used by Eisenmenger in 1893 (Goerig and Schulte am Eich 2003).

Franz Kuhn (1866–1929), working as a general surgeon in Kassel, Germany, was a proponent of tracheal intubation (Kuhn 1901). He employed flexible metal pipes. In March of 1905, he described his experiments on dogs as follows: «In deep narcosis the right thorax is entered. Due to

the pressure ventilation, the lung is expanded and breathes very calmly and regularly. When the pressure pipe is disconnected from the endotracheal tube, the lung collapses.» Kuhn saw the advantages of this method for an undisturbed gas exchange and superior kinetics of the inhaled narcotic agents, which lead to a better control of narcosis. In describing his experiments, he obviously saw also the advantage of avoiding pneumothorax during his open chest experiments; however, he was not a thoracic surgeon (Schober 1993).

At almost the same time, Franz Kuhn was performing his endotracheal intubation experiments, in 1904 Ferdinand Sauerbruch (1875–1951), assistant to Johannes (born: Jan) von Mikulicz-Radecki (1850–1905) in Breslau, Germany, performed open chest surgery on a lung in a low-pressure chamber developed and constructed by himself (Sauerbruch 1904b, c). To avoid pneumothorax, he employed a low-pressure technique he developed, in which the patient's head was exposed to normal atmospheric pressure outside the box, while the other parts of the body were in subatmospheric pressure within the low-pressure chamber. When opening the chest in the low-pressure chamber (in which, in addition to the

patient, the whole surgical team had to fit), the lung did not collapse, and the patient could breathe spontaneously. Sauerbruch, who got worldwide attention for this discovery, rejected the endotracheal positive pressure ventilation as suggested by Kuhn, which he viewed to be unphysiological (Sauerbruch 1904a, b, and c; Schober 1993). In his mind, positive pressure ventilation represented a permanent Valsalva maneuver, potentially leading to circulatory disturbance. On another occasion he wrote, «The low pressure procedure creates the pressure difference (necessary to keep the lung expanded) by thinning the air on the lung surface, while the positive pressure procedure increases the air pressure in the lung» (Schober 1993). After a visit in New York City in 1908, bringing over his low-pressure chamber from Germany for demonstration, Sauerbruch left it with Willy Meyer (1858–1922) at Lennox Hill Hospital. He may not have liked when Willy Meyer and his brother, who was an engineer, later tried to reverse the low pressure into a high-pressure chamber («universal chamber») with having the patient's head inside and the surgical team operating on the patient's chest outside under normal pressure.

The air insufflation method, developed by John Auer (1875–1948) and his father-in-law James Meltzer (1851–1920) in New York City, also was rejected by Sauerbruch (Meltzer 1910; Schober 1993). Oxygenation was achieved by a continuous flow of air via a small pipe introduced into the patient's upper airway. In animal experiments the depth of insertion of that pipe into the trachea correlated with the length of survival. In 1910, the neurosurgeon Charles Elsberg (1872–1948) employed the Meltzer/Auer method successfully in a patient at Mount Sinai Hospital in New York City (Schober 1993). Not surprisingly, Sauerbruch also rejected the concept of high-pressure respiration, as suggested by the internist Ludolf Brauer (1885–1951) in Marburg, Germany (Brauer 1904). In high-pressure respiration, the patient had to exhale against a high airway pressure delivered by an airtight face mask. With the overwhelming authority of Sauerbruch in opposition, endotracheal ventilation and endotracheal anesthesia had no chance to develop in Germany at that time. Interestingly, both Ferdinand Sauerbruch's and Ludolf Brauer's papers were published in the same journal, both receiving editorial comments by von Mikulicz-Radecki, the authoritative contemporary thoracic

surgeon in Germany. In his comments he did not favor one technique over the other (Goerig and Schulte am Eich 2003; Schober 1993).

High-pressure and low-pressure techniques, as well as the insufflation techniques, illustrate the struggle of the different schools for the best method to avoid pneumothorax and at the same time provide the best gas exchange during thoracic surgery. The superior solution that was ultimately accepted, however, had already been published in 1886 by the French surgeon Théodore Tuffier (1857–1929). Employing a snugly fit endotracheal tube, he intermittently delivered high-pressure air. This optimal French solution was only reluctantly accepted in Germany (Goerig and Schulte am Eich 2003; Schober 1993).

At this point we like to briefly focus on Ferdinand Sauerbruch and his professional career. After medical school education at the universities of Marburg, Greifswald, Jena, and Leipzig, he took his first resident position in Breslau 1903. Six days after he finished his PhD thesis on experimental thoracic esophageal surgery, he had to attend the funeral of his teacher, von Mikulicz in 1905. He went to work with Paul Leopold Friedrich (1864–1905) in Greifswald. Friedrich was already a respected thoracic surgeon at that time (Cherian et al. 2001; Dewey et al. 2006; Schober 1993). When he took a university chair in Marburg in 1907, Sauerbruch went with him and was appointed Professor in Marburg. In 1910 his reputation in lung surgery made him chairman and Professor of Surgery at the University of Zurich, Switzerland, the country of tuberculosis hospitals and spas. He published the standard text book *Techniques of Thoracic Surgery* in 1911 (Sauerbruch and Schumacher 1911). In 1918 Ferdinand Sauerbruch went to become Professor in Munich, Germany, just in time to receive the title of Geheimer Hofrat (privy councillor) from the last Bavarian King (Cherian et al. 2001; Dewey et al. 2006). There he founded what was called the Sauerbruch school, which later peaked at the Charité in Berlin (1928–1949).

Nobody could overrule his judgement. In Sauerbruch's defense, Rudolf Nissen stated in his book *Real-life in Thoracic Surgery (Erlebtes aus der Thoraxchirurgie)*:

- » Sauerbruch's rejection of the endotracheal intubation today seems unbelievable to us. However, it was only in a small portion related to stubbornness. The main reason

was a lack of an organized management for anaesthesia. Sauerbruch opposed the establishment of anaesthesia as a specialized discipline. He saw it as a step forward to the decomposition of the discipline of surgery into different subspecialties. (Nissen 1955)

1.6.2 Cardiac Catheterization

Similarly, cardiac catheterization was not recognized as diagnostic tool. There was a lack of clinical questions and therapeutic options. Werner Forssmann (1904–1979) was a young resident in the hospital of Eberswalde, a small town near Berlin. Motivated by a picture he saw in a textbook of physiology, in 1929 he pushed a thin, well-lubricated urine catheter through a cubital vein directly into his heart (Lichtlen 2002). He went to radiology to document this experiment on himself by x-ray. His idea was to later inject drugs directly into the heart and immediately study the response (Forssman 1929). In 1931 he published an article about contrast images of heart cavities with the same experimental setup (Forssmann 1931). The importance of Forssmann's experiments was recognized by his chief, Dr. Schneider. He advised Forssmann to go to the most authoritative surgeon in Germany, who happened to work in the close-by Charité. Sauerbruch had not the slightest recognition of the potential of Forssmann's work, and he dismissed the young colleague with the words, «With this you cannot do anything at all in surgery... for such tricks you may receive your PhD in a circus but not at a respectable German medical department» (Forssmann 1972). In 1956 Forssman and the Americans André F. Cournand (1896–1988) and Dickinson Richards (1895–1973), both working at the Bellevue Hospital in New York City, became Nobel Laureates in Medicine for their pioneering work in cardiac catheterization (Bircks 2002; Lichten 2002).

1.6.3 Decline of German Surgery Pre-World War II

It became evident that after the stunning developments up to the beginning of World War I in 1914—a period during which the names of Ernst von Bergmann, Curt Schimmelbusch, Robert Koch, August Bier, Rudolf Virchow, Konrad Röntgen, and Karl Landsteiner can be mentioned—

an inactivity in progress in German medicine occurred. This cannot be explained with the war and its consequences alone (Schober 1993; Wachsmuth 1985b). German medicine and surgery fell below the level of the leading nations. The North American, British, and Scandinavian proponents of thoracic surgery took over the field (Schober 1993).

Looking through the congress communications of the German Society of Surgery after 1920, the successful Trendelenburg operation in 1924 performed by Martin Kirschner and the aneurysmectomy done by Ferdinand Sauerbruch in 1931 were the only highlights. Several reasons are named and discussed; others may be added; many of them may be interdependent (Sauerbruch 1924; Schober 1993):

- Fear of splitting the field of surgery into independent subspecialties: The best will only become master in a subspecialty (Nissen 1955).
- Lack of diagnostic options (only very few internists were willing to expose their patients to risky therapies).
- Exclusion of the German Society of Surgery from the Société Internationale de Chirurgie after World War I.
- Lack of cooperation within Germany, especially as compared to the situation in the United States.
- Both World wars with tremendous human sacrifice and waste of material resources and wealth.
- The hierarchical structure of the German society, in which only a few opinion leaders had the say (Forssmann 1972).
- Decline of the German language as the scientific language. Most scientific publications were now in English, a language only very few of the German opinion leaders spoke (Leitz 2005).
- The therefore difficult information transfer as compared to today (e.g., when the German surgeon Werner Wachsmuth was prisoner of war in England after 1945, he was asked whether the Germans used penicillin: He had never heard about it before, even though Alexander Fleming had already discovered penicillin in 1928, and the Allied Troops used it since 1940 routinely (Wachsmuth 1985a).
- The exodus and murder of a vast number of scientists with Jewish background due to the Nazi racial discrimination politics, which had been sharpened with the law launched April 7, 1933, to restore the civil servants career with the Arian paragraph (Nissen 1969).

1.7 Heart Valve Surgery in the Time Before Extracorporeal Circulation

The first operation on a heart valve is attributed to Theodore Tuffier (1857–1929). On July 13, 1912, he operated a patient with aortic valve stenosis. After consulting Carrel, who was present at the operation in Paris, France, he did not incise the aortic wall but tore the aortic valve as he invaginated the aortic wall with the index finger, tearing the valve open in this way (Tuffier 1914). The idea of bursting stenotic valves dominated the surgical circles of that time. Valvulotomes and cardioscopes were constructed, e.g., by E. Cutler, S. Levine, and C. Beck but also by others (Westaby 1997). But cardioscopes were never successful due to the bad viewing conditions.

Encouraged by his experimental experience with animals, in 1923 Elliot Cutler (1888–1947) operated a 12-year-old girl with hemoptysis at Peter Bent Brigham Hospital in Boston, Massachusetts. Via a modified sternotomy, he exposed the heart without opening the pleurae and drove a valvulotome from the apex of the left ventricle through the mitral valve and burst it open. The girl survived for four and a half years, the hemoptysis diminished (Cutler and Levine 1923). Cutler abandoned this type of surgery after further clinical treatments failed.

Sir Henry Souttar (1875–1964), a surgeon from London, England, operated in 1925 on a 19-year-old woman with rheumatic mitral stenosis through a left thoracotomy. Employing positive pressure ventilation and ether anesthesia, he dissected the heart and inserted his index finger into the left atrium. In this way he divided the leaflets of the mitral valve; however, this caused regurgitation (Souttar 1925). The woman was hospitalized again in 1930 but died of multiple cerebral embolisms and heart failure.

Souttar performed mitral valvulotomy only once, and when asked why, he explained his decision in a letter to Harken: «. . . The physicians declared that it was all nonsense and in fact that the operation was unjustifiable. In fact it is of no use to be ahead of time. . . .» (Harken and Curtis 1967; Westaby 1997).

In summary, it may be concluded that the first attempts to divide heart valves were not very successful. But these attempts established sternotomy

as the access to the heart and the left auricle as the entry for the digital disruption of the mitral valve.

After World War II, it was Russell Brock (1903–1980) in London who tried to treat aortic valve stenoses. Coming either from the brachiocephalic trunk, the subclavian artery, or through the left ventricular apex, he inserted valvulotomes through stenotic aortic valves to relieve stenotic aortic valves. The results, however, were bad (Brock 1950). Horace Smithy (1914–1948) in Charleston, South Carolina, had similar experiences. He tried to perforate the mitral valve with a punch, which rarely went smoothly. However, five out of his seven patients with mitral stenosis survived. Smithy himself died of rheumatic aortic valve stenosis. His paper on his surgical achievements was published shortly thereafter (Smithy et al. 1950). Just before he died, he had visited Alfred Blalock in Baltimore, who offered to operate on him after he would have assisted Dr. Smithy operating on a few patients there. The first patient fibrillated after thoracotomy and died, and Blalock refrained from further operations like this (Crawford 2010).

At Hahnemann Hospital, Philadelphia, Pennsylvania, Charles Bailey (1910–1993) took his chance. After numerous animal experiments, he operated on five patients with mitral stenosis, but only one patient survived (Bailey 1949). For disrupting the mitral valve, Bailey utilized little knives mounted to his index finger. Due to his failure, he was referred to as the «butcher of Hahnemann Hospital» and was prohibited by the administration of his hospital from operating on any other patients for mitral stenosis (Stephenson 1997). Therefore, he in part started operating in other hospitals. At the meeting of the American College of Chest Physicians in Chicago, 1948, he presented his only successful mitral commissurotomy case, a young woman (Stephenson 1997).

Shortly after Bailey's success with his first case, Dwight Harken (1910–1993) in Boston, Massachusetts, was also successful with his first mitral commissurotomy. When his next six consecutive patients died, Harken decided to quit cardiac surgery; however, colleagues persuaded him to continue. In England, Russell Brock reported in 1950 on six successful closed mitral commissurotomies (Baker et al. 1950).

1948 was the year of the closed mitral commissurotomies (Westaby 1997) (see ■ Table 1.1).

It was Brock, DuBost (1914–1991), and Tubbs (1908–1993) who earned the credit to have

Table 1.1 Closed mitral commissurotomies of 1948

Date	Surgeon	Location
January 30, 1948	Smithy	Charleston, SC, USA
June 10, 1948	Bailey	Philadelphia, PA, USA
June 16, 1948	Harken	Boston, MA, USA
September 16, 1948	Brock	London, England

decisively improved valvulotomies. They developed parachute-like instruments, which could be transformed into two or three jawed instruments, depending on the type of valve. In addition, the effective width of the instrument could be modified by an adjusting screw. It became standard to introduce the dilatation instrument through the apex of the left ventricle. Lead by the index finger introduced through the left atrial appendage, it was placed within the stenotic valve to perform the disruption. The initially high mortality decreased, and the degree of resulting mitral regurgitation progressively diminished. From there, the closed mitral commissurotomy started its triumph until it was replaced on a larger scale by the open commissurotomy about 30 years later (Westaby 1997).

Bursting procedures for aortic valve stenosis, as well as the treatment of mitral insufficiency, were attempted in the era before extracorporeal circulation was in clinical use, but they were more or less unsuccessful.

The efforts to surgically treat aortic insufficiency were more promising. Charles Hufnagel (1917–1989) in Washington, D.C., had the idea to implant a to-and-fro moving nylon ball, enclosed in a cage made of firm synthetic material (Plexiglass) into the descending aorta. The original idea to design a caged ball valve prosthesis (ball in cage) traces back to US patent No.19323 for a bottle closer (Matthews 1998). Hufnagel performed his first clinical implantation on September 11, 1952. The ball, initially made of nylon, was too noisy for the patients. Therefore, future models contained a silicon-coated caged ball. The first series published reported on 23 patients with a mortality of 26%. The surviving patients showed marked clinical improvements with a shrinking heart size as seen on x-ray (Hufnagel 1951, 1954).

1.8 History of Extracorporeal Circulation

Physiologists and pharmacologists were the first to be interested in organ perfusion. They perfused selected organs to study their function and also their reaction to certain drugs. The first device constructed for a whole-body perfusion was the «respiration apparatus» developed in 1885 by Frey and Gruber in Leipzig, Germany, which is regarded as the predecessor of the modern heart-lung machine for extracorporeal circulation (Frey and Gruber 1885). Ten years later Jakoby in Tuebingen, Germany, experimented with isolated lungs of animals to be used as an oxygenator (Jakoby 1895). In 1926 it was the Russian S.S. Brunkhonenko who developed a heart-lung machine which he called «Autojektor.» His experimental device comprised two pumps, one pump to propel the venous blood through an isolated lung and another pump for the systemic circulation of their experimental animals (Brunkhonenko 1928; Rukosujew et al. 2007). Alexis Carrel and Charles Lindbergh also built perfusion devices in the 1930s, first for isolated organs only, later they also looked into human total body perfusion (Edwards and Edwards 1974). An in-depth overview about the evolution of extracorporeal circulation can be found in Galletti and Brecher (1962), Galletti (1993), and Lillehei (1993).

It was around 1950 when all closed surgical interventions to treat congenital and acquired heart defects seemed to have reached a limit. To introduce instruments blindly into the heart cavities did not directly address the problem, and very often did not solve it. It was every surgeon's desire to perform his work under direct vision and therefore perform it precisely. If this should not be accomplished, cardiac surgery would have to play an inferior role within the surgical specialties (Kirklin 1989).

Three experimental ways, partly underway already since the 1930s, were further pursued:

- Hypothermia by Wilfred Gordon Bigelow (1913–2005), Toronto, ON, Canada
- Controlled cross circulation by C. Walton Lillehei (1918–1999), Minneapolis, MN, USA
- Heart-lung machine by John H. Gibbon (1903–1973), Philadelphia, PA, USA

Bigelow's approach was simple. Cooling down an organism would reduce its oxygen consumption,

allowing interruption of the circulation for some time to have a direct look into the heart and eventually perform a procedure. Animal experiments showed that oxygen consumption could be only reduced linearly with body temperature, when muscle shivering was suppressed (Bigelow et al. 1950a). Bigelow also learned that an adult laboratory animal can be cooled down without risk of adverse sequelae to 20 °C body temperature. At 20 °C body temperature, oxygen consumption was only 20% as compared to 37 °C; 20 min would be allowed to perform controlled heart surgery under direct vision (Bigelow et al. 1950b, 1969).

In Bigelow's experiments the anesthetized and ventilated animals were placed on cooling blankets and cooled down to 20 °C. After thoracotomy, caval inflow occlusion was initiated, and the right atrium was opened. It was closed again after 15 min. Survival was 50% in these laboratory animals (Bigelow 1950a). Bigelow presented his experimental results in 1950 at the annual meeting of the American Surgical Association (Westaby 1997).

F.J. Lewis and M. Taufic at the University of Minnesota in Minneapolis were the first to clinically apply hypothermia and caval inflow occlusion after having done numerous experiments themselves. On September 2, 1952, they operated on a 5-year-old girl after cooling her down to 28 °C rectal temperature. The atrial septum defect they found measured 2 cm and has been closed directly. After five and a half minutes, the inflow to the heart was opened again; the heart started beating (Lewis and Taufic 1953). Shortly thereafter, Henry Swan from Denver, Colorado, reported on 13 patients he had operated upon in the same way (Swan et al. 1953). See also ► Chapter «Surgery for Congenital Heart Defects: A Historical Perspective», Sect. 11.2.

Ernst Derra (1901–1979), University of Düsseldorf, Germany, was the first in Europe to perform open-heart surgery employing surface hypothermia; when in 1955, he closed a secundum atrial septum defect (Derra et al. 1965; Bircks 2002). Without any doubt, Derra and his group have set the standard in employing surface hypothermia for open-heart surgery in atrial septum defect and pulmonary stenosis. Ranging well into the 1960s, Derra's group performed the largest single hospital series of surface hypothermia in the world, comprising 1851 patients (Schulte 2001).

At the University of Minnesota in Minneapolis, C. Walton Lillehei (1918–1999) developed the so-called «controlled cross circulation» (Lillehei et al.

1955a; Lillehei et al. 1955b). Usually an adult served as the «circulation donor» who continuously supported with part of his arterial blood the perfusion of the arterial system of a usually much smaller patient. The blood flow was controlled by a pump. The venous blood of the patient was pumped back to the donor's venous system. The donor only required his groin vessels to be cannulated. With adequate cannulation of the patient, the heart was taken out of the circulation, and the cardiac cavities could be opened for direct vision heart defect repair (Lillehei et al. 1955a; Lillehei et al. 1955b) (see also ► Chapter «Surgery for Congenital Heart Defects: A Historical Perspective», Sect. 11.2).

With this approach, Lillehei and his team set the following milestones in surgical repair of congenital heart disease (Lillehei et al. 1955a; Lillehei et al. 1955b):

- Ventricular septal defect (1953)
- Complete atrioventricular canal (1954)
- Tetralogy of Fallot (1954)

Lillehei endured almost hostile opposition. Critics talked about the potential of a 200% mortality, as two persons were operated upon for only one patient to be treated. But the head of the Department of Surgery in Minneapolis, Owen H. Wangensteen, always protected him and greatly supported his intellectual and surgical enthusiasm (see ► Chapter «Surgery for Congenital Heart Defects: A Historical Perspective», Sect. 11.2).

Hypothermia and cross circulation had opened the window of direct vision-controlled heart surgery. The real breakthrough, however, only came when finally the heart-lung machine became available for support of extracorporeal circulation. It was John Gibbon (1903–1973) who worked his whole professional life, together with his wife Mary, on the development of a machine to support extracorporeal circulation. As early as 1937 he could demonstrate that heart and lung would, in principle, resume their full function after their work had been temporarily taken over by an artificial pump and oxygenator. However, only a few animals survived and those only for a few hours (Gibbon 1939). Gibbon became more successful when, after World War II, he met Thomas Watson, Chairman of IBM, who was fascinated by Gibbon's ideas and promised to help him. A heart-lung machine was built with modified DeBaake roller pumps and with a grid oxygenator (Stephenson 1997). Employing this new Gibbon-IBM heart-lung

machine, he successfully closed an ostium secundum atrial septal defect in an 18-year-old girl on May 6, 1953 (Gibbon 1954). When his next two patients died, he retired to investigate the potential causes of the failure of his heart-lung machine. Later he retired completely from cardiac surgery and exclusively worked on issues in thoracic surgery (Stephenson 1997).

As other groups also worked on the development of a heart-lung machine, so did C. Dennis (1902–2005) in Minneapolis; he, however, was unsuccessful with his first clinical case (Dennis et al. 1951). F. Dodrill (1902–1997) in Detroit, who had built a heart-lung machine with the support of General Motors, successfully used it as a left heart bypass in a mitral valve operation (Dodrill et al. 1952). Shortly thereafter he also used it as a right heart bypass in pulmonary valve surgery (Dodrill et al. 1953).

In Europe, among others, Clarence Crafoord (1899–1984), Viking Björk (1918–2009), and Ake Senning (1915–2000) in Sweden (Andersen and Senning 1946; Björk 1948), J. Jongbloed in Holland (Jongbloed 1949), and AM Dogliotti in Italy (Dogliotti 1951) experimented with extracorporeal circulation. The world's second successful operation with a heart-lung machine was the excision of a left atrial myxoma in Stockholm, Sweden (Senning 1954).

The final breakthrough in using the heart-lung machine as a routine tool in open-heart surgery was accomplished by John W. Kirklin (1917–2004) in the Mayo Clinic. After having visited Gibbon and Dodrill, the Mayo group decided to build their own oxygenator-pump, based on the work they were shown. During the winter of 1954/1955, nine of ten experiments in dogs employing the new Mayo-Gibbon heart-lung machine were successful. The group decided to choose eight patients to be operated upon. All of these patients would be operated, even if the first seven surgeries had a fatal outcome. Four patients survived, and with this the success story of cardiac surgery began (Kirklin et al. 1955; Kirklin 1989).

The Mayo-Gibbon oxygenator represented a stationary grid oxygenator, in which the blood passes along stiff narrowly spaced grids. Another principle is that of a cylinder oxygenator described in 1953 by Denis Melrose (1953) or the rotating disk oxygenator described in 1956 by E. Kay and FS Cross (Cross et al. 1956; Kay et al. 1956). In both types of oxygenators, rotation produces a

thin blood film which provides a rapid gas exchange. The disadvantage of both film oxygenators is the complicated maintenance and assembly, which requires a lot of time and personnel.

Extracorporeal circulation was simplified when a new, less complex and therefore easier to set up oxygenator, the bubble oxygenator, was finally developed by DeWall and Lillehei in 1955 (Lillehei et al. 1956; DeWall and Lillehei 1958). This development was made possible by LC Clark's findings published 1950, who had demonstrated that excess gas bubbles could be eliminated from blood by adding silicone components to the oxygenator setup (Clark et al. 1950). The previous inability to get rid of these bubbles, to defoam the oxygenated extracorporeal blood, had delayed the development of this type of oxygenator significantly.

When Vincent Gott succeeded in building a one-way bubble oxygenator and have it produced, it made preparation for cardiac operations much easier and significantly less time consuming (Gott et al. 1957). From then on, the DeWall-Lillehei oxygenator became a standard element in the setup for extracorporeal circulation until the late 1970s. IH Rygg in Denmark succeeded in constructing a similar device (Rygg and Kyvsgaard 1958). WJ Kolff and SA Clowes developed the first membrane oxygenators (Clowes et al. 1956; Kolff et al. 1956). They came into practical use once appropriate membranes could be produced successfully with the reliability required. AJ Lande described the first commercially available one-way membrane oxygenators for routine clinical use (Lande et al. 1967). Frank Gerbode and his group later reported success with other types of membrane oxygenators (Gerbode et al. 1967; Hill et al. 1972; Zapol et al. 1979). See also ► Chapter «Advances in Cardiopulmonary Bypass for the Neonate and Infant», Sect. 7.2.1 and chapter «Surgery for Congenital Heart Defects: A Historical Perspective», Sect. 11.2).

Further innovations in extracorporeal circulation comprised hemodilution, respectively, non-blood prime, when 5% glucose or dextran was used as reported by Zuhdi, Long, Cooley, and Neville in the early 1960s (Westaby 1997). Another new feature was the integration of a heat exchanger into the arterial side of the circuit (Sealey et al. 1958, 1959). With this, the advantages of hypothermia could be integrated into the concept of extracorporeal circulation. The combination of deep hypothermia and

1
extracorporeal circulation was developed by Hans Borst in Germany for aortic arch surgery (Borst 1959; Borst et al. 1964) and by Y Hikasa in Japan and Brian G Barratt-Boyes in New Zealand for surgical correction of congenital heart defects (Hikasa et al. 1967; Barratt-Boyes et al. 1972).

A prerequisite for extracorporeal circulation and whole-body perfusion had been the discovery of heparin by J McLean in 1916 (McLean 1916) and protamine by E Chargaff and KB Olson in 1937 (Chargaff and Olson 1937).

In order to limit the ischemic time of heart on one side, and still having sufficient time to operate on the immobilized heart, various methods were developed. Ake Senning (1952) very early on used electrically induced ventricular fibrillation. For aortic valve replacement, Dwight McGoon (1925–1999) utilized selective coronary perfusion employing special cannulas (McGoon 1976). In the beginning many groups used intermittent interruption of coronary circulation by intermittent aortic cross clamping. The time intervals provided by this way were 15–20 min, which seemed to be sufficient for some (Cooley et al. 1958a). But Denton Cooley also described the «stone heart» (Cooley et al. 1972). Further tolerance to ischemia was achieved by topical cooling as suggested by the Stanford group (Shumway et al. 1959). Simple cardioplegia solutions were ready for clinical use as early as 1955, like the potassium citrate cardioplegia of Melrose (Melrose et al. 1955), the magnesium cardioplegia of Kirsch (Kirsch et al. 1972), or the sodium extraction cardioplegia of Bretschneider (1964, 1980). Bretschneider's solution was clinically tested by Sondergaard (Sondergaard and Senn 1967). From 1975 on, experimentally proven solutions were commonly available, like the crystalloid HTK solutions after Bretschneider (1980) and the St. Thomas solution (Hearse et al. 1978) or blood cardioplegia after Buckberg (1982), which later was modified by Calafiore (Calafiore et al. 1994).

Although extracorporeal circulation was and is an integral part of the success story of cardiac surgery, it had to be learned that through temporary whole-body perfusion with extracorporeal devices, harm can also be produced (Blackstone et al. 1982; Kirklin et al. 1986; Kirklin and Barratt-Boyes 1993; Edmunds 1997). The contact of blood with artificial extracorporeal surfaces activates about five plasma proteins and five cell systems, which through a cascade-type activation can to

different degrees lead to bleeding tendency, thromboembolism, fluid retention, and primary or secondary organ damage (Edmunds 1998). See also ► Chapter «[Extracorporeal Circulation and Myocardial Protection in Adult Cardiac Surgery](#)», Sect. 6.1.4.

1.9 Development of Heart Valve Surgery in the Era of Extracorporeal Circulation

The first aortic valve replacement with an artificially manufactured valve was accomplished in 1960 by Dwight E. Harken (1910–1993) in Boston, Massachusetts. He implanted a prosthesis consisting of a ball in a steel cage. It was implanted with single interrupted sutures into the aortic anulus. As he thought that the aortic wall could interfere with the ball in the cage and thus be affected, his valve had a double cage (Harken 1989). For the implantation, he used extracorporeal circulation at a temperature of 26 °C (Harken et al. 1960). Albert Starr (born 1926) in Portland, Oregon, constructed a similar prosthesis for the mitral position in cooperation with the retired engineer Lowell Edwards (1898–1982). Their cooperation started in 1958. As did so many others, they started out to develop a bileaflet valve, which, in most cases, completely thrombosed within 2–3 days in their dog experiments. Therefore, they had to go back to the conception of the caged ball valve, the concept used already in Hufnagel's first off-pump descending aortic valve implantation in 1952 (see ► Sect. 1.7, «Heart Valve Surgery in the Time Before Extracorporeal Circulation»).

Ball valves absolutely did not resemble a natural valve, but flawless function was more important than the shape and design. An advantage of the ball valve concept was the fact that the ball was not fixed to the ring, and in this way thrombus formation beyond the ring, especially in mitral position, was completely eliminated. In addition, the constant to-and-fro oscillation of the ball had a cleansing effect on the ring. Furthermore, dogs with ball valve implants in the mitral position showed clearly less problems, and many of them became long-time survivors (Matthews 1998). The model chosen for human use consisted of a cage of steel, a silastic ball, and a Teflon sewing ring. After the first patient died 10 h postoperatively caused by an air embolism, Albert Starr successfully implanted this type of ball valve in mitral position in the eight following patients between July 1960 and February 1961.

With the support of extracorporeal circulation, he operated through a right thoracotomy. Six patients became long-term survivors, with two even going back to work (Starr and Edwards 1961; Pluth 1991; Matthews 1998). The original model of the Starr-Edwards valve has been modified several times. Sheathing the brackets of the cage with Teflon cloth in order to reduce the incidence of thromboembolism did not prove successful. Only model 1260 and model 6120 received subsequent FDA approval (Akins 1991), which entered the medical manufacturing environment in 1976 (Siposs 1989). Another caged ball valve model is the Smeloff-Cutter valve, which was introduced on the market in 1966. Remarkable is its double-cage construction; the smaller dimensions of the cage were favorable, especially for implantation in the mitral position, as this caused left ventricular outflow tract obstruction less often and to a lesser degree (Smeloff 1989). Numerous artificial heart valves were developed, but did not find widespread acceptance or had been implanted only by a few, like the Barnard-Goosen valve or the Gott-Daggett valve (Westaby 1997).

Progress came with the development of the tilting disk heart valve prosthesis. Its design concept, a mobile disk occluder contained in a ring, was developed by Juro Wada (1922–2011) from Sapporo Medical College, Japan, in 1966. The Wada-Cutter valve was characterized by a very low profile, in addition it had a significantly lower-pressure gradient compared to all other artificial heart valve models available at that time, as the central blood stream was not obstructed (Wada et al. 1989). Viking Björk (1918–2009) in Stockholm, Sweden, visited Wada in Japan and immediately started implanting the Wada-Cutter valve. He compared its performance with the Kaye-Shiley valve, which revealed a significantly higher-pressure gradient (Westaby 1997). Therefore, Björk convinced Don Shiley to design and build a prosthesis according to Wada's conception. Shiley was a former Edwards Laboratories engineer, who later worked independently. The result was the Björk-Shiley valve, which was implanted for the first time on January 16, 1969, in Stockholm by Björk himself (Björk 1969, 1984; Westaby 1997). The original model consisted of a ring with two brackets which lay within the ring plane, in between which the disk moved. The opening angle originally was 60°. The disk underwent various modifications, and from 1976 it became a convex-concave shape (Björk 1978). After a significant number of fatal bracket fractures, which for

the first time were reported in 1978, the convex-concave valve was taken off the market in 1986 (Lindblom et al. 1986; Ostermeyer et al. 1987). A follow-up model, the so-called monostrut valve (Björk and Lindblom 1985), which was manufactured out of one block of metal, therefore not requiring weld joints anymore, was introduced in response to the failures. Success was limited; when due to the worldwide problems with the old valve and the consecutive law suits, Shiley's company finally collapsed after a settlement (Westaby 1997).

Walt Lillehei also participated in the development of tilting disk valve prostheses. In 1966 the Lillehei-Nakib toroidal discoid prosthesis was described, and it was followed in 1967 by the improved Lillehei-Kaster pivoting disk valve (Lillehei et al. 1974, 1977, 1989). Almost a cross-breed between the Björk-Shiley and the Lillehei-Kaster valve is the Medtronic-Hall tilting disk prosthesis, inserted for the first time in a patient in June 1977. It was developed by the Norwegian Karl Victor Hall (1992, 1989) and received worldwide recognition (Akins 1995).

It also was in Lillehei's laboratories where the design of the first artificial double leaflet valve, the St. Jude valve, was thought of. In these models the suture ring as well as the leaflets were made of synthetic nonthrombogenic pyrolytic carbon. The leaflets, which are mounted into articular caves in the valve prosthesis ring, open up to 85° and allowed for almost laminar blood flow. The first clinical implantation was on October 3, 1977, by DM Nicoloff in Minneapolis, Minnesota (Emery et al. 1978; Lillehei et al. 1989).

Only a few of the 32 mechanical heart valve prostheses that were developed from the mid-1960s to the end of the 1980s received FDA approval and survived (Akins 1991). These are the Starr-Edwards valve, the Medtronic-Hall valve, the St. Jude Medical valve, and the Omniscience valve (Akins 1991). In 1993 the Carbomedics valve was approved as the second bileaflet valve in the United States (Akins 1995).

The era of homografts (postmortem-harvested human heart valves) began in 1962 with the implantation of homografts by the Toronto group (Heimbecker et al. 1962). Donald Ross (1922–2014) in London, England, on July 24, 1962, and independently Brian Barratt-Boyes in Auckland, New Zealand, on August 23, 1962, performed the first aortic valve replacements with aortic homografts (Ross 1962; Barratt-Boyes 1965).

Experimentally Alfred Gunning (1918–2011) and Carlos Duran in Oxford, England (Binet et al. 1971) worked on the extraction, conservation, and implantation of homografts but also of heterografts (Duran and Gunning 1962). They suggested the technique Ross employed in his first successful clinical case (Ross 1962). As the implantation of homografts was technically considerably complex, Angell mounted homografts to a stent which made a mitral valve replacement possible (Binet et al. 1971). Instead of homografts, Ake Senning in Zürich and Marion Ionescu in Leeds, U.K., used valves constructed out of autologous fascia lata and mounted them on a stent (Senning 1967; Ionescu et al. 1970). These fascia lata valves, however, had a high failure rate and were soon abandoned (Thiede et al. 1971). Donald Ross in 1967 for the first time used the pulmonary artery valve of a patient as an aortic valve replacement and restored the continuity between the right ventricle and the pulmonary artery with an aortic or a pulmonary homograft (Ross operation) (Ross 1967). The first successful Ross operation in a neonate, employing the autograft's growth potential, was performed by Gerhard Ziemer in 1989 in Hannover, Germany in a 2.7 kg baby (Ziemer 1992). After root remodeling surgery at 13 years, the autograft got finally replaced at 26 years of age with a mechanical valve.

In 1964 Duran and Gunning in Oxford clinically implanted for the first time a porcine valve prosthesis mounted on a stent (Binet et al. 1971). In Paris Binet and Carpentier implanted heterografts/xenografts mounted on a stent including the first stented mitral heterograft prosthesis in 1967 (Carpentier 1972). Originally, the animal valves used, mainly porcine valves, were preserved in organic mercurial salt solution or 4 % formaldehyde, from 1968 on in glutaraldehyde. Glutaraldehyde was introduced by Alain Carpentier. As an associate Professor of Surgery, he interrupted his surgical activity 2 days a week to study chemistry and discovered glutaraldehyde (Spencer 1983; Carpentier 1989). Glutaraldehyde diminishes antigenicity and avoids denaturation of collagen fibers, strengthening the tissue by intense collagen cross-linking at the same time. Carpentier summarized: «The valve substitute obtained on this way is a bioprosthesis rather than a heterograft» (Binet 1989; Carpentier 1989; Stephenson 1997). These experimental and first clinical experiences lead to the first commercially available bioprostheses: Ionescu-

Shiley and Carpentier-Edwards biological heart valves (Carpentier 1972). Warren Hancock, employed at Edwards Laboratories until 1967, developed a porcine valve, which was implanted clinically by Robert Litwak (Kaiser et al. 1969). Later models incorporated flexible stents (Westaby 1997). Because of transvalvular obstruction, especially in the smaller porcine bioprosthesis, a technique was devised to remove the native right coronary cusp, which contains in pigs a bar of ventricular muscle. The removed cusp was substituted by a cusp of a second animal. The first Hancock modified orifice valve was used clinically in 1976 (Cohn et al. 1989).

During the 1980s, the early enthusiasm to use glutaraldehyde-treated bioprostheses cooled down since bioprostheses calcified with time and the decreased durability became an established fact (Carpentier et al. 1984). This opened up the development and use of stentless bioprostheses experimentally and in humans (David et al. 1992).

To preserve the mitral valve in clinical mitral insufficiency had already been suggested by Walt Lillehei (Lillehei et al. 1957) and later on by GH Wooler (Wooler et al. 1962), GE Reed (Reed et al. 1965), and JH Kay (Kay et al. 1978). But it is Alain Carpentier who is entitled to the leadership of reconstructive mitral valve surgery. Since 1971, he concentrated his work on the anatomical changes in mitral regurgitation and published a classification based on the involved segment of the valve. It dates back to him developing the understanding that mitral valve annulus dilatation primarily relates to the posterior portion of the annulus. He was the first to suggest a rigid ring for stabilizing the mitral valve annulus and developed various technical details for reconstructive mitral valve surgery. He summarized his experience in the famous paper published in 1983: *Cardiac Valve Surgery-The French Correction* (Carpentier 1983).

1.10 Development of Coronary Surgery

The first surgical attempts to treat coronary heart disease were sympathectomy of cervical ganglia to achieve analgesia and thyroidectomy to lower metabolism and, in this way, cardiac oxygen consumption (Parsons and Purks 1937; Mueller et al. 1997). Claude Beck, professor at the Western Reserve University in Cleveland, Ohio, went a step

further following the idea of creating collateral vessels to increase myocardial blood flow (Beck and Tichy 1934; Beck 1935). He employed mechanical irritation to create adhesions between the pericardium and epicardium. He also interposed pectoral muscle or omentum to induce neovascularization (Beck 1935). Similar procedures were reported by O'Shaughnessy in London, England, and by A. Lezius in Hamburg, Germany (O'Shaughnessy 1936; Lezius 1938). To achieve the same result, Lezius also sewed the lung to the epicardium, a procedure he called cardiopneumopexy (Lezius 1951).

Arthur Vineberg (1903–1988) from Montreal, Canada, went a step further when, in an experimental setting in 1947, he implanted the mammary artery into a tunnel made into the left ventricular myocardium. To his surprise, there was no hematoma formation, as he had seen after implantation of an artery into a skeletal muscle in the same way. So the myocardium seemed to have properties like a sponge. He explained this with sinusoids known from embryology. In cases of ischemia caused by coronary disease, the sinusoids were supposed to open up. He proved the existence of the assumed connections by stain injections. Clinically he performed this procedure in 1950 for the first time and reported his 140 operations 1964 with a final mortality of 2% (Vineberg 1946, 1958; Vineberg and Buller 1955; Westaby 1997). Vineberg had his late satisfaction through Mason Sones, who proved by angiography that most internal mammary artery implants remained open and even developed anastomoses to the native coronary arteries in 70–80% of the patients (Effler et al. 1963).

The evolution from the indirect to direct procedures in coronary surgery would not have been possible without the development of coronary angiography by Mason Sones (1918–1985) at the Cleveland Clinic in Cleveland, Ohio. Before 1959 coronary arteries were visualized only nonselectively by injecting contrast through a catheter positioned in the aortic root. On October 30, 1958, the catheter migrated unnoticed into the right coronary artery during contrast injection and an image was taken; the error was only noticed after the angiography film was developed and ready to be inspected. The patient went through the nonvoluntary maneuver without subjective or even objective harm (Westaby 1997). After repetition of direct coronary angiography on 1,020 patients, Sones stated correctly that now the era of selective coronary angiography had

begun. Not only new diagnostic means to detect the pathology of coronary artery disease were created, but also the efficacy of the utilized surgical treatment modalities could be directly evaluated (Sones and Shirey 1962; Lichtlen 2002).

Lillehei (Absolon et al. 1956) and Bailey (Bailey et al. 1957) were the first to envision direct coronary artery surgery with their experimental open and closed coronary thromboendarterectomy. Longmire in Los Angeles, California (Longmire et al. 1958), and Ake Senning in Stockholm, Sweden (Senning 1959), were the first who applied these techniques in clinical cases. Rene Favaloro (1923–2000) from the Cleveland Clinic reported about 163 patients who underwent open coronary thromboendarterectomy and vein or pericardial patch plasty between January 1962 and May 1967. These procedures were performed on a fibrillating heart with extracorporeal circulation at a temperature of 30 °C. It was primarily the right coronary artery which was treated. Twenty-eight patients died during hospital stay (17%). Of 94 patients who underwent postoperative angiography, the result was considered good in 53 (Favaloro 1970).

As these results were not satisfying, Favaloro proceeded with direct coronary bypass surgery. On May 9, 1967, he implanted an aortocoronary venous bypass in a 51-year-old female patient who had proximal obstruction of the right coronary artery on angiography. The left coronary artery was unobstructed and fed via collateral vessels the peripheral right coronary artery which had no further arteriosclerotic changes. On this healthy periphery, Favaloro anastomosed the bypass vein. Twenty days later, the patient underwent postoperative coronary angiography. The aortocoronary artery venous bypass was open (Favaloro 1968, 1970). Between May 1967 and December 1968, 171 coronary artery venous bypass surgeries were performed. From this point on, the success story of coronary artery bypass surgery took off. Favaloro summarized the advantages of the bypass graft technique as follows:

- Low mortality
- Accessibility of all regions of the coronary artery system and hence
- Enlarging the indication for coronary surgery

Next to Favaloro, it is Dudley Johnson from Milwaukee, Wisconsin, who was part of the inauguration of routine coronary surgery. In 1969 he

reported on 301 coronary patients whom he had operated upon since February 1967 and who in most cases received a vein graft (Johnson et al. 1969). His conclusions were similar to Favaloro's. Johnson noted that there have been others who reported on sporadic cases of coronary artery bypass surgery between 1962 and 1967. But none of these publications had any influence on further development. Among those, for example, was a venous bypass to the left anterior descending coronary artery in 1964, which, however, was reported only much later (Garret et al. 1973).

Originally, coronary bypass surgery favored vein grafts. Years later, Loop and Lytle, also from the Cleveland Clinic, demonstrated the superiority of arterial grafts. Consequently, this made arterial revascularization the technique of choice, especially in young patients (Loop et al. 1986; Lytle et al. 2004). The use of the internal mammary artery as a bypass graft was reported as early as 1967 by Vasilii Kolesov from St. Petersburg, Russia. He operated through a left thoracotomy on the beating heart without extracorporeal circulation. Donald Effler (1915–2004), cardiac surgeon-in-chief at Cleveland Clinic, discussed this technique and suggested a pre- and postoperative angiographic control (Kolesov 1967). In the United States, Goetz, Bailey, and Green worked using the mammary artery (Borst and Mohr 2001). But its widespread use started only after the convincing publication out of the Cleveland Clinic. The radial artery as a bypass graft was brought into discussion by Carpentier in 1973 (Carpentier and Guernonprez 1973). Because of frequently seen graft spasms, the radial artery did not gain acceptance at the beginning, but rather experienced a renaissance in recent years.

Following Dudley Johnson's dictum: «anastomoses on small vessels can't be performed on a moving object» (Johnson et al. 1969), it was through the late 1990s that employing extracorporeal circulation in coronary surgery seemed to be mandatory. Nevertheless, there were already large off-pump coronary surgery series reported showing acceptable results (Buffolo et al. 1985). SIRS (systemic inflammatory response syndrome) frequently is a response of the immune system to blood contact with artificial surfaces. In order to avoid SIRS whenever possible, many groups almost exclusively embarked on off-pump coronary surgery (Calafiore et al. 1996; Subramanian 1997; Borst and Mohr 2001).

Off-pump resections of ventricular aneurysms by simply applying big clamps between aneurysmal sac and left ventricle were described by Likoff and Bailey (1955). It was Denton Cooley in 1957 who for the first time employed extracorporeal circulation to resect a ventricular aneurysm (Cooley et al. 1958b). A further development in cardiac aneurysm surgery came from Vincent Dor, Monte Carlo, Monaco, who suggested an endocardial patch plasty to maintain and receive a better remodeling of the heart leading to improved function (Dor et al. 1989).

The first closure of a postinfarction ventricular septal defect was performed by Cooley in 1957 (Cooley et al. 1957). The early operations were performed only on hemodynamically stable patients through an incision in the right ventricle. Later on, emergency patients with huge left to right shunts were also operated on. Heimbecker et al. (1968), Dagett et al. (1970, Dagett (1990), Kitamura et al. (1971), and David et al. (1972) are among those who developed the techniques currently used with incision through the infarcted area and application of synthetic patch material.

1.11 Pacemaker, Defibrillators, and Arrhythmia Surgery

P.M. Zoll opened the modern era of pacemaker therapy in 1951, when he treated Adam-Stokes syndrome with externally applied stimulation (Zoll 1952). He fixed electrodes precordially to the skin and stimulated the heart with intermittent electrical impulses. Skin changes were caused and patients complained about bad pain.

An important push to the development of pacemakers came from Lillehei's group in Minneapolis. Following VSD surgery, they repeatedly had to deal with the problem of complete AV block. In experiments on dogs, they created complete heart block and applied low voltage current. This leads to continuous heart beats again and reestablished normal blood pressure.

Lillehei immediately put this laboratory experience into clinical practice. He must have been the first to implant temporary pacemaker wires on the right ventricle. They could be removed by simply pulling them once postoperatively the patient's heart rhythm was stabilized. Lillehei also realized that wires could be introduced through cannulas into the closed chest and placed on the

right ventricle, so that patients with Adam-Stokes syndrome could be helped without further surgical interventions (Westaby 1997). Together with Earl Bakken, he built a pacemaker generator as big as a cigarette box, which could be carried around outside the body. Attached to suspenders, it hung over the shoulder. The steel wires being connected to the right ventricle and transmitting the impulse were isolated with Teflon (Lillehei et al. 1960). In this way pain and skin changes which annoyed Zoll's patients were eliminated.

The first totally implantable pacemaker was inserted by Senning and Elmquist in 1958 in Stockholm, Sweden (Elmquist and Senning 1959). The electrical switch had been embedded in epoxy resin. The patient had a total AV block with frequent Adam-Stokes attacks. As the quicksilver batteries used at that time had a short life span, a patient might have to experience quite a lot of battery changes. In the United States, it was William Chardack in 1960 who implanted the first pacemaker in Buffalo, NY (Chardack et al. 1960). He worked together with Wilson Greatbatch, an electrical engineer. Other types of implantable pacemakers were developed by Zoll in 1960 (Zoll and Linenthal 1960). A further milestone in pacemaker therapy was the development of tranvenous electrodes, which avoided surgery to expose the right ventricle. Both in 1962 it was Parsonnet in the United States (Parsonnet et al. 1962) and Ekstrom and Lagergren in Sweden (Ekstrom et al. 1962) who were the first to implant transvenous electrodes. Not only the demand function in 1964 but also the principle of bifocal, AV-sequential stimulation in 1969, was developed by Castellanos et al. (1964) and Berkovitz et al. (1969).

The cumbersome short life spans of pacemaker generators could be significantly prolonged when W Greatbatch developed lithium batteries, which have a life span five to ten times longer than quicksilver batteries (Greatbatch et al. 1978).

The first implantable defibrillator (automatic internal cardioverter/defibrillator: AICD) was implanted by M Mirowsky at Johns Hopkins Hospital in Baltimore, Maryland (Mirowsky et al. 1980). The first systems required a thoracotomy to implant patch electrodes on the heart; however, from 1991 on the transvenous implantation became possible (Moore et al. 1991).

As a result of the rapid development in pacemaker and defibrillator technology, including less invasive catheter methods, many of the techniques

designed for the surgical therapy of arrhythmias became obsolete. The complex surgical procedures for atrial fibrillation, developed by Gerard Guiraudon in France and by James Cox in St. Louis, Missouri, the so-called Maze procedure, underwent multiple variations following the development of various ablation devices (see ► Chapter «Surgical Therapy of Atrial Fibrillation», Sect. 29.6).

1.12 Thoracic Organ Transplantations

After initial experimental work by Carrel and Guthrie (1905), Demichov (1962), and Mann et al. (1933), Richard Lower (1930–2008) and Norman Shumway (1923–2006) at Stanford University in California developed the experimental foundation for clinical heart transplantation (Lower and Shumway 1960; Lower et al. 1962). Starting from the experiments on surface cooling for myocardial protection, they perfected the surgical technique of orthotopic heart transplantation. With the recipient animal being on extracorporeal circulation in mild hypothermia for excision of the «sick» heart, they developed the technique of leaving portions of the posterior wall of the left and right atrium as a cuff to be anastomosed to the donor heart. Thereafter, aorta and pulmonary artery were anastomosed. Some of their experiments were autotransplantations; others were heterotopic transplantations in dogs. When in 1967 they got the first dogs to survive more than 250 days with the aid of immunosuppressive drugs (azathioprine, cortisone), they thought to be ready for the first clinical heart transplantation (Lower et al. 1965).

The first homologous human heart transplantation in the world took place on December 3, 1967; however, it was not performed at Stanford University, California, but at Groote Schuur Hospital in Cape Town, South Africa. The donor was a young woman who died from a car accident, the recipient was a 54-year-old grocer named Louis Washkansky, who had end-stage ischemic cardiomyopathy after multiple myocardial infarctions, being considered inoperable by various authorities. He was in irreversible heart failure. After donor brain death was confirmed, the transplantation process started, in which a team of 30 people under the leadership of Christiaan Barnard (1922–2001) participated. Before this, Barnard had visited Richard Lower's laboratory to get first-

hand information about the transplantation technique developed by Shumway and Lower, the technique he employed (Barnard 1967).

After the donor heart was cooled to 16 °C, it was put in 10° cold saline and transported to the next door recipient operating room, where it was perfused with blood. The ischemic time was 4 min. Barnard described the moment after he had excised the diseased recipient's heart that for the first time in his life he looked into an empty chest (Schmid et al. 2003). Louis Washkansky died on December 21, 1967, of pneumonia.

The second heart transplantation in the world was performed 3 days later, on December 6, 1967, by A. Kantrovitz at Maimonides Hospital in Brooklyn, New York. But the recipient, a 2-day-old baby, died immediately after the operation (Schmid et al. 2003).

On January 2, 1968, Barnard transplanted the heart of an organ donor who died of subarachnoid bleeding to the 58-year-old dentist Philip Blaiberg. Blaiberg survived for 18 months. He finally died of chronic rejection (Westaby 1997).

Soon thereafter, other heart surgeons followed with their first clinical heart transplantations: Shumway in Stanford; again Kantrovitz in Brooklyn; Sen in Bombay, India; Cabrol in Paris, France; Ross in London, England; and independently Cooley as well as DeBakey, both in Houston, Texas. The results of the more than 100 patients transplanted within a year after Barnard's first operation were very poor. More than 60 patients died within the first postoperative week; average survival for the remaining patients was less than 30 days (Westaby 1997). The problems of indications, definition of brain death, myocardial protection, as well as rejection and its diagnosis diminished the initial enthusiasm. Most of these problems were solved in the following years, mainly by the Stanford group:

- Exclusion criteria for heart transplantation were specified (Jamieson et al. 1982).
- Transvenous biopsy was introduced for rejection diagnosis (Caves et al. 1973).
- New concepts for myocardial protection made long-distance organ procurement possible. Ischemia of up to 4 h could be accepted (Thomas et al. 1978).
- Improvement of immunosuppressive medication, first by human antithymocyte globulin with introduction of T-cell monitoring (Bieber et al. 1976), thereafter by introduction of cyclo-

sporin A, which was available to the Stanford group in 1980 (Oyer et al. 1983).

- The concept of retransplantation for acute and chronic rejection was established (Copeland et al. 1977).

Due to the new facilitating supportive features, the number of heart transplantations rose up to almost 4,500 worldwide cases in 1995. By that time, heart transplantation had become an established surgical treatment for end-stage cardiac failure (see ► Chapter «Heart and Heart-Lung Transplantation», Sect. 37.1.1).

The first attempts of combined heart and lung transplantation were undertaken 1968 by Cooley, 1969 by Lillehei, and 1981 by Barnard. They all were not successful (Westaby 1997). It was Bruce Reitz in Stanford, California, who, after exhaustive animal experiments on monkeys (Reitz et al. 1980) based on Castañedas heart-lung autotransplantation experiments in baboons (Castañeda et al. 1972), succeeded in applying this surgery on a 45-year-old woman with primary pulmonary hypertension on March 9, 1981. The woman was extubated 48 h after surgery and survived for more than 5 years. Reitz's second patient, who had Eisenmenger's syndrome caused by a VSD, was a long-term success, also (Reitz et al. 1982).

The first isolated lung transplantation was performed by James Hardy in 1963. His patient died 7 days after surgery (Hardy et al. 1963). More success had Fritz Dermon (Dermon et al. 1971) from Belgium, whose patient survived for 10 months. The final scientific and clinical breakthrough in lung transplantation surgery was achieved by Joel Cooper's group in Toronto, Canada. They reported on two patients who had returned to normal life activities after surgery and survived lung transplantation 14 and 26 months (Cooper et al. 1986). Since then, the number of lung transplantations performed yearly has progressively risen all over the world. In 2013, lung transplantation was performed in more than 4000 patients (see ► Chapter «Lung Transplantation», Sect. 36.1, ■ Table 36.1).

1.13 Circulatory Assist Devices

The idea of mechanical circulatory assist devices is old. Different approaches were followed. The concept of diastolic augmentation to improve coronary perfusion was developed in experimental animal

studies by the brothers Kantrowitz (1953) and Kantrowitz and Kinnen (1958). Internal counterpulsation was employed by Claus and coworkers (1961). Thereby the blood was aspirated from the aorta during systole and injected back during diastole. With modifications and, most importantly, the availability of inflatable latex balloons, Mouloupoulos and coworkers succeeded in 1962 in the development of the intra-aortic balloon pump (IABP) (Mouloupoulos et al. 1962). Inflating and deflating of gases, at first CO₂, later helium, were ECG triggered. The first clinical successes were reported by Kantrowitz in 1968 (Kantrowitz et al. 1968). Since 1979, the Seldinger technique allowed insertion of the IABP balloon pump from the periphery through the femoral artery (Bregman and Cassarella 1980). The intra-aortic balloon pump, in addition to increasing coronary perfusion in diastole, also causes systolic afterload reduction.

Extracorporeal membrane oxygenation (ECMO), developed by Hill et al. (1972) and Zapol et al. (1979) and modified by Gattinoni (Pesenti et al. 1993), is another principle for treating post-cardiotomy heart failure. The ECMO principle is a long-term extracorporeal circulatory and respiratory support, derived from its use during cardiac surgery. As left ventricular afterload cannot be reduced with the ECMO system alone, the combination of both support systems, ECMO and IABP, has been suggested (Bavaria et al. 1990).

The first realistic attempts to replace the heart with an artificial implant are attributed to Willem Kolff and his coworkers T. Akutsu and Y. Nose at the Cleveland Clinic. They implanted in the mid-1960s four-chambered air-driven artificial hearts into calves in an orthotopic position. The animals could be kept alive for more than 24 h. In 1967 Kolff became head of the Division of Artificial Organs and Institute for Biomedical Engineering at the University of Utah. He worked with Kwan-Gett and Robert Jarvik on the design of a completely implantable artificial heart (Westaby 1997).

In Houston, Texas, Domingo Liotta (born 1924) designed artificial ventricles, planned to be used as pumps for extracorporeal circulation or as an artificial heart. Already in 1966 Michael DeBakey (1908–2008) successfully employed an artificial Liotta ventricle as part of a left heart bypass in a 37-year-old woman for postcardiotomy heart failure. After 10 days, she was weaned off bypass and became a long-term survivor (DeBakey 1971). DeBakey was successful with

two more patients (Campbell et al. 1988). PE Oyer in Stanford did the first successful «bridge to transplant», when he successfully transplanted a heart after having implanted a Novacor left heart assist system before (Portner et al. 1985), see also ► Chapter «[Cardiac Assist Devices and Total Artificial Heart](#)», Sect. 38.2.

The patient Barney Clark was the first to undergo a complete artificial orthotopic heart replacement. In December 1982, a Jarvik Type 7 total artificial heart was implanted in the University of Utah by William DeVries. The patient was extubated on the second postoperative day, but he died on the 112th postoperative day after multiple, mostly thromboembolic, complications (De Vries et al. 1984; Westaby 1997).

The idea of using peripheral muscles to augment cardiac performance came from Kantrowitz and MiKinnen (1958). But the idea could only be realized once the fatigability of peripheral muscles was understood and managed (Macoviak et al. 1982). Of same importance was the knowledge to correctly stimulate the skeletal muscle (Drinkwater et al. 1980). The first one to apply the cardiomyoplasty clinically was Carpentier in 1985 with a transformed latissimus dorsi muscle wrapped around the heart (Carpentier and Chachques 1985). See also ► Chapter «[Left Ventricular Reconstruction and Conventional Surgery for Cardiac Failure](#)», Sect. 23.3.4.

1.14 The History of (Thoracic) Aortic Surgery

The first surgeons who concentrated their efforts on the thoracic aorta and its branches were HB Shumacker (1947), Henry Swan et al. (1950), Henry Bahnson (1953), as well as Michael DeBakey and Denton Cooley (1953). The first infrarenal aortic aneurysm was resected by Charles DuBost in 1951 (DuBost et al. 1952). They all replaced the aortic segments resected with aortic tube homografts.

The first synthetic tube graft, made from Vinyon-N, was implanted in 1952 by Arthur Voorhees (1921–1991) at Columbia University in New York, NY (Voorhees et al. 1952). They had found that synthetic grafts were accepted by the body as a vessel substitute, when the material used had a rather porous structure and was biologically indifferent. Around the same time, DeBakey started using Dacron, with the first grafts being manufactured

on a household sewing machine (DeBakey et al. 1958; Spencer 1983; Stephenson 1997).

The first replacement of the ascending aorta with a graft, employing extracorporeal circulation, was carried out by Cooley and DeBakey in 1956 (Cooley and DeBakey 1956). Albert Starr reported substitution of the supracoronary aorta with a synthetic prosthesis concomitant with an aortic valve replacement (Starr et al. 1963). A more radical procedure, requiring reimplantation of the coronary arteries, was described by Wheat replacing aortic valve and ascending aorta separately (Wheat et al. 1964) and by Bentall and De Bono as the combined aortic valve and ascending aortic replacement with a valve carrying tube prosthesis (Bentall and De Bono 1968). For many years, a graft inclusion technique, wrapping the aneurysm wall around the implanted prosthesis, was used. In case of persistent significant bleeding from any prosthetic anastomose inside the wrapped space, not amenable to direct suture, Christian Cabrol suggested implantation of a prosthetic shunt between the periprosthetic wrapped space and the right atrium (Cabrol et al. 1981). Today the inclusion technique has been abandoned in favor of a free-standing open technique with total resection of the diseased aorta, as a consequence of reported pseudoaneurysm formation at coronary and aortic anastomotic sites with the inclusion technique (Kouchoukos et al. 1986).

In 1957 the Houston group with DeBakey, Crawford and Cooley replaced an aortic arch on extracorporeal circulation (DeBakey et al. 1957). After Hans Borst was the first to successfully employ deep hypothermia for aortic arch surgery (Borst et al. 1964), the later publications of Randall Griep et al. (1975), DA Ott et al. (1978), and ES Crawford (Crawford and Saleh 1981; Crawford et al. 1987) lead to the technique of aortic arch replacement performed in deep hypothermia with the shortest possible circulatory interruption. In those cases in which the hypothermic circulatory arrest takes a relatively long time, Jean Bachet in France and Teruhisa Kazui in Japan established antegrade selected cerebral perfusion as a method of cerebral protection (Bachet et al. 1991; Kazui et al. 1994).

For the further development of aortic surgery, especially with reference to interventional and hybrid procedures, please refer to ► Chaps. 27 and 28.

2.1 What Is a Score?

Scores can influence the ultimate survival of patients. For example, the urgency of need for hepatic transplantation is determined by scores (Asrani and Kim 2010). Scores also can influence survival of hospitals or departments. If the scores of performance of a hospital or department are considered too low, they are at risk for closure. Therefore, scores can be rather important. The term «score,» however, can have multiple meanings. The following chapter tries to define the appropriate interpretation of the word «score,» explains various ways of constructing scores, and provides orientation about scores currently used in the field of cardiothoracic surgery.

Generally speaking, «score» means a simplified method of counting. The Old English word «scoru» is derived from Norwegian and means «twenty» (► www.etymonline.com). Later on, a notch in a stick, made as a mark to remember a certain number of counted items, e.g., 20 sheep, was called a score. Today, the word «score» has a wide variety of meanings. The multiple interpretations today comprise such different domains as the instructions for playing a piece of music, a vote in sporting competitions, a container of fruit, or the sum of points achieved points in a game on a computer. Of specific relevance to this chapter, probabilities for mortality (Abel 1993) and other classifications of humans are summarized or characterized by scores, which can be used to simplify more extensive descriptions (Lee et al. 2006, Harrell 2001, Hosmer and Limeshow 2000, Tischendorf et al. 2007).

In cardiac surgery, scores mainly classify patients according to certain symptoms, laboratory values, or other properties and aim to estimate the risk for an adverse event such as mortality, renal failure, or complicated wound healing (Overman et al. 2013). Scores can be used to group patients according to a comparable risk for events (Budoff et al. 2007, Higgins et al. 1992, Tu et al. 1995). A good score predicts results reliably (*good calibration*) and differentiates well between patients with higher and lower risk (*good discrimination*). Clinicians like scores that are easy to calculate, easy to interpret, and are both applicable and relevant for many patients.

Propensity scores are a statistical method originally introduced by Rosenbaum and Rubin (1983) and re-presented to the community of cardiac surgeons by Blackstone (2002): calculating

propensity scores applying Cox' regression (Cox 1972) with treatment as endpoint permits within certain limits a kind of «retrograde randomization». Meanwhile the number of citations for «propensity score» AND «cardiac surgery» in PubMed exceeds 500.

Scores are the subject of the following chapter. This chapter describes six widely used scores, three for patients with acquired cardiac disease and three for patients with congenital cardiac disease. Several other risk stratification models have been applied in cardiac surgery (Nilsson et al. 2006 and Parsonnet 1995). Some remarks are provided about the appropriate use of scores and some of the potential limitations of these scores.

2.2 Prominent Risk Scores in Cardiac Surgery

2.2.1 Society of Thoracic Surgeons Score

The Society of Thoracic Surgeons (STS) database is one of the largest cardiac surgical databases in the world and receives data from over 90 % of the units performing cardiac surgery in the USA. The total number of included operations amounts to more than 5.3 million. Around 250,000 cardiac surgery procedures are added each year. STS uses one of the largest surgical audit programs in the world to assure accuracy and completeness of data in the STS databases.

After entering the data (risk factors) from a specific patient, the risk calculator of the STS website (► <http://riskcalc.sts.org/STSWebRiskCalc273/de.aspx>) will calculate the risk for mortality and a series of complications for patients receiving coronary artery bypass grafts and/ or aortic or mitral valve replacement or repair.

The following probabilities are calculated from STS database entries:

- Mortality
- Morbidity or mortality
- Length of stay more than 14 days
- Length of stay less than 14 days
- Permanent stroke
- Prolonged ventilation time
- Deep sternal wound infection
- Renal failure
- Reoperation

Risk determination is accomplished via logistic regression models that base on roughly 500,000 STS data sets entered between 1/2002 and 12/2006.

The STS risk calculator has by far the largest underlying database for its risk models. Some of the specific prediction—at least for mitral valve operations—cannot to be obtained elsewhere.

With a limited effort of entry of data, the internet-based STS risk calculator is suitable to obtain reliable predictions for individual cardiac surgical patients for the most frequent operations. Immediately after data entry, the calculated probabilities for mortality of a variety of potential morbidities are provided.

2.2.2 EuroSCORE

The EuroSCORE (European System for Cardiac Operative Risk Evaluation; Nashef et al. 1999; ► <http://www.euroscore.org/calc.html>) predicts the in-hospital mortality risk after cardiac surgery. The score was constructed to be applicable on a large fraction of cardiac surgery patients, such as:

- CABG
- Valve repair or replacement
- Replacement of part of the aorta
- Repair of a structural defect
- Maze procedure
- Resection of a cardiac tumor

Originally derived from 19,030 data sets of numerous European clinics in 1995, the EuroSCORE database was updated in October 2011 (22,000 data sets). It is a robust, simple-to-use, and reliable tool to estimate mortality after cardiac and intrathoracic aortic surgery. Eighteen well defined and easily available factors are entered. The resulting risk is returned either by addition of risk points (additive model, old version) or by inclusion of the factors in a regression model (regression model, new model). The latter can be programmed on the user's computer (for larger data sets), because the complete model is published. Alternatively, the EuroSCORE risk of

mortality risk can be requested interactively on the website (► <http://www.euroscore.org/calc.html>).

The revised version no longer recommends the use of an additive model. A continuous prospective data harvesting of the EuroSCORE study group at selected centers has finished recently a recalibration. A sentinel group of hospitals is continuously observed and will trigger the next recalibration if their mortality rates diverge too far from the currently observed ones. The calculator website mentioned above is followed by a one-page section of definitions section that contains:

1. Short definitions of various items.
2. A listing of the choices for some items with multiple answers.
3. A calculator for estimation of creatinine clearance from the level serum creatinine, age, height, and weight (according to Cockcroft-Gault). (If present, the user can enter the creatinine clearance directly.)

A detailed description of how to calculate the score is given in the paper of Nashef et al. (2012) This paper provides:

1. The factor weights for a total of 29 status descriptions
2. The constant of the final regression model
3. A detailed calculation instruction

The EuroSCORE II is useful if one intends to estimate mortality of a broad range of cardiac surgery patients, especially if the patient group is large and thus manual data entry into a website is challenging. Another advantage is its recent recalibration to current results of surgery and the continuous surveillance for the necessity of future recalibration.

2.2.3 German Quality Assurance: Aortic Valve Replacement and Coronary Artery Bypass Scores (KCH-SCORE 3.0)

The section for cross-sectoral quality assurance in health care, SQG, of the AQUA-Institut (Göttingen, Germany) regularly evaluates a virtually complete data set (98.8%) of all German isolated coronary artery bypass grafting procedures,

isolated aortic valve replacements, and the combination of both ($n=66,365$ in 2011), as well as transplantations of the heart, lungs, and both. The institution uses a set of well-defined risk factors. A random validation of source data was performed and did not reveal any evidence of purposeful manipulation of entry of data. The most recent data set used to develop regression models for in-hospital mortality is based on patients operated on in 2010. The regression coefficients and the constant of the models derived from this huge data set can be downloaded from the following website hyperlinks:

- ▶ <http://www.sqg.de/ergebnisse/leistungsbereiche/koronarchirurgie-isoliert.html>
- ▶ <http://www.sqg.de/ergebnisse/leistungsbereiche/aortenklappenchirurgie-konventionell.html>
- ▶ <http://www.sqg.de/ergebnisse/leistungsbereiche/kombinierte-koronar-undaortenklappenchirurgie.html>

■ Table 2.1 gives the 2011 results for isolated cardiac surgery based on data of 40,353 such operations.

Unlike for the EuroSCORE, data for this KCH-SCORE 3.0 model are specific for the described procedures and come from German centers only, so they should be more specific for comparisons with or within Germany. The AQUA-Institut updates the regression models in short intervals, making current factor weights available. When using these models outside Germany, it is advisable to consider the usual postoperative length of hospital stay in German hospitals (isolated aortic valve replacement: 5% up to 7 days, 56.5% 8–14 days, 22.2% 15–21 days, 15.8% >21 days; isolated CABG: 9.5% up to 7 days, 61.7% 8–14 days, 17.6% 15–21 days, 11.2% >21 days; CABG plus aortic valve replacement: 6.0% up to 7 days, 48.2% 8–14 days, 25.2% 15–21 days, 20.5% >21 days).

The KCH-SCORE 3.0 is very useful to compare results of isolated coronary artery surgery, aortic valve replacement, or both of them to actual expectations in Germany. The KCH-SCORE 3.0 is best used to compare outcomes with or within Germany.

2.2.4 Risk Adjustment in Congenital Heart Surgery, 1st Version (RACHS-1)

RACHS-1 (Jenkins et al. 2002, 2004) is a score that groups most of the procedures performed in patients with congenital cardiac malformations according to their risk of postoperative in-hospital mortality. The developers of RACHS-1 wanted to keep the score relatively as simple, with minimal entry of data that could all be obtained from the usual hospital discharge data sets. The developers of RACHS-1 used a data set of 3,709 surgical procedures performed in 1996, including patients from 32 institutions. The procedures were first classified by their estimated mortality risk, and then the group assignment was adapted to reality. Finally, a validation using 3,419 discharge data sets was performed and confirmed good calibration and discrimination. For 5 of the 79 procedures (■ Table 2.2), an age split was introduced. The 79 procedures are divided into six categories. The applicability of this simple scoring system for dividing patient populations into groups with significantly differing operative risk has been shown repeatedly in various countries (■ Table 2.3)

RACHS-2, an updated version of RACHS-1, has not yet been published. In the future, increasing availability of computer power and larger data sets may lead to the development of procedure-specific mortality prediction models based on the primary procedure of the index operation carried out during a hospital stay. Such a procedure-specific mortality prediction model may be applicable for common operations but will likely not obviate the need for a grouping process such as RACHS-1 to deal with the multiple rarer operations. The large databases for congenital heart surgery (STS Congenital Heart Surgery Database and European Association for Cardio-Thoracic Surgery [EACTS] Congenital Heart Surgery Database) can provide the large numbers required for both procedure-specific mortality prediction model and complexity stratified models.

RACHS-1 is suited to group pediatric cardiac surgery patients according to their risk of mortality after cardiac surgery.

Table 2.1 Risk-adjusted in-hospital mortality according to the log. (KCH-SCORE 3.0)

Risk factor	Definition	Regression coefficient
(Constant)	–	$-5.7503853602647300 = \beta_0$

Other lung diseases		$0.4186316551698350 = \beta_{18}$
Neurologic dysfunction		$0.1342343822193820 \cdot 0.245 = \beta_{19}$
Preoperative renal replacement therapy or preoperative serum creatinine >2.3 mg/dl		$1.0294845545444300 \cdot 0.829 = \beta_{20}$
Emergency		$0.6794065906504790 \cdot 0.600 = \beta_{201}$
How to calculate the mortality risk:		
Mark all applying risk factors		
Add their regression coefficients		
Add the constant (in this case: -5.7503853602647300), name the result «R,» and replace «R,» with the result in the following formula:		
$2.718259^R / (1 + 2.718259^R)$		
The result of this calculation multiplied by 100 is the mortality risk in %		

Table 2.2 Risk classes of the score «Risk Adjustment in Congenital Heart Surgery, 1st version» (RACHS-1)

Risk class	Procedure	
1	Atrial septal defect surgery (including secundum atrial septal defect, sinus venosus atrial septal defect, patent foramen ovale closure)	
	Aortopexy	
	Patent ductus arteriosus surgery at age >30 days	
	Coarctation repair at age >30 days	
	Partially anomalous pulmonary venous connection surgery	
	2	Aortic valvotomy or valvuloplasty at age >30 days
		Subaortic stenosis resection
Pulmonary valvotomy or valvuloplasty		
Pulmonary valve replacement		
Right ventricular infundibulectomy		
Pulmonary outflow tract augmentation		
Repair of coronary artery fistula		
Atrial septal defect and ventricular septal defect repair		
Primum atrial septal defect repair		
Ventricular septal defect repair		
Ventricular septal defect closure and pulmonary valvotomy or infundibular resection		
Ventricular septal defect closure and pulmonary artery band removal		
Repair of unspecified septal defect		
Total repair of tetralogy of Fallot		
Repair of total anomalous pulmonary venous at age >30 days		
Glenn shunt		
Vascular ring surgery		
Repair of aortopulmonary window		
Coarctation repair at age ≤30 days		
Repair of pulmonary artery stenosis		
Transection of pulmonary artery		
Common atrium closure		
Left ventricular to right atrial shunt repair		

Risk class	Procedure
3	Aortic valve replacement
	Ross procedure
	Left ventricular outflow tract patch
	Ventriculomyotomy
	Aortoplasty
	Mitral valvotomy or valvuloplasty
	Mitral valve replacement
	Valvectomy of tricuspid valve
	Tricuspid valvotomy or valvuloplasty
	Tricuspid valve replacement
	Tricuspid valve replacement repositioning for Ebstein anomaly at age >30 days
	Repair of anomalous coronary artery without intrapulmonary tunnel
	Repair of anomalous coronary artery with intrapulmonary tunnel (Takeuchi)
	Closure of semilunar valve, aortic or pulmonary
	Right ventricular to pulmonary artery conduit
	Left ventricular to pulmonary artery conduit
	Repair of double-outlet right ventricle with or without repair of right ventricular obstruction
	Fontan procedure
	Repair of transitional or complete atrioventricular canal with or without valve replacement
	Pulmonary artery banding
	Repair of tetralogy of Fallot with pulmonary atresia
	Repair of cor triatriatum
	Systemic to pulmonary artery shunt
	Atrial switch operation
	Reimplantation of anomalous pulmonary artery
	Anuloplasty
	Repair of coarctation and ventricular septal defect closure
	Excision of intracardiac tumor

■ **Table 2.2** (continued)

Risk class	Procedure
4	Aortic valvotomy or valvuloplasty at age ≤30 days
	Konno procedure
	Repair of complex anomaly (single ventricle) by ventricular septal defect enlargement
	Repair of total anomalous pulmonary veins at age ≤30 days
	Atrial septectomy
	Repair of transposition, ventricular septal defect, and subpulmonary stenosis (Rastelli)
	Atrial switch operation with ventricular septal defect closure
	Atrial switch operation with repair of subpulmonary stenosis
	Arterial switch operation with pulmonary artery band removal
	Arterial switch operation with ventricular septal defect closure
	Arterial switch operation with repair of subpulmonary stenosis
	Repair of truncus arteriosus
	Repair of hypoplastic or interrupted aortic arch without ventricular septal defect closure
	Repair of hypoplastic or interrupted aortic arch with ventricular septal defect closure
	Transverse arch graft
5	Tricuspid valve repositioning for neonatal Ebstein anomaly at age ≤30 days
	Repair of truncus arteriosus and interrupted arch
6	Stage 1 repair of hypoplastic left heart syndrome conditions
	Damus–Kaye–Stansel procedure
A groupwise mortality comparison based on these reference values is achieved by comparing observed and expected mortality:	
Expected mortality. For each RACHS-1 group, the following product is calculated: number of performed operations pertaining to the designated group by mortality in the comparison group	

Risk class	Procedure
	The products are added, and their sum indicates the number of expected deaths. This number can then be expressed as percentage of the entire group of operated patients: the mortality rate expected if mortalities were equal in the observed and the reference population
	Comparison: The quotient of observed and expected mortality rates (in %) shows the relationship of observed and expected mortality. Another intuitive measure of comparison is to indicate the mortality rate difference: it shows how many lives per 100 were saved (or lost) in one group (hospital, country) in respect to the reference group
	(From Jenkins et al. (2002), Jenkins (2004); used with permission)

2.2.5 The Aristotle Score

In 1999, under the leadership of Dr. Francois Lacour-Gayet, the Aristotle Committee was created to address the issue of stratification of complexity in surgery for congenital cardiac diseases (Lacour-Gayet 2002, 2004a, and 2004b; Mavroudis and Jacobs 2000). The developers of this tool recognized that standard methods of benchmarking in quality of care assessment were based on stratification of risk, with nearly exclusive emphasis on the measurement of the outcome of operative mortality. They believed that to assess outcomes, including comparison of outcomes between centers, and to establish a platform for continuous improvement in quality, stratification based on the risk for mortality alone is insufficient. The fundamental principle of the Aristotle Complexity Score is to define complexity as a constant for the challenge presented by a given surgical procedure. The Aristotle Committee postulated that the complexity of a given procedure in surgery for congenital cardiac diseases is the sum of three factors or indices: (1) the potential for operative mortality, (2) the potential for operative morbidity, and (3) the technical difficulty of the operation (Jacobs et al. 2006a).

Lacour-Gayet and the Aristotle Committee created a tool for stratification of complexity and called it the Aristotle Complexity Score, following Aristotle's belief in the importance of current opinion. In the

CHSS Congenital Heart Surgeons Society, HDD Hospital Discharge Data Sets, PCCC Pediatric Cardiac Care Consortium, RACHS-1 Risk Adjustment in Congenital Heart Surgery, 1st version

^aRACHS-1 categories 5 and 6 were combined to calculate the mortality rate

year 350 BCE, in *Rhetoric*, Book 1, Aristotle stated, «When there is no scientific answer available, the opinion (Doxa) perceived and admitted by the majority has the value of truth.»

Lacour-Gayet and the Aristotle Committee have differentiated the concepts of complexity and risk and have stated, «Complexity is a constant precise value for a given patient at a given point in time; performance varies between centers and surgeons. In other words, in the same exact patient with the same exact pathology, complexity is a constant precise value for that given patient at a given point in time. The risk for that patient will vary between centers and surgeons because performance varies between centers and surgeons.»

Under the leadership of Lacour-Gayet and the Aristotle Committee, the Aristotle Basic Complexity Score was developed by a panel of experts, made up of 50 surgeons who repair congenital cardiac defects in 23 countries and represent several major professional societies. The Aristotle Basic Complexity Score allocates a basic score to each operation, varying from 1.5 to 15, with 15 being the most complex, based on the primary procedure of a given operation. The Aristotle Basic Complexity Score represents the sum or aggregate of scores assigned to a given procedure for the three components of complexity—potential for mortality, potential for morbidity, and technical difficulty—each of which varies from 0.5 to 5. To facilitate analysis across large populations of patients, each procedure is then assigned an Aristotle Basic Complexity Level, which is an integer ranging from 1 to 4 based on the Aristotle Basic Complexity Score (■ Table 2.4) (O'Brien et al. 2007).

The Aristotle Comprehensive Complexity Score adds further discrimination to the Basic Score by incorporating two sorts of patient-specific complexity modifiers: (1) procedure-dependent factors, including anatomic factors, associated procedures, and age at procedure, and (2) procedure-independent factors, including general factors such as weight and prematurity, clinical factors such as preoperative sepsis or renal failure, extracardiac factors such as duodenal atresia and imperforate anus, and surgical factors such as reoperative sternotomy. Additional points, up to a maximum of 10, are added to the Basic Score to account for the added complexity and challenge imputed by these modifying factors. The Aristotle Comprehensive Complexity Score has been used by numerous investigators to analyze the outcomes

from complex procedures, such as Sinzobahamvya et al. (2006), Miyamoto et al. (2005), Artrip et al. (2006), and Derby et al. (2007).

The Aristotle Score is suited to group pediatric cardiac surgery patients according to their risk of mortality after cardiac surgery.

2.2.6 The STS–EACTS Congenital Heart Surgery Mortality Score (STAT Mortality Score)

First published in 2009 by O'Brien et al., the STS–EACTS Mortality Score (later abbreviated as STAT Mortality Score: Society of Thoracic Surgeons – European Association for Cardio-Thoracic Surgery Congenital Heart Surgery Mortality Score) was derived from 77,294 congenital heart surgery data sets. They were pooled from the databases of STS and EACTS, collected between 2002 and 2007, and describe outcomes of 148 different operations. Similar to RACHS-1, only the most complex component procedure of a given operation is considered (Jacobs et al. 2009b).

To create the STAT Mortality Score, at first the observed hospital discharge mortality rates were adjusted by approaching the mortality rates of rarely encountered procedures to the average mortality, in order to limit over- or underestimation by chance. The applied Bayesian algorithm modified the observed rates stronger if the total case number was lower. Then, the adjusted mortality rates were transformed by shifting and rescaling, in order to fit into a scale ranging from 0.1 to 5. The result is the «STS–EACTS Congenital Heart Surgery Mortality Score (O'Brien et al. 2009).»

In a further step, these score values were grouped into the five «STS–EACTS Congenital Heart Surgery Mortality Categories (STAT Mortality Categories).» The comparative validation on 25,106 data sets collected (2007–2008) from the same database showed optimal discrimination of the STAT Mortality Score for the procedure-specific mortality rates (C-index=0.787), followed by the STAT Mortality Categories (C-index=0.778), then the RACHS-1 categories (C-index=0.745), and then the Aristotle Basic Score (C-index=0.687). Addition of patient-specific variables improved the C-indexes to 0.816, 0.812, 0.802, and 0.795, respectively.

Table 2.4 The Aristotle basic complexity score (ABC score) and the Aristotle basic complexity levels (ABC levels) (January 1, 2010)

2

Score	Mortality	Morbidity	Difficulty
1 pt	<1 %	ICU 0–24H	elementary
2 pt	1–5 %	ICU 1D–3D	simple
3 pt	5–10 %	ICU 4D–7D	average
4 pt	10–20 %	ICU 1W–2W	important
5 pt	> 20 %	ICU > 2W	major

Complexity	Score
1.5–5.9	1
6.0–7.9	2
8.0–9.9	3
10.0–15.0	4

Procedures	Total (Basic score)	Complexity (Basic level)	Mortality	Morbidity	Difficulty
Pleural drainage procedure	1.5	1	0.5	0.5	0.5

This classification had been also applied to 111,494 pooled data sets from the STS Congenital Heart Surgery Database and the EACTS Congenital Heart Surgery Database for patients operated between 2006 and 2009 (Jacobs et al. 2012).

In contrast to RACHS-1 and the Aristotle Score, the STAT Mortality Score and the STAT Mortality Categories (O'Brien et al. 2009) are not based primarily on expert opinion, but are instead based on objective data (77,294 observations) and their exact evaluation.

Using methodology similar to that used to develop the STAT Mortality Score and the STAT Mortality Categories, the STAT Morbidity Categories have recently been developed to facilitate grouping pediatric and congenital cardiac operations into five categories associated with operative morbidity (Jacobs et al. 2013).

The role of preoperative morbidities as well as of concomitant procedures is currently being analyzed by the STS and EACTS Congenital Heart Surgery Databases (■ Table 2.5).

The STS–EACTS Congenital Heart Surgery Mortality Score (O'Brien et al. 2009) (STAT Mortality Score) is a grouping system for pediatric and congenital cardiac surgery mortality comparisons that encompasses a wide range of surgical procedures. The tool is contemporary, observation based, validated, and simple to use.

2.3 Appropriate Use of Risk Scores

■ Table 2.6 summarizes the appropriate and inappropriate use of risk scores. These topics are then discussed in more detail.

2.3.1 Comparison of Therapy

Despite great efforts, cardiac surgery is not immune to undesired results (Jacobs et al. 2014). These undesired results occasionally must be confronted by the best and most experienced surgeons, leading institutions, and even the most vital patient. At which point are what consequences to be drawn? How can the success of taken measures be assessed? Such questions are

often left to some leader's gut feelings; however, scores are an alternative and more objective methodology of outcome research (Jacobs et al. 2005). A comprehensive comparison of risk-adjusted, expected, and observed results informs about the current state and its development, both before and after implementation of structural or procedural changes. Scores address a broad variety of end points and are quite helpful for such endeavors (Jacobs 2008).

2.3.2 Quality Monitoring

Differences between expected and achieved results are an appropriate tool to assess quality development. Professor Paul T. Sergeant explains very clearly how to deal with such expectations and their fulfillment, using the analogy of a bank account (Sergeant et al. 2001):

» A successfully performed procedure adds a certain sum to the surgeon's «life bank account». The sum equals the average risk of mortality of the patient. If the procedure had a mortality risk of 20% and the patient survived, the surgeon gains 1/5 life on his account. In contrary, if the surgeon loses one of such patients, the probability of survival (80%) gets withdrawn from his account. So, if one of 5 patients with a 20% risk of mortality dies and four survive, the surgeon has saved up 0.8 lives and withdraws 0.8 for the lost patient from his account. His performance corresponds to the average of the reference population. Using this method, patients with inhomogeneous risk can be summarized objectively, just by adding the risks of mortality of the survivors and subtracting the probabilities of survival of the patients that die.

Scores can be used for this purpose even if detailed information about specific procedures is not available. Using this methodology of the surgeon's «life bank account» (mortality risk is credited in case of patient survival, survival chance is withdrawn in case of patient death), the relevant number for comparisons would be the number of saved lives per 100 operations, related to a defined reference group, such as the 43,934 STS-, or 33,360 EACTS-data base patients described by O'Brien et al. (2009).

Table 2.5 STAT mortality score and the STAT mortality categories

Procedure	Mortality			
	Score	Category	Unadjusted ^a	Model based ^b
ASD repair, patch	0.1	1	0.2 % (0.1–0.4 %)	0.3 % (0.1–0.5 %)
AVC (AVSD) repair, partial (incomplete) (PAVSD)	0.1	1	0.3 % (0.1–0.8 %)	0.5 % (0.2–0.9 %)
ASD repair, patch + PAPCV repair	0.2	1	0.2 % (0.0–1.3 %)	0.6 % (0.2–1.4 %)
Aortic stenosis, subvalvular, repair	0.2	1	0.5 % (0.3–1.0 %)	0.6 % (0.3–1.0 %)
ICD (AICD) implantation	0.2	1	0.3 % (0.0–1.4 %)	0.7 % (0.2–1.6 %)
DCRV repair	0.2	1	0.4 % (0.1–1.5 %)	0.8 % (0.2–1.6 %)
ASD repair, primary closure	0.2	1	0.8 % (0.5–1.3 %)	0.9 % (0.5–1.3 %)
VSD repair, patch	0.2	1	0.9 % (0.7–1.1 %)	0.9 % (0.7–1.1 %)
Vascular ring repair	0.2	1	0.8 % (0.3–1.6 %)	0.9 % (0.4–1.6 %)
Coarctation repair, end to end	0.2	1	0.9 % (0.5–1.5 %)	1.0 % (0.6–1.5 %)
ICD (AICD) procedure	0.2	1	0.0 % (0.0–2.9 %)	1.0 % (0.2–2.9 %)
PFO, primary closure	0.2	1	0.5 % (0.0–2.6 %)	1.1 % (0.3–2.5 %)
AVR, bioprosthetic	0.3	1	0.0 % (0.0–3.6 %)	1.2 % (0.2–3.4 %)
VSD repair, primary closure	0.3	1	1.1 % (0.5–2.1 %)	1.2 % (0.6–2.1 %)
PVR	0.3	1	1.2 % (0.5–2.3 %)	1.3 % (0.6–2.3 %)
Conduit reoperation	0.3	1	1.3 % (0.8–2.1 %)	1.4 % (0.8–2.1 %)
Pacemaker procedure	0.3	1	1.3 % (0.8–2.1 %)	1.4 % (0.9–2.1 %)
PAPVC repair	0.3	1	1.2 % (0.5–2.7 %)	1.5 % (0.7–2.7 %)
TOF repair, ventriculotomy, non-transannular patch	0.3	1	1.4 % (0.7–2.4 %)	1.5 % (0.8–2.4 %)
TOF repair, no ventriculotomy	0.3	1	1.4 % (0.7–2.4 %)	1.5 % (0.8–2.3 %)
Glenn (unidirectional cavopulmonary anastomosis; unidirectional Glenn procedure)	0.3	1	0.0 % (0.0–5.5 %)	1.5 % (0.2–4.3 %)
AVC (AVSD) repair, intermediate (transitional)	0.3	1	1.4 % (0.5–3.1 %)	1.6 % (0.7–3.0 %)
Coarctation repair, interposition graft	0.3	1	0.9 % (0.0–4.8 %)	1.7 % (0.4–4.1 %)
Fontan, TCPC, lateral tunnel, fenestrated	0.3	1	1.6 % (0.8–2.8 %)	1.7 % (0.9–2.7 %)
Sinus of Valsalva, aneurysm repair	0.3	1	0.0 % (0.0–6.7 %)	1.7 % (0.3–5.2 %)
AVR, mechanical	0.3	1	1.6 % (0.6–3.4 %)	1.7 % (0.7–3.2 %)
PDA closure, surgical	0.4	2	1.8 % (1.3–2.5 %)	1.9 % (1.3–2.5 %)
PA, reconstruction (plasty), main (trunk)	0.4	2	1.6 % (0.3–4.5 %)	1.9 % (0.6–4.0 %)
LV to aorta tunnel repair	0.4	2	0.0 % (0.0–8.4 %)	1.9 % (0.3–5.9 %)

■ Table 2.5 (continued)

Procedure	Mortality			
	Score	Category	Unadjusted ^a	Model based ^b
Valvuloplasty, mitral	0.4	2	1.9% (1.3–2.6%)	1.9% (1.3–2.6%)
Valvuloplasty, aortic	0.4	2	1.9% (1.1–3.0%)	1.9% (1.1–2.9%)
11/2 ventricular repair	0.4	2	0.0% (0.0–9.0%)	2.0% (0.3–6.2%)
Arrhythmia surgery—ventricular, surgical ablation	0.4	2	0.0% (0.0–10.6%)	2.2% (0.3–6.8%)

^aDenotes 95 % exact binomial confidence interval

^bDenotes 95 % Bayesian credible interval (Table 2.5 derives from O'Brien et al. (2009))

Another application of such data would be the construction of plots showing the development of cumulated risk-adjusted mortality (CRAM plots, ■ Fig. 2.1) corresponding to the running total a life bank account on which mortality risks of survivors are deposited and survival chances of nonsurvivors are withdrawn. Continuous performance monitoring, based on any group that has published its data, is made feasible by applying CRAM plots. Confidence limits for such curves can be calculated according to Kang (2006).

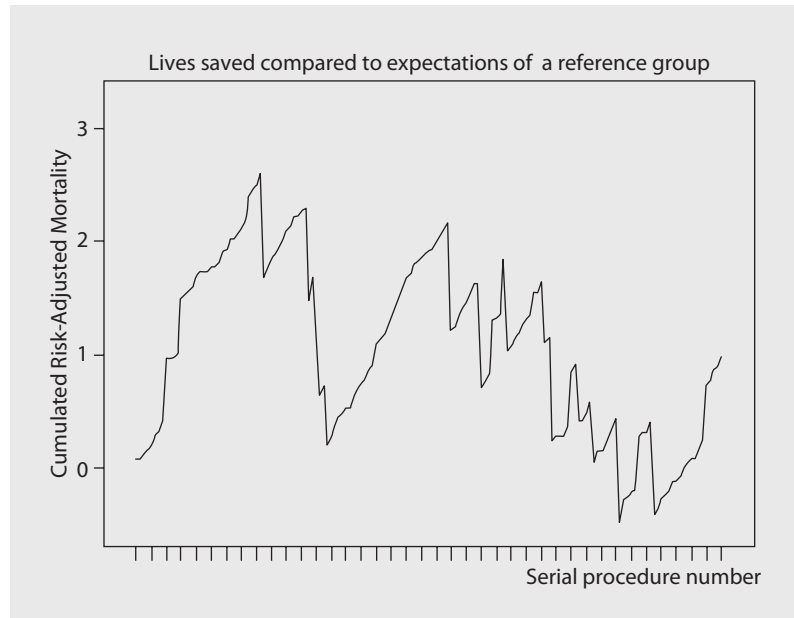

Alternative approaches to assessing the performance of hospitals in the context of multi-institutional performance have been presented for adults with acquired heart disease, using quarterly overall adjustment (Jin et al. 2010), and for congenital cardiac surgery, using funnel plots (Jacobs et al. 2011, 2012b).

Computers are required in order to capture all relevant data necessary for complex scores with reasonable (van Gameren et al. 2011) effort and reliability. Unfortunately, a completely automatized system of data entry and analysis is currently not freely available. Such a completely automatized system of data entry and analysis would include the following components:

1. A standardized and complete methodology of data collection that would be applicable in the heterogeneous environment of a large number of participating units
2. A reliable centralized system of storage Zof data
3. The generation of clinically relevant, well-founded, and statistically correct information from these data

Table 2.6 Appropriate use of risk scores and associated potential limitations		
Topic	Use	Potential limitations
Individual prognoses	Scores ought to enable the surgeon to objectively select the most promising therapy	Score-based therapy decision-making might promote a shift from being patient centered to literature centered; scores might consider only a subset of a patients' risk factors
Comparison of therapy ^a	Inhomogeneous groups become better comparable	The risk of ignoring (locally) important factors grows
Quality assessment (CRAM plots; Kang et al. 2006; Sergeant et al. 2001)	Early recognition of (un)favorable treatment options developments	Premature assumption of significance; statistical efforts required; possible misinterpretation of confounding factors
Effort	Recognition of risk bearing or inappropriately expensive treatment options or institutions	In case of already high efficacy of a unit that does not do scoring, the time and money spent for quality or risk assessment (that are detracted from patient care) are theoretically wasted. However, the act of participating in a database and benchmarking can lead to further increase in quality even in a high performing unit
Inadequate score	Suboptimal tools are more useful than no tools at all	Neglecting of relevant or rare factors; new developments might shift risk factor weight before being integrated in a new version
Manipulation ^a	Score defects might be circumvented	«Upcoding» as well as selection of patients and data might compromise the treatment of severely ill patients (Epstein 2006; Steinbusch et al. 2007), obfuscate underperforming units, and distort score development itself
Usefulness ^a	Personnel and money can be allocated more effectively	A general lack of resources cannot be overcome by redistribution
External vs. internal quality assurance ^a	More objective (knowledge-based) evaluation	Risk of inadequate interpretation and reactions
Publication (public reporting) ^a	Large patient numbers might be guided to better performing institutions	In case of manipulations or errors, patients might be misled (www.health.state.ny.us). Risk aversion can develop, but can be prevented with appropriate risk adjustment
Health politics ^a	Sanctions can be appropriate, closing underperforming units can be beneficial for patients	(Severe) sanctions might be applied based on scores that disregard important locally specific risk factors
Publicity ^a	Evidence-based information instead of «smart» advertising might direct patients to better treatment	Information might be selected or difficult to interpret; «evidence» may not be absolute truth
CRAM cumulated risk-adjusted mortality		
^a Represents topics discussed in more detail in text		

■ **Fig. 2.1** Fictitious example of a CRAM plot. CRAM cumulated risk-adjusted mortality

Especially in times of restricted funding for health care, outcomes analysis and quality assessment using scores require a shift of money away from patient care toward outcomes analysis and quality assessment. Although many diagnoses and procedures must be coded anyway at various institutions in order to comply with regulatory requirements and generate documentation for billing, every cent that is needed to fund additional collection and analysis of data often has to be generated by and diverted from the direct care of patients. We must keep in mind that the results from any work with outcomes analysis and quality assessment using scores must have benefits that outweigh the resources used to construct and apply them. Otherwise, we can harm patients by wasting their money.

2.3.3 Inadequate Score

Even the most sophisticated score uses only a part of the information pertaining to a patient: the elements of data that have been defined and are included in the score. It is simply not possible to create and use a scoring system that considers all possible circumstances and elements of data; such a system would drive the effort of acquisition to an impossible level. Meanwhile, scores that disregard important factors do not reflect reality well and might lead to distorted conclusions. The risk of mortality of patients with important disregarded factors is underestimated, and if the patient dies,

an inappropriately high amount is subtracted from the «life accounts» of the surgeon and hospital. Such errors are likely to remain uncompensated. Furthermore, such errors can have increased significance and impact in low-volume programs where patient numbers are small.

2.3.4 Manipulation

Score-based results are at risk to be manipulated. Such alterations might be triggered by threats with undesired consequences such as closure of departments or simple comparative publication of results (Epstein 2006; Steinbusch et al. 2007; ► www.health.state.ny.us). On the other hand, MELD scores used for liver allocation were reported to have been intentionally worsened in order to bypass patients on the waiting list (► <http://www.aerzteblatt.de/archiv/128320/Transplantationsskandal-an-der-Universitaet-Goettingen-Erschuetterndes-Mass-an-Manipulation>; ► <http://www.wseas.org/multimedia/journals/biology/2012/54-918.pdf>; Sumeet 2010). Manipulation of data can influence several domains: quality improvement, «upcoding,» «outcoding,» and selection of patients:

- Quality improvement. The ideal consequence of outcomes analysis and quality assessment is improvement of the quality of treatment (Jacobs et al. 2007). This goal can be achieved frequently, but often might be difficult to reach. Frequently, the necessary measures are

obvious, but the surgeon is not enabled to implement these measures. Many obstacles may exist that prevent improvement of quality including lack of personnel, deficiencies of infrastructure, shortages of money, and inappropriate hierarchical structures within a hospital; the surgeon may have only limited independent influence on any or all of these obstacles (Jacobs et al. 2006b).

- Upcoding. With the growing severity of the consequences of bad result, a scenario develops with increased perverse motivation to fictitiously enter data that «aggravates diagnoses» or, in other words, adds risk factors that create a more difficult case mix. This strategy might be observed in borderline cases or in cases that leave room for interpretation. This strategy can be applied to the coding of the procedures performed as well as the underlying diagnoses.
- Outcoding. Options such as «Other» or «Else, please indicate» or «Please describe» in a system of scoring make it easier to describe procedures that may be associated with special risk, but open the possibility of manipulation of the coding by excluding these operations from routine analysis of outcome. Variations of operations with bad outcome can be coded as «Other» if such a category is offered. The effects of such operations can then be mitigated or hidden.
- Selection of patients. Each score is a simplification, because certain factors are excluded from the observational focus. A score classifying only procedures that have been performed will disregard other therapeutic options. This scenario might lead to preference of alternative therapeutic options, such as interventional transcatheter treatment and compassionate care, especially for patients with presumed high procedural risk due to unaccounted concomitant morbidity. Departments that try to help patients even in desperate or rescue conditions are at high risk to look worse than a unit that selects low-risk patients and leaves the complicated patients to other departments. Such risk aversion is mitigated with proper risk adjustment within a system of scoring. Undesired effects of this kind have been previously observed, even in situations where results of single surgeons were differentiated and published (► www.bqs-outcome.de).

2.3.5 Usefulness

Internal quality assessment can only be useful if suboptimal results are followed by adequate reactions. If deficiencies are detected, they might be related to lack of staffing or funding, and the involved institutions must be given the opportunity to change this. The results of quality assessment can be used to show the need for improvements. These necessary improvements can be allocated within the hospital itself, if local changes in personnel, structure, or organization can ameliorate the circumstances. Alternatively, the necessary improvements might have structural character and require changes on the political level (Jacobs et al. 2011). Risk-adjusted comparisons of outcomes can also identify institutions with outstanding performance that might serve as an example.

Quality assessment should consider the analysis and distribution of good performance at least as important as the detection and repair of suboptimal results.

2.3.6 External (Third Party) Versus Internal (Within Medical Associations) Quality Assurance

Dealing internally with a high rate of undesired events allows the concerned institution to take measures considered appropriate directly after detection of the necessity for change. Such actions should be taken without undue delay. Responsibly minded units should not need external pressure for such work. Reasons for spreading information about presumed underperformance beyond the borders of a hospital could include persisting failure, general mistrust of improvement attempts of single units, or the need for political changes resulting from systematic underfunding. Purely internal quality assurance requires the confidence of patients that surgeons, hospitals, and politicians will do their very best to deliver optimal care. This confidence is often dependent on the transparent reporting of outcomes to patients and the public, especially in the inhomogeneous field of pediatric cardiac surgery.

Misinterpretation of data about outcomes is a risk that comes inevitably with quality assurance, and the importance of this risk increases when results are circulated to wider audiences. Public reporting of outcomes data must be accompanied by detailed explanatory documentation that is written so that it can be easily understood by the target audience, and the actual data must also be presented so that these data are easily understood by the target audience.

2.3.7 Publication

Some patients and their families will not fully appreciate many of the details of outcomes analysis including:

1. The meaning of confidence intervals
2. The role of insufficient consideration of risk factors
3. Suboptimal or incomplete acquisition of data
4. The limitations of statistical modeling

All such factors, and more, contribute to the analysis of outcomes. Consequently, the public reporting of outcomes must present these data using techniques that can be understood by the general public (Jacobs et al. 2009a). Detailed explanatory documentation must accompany these data and must also be written so that the explanations can be understood by the general public. Additional more detailed data should be made available for those interested. Public reporting of outcomes can have the unintended consequence of risk aversion, but risk aversion can be prevented by proper risk adjustment. The public reporting initiative of the Society of Thoracic Surgeons (Shahian et al. 2011a, b) exemplifies the concepts of using proper risk adjustment to prevent risk aversion and presenting data with fair and unbiased techniques that can be understood by our patients and the general public.

2.4 Summary

Risk scores are a helpful tool that can facilitate the assessment of outcomes and the improvement of quality. Risk scores can offer caregivers the chance to objectively recognize undesired trends and the opportunity to implement and assess strategies for improvement.

3.1 Introduction

Providing high-quality medical services was and still is the self-imposed demand physicians and hospitals wish to be measured by. However, now it is no longer sufficient to merely formulate high demands; medical service providers also have to document these services to achieve comparability. Exacerbated by increasing economic constraints and an ever-increasing competitive situation, on the one hand, as well as increasing patient expectations, on the other hand, physicians and hospitals can no longer get by without the introduction and permanent establishment of quality management systems (Korenstein et al. 2012).

It has been shown in the recent past that in addition to an improved medical reputation, the pursuit of maintaining and improving patient care also offers *economic advantages*. Documentation and the evaluation of the services rendered, namely, quality assurance, as well as the identification and prevention of risk situations and risk management, play a very essential role. For both tools, medical care oriented toward patient needs and demands is central.

From the perspective of a hospital setting, we would like to elucidate the essential elements of quality assurance and present the key elements of a functional risk management system in everyday hospital routine.

3.2 Fundamentals of Quality Assurance

In 1988, the German Physician's Board included the obligation of all physicians to participate in quality assurance measures in their own professional code of conduct. This decision has been implemented by all State Medical Boards in the professional regulations. For this reason, participation in quality assurance programs has become a part of the ordinary professional duties of the physician. The obligation of a physician to participate in quality assurance is, however, also defined by Articles 135–137 of Volume V of the German Code of Social Law V (SGB V) by the legislator. In this code, it is stated that: «Approved hospitals, inpatient care facilities and inpatient rehabilitation facilities are committed to introduce and further develop internal quality management» (Ennker et al. 2004).

In surgery departments, quality assurance measures have been a constant factor since the 1970s; a

binding requirement for systematic quality assurance was introduced, and it has become the governing concept in this professional field. The applied quality assurance measures comprising not only internal and external quality assurance with mortality and morbidity conferences but going far beyond this concept.

3.2.1 Quality Assurance as an Essential Part of Quality Management

Quality assurance is an essential part of the quality management system. Quality assurance measures in hospitals, medical facilities, and practices have the aim of increasing the trust of all interest groups («stakeholders») by fulfilling precisely formulated requirements.

Medical quality assurance and patient interest are thus closely linked with one another.

The aim of medical quality assurance is an improvement of treatment quality and as a result patient satisfaction—one of the strongest arguments in quality management systems.

The common target of the various quality management systems is to bring more transparency into the quality of medical care and to ensure the long-term survival and continuous improvement of physician practice (Lack and Schneider 2005; Lack and Gerhardinger 2010).

The wish for *continuous improvement in medical services* has been present in the medical profession for a long time. It goes beyond the measures for medical self-regulation (medical case discussions, conferences, hygiene commissions, drug commissions, clinical studies, seminars, and autopsies) established to date.

3.2.2 Excursus into Quality Management

According to the definition of the International Organization for Standardization (ISO), quality is «. . . the degree to which a set of inherent characteristics meets the requirements . . .» The term «quality management» (QM) is defined as «. . .

a process within an organization, which attempts to achieve continuous improvement of a process or a service . . .» (► www.iso.org/iso/iso_9000).

However, quality management established in practice goes beyond these measures. For application in a hospital, there are several quality management models. Despite differently weighted target parameters (patient and referring physician satisfaction, process optimization, and responsibility of the management), all current concepts in Germany have one central pillar, the *PDCA cycle*. This cyclic process was formulated and described by William Edwards Deming and Walter Andrew Shewhart in the 1980s (Deming 1982, 1986). PDCA stands for the terms «plan,» «do,» «check,» and «act» and describes the planning of a process or the improvement of an existing process («plan»), implementing a change («do»), checking the results achieved («check»), and correcting based on the results of the process («act»), which can in turn lead to a new plan («plan»). This cycle has also entered into the literature as the Deming Cycle.

3.2.2.1 Quality Management Models in the Hospital

Several quality management models have been developed for application in hospitals, which each have different focuses. This partly has historical origins because the models were not originally developed for the medical field or for pragmatic reasons because they place particular emphasis on certain specializations and medical disciplines. The most frequently used models of quality management in Germany are as follows:

- DIN EN ISO 9001:2000 (DIN: German Institute for Standardization; EN: European Standard; ISO: International Organization for Standardization)
- Cooperation for Transparency and Quality in the hospital (CTQ) with proCum Cert
- European Foundation for Quality Management (EFQM)
- Joint Commission on Accreditation of Healthcare Organizations (JCAHO)

All four models are to be illuminated briefly in the following.

3.2.2.2 DIN EN ISO 9001:2000

DIN EN ISO 9001:2000 is a quality management standard and stipulates what requirements the overall management of an enterprise must fulfill to meet a certain standard in the implementation of quality

management and to receive certification. DIN standards are generally a universal standard that is familiar to many people outside the medical field and whose merit and significance have achieved general acknowledgement. Additionally, the quality management system in accordance with DIN EN ISO 9001:2000 can be applied to complex hospitals and university clinics as well as in their departments and sections, which can then be certified accordingly. The central issue of the DIN-ISO standard is the written documentation of the essential procedures of a facility (hospital, laboratory area, and medical care center) in a *QM handbook*. Based on this electronic or printed document, everyday hospital processes are made comprehensible and transparent to third parties. Moreover, the QM handbook also includes instructions and stipulations as the permanent focus of the overall work process. The QM handbook according to DIN ISO is divided into five chapters, which inquire into the different areas systematically (quality management system requirements, definition of management responsibilities, resource management, product realization, and nature of the best possible form of continuous process improvement).

3.2.2.3 Cooperation for Transparency and Quality in the Hospital (CTQ) and proCum Cert

The Cooperation for Transparency and Quality (CTQ) model is a quality management system developed by one of the federal associations of the health insurance funds, the German Hospital Federation, the Chambers of Physicians, and the German Nursing Council; it was developed explicitly for implementation in hospitals. ProCum Cert is closely based on CTQ but was adapted for denominational sponsoring organizations.

CTQ is based on a *structured hospital self-assessment* in accordance with defined prescribed criteria. The report is divided into six criteria, and the hospital is assessed on the basis of the PDCA cycle by the applicants themselves. This is followed by an external assessment (inspection) by external CTQ inspectors where points are awarded and facilities must reach a certain level to achieve certification. This may involve some areas that are assessed at a lower level being compensated for by higher-rated partial criteria. However, in all areas, at least 55 % of the possible points must be achieved.

In the case of proCum Cert, this model has been extended by a Christian mission statement

and a Christian self-understanding within the CTQ requirements:

- Pro: for the patients and for good and proven quality in denominational hospitals.
- Cum: with the patients and their concerns and wishes and with other denominational hospitals.
- Cert: structures, standards, and procedures, which have to exist, are laid down by an «Expert Advisory Committee» and monitored by trained inspectors.

3.2.2.4 European Foundation for Quality Management (EFQM)

The underlying quality management concept of the European Union (European Foundation for Quality Management, EFQM) was initially focused on facilities in health care. Originally its intention was to comprise a concept for industrial working areas and service providers. Nine criteria were defined for application in hospitals. The basic idea of the concept is the requirement that the best in a branch or field set the standard and competitors are benchmarked according to this standard. More specifically, the EFQM comprises *five eligibility criteria*, which show the nature of the services an organization provides. The results achieved by the organization are presented in *four outcome criteria*.

In this model, the petitioner also initially gives a self-assessment. In the event of a prize being attributed, this assessment is checked by the EFQM within the scope of a visit (external assessment). The organizations with the highest point scores can receive the European Quality Award (EQA) from the European Organization for Quality (EOQ).

Since the criteria for this award are very comprehensive, this model of quality management is principally suitable for large hospitals and not necessarily for subsections or individual departments of a hospital. Similarly, this model is recommended for enterprises that already have experiences with quality management systems and have already experienced certification procedures (Kastenholz et al. 2011).

3.2.2.5 Joint Commission on Accreditation of Healthcare Organizations (JCAHO)

Historically, this assessment procedure originally developed in the USA for hospitals had a great influence on the development of German and European quality management systems.

In the JCAHO handbook, 562 different standards are defined for medical performance assessments. Upon fulfillment of these standards, JCAHO certificates are awarded. These certificates are, however, graduated and correspond to accreditation steps, each time imposing more stringent requirements on the hospital. In 2000, the first quality standards for hospitals valid worldwide were published. For the first time, these standards take the different economic, political, and cultural peculiarities of the countries into account.

3.3 External Quality Assurance

The measures outlined above all have a quality assurance character, but do not, however, guarantee optimal therapeutic quality. The diversity in medical therapeutic quality principally arises from the skills and ability of the physicians and the health care staff as well as the experience and motivation of the team assigned to the patient. The compliance of the patient also contributes to diversity in care. Therefore, therapeutic results obtained under study conditions can also not always be reproduced and therefore can differ from clinic to clinic (Moreland 1999).

With the help of external quality assurance, an attempt can be made to record the *therapeutic quality* of the participating facilities, thereby making them comparable. The objective of such measures may simply be the documentation of an applied standard. However, they can also be used to achieve transparency and to provide comparability for referring physicians, health insurance companies, patients, and relatives (hospital clients).

Additionally, with the aid of external quality assurance, competition can develop between the participating enterprises and can result in the initiation of an improvement of therapeutic quality.

However, there are a number of problems associated with the introduction of external quality assurance measures. For example, the health of the patient populations at different hospitals can vary considerably. Although part of this difference can be compensated for by risk adjustment

and/or risk modeling, diversity remains which is often difficult to identify and take into consideration resulting in an imbalance between the participating institutions. Further, the documentation of a large number of parameters over a longer period of time is not always possible without problems arising, so that important data may become lost. Until now there has been no control over the validity of the documented data from physicians, practices, or hospitals. Therefore, the quality indicators used does not necessarily reflect the real situation.

All these factors may influence the establishment and assessment of quality assurance systems and may diminish their validity. However, the advantages of an established quality management system are clearly reflected in a cost-effectiveness analysis. Legislators have recognized the advantages of a quality management system by supplementing the DRG law (Article 137 SGB V) which obligates hospitals to publish a structured quality report and introducing of the German National Institute for Quality Assurance.

3.4 Internal Quality Assurance

Since the demands and defined tasks in the area of inpatient and outpatient health care in a hospital are multifarious and the facilities differ considerably as a result, not all health care areas are suitable for participation in external quality measures. Considerable areas of patient care were therefore excluded. Thus, for a structured approach to patient care, internal facility quality assurance is absolutely essential. External quality assurance measures support the internal quality assurance measures, as they are implemented in many hospitals, for example, already within the scope of in-house quality circles.

Internal quality assurance is thus an *instrument of in-hospital control*. It provides the persons involved with a structure to make medically valid statements on therapeutic successes in their facility and to promptly correct any errors that may occur. This only succeeds, however, if the measures taken are accompanied by continuous monitoring, reflection, and statistical analysis of the data acquired (Albert et al. 2004). Risks of the treatment should be compared with the actual therapeutic success, which can often only be measured after a number of years.

Table 3.1 Core issues of quality assurance

External quality control	Internal quality control
Restriction of the documented data to a few indicators, which are jointly available in all participating hospitals and are part of a protocol. The parameters are specified	A further range of important parameters may be used for the assessment of the course of the disease and therapy. Individual selection of the parameters is made by hospital management
Analyses of the data are performed with a marked delay in time from the events to be observed	The therapeutic results can be acquired continuously and be promptly corrected
Registration of quality indicators is sometimes incomplete and subject to a time limit (usually only 30-day mortality)	Adequate data for the assessment of specific therapeutic effects can be analyzed and presented
Risk adjustment models are limited to simple indicators (Euroscore)	Statistical models can be adapted to defined criteria and can consider the multifactorial emergence of therapeutic effects and their chronologies
The evaluation of the endpoint of the course of treatment is performed without viewing the cause and effect relationships	Special analyses of certain time patterns in the data collected may provide information on the consequences of changes in therapy and/or personnel
From Ennker and Zerkowski (2006); used with permission	

In cardiac surgery, for example, the risk of a heart valve or coronary bypass operation in a particular hospital should be measured in the short term using risk score systems (e.g., Euroscore and Parsonnett Score) (Jones et al. 1996; Nashef et al. 1999; Metzler and Winkler 2012; Head et al. 2013). The durability of a bypass or an implanted valve, however, often manifests itself only after several years or decades. This must be considered when interpreting the data material.

An overview of the important core issues of internal and external quality assurance is given in

Table 3.1.

3.5 Measurability of Quality Assurance

To be able to subject the therapeutic success to a statistical analysis, *three markers of therapeutic success* have to be defined:

- Postoperative mortality and complication rate
- Number of reoperations
- Operating time and operating costs

3.5.1 Markers of Therapeutic Success: Postoperative Mortality and Complication Rate

These markers include quality indicators such as perioperative occurrence of a stroke, hemorrhages, renal failure, infections, and long-term ventilation (Borracci et al. 2007). For Germany, they can be looked up at ► www.bqs-online.de, provided by the German National Institute for Quality Assurance (BQS).

To be able to achieve valid collection and assessment of these operative complications, for example, in the case of coronary bypass and valve operations, follow-up observation periods of 6–12 months are required (Osswald et al. 1999; Seghieri et al. 2012). Further, due to age-related poor reconstitution capabilities, elderly patients require a longer recovery phase and often still suffer from postoperative sequelae within the specified period.

To be able to discuss *surgical success* in the widest sense, the actual goal of the operation must be reached, that is, an improvement of the complaint in comparison to the time before the operation must have occurred (improved status of the patient). In the field of cardiac surgery, this can be an increase in the stress level tolerated and an improvement of quality of life or extension of the remaining lifetime possible.

3.5.2 Markers of Therapeutic Success: Number of Reoperations

Reoperations can also be seen as the consequence of the surgical technique applied; a reoperation for the patient generally means an enhanced perioperative morbidity and mortality risk (Kara et al. 2013).

For this reason, the aim of modern surgical techniques is to avoid reoperation.

Therefore, within the field of coronary bypass surgery, arterial conduits are being increasingly used as bypass materials due to their longer patency rate (Tranbaugh et al. 2012; Dimitrova et al. 2012). In heart valve surgery, state-of-the-art heart valves are used which, due to the innovative materials and surface treatments, should have longer durability and as a consequence have a lower reoperation rate. However, the decisions made by the surgeon during the operation as well as the technical precision of the operation may influence the postoperative results decisively. These problems appear particularly frequently in the area of mitral valve reconstruction and make follow-up observation periods of several years necessary (Flameng et al. 2003).

3.5.3 Markers of Therapeutic Success: Operating Time and Operating Costs

The length of an operation is also considered a benchmark for surgical and intervention quality, as they can reflect the expertise of the surgeon and his operating team. However, speed alone is not necessarily a quality indicator, because speed may also mean carelessness and imprecise work (Rosser et al. 1997). For this reason, in the case of this marker, the complexity of the operation and further event variables must also be registered. The same also applies to recording the operation costs as a quality indicator. The seasoned and experienced surgeon with his team can work more cost-effectively than an inexperienced surgeon. Subject to certain reservations, this can also enable the quality of the surgical intervention to be assessed.

3.6 Evaluation of Internal Quality Assurance Data

In order to be able to achieve a valid evaluation of the internal quality assurance data, the various risk profiles of the patients must be added to the statistical analysis of the postoperative mortality and complication rate, the success of the operation, and reoperation rate to the surgical technique, surgical material, and the perioperative therapy (MacKenzie et al. 2012; O'Brien et al. 2009; Shahian et al. 2009).

Table 3.2 Key elements of computer-assisted internal quality assurance

Key elements	Explanation
IT documentation and data acquisition	To carry out a statistically valid data analysis, it is necessary to put together several sources of data within a hospital. In practice, this often represents much difficulty:
	The data sources in autonomous departments are often unlinked
	Date acquisition is often of a redundant nature
	Data acquisition is only partially consistent
	Due to external agreements, combining data sources is not always possible
	The individual departments as «owners» of the data sources insist on their autonomy
	Complying with the data regulations can in individual cases be problematic
	Integration of old data can be technically challenging
Acquisition of patient data following transfer	For a more detailed, postoperative follow-up, observation data must be accessed. To do this, it is necessary to develop and implement a multitiered system. This enables continuous documentation of the important anamnestic perioperative data. It is recommended that, in addition to the current daily routine work, a follow-up collection of data should be carried out 6 months and 1 year postoperatively. This includes follow-up of physicians and hospitals (hospitals for follow-up treatment, rehabilitation clinics, etc.) as well as the patients themselves
Risk adjustment	To evaluate the results of new therapies as well as the individual surgeons and departments, it is necessary to compare the risk profiles of the patient population adequately. This is possible with the help of established risk models such as Euroscore or Parsonnet Score. In the representation of hospital-specific risk profiles, however, they are sometimes insufficient for adequate presentation and can be supplemented by additional and, in some cases, specific models. Moreover, it has to be taken into consideration that the collected data can only be acquired retrospectively and can potentially result in error. Using modern statistical methods such as balancing scores enables an adjustment of the patient characteristics and hence leads to comparability between different institutions
Assessment plausibility	As the results of surgical interventions are subject to multifactorial influences, the elucidation of a cause and effect relationship is desirable. Depending on the method, statistical methods alone can only show correlations and may not provide any actual evidence. Therefore, the evaluated results must be subjected to a plausibility test

Due to the mass of collected data and the complexity of the analysis, this internal quality assurance task is only possible with the help of computer-assisted systems. Core issues of such a form of data acquisition are summarized in **Table 3.2**.

In the current conflict of dwindling financial resources, computer-assisted data acquisition represents a great challenge as an internal quality assurance tool. Thus, it is essential when setting up and permanently maintaining such a system to combine the multiple ranges of applications with a high standard of quality. Further, one should also not shy away from communicating the data gained within the scope of transparency and comparability in the health care sector to the outside. In addition to the written information for the

referring physician, health insurance associations, and patients, presentation within the scope of an Internet website is also recommended.

3.7 Risk Management

3.7.1 Fundamentals of Risk Management

In 1998, the Control and Transparency in Enterprises Act (ConTraA) took effect in Germany. According to this act, the board of an incorporated company must «... adopt appropriate measures to identify developments endangering the continued existence of the corporation at an

early stage.» This legal requirement also refers to limited liability companies (Ltd) and its CEOs and applies to a number of privately sponsored hospital associations.

Derived from this act is the contractual accessory obligation of the hospital management to create and permanently guarantee the organizational principles for a smooth course of treatment. In concrete terms, for the hospital owners and hospital management, this means that an appropriate department for legal as well as technical-medical guidelines must be established. This begins with the decision for a specific legal form of the enterprise progressing up to the allocation of departmental responsibilities. Furthermore, the hospital management also has the obligation to ensure the organizational structures become effective in everyday medical treatment and, if necessary, to intervene. The hospital manager is also responsible and accountable for the financial, spatial, personnel, and equipment planning of the hospital.

In 1952, the BGH formulated a «Postulate of Jurisdiction»: «Responsibility will be held for organizational errors irrespective of financial, structural, personnel or material bottlenecks because protection and safety of the patient has absolute priority over all other issues.»

Emerging from the legislation described above is the legal obligation of a medical care facility to define a corporate strategy for the enterprise to prevent damage and risks and to minimize any damage that may occur.

On the other hand, the development within the health care system has led to manifold advances in therapy options. As a result, a marked improvement in the therapeutic results could be achieved (Ulrich 2012; Fehr et al. 2012). At the same time available medical technology has continued to develop so that therapeutic results which were still unthinkable several years ago are taken for granted today. Through the publication of data, the general awareness and demands of patients are growing accordingly.

On the other hand, the increased frequency of high-risk operations also leads to an increasing number of civil proceedings with increasing claims for damages and compensation from

physicians, practices, and hospitals. It is precisely modern medicine which involves a great potential for complications, mistakes, and damage.

The problem is accentuated by the demand of the legislator to reduce treatment costs. Ultimately, this leads to a shortened hospital stay of the patient and to increased pressure of time for the treatment of the patient group involved.

All these criteria taken together lead to an increased risk for the patient.

This became clearly apparent when the Institute of Medicine (IOM) published its report «To Err Is Human» in 2000 (Institute of Medicine 2000; Leape and Berwick 2005). According to their definition, the term «*patient safety*» means the absence of adverse events during treatment. However, about 10% of all hospital patients suffer from adverse events, of which approximately half can be attributed to direct errors in hospital activity and would have been avoidable (Institute of Medicine 2000, 2001). As a result, in the USA alone, up to 100,000 deaths per year have to be expected, which in principle would have been avoidable. There are no exact figures available for Germany but it may be assumed that they are of similar dimensions.

The topic «patient risk, patient safety, and improvement of risk safety» is of enormous importance for patients, hospital staff, and insurance companies. Accordingly, there is also in Germany an ever-increasing ambition both on the part of the insurance companies as well as for patients and physicians' representatives to make important aspects of hospital activity a part of a functioning risk management system.

3.7.2 What Is Understood by Risk?

The term «risk» can be characterized as the probability of damage occurring in the negative case or benefit in the positive case. How the damage or benefit is understood depends on the values and objectives of the organization concerned in each case. In the area of risk management, this approach, however, is limited exclusively to the negative viewpoint, that is, the potential damage to the patient or financial loss for the organization.

There are often several concomitant risks that may jeopardize a patient's therapeutic success. One problem regarding risk assessment is that not

Definition of Risk

Risk: Probability of an incident multiplied by the possible consequences (complication or death of a patient, financial loss).

only one possible risk event is involved but often several individual events which are closely related to one another. Frequently there is a tendency to ignore the entirety of the risks and only consider the most likely individual event involved. This may result further in a systematic *underestimation of the risk potential* in a given situation.

3.7.3 What Is Understood by Risk Management?

The term «risk management» is the professional and systematic handling of risks, their identification, the prevention of damage, and claims for damages. The primary target parameter of risk management is the prevention of damage by identification of causes. Risk management is a method of identifying errors that may occur, their causes and possible consequences in a systematic manner, and analyzing and focusing on avoiding these in the future.

An adequate risk management system ensures that an organization, a process, or a service is safer

Adequate risk management therefore begins to take effect before errors with serious consequences can occur.

in its entirety. An optimally running risk management system cannot mean complete prevention of errors. Risk management improves the ability of an organization to deal with errors and the resulting risks and damages. A solid risk management system will increasingly become an important guarantor of the overall success of an enterprise.

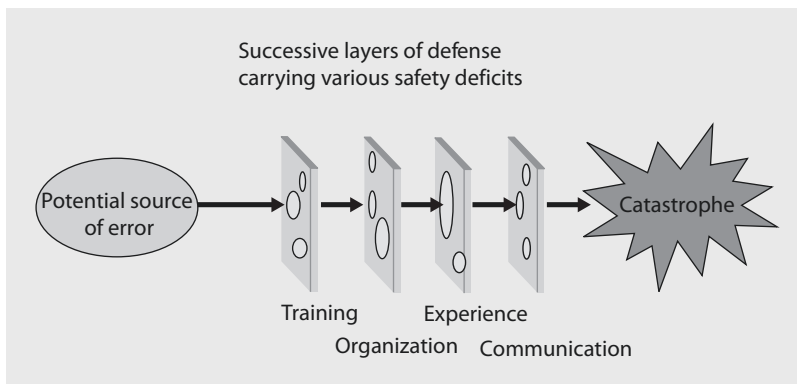

The primary target parameter of risk management is *prevention of damage and claims* by identifying the causes.

3.7.4 How Errors Originate

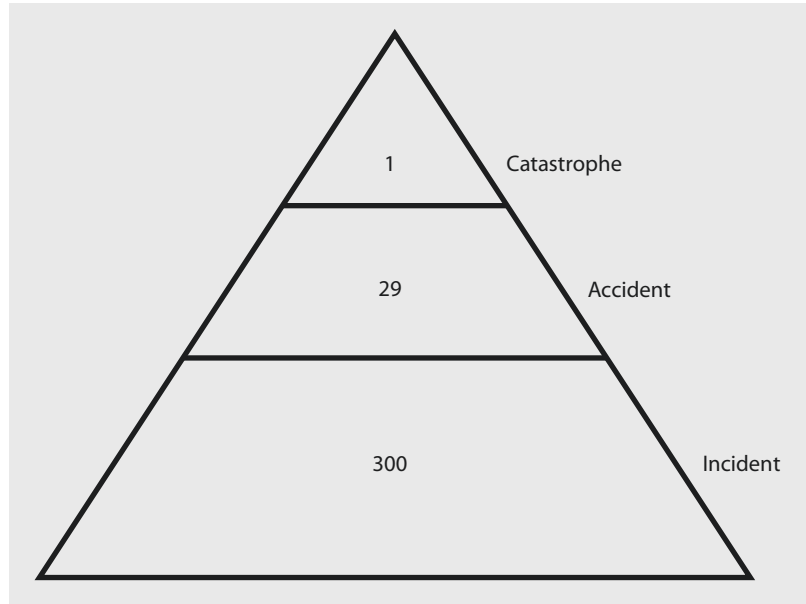

If it is assumed that people are fundamentally fallible, then the provision of continuous services will inevitably not proceed continuously free of error. Thus, errors are also to be expected in those institutions which have an above-average aspiration regarding avoiding mistakes, as should be the case in a hospital, for example. Mistakes are thus not considered as a cause, but as a consequence of the «weak points» in the system. This concept was developed by J. Reason in the 1990s and can be illustrated using a «Swiss cheese model» (Reason 1997, 2000, 2012; ■ Fig. 3.1).

In every organization, there must be defense mechanisms and protective barriers on different levels that prevent the emergence of errors. These barriers can, for example, be alarm signals indicating device error functions, the exact regulation of responsibilities, the «four-eyes principle» or the improvement of the safety awareness of the staff. Nevertheless, all barriers and protective functions show smaller or larger gaps in different places. As a result of unfavorable

■ Fig. 3.1 Risk model according to (J. Reason 1997, 2000)

■ Fig. 3.2 Damage pyramid according to Heinrich

constellations, a situation may arise in which all defense mechanisms for a specific error suddenly become permeable. As a consequence, a catastrophe or a fatal event emerges.

Also, from a statistical point of view, the emergence of catastrophic events are not unpredictable but instead are preceded by numerous smaller mishaps, work errors, and minor incidents.

This correlation was already presented by Heinrich in 1941 and is the central thesis of «Heinrich's Law» (Heinrich 1941). In the 4,000 incidents examined, approximately 300 smaller and inconspicuous errors occurred, and of these in 29 incidents, a catastrophic error was avoided in time, but in one case, according to this law, a serious catastrophe occurs (■ Fig. 3.2). This *damage pyramid* demonstrates that between the occurrence of the most serious error and smallest error, there is a relevant relationship; therefore, a strategy must be formulated with the avoidance of catastrophes by preventing small errors.

This correlation exists in the entire field of the health care system. Catastrophic events can result in the death or serious injury of a patient as well as serious financial losses for the enterprise, whose causes lie in avoidable errors.

3.7.5 Components of Risk Management

A risk management system comprises four essential building blocks (■ Fig. 3.3):

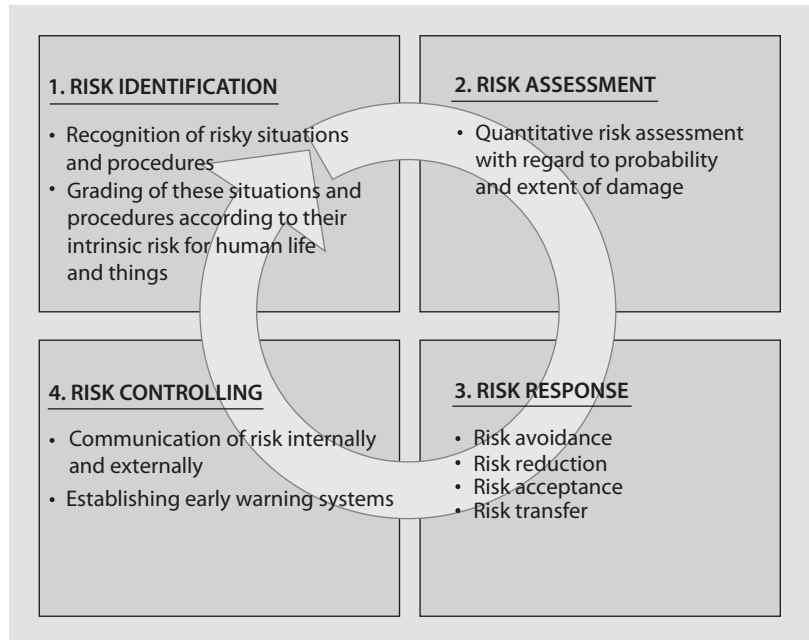

- Risk identification
- Risk assessment
- Risk solving
- Risk controlling, which includes internal and external communication

The entire process of an actively used system of risk management should be understood as being a cycle (cf. quality management), which continuously keeps questioning itself and adapts itself to new developments.

3.7.6 Methods of Risk Identification

To identify risks in a system, they must be recognized as such. Only then can their significance be quantified and classified qualitatively in a system, that is, the identification of previously unknown risks is difficult, but nevertheless an essential prerequisite to successfully setting up a risk management system. Individual risk events, under certain circumstances, occur only very rarely, and their significance is thus often underestimated. In some cases, errors are not named by the persons concerned, either due to a feeling of shame or because

■ Fig. 3.3 Risk management cycle according to Ennker et al. (2006)

legal implications are feared. Ultimately, risk analysis is a purely retrospective process, so that important aspects may simply become forgotten.

This means that in many cases, the «catastrophe» has already happened and only then is an investigation started to determine how this calamity could occur (Duthie et al. 2005).

The most common reaction to a major calamity is the provision of prevention measures, so that this particular catastrophe can never happen again. The essential aspect of far-reaching risk prevention, however, is that the calamity is often only the tip of an iceberg and under the surface lays the hidden potential for a complete series of further and different calamities that cannot be resolved by the specifically tailored individual measures.

Whereas in Anglo-Saxon countries the assessment of errors and causes of errors has changed, in Germany errors are still primarily considered under the aspect of personal responsibility. Although physicians are often threatened with sanctions, those concerned usually accept the consequence of, if possible, covering up the mistakes or not revealing their own involvement. Due to the paucity of information, the consequence of such behavior is the exact causes of the emergence of the error cannot be or can only inadequately be recognized (Department of Health 2000).

In the aviation transport or the atomic industry, errors that occur are not always the result of human error. This erroneous assumption then

usually does not lead to the discovery of the actual causes and the error analysis also does not lead to a real improvement in the causative process.

The origin of errors and the erroneous handling as a result is a multifactorial process, whose causes, as a general rule, are to be sought in different working areas and only in the rarest cases can they be reduced to a direct, exclusively human cause (Carthey et al. 2001). The principle possible causes are frequently ignorance and/or indifference, a heavy or excessive workload, communication deficiencies, monitoring problems, inadequate resources, and in the health care system often patient factors. They may make a contribution toward the occurrence of an error on an individual basis or in their entirety.

The vast majority of errors here is not to be ascribed to an individual person but often arises at communication interfaces between different service areas and types of service.

However, in order to learn from mistakes and to avoid the repetition of the same mistake, errors and previous incidents must in the first instance be documented in a reproducible system. When doing this, it is of decisive importance that reporting is performed free of sanctions and anonymously. Only when it has been accepted in an organization that everyone is

capable of making mistakes and that this may constitute a part of normal working procedures can a valid system be established to identify the sources of error—the prerequisite for reliable prophylaxis (Leape 2002; Emanuel et al. 2008). In the following, a selection of such systems, which have already proved their validity in practice, are presented.

3.7.6.1 Adverse Occurrence Screening

Using adverse occurrence screening and a targeted search for previously defined adverse events, it is possible to make a risk assessment of defined sections of a process or a service (Pagnamenta et al. 2012).

In a hospital, for example, this can be the death of a patient, unplanned readmission into a hospital, unplanned return transfer to the intensive care unit, an unplanned operation, or hospital stay of more than 30 days. With the help of a computer-assisted database, an assessment of the occurrence and chronological sequence of defined risks may be gained. The disadvantage of this method is, however, the fact that only retrospective registration of the defined target variables is possible, thus hampering the search for the causes due to delays (Reason 1995).

3.7.6.2 Sentinel Event Report

Certain events in a hospital can be considered as key events, based on a combination of similar error structures. Examples of this are (Leape et al. 1995):

- Operation of the wrong patient or the wrong side
- Suicide of a patient during the hospital stay
- Unexpected death of a patient
- Reoperation due to forgotten material or surgical instruments
- Blood transfusion despite blood group incompatibility
- Medication mix-ups as the direct cause of death of a patient

3.7.6.3 Incidence Report

This reporting system involves the acquisition and assessment of all error incidents within an organization, independent of whether they are severe or only minor incidents (WHO 2005). In such a complex organization such as hospital, errors and near errors are an integral part of the daily routine. Although several of the incidents rated as especially serious are discussed within the scope of ward handovers or medical rounds, a large majority of these do not, however, undergo any further processing as they are not really considered to be relevant, as «nothing happened.» With the help of a reporting system for

incidents (incidence reporting system), an attempt is made to record all incidents independent of their potential repercussions and to derive suitable measures from this for organizational processes (Gausmann and Schmitz 1998). The underlying principle behind this form of recording is based primarily on the abovementioned statistical relationship between a multitude of preceding incidents of smaller significance and a catastrophe ultimately resulting from these (cf. Heinrich's Law).

3.7.6.4 Complaint Management

The systematic introduction of a functional complaint management system is based on the following observation: a patient who is satisfied with his treatment tells an average of three additional persons about his/her experiences. A patient who is dissatisfied with his treatment informs nine additional persons about this, and a patient who was dissatisfied who could then be satisfied again (e.g., with the help of a functional complaint management system) recounts this very satisfying experience for him/her to 20 additional persons.

In this example, it is evident that the reputation of a hospital can be dependent on positive and negative incidents and that it is important to react appropriately to the complaints made by patients.

Every complaint must be seen as being an opportunity for improvement. Patients who express complaints are in principle interested in contact with the hospital and/or its staff.

Patients who have the feeling that their complaints are handled attentively and satisfactorily believe that their decision to choose this hospital has been confirmed, and they then communicate their experience to others.

Further, important avenues for internal quality management can be derived from where there are deficits in the everyday routine or where potential for improvement exists.

3.7.6.5 Patient Questionnaire

The aim of patient questionnaires is to improve patient satisfaction and the competitiveness of the facility concerned. One of the greatest challenges in the implementation of this tool consists initially in detachment from an antiquated doctor-patient relationship. A patient generally possesses only limited medical competence and must be considered

as a partner who is involved in relevant decisions. To be a partner, he/she should be put into the position by the medical personnel to be able to properly judge his/her own clinical situation (Merten 2005). If attention is given to patient questionnaires which particularly describes situations that include risk and regards potential for improvement, then implementing a questionnaire leads to gaining important information that may have escaped the attention of the staff. From this point of view, patient questionnaires represent an important source of information for exposing risk potentials.

In order to gain as much information as possible from such questionnaires, a patient questionnaire should be constructed in such a way that it allows not only yes and no answers but also allows rating. This is usually achieved by an evaluation of the predefined statements or scaling of «not/never true» up to «completely/always true,» usually in five to six steps.

3.7.6.6 Failure Mode and Effects Analysis (FMEA)

The FMEA is an analytical method designed to find potential weaknesses in a workflow procedure, a process, or an organization. Within the framework of risk management, the FMEA can be implemented to avoid errors and to act as a preventative measure. The FMEA is premised on precautionary accident prevention as opposed to error detection and correction (error management), emphasizing early identification of potential causes of error. In practice, this usually functions by a team of employees from the departments concerned having a discussion on errors and the assessment of the errors, which should take place in predefined steps:

- Identification of potential error possibilities
- Evaluation of the possible error consequences
- Analysis of the causes
- Risk assessment according to the estimated probability of the occurrence of the error concerned and classification in a mathematical scale system
- Classification of the possible damage
- Classification of the probability of discovering this error
- Multiplication of the values of occurrence, significance, and discovery (this gives a grading system with a risk priority number which regulates the urgency of the further need for action)
- Result-oriented discussion of measures to make the occurrence of the error impossible

- Checking the effectiveness of the measures taken to prevent errors
- Reassessment of the risk after the corrective measure based on the abovementioned key points (gives a new risk priority number, which in turn regulates the further need for action)

A comparative analysis of the risk priority numbers gives the possible risk reduction and the most suitable measure to prevent the occurrence of a specific error and damage associated with it (cf. Stauss and Seidel 2002).

3.7.7 Risk Analysis and Risk Assessment

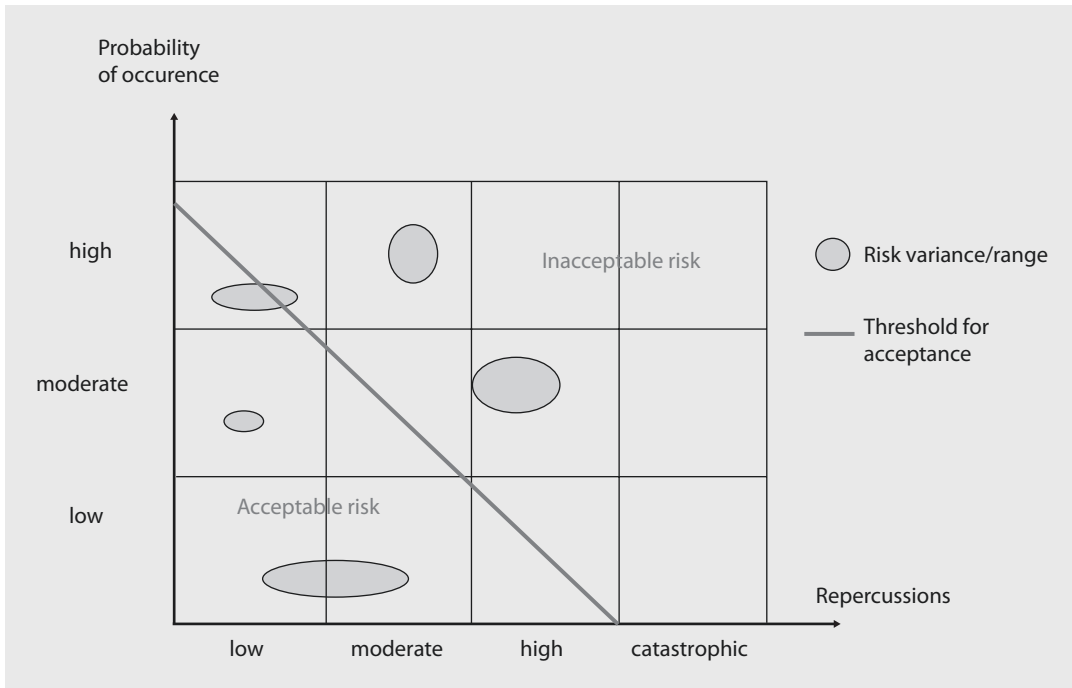

Following risk identification is an analysis, an assessment, and an estimation of the risks, and potential risk areas are discovered. These are attributable the product of the probability of the occurrence of the analyzed error and the degree of the damage associated with it. This relationship can be depicted graphically as in ■ Fig. 3.4. The risks here cannot always be seen as single, independent points, but rather they may include larger areas which are then described as «*risk areas.*» In certain special cases, these areas may also shift into areas that exceed a predetermined risk threshold. A section of the risk which is not located within an acceptable range must be considered separately and re-analyzed.

At the beginning of a risk analysis, the probability of the occurrence of the risk should be determined. This is especially important because risks that occur regularly show a habituation effect and as a result are underestimated in the future. It is therefore recommended to follow a time frame scheme. An example of this is presented in ■ Table 3.3.

Following the determination of the probability of occurrence are an evaluation and classification of consequential damage. For a hospital, this can be presented as in ■ Table 3.4.

From ■ Tables 3.3 and 3.4, it is possible to set up a risk rating matrix, and the classified events can be assigned to specific levels of activity, which must be implemented by those bearing responsibility in order to prevent the future occurrence of these risks and/or damage (■ Table 3.5).

Based on this structured risk estimate and the potential consequence, a ranking list can be created, in which ranking of the potential consequences and error sources takes place. A catalog of measures can then be derived from this list to deal with risks.

■ Fig. 3.4 Relationship between probability and damage (From Ennker et al. 2006; used with permission)

■ Table 3.3 Risk-time scheme

Frequency of occurrence	Time frame
Very common	Occurs weekly or several times per month
Common	Occurs several times per year
Uncommon	1–3 events per year
Rare	Occurs now and again in a 5-year interval
Very rare	Occurs once in a 5–30-year interval

■ Table 3.4 Consequential damage

Consequences	Definition
Extreme	Death of a patient which is not directly related to the disorder and does not correspond to the expected therapeutic result
Considerable	Serious persistent dysfunction which is not directly related to the disorder and does not correspond to the expected therapeutic result
	Every form of disfigurement
	Urgent need for surgery
Moderate	Persistent dysfunction which is not directly related to the disorder and does not correspond to the expected therapeutic result
	Every case of extended hospitalization
	Need for additional surgery
Minor	Increased need of nursing care
Very minor	Incident, which does not, however, require any further medical care or surgical measures whatsoever

3.7.8 Handling Risks

Within the scope of a risk analysis, one should be aware that despite excellent risk management, it is impossible to completely and permanently exclude all existing risks. Therefore, *four strategic considerations* for handling identified and ranked risks in a hospital are key:

- Risk avoidance
- Risk reduction
- Risk acceptance
- Risk transfer

Table 3.5 Risk rating matrix

Probability	Consequential damage				
	Extreme	Considerable	Moderate	Minor	Very minor
Very common	1	1	2	3	3
Common	1	1	2	3	3
Uncommon	1	2	2	3	4
Rare	1	2	3	4	4
Very rare	2	3	3	4	4

The numerical values given correspond to the different levels of consequences with the corresponding measures derived from these, which are listed below

Level 1: Unexpected death or persistent dysfunction that is not normally related to the disorder. The immediate intervention of the functionaries is required here. For a hospital, especially in private ownership, such events threaten its very existence. A single occurrence here may also be sufficient to lead to serious consequences for the hospital

Level 2: An event that is fraught with a high risk or an incident fraught with a high risk which may potentially lead to death, severe complications, or a permanent dysfunction of the patient. Immediate intervention of the functionaries is necessary

Level 3: Events that lead to health impairment of the patient and are related to inadequate handling of medical care, clinical practice, and quality of the operation. A report to those bearing responsibility is required that stipulates appropriate measures to prevent future repetitions

Level 4: Events which involve a minor health impairment, but which harbor a risk potential. A remedy for this may often already be achieved by means of a qualitative improvement in routine procedures

In this way, within the scope of a risk avoidance scheme, a patient can be transferred to a specialty hospital when adequate treatment cannot be guaranteed in an organization's own hospital.

Therefore, to deal with risks, it makes sense to implement error-tolerant systems and to organize the everyday clinical routine in a number of stages, so that it is possible to intervene in a regulative manner at different interfaces.

Often the demands of a functional risk prevention scheme are also considerably easier. In this way, errors attributable to overtiredness in the physician sector can be minimized by compliance with legal regulations.

In certain cases, however, a risk cannot be prevented completely by regulations and measures. This residual risk must be accepted, and its consequences must as be cushioned, for example, by transferring the risk, such as in the financial sector by taking out insurance policies.

Despite all efforts to regulate the handling of risks, one will not be able to completely avoid the occurrence of errors in the hospital.

3.7.9 Risk Controlling

Regarding risk controlling, it is important not to destroy the trust afforded to the staff by control measures being perceived as excessive and absurd. Rather, risk controlling must serve to check whether the joint efforts show truly measureable successes toward risk reduction. To do this, it is, on the one hand, important that risk management is understood as being a constant process that cannot already be terminated a few months after its introduction. On the other hand, it is necessary that the measures employed to identify risks are repeated and analyzed at regular intervals or preferably established from the beginning on a continuous basis, as is possible with the help of an incidence reporting system. If concrete measures emerge from the strategies for dealing with risks, it is necessary to communicate the measures adopted and the resulting improvements not only to all members of staff but also to external partners and the patients to increase the level of trust in the enterprise—a fact that in the light of

increasing competition is becoming more and more important and is essential to the survival of the enterprise and the employees working there.

4.1 Introduction

In recent years, quality control, outcome measurement, and reporting of performance criteria have become central parts of daily activities for cardiac surgeons in the United States (Loebe et al. 2009). Several layers of outcome reporting and quality control have been introduced by a number of players in the health-care industry. Hospitals, practitioners, and entities such as insurance companies, provider networks, and state health-care agencies are all subject to public reporting and have to compare their performance with national and regional benchmarks.

While public reporting is expected to generate awareness and influence decision-making by consumers, insurance companies as well as government agencies use outcome reports for credentialing, re-credentialing, and regulation of health-care providers. Payments and financing are now modified based on the outcomes reported. To position oneself in the competitive market of health-care providers in the United States, institutions have expanded the requirements on internal reporting. Frequent reviews of individual practitioners as well as service lines outcomes, internal reporting, and internal benchmarking are increasingly applied to improve performance of programs and institutions and increase their standing in public reporting and contractual negotiations. Furthermore, institutions are investing in ancillary staff to maximize coding on each patient so that they can benefit from the risk adjustment of outcomes and improve reimbursement. The majority of the work on additional documentation now falls on the clinical staff at each level of patient care.

There is no doubt that cardiac surgery lends itself particularly well to such efforts of intense outcome monitoring and public reporting due to the relative homogeneity of cases treated by cardiac surgeons and the length of time that has been spent recording and developing the databases. Comparably few procedures make up the vast majority of surgeries performed in the field (Guru et al. 2009). The key procedures, such as coronary artery bypass grafting (CABG) or aortic valve replacement, have been extensively studied, and there is fairly good evidence that can be used as a basis for performance measurement and outcome reporting. In addition, risk models have been developed and extensively tested in the field of

cardiac surgery for many years. These models are accepted by the cardiac surgery community and their representative societies.

With the interest growing in control of cost in health care, the general belief has developed that quality measures are one of the strongest vehicles to reduce expenditures. A good outcome leads to decreased resource utilization at all levels, shorter length of stay (LOS), and less cost. In an environment where reimbursement is based on diagnosis-related group (DRG) methodology, this is a necessary element in maintaining financial viability of both nonprofit and for-profit organizations and individuals. Therefore, as health care has moved from a type of free-market economy to a more regulated and controlled field, payors and governments have adapted. In the United States, the Federal Government has become the largest provider of health care; it will be unavoidable that mechanisms of central governance will be more and more influential in how health care is provided. Again, cardiac procedures are in the forefront as they are both very common and quite expensive, but other areas such as vascular surgery and general surgery are soon to follow. There is little doubt that in the near future, all health-care providers will be increasingly subject to intense outcome monitoring and quality reporting.

About 60% of cardiac patients in the United States are covered by Medicare, a federal government agency. Patients covered through Medicaid (state government entities) add another 10% of government-sponsored health care. Veterans are entitled to receive care in a separate health-care system, fully funded by the Federal Government and with a unique quality control system, as all information is centrally collected by the Department of Veterans Affairs (VA) (Takaro et al. 1986). VA funding is separate from Medicare. The number of private-paying patients, either through private insurance or directly, has constantly declined, and today is less than 6%. That leaves about 20% of patients who have insurance through commercial carriers nearly always bought and provided by the employer. These commercial insurance companies and networks have their own benchmarks and quality standards.

Performance data are used within the *United States* in different ways: some basic criteria are adopted from the Medicare system, but additional performance requirements may be established by the commercial payors to restrict the number of

certified providers, particularly in specialty programs such as solid organ transplant. Different levels of partnership (provider network, center of excellence, etc.) have been implemented to direct patients to specific institutions. Quality parameters are the most important factors in such grading, but they are not the only ones: center volume, location, spectrum of other services, and pricing do play a substantial role in becoming a center of excellence.

Recently, the Federal Government, through Medicare, has started to link reimbursement with quality parameters in that certain complications are not paid for at all (such as hospitalization for line sepsis and decubitus ulcers) and, in general, reimbursement is reduced if the hospital is not in compliance with pre-specified benchmarks. For example, if performance criteria in discharge education and discharge medication for heart failure patients are not fulfilled, the total Medicare reimbursement for all services to the hospital will be reduced by 3%. These are substantial punishments for health-care providers and require hospitals to increase their supervision of practitioners to change the way they deliver health care and may force hospitals to remove physicians from the staff in order to control noncompliant personnel.

The Federal Government has long focused on quality reporting in health care. Under the Clinton administration and continued under the second Bush administration, the Centers for Medicare and Medicaid Services (CMS) through the Agency for Healthcare Research and Quality (AHRQ) developed the Healthcare Cost and Utilization Project (HCUP) to identify Quality Indicators (QIs) in response to the increasing demand for information regarding the quality of health care. These measures, based on discharge data obtained through Medicare, were intended to flag potential quality problems in hospitals or regions. Out of 200 possible indicators, 45 were selected, with 25 indicators evaluating quality of care at the hospital level. These included seven volume indicators, and among these were five cardiovascular indicators: abdominal aortic aneurysm (AAA) repair, carotid endarterectomy (CEA), CABG, percutaneous transluminal coronary angioplasty (PTCA), and pediatric heart surgery. In addition to AAA repair, pediatric heart surgery and CABG in-house mortality appear as indicators. CABG and PTCA per capita are listed as indicators for regional quality in health-care delivery. Obviously,

cardiovascular procedures play a primary role in the quality assessment through the Federal Government. Hospitals and regions are measured by their utilization of and performance in cardiac procedures. Consequently, great attention is directed to outcomes in this field by the administrative leadership of hospitals (Klein and Nashef 2008).

4.2 Levels of Quality Control

4.2.1 Local/Institutional Level

Several levels of quality assurance in cardiac surgery have been established (■ Table 4.1). One level is the measurement of care performance on the institutional level. This would include documentation and reporting of medication errors, sentinel events (e.g., retained sponges), patient falls, and patient satisfaction. Medication errors are documented and reported by the pharmacy service of the hospital, and these reports are based on computerized records. Ongoing monitoring of patient satisfaction by interviews and sending out questionnaires after hospital discharge is mandated and can be performed by commercial service providers.

The quality of physician performance is monitored and reported internally. In most institutions, this is based on the data derived from the Society of Thoracic Surgeons (STS) registry. Individual outcomes are made available to the surgeon and to his peers. Usually, this includes number of cases, mortality, time on ventilator, use of blood products, and LOS. Furthermore, cases are identified and reviewed by peers based on certain triggers, such as mortality, unplanned return to the operating room (OR), or complaints by nonphysicians. These reviews are protected as confidential and should not be confused with educational events such as mortality and morbidity conferences, which are open to residents and fellows and not part of quality assurance.

4.2.1.1 Morbidity and Mortality Conferences

Morbidity and mortality conferences are departmental events that are not protected under the laws regulating quality control and reporting for the hospital. They are, of course, protected by confidentiality rules governing health care in general. These conferences cannot substitute for the

Table 4.1 Levels of quality assurance in cardiac surgery

Medical Services Quality Management (MSQM) or Care Management and Performance Improvement (CMPI) processes outlined below. Morbidity and mortality conferences are primarily reviews within the department and serve, to a large extent, an educational purpose. Participation is voluntary, and cases can only be reviewed with the consent of the practitioner.

4.2.1.2 Care Management and Performance Improvement

In the Care Management and Performance Improvement (CMPI) process, service lines within the hospital review their performance in a multidisciplinary fashion. Generic indicators such as mortality, LOS, preventable falls, and patient satisfaction are reviewed. The service line may set their own criteria or the hospital may hand down benchmarks to the service line. Most of the time, these benchmarks are derived from outside sources such as University Hospital Consortium (UHC) or STS databases. Service line-specific criteria, like in transplantation, may be added. During the CMPI process, quality goals for the future are set, and plans to obtain these goals are established. The role of CMPI is to choose specific quality improvement projects that are highlighted by the review of outcomes from administrative databases. Appointments to CMPI are annual.

4.2.1.3 Medical Services Quality Management

Medical Services Quality Management (MSQM) is a formal, multidisciplinary peer review of cases based on medical service lines. The hospital identifies indicators that lead to review. In cardiac surgery, these indicators might be mortality, unplanned return to OR, LOS, time on ventilator, or a sentinel event. The members of this committee are appointed by the president of the medical staff. The committee performs a peer review process. The case review is mandatory and includes all practitioners in the service line. The committee can investigate, send out inquiries, and get other service line MSQM committees involved.

Cases are reviewed by peers and graded according to performance. The service line subcommittee reports to the hospital's MSQM steering committee. This oversight committee may hear appeals from the practitioner and/or invite outside reviews. Quality problems have to be reported to the service line's departmental chairman, who decides the appropriate actions. For example, a performance improvement plan may be established between the chairman and the practitioner. Its progress, then, has to be reported back to the MSQM committee. Serious issues may have to be reported to the State Board and can result in disciplinary action from the medical licensing board. The MSQM process is protected

under confidentiality law. Actions by the hospital that alter a physician's credentials/privileges lead to dismissal from the attending staff, or require retraining reports to a Federal National Practitioner Database, which is accessible by any health-care facility to which a physician applies to work.

4.2.2 Regional Level

Several regions have established reporting mechanisms for cardiac surgery outcomes. The most widely known example is the reporting of volume and outcomes in the State of New York. Here, both hospital and individual practitioner data are made available to the public by the state government. Similar reporting structures have been established in other regions, including the Northern New England Cardiovascular Disease Study Group and the Dallas City-Wide Conference.

4.2.3 National Level

4.2.3.1 The Joint Commission

On a national level, quality reporting is provided through several avenues. One level is the agencies that accredit hospitals. The Joint Commission (TJC), formerly the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) and previous to that the Joint Commission on Accreditation of Hospitals (JCAH), is a US-based nonprofit organization that accredits more than 19,000 health-care organizations and programs in the United States. A majority of state governments have come to recognize The Joint Commission accreditation as a condition for licensure and the receipt of Medicaid reimbursement. Surveys (inspections) typically follow a triennial cycle, with findings made available to the public in an accreditation quality report on the Quality Check Website. Recently, a new law regulating Medicare removed The Joint Commission's statutorily guaranteed accreditation authority for hospitals, opening the field for other accreditation companies. Another provider of hospital accreditation that has entered the US market is Det Norske Veritas (DNV), a Norwegian insurance and logistics company.

Joint Commission International (JCI) was established in 1997 as a division of Joint Commission Resources, Inc. (JCR), a private, not-for-profit affiliate of The Joint Commission. Through international accreditation, consultation, publications, and education programs, JCI extends The Joint Commission's mission worldwide by helping to improve the quality of patient care by assisting international health-care organizations, public health agencies, and health ministries, and others evaluate, improve, and demonstrate the quality of patient care and enhance patient safety. International hospitals may seek accreditation to demonstrate quality, and JCI accreditation may be considered a seal of approval by medical travelers from the United States.

All health-care organizations are subject to a 3-year The Joint Commission accreditation cycle, while laboratories are surveyed every 2 years. With respect to hospital surveys, the organization does not make its findings public. However, it does provide the organization's accreditation decision, the date that accreditation was awarded, and any standards that were cited for improvement. The unannounced full survey is a key component of The Joint Commission accreditation process. «Unannounced» means the organization does not receive an advance notice of its survey date. Substantial time and resources are devoted by health-care organizations ranging from medical equipment suppliers and staffing firms to tertiary-care academic medical centers to prepare for and undergo The Joint Commission surveys.

4.2.3.2 Centers for Medicare and Medicaid Services

The Centers for Medicare and Medicaid Services (CMS), previously known as the Health Care Financing Administration (HCFA), is a federal agency within the US Department of Health and Human Services (DHHS) that administers the Medicare program and works in partnership with state governments to administer Medicaid, the State Children's Health Insurance Program (SCHIP), and health insurance portability standards. CMS establishes criteria for reimbursement of services. As mentioned above, CMS recently joined reimbursement to quality reports and will reduce payment to hospitals that do not meet performance criteria. This signifies a dramatic shift in the role that CMS plays and will

force health-care providers to dedicate significant resources to quality management and outcome reporting (Lindenauer et al. 2007).

4.2.3.3 Society of Thoracic Surgeons National Database

The STS National Database was established in 1989 as an initiative for quality improvement and patient safety among cardiothoracic surgeons. The STS database now has over 1,000 participating surgeons and data on almost four million operations (Brown et al. 2010). There are three components to the STS National Database, each focusing on a different area of cardiothoracic surgery: adult cardiac, general thoracic, and congenital heart surgery, with the availability of anesthesiology participation within the Congenital Heart Surgery Database. The component databases provide opportunities for quality improvement to their participants. The STS has developed quality performance measures in all three subspecialties of surgery.

By collecting outcomes data for submission to the STS National Database, surgeons are committing to improve the quality of care that their cardiothoracic surgery patients receive. STS continues to develop and maintain quality performance measures in the areas of adult cardiac, general thoracic, and congenital heart surgery. Many of these measures are included in CMS's Physician Quality Reporting System. In the interests of transparency, STS has also established STS Public Reporting Online: the publishing on sts.org of CABG composite quality ratings from STS Adult Cardiac Surgery Database participants who have volunteered to participate. STS initially received consent from 226 database participants to report their information through STS Public Reporting Online.

With over 1.5 million patients, the STS database provides unmatched outcome comparisons. The STS National Database is about 97% complete and ready to support longitudinal research on the outcomes of cardiothoracic surgery, according to results of a study that matched STS database records to records kept by CMS. A study by the Duke Clinical Research Institute matched records in the STS database and CMS database for CABG hospitalizations of Medicare patients over age 65 from 2000 to 2007 (Guru et al. 2008). The researchers evaluated the representativeness of the STS database by comparing data from the CMS records that were not matched to STS records with the CMS records that did have an

STS match. They found that the unmatched cases were more likely to be minority patients and/or emergency operations. They also discovered that the cases excluded from the STS database were more likely to be associated with mortality. Some of the explanations for these discrepancies could include potential selective underreporting of patients with poor outcomes.

4.2.3.4 University Hospital Consortium

University Hospital Consortium (UHC), Chicago, Illinois, formed in 1984, is an alliance of 116 academic medical centers and 276 of their affiliated hospitals representing approximately 90% of the nation's nonprofit academic medical centers. The Consortium's membership includes academic health systems from across the United States. These systems came together to develop the Quality and Accountability Study, so they could have a truly objective, data-driven measure for comparing their systems. UHC offers an array of performance improvement products and services. Extensive databases provide comparative data in clinical, operational, faculty practice management, financial, patient safety, and supply chain areas. Programs such as UHC's Imperatives for Quality and the UHC/AACN Nurse Residency Program™ offer opportunities for knowledge sharing and education. List servers allow members from across the United States to share information on outcomes and performance.

4.2.3.5 Hospital Quality Alliance

In December 2002, the American Hospital Association, the Federation of American Hospitals, and the Association of American Medical Colleges launched the Hospital Quality Alliance (HQA), a national public-private collaboration to encourage hospitals to collect and report data regarding the quality of care on a voluntary basis. The HQA was designed to provide information about the quality of hospital care to the public and to «invigorate efforts to improve quality.» Financial incentives were suggested and have been since implemented.

4.2.3.6 American College of Cardiology

Medical outcome research has traditionally used three different sources of data: randomized clinical trial data, administrative data, and registry

data. All forms of data have their respective advantages and shortcomings. In recent years, government agencies such as the FDA or CMS have increasingly requested registries for certain procedures or devices. These post-marketing registries allow for evaluation of therapies in daily practice. However, the quality of data reported and provided to the agencies determines the value of such registries.

To improve the quality of cardiovascular patient care by providing information, knowledge, and tools; implementing quality initiatives; and supporting research that improves patient care and outcomes, the American College of Cardiology (ACC) launched the National Cardiovascular Data Registry (NCDR) as a result of its exploration of various strategies for collecting and implementing clinical data in order to improve cardiovascular care (Messenger et al. 2012). As part of a data quality assurance program, annual audits are performed to assure the completeness and correctness of the information transferred into the registries by the sites. Educational tools to improve performance of documentation and reporting are provided to the participating centers. Through this effort, it is guaranteed that stakeholders using the information derived from the registries can base their decisions on high-quality data.

The outgrowth of the NCDR effort has focused on quality patient care through standardized measurement of clinical practice and patient outcomes. The first registry, encompassing cardiac catheterization and percutaneous coronary intervention (PCI) activities, was designed to help health-care provider groups and institutions respond to increasing requirements to document their processes and outcomes of care. Today, the NCDR maintains several registries in the field of cardiovascular medicine. Among them are the ICD registry, collecting information about defibrillator therapy; the CARE registry, collecting information about carotid interventions; and the TVT registry which has recently been started in conjunction with STS to monitor percutaneous aortic valve interventions.

Today, more than 2,200 hospitals nationwide participate in the NCDR. As the preeminent US cardiovascular data repository, the NCDR provides evidence-based quality improvement solutions for cardiologists and other medical professionals. As a patient-centered resource, the NCDR has developed clinical modules, programs,

and information solutions that support the areas of cardiovascular care where quality can be measured, benchmarked, and improved.

4.2.3.7 Vascular Quality Initiative

In 2011, the Society for Vascular Surgery (SVS) launched the Vascular Quality Initiative (VQI) to improve the quality, safety, effectiveness, and cost of vascular health care by collecting and exchanging information. VQI combines the concepts of regional quality improvement developed in New England with the intention of becoming a robust national vascular database and leader in quality improvement in limb salvage. The New England registry is a validated regional data registry within a quality improvement initiative that has been associated with improved preoperative medication usage and has helped define real-world practice and potential practice improvements.

VQI provides a potential vehicle for future public and pay-for-performance reporting and has the potential to improve patient outcomes. It uses the structure of a Patient Safety Organization (PSO) to ensure a focus on quality improvement and to provide the necessary safeguards for data confidentiality. The SVS PSO was listed by AHRQ in February 2011. The SVS PSO collects data related to commonly performed major vascular procedures. These include carotid endarterectomy (CEA), carotid artery stenting (CAS), infrainguinal bypass (INFRA), suprainguinal bypass (SUPRA), open infrarenal abdominal aortic aneurysm (oAAA) repair, endovascular infrarenal AAA repair (EVAR), thoracic endovascular aortic repair (TEVAR) including branch/fenestrated AAA repair, peripheral vascular intervention (PVI) of aortoiliac and lower extremity arterial disease, and hemodialysis access (ACCESS). Participants in VQI must commit to entering data for all consecutive procedures performed and must submit billing data periodically to allow an audit that confirms complete entry of all procedures. Follow-up information is collected at 1 year for all procedures, an element unique to VQI, and at additional time points for selected procedures that may require interval or longer follow-up.

Analysis of aggregated data within the SVS PSO is directed by the Quality Committee and performed by PSO staff. This includes the development of risk-adjustment algorithms to allow fair comparisons of hospitals or physicians, adjusted

for potentially important differences in patient characteristics. Based on these analyses, the Quality Committee develops and disseminates information to improve patient safety, such as recommendations, protocols, or information regarding best practices. The Quality Committee also coordinates and facilitates quality efforts of regional quality groups, as discussed above (Sect. 4.2.2). The SVS PSO is permitted to publish data that are non-identifiable in terms of patient, physician, or hospital. This allows regional quality groups to obtain non-identifiable data for their centers for specific regional quality analyses or research projects. It is also possible for multiple regional groups or centers to pool non-identifiable data for analysis, and such projects are approved and coordinated by the SVS PSO Quality Committee.

4.2.3.8 Registries in Other Nations

Proponents have long recognized the potential value of collaborative registries to answer clinical questions and provide benchmarking for quality improvement or assurance. While their value is significant, so are the logistical issues associated with data collection, auditing data accuracy, ensuring confidentiality, obtaining patient consent, and funding such efforts. In vascular surgery, one of the earliest registries that has been maintained is the Swedvasc effort, which has been in place since 1987. Subsequently, several other European vascular registries were organized, and more recently integrated as Vascunet, under the auspices of the European Society for Vascular Surgery. The United Kingdom (UK) Audit and Australasian Vascular Audit (Australia and New Zealand) have been organized in the UK and in Australia and New Zealand to function as quality assurance registries.

4.2.4 Commercial Quality Review and Reporting

Several companies have entered the market in reviewing and reporting health-care outcomes. Again, cardiovascular medicine is the most documented and watched area in this regard. As the US health-care system is a quasi-free market, these companies exercise their influence to stir decision-making towards certain health-care providers. Some companies advise insurance companies in contracting with hospitals and physicians based

on quality and performance measures. Other companies provide advice to health-care providers how to improve their performance. Finally, some media attract advertisement by providing «best of» lists (best doctor, best hospital, etc.). Discussed here are some of the most important entities in the field of commercial quality review and reporting. In addition to these entities, there are several other smaller enterprises providing ratings, all with very different procedures to establish their ranking. As a consequence, at any given time, one can find several hospitals advertising their services by claiming to be «the best» in cardiac care in the region.

4.2.4.1 The Commonwealth Fund

The Commonwealth Fund is a private US foundation whose stated purpose is to «promote a high performing health-care system that achieves better access, improved quality, and greater efficiency, particularly for society's most vulnerable» and the elderly. This foundation covers many areas of national and international health-care policy. One of these many fields of activity is the gathering and dissemination of evidence on excellence in health care from across the country and the world. National and international comparisons should help to show what is possible to achieve and stimulate health-care providers, policymakers, and stakeholders to take action to improve performance. Since 2006, The Commonwealth Fund and its Commission on a High Performance Health System have tracked the performance of US health care through a series of national, state, and regional scorecards.

4.2.4.2 Leapfrog

Leapfrog is a for-profit organization advising employers on what health insurance coverage to offer to their employees. Its goals are to inform Americans about hospital safety and quality, promote full public disclosure of hospital performance information, and help employers provide the best health-care benefits to their employees. Leapfrog sets and publishes certain standards on which to base health-care plan purchasing decisions. For the most part, these standards are taken from local or national databases, but they also include recommendations on such organizational and structural issues as participation in databases, intensive care unit staffing with board-certified intensivists, door-to-needle time for acute myocardial infarction, and technical equipment. As

Leapfrog acts on behalf of purchasers and employers across the country, it represents a substantial market force in health care. Through its guidelines and criteria, the group has substantial influence on how health care is delivered.

4.2.4.3 Healthgrades

Healthgrades Inc. is a US company that develops and markets quality and safety ratings of health-care providers, including hospitals, nursing homes, physicians, and dentists. Quality ratings are devised from publicly available patient safety data and analyzed with proprietary technology developed by Healthgrades. In addition to these ratings, Healthgrades offers consulting services to health-care providers to improve on safety measures and how to enhance marketing and public relations. As a for-profit organization, it has a strong presence on the internet, where it provides gradings for hospitals and physicians.

4.2.4.4 US News & World Report

US News & World Report is a former print magazine that now offers its ratings online. A multitude of reports are available (schools, universities, hospitals, etc.). The report on hospital rankings is one of the most prominent and offers a ranking of hospitals by specialty. If a hospital is ranked in multiple specialties among the top performers, it is included in an Honor Roll. Recently, *US News & World Report* started to offer regional comparisons as well. Its findings are hugely used for promotion and advertisement of hospitals in the United States. In their reporting, cardiac surgery is ranked together with cardiology. Factors influencing the rank are volume, outcome, technical equipment, reputation score, and number of nurses. In the upper segment, the ranking is largely driven by a reputational score, which is obtained through a questionnaire sent out to peers in the field.

4.2.5 Quality Control in Thoracic Transplant

In addition to the quality reporting and performance control described above, solid organ transplantation is subject to further surveillance. Transplanting centers must be certified by CMS and the United Network of Organ Sharing (UNOS) in order to perform transplants. Certification is based on case volume, outcome, and physician

qualification. The Scientific Registry of Transplant Recipients (SRTR) is the basis of outcome evaluation. Here, every 6 months, detailed reports on the performance of transplant centers are made available to the public. This includes survival, graft function, wait time, and demographics of recipients. Centers that do not meet expected performance levels get flagged and risk the loss of their certification if they continue to underperform. Both CMS and UNOS visit transplant centers unannounced to perform chart reviews. This has led transplant centers to dedicate substantial amounts of time and personnel to documentation and reporting. It has also urged numerous small transplant programs to close down as the demand in resources and outcome quality was deemed to be too economically challenging.

4.3 Conclusion

Quality control in cardiac surgery in the United States has grown rapidly in recent years. Efforts in documentation and reporting of outcome data have become a substantial part of the cardiac surgery practice. Through their administrations, hospitals have taken a leading role in implementing benchmarks, monitoring outcome, and reporting these numbers to regional and national databases. Reimbursement has now been tied to performance criteria. Multiple layers of documenting and reporting have been implemented. To remain competitive in this environment, institutions have no choice but implement processes of quality control and quality improvement. Constant internal reporting and rapid intervention on data suggesting a process or practitioner underperforming are necessary to maintain effective health-care delivery. The hope is that these efforts will result in improved outcomes for patients and a more efficient use of resources in cardiac surgery.

5.1 Introduction

There is a worldwide consensus in cardiac surgery that the use of complex and risky therapies can merely be justified by solid knowledge about their results.

Thus, cardiac surgery was and still is an expediting motor for the introduction of database systems in medicine.

Furthermore, by the end of the twentieth century in numerous countries, partners of health care have realized a necessity of quality assurance. As a consequence, national databases have been constituted in several countries (Germany, United Kingdom, USA). Primarily initiated by national medical societies, some of these databases have evolved from systems producing output figures with crude mortality rates to sophisticated databases with extensive analyses and risk stratification tools.

Aims of these databases include reporting and providing information to the public and partners in health care, participating in audit programs, enabling benchmark evaluations and performance assessments, and improvement of outcomes.

Databases distinguish from each other not only according to geographical catchment areas (region, nation, continent), but also some are linked to healthcare providers, social security systems, medical societies, or research projects. The design of a database and its properties is essential for the significance and interpretation of the reports and analyses derived from it (■ Table 5.1).

5.2 Databases in Cardiac Surgery: Germany

5.2.1 Annual Report of the German Society for Thoracic and Cardiovascular Surgery

Annual reports of the German Society for Thoracic and Cardiovascular Surgery (DGTHG performance statistics, until 2003; Hamburg Statistics) were first introduced in 1978.

Further, since 1989, results have been published in the Journal of Thoracic and Cardiovascular Surgery (Kalmar and Irrgang 1990; Funkat et al. 2012).

■ Table 5.1 Properties of databases are influencing the possible results and are important for the interpretation of outcomes

Database property	Option
Mode of participation	Mandatory/voluntary
Participants	Institutions (hospitals)/single surgeons/group of institutions
Trigger criteria	Diagnoses related/procedure related all procedures/selected key procedures (e.g., isolated CABG)
Term of data acquisition	Ongoing/time-limited
Data validation	Plausibility checks, feedback, and correction system
	On-site data monitoring/statistical checks
Verification of completeness	Validation with reimbursement data, local visits
Data set	Patient-/case-/procedure related
	Type and definition of variables
	Obligatory/optional data/minimum data set
Outcome variables	Plausibility checks follow-up data
	Descriptive statistics, mortality rates (in-hospital, 30 days, follow-up); morbidity variables (e.g., stroke, renal failure, mediastinitis, length of hospital stay); process variables, composite scores, risk adjustment
Reporting	Regularly (e.g., annually/with multiple years) public, specific for participants, anonymous, scientific aggregation

The DGTHG performance statistics is giving / gives a complete overview of cardiac surgery procedures performed in Germany. ■ Figure 5.1 shows the development of annually performed main cardiac surgical procedures from 1994 to 2012.

These statistics are based on voluntary and anonymized annual data delivery of all German cardiac surgery departments. Procedure type as well as hospital mortality has to be reported.

■ **Fig. 5.1** DGTHG performance statistics: annually performed main cardiac surgical procedures since 1994 (Copyright: German Society for Thoracic and Cardiovascular Surgery)

In Germany, every diagnostic or surgical procedure has to be coded for reimbursement reasons. Coding is based on a German Operation and Procedures System (OPS) which was derived in 1994 from the «International Classification of Procedures in Medicine» (ICPM), and since that time, new methods have been adopted on an annual basis. Therefore, it represents not only the state-of-the-art medical therapies but also new procedures. For example, transcatheter aortic valve implantation (TAVI) could be coded as early as 2006 with the code «5–35a.0 endovascular aortic valve implantation» which was later subdivided in «5–35a.00 endovascular implantation» and «5–35a.01 transapical implantation.»

Software that processes administrative data with OPS codes is free to every institution. Each operation is assigned to defined classes according to an open and accessible specification.

Since 2004, data can be submitted electronically, and for each procedure, risk variables can also be transmitted at the discretion of the institution. Thus, a risk-adjusted presentation of the results is possible and a more detailed sub-analysis can be performed. Currently, not all departments are using this opportunity; thus, risk adjustment is possible only for a subset of data.

The top priority of this database is the completeness of annual data collection. For comparability reasons, the basic structure of cardiac operations classification was maintained. It was subdivided or enlarged when more information had to be reported or new methods have been introduced, always in mind a backward compati-

bility to preserve the comparability of data even over decades.

The database registers procedures, not patients. Thus, the number of procedures is higher than the number of treated patients. As a result, mortality is declared on a slightly lower level than an effective one; however, analyzing electronically submitted data showed that this difference is neglectably small.

Future development of this database will provide a risk-adjusted presentation of all cardiac surgical procedures performed in Germany.

Besides the publication in the Journal of Thoracic and Cardiovascular Surgery, selected data are published by the «Deutsche Herzstiftung» (German Heart Foundation) in «Deutscher Herzbericht» (German Heart Report) along with data concerning interventional therapies in Germany (► www.herzstiftung.de).

For further information, visit ► www.dgthg.de.

5.2.2 National Mandatory Quality Assurance in Germany

Since 2001, results of isolated aortic valve procedures, isolated coronary artery bypass grafting (CABG) and combined aortic valve and coronary surgery have been reported to the German Head Office for Quality Assurance (AQUA-Institute, Göttingen, until 2008; BQS-Institute, Düsseldorf). For economic reasons, this mandatory quality assurance is restricted to a numerically essential part of the entire cardiac surgery activity. This

type of external quality assurance is a legally required process.

Historically, this quality assurance initiative goes back to the QUADRA study performed in Germany beginning in 1989 (Struck et al. 1990). In 2000, the data set was adopted to the definitions for EuroSCORE variables as risk-adjusted outcome measurements had to be performed by means of EuroScore. As observed, mortality rates turned out to be only half of the predicted ones; new scores for isolated CABG (KCH-Score) and isolated AVR (AKL-Score, published as German AV-Score) (Kötting et al. 2013) and the combination of both (KBA-Score) have been developed.

Data analysis is performed on an annual basis, and reporting to hospitals is accompanied by an audit of departments with suspicious quality indicators. In the case of serious irregularities, the clinic will be de-anonymized for the assessment panel. Thus, an inspection or a professional audit will be carried out to bring about quality improvement by defining common objectives. If no improvement can be achieved with these arrangements, the professional group can recommend a de-anonymization to the federal commission.

Data validation is implemented via statistical control measures as well as on-site in randomly selected hospitals.

Today, quality assurance in Germany is mandatory for 13 different organs or regions of the body comprising 31 different types of treatment. Of these, 14 components refer to the cardiovascular system: revascularization of the carotid artery, heart transplantation, lung and heart-lung transplantation, implantation of a cardiac pacemaker, exchange of a pacemaker, revision of a pacemaker, implantation of an implantable cardioverter defibrillator, exchange of an implantable cardioverter defibrillator, revision of an implantable cardioverter defibrillator, percutaneous coronary intervention (PCI), coronary artery bypass grafting (CABG), isolated conventional aortic valve implantation, isolated transcatheter aortic valve implantation (TAVI), combined coronary artery bypass grafting and conventional aortic valve implantation, and heart transplantation.

The regulatory authority and contracting entity is the «Gemeinsamer Bundesausschuss» (G-BA; Common Federal Committee) which is the body of the self-governing partners in

German health care including physicians, hospitals, and health insurances. In Germany, these self-governing partners have the order to transpose legislation into daily practice.

■ Table 5.2 is derived and translated from the Quality Report 2012, AQUA-Institute (AQUA-Institut für angewandte Qualitätsförderung und Forschung im Gesundheitswesen GmbH 2013). It gives procedural and outcome results for isolated coronary artery bypass grafting in Germany.

For further information, visit ► www.sqg.de.

5.2.3 German Quality Assurance for Congenital Heart Diseases

In 2006, the German Society for Thoracic and Cardiovascular Surgery (DGTHG) together with the German Society for Pediatric Cardiology established a task force to develop national quality assurance for congenital heart disease. On the basis of the EACTS Congenital Database, a data set was defined not only for surgical therapies but also for interventional treatment. Follow-up data of the patients is requested 3 months and 1 year after the initial operation or intervention.

After a successful pilot study, the database was launched in October 2011. The vast majority of German institutions performing interventional or surgical treatment for congenital heart disease is participating on a voluntary basis. Hospitals have to pay for participation, and the database is sponsored by «Deutsche Herzstiftung» (German Heart Foundation).

With this longitudinal database, estimations of outcome regarding multistage procedures will be possible.

For further information, visit ► www.nationale-qs-ahf.de.

5.3 The Society of Thoracic Surgeons National Database (STS-NDB)

After the publication of unadjusted outcome data on the basis of administrative data by the US Health Care Financing Administration (HCFA) in the late 1980s, several databases and risk models for risk-adjusted outcome measurements had been developed. One of these databases is the

■ **Table 5.2** Isolated coronary bypass grafting in Germany, from Quality Report 2012

Indicator of quality		2011		2012			Tendency
		Result	Result	Counts (O E) ^a	Denominator		
ID	Description	Result	Result	Counts (O E) ^a	Denominator		Tendency
332	Utilization of the left internal thoracic artery	93.7%	94.1%	32,401	34,417		↑
2256	Postoperative mediastinitis after elective/urgent operation	0.5%	0.4%	128	34,398		↑
2257	Postoperative mediastinitis in patients with risk class 0 or 1 according to NNIS	0.4%	0.4%	114	31,373		↑
2259	Neurological complications after elective/urgent operation	0.9%	0.8%	277	32,800		↑
348	In-hospital mortality	3.0%	3.1%	1,228	40,160		↑
349	In-hospital mortality after elective/urgent operation	1.9%	2.0%	684	34,429		↑
11617	Ratio of observed to expected mortality (O/E)	1.00%	1.04%	1,177 3.00%	1,128 2.87%		→
353	Status at the 30th postoperative day is known	78.3%	79.2%	31,798	40,160		↗
351	Mortality after 30 days	3.2%	3.1%	730	23,274		↑

NNIS National Nosocomial Infections Surveillance

^aIn case of regression-based indicators of quality

Society of Thoracic Surgeons National Database (STS-NDB) that was founded in 1989. With the first software release in 1990 and 105 voluntary reporting sites from the USA and Canada, the STS-NDB has grown exponentially to one of the largest medical databases with more than 1,000 participants and over five million data sets. The STS-NDB comprises three components:

- Adult Cardiac Surgery Database
- General Thoracic Surgery Database
- Congenital Heart Surgery Database

One of the most internationally recognized achievements of the STS-NDB is the risk models which imply different risk scores for isolated CABG, isolated valve procedures, combined CABG plus isolated valve procedures, and most recently risk models for multiple valve procedures (Shahian and Edwards 2009; Shahian et al. 2009a, b; O'Brian et al. 2009; Rankin et al. 2013). For isolated CABG risk scores, data related to postoperative renal failure, stroke, prolonged intubation time, surgical re-exploration, and deep sternal wound infection are available. The STS CABG Composite Score and the STS AVR Composite Score are combining pre-, intra-, and postoperative process and outcome measures, which is unique in this manner.

In 2011, the Adult Cardiac Surgery Database was opened to participation by international institutions.

The data set last updated in 2011 (version 2.73) comprises 217 core panels and 255 additional variables. General statistics are published regularly. Cooperating clinics are provided with extensive reporting suitable for inter-institutional benchmarking.

Until recently, the STS-NDB offers the possibility of public reporting to hospitals and surgeon groups on a voluntary basis for isolated CABG and isolated AVR.

On an aggregate level, star ratings (one to three stars) are given for the participant. The ratings are based on a composite score, absence of mortality (CABG and AVR), absence of morbidity (CABG and AVR), use of internal thoracic artery as bypass graft, and receipt of required perioperative medications only for isolated CABG (■ Fig. 5.2).

For further information, visit ► www.STS.org.

5.4 Databases of the European Association for Cardio-Thoracic Surgery (EACTS)

The European Association for Cardio-Thoracic Surgery (EACTS) currently supports two databases—the EACTS Congenital Database and the EACTS Adult Cardiac Database.

5.4.1 EACTS Congenital Database

In 1999, the EACTS Congenital Database was developed from a London database project of the European Heart Surgeons Association (ECHSA) and has since grown to a high-level database with worldwide acceptance.

Currently, Bohdan Maruszewski in Warsaw manages the database while Zdzislaw Tobota secures the project's functionality. Further, 411 departments of 35 European and 43 non-European countries are registered.

The EACTS Congenital Database offers participating centers' sophisticated outcome reports about their own performance in relation to national results or analysis by continent (■ Fig. 5.3). Public reporting provides for outcome data related to specific procedures and is aggregated for continents. A list of the best five units and some of their outcome variables are also available. Risk stratification is performed by means of the «Aristotle Score» and «Mortality Score.» The latter was developed on the basis of real outcome data derived from the EACTS Congenital Database and the STS-NDB. The STS Congenital Database Task Force and the Joint EACTS-STS Congenital Database Committee developed coding specifications for diagnoses and procedures in congenital heart disease, which are used in both databases (Jacobs et al. 2007). As a consequence, mortality and morbidity risk indices have also been developed (Jacobs et al. 2006, 2007).

Annually up to ten participants are visited for data validity and verification audits.

The graphs show the results of one unit (*red*) over the mean values of the other units split by hospitals. Each bubble represents one hospital; X-axis, mortality-score, Y-axis, 30d mortality; the bubble sizes are correlating to the relative case numbers of each institution (Courtesy of B. Maruszewski)

5.4.2 EACTS Adult Cardiac Database

EACTS Adult Cardiac Database aims at collecting data on procedures from all European countries and to publish them as a comprehensive report. In the future, structure and quality standards that align closely with those of the STS-NDB will be implemented.

The first report was based on 220,000 data sets of procedures from 2001 to 2002 including 12 countries (at that time without German participa-

tion). The second report was published in September 2005 with additional data sets from 2003. It included 350,000 data sets of 18 countries, and for the first time, Germany participated in the report. The third report was published in September 2007 using additional data sets from 2004 to 2005. This report was based on 627,000 data sets and was the first to analyze total lethality when sufficient data was available. In July 2010, the Fourth European Association for Cardio-Thoracic Surgery Adult Cardiac Surgical Database

Report was published. The report contains information about over one million patients undergoing adult cardiac surgery in the period up to the end of 2008. The submissions are from 366 hospitals in 29 countries across Europe and China (Bridgewater et al. 2010).

Currently, the major problem of this database system lies in its heterogeneous data quality due to markedly different local structures and historically evolved data collecting cultures in the participating countries (Bridgewater et al. 2010).

Moreover, in some countries, there are legal considerations concerning data protection, which hamper hospitals participation in this registry (Hickey et al. 2013).

5.5 The Society of Cardiothoracic Surgery in Great Britain and Ireland's National Adult Cardiac Surgery Audit and the British Congenital Cardiac Association's Congenital Heart Disease Audit

In the United Kingdom, monitoring of survival rates after cardiac surgery began in 1977 with voluntary submission of data to the Society of Cardiothoracic Surgery in Great Britain and Ireland (SCTS). A more detailed National Adult Cardiac Surgery Audit data set was first released in 1996 and was later updated in 2003 and 2010. Comprehensive reports with analysis of the National Adult Cardiac Surgery Audit data at national level were published in the so-called Blue Books. The most recent Blue Book (Demonstrating Quality) was published in 2009 (Bridgewater et al. 2009). «Blue Book» analysis is now available online and updated on a regular basis (► www.bluebook.scts.org).

In 2003, the SCTS agreed to join the Central Cardiac Audit Database (CCAD), which was established in 1996 in order to coordinate different data collection activities. CCAD has now become part of the National Institute for Cardiovascular Outcomes Research (NICOR), based at University College London (UCL), which manages seven cardiovascular audits and regis-

tries. NICOR is funded by the Healthcare Quality Improvement Partnership (HQIP), which is a charity contracted by the Department of Health in England to deliver outcome-focused quality improvement programs structured around collection of clinical data.

Participation in the National Adult Cardiac Surgery Audit is mandatory for all National Health Service (NHS) hospitals in England and Wales as part of the National Clinical Audit Patient Outcomes Programme (NCAPOP). Data from the National Adult Cardiac Surgery Audit are used to publish mortality rates for all NHS hospitals in the United Kingdom (and of some voluntarily participating private hospitals), which carry out major adult cardiac surgery. Moreover, since 2005, individual consultant adult cardiac surgeon's mortality rates have been reported to the public (■ Fig. 5.4). Over 90% of adult cardiac surgeons chose to «opt in» to having their individual data published for the most recent publication of these data on the SCTS website (► www.scts.org/patients).

NICOR tracks long-term mortality and re-interventions centrally by using a unique patient identifier (the NHS number), along with other data set fields such as date of birth.

The Congenital Heart Disease Audit is managed by NICOR, with professional leadership provided by the British Congenital Cardiac Association (BCCA) and the SCTS. All pediatric cardiac centers in the United Kingdom participate in the Congenital Heart Disease Audit. The first report was published based on 2000/2001 data from CCAD together with BCCA and SCTS. It contains hospital mortality rates for specific operations or catheter interventions. Today, mortality rates for congenital heart procedures are published online (► https://nicor4.nicor.org.uk/CHD/an_paeds.nsf/vwContent/home?Opendocument) at hospital level only, as low procedure rates per surgeon and per type of procedure mean that mortality reporting on individual surgeon basis would risk making analysis patient identifiable (■ Fig. 5.5).

5.6 Databases Answering Specific Questions

5.6.1 TAVI Databases

Due to the enormous growth potential in the relatively new procedure of transcatheter aortic valve implantations (TAVI) and the steep rise in implantation in some countries, there are several national activities to evaluate the TAVI procedure.

5.6.1.1 German Aortic Valve Registry (GARY)

As transcatheter aortic valve implantations (TAVI) in Germany increased enormously (2010, 2,565 patients; 2011, 7,231 patients; 2012, >9,000 patients), the German Society for Cardiology (DGK) and the German Society for Thoracic and Cardiovascular Surgery (DGTHG) initiated a registry to evaluate this method in comparison to conventional aortic valve replacement. The German Aortic Valve Registry (GARY) is a prospective, controlled, multicenter registry. All patients undergoing an invasive therapy for acquired aortic valve disease are consecutively

included if informed consent is given. Data management is performed by an independent institution (BQS-Institut für Qualität & Patientensicherheit, Düsseldorf, Germany), which also gathers follow-up data up to 5 years post implantation. With this, the 1-year follow-up reached an exceptional completeness of 98.1%. GARY is an investigator-initiated study with an unrestricted grant from medical device companies, active in the TAVI field.

The data set of GARY is based on the data set of the National Mandatory Quality Assurance in Germany (see ► Sect. 5.2.2). Additional data regarding indication, anatomical parameters like distance of the coronary ostia to the aortic anulus, procedural data, and outcome data are requested. The survey of quality of life (EQ-5D) preoperatively and with each follow-up gives an additional focus to this registry, which goes beyond the usual outcome parameters of mortality and complication rates. All centers performing TAVI procedures in Germany are participating in this nationwide voluntary registry (Beckmann et al. 2012).

For further information, visit ► www.aortenklappenregister.de.

5.6.1.2 STS/ACC TVT Registry™

The Society of Thoracic Surgeons (STS) and the American College of Cardiology (ACC) developed a registry in order to investigate practice patterns and patient outcomes regarding the TAVI procedure within an observational period of 30 days and 1 year post implant. The sophisticated data set (version 1.2) of this registry contains all commonly known pre-, intra-, and postprocedural parameters with cath and lab findings and a long list of possible complications. Moreover, it comprises preoperative indication parameters like «Hostile chest,» «Porcelain aorta,» or «EuroScore II» as well as the «Kansas City Cardiomyopathy Questionnaire» in its short form KCCQ-12 and the «Five-Meter Walk Test» preoperatively and in the two follow-ups. As many of these parameters are not obligatory, the validity of derived analyses will depend on the collaboration of participants. Participation is voluntary and bound to fees that have to be paid by each facility.

For further information, visit ► www.ncdr.com/TVT.

5.6.1.3 The United Kingdom Transcatheter Aortic Valve Implantation Registry

In the United Kingdom, the British Cardiovascular Intervention Society (BCIS) and the Society of Cardiothoracic Surgeons in Great Britain and Ireland (SCTS) have developed a data set for TAVI, as the National Institute for Health and Clinical Excellence (NICE) suggested that all TAVI procedures should be recorded in a national database.

Similar to the SCTS National Adult Cardiac Surgical Database, this TAVI registry is implemented and managed by the National Institute for Cardiovascular Outcomes Research (NICOR).

This data set contains typical pre-, intra-, and postprocedural parameters as well as variables concerning the indication for TAVI like «extensive calcification of ascending aorta,» «poor mobility,» the Canadian Study of Health and Aging (CSHA) Clinical Frailty Scale score, or the Katz Index of Independence in Activities of Daily Living.

Follow-up data after 1 and 3 years contain the CCS angina class and the NYHA heart failure class of each patient. Late valve deterioration together with «valve failure mode» or late paravalvular leakage can be documented together with the date of occurrence

and the need for «intervention for paravalvular regurgitation». All units performing TAVI procedures in the United Kingdom submit data for every consecutive patient where TAVI was attempted. The first long-term results derived out of this database have been published in 2011 (Moat et al. 2011).

For further information, visit ► www.ucl.ac.uk/nicor/audits/tavi/.

5.6.2 National Pediatric Cardiology Quality Improvement Collaborative (NPC-QIC)

The database of the NPC-QIC is primarily not based on cardiac surgery initiatives, and it is not a database for quality measurement of cardiac surgery procedures. But it is very closely linked to cardiac surgery, as the underlying aim is for it to improve the outcomes of care for children with congenital heart disease, and it is the first project «to improve survival and quality of life in infants with a single ventricle during the interstage period between discharge after neonatal cardiac surgery and admission for bidirectional Glenn.»

The NPC-QIC is an initiative of the Joint Council on Congenital Heart Disease (JCCHD), which consists of delegates from four key organizations related to pediatric cardiology and liaison representatives from different other organizations including the Society of Thoracic Surgery (STS).

The first achievement of this voluntary multicenter project with the involvement of parents is the development of clinical and monitoring processes together with an interstage feeding protocol that promises to improve interstage growth. The project started in 2007 with pilot funding obtained from the Cincinnati Children's Heart Association. One of the first tasks was to develop the longitudinal NPC-QIC database as the basis for the whole project. In contrast to other databases presented in this chapter, which are used to measure quality of care and deriving conclusions, the NPC-QIC database is primarily a research tool to improve quality by developing and validating methods.

For further information, visit ► www.jcchdq.org.

6.1 Conduct of Cardiac Surgery with Extracorporeal Circulation

Adult cardiac surgery can be performed in different ways. For the majority of cardiac surgical procedures, extracorporeal circulation is employed, i.e., a standard heart-lung machine is connected, whereas some operations such as off-pump coronary artery bypass surgery or the transcatheter aortic valve replacement (TAVR) can be carried out without it (see also ► Chapter «Minimally Invasive Surgery», Sect. 26.3.4). Minimized heart-lung machines basically consisting of a combined pump-oxygenator provide another tool, which is predominantly used for coronary artery bypass surgery and in a few centers for aortic valve replacement too.

6.1.1 Physiology During Extracorporeal Circulation

The purpose of extracorporeal circulation is the maintenance of peripheral perfusion and gas exchange during open-heart surgery and in cardiopulmonary failure. Therefore, extracorporeal circulation has a profound influence on the hemodynamic status and the oxygenation/acid-base status of the patient. The hemodynamic status is optimized via the pump flow, whereas the gas exchange is adjusted with the oxygenator. The blood flow over artificial surfaces necessitates anticoagulation and compromises end-organ function with time. A prolonged cardiac arrest requires cardioplegic myocardial protection.

6.1.1.1 Hemodynamics

The main task of circulatory support is the maintenance or reestablishment of a physiological systemic perfusion. As the required cardiac output (CO) is related to the patient's body size and shape, the necessary pump flow has to be normalized to the body surface (■ Table 6.1).

The pump flow aimed at for standard adult open-heart surgery employing extracorporeal circulation is commonly defined to 2.4 L/min/m². In miniaturized systems, less hemodilution allows for a lower pump flow. The regulation of the mean arterial pressure is achieved by adjusting the pump output and the systemic vascular resistance

■ Table 6.1 Necessary pump flows related to the body temperature

Body temperature	Pump flow L/min/m ²
Normothermia	2.2–2.6
Mild hypothermia (32–35 °C)	2.0
Moderate hypothermia (26–31 °C)	1.5

(SVR). Under normal perfusion conditions, the central venous saturation (SvO₂) should be >65%, and the serum lactate should be normal. A decreasing SvO₂ during extracorporeal circulation indicates insufficient circulatory support.

Cerebral autoregulation keeps cerebral perfusion constant for an arterial blood pressure range of 50–150 mmHg. As brain metabolism decreases to as low as 40% of normal during anesthesia, a perfusion pressure of 40–60 mmHg at full flow suffices during normothermia or mild hypothermia. In elderly hypertensive patients and those with significant carotid artery stenosis, however, one is inclined to maintain the perfusion pressure somewhat higher to prevent ischemic complications.

The oxygenator of the heart-lung machine usually contains a heat exchanger, which allows cooling and rewarming of a patient with a hypo-/hyperthermia system. Between 22 and 37 °C, cerebral perfusion remains constant, again due to autoregulation, and drops below 22 °C down to 15% of normal. For that reason, the pump flow of the heart-lung machine can be lowered to 1.5 L/min/m² at a temperature of about 28 °C and even further with more pronounced hypothermia.

The benefit or harm of total body hyperperfusion is still unclear. In vasoplegic or septic patients, who normally present with high cardiac output and high central venous saturation, respectively, it is probably advantageous to offer a maximized pump flow. So far, high pump flows have been successfully offered only in patients with a total artificial heart, but this phenomenon has not been analyzed in proper studies (Copeland et al. 2003).

6.1.1.2 Pulsatility

The significance of pulsatility during extracorporeal circulation was a matter of research for many years. Frequently, there is an erroneous assumption that a roller pump generates only a

weak pressure profile. In fact, roller pumps create a high pulsatility with a hard pulse (dp/dt , pressure increase over time), which is dampened by the long tubing system as well as by the windpipe function of the aorta. For practical purposes, pulsatility can be most simply generated by varying the rotational speed of the pump, even with an a priori nonpulsatile centrifugal pump. However, most of the pressure pulse does not reach the aorta as the compliance of the oxygenator absorbs the pressure pulsation.

Important knowledge with regard to the physiological relevance of pulsatility has been gained with the introduction of axial and centrifugal flow pumps for long-term ventricular assist. Taken together, it seems that pulsatility is meaningless as long as the pump flow is normal or mildly elevated (>100 mL/kg/min). The same is true for an inadequate low flow (<40 mL/kg/min) with inadequate oxygen supply, anaerobic metabolism, and acidosis. Only in a borderline low but not critical range pulsatile perfusion may offer an advantage (Bartlett 2005). The reason for this is a stronger stimulation of aortic and carotid sinus pressure receptors by the nonpulsatile flow, which ensues a worse microcirculation following an increased endogenous catecholamine release. As the extracorporeal circulation always provides sufficient oxygen, this mechanism does not play a role in daily practice, i.e., nonpulsatile flow per se is not harmful.

6.1.1.3 Oxygen Consumption

The oxygen consumption (VO_2) is a global instrument to measure cardiopulmonary function and oxygen transport. In adults, oxygen consumption is 3–5 mL/kg/min and depends mainly on the tissue metabolism. At rest, oxygen consumption equals the basal metabolism and increases with physical activity accordingly (up to tenfold). With fever or following catecholamine application, it only rises about 50–60%. In healthy people, there is also a linear relationship between oxygen consumption and heart rate. Oxygen is taken up by the lung as necessary, independent of lung function. Therefore, oxygen consumption can be measured with respiratory parameters. As the arterial oxygen content is independent of age and body size and oxygen requirement is regulated by cardiac output, the oxygen consumption (VO_2) can be calculated as product of the difference between arterial (C_aO_2) and venous (C_vO_2) oxygen content and the cardiac output according to Fick:

$$VO_2 = (C_aO_2 - C_vO_2) \times \text{Cardiac output} \\ \times 10 \quad [\text{normal: } 200 - 250 \text{ mL/min}]$$

The arterial oxygen content (C_aO_2) defines the amount of oxygen, which is bound to hemoglobin and dissolved in plasma, and can be calculated with the following formula (arterial oxygen saturation S_aO_2)¹:

$$C_aO_2 = (\text{Hb} \times 1.39 \times S_aO_2) + (P_aO_2 \times 0.003) \\ [\text{normal: } 20.4 \text{ mL } O_2 / 100 \text{ mL blood}]$$

The central venous oxygen content (C_vO_2) can be calculated in a similar way (venous oxygen saturation S_vO_2):

$$C_vO_2 = (\text{Hb} \times 1.39 \times S_vO_2) + (P_vO_2 \times 0.003) \\ [\text{normal: } 15.7 \text{ mL } O_2 / 100 \text{ mL blood}]$$

The arteriovenous oxygen difference ($AVDO_2$), which is normally 4–6 mL O_2 /100 mL blood, is a parameter of tissue perfusion. A high difference (>6 vol.%) is seen with physical activity and cardiovascular decompensation and a low difference during hypothermia and sepsis.

The systemic oxygen delivery (DO_2) is fourfold higher as the oxygen consumption (VO_2) and can be calculated from the arterial oxygen content and the cardiac output and therefore depends on the amount of hemoglobin, its saturation, as well as the arterial partial oxygen tension. Accordingly, oxygen extraction describes the quantity of oxygen which actually participates at the gas exchange. The normal level is $26 \pm 2\%$. Calculation is as follows:

$$O_2ER = \frac{VO_2}{DO_2} \times 100$$

DO_2 is independent of the patient's size:

$$DO_2 = C_aO_2 \times CO \times 10 \\ [\text{normal: } 800 - 1000 \text{ mL/min}]$$

If the oxygen delivery declines, oxygen consumption first remains normal, i.e., more oxygen is retrieved in the periphery and the central venous

¹ S_aO_2 = arterial oxygen saturation, 1.39 = Hüfner's constant (1 g hemoglobin can bind 1.39 mL of oxygen theoretically), P_aO_2 = arterial partial oxygen tension, and 0.0003 = Bunsen solubility coefficient

oxygen saturation drops. Only when DO_2 is no more but twice of the oxygen demand, an oxygen debt and anaerobic metabolism develop. A 1:1 use of delivered oxygen is impossible since a few tissues with a low oxygen need (skin, tendons, body fat) are relatively oversupplied.

In the daily routine of cardiac surgery, oxygen delivery is hardly ever determined, as oxygenation can be analyzed quite reliably with pO_2 and oxygen saturation. In critically ill patients, this can be problematic since more oxygen can be available with normal hemoglobin and a pO_2 of 40 mmHg as in an anemic patient with a pO_2 of 100 mmHg. Interestingly, the human organism has physiologic regulatory mechanisms which always aim at a normalization of DO_2 . In this regard, cardiac output increases in case of anemia or hypoxia until normal levels are regained. In chronic hypoxia, the number of red blood cells increases, additionally. Artificially ventilated, hypoxic, anemic, and hypermetabolizing patients should therefore be generously treated with red blood cell transfusion, and not only the FiO_2 (fraction of inspired oxygen) of the ventilator increased.

Carbon dioxide elimination (VCO_2) corresponds closely to the oxygen consumption. However, the carbon dioxide does not have a linear relationship with increasing exercise. At about 70% of maximal oxygen consumption, carbon dioxide elimination rises exponentially, and a non-compensated metabolic acidosis occurs. The relationship between carbon dioxide production and oxygen consumption is termed respiratory quotient ($\text{RQ} = \text{VCO}_2/\text{VO}_2$), which is also dependent on nutrition. In Europe the respiratory quotient is about 0.82.

The pCO_2 in arterial blood is 40 mmHg and is kept constant by autoregulation. A metabolic increase in carbon dioxide production is followed by an increased respiratory elimination. Accordingly, carbon dioxide elimination is not only dependent on hemoglobin and cardiac output but also on respiration. As the carbon dioxide elimination via the lung is much more effective than oxygenation, it remains intact for a long time in case of severe pulmonary dysfunction.

6.1.1.4 Gas Exchange During Extracorporeal Circulation

During extracorporeal circulation as long as the heart is ejecting, gas exchange occurs by both the lung and the oxygenator. Once the aorta is

cross-clamped, the lung cannot contribute to gas exchange. For oxygen transfer through the oxygenator, especially during aortic cross-clamp, the pump volume plays an important role as the oxygen transfer increases almost linearly with the pumped volume. Further influencing variables are related to the properties of the oxygenator. All available oxygenators have a different internal resistance and oxygenation performance. The so-called rated flow of an oxygenator determines its capacity, i.e., the flow at which venous blood ($\text{S}_v\text{O}_2 = 75\%$) with a hemoglobin of 12 mg/dL can be still fully oxygenated. For most oxygenators, maximal rated flows are about 7 L/min. As long as the pump flow is below this limit, all blood is fully saturated, and the oxygen content is determined by the blood flow and the arterial oxygen content. The *sweep gas* is the ventilating gas blown into the oxygenator, which is either a mixture of oxygen and carbon dioxide (heart-lung machine) or pure oxygen (ECMO). In exclusive carbon dioxide elimination, the gas flow can be raised up ten times (gas: blood = 10:1).

If blood is fully saturated, the maximum oxygen uptake capacity corresponds to the arteriovenous oxygen difference (AVDO_2). With low hemoglobin and a high central venous saturation, the maximum oxygen uptake capacity is diminished. It can be counteracted by an augmentation of the pump flow. In low flow situations, more oxygen can be provided only by an increase of the oxygen uptake capacity.

With a *venoarterial perfusion*, the arterial blood reinfused is saturated to 100%, and the pO_2 can be increased up to 500 mmHg (commonly, only 150–200 mmHg are used!). If pulmonary function would be totally lost, the left ventricular blood would be identical with the right atrial blood, which would ensue a saturation of about 75% and pO_2 of 35 mmHg. In the body, the well-oxygenated perfusate would mix with the badly/non-oxygenated blood from the lung. With the assumption of a 50% perfusion by the extracorporeal circulation, an oxygen content of c. 18 mL/100 mL blood with a saturation of 90% and a pO_2 of 55 mmHg would be achieved (Bartlett 2005).

In case of *venovenous perfusion*, which is performed only as an ECMO treatment, the P_aO_2 and the arterial saturation in a hypothetically complete lung failure would be identical to the post perfusion central venous saturation. In a venovenous

ECMO, the arterial saturation would not raise higher than 95% and would be typically even lower, P_aO_2 would be only around 40 mmHg, and the patients would be cyanotic and hypoxic (Bartlett 2005). However, normally, cardiac output in these patients is compensatorily increased and the systemic oxygen supply sufficient. An improvement of lung function increases arterial oxygenation, so that recovery of native pulmonary function can be monitored by the difference of arterial and venous saturation.

As in the native lung, carbon dioxide elimination in the oxygenator is much more efficient than oxygen uptake. Carbon dioxide elimination during extracorporeal circulation is (as in the native lung) mainly determined by the properties of the oxygenator and hardly by the pump flow. An increase of the membrane surface or the gas flow improves carbon dioxide elimination, but not the oxygen uptake.

In both venoarterial and venovenous ECMO, carbon dioxide (but not oxygen) levels can be adjusted to any desired level by choosing the respective membrane surface and the appropriate gas flow. In clinical practice, the oxygenator is usually oversized, and increased carbon dioxide elimination with a respiratory alkalosis can develop if the gas flow is not reduced. This overdimension can be useful for long-term use when the gas exchange surface gradually declines.

6.1.1.5 pH Management: α [Alpha] Stat and pH Stat

The gas exchange by the oxygenator does not only allow sufficient oxygenation and elimination of carbon dioxide, it also has a profound impact on the acid-base balance and the blood pH. As changes in the acid-base balance and blood pH have significant consequences in the physiology of the circulation, close monitoring and an adequate management are crucial.

There are two possibilities for the pH and pCO_2 management. With lower body temperatures, pCO_2 drops and the pH increases with $0.017^\circ C$, i.e., at $25^\circ C$ the pH is 7.6. Employing the α -stat management, the pH changes are not counterbalanced; a relative alkalosis is the consequence. With the pH -stat approach, the temperature related pH changes are counterbalanced with an increased carbon dioxide application to maintain pH as in respiratory acidosis. In case of the α -stat management, the cerebral blood

flow correlates with cerebral oxygen consumption during hypothermia as the cerebral auto regulation remains intact. It is the temperature regulation type in poikilothermic animals, where the degree of ionization of several important enzymes remains intact. Accordingly, the α -stat management seems to be more physiologic and is mostly preferred in adult perfusion. The advantage of the pH -stat approach, which is found in hibernating animals, is the better cerebral perfusion due to the carbon dioxide-related vasodilatation. This technique is partially favored in pediatric surgery (see also ► Chapter «Advances in Cardiopulmonary Bypass for the Neonate and Infant», Sect. 7.3.2.2).

6.1.2 Anticoagulation During Extracorporeal Circulation

Intact vessel endothelium has active and passive antithrombogenic properties such as the release of prostacyclin and endothelium relaxation factor, which inhibit platelet aggregation. It also activates the physiologic anticoagulant protein C and inactivates thrombin.

The artificial surfaces inside the oxygenator, the reservoir, the pump, and tubing (PVC, polyurethane, silicone) have no endothelial coverage and are thrombogenic. There is immediate platelet adhesion and consecutive thrombus formation. An activation of the coagulation cascade, the kinin-kallikrein system, the fibrinolytic system, and the complement system follows. The intrinsic coagulation pathway is initiated by the factor XII high-molecular-weight kininogen-prekallikrein complex, whereas the extrinsic cascade is activated with the release of tissue phospholipids. The median sternotomy also releases tissue thromboplastin, which activates platelets as well. The hemodilution during extracorporeal circulation further reduces the concentration of anticoagulation factors, platelets, and physiologic anticoagulants protein C, protein S, and antithrombin III.

Due to the activation of the coagulation systems by the surgical procedure and the use of the heart-lung machine, a strict anticoagulation is necessary. This is generally accomplished with heparin at a dose of 300–400 IE/kg. This dose is termed «full heparinization.» During surgery, anticoagulation is monitored with the activated clotting time (ACT). An ACT of 350–450 s is considered ade-

quate. In case of heparinized minimized extracorporeal systems, an ACT of >250 s seems sufficient. After termination of cardiopulmonary bypass, a 1:1 antagonization of heparin with protamine normalizes the ACT to a level of about 120 s.

6.1.2.1 Heparin

Heparin was discovered at the Johns-Hopkins University in Baltimore in 1916 and was introduced into clinical practice in the 1930s (McLean 1916). In 1939, it became evident that a plasmatic factor is necessary for the anticoagulant action of heparin. The identification of this factor, termed antithrombin III, succeeded not before the 1970s (Brinkhous et al. 1939).

Standard heparin (unfractionated heparin, UFH, chain length ≥ 18 saccharides) is a mixture of polysaccharides (negative loaded sulfated glycosaminoglycans) and is mainly obtained from porcine small bowel and bovine lungs. Fractionated low-molecular-weight heparin (LMWH, chain length 5–17 saccharides) has a shorter chain length and differs with regard to the various coagulation factors.

Both types of heparin bind antithrombins (AT), predominantly AT III, by which a complex is formed, which accelerates the activity of AT III a thousand times. UFH acts faster as LMWH, since it inactivates not only the prothrombinase complex (consisting of the activated factor X, activated factor V, calcium ions, and phospholipids) as does LMWH but also thrombin. Further mechanisms of action include the inactivation of the factors IX, XI, XII and kallikrein, and the binding of calcium ions, which augments the anticoagulant properties. Because of the different effectiveness, the heparin dosage is standardized in international units (IU) and not in milligram (mg). One unit of heparin prevents coagulation of 1 mL citrate plasma after addition of calcium chloride at 37 °C for an hour. AT III is substituted at levels <50 % of normal because of its importance.

It is noteworthy to recognize, that thrombin is not totally inactivated during extracorporeal circulation despite high dosages of heparin. As a consequence, thrombus formation may occur in the clinical setting despite full heparinization.

Apart from the anticoagulation properties, heparin exhibits various other traits. It increases fibrinolysis by release of tissue plasminogen activator (tPA) and has an anti-inflammatory effect by hindering granulocyte migration into the tissue.

6.1.2.2 Heparin-Induced Thrombocytopenia (HIT) and Heparin Analogues

During treatment with heparin, thrombocytopenia can develop, where two different types can be distinguished:

- Heparin-induced thrombocytopenia type 1 (HIT 1): 2–4 days after the start of heparin treatment, the count of platelets mildly decreases due to direct activation. Within a few days, the number of platelets spontaneously normalizes without therapeutic means. The exact incidence is unknown. In the literature, reported incidences vary from 1 to 25 % with unfractionated heparin, while LMWH heparins are told to have a lower risk.
- Heparin-induced thrombocytopenia type 2 (HIT 2): The HIT 2 occurs less often and manifests after 4–14 days with a much more dramatic drop of platelet numbers. The underlying pathophysiology bases on an antibody formation against heparin bound to antithrombin III. In about 75 % of cases, the heparin-platelet factor 4 (H-PF 4) complex is the causative antigen. The antibody, mostly IgG, recognizes H-PF 4 and activates platelets via the Fc receptor leading to platelet aggregation. Despite the thrombocytopenia, bleeding complications are infrequent, whereas thromboses with so-called white clots are reported to form in arterial and venous vessels in 50–70 % of cases (Greinacher et al. 2003). HIT 2 is a life-threatening complication with a mortality rate of more than 20 %.

Patients with a HIT 2 syndrome must not be treated with heparin, i.e., heparin therapy has to be stopped immediately. Anticoagulation can only be performed with *alternative drugs*, of which a few are available (Magnani 1993; Warkentin and Greinacher 2003) (■ Table 6.2):

- *Argatroban* (ArgatraTM): Argatroban is a synthetic direct thrombin inhibitor (arginine analogue), which is only used in patients with HIT 2. The dosage is adjusted with the aPTT, which is 1.5–3 times augmented. The metabolism is mostly hepatic and elimination over the feces. Therefore, renal failure is not problematic. As half-life is only 50 min, argatroban is the mostly used alternative drug to replace heparin, also in ECMO therapy.

Table 6.2 Heparin and alternative anticoagulants for extracorporeal circulation

Anticoagulant drug	Mechanism of action	Neutralization	Administration and dosage	Control parameter and therapeutic range	Elimination and half-life (HL)
Heparin, UFH	Inhibitor of thrombin and prothrombinase complex	Protamine 1:1	I.v. bolus: 300–400 U/kg	ACT >400 s	(40%) Binds to endothelium, macrophages, and plasma proteins –5–15 min, thereafter renal elimination HL: 60–90 min
Argatroban (Argatra)	Synthetic direct thrombin inhibitor (arginine analogue)	Not possible	I.v. bolus: 0.3–1 mg/kg Infusion: 2–40 µg/kg/min	ACT >400 s	Liver, HL: 52 min
Bivalirudin (Angiomax)	Synthetic direct thrombin inhibitor (arginine analogue)	Not possible	I.v. bolus: 1 mg/kg Infusion: 2.5 mg/kg/h	Kaolin-ACT >400 s, ecarin clotting time (ECT): 400–500 s	Proteolysis, kidney c. 20% HL: 25–34 min
Danaparoid (Orgaran)	Anti-factor Xa	Not possible		Factor Xa: 1.5 ± 0.3 U/mL	Kidney: 40–50% HL (anti-Xa): 19–24 h
Lepirudin (Refludan)	Direct thrombin inhibitor	Not possible	I.v. bolus: 0.25 mg/kg Infusion: 0.5 mg/min	Ecarin clotting time (ECT)	Catabolic hydrolysis kidney c.50–60% HL: 1.3 h

- *Bivalirudin* (AngiomaxTM): Bivalirudin is a synthetic bivalent reversible thrombin inhibitor (polypeptide containing 20 amino acids), which has been occasionally used for extracorporeal circulation in HIT 2 patients. A rather short half time of only 25–34 min due to a proteolytic degradation independent of liver and kidney function is advantageous (renal elimination 20%). Moreover, bivalirudin can be cleared via dialysis (Almond et al. 2006). The dosage is monitored with the ecarin clotting time, which is a meizothrombin generation test that can be used to measure the activity of the direct thrombin inhibitors. It should be increased to 400–500 s. A longer-term use of bivalirudin has been reported in ECMO therapy, where the ecarin clotting time was kept at 300–350 s (Koster et al. 2007).
- *Danaparoid* (OrgaranTM): Danaparoid sodium is extracted from porcine intestinal mucosa and is a mixture of low-molecular-sulfated glycosaminoglycans (heparan sulfate 84%, dermatan sulfate 12%, chondroitin sulfate 4%) with only low activity against antithrombin but strong AT III-mediated anti-factor Xa activity. The cross-reactivity with HIT 2 antibodies is low. The monitoring of anticoagulation is only possible by analyzing factor Xa levels as no antidote exists. Accordingly, overdosing may lead to bleeding complications. The biocompatibility is close to 100%; the half-life is 19–24 h, being hardly affected by renal insufficiency (Wilde and Markham 1997).
- *Lepirudin* (RefludanTM): Lepirudin is a recombinant hirudin (single-stranded polypeptide), which is produced with genetically engineered yeast cells ([Leu1, Thr2]-63-desulfohirudin). It binds noncovalent without the aid of cofactors to thrombin and inhibits its prothrombotic activity. Thus, lepirudin is a selective and irreversible thrombin inhibitor. The dosage is guided by the activated partial thromboplastin time (aPTT). With high dosages at an aPTT >70 s as it is necessary for extracorporeal circulation, the validity of aPTT is limited, and the measurement of the ecarin clotting time (measurement of anti-IIa activity) is superior (Greinacher et al. 2003). Lepirudin undergoes only minimal metabolism in the liver, and up to two thirds are eliminated unaltered via the kidney. Half-life is about 1.3 h and considerably prolonged in case of renal failure.

If patients just have a HIT 2 history without detectable antibodies, surgery can be performed with heparin, and the bleeding risk will be lower than with intraoperative alternative anticoagulation. As new antibodies may be generated with the repeated heparin use, immediately after this second surgery, anticoagulation has to be changed to alternative drugs in all cases with history of HIT 2. Due to the significant bleeding risks with alternative anticoagulation, there is a new discussion about considering heparin use during extracorporeal circulation even in the presence of HIT antibodies.

Heparinized systems do not require full heparinization. However, these systems renounce the sucker as the collected blood would coagulate in the reservoir despite heparinization. Heparin is covalently bound on the inner surface (e.g., with the Carmeda technique) of all blood-contacting elements including cannulas, tubing, oxygenator, and filter and can remain efficacious over months without provoking systemic coagulation. A development of HIT 2 has not been reported so far. A routine use of the heparinized system is hindered by the increased costs.

6.1.2.3 Platelet Aggregation Inhibitors

Platelet aggregation inhibitors (■ Table 6.3) are an integral part of modern interventional cardiology of coronary artery disease. Especially the long-term success of percutaneous interventional stent placement is significantly related to the combined treatment with acetylsalicylic acid (aspirin) and thienopyridine derivatives (clopidogrel). These platelet inhibitors as well as a medication with GP IIb/IIIa inhibitors (Aggrastat) increase the risk for bleeding complications in a surgical procedure. Even if a high bleeding tendency does not manifest in all patients, it seems advantageous to wait prior to surgery until the drugs' platelet-inhibiting properties ceased, if possible. For acetylsalicylic acid medication, halting the medication for 5–7 days is usually sufficient; the best control parameter is the normalization of the bleeding time. In emergency situations, such as unstable angina, acute myocardial infarction, or PTCA complication, a delay of surgery is not possible, but the surgical procedures can still be performed with an acceptable risk, which in general is limited to an increased use of blood and blood products.

The significance of excessive thrombocytosis is not well known, but successful open-heart

Table 6.3 Platelet aggregation inhibitors used in cardiac surgery

Drug	Mechanism of platelet inhibition	Reversibility	Administration	Elimination half-life	Recovery of platelet function
Aspirin	COX-1 inhibitor	Irreversible	Oral (1x daily)		Production of new platelets
Thienopyridine	ADP P2Y ₁₂ receptor antagonist	Irreversible	Oral (1x daily)		Production of new platelets
Ticlopidine					
Clopidogrel					
Prasugrel					
Ticagrelor	ADP P2Y ₁₂ receptor antagonist	Reversible noncompetitive	Oral (2x daily)	7 h	80% recovery by 72 h
Abciximab	Fibrinogen receptor antagonist (GP IIb/IIIa)	Monoclonal antibody	Intravenous		≥50% recovery by 48 h
Eptifibatide	Fibrinogen receptor antagonist (GP IIb/IIIa)	Reversible	Intravenous	2,5 h	50% recovery by 4 h
Tirofiban	Fibrinogen receptor antagonist (GP IIb/IIIa)	Reversible	Intravenous	2 h	4–8 h
Cilostazol	PDE inhibitor	Reversible	Oral (2x daily)	11–13 h	
Dipyridamole	PDE inhibitor and other mechanisms		Oral	14 h

■ **Table 6.4** Surface-coating techniques

Trade name	Type of surface coating	Manufacturer
Bioline	Covalent heparin binding	Maquet
Carmeda	Covalent heparin binding	Medtronic
Physio	Synthetic phosphorylcholine coating (heparin-free)	Dideco-Sorin
Softline	Synthetic polymer coating (heparin-free)	Maquet
Trillium	Covalent heparin coating	Medtronic
X-coating	Synthetic polymer coating (poly-2-methoxyethylacrylat, heparin-free)	Terumo

surgical procedures with a heart-lung machine have been described.

6.1.2.4 Surface Coating

The aim of surface coating (■ Table 6.4) is to augment biocompatibility of foreign material, i.e., to lower the risk of thrombus formation. Since many years, several different techniques of surface coating, mainly various types of heparin coating, are tested experimentally and in clinical practice. Distinct advantages and disadvantages of the coating techniques are not evident, so far. However, it seems important to achieve complete coverage of the whole extracorporeal circuit from «tip to tip» as only that allows abdication of full heparinization. As many adverse events manifest only after longer-term extracorporeal circulation, the value of surface coating in the daily routine of extracorporeal circulation is controversially discussed.

For heparin coating, heparin is covalently bound to the artificial surface in order to mimic the antithrombogenic properties of heparan sulfate on the natural endothelium. The exact mechanism of action of the bound heparin is still unclear, but a diminished activation of complement, of proinflammatory cytokines, and of platelets has been widely demonstrated.

Polypeptides are attached to the artificial surface with electrostatic forces and van der Waals forces. As a consequence, the surface is hydrophilized and more rapidly moistened, which hinders the adhesion of plasma proteins.

The polymer coverage X-coating (PMEA = poly(2-methoxyethylacrylate)) consists of two layers. A hydrophobic layer binds to the foreign surface; the hydrophilic layer is at the luminal side and in contact to the blood. The hydrophilic layer forms

a barrier by an uptake of water, allowing the blood proteins to move along without adherence and denaturation. Platelet adhesion is inhibited too.

6.1.3 Myocardial Protection

The aim of myocardial protection is to create conditions which allow a surgical procedure on the heart while myocardial integrity and function are preserved. The optimal conditions are not the same for all operations but depend on the pathology of the heart and the surgical requirements to repair it. Finally, there is always an individual compromise between optimal surgical conditions and ideal myocardial protection (Guyton 1995).

6.1.3.1 Concepts of Myocardial Protection

Several concepts have been devised for myocardial protection, which can all be employed consecutively (Guyton 1995):

■ ■ Myocardial Protection Prior to Cardiac Arrest

The induction of anesthesia in patients with impaired left-ventricular pump function or coronary heart disease is more dangerous than in healthy patients. Several reports have shown that an injury of myocytes starts already before initiation of extracorporeal circulation in 18% of patients (Delva et al. 1978). As many patients reach the operation room in a suboptimal status (agitation, tachycardia, hypoglycemia, hypovolemia) and are thus opposed to an increased risk, a careful hemodynamic and pharmacological optimization should be performed prior to surgery in elective cases.

The decline of mean arterial pressure during extracorporeal circulation below 60 mmHg can lead to subendocardial ischemia even in healthy patients. Accordingly, special care has to be taken to maintain sufficient perfusion pressure in patients with coronary artery disease. If necessary, perfusion pressure should be augmented with α -adrenergic drugs like norepinephrine, despite the risk of significant side effects. Furthermore, the heart-lung machine implies hemodilution, which also may lower subendothelial perfusion (Kleinman et al. 1978). Hypothermia can impair autoregulation of local blood flow and translate into local hypoperfusion. In hypertrophied hearts and those with coronary artery stenosis, ventricular fibrillation can also favor subendothelial ischemia. The same is true for overdistension of the ventricle. Therefore, an immediate vent placement should follow if a distended ventricle cannot be rapidly arrested by clamping the aorta.

■ ■ Lowering the metabolic rate during cardiac arrest

After optimal preparation for the ischemic arrest, the latter should be withstood in the best way possible. For the myocardium, rapid surgery with brief ischemia is best—this, however, is rarely possible. Therefore, the heart is protected with hypothermia and cardioplegia.

It is long known that the heart can be protected with hypothermia. In the nineteenth century, Van't Hoff demonstrated a decline of myocardial metabolism of 50% for every 10 °C drop in cardiac temperature. Thus, the use of hypothermia during cardiac surgery was suggested early and initially applied to the whole body. Later, surface cooling with irrigation of cold saline was introduced.

Simple cardiac surgical cases are operated upon with adequate cardioplegia in normothermia. In more difficult cases with extended ischemic times exceeding 1.5–2 h, hypothermia around 30 °C is mostly favored. Only if a long ischemic time beyond 2 h is anticipated, hypothermia below 28 °C is recommended. Nowadays, even rather complex operations with ischemic times of 3 h can be performed safely if myocardial protection is adequate.

Many earlier publications emphasized a cooling rate not to exceed 1 °C/min for the patient. This is no longer true as an improved gas exchange

management at the membrane oxygenator allows faster cooling, as it is our practice for years. Yet, the temperature difference between heat exchanger and blood in the oxygenator should not exceed 10 °C, even if scientific evidence is lacking. If deep hypothermia below 20 °C is aimed at, e.g., for aortic arch surgery, administration of an α -blocker can be helpful as it enables a more evenly and faster temperature decline. During deep hypothermia, a circulatory arrest is relatively well tolerated for up to 45 min.

Historically, rewarming was even more carefully performed than cooling, since the high pO₂ in bubble oxygenators could lead to gas embolism. Since introduction of membrane oxygenators and a precise pO₂ management to achieve 150 mmHg at the outlet, the formation of microbubbles is much less, and therefore a faster rewarming is possible. Nevertheless, blood temperature in the oxygenator should not exceed 38 °C.

The underlying pathophysiology during hypothermia and rewarming are only partially known. With cooling, the metabolism responds rather inconsistent, which also leads to a significant alteration of myocardial homeostasis. This means that the supply of the hypothermic heart with oxygen and substrates does not maintain normal cellular function (Cameron and Gardner 1988). A further disadvantage, especially for deep hypothermia, is a significant postoperative coagulopathy and cardiac edema formation.

Cardioplegia is more effective in protecting the heart than hypothermia alone. The oxygen consumption of an arrested heart is only about one fifth of a normal beating heart at 37 °C. The combination of hypothermia and cardioplegia potentiates cardiac protection. Studies have shown that even rather cold solutions (2 °C) do not harm the myocardium, but the cooling of heart with infusion of cold solutions is quite heterogeneous, especially in patients with coronary artery disease. A topical cooling may help to create a more uniform hypothermia. The optimal myocardial temperature is still discussed controversially. While crystalloid cardioplegic solutions are applied with 4 °C, the assumed temperature optimum for blood cardioplegia is higher (15–20 °C). Even normothermic blood cardioplegia protocols have been established in some institutions (Abah et al. 2012). Due to the higher temperature range, blood cardioplegia requires reinfusion about every 20 min.

■ ■ A Favorable Metabolic Milieu Increases Safety During Cardiac Arrest

During cardioplegic arrest, cardiac metabolism is altered. Accordingly, it is important to maintain an adequate metabolic milieu during cardioplegic arrest. This task is in part accomplished with cardioplegia in various ways:

1. By minimizing interstitial and intracellular edema formation
2. By hindering loss of cellular metabolites
3. By supplying sufficient substrates for the metabolism
4. By preserving an equated acid-base balance

Frequently, the metabolism is not properly kept up, as coronary artery stenosis and myocardial hypertrophy lead to regional underperfusion and hyperperfusion. Moreover, cardioplegia can be washed out in part by collateral flow. In this regard, blood cardioplegia seems advantageous as blood is the natural perfusion media with all nutritive elements and excellent buffering properties. In the same way, reconvalescence of ischemic myocardium with blood cardioplegia is probably superior (see below).

■ ■ Controlled Reperfusion Lowers Structural and Functional Myocardial Damage

The problem of reperfusion injury caused by oxygen free radicals and a massive increase of endothelial permeability with cellular edema formation is well known. The increasing tissue pressure hinders reperfusion, and the tissue edema leads to an increased diffusion distance through the tissue. Both worsens metabolism. Several concepts for controlled reperfusion with warm and cold, low calcium, and substrate-enriched solution have been designed and present advantages in experimental and clinical studies. However, there is still no defined optimum and no concept for daily routine established for controlled reperfusion after cardiac ischemia (Mohan Rao and Simha 2011).

6.1.3.2 Cardioplegia Strategies

Over the years, a wide spectrum of cardioprotective (protecting the myocardium) strategies has evolved. Multidose crystalloid cardioplegia was introduced in 1976. Cold blood cardioplegia followed in 1978 with the idea to add myocardial nourishment to the substrate-depleted heart (Buckberg 1995). The idea of warm cardioplegic

reperfusion («hot shot») was to limit reperfusion damage (1977). The rationale for this cardioprotective action is that amino acids like glutamate and aspartate play an important role in myocardial intermediary metabolism and their relative importance is further enhanced during and after ischemia (Caputo et al. 1998). Before the release of the aortic cross-clamp, a normothermic substrate-enriched blood cardioplegia is applied, mostly via the coronary sinus to actively resuscitate the ischemically damaged, substrate-depleted myocardium by maximizing the kinetics of repair. Thereafter, reperfusion with normothermic blood follows until cardiac activity resumes (Ascione et al. 2008). Considering the induction of cardioplegia as first phase of reperfusion, warm cardioplegic induction was extensively studied in 1983 to prove the «active resuscitation» of the heart (Buckberg 1995) (■ Table 6.5).

The techniques of delivery include single and multidose, continuous, antegrade, and retrograde (either, both alternatively or simultaneously). For single-dose cardioplegia application, low- and high-volume concepts exist, which means that some centers administer less than 1000 mL and others more than 2000 mL. The rationale for multidose cardioplegia derives from the occurrence of noncoronary collateral flow, which replaces the carefully formulated cardioplegic solution with systemic blood at the temperatures prevailing in the surrounding systemic arteries. Additional benefits of multidose cardioplegia are formulations that include buffering and hypocalcemia which may limit reperfusion damage during subsequent doses (Buckberg 1995).

Microplegia is a more recent concept. It is marketed as a cost-effective strategy utilizing undiluted blood with targeted amounts of cardioprotective additives, adjustable to meet the changing requirements of each patient during cardioplegia procedures (Menasché 1996, 1997). As it delivers blood from the circuit and additives for cardioplegia with minimal crystalloid, it is sometimes called blood cardioplegia without the crystalloid. Standard blood cardioplegia contains crystalloid in a 4:1 or 8:1 dilution. The constituents of microplegia total 1.5 mL of crystalloid for each 100 mL of circuit blood, equalling a ratio of 66.6:1.

Regardless the delivery technique, no superiority of either could be proven. As a consequence, cardioplegia administration is far from being

standardized, and every surgeon chooses the most convenient and in his eyes superior technique to deliver cardioplegia.

6.1.4 Side Effects of Extracorporeal Circulation

6.1.4.1 Respiratory System

Open-heart surgery employing cardiopulmonary bypass can compromise the whole respiratory system including the lung, bronchial system, chest wall, and diaphragm, especially if there is extensive preexisting disease. The most frequent comorbidities are nicotine abuse and pulmonary emphysema, but chronic bronchitis, subclinical pneumonia, preoperative lung edema, and muscular weakness are also important. During extracorporeal circulation with the heart arrested, the lung is only perfused by the bronchial arteries since the pulmonary blood flow is interrupted or virtually absent. It is unclear whether the alveolar cells suffer ischemia/reperfusion injury during surgery. Various other factors including hemodilution, lowered oncotic pressure, microembolism, and release of vasoactive and inflammatory substances increase vascular permeability, perivascular edema, and bronchial secretion. The combination of the aforementioned factors leads to a decline of pulmonary compliance and functional residual capacity, as well as to an increase of breathing work. Moreover, a sternotomy or thoracotomy has an immense influence on the compliance of lung and chest wall (Peters et al. 1969). Three days after surgery, a maximal loss of compliance of about 30% is present, and after 6 days, a significant decrease of compliance is still evident (Vargas et al. 1992). Lung volume and pulmonary flow rates drop immediately after surgery and can persist for 6 weeks (Berrizbeitia et al. 1989). Disconnection of the ventilator, the complete withdrawal of the positive end-expiratory pressure (PEEP), and single-lung ventilation frequently have the consequence of a relevant gas exchange disorder during weaning off cardiopulmonary bypass and thereafter. Immediately after extubation, functional residual capacity is decreased by 40–50% and hardly recovers during the first 72 h (Stock et al. 1986). The entry into the pleural space and the preparation of the ITA vessels have no isolated impact.

The problem of postperfusion syndrome, also known as «pump lung,» is rather historical. In the early days of extracorporeal circulation, 15–25% of patients suffered fatal postoperative lung failure. During autopsy, atelectasis, abnormal elastic fibers, but no edema or cellular infiltrates were seen (Baer and Osborn 1960). Due to comparable findings in postmortem examination, it is assumed that the postperfusion syndrome is a special type of adult respiratory distress syndrome (ARDS). Nowadays, ARDS is a rare finding after extracorporeal circulation and mostly a consequence of intrabronchial bleeding due to a traumatic lesion following intubation or right heart catheterization. The impact of blood product transfusion is still unclear.

6.1.4.2 Renal System

The influence of extracorporeal circulation on kidney function has been already studied 40 years ago. At that time, a decline of renal blood flow and glomerular filtration during extracorporeal circulation of 25–75% was reported (Lundberg 1967; Porter et al. 1966). These alterations were only partially reversible within the early postoperative days. Likely underlying causes were hypothermia, renal vasoconstriction, and the loss of pulsatile perfusion. In summary, the best results with nonpulsatile perfusion could be achieved with a mean systemic blood pressure >65 mmHg and a pump flow of 30–50 mL/kg (Hilberman et al. 1979; Yeboah et al. 1972).

It has been shown that the preoperative organ function of the kidney and all other organs is decisive for its behavior during extracorporeal circulation. The most important negative impact factors are age >70 years, diabetes mellitus, heart failure, and a prolonged duration of surgery and/or cardiopulmonary bypass, respectively (Bhat et al. 1976; Stafford-Smith et al. 2008).

During surgery with extracorporeal circulation, a certain degree of kidney injury seems to be unavoidable. Renal flow, creatinine clearance, water elimination, and urine volume decrease. A mild proteinuria is common. Hemodilution ameliorates these side effects by improving renal blood flow, glomerular filtration rate, creatinine and water clearance, and urine excretion.

After surgery, hypotensive periods are the main reason for acute renal failure. A diminished renal perfusion augments production and release of renin and angiotensin II, which further impair renal perfusion. Kidneys with preexisting

dysfunction and those with ischemic damage are very susceptible to additional injury. Overall, a postoperative oliguric renal failure increases the mortality and morbidity risk eightfold.

6.1.4.3 Gastrointestinal System

The incidence of severe gastrointestinal complications is estimated to be about 1%, i.e., gastrointestinal complications during and after extracorporeal circulation are rare (Filsoufi et al. 2007). Until now, there are only few data on this topic available. In contrast to the lung, there seem to be no typical gastrointestinal consequences or lesions during extracorporeal circulation. In a clinical inconspicuous setting, blood chemistry may present elevated liver enzymes, an increase of serum amylase, and in animal studies also mild edema formation in intestines and pancreas. The main cause of gastrointestinal complications is probably hypotension, however, still an unproven assumption. Arterial hypotension seems to promote gastric acidosis, where a relationship between gastric pH level and duration of extracorporeal circulation has been found. In the intestines, an increased endotoxin release suggests a disturbance of the intestinal barrier (Andersen et al. 1993).

The role of extracorporeal circulation in the development of nonocclusive mesenteric ischemia (NOMI) is unclear. Nevertheless, NOMI is a serious complication in open-heart surgery and associated with a significant mortality (Klotz et al. 2001). Initially, NOMI leads to intestinal distension and paralytic ileus, which is followed by intestinal necrosis.

Human and animal studies on liver and pancreas during nonpulsatile extracorporeal circulation demonstrate a considerable decline of organ perfusion. Complications are less when pulsatile flow is established (Ranmsey 1995).

6.1.4.4 Endocrine System

Through many physiological interactions, extracorporeal circulation affects the endocrine system in multiple ways. A distinct analysis of the hormonal changes is difficult as further parameters including age, comorbid conditions, and anesthetics also have impact on the endocrine system.

■ ■ Glucose/Insulin

Alterations of glucose and insulin levels are primarily influenced by infusions and priming liquids of the heart-lung machine. The

consecutive impact of the extracorporeal circulation on pancreatic function and glucose metabolism is different in diabetic and non-diabetic patients:

- In nondiabetic patients, glucose levels during extracorporeal circulation are elevated and normalize thereafter within 1–2 days. When employing hypothermia, the increase in glucose levels is less pronounced and starts immediately with rewarming of the patient (Kuntschen et al. 1985). High postoperative glucose levels have been associated with a poor neurological recovery after cerebral events (Longstreth and Inui 1984). The insulin level declines with induction of anesthesia, remains low during extracorporeal circulation, and rises again with rewarming.
- Diabetic patients suffer insulin deficiency during extracorporeal circulation, which is far smaller under hypothermic conditions. During rewarming of the patients, insulin levels can increase up to sixfold and then normalize within 3 days (Crock et al. 1988).

■ ■ Thyroxine

With the initiation of extracorporeal circulation, triiodothyronine (T3) levels drop and consecutively recover to about 60% of normal. Thyroxine (T4) and thyrotropin (TSH) decline insignificantly, although heparin augments free T3 and T4 levels. The combination of a low T3, low normal T4, and normal TSH is also seen in numerous other diseases and also in trauma patients and is called euthyroid sick syndrome or low T3 syndrome (Holland et al. 1991).

■ ■ Parathyroid Hormone (PTH) or Parathormone

With going on cardiopulmonary bypass, PTH levels decrease and normalize again 90 min after termination of extracorporeal circulation. The impact of hypothermia is unclear and controversially discussed (Bannister and Finalyson 1995).

■ ■ Antidiuretic Hormone (ADH), Also Known as Vasopressin or Arginine Vasopressin (AVP)

Trauma and surgical stress promote ADH release, which can be counteracted by an appropriate narcosis (with opioids). Despite anesthesia, cardiopulmonary bypass increases ADH, which returns to normal the following day (Kuitunen et al. 1993).

6.2 Components of Extracorporeal Circulation Systems

The standard heart-lung machine is the central part of the most frequently utilized type of extracorporeal circulation (ECC). It is the workplace of the perfusionist, who monitors and pilots the extracorporeal circulation during the surgical procedure. All steerable parts of the device are mounted on a console and aligned to each other in order to be easy to read and to reach and to keep the workplace ergonomically optimized.

6.2.1 Standard Heart-Lung Machine

The heart-lung machine (■ Fig. 6.1) enables surgical procedures on the arrested heart by maintaining systemic perfusion and replacing pulmonary function, also. Moreover, operations can be executed with the heart beating. Surgery on neighboring structures, which would not be tolerated hemodynamically without extracorporeal sup-

port, is also facilitated avoiding considerable blood loss in these cases, too.

With a standard heart-lung machine circuit, blood is drained from the right atrium or the caval veins with cannulas. With the aid of a pump, it is transported through an oxygenator back into the aorto-arterial tree. An arterial filter lowers the load of systemic emboli (microparticles and air bubbles). One or more suckers or vent lines collect blood from the operative field and take it back to the reservoir after passing a venous filter with an integrated bubble trap. Usually, there is also a separate system for cardioplegia application. Multiple sensors with an online display for line pressures, temperatures, electrolyte concentrations, and blood gases guarantee monitoring of the physiologic milieu and enhance the security of the extracorporeal circulation system.

A hypo-/hyperthermia system can be optionally used to cool and to rewarm a patient during the surgical procedure. The hypo-/hyperthermia system cools down and heats a water circulation, which is connected to the oxygenator and thus alters blood temperature.

■ Fig. 6.1 Configuration and setup of a standard heart-lung machine (Courtesy of Terumo)

6.2.1.1 Pumps

The arterial pump and the oxygenator are the most important components of the extracorporeal circulation. The main task of a pump is to sustain sufficient blood flow for systemic circulation and to assure adequate end-organ perfusion during cardiac arrest. The pumps further allow unloading and venting of the heart, suction with various types of suckers, and also application of cardioplegic solution.

■ ■ Roller Pump

The traditionally used pump is the peristaltic roller pump (■ Fig. 6.2). A peristaltic pump works by an alternating pattern of squeezing and releasing flexible tubing to move fluid through the pump. The roller pump consists of a stator and a rotor, connected to a drive unit. The stator is a pump bed holding an elastic silicon tube which is arranged around the rotor. Small amounts of blood are trapped in the silicon tube and massaged forward along the tube by rotating cylindrical rollers. Valves are not necessary for unidirectional flow. Several types can be discriminated with regard to number of rollers, with double roller pumps being the mostly used.

Pump flow primarily depends on the rotational speed and the diameter of the tube. It is important for the rollers to be occlusive, i.e., the wipers are totally compressing the lumen of the tube, as

backflow would considerably increase the degree of hemolysis.

The design of the roller pumps is variable and has undergone certain modifications with time. The pure U form has merged into an omega style, which is hemodynamically beneficial. A lower-pressure increase (dp/dt) reduces the stress of blood components. There are large and small pumps and double-headed pump consoles available. All are driven by electric motors adjustable from 1 to 250 rpm.

■ ■ Centrifugal Pump

Centrifugal pumps (■ Fig. 6.3) are hemodynamically equally effective as roller pumps, but much less traumatic to blood elements (cells and proteins), and hence advantageous. The inlet in the central axis takes up the blood which is then expelled at the peripheral outlet by rotation of the pump head. As there is no valve, blood can pour through the pump in both directions (depending on the pressure gradient), if the pump head halts. Accordingly, the arterial line has to be immediately clamped in case of a pump stop. The pump flow is continuous and pulseless and increases with the rotational speed. However, in contrast to the roller pump, the pump flow of a centrifugal pump is dependent on preload and afterload. It rises with an augmented preload and a reduced afterload. A deleterious increase of the line pressure, e.g., with a kinking tubing, therefore does not occur. But due

■ Fig. 6.2 Roller pumps from Stöckert/Sorin (Courtesy of Sorin)

to the preload and afterload sensitivity, surveillance of the line pressure is not sufficient. A flow measurement is mandatory and can be achieved with electromagnetic or Doppler sonography devices. Centrifugal pumps can generate forward pressures up to 900 mmHg; maximal suction is about 400–500 mmHg. As a consequence, cavitation phenomena as well as gaseous and microparticle embolism are reduced (■ Table 6.6).

6.2.1.2 Oxygenators

The purpose of an oxygenator (■ Fig. 6.4) is to replace the gas exchange function of the lung during extracorporeal circulation. An oxygenator not only enriches venous blood with oxygen but also eliminates carbon dioxide. By doing this, blood elements should not be traumatized, and the priming volume to fill the oxygenator should be as low as possible. Basically, there are different possibilities for a blood and gas interaction: blood can be fed to a gaseous phase (film oxygenator—obsolete in clinical practice), gas can be added to blood (bubble oxygenator—rarely used anymore), or blood and gas can be separated by a membrane (today's membrane oxygenator).

■ Fig. 6.3 Schematic drawing of a centrifugal pump (Courtesy of Maquet)

The 300 million alveoli of the human lung generate a gas exchange area of 160 m². Within the alveoli, the red blood cells come as close as 0.7 μm to air, which allows sufficient diffusion of oxygen and carbon dioxide in either way. In the oxygenators, the blood capillaries are much larger, and the gas exchange area is considerably smaller as compared to the human lung.

■ ■ Bubble Oxygenator

Bubble oxygenators consist of three components including the oxygenation chamber, the defoamer, and an arterial filter. These components can be aligned in series or in a concentric manner from inside to outside. First, oxygen is passed through a dispersion plate into the venous blood. Bubbles are generated, with their size depending on the outlet size of the dispersion plate, gas flow, blood viscosity, and surface tension of the blood. Gas exchange takes place at the surface of the bubbles. Smaller bubbles offer a larger gas exchange area but are more difficult to be removed afterward. Nitrogen cannot be added to the gas inflow as a significant risk for embolism would evolve due to its low solubility.

The elimination of the gaseous bubbles occurs in the defoaming chamber. The defoamer is mainly composed of polypropylene fibers and polyurethane foam, coated with anti-foam silicone. The remaining air bubbles are destroyed or finally trapped by a filter (125–175 μm). Important functional parameters are blood flow behavior and velocity, surface active substances, and absorption mechanisms. As nitrogen cannot be supplemented as part of the gas flow, considerable nitrogen losses can occur. Finally, the blood is collected in a reservoir. The maximal operating time of a bubble oxygenator is limited to 6–8 h.

■ Fig. 6.4 Oxygenator with semi-permeable silicone membrane a and microporous membrane b (Courtesy of Maquet, Sorin and Medtronic)

■ ■ Membrane Oxygenator

The membrane oxygenator mimics the human lung better as blood and gas are separated by a gas permeable membrane. The blood is pressed in between numerous small capillaries. The membrane was formerly manufactured of cellulose, polytetrafluoroethylene, and polyethylene; now there are only two types left: diffusion membrane (silicone) and microporous membrane oxygenators.

■ ■ Microporous Membrane Oxygenators

Nowadays, the majority of oxygenators are made of capillaries with a micro porous surface structure. The membrane of these microporous capillary membrane oxygenators consists of polypropylene, a hydrophobic material containing pores with a size $0.03\text{--}0.07\ \mu\text{m}$ in half of the surface. Gas exchange is by free diffusion through the pores, i.e., blood is in direct contact to the gas. Since the membrane surface is hydrophobic and the pores are small, no ultrafiltration of water occurs and gas and serum remain separated. If the gaseous pressure in the capillaries exceeds that of blood, gas can pass the micropores. So membrane oxygenators have a lower diffusion resistance and an excellent carbon dioxide transfer without the need of enlarging the membrane surface. Longer use may lead to adsorption of plasma proteins to the wall of the pores, which renders them hydrophilic and decreases surface tension. Eventually, plasma leakage can develop necessitating an oxygenator replacement.

■ ■ Diffusion Capillary Membrane Oxygenators

In this type of oxygenator, the capillaries are additionally covered with a thin ($<1\ \mu\text{m}$) skin as a barrier to prevent plasma leakage. This barrier is frequently composed of silicon rubber, a homogeneous nonporous material. The gas exchange occurs (as before) in the microporous part by diffusion. The driving force is the diffusion pressure or the difference of partial pressures of the gases, respectively. Within the barrier, transportation is based on a solution process, i.e., the gases dissolve in the polymer matrix, penetrate the barrier, and pass out again. The diffusion rate is related to the pressure drop and to the permeability of the membrane but independent of the gaseous substances. As the pressure difference is high for oxygen (up to 720 mmHg) and low for carbon dioxide (45 mmHg), oxygen transfer is sufficient, and carbon dioxide elimination is more difficult. The diffusion of anesthesiology gases is limited due to their large molecule size.

■ ■ The Newest Developments

are oxygenators with a polymethylpentene coating. A better gas transfer coefficient enables an unrestricted gas exchange, and plasma leaking during long-term use does not occur. Priming volume and pressure gradients are comparable to the microporous design.

Membrane oxygenators are considerably safer than bubble oxygenators since only few solid and gaseous emboli are generated and the regulation

of the gas exchange is simplified. In all membrane oxygenators, oxygen diffuses along a concentration gradient through a membrane according to Fick's principle, depending on the oxygen pressure gradient and the permeability of the membrane. Since gas and blood are physically separated, other gases like nitrogen or air can be added to alter the oxygen concentration (FiO_2) or transfer. The carbon dioxide elimination works similarly, as it diffuses along a concentration gradient from the venous blood to the gaseous phase. The exchange rate is related to the surface, the carbon dioxide gradient, and the permeability. A loss of nitrogen can be counteracted by a high nitrogen supplementation at the inflow gas (which is not possible in the bubble oxygenator).

The effective gas exchange area for adults in the current oxygenators is ranging from 1.3 to 2.5 m²; the respective heat exchange area is 0.14–0.6 m². Transfer rates for oxygen and carbon dioxide may be as high as 450 mL/min. During

long-term use (as in ECMO), aqueous vapor can condensate in the capillaries and compromise gas exchange. Nevertheless, membrane oxygenators have much longer run times than bubble oxygenator, they may run up to several weeks, and the impairment of the blood components is less.

6.2.1.3 Venous Reservoir

The venous reservoir (■ Fig. 6.5) receives the venous return and the spilled blood from the operative field is collected by the suckers in a large container or bag. Drainage of the venous system and/or the heart is usually passive by gravity with the reservoir being mounted 40–70 cm below the level of the heart. Apart from the position of the reservoir, central venous pressure, cannula size, and tubing affect drainage. Cardiopulmonary bypass can run on rather low central venous pressures by partially exsanguinating the patient (minus 1–3 L), namely, shifting part of the combined patient/ECC circuit into the venous reservoir.

■ Fig. 6.5 Venous reservoir: hard shell (left) and soft bag (right) (Courtesy of Maquet)

Most reservoirs have an integrated blood filter. It is composed of Dacron wool or polyurethane foam and catches particles from 20 to 100 μm , depending on the filter size. An incorporated bubble trap allows elimination of air bubbles. Furthermore, the venous reservoir offers access for drug application and blood sample withdrawal.

Technically, reservoirs can be constructed as a rigid container or a soft bag. The rigid systems are advantageous as they are larger, and volume estimation and air elimination are simpler. Likewise, priming and vacuum-assisted drainage are easier.

6.2.1.4 Bubble Trap and Arterial Filter

Bubble traps are incorporated as first element into the venous line, i.e., prior to the pump and oxygenator. Blood and air bubbles are split up by gravity and centrifugal forces, and the blood additionally passes a membranous sieve with a porosity of 40–200 μm . The priming volume is about 150 cm^3 , which is not problematic in a normal heart-lung machine but is of significance in a mini-ECC setting. Special air removal devices consist of combined bubble detection and bubble elimination, which functions as an automatic process in a rather effective manner.

Arterial filters are integrated into the arterial line prior to the blood returning into the patient. They also have a sieve with a pore size of 20–40 μm , trapping air bubbles and small solid particles. A peculiar variant is the so-called dynamic bubble

trap, which accumulates the bubbles in the mid-line stream and eliminates them from there.

Bubble traps and arterial filters are available as single components as well as an integrated part of a complete system, e.g., cardioplegia sets. The sizes have to be adapted because of priming volumes and flow limitations in very small patients only. The efficacy of bubble traps and arterial filters is judged rather inconsistently. However, most studies demonstrate a reduction of air bubbles and microembolism in transcranial Doppler sonography measurements.

6.2.1.5 Gas Blender

With only few exceptions, oxygen and carbon dioxide transfer is determined by a gas blender. Gas flow can be altered from 0 to 16 L/min, and air can be supplemented so that an oxygen tension of 21–100% can be offered to the patient. A high oxygen concentration leads to a higher pO_2 and consecutive enhanced oxygen transfer. In contrast, carbon dioxide transfer is governed by the gas flow. A higher gas flow accelerates carbon dioxide washout by better maintaining the pCO_2 pressure difference. Another way to regulate carbon dioxide exchange is to admix it to the sweep gas.

6.2.1.6 Cannulas and Tubing

Various cannulas (■ Fig. 6.6) are available to connect an extracorporeal circuit to a patient. Standard cannulas are manufactured by a translucent flexible synthetic material. The cannula

■ Fig. 6.6 Curved and straight arterial cannulas, curved and straight venous wire-enforced cannulas, two-stage venous cannula (Courtesy of F. Merkle)

tips are composed of a rigid material, either of synthetic material or of metal. The cannula tips are also the narrowest part of the cannula and therefore responsible for pressure drops, jets, turbulences, and cavitation phenomena (vein collapse around the cannula due to excessive drainage). Cannulas can become either directly or indirectly (jets) most dangerous as they can lacerate the arterial wall (dissection!), loosen atherosclerotic plaques, and cause hemolysis. Hemolysis and protein disintegration may also occur with pressure gradients >100 mmHg. Kinking is prevented in all cannulas. Arterial cannulas are most often have a stiffened wall of various kinds, while venous cannulas have a metallic spiral reinforcement inside the cannula wall. Numerous cannula heads have been designed to accommodate the clinical needs. Angled cannula heads are advantageous for bicaval cannulation; single cannulas for the right atrium can be straight or angled. As drainage can be impaired with single (one-stage) right atrial cannulation, a so-called two-stage cannula was designed, which drains the superior caval vein indirectly via the right atrium and the inferior caval vein directly.

Central cannulation of the heart and/or the adjacent large vessels offers the best drainage and consequently provides the best cardiopulmonary support/temporary cardiopulmonary replacement. According to the planned procedure, the arterial cannula can be either inserted into the ascending aorta, the aortic arch, or brachiocephalic trunk. A more distal cannulation, especially in the aortic arch, reduces the risk for cerebral embolism. Extrathoracic but still central cannulation can be accomplished via the axillary, subclavian, or carotid artery. All aortic cannulas are introduced after a 5 mm stab incision and during a mean arterial pressure of 60–80 mmHg. They are fixed with purse-string sutures in the adventitial layer, which can be reinforced by pledgets. Thus, the aortic insertion can be sealed and the cannula fixed. Transmural stitches are avoided as they would increase the risk of subadventitial hematomas and continuous bleeding. During cannula placement, it is important to verify that the tip is readily inserted into the aortic lumen and directed toward the aortic arch. Extrathoracic cannulas are inserted in the same manner as any other peripheral cannula. Possible complications include vessel wall tearing and dissection (aortic

dissection $<1\%$), dislodgement of atheromas, and thrombi (stroke!). A screening for endovascular atheromas can be performed by palpation, echocardiography, or with epi-aortic ultrasound (Bolotin et al. 2005). The latter has been recommended in patients with a history of transitory ischemic attack or stroke, severe peripheral arterial occlusive disease, and palpable or visible aortic wall calcifications and even in any patient beyond an age of 50–60 years! The practicality of these measures has to be assessed on an individual basis. An extraordinary risk for thromboembolism and stroke is present in patients with a porcelain aorta, which is evident in 1.2–4.3% of cases. A special protection system positioning a sieve as a filter (pore size 120 μm) just before the aortic cannula did not gain widespread acceptance, even if clinical studies demonstrated collection of embolic debris in 97% of patients (Banbury et al. 2003) (■ Fig. 6.7).

The purse strings for the venous cannulas either into the right atrium or into the caval veins are best performed with transmural sutures. If the right atrium has not to be entered during the procedure, e.g., none or only left-sided structures are opened, a two-stage cannula placed into the right atrial appendage will sufficiently drain both caval veins. A surgical procedure involving entry into the right atrium or the presence of an intracardiac shunt mandates separate bicaval cannulation employing tourniquets around both caval veins also. Right-angled cannulas for individual caval cannulation may be least disturbing. The cannulation of the superior caval vein can be achieved at the base of the right atrial appendage, i.e., via the right atrium, with a long tip cannula, or by direct access to the vein with a short tip cannula. It is important not to injure the sinus node and to avoid vessel narrowing after removal of the cannula. The inferior caval vein is best entered 1 cm above the diaphragm, more laterally than anterior. Both a straight or angled cannula serve the purpose well (■ Figs. 6.8 and 6.9).

A persisting left superior vena cava (LSVC), which is present in 0.3–0.5% of patients (Wood 1956), is usually connected to the coronary sinus and therefore drains into the right atrium. In 10% of these cases (unroofed coronary sinus), however, it drains directly into the left atrium. These very rare cases should be picked up clinically due to oxygen saturations only around 90%, unless they are masked by a large ASD with a supervening left to right shunt.

Fig. 6.7 Cannulation of ascending aorta. A purse-string suture is placed and the cannula inserted after a stab incision **a** or with the aid of a small Satinsky clamp in children **b**

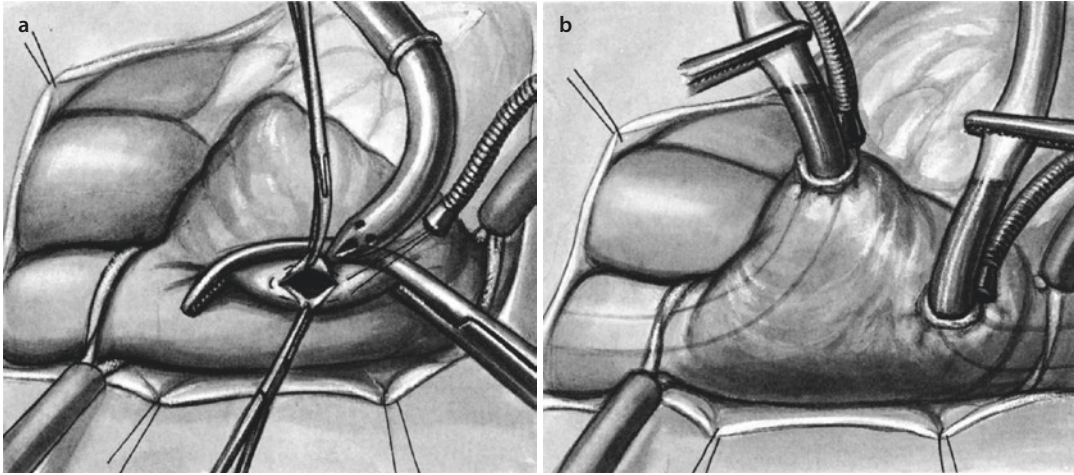

Fig. 6.8 Exposition of the superior caval vein **a**, the inferior caval vein is provided with a tourniquet **b**

Suspicion for any LSCV should arise when no or only a diminutive brachiocephalic vein or an unusually large/dilated coronary sinus is visible. In presence of a brachiocephalic vein, it may sufficiently drain the LSCV when temporarily or even definitely occluded. If probatory clamping of a LSCV without visible connection to the right side does not result in a left-sided caval pressure

much higher than 15 mmHg, simple clamping may be allowed during ECC. Otherwise, clamping of the vessel could lead to venous stasis and finally to a cerebral impairment. In these cases, the left superior caval vein should be cannulated, either directly close to the left atrial appendage or via the coronary sinus. A retrograde cardioplegia has to be adapted to the anatomical findings.

■ Fig. 6.9 Cannulation of the superior caval vein via the atrial appendage a; both caval veins are placed b

Absent or dilated coronary sinus may not allow for administration of retrograde cardioplegia.

The size of the aortic cannula is kept small to avoid extensive laceration of the aortic wall. However, the tip of the cannula is the narrowest part, where pressure drops and jets and turbulences develop which can injure the aortic wall from inside. Venous cannulas are chosen as large as possible to guarantee optimal drainage from the heart. According to Hagen-Poiseuille's law (at laminar flow), the resistance correlates with the 4 power of the radius of the cannula. Therefore, a short cannula with a large diameter allows for maximal pump flow.

At the arterial side, blood is propelled by the pump, i.e., flow resistance in cannula and tubing have to be overcome. The pressure in the arterial line rises in relation to the pump flow. Usually the flow is set, and the resultant pressure is measured. Line pressures up to 300 mmHg are tolerated. Systemic relationships of flow and pressure in cannulas and tubing are expressed with the help of the so-called M-figure. Small cannulas have a high shear stress which destroys blood cells. The critical limit of shear stress dependent hemolysis is unknown; in the literature, values from 80 to 400 N/m² have been reported. The limit for platelets is significantly lower with 10–35 N/m². The venous blood is mainly drained by gravity, where the central venous pressure and the hydrostatic pressure (difference in height between patient and reservoir) are the driving forces. With a known blood viscosity (c. 3 cP), the necessary minimal cannula size can be chosen.

Peripheral cannulation is an alternative to central cannulation. In standard surgical procedures with median sternotomy, it is no longer used, except for emergency situations including severe bleeding, cardiac arrest, acute aortic dissection, reoperation, and minimally invasive procedures. During recent years, the cannulation of the subclavian artery has proven very advantageous in patients with acute aortic dissection, since this vessel is only rarely involved in the disease, giving unrestricted flow access to the aortic arch. Mostly, the vessel is not directly cannulated. Instead, a Dacron graft (size 6–8 mm) is anastomosed to it in an end-to-side manner, and a straight aortic cannula is tied into it. Lacerations of the subclavian vein and the brachial plexus may occur but are infrequent. Apart from the subclavian vessels, iliac and femoral arteries as well as the jugular vein may serve as access for extracorporeal circulation. Arterial cannulas can be rather short; venous cannulas should be long enough to reach the right atrium in order to prevent collapse of the inferior caval vein resulting in poor drainage.

In contrast to intrathoracic cannulation, a peripheral access with a single venous cannula usually does not permit total bypass, i.e., complete mechanical support. Only 80% of blood volume can be drained via peripheral cannulas, whereas 20% of blood volume passes the lung. This means also that the maximal pump flow is lower as compared to central cannulation (3.5–4 L/min). With a femoral perfusion and a still ejecting heart, the arterial ECC blood hardly reaches the aortic arch.

■ Fig. 6.10 Cardioplegia cannula with sidearm for venting a, coronary sinus catheter b

Venous drainage can be improved with suction by integrating a roller pump or centrifugal pump into the venous line or by connecting the hard shell reservoir to a vacuum. Venous suction for optimizing drainage has several advantages: (1) unloading of the right atrium and ventricle is improved; (2) the cannula size can be reduced by 25%, which is very usefully in peripheral cannulation; (3) the extracorporeal circulation is less susceptible to an air block after lacerating of the right atrium; and (4) procedures at the pulmonary artery can be performed with a two-stage cannula.

The term «total bypass» is used when on full ECC flow, all systemic venous flow is forced into the venous cannulas by closing the tourniquets around the individual caval cannulas. This term may not be applicable for two-stage venous cannulation, although it may come close with excellent drainage.

6.2.1.7 Cardioplegia Administration

For the application of cardioplegia, a large bore sharp needle is sufficient. Alternatively, special catheters can be inserted and fixed with a suture. Most of the latter have a sidearm, which allows

measurement of the aortic pressure during cardioplegia delivery. In case of retrograde cardioplegia administration, a balloon catheter is placed ventrally to the venous cannula with a purse-string suture and into the coronary sinus. There are self-inflating balloons and those to be manually inflated with the aid of a syringe. Catheter placement is simple and can be achieved even if only the right atrium and ventricle are prepared in redo procedures. Its highest value of retrograde catheters is in aortic root surgery as well as in coronary reoperations. Correct positioning can be judged best by digital palpation of the balloon just below the left atrial appendage. Failure of catheter placement is rare and then caused by a Chiari net (remnant of the embryologic large valve of the sinus venosus) or an extraordinary small coronary sinus. After initiation of extracorporeal circulation, a constant flow from the catheter must remain evident, despite proper venous drainage and low central venous pressure. If the heart is lifted up during retrograde cardioplegia, swollen veins including the posterior descending vein (V. cordis media) should be visible (■ Fig. 6.10).

6.2.1.8 Vent Placement

With institution of extracorporeal circulation, pulsatility decreases and with good drainage may finally cease on full flow and/or total cardiopulmonary bypass and an empty heart. However, as bronchial and Thebesian veins drain into the left atrium and ventricle even with total bypass, the left ventricle will fill and distend, or blood will spill into the operative field if the heart is entered and not vented after cross-clamping.

A vent catheter usually has a mandrel or a reinforced but flexible tip, which facilitates its placement. Main indication is a left-sided valve replacement or LV aneurysm resection. Thus, the operative field is kept bloodless, and de-airing the heart at the end of the procedure is easier. Standard approach is the right superior pulmonary vein. Cannulation through the interatrial groove just anterior to the pulmonary vein may prevent pulmonary vein obstruction in the rare event of tears in the vein requiring extensive sutures/repair. Alternatively, especially in emergency situations, vent placement can occur via the left ventricular apex after a stab incision. Insertion of the vent into the pulmonary artery trunk is also possible. For coronary artery bypass surgery, a vent is placed into the aortic root, often as a combined cannula for antegrade cardioplegia delivery.

6.2.1.9 Tubing

The tubing system connects the various components of the ECC with the patient. In many institutions, the ECC components are individually selected and preassembled in a custom pack, which eliminates the infectious risk almost completely. The length of the tubing must be appropriately sized to provide sufficient distance to the non-sterile heart-lung machine. In general, the diameter should be large enough to keep flow resistance and shear stress which impair blood components as low as possible. On the other hand, tubing should be shortest possible and small in diameter to allow minimal priming and low gradients along the tubing. Most commonly, for adult patients, the arterial line is 3/8" in diameter and the venous lines 1/2" in diameter.

Cannulas and tubing are transparent to facilitate the evaluation of the blood with regard to color, air bubbles, and clots. Most of the tubes are available with heparin coating, which is supposed to reduce the heparin need and thus lessens the risk of bleeding complications.

6.2.1.10 Open and Closed Systems

In open systems, the venous reservoir can be deaired during operation. Mostly, the venous reservoir is built with a rigid housing and an integrated defoamer. The latter allows removal of air in a simple manner, but if the blood levels drop below a critical level, air embolism may occur. Therefore, a blood level sensor is necessary, which not only monitors the level and alarms in time but also stops the heart-lung machine automatically.

Closed venous reservoirs are flexible bags which can crumple. Air is trapped on top of it and can be removed via a valve. If the blood levels decrease, the walls of the bag collapse and prevent dislodgement of critical amounts of air to the patient.

Reliable data suggesting preference for one system over the other are not available; both systems are on the market with the rigid housing/open system taking the larger share.

6.2.2 Miniaturized Extracorporeal Systems

After more than 30 years of clinical success with standard ECC, about two decades ago the side effects of extracorporeal circulation became the focus of intensive discussion. Off-pump coronary artery bypass surgery (OPCAB) emerged, but the technical challenge of this new surgical technique could not be met by all surgeons. Even when OPCAB surgery could not convince the cardio-surgical community with clearly superior results, the desire for less traumatic tools and techniques remained and led to the development of miniaturized extracorporeal systems. They combine an adequate safety standard with reduced side effects claimed (Remadi et al. 2004; Wiesenack et al. 2004).

A miniaturized heart-lung machine is not only a reduced size system but also a new concept of extracorporeal circulation. Its goal is a constant volume perfusion with minimal blood trauma, reduced hemodilution, less postoperative systemic inflammatory response syndrome (SIRS), lower transfusion requirements, and finally faster and better reconvalescence. The first mini-systems were slimmed standard heart-lung systems, i.e., suckers and the venous reservoir were left off and the tubing was shortened. The pump consisted (and still does) of a

■ Fig. 6.11 MECC system. Set-up a, schema b (Maquet) (Courtesy of Maquet)

centrifugal pump and a low flow oxygenator with a small priming volume. Some systems are heparin coated including all tubing. A separate heating device is unnecessary as a heat exchanger is an obligate and integral part of each oxygenator. Bubble traps are optional. Cardioplegia is administered with low-volume techniques too. Most often, the Calafiore technique is employed, where arterial blood is deviated from the main line, enriched with potassium, and afterward reintegrated into the venous return (Calafiore et al. 1995). A systemic blood sucker does not exist as spilled blood is not immediately fed to the venous line to keep the circuit closed. Instead, it is collected and washed with a cell saver and returned to the patient thereafter.

All these individual procedures are not new, but their combination delineates a completely new principle of extracorporeal circulation. The main indication for miniaturized extracorporeal systems is coronary artery bypass (CABG) surgery where the cavities of the heart are not entered. An aortic valve replacement and a resection of a left ventricular aneurysm may also be achieved with a mini-system, but the surgical procedure is more complex and needs further refinements of the system, and the basic idea to prevent the blood air contact is partially undermined. It is self-evident that before starting valve surgery with a mini-bypass system, significant experience with coronary bypass surgery employing this system should have been obtained.

There are several mini-systems commercially available. Their components can be individually

assembled, or the system can be purchased as a complete set. Due to the different technical features, the mode of operation of the systems varies. An optimum cannot be defined, yet.

6.2.2.1 MECC System (Maquet®)

The MECC (*miniaturized extracorporeal circulation*) system (■ Fig. 6.11) was developed in the late 1990s and was the first mini-system which was commercially available. It is completely assembled from Maquet products (Maquet Cardiovascular, Rastatt, Germany; Wayne, NJ, USA): A Rotaflow® centrifugal pump, a Quadrox D® oxygenator with a diffusion membrane, and an optional venous bubble trap to eliminate circulating air bubbles. All components are heparin coated (Bioline®), allowing a short-term run of the device without full heparinization. This is truly advantageous for patients with a high bleeding risk. The arterial Quart® filter may be added as well but also increases the priming as does the bubble trap by 25%. The preparation of the systems requires only about 1–2 min.

The Rotaflow® pump can propagate 4.0–4.5 L/min and has a priming volume of 32 mL. The Quadrox D® oxygenator offers a membrane surface of 2.4 m² and requires a priming volume of 250 mL. The great advantage of the MECC systems is that the bubble traps and the arterial filter can be easily left out which lowers the basic priming volume to 500 mL and hemodilution is minimal. No other system provides this opportunity.

6.2.2.2 Resting Heart System (Medtronic)

The Resting Heart[®] system (■ Fig. 6.12) is a complete set based on Medtronic products (Medtronic, Minneapolis, MN, USA): the centrifugal Bio-Pump Plus[®] and their Affinity NT[®] membrane oxygenator. The whole system is heparin coated with the Carmeda[®] technology. The Bio-Pump Plus[®] can

■ Fig. 6.12 Resting Heart system (Medtronic) (Courtesy of Medtronic)

propel 1–6 L/min. The oxygenator has a membrane surface of 2.5 m² and a priming volume of 250 mL. An interesting feature is the Affinity Venous Air Removal Device (VARD[®]). With the help of two ultrasound detectors, air bubbles are recognized, an audiovisual signal is turned on, and the bubbles are automatically removed. A filter with a pore size of 38 μm is integrated in the VARD[®].

The advantages of this system are its high safety level and the perfect bubble elimination. The large priming volume of 1400 mL is a disadvantage as it equals or even exceeds that of a normal heart-lung machine ECC circuit. Thus, hemodilution and inflammation are not substantially influenced.

Since April 2013, the complete ECC set is no longer available in the United States, but all components are still obtainable to assemble the system.

6.2.2.3 Synergy-Mini-Bypass System (Sorin[®])

The Synergy[®] system (■ Fig. 6.13) is a fully integrated complete system from Sorin (Sorin S.P.A, Milan, Italy) and includes a centrifugal pump, a microporous polypropylene oxygenator with a membrane surface of 2.0 m², an arterial filter, a venous bubble trap, and a heat exchanger within

■ Fig. 6.13 Synergy-Mini-Bypass system (Sorin) (Courtesy of Sorin)

one device body. The maximal pump flow is reported as 8 L/min. The compact construction renders the priming volume with 680 mL in an acceptable range, but the tubing system has to be added. An air purge system for automatized air bubble elimination can be well added to the system.

The Synergy system differs from its competitors by its compact construction. Another advantage is the possibility to convert the closed system in an open system with a reservoir with a few steps.

6.2.2.4 ROC-Safe System (Terumo®)

The ROC-Safe® system (Terumo Corp., Hatagaya, Japan), R, O, and C (■ Fig. 6.14) being the initials of the perfusionist who invented the system, is a closed perfusion system, which was developed for coronary bypass surgery. With an additional module, other surgical procedures can be accomplished as well. Its centrifugal pump offers up to 6 L/min, whereas the polypropylene oxygenator has a surface of 1.8 m² and a heat exchanger integrated. A venous bubble trap removes larger bub-

bles; an arterial filter eliminates microbubbles. In case of air entering the circuit, an ultrasound detector reduces pump speed and finally blocks the venous line in an automated process. The inner surface of the whole system is equipped with the biocompatible X-coating.

The safety feature with the venous bubble trap and the arterial filter is opposed by a large priming volume which may lead to a considerable hemodilution. A retrograde autologous filling can lower the priming volume.

6.2.2.5 Modifications for Aortic Valve Surgery

Aortic valve replacement with mini-systems has been performed with several systems. Cannulation of the aorta and right atrium is as usual; blood cardioplegia is administered ante- or retrogradely. The main problem is to keep the aortic root dry. As a standard vent in the left atrium would aspirate large amounts of air and cause air blockade, it cannot be used when the aorta is opened. Instead,

■ Fig. 6.14 ROC-Safe system (Terumo) (Courtesy of Terumo)

a (second) vent catheter is inserted into the pulmonary artery, which drains the pulmonary vascular bed and the left atrium. All blood which is collected by the vent is immediately returned to the patient's venous line via a vacuum bag or cell saver system. Accordingly, the system has also been termed «semi-closed.» Despite the increased complexity, a small incision, minimal access aortic valve surgery is possible.

6.2.2.6 Functional Differences Between Mini and Standard Systems

The operation of both, the mini and standard systems, is comparable, but there are some differences due to the composition of the devices:

- The tubing of the mini-systems is usually shorter, so that the device has to be placed much closer to the surgeon. Heparin coating and the biocompatible surfaces which are hardly seen in standard heart-lung machines seem to be advantageous for the reduced need of anticoagulation, but there is hardly any evidence for that.
- Since mini-systems are closed systems, prior to initiation of extracorporeal circulation, all air bubbles have to be meticulously removed from both the arterial *and* venous line. Bubble traps, if present, are only useful for small amounts of trapped air.
- The principle of closed systems also includes that back bleeding during coronary artery bypass surgery cannot be arbitrarily removed by suction at the arterial vent, as air bubbles can enter the arterial line over the vent line with a high suction force. If back bleeding significantly interferes with the surgical efforts, a small probe or shunt or a lower flow may have to be chosen.
- The main risk with the use of a mini-system evolves once a severe surgical bleeding occurs. Hypovolemia can develop and jeopardize extracorporeal perfusion as an immediate retransfusion of large amounts of blood via the cell saver is impossible. The blood loss has to be replaced by transfusion of blood products as long as the patient's blood is prepared for retransfusion. That's why for open-heart surgery, the use of these mini-systems is not primarily recommended. In an emergency situation, only the Synergy system can be converted into an open circuit.

Though there are numerous differences in study parameters between standard and mini-ized heart-lung machine circuit, they translate hardly into advantages or disadvantages of either system, respectively. The large heterogeneity of mini-systems renders comparison difficult. A recent meta-analysis of randomized studies showed that mini-systems are associated with less hemodilution; less postoperative drainage and transfusion requirements; earlier extubation; reduced incidence of postcardiotomy heart failure; higher number of platelets; lower serum creatinine, C-reactive protein, troponin T, and creatinine kinase; lower interleukins (IL-8, IL-6, IL-10) and tumor necrosis factor alpha; and lower thromboxane B2, prothrombin fragment, neutrophil elastase, circulating endothelial cells, terminal complement complex, n-acetyl-glucosaminidase, intestinal fatty acids, and Clara cell 16 (Biancari and Rimpilainen 2009). The overall conclusion from thesis studies was that mini-systems are associated with a lower stroke risk, less blood loss, and lower mortality. These results still have to be critically interpreted.

6.2.3 Conduct of Cardiopulmonary Bypass

While there are rules to be obeyed during the conduct of cardiopulmonary bypass, within certain limits there is room for a rather wide variability. The reason for this is that most of the suggested parameters to be followed or aimed for have been empirically determined and the individual experience plays an important role on how to reach and maintain them.

6.2.3.1 Preparation of Extracorporeal Circulation

At the beginning, all sterile packed components of the heart-lung machine are assembled which takes about 15 min. Such a «dry» circuit can be stored as a stand-by tool for about 7 days. The so-called priming of the heart-lung machine, namely, filling with the perfusate chosen and de-airing the tube system, is not uniform. The basic perfusate consists of a balanced electrolyte solution. At several centers it is preferred to add colloidal solutions containing albumin, hydroxyethyl starch (HAES), or dextrane to obtain some osmotic pressure and thereby reduce extracellular fluid

retention. However, a clear advantage for the use of colloidal solutions has not been demonstrated, yet. The priming is recirculated sufficiently long to remove all air from the circuit. As the filling volume of the extracorporeal circuit equals about one third of the patient's blood volume, the hematocrit drops to about two thirds with the initiation of cardiopulmonary bypass. In case of hypothermic perfusion, the hematocrit is lowered even further. So far, an optimum for the hematocrit on extracorporeal circulation in adult patients has not been defined. After the priming, the heart-lung machine should be used within 8 h.

Prior to the start of extracorporeal circulation, the patient has to be sufficiently, so-called «fully» heparinized. For a standard heart-lung machine extracorporeal circuit in open-heart surgery, 300–400 IU/kg of heparin is considered a full heparinization. It is administered intravenously (see above). In (closed) heparinized (surface-coated) systems, one third to 50 % of this dose are usually sufficient for anticoagulation. Additionally, 2500–10,000 IU is added to the priming to make up for the additional volume and to prevent thrombotic complications within the circuit prior to go on bypass in case of blood priming. Two to 5 min after heparin administration and prior to the initiation of cardiopulmonary bypass, coagulation is controlled by the activated clotting time (ACT). Over the whole perfusion period, ACT should be kept between 350 and 400 and is therefore controlled regularly, i.e., at a 30 min interval.

6.2.3.2 Monitoring During Extracorporeal Circulation

During extracorporeal circulation, cardiovascular function, gas exchange, and acid-base balance have to be surveyed not only by the anesthesiologist but also by the certified clinical perfusionist. The perfusionist has to keep an eye on the monitor to read the electrocardiogram (ECG), the arterial blood pressure, the central venous pressure, the arterial saturation, and the body temperature(s). During complex surgical procedures, further parameters such as the left atrial pressure can be important too. Furthermore, an adequate urine production of 0.5–1 mg/kg/h should be present. If the latter is insufficient, augmentation of the pump flow should follow prior to the use of diuretics. During deep hypothermia, urine output decreases and may cease.

The perfusionist controls pump flow and line pressures as well as the filling of the venous reservoir

at the steering console to maintain adequate cardiopulmonary support. Mean arterial pressure and pump flow depend on the degree of hypothermia; the latter and the amount of cardioplegia are related to the type of surgery planned. The important surveillance parameters are noted in the perfusion protocol. The interaction between perfusionist, anesthesiologist, and cardiac surgeon and the strict surveillance of the perfusion parameters allow the optimal conduct of cardiopulmonary bypass, as well as the prevention or early detection of complications.

6.2.3.3 Termination of Extracorporeal Circulation

After the surgical repair of the heart or great vessels has been completed, the patient can be weaned from cardiopulmonary bypass. At this point, the patient has to be rewarmed to at least 34 °C, and the intravascular compartment and the heart have to be refilled and de-aired by reducing the venous unloading. Myocardial contractility is judged visually by the cardiac surgeon and optionally by transesophageal echocardiography (TEE) also. If myocardial contractility is insufficient, it has to be augmented by appropriate drugs, mainly by catecholamines and phosphodiesterase inhibitors. Atrial fibrillation can be converted to sinus rhythm to improve cardiac performance; likewise, bradycardia can be counteracted by various pacemaker stimulation modes (A00, AAI, DVI, DDD, VVI, see ► Chapter «[Device Therapy of Rhythm Disorders](#)», Sect. 30.2.1, Table 30.2). In case of severely compromised cardiac pump function, biventricular stimulation and/or an intra-aortic balloon pump is favored, as is nitric oxide (NO) (up to 30 ppm) or prostaglandin (iloprost) inhalation in situations with right heart failure due to elevated pulmonary resistance/pulmonary hypertension.

When a normotensive pulsatile blood pressure is reached, the flow of the heart-lung machine is stepwise reduced and finally stopped. After termination of cardiopulmonary bypass, venous decannulation follows. When hemodynamics are stabilized, heparin is antagonized with protamine, mostly 1:1. ACT rapidly normalizes to a level <130 s. In contrast to heparin, protamine is not administered as a bolus but as a brief infusion over about 5 min or more. A rapid protamine application can cause a so-called protamine reaction, which is a life-threatening complication with pulmonary vasoconstriction and pulmonary edema. The blood, which has been collected in the

heart-lung machine, can be retransfused via the arterial cannula, with the help of vasodilative drugs, if necessary. The use of the pump suckers has to be stopped when 50% of the protamine is given. If there is further bleeding, the blood is collected and retransfused by the anesthesiologist after being washed in a cell saver.

6.2.3.4 Anesthesia During Extracorporeal Circulation

During extracorporeal circulation, volatile anesthetic drugs can be administered at the heart-lung machine directly into the extracorporeal circuit, when the gas exchange membrane of the oxygenator is permeable for it (the diffusion membrane of polymethylpentene is not suitable!). Most of the volatile anesthetic drugs (sevoflurane, isoflurane, desflurane) act rapidly and allow for a reliable narcosis without hemodynamic compromise. They also cease their action fast. As the conductance of anesthesia is excellent and safe, volatile narcotics are used for many years in cardiac surgery. The use of a vaporizer mounted on a heart-lung machine, however, is somewhat problematic since this combination is not commercially available and self-assembled systems have to get approval by the respective authorities. In contrast to the legally optimal intravenous anesthesia, volatile anesthetics seem to increase end-organ tolerance against adverse influences. On the heart, they have a cardioprotective effect by an anesthesia induced preconditioning, and they lessen the reduction of the cerebral perfusion. A recent meta-analysis of the literature shows that volatile anesthetics increase cardiac performance and reduce the need of inotropic support and length of postoperative ventilation (Symons and Myles 2006).

6.2.3.5 Hemofiltration During Extracorporeal Circulation

The number of patients with impaired renal function or even with terminal renal failure who undergo open-heart surgery is steadily rising. Sufficient turnover and elimination of the fluids by the patient are not possible, neither during nor after the procedure. To prevent a fluid overload, a hemofiltration system can be integrated into the extracorporeal circuit. The hemofilter is connected between the arterial and venous line distal to the pump. It generates an ultrafiltrate over a highly permeable membrane as does a native glomerulus.

6.2.3.6 Problems and Complications During Extracorporeal Circulation

Problems and complications may arise from cannulas and tubing, from insufficient heparinization, and from unexpected cardiac findings.

■ ■ Aortic Cannulation

Aortic cannulation should be a technically simple procedure. As a consequence of malpositioning, the tip of the cannula can be within or close to the vessel wall. It also may be inadvertently directed toward the aortic valve. A thin vessel wall can tear, and in the worst case aortic dissection may occur. The latter can often be immediately recognized by a bluish coloration of the aortic wall and verified with transesophageal echocardiography. Then, an immediate aortic replacement with an interposition graft is necessary, but mortality is high. In case of atherosclerotic aortic vessel walls (high correlation with carotid stenosis and peripheral occlusive arterial disease), debris can loosen and embolize. Therefore, some institutions favor an intraoperative epiaortic ultrasound in patients with severe atherosclerotic disease. For coronary surgery, off-pump surgery may serve as alternative. Air embolism can be prevented with careful de-airing of the aortic cannula and arterial tubing.

■ ■ Venous Cannulation

The placement of the venous cannula(s) in patients with fragile atrial and/or caval walls may lead to considerable bleeding complications and also to air embolism. If a large amount of air is aspirated into the venous line, an air block will develop, i.e., the venous blood flow and finally also the heart-lung machine stop. A rapid de-airing procedure is necessary with head down positioning, compression of the liver, and initiation of venous suction. Sutures for repairing tissue tears as well as normal cannulation sutures can trap venous monitoring lines and catheters. They may also obstruct caval veins. Malpositioning of a venous cannula can render venous drainage inadequate and lead to venous congestion, which in case of temporary hepatic vein obstruction can lead to early postoperative (reversible) liver failure. Further causes of inadequate venous return are small or obturated cannulas and hypovolemia.

■ ■ Peripheral Cannulation

Peripheral cannulation, especially via femoral vessels, is prone to multiple complications including

leg ischemia, vessel wall laceration, vessel dissection, postoperative stenosis, thrombosis, lymphatic fistula, and infection. Most deleterious is leg ischemia during long-lasting surgery in patients with preexisting vascular disease. In these cases, it is advisable either to use a Dacron graft sutured to the vessel or a selective distal vascular perfusion over a sidearm of the arterial cannula.

■ ■ Aortic Valve Incompetence

(Over-)distension of the left ventricle after initiation of extracorporeal circulation with the heart arresting can be a sequela of aortic valve incompetence, or much less often due to an nondiagnosed patent ductus arteriosus. The first step is to decompress the heart manually; a brief halt of extracorporeal circulation is another option. If the heart continues to dilate, a rapid vent insertion, e.g., through the left ventricular apex, is recommended. Another option is to quickly clamp the aorta and to apply cardioplegia retrograde through the coronary sinus or directly into the coronary ostia.

■ ■ Low Perfusion Pressure

A drop of the systemic blood pressure during cardioplegia administration is normal. If the pressure remains low after termination of cardioplegia, vasopressors such as norepinephrine have to be applied.

■ ■ Myocardial Failure

If weaning from extracorporeal circulation mandates relatively high doses of catecholamines for sufficient myocardial contractility, a transesophageal echocardiography should be performed to analyze myocardial pump function and ventricular filling. Insertion of an intra-aortic balloon pump can be helpful to reduce the catecholamine demand and its related complications. Moreover, monitoring of the patient's left ventricular preload can be improved by placement of a left atrial catheter or a Swan-Ganz catheter. When catecholamine application leads to pulmonary hypertension, they can be administered over the left atrial catheter to avoid the pulmonary vascular complications. The right heart can be indirectly supported with inhalation of nitric oxide (NO) or prostaglandin administration, both lowering pulmonary artery resistance when elevated. A further option is the use of phosphodiesterase inhibitors, which also lower the pulmonary vascular resistance.

■ ■ Coagulation Disorder

A severe coagulopathy following termination of cardiopulmonary bypass is treated with transfusion of fresh frozen plasma (FFP), and platelets, as well as with packed red blood cells (PRBC) to replace the blood loss. Alternatively, the (important) various clotting factors can be measured and separately substituted—this philosophy has not yet gained widespread acceptance. Rather advantageous was the routine use of aprotinin, a fibrinolysis inhibitor which inhibits plasmin and kallikrein and also stabilizes the platelet membrane. However, due to a mildly elevated incidence of renal failure, the approval for aprotinin was withdrawn in some countries. It was substituted by tranexamic acid, which is less effective and also administered with various protocols. Platelet dysfunction is frequently treated with a vasopressin analogue (1-desamino-D-arginine vasopressin), but some studies question its advantageous properties as transfusion requirements were frequently unaltered (Mannucci 2000).

In case of large drainage losses, the blood should be collected in a reservoir and washed and retransfused with the CATS (Fresenius Continuous AutoTransfusion System, Terumo, Ann Arbor, MI) system. This is one of the few options which Jehovah's witnesses mostly accept, among other additional measures like preoperative iron and EPO treatment. Jehovah's witnesses further allow based on an individual patient decision the use of a cell saver, intraoperative autotransfusion without blood storage, and administration of coagulation factors (but not red and white blood cells, platelets, and fresh frozen plasma).

6.3 Extracorporeal Membrane Oxygenation

With the development of the heart-lung machine, mechanical support of the circulation by temporarily replacing heart and lung function allowed for open-heart/direct vision cardiac surgery since the mid-1950s. When the need for more prolonged support became evident, adequate long-lasting oxygenators had to be developed. With the availability of membrane oxygenators for this purpose, this prolonged type of extracorporeal circulation, in principle the same support as needed for open-heart surgery, was coined extracorporeal

membrane oxygenation (ECMO). Two types of ECMO have emerged as basic configurations: venoarterial and venovenous ECMO.

As in the standard ECC setup for on-pump cardiac surgery, the essential components of an ECMO circuit include a pump and an oxygenator. Oxygenator and pump are connected in a closed circuit to avoid blood-air contact. A venous reservoir is mostly absent. Some systems use a reservoir initially after setup to facilitate volume management. A bubble trap is optional. Integrated systems have bubble traps, sometimes working in an automated mode. In custom-made systems, they are often absent.

All components of the ECMO system are mounted on a steerable console, which can be placed aside the patient's bed. With special brackets, oxygenator and pump can also be fixed to the bed frame to alleviate patient care. The driving console has to be equipped with batteries, capable to maintain ECMO support for a minimum of 1 h. A heat exchanger can be implemented to cool or warm up patients as necessary. Meanwhile, there are also driving consoles available for use outside the cardiac surgery units. With these driving consoles, ECMO patients can undergo computed tomography or other diagnostic procedures, or ECMO can be available as a backup for high-risk interventional procedure in the cath lab.

The latest developments are ECMO systems allowing patient transport with an ambulance car or even a helicopter. The Emergency Life Support (ELS) system from Maquet® was the first device to get approval for air transportation from the European Aviation Safety Agency (EASA). These integrated devices are available as complete sets and are functionally well designed. Among the systems available, the Cardiohelp® (Maquet, Rastatt, Germany) is the most sophisticated and versatile device, currently FDA approved for the USA. This unique concept offers different versions for different tasks. With its tip-to-tip surface coating and approval for up to 14 days of support its short-term use, e.g., high-risk PTCA, as well as longer-term use including interhospital patient transport is possible (Philipp et al. 2011). For the other systems (Lifebridge®, Lifebridge, Ampfing, Germany; Life-Box®, Sorin, Milano, Italy), support is limited to 6 h and 5 days, respectively.

6.3.1 ECMO Parameters

The components of an ECMO circuit are selected in order to achieve a total support of the patients' cardiopulmonary function. Only in special cases, e.g., for carbon dioxide elimination when oxygenation may not be a problem, partial support with 25 % of normal cardiac output is sufficient.

According to the guidelines of the Extracorporeal Life Support Organization (ELSO), a blood flow up to 3 L/min/m² is necessary for sufficient support of heart and lung function. With regard to the age groups, this means pump flows of 100 mL/kg/min in newborns, 80 mL/kg/min in children, and 60 mL/kg/min in adults. The perfusion pressure in the arterial tubing should not exceed 400 mmHg; maximal suction at the venous line should be less than 300 mmHg. Adequate pump flow is present when continuous monitoring of the central venous oxygen saturation shows values >70 %. Most venoarterial and venovenous ECMO setups achieve about 3–4.5 L/min, depending on cannula size and pump characteristics and allow sufficient gas exchange and normal metabolism (O₂ supply in newborns 6 mL/kg/min, children 4–8 mL/kg/min, adults 3 mL/kg/min). Cardiopulmonary function can be well stabilized, allowing for recovery of heart and lung with strain taken off of them. With a complete loss of cardiopulmonary function, a less than optimal pump flow may still be sufficient to enable patient transport to another hospital for definite and potentially successful treatment.

6.3.2 Venoarterial ECMO

The primary indication for venoarterial ECMO (va-ECMO) is myocardial pump failure. Concomitant lung failure is thereby supported as well. For an emergency indication, cannulation should be simple and not require any or only limited surgical expertise. As a routine, peripheral cannula placement is generally favored. Percutaneous vessel cannulation, however, is much more demanding as it is more prone to complications when compared to a primary surgical cannula insertion. Peripheral venous drainage is performed through a femoral vein; arterial return can occur via a femoral or a subclavian artery. A complete unloading of the heart and support, respectively, is

not possible, mainly due to the limiting capacity of the peripheral venous drainage system. As a rule, about 80% of blood is directed toward the ECMO, whereas 20% still find its way into the pulmonary vascular bed and protect the latter.

Patients with immediate postcardiotomy failure, who are still centrally cannulated at the ascending aorta and right atrial appendage, are usually connected to the ECMO system employing these cannulas in place. In this ECMO circuit, the blood is drained from the right atrium and reinfused into the ascending aorta, as with the routine intraoperative extracorporeal circulation (■ Fig. 6.15).

sen, with a short drainage cannula and a long cannula for arterial reinfusion. As the drainage of a short cannula is worse and the inferior caval vein may collapse with increased suction, these techniques are less effective. Another alternative provide the double-lumen cannulas, which are inserted in the right jugular vein. As they drain mainly from the inferior caval vein and the out-flow should be directed toward the tricuspid valve orifice, its placement is much more demanding. More effective than for oxygenation in adult applications is the use for venovenous CO₂ removal (see below: ECCO₂R) (■ Fig. 6.16).

6

6.3.3 Venovenous ECMO

The indication for venovenous ECMO (vv-ECMO) is respiratory failure without significant ventricular dysfunction. As in va-ECMO, peripheral cannulation is favored to lower bleeding complications. In the standard setup, venous blood is drained from the femoral vein and the arterialized blood returned into the (right) jugular vein. It is important to have the tips of both cannulas at a distance large enough to prevent a short circuit, i.e., pump recirculation. If a jugular access is impossible, a femorofemoral configuration is cho-

6.3.4 Indication for ECMO

There are no clear-cut indications for ECMO therapy. The large societies for cardiopulmonary medicine/surgery have not established respective guidelines. There are only guidelines from the Extracorporeal Life Support Organization (ELSO) which recommend ECMO placement when the risk to die without would be 50%. Immediate ECMO is to be performed if the mortality risk approaches 80%. In most institutions, the indication is determined by the institutional experience. A large experience with ECMO leads to a more liberal indication

■ Fig. 6.15 Peripheral (femorofemoral) venoarterial ECMO (Courtesy of Maquet)

■ Fig. 6.16 Femorojugular venovenous ECMO (Courtesy of Maquet)

for its application and ultimately to better results (Muller et al. 2009; Schmid et al. 2009).

In myocardial pump failure, a cardiac index of 2.0–2.3 L/min/m² or lower defines today's indication for mechanical circulatory support with a ventricular assist device. Accordingly, refractory medical treatment for cardiac failure is an accepted indication for va-ECMO therapy. Postcardiotomy circulatory failure offers more therapeutic options. In case of myocardial contractile failure, the usual primary attempts for cardiovascular stabilization include augmented catecholamine administration followed by an intra-aortic balloon pump placement. Only after failure of both combined and an expected recovery of myocardial pump function, va-ECMO is indicated. If there is no recovery potential, assist devices for long-term support are the better choice (see ► Chapter «Cardiac Assist Devices and Total Artificial Heart», Sect. 38.4).

While va-ECMO is indicated for emergency treatment of primary myocardial failure, replacing the function of the lungs also, vv-ECMO is to replace the impaired gas exchange in primary pulmonary failure (endpoints: recovery, transplantation, or death), thereby preventing secondary cardiac failure also. Since these therapies require a high logistic effort, considerable resources, and a

high skill level, vv-ECMO in adults is not widespread. As for va-ECMO, criteria when to install vv-ECMO are not well defined and differ among centers. In a prospective study in 1979, two indications for pulmonary support with ECMO were proposed (Zapol et al. 1979):

1. A $pO_2 < 50$ mmHg at an FiO_2 of 1.0 requires immediate ECMO placement.
2. Whereas a $pO_2 < 50$ mmHg at an $FiO_2 > 0.6$ and a PEEP > 5 cmH₂O for more than 12 h was defined as slow entry criterion.

Nowadays, emergency ECMO placement for pulmonary support is indicated when the predicted risk for conventional respirator management is high. Such a high risk is seen with an oxygenation index [(mean airway pressure \times $FiO_2 \times 100$)/ pO_2] >40 and with a $pO_2/FiO_2 < 60$ –80. In this regard there is no difference between venovenous and venoarterial ECMO. However, prior to an ECMO installation, all other treatment options should be considered, and a lung protective ventilation aspired (tidal volume 6 mL/kg, PIP < 35 cmH₂O, $FiO_2 < 0.6$, cmH₂O and pO_2 goal: arterial $pO_2 > 60$ mmHg) (Schmid 2009).

A special type of ECMO is ECCO₂R (extracorporeal carbon dioxide removal). Here, carbon

Table 6.7 Indications for va-ECMO and vv-ECMO (Schmid et al. 2009)

Indication	va-ECMO	vv-ECMO
Urgent	Cardiac index <2.0 L/min/m ² (catecholamines ↑, IABP)	PaO ₂ /FiO ₂ <80 mmHg; (FiO ₂ = 1.0)
		Protective ventilation impossible
Emergency	Resuscitation with insufficient cardiac function	PaO ₂ /FiO ₂ <60 mmHg; (FiO ₂ = 1.0; PEEP = 20 cmH ₂ O), severe respiratory acidosis

dioxide is eliminated with an ECMO pump flow of 1–2 L/min, whereas oxygenation is achieved by the native lung by endotracheal/bronchial oxygen insufflation without significant ventilation.

There are only few absolute contraindications for ECMO. These are mainly situations, where recovery of end-organ function (late tumor stage, significant cerebral disease/damage) cannot be expected. All other contraindications are relative, i.e., in every case benefit and risk have to be weighed such as peripheral vascular disease and abdominal aortic aneurysm with thrombus formation. This is also true for the bleeding risk in polytraumatized patients, when an ECMO with heparin coating is used (Arlt et al. 2010). Yet, maintenance of ECMO without heparin administration is only possible for a few days. The carbon dioxide-lowering properties can also be beneficial for neurosurgical patients (Bein et al. 2002). A septic patient can be supported with ECMO too, but loss of peripheral resistance with a consecutive increase of cardiac output may not be fully mastered with peripheral ECMO systems, if at all (Table 6.7).

6.3.5 Physiological Consequences and Problems

The main goal of mechanical support with ECMO is to allow for recovery of heart and/or lung function. This works well as long as there is no total loss of cardiopulmonary function, i.e., if the ECMO supports but not replaces heart and lung, although this may be initially the case. A total loss of cardiac pump function can be compensated with a peripheral ECMO in small patients with large vessels only. Otherwise, the left heart is not sufficiently unloaded and distends. Consecutively, an additional vent may become necessary, which can be inserted into the left atrium with several

approaches: on the right side into or between the pulmonary veins and on the left side through the left atrial appendage. The LV apex may be cannulated for drainage also. A transition from peripheral to central cannulation can be helpful too. An alkalotic hyperoxygenation by lowering pH/pCO₂ and pulmonary vascular resistance is a further means to benefit the right ventricle.

A recovery of myocardial pump function with persistent respiratory impairment can cause problems during femorofemoral venoarterial perfusion. The lower half of the body is well perfused with arterialized blood, whereas the upper body including the brain and coronary arteries is provided with hypoxemic blood from the native (malfunctioning) lung only. Diagnosis can be established by percutaneously measuring oxygen saturation at a right-sided finger or directly with a radial artery blood gas drawn. Therapeutic options consist of a transition to central cannulation or of a relocation of the arterial cannula into the right subclavian artery.

Major complications are bleeding and thrombosis at the cannula sites, followed by ischemic complications at the respective extremities. Therefore, it is advisable to anastomose a (6–8 mm) Dacron graft for cannulation to the arterial vessel if the latter is small in size. Most institutions follow that strategy always when accessing the subclavian artery due to the risk of deleterious complications. At the femoral artery, a separate small cannula placement for distal perfusion is another option.

Further problems arise during long-term support. Patient mobilization and physiotherapy are difficult. The patients are usually bedridden and tethered to the bed by the tubing. A successful extubation to benefit lung function and to prevent respiratory infections hardly facilitates mobilization. The use of a solitary double-lumen cannula for venovenous ECMO inserted into the jugular vein increases the mobility but may limit pump output (Chimot et al. 2013).

6.3.6 Long-Distance Transport on ECMO

Critically ill patients with cardiac and/or pulmonary failure may not have access to all therapeutic means in a primary care center; they have to be referred to a tertiary care center or a specialized heart and lung failure unit. However, the clinical state of patients being on high-dose inotropes or being maximally ventilated is rather unstable, and conventional patient transport is associated with a high risk.

With the availability of the miniaturized ECMO systems (see above ► Sect. 6.2.2), patient transport became safe, both in a venovenous and venoarterial configuration. Prerequisites are a hub and a radio system for the participating hospitals as well as an on call system in the hub hospital/unit which can be organized in various ways. An incoming request for ECMO transportation demands immediate response: (1) Verifying that the patient is an appropriate candidate for ECMO treatment with further definitive therapeutic options to be offered. The cause of heart failure, reversibility of cardiac dysfunction, end-organ failure, neurology, tumor, and other terminal diseases should be asked for to judge whether the patient may be weaned from ECMO, can undergo conventional open-heart surgery, or will need long-term mechanical support. (2) Availability of staff and equipment. ECMO transport teams usually include an anesthesiologist or an intensivist, a cardiac surgeon, a perfusionist, and a paramedic. Depending on the organizational structure and individual skill level, the team can be reduced to two staff members, as the space in most helicopters and ambulance cars is limited. (3) Availability of ICU capacity. In Europe, adult ECMO transportation is a new mission, predominantly created by cardiac surgeons. Therefore, not only the staff but also ICU capacity is shared. Shortness of ICU beds is common.

After arrival at the distant hospital, the patient's clinical condition is reviewed again. If the patient unexpectedly is no longer a candidate for ECMO according to (1), the mission is aborted. If the patient, now with specialists support available, can be stabilized for normal patient transfer, ECMO is not installed either. For ECMO placement, the size of the femoral vessels can be measured by ultrasound, and appropriate cannulas are chosen to minimize the risk of limb ischemia (arterial 15–17 Fr, venous 17–23 Fr). For va-ECMO, the tip of the arterial cannula is positioned in the common iliac artery

or the distal abdominal aorta; the tip of the venous cannula was placed in the inferior vena cava. A so-called distal perfusion can be established but is frequently omitted. Central cannulation is not performed. In cases of vv-ECMO, outflow was achieved via the femoral vein, and inflow was gained by cannulation of the right internal jugular vein and thereafter into the superior vena cava. Before vessel cannulation 5000 IU heparin is administered intravenously, except when the partial thromboplastin time (PTT) value is ≥ 1.5 times above normal range. With a heparin-coated circuit, no further anticoagulation is needed during transport. After starting the ECMO, circulatory state and respirator settings are optimized in a brief period. A dramatic reduction of catecholamine requirement is common; a mean systemic blood pressure of 50–70 mmHg is sufficient. The patient is transferred to the helicopter or ambulance car, and monitoring is established in the vehicle. Monitoring includes continuous electrocardiographic surveillance, invasive blood pressure measurement, pulse oximetry, and capnography. Tissue perfusion and oxygen delivery are assessed by pulse oximetry and estimation of arterial blood gas exchange and mixed venous oxygen saturation if available. Minimal requirements are electrocardiogram, blood pressure, pump flow (3–5 L/min), and right radial arterial saturation. During transport, low flow situations are treated with crystalloid infusions and impaired oxygenation with airway toilet and increased oxygen supply. An ischemic leg cannot be treated, but will not become a clinical problem for the few hours in the air/on the road. Upon arrival, the patient is immediately referred to the cardiac ICU, and further treatment options are discussed and applied (Arlt et al. 2008).

6.3.7 ECMO Resuscitation

Acute cardiovascular collapse is life threatening and mandates immediate action. In most instances, an appropriate drug therapy is sufficient to stabilize the patient; some, however, may require chest compressions/external heart massage and artificial ventilation. Further treatment options are usually not available except in institutions offering ECMO placement during resuscitation. Systems for ECMO as a resuscitation tool

include mobile larger devices and light-weight portable systems.

For ECMO resuscitation, femoral artery and vein—preferably on opposite sides—are punctured percutaneously during brief periods of halting external cardiac massage. With Seldinger's technique, a borderline small arterial cannula (e.g., 15 Fr) and a long venous cannula (21 Fr or 23 Fr) are inserted and connected to the ECMO circuit after careful de-airing. When ECMO is started, both cannulas are fixed to the patient, and echocardiography is performed to assess cardiac function and filling/unloading. Ventricular fibrillation is terminated with defibrillation. Inotropic drug support and volume administration are optimized, and the pH is normalized. The afterload of the heart is lowered to prevent cardiac distension, and the respirator is set to lung protective ventilation, if possible. The time period needed to establish mechanical support is about 15–20 min.

Recent studies showed that longer pre-ECMO resuscitation duration was associated with poor prognosis. The same was true for patients with pulseless electrical activity or asystole as compared to ventricular tachycardia or ventricular fibrillation as the initial rhythm. These findings suggest that the main factors associated with outcome are baseline condition, underlying cause, and the rapid response of the resuscitation team. Overall, a survival of about 30% with resuscitation periods up to 1 h has been reported (Chen et al. 2008). It has been suggested that applying mild hypothermia (34 °C) for 24 or 48 h after ECMO initiation may add a benefit to the patient, as therapeutic hypothermia is currently recommended after cardiac arrest. Survival among the elderly supported on ECMO is lower than that for younger adult patients; however, age should not be a principle contraindication for the use of ECMO in older patients (Mendiratta et al. 2013).

Several important issues have to be considered when performing ECMO resuscitation. (1) The complication rates from femoral vessel cannulation are high including limb ischemia, severe vessel laceration, retroperitoneal and thigh bleeding, and placement of a cannula in a wrong vessel. Once the patient is stabilized, these problems have to be fixed. (2) As the effectiveness of resuscitation is never known, patients may end up being invalidated by severe cerebral injury. If the family and the treating physicians do not share

the same opinion with regard to maintenance or withdrawal of therapy, ethical debates are difficult. (3) If ECMO resuscitation was successful and the patient denies consecutive necessary treatment such as VAD therapy, mechanical support must be terminated.

7.1 Introduction

The results of surgery for congenital heart anomalies in neonates and infants have improved dramatically over the last two decades. Not only is mortality less but in addition duration of time in the intensive care unit and overall morbidity have continued to decline. There is no single explanation for this progress. ■ Table 7.1 suggests that the development of cohesive multidisciplinary teams managing neonates and infants with congenital heart disease has been one of the most significant factors. However, the second factor listed is also extremely important and that has been improvements in both the hardware and techniques of cardiopulmonary bypass.

In the early years of cardiopulmonary bypass in the 1950s, 1960s, and 1970s, both the hardware and techniques of bypass that were used for infants and neonates were no more than slight modifications of the hardware and techniques used for adults undergoing cardiopulmonary bypass. It wasn't until the late 1980s that developments in cardiopulmonary bypass were focused specifically on neonatal and infant cardiopulmonary bypass. Continuing developments in the 1990s and in the new millennium have been accompanied by further improvements in outcomes.

Other
Diagnosis more accurate/less invasive
Better operations (switch vs. Senning)
3 stage single ventricle track

7.2 Improvements in the Hardware of Cardiopulmonary Bypass for Neonates and Infants

7.2.1 Oxygenator

The earliest oxygenators such as the Gibbon oxygenator relied on a thin film of blood adhering to a disk or mesh that rotated through a trough of blood. Not only did this system require a huge priming volume, but in addition it generated a large number of emboli. The many deleterious effects of cardiopulmonary bypass (■ Table 7.2) include emboli, hemolysis, and the systemic inflammatory response to cardiopulmonary bypass (Edmunds 1998). In addition for the neonate and infant, exposure to a massive volume of homologous blood (bank blood) was equivalent to many exchange transfusions. Even in the adult world, the «homologous blood syndrome» had been recognized in the early years of cardiopulmonary bypass (Gadboys et al. 1962). This response to massive transfusion was definitely exaggerated in the neonate and infant and was responsible for much of the morbidity of cardiopulmonary bypass in its early years.

When bubble oxygenators came into commercial use in the 1970s, there was an even greater exposure to gaseous microemboli than had been the case with disk and mesh oxygenators (Dewall et al. 1956). Arterial line filters at this time required a large priming volume of their own, and they were generally ineffective. They were likely to generate as many emboli as they removed because platelets and fibrin adhered to the downstream side of the filter mesh. Early attempts to introduce membrane oxygenators in the 1970s required an extremely large priming volume. The first widely

used membrane oxygenator for pediatric use did not come into existence until the late 1980s. This was the Cobe variable prime flat sheet membrane oxygenator or «VPCML» (Cobe Cardiovascular Inc., Arvada, CO, USA) (Nagatsu et al. 1987). This early membrane oxygenator was used, for example, in the Boston circulatory arrest study of the late 1980s without an arterial line filter (Newburger et al. 1993). It was not until the early 1990s that an oxygenator specifically designed for neonates, the Lilliput hollow fiber membrane oxygenator, was available (Sorin S.P.A, Milan, Italy). Subsequent improvements in oxygenator design have resulted in an ever decreasing priming volume. Today neonatal and infant oxygenators are likely to have an integrated arterial filter within the oxygenator itself thereby avoiding the additional priming volume, for example, the Terumo FX oxygenator (Terumo Corp., Hatagaya, Japan) (■ Fig. 7.1). The priming volume required for the heat exchanger component of oxygenators has also become remarkably small. Taken in conjunction with the

■ Fig. 7.1 The Terumo Capiox FX oxygenator has an integrated arterial filter with self-venting technology. The filter surrounds the hollow fiber layer of the oxygenator where gas exchange occurs. This design reduces prime volume and therefore blood exposure by eliminating a separate filter component from the circuit

design of the modern heart-lung pump, it has been possible to reduce total priming volume to approximately 200–250 cc in most centers. Some centers are using custom-developed microcircuits with even smaller priming volumes.

7.2.2 Pump Design

Like oxygenators, early heart-lung pumps used for pediatric bypass were essentially the same as those used for adult cardiopulmonary bypass. Thus, long lengths of tubing were required to reach to the sucker heads as well as to the main pump head. With the development of specific pediatric heart-lung machines, it is now possible to bring the principal pump head extremely close to the patient so that the tubing length is very short (Ando et al. 2004) (■ Fig. 7.2). Furthermore both the oxygenators and the pumps accommodate 3/16 diameter arterial line tubing as well as ¼ in. or even 3/16 in. venous line tubing. The sucker pump heads also can be brought much closer to the patient thereby further decreasing the priming volume. The advantages and disadvantages of centrifugal versus roller head pumps continue to be debated as well as pulsatile versus nonpulsatile systems. The majority of centers continue to favor nonpulsatile roller head pumps because of their safety and simplicity as well as cost considerations.

7.2.3 Cannulas

Important improvements in cannulas designed for neonates and infants have resulted in far greater ease and safety in conducting continuous cardiopulmonary bypass than in prior years when relatively rigid thick-walled cannulas were used. Modern thin-walled plastic cannulas with a much larger internal to external diameter ratio allow safe cannulation of the superior and inferior vena cava in infants as small as 2.5 kg (■ Fig. 7.3a, b) (Rider et al. 2008). Very small cannulas can be used for continuous bypass in even smaller babies though there are risks involved in incising directly into very small and fragile veins including thrombosis and late stenosis. Thus, there continues to be a place for hypothermic circulatory arrest in the smallest premature babies as well as babies undergoing aortic arch reconstruction.

■ **Fig. 7.2** The Sorin S5 heart-lung machine allows the pump heads to be brought very close to the neonate or infant, thereby reducing prime volume by shortening tubing length

■ **Fig. 7.3** Venous cannulas used for neonatal and infant cardiopulmonary bypass. **a** DLP Single Stage cannula features the multiport tip that makes insertion easier for single atrial cannulation. **b** The right-angled Terumo Tender Flow provides a unique step-down design, which maximizes flow performance and minimizes pressure drop, available in a range of sizes from 8Fr to 24Fr

7.3 Improved Techniques of Neonatal and Infant Cardiopulmonary Bypass

■ **Table 7.3** illustrates the advances in the technique of neonatal and infant cardiopulmonary bypass that have contributed to improved outcomes for surgery. Many of the insights that led to the improved techniques of neonatal and infant bypass were derived from prospective randomized trials that in addition to perioperative outcomes used late neurodevelopmental outcomes as sensitive endpoints for determining cardiopulmonary bypass related factors that were responsible for morbidity. Although subsequent studies have shown that patient-related fac-

Improved monitoring of neonatal and infant bypass

tors including prenatal brain injury caused by abnormal fetal circulation also are important in determining cognitive and motor deficits, neverthe-

7

■ **Fig. 7.4** In a randomized prospective trial of low flow bypass versus circulatory arrest (alpha stat, hemodilution to 20%) conducted at Children's Hospital Boston in the 1980s using now outmoded bypass equipment, there was a strong correlation between duration of circulatory arrest and the occurrence of seizures. However, no child who had an arrest time less than 35 min had a seizure either clinically or by encephalography (From Newburger et al. 1993; used with permission)

less these studies did allow a better understanding of the consequences of different bypass techniques leading to subsequent improvements (Zeltser et al. 2008; Limperopoulos et al. 2010). The first major prospective randomized trial of bypass technique for neonates and infants was the Boston Circulatory Arrest Study (Newburger et al. 1993).

7.3.1 Boston Circulatory Arrest Study

The Boston Circulatory Arrest Study was a randomized prospective trial of neonates and infants less than 3 months of age undergoing an arterial switch procedure for d-transposition between 1988 and 1992. As noted above, the hardware used for that study was primitive by today's standards and included a flat sheet membrane oxygenator with a priming volume of 750 cc. Also no arterial line filter was employed. The perioperative results of that study included a higher incidence of seizures in babies undergoing circulatory arrest relative to those undergoing continuous low flow bypass at deep hypothermia with a flow index of 50 cc/kg/min which is equivalent to a

flow index of approximately 0.75 L/min/m² (Newburger et al. 1993) (■ Fig. 7.4). Although in the early neurodevelopmental follow-up studies, there tended to be a worse outcome in patients who underwent hypothermic circulatory arrest, by 8 years of age, and in subsequent follow-up studies there were minimal differences (Bellinger et al. 2003). For example, in academic achievement at 8 years of age, there were no differences between circulatory arrest and low flow patients in reading score, math score, any WIAT (*Wechsler Individual Achievement Test*) subscale score, or the competence scales of teacher reports. However, both groups scored lower than population norms. While today those reduced scores for both groups might be solely attributed to the prenatal effects of a hypoxic cerebral circulation, at the time of the study, they were attributed solely to the deleterious effects of cardiopulmonary bypass. This resulted in the generation of a new hypothesis, namely, that the technique of bypass that was employed in the late 1980s resulted in limited oxygen delivery secondary to the interaction of several points of bypass technique. The most important factors that interacted were thought to be reduced overall flow rate relative to

normal, the alkaline pH of hypothermic bypass using the alpha-stat strategy and the impact of hemodilution.

7.3.2 Subtle Brain Injury Secondary to Hypoxia

The concept that a subtle degree of brain injury could occur during heart surgery in the absence of gross neurological findings such as a stroke was a new one in the field of cardiac surgery in the 1980s. However in other fields, the concept of subtle cumulative cognitive injury has become increasingly appreciated. In the field of sports medicine, for example, the cumulative effect of multiple concussions in American football has received increasing attention from the lay press as the science of this field becomes more focused. In the sport of high-altitude climbing, there are several reports, some including MRI studies, that have documented the injury that can occur from hypoxia related to high altitude. Cognitive studies of mountain climbers who have climbed without supplementary oxygen have documented persistent memory impairment (Cavaletti et al. 1990).

7.3.2.1 Factors That Potentially Limit Oxygen Delivery During Cardiopulmonary Bypass

■ ■ Fixed Flow Rate

A normal cardiac index is approximately 3.5–4 L/min/m². If there is acute hemodilution, an individual can increase cardiac output to at least 10–15 L/min/m² in order to maintain oxygen delivery. However, the individual who is placed on cardiopulmonary bypass has a fixed cardiac output that is determined by the perfusionists and not by oxygen and substrate needs. The usual maximal perfusion flow rate is 2.4 L/min/m².

■ ■ Why Is Maximal Perfusion Flow Rate Limited to Only 2.4 L/min/m²?

The flow rate that is used during cardiopulmonary bypass is a trade-off between achieving safe oxygen delivery and avoiding an excessive priming volume and excessive delivery of microemboli. Particularly in the early years of cardiopulmonary bypass when there was no arterial line filter and bubble oxygenators were used, it was well known that a high flow rate resulted in greater delivery of

gaseous microemboli. A high perfusion flow rate also can result in the reservoir level dropping abruptly if there is any interference with systemic venous return. Thus, the safety margin for the perfusionist becomes much narrower, and there is a risk of pumping air into the patient if there is inattention for just a few seconds and if modern safety mechanisms such as level sensors fail (De Somer 2007; Murphy et al. 2009).

■ ■ pH Strategy

The cardiac surgeon and perfusionist must have a very good understanding of the oxyhemoglobin dissociation curve (■ Fig. 7.5) (Hamilton et al. 2004). A shift of the oxyhemoglobin dissociation curve to the left means that oxygen is bound more tightly to hemoglobin. Thus, tissues that require oxygen for ongoing metabolism may be unable to obtain an adequate amount. This will result in the venous oxygen saturation being falsely elevated. This is extremely important because venous oxygen saturation is the principal means of monitoring the «safety» of cardiopulmonary bypass. It is a fundamental premise that if the venous oxygen saturation is greater than 70%, then oxygen delivery is being adequately maintained (Swan et al. 1990).

■ ■ Factors that Shift Oxyhemoglobin Dissociation Leftward

Several factors in the neonate and young infant undergoing hypothermic cardiopulmonary bypass can shift oxyhemoglobin dissociation leftward. These include the presence of fetal hemoglobin as well as reduced 2,3-diphosphoglycerate. Reduced diphosphoglycerate in red blood cells occurs in bank blood which is used in greater relative volume in the small neonate. This was particularly a problem in the early years of cardiopulmonary bypass when large prime volumes were required. Other important factors that shift the oxyhemoglobin dissociation curve leftward are hypothermia and alkalinity. Hypocarbica also has the same effect. Hypothermia also has the effect of shifting the pH of neutrality in an alkaline direction. It is for this reason that in the early years of perfusion, carbon dioxide was routinely added to the sweep gas passing through the oxygenator in order to counteract that alkaline shift. Today, however, there is controversy regarding whether carbon dioxide should be added for pediatric bypass.

■ **Fig. 7.5** The oxyhemoglobin dissociation curve is shifted to the left by both acidosis and hypothermia. A left shift results in oxygen being more tightly bound to hemoglobin. Thus, venous oxygen saturation may be inappropriately elevated during hypothermic bypass. It may fail to indicate that an intracellular oxygen debt is being incurred because of inadequate flow

7.3.2.2 Alternative pH Strategies During Hypothermic Bypass

■ ■ pH-Stat Strategy

The pH-stat strategy was popular from the earliest years of hypothermic bypass in the 1960s until the mid 1980s. The strategy involved adding carbon dioxide. A nomogram was used by perfusionists to «temperature correct» the blood gas result to the patient's body temperature (Severinghaus 1966). Thus even though the blood gas machine, which warms the blood gas sample to 37 °C, would read out a very high CO₂ level directly from the machine, when corrected to patient body temperature, the pCO₂ should read 40 mm. This is a much more acidotic strategy than the alternative alpha-stat strategy.

■ ■ Advantages of the pH-Stat Strategy

The pH-stat strategy increases oxygen availability during bypass because it counteracts the leftward shift of oxyhemoglobin dissociation induced by hypothermia and alkalinity. It also has the effect of suppressing metabolic rate and is therefore additive to the effects of hypothermia (Aoki et al. 1993). The principal potential disadvantage of the

pH-stat strategy is that it increases cerebral blood flow and can therefore increase the embolic load to the brain. This is of greater relevance in adults who have atheromatous disease of the aorta and head vessels than it is in pediatric bypass.

■ ■ Alpha-Stat Strategy

The alpha-stat strategy involves no compensation for the alkaline shift that is induced by hypothermia (■ Fig. 7.6). Thus, the blood gas machine should read out an arterial pCO₂ of 40 mm and a pH of 7.4 since it warms the blood specimen to 37 °C. If a nomogram is used to correct to the patient's body temperature, the pH will be quite alkaline. The alpha-stat strategy was introduced in the mid 1980s mainly based on theoretical considerations that focused on the metabolic changes that occur in cold-blooded animals. Animals that must remain active at hypothermia tend to use the alpha-stat strategy because there is less suppression of metabolic rate. However, hibernating animals tend to use the pH-stat strategy to suppress their metabolic demands (Wilson 1977). Today the alpha-stat strategy is the standard technique employed in adults undergoing cardiopulmonary bypass, principally because of the perception that it

■ **Fig. 7.6** Cooling results in an alkaline shift in the pH of both blood and water because there is less dissociation of water molecules (pH is the negative log of free hydrogen ions). This alkaline shift moves the oxyhemoglobin dissociation curve leftward thereby binding oxygen more tightly to hemoglobin and exacerbating the leftward shift induced by hypothermia itself (From Swan et al. 1990; used with permission)

will reduce the number of cerebral emboli by reducing cerebral blood flow (Henriksen 1986). However, there are few studies that have directly demonstrated this fact or that have demonstrated an improved clinical outcome, particularly with respect to neurological factors (Murkin et al. 1995).

■ ■ Prospective Randomized Study of pH Strategy

A prospective randomized trial of pH strategy was undertaken at Children's Hospital Boston between 1992 and 1996 (du Plessis et al. 1997). One hundred eighty-two patients less than

9 months of age were randomized to either the pH-stat or alpha-stat strategy. The study supported the hypothesis that had been proposed, namely, that the pH-stat strategy is safer for neonatal and infant bypass. All perioperative complications were more common with the alpha-stat strategy. Even mortality approached a significant *p* value of 0.05. In addition the hospital course of patients with transposition was significantly improved with the pH-stat strategy including a significantly shorter duration of intubation and a shorter stay in the intensive care unit. Subsequent neurodevelopmental studies in these patients

■ **Fig. 7.7** In a retrospective analysis of 16 patients who underwent deep hypothermic circulatory arrest between 1983 and 1988, there was a strong positive correlation between arterial PCO₂ during cooling and developmental score, that is, children undergoing the alpha-stat strategy had a worse developmental outcome (From Jonas et al. 1993; used with permission)

using the Bayley scale of infant development demonstrated a consistent trend toward an improved psychomotor development index in patients randomized to the pH-stat strategy (Bellinger et al. 2001). However, this was a diverse group of patients (in contrast to the circulatory arrest trial that enrolled only patients with transposition), and it also predated the era of genetic testing. Therefore, overall and perhaps not surprisingly, there was not a statistically significant advantage for the pH-stat strategy with respect to developmental outcome though once again the overall trend was definitely in this direction. Furthermore the perioperative results alone convincingly documented that the pH-stat strategy is preferable to the alpha-stat strategy for hypothermic bypass.

■ ■ Retrospective Studies of Development

A small retrospective study of development looked at patients who underwent the Senning operation under circulatory arrest during the period when the pH strategy was being changed from a more acidotic (pH stat) to more alkaline (alpha-stat) strategy (Jonas et al. 1993). Despite the fact that only 16 patients were studied, there was a remarkably powerful influence of pH strategy on developmental outcome with a *p* value of 0.002 (■ Fig. 7.7). This finding was also consistent with the fact that an epidemic of choreoathetosis occurred at Children's Hospital Boston beginning in the mid 1980s and coincident with the introduction of the alkaline alpha-stat strategy (Wong et al. 1992). Patients who appeared

particularly susceptible to choreoathetosis were patients with multiple aortopulmonary collateral vessels. Particularly for these patients, there is a risk that alkalinity will result in cerebral vasoconstriction and pulmonary vasodilation exacerbating the steal of blood from the cerebral circulation into the lungs. The findings of these retrospective studies resulted in an enhanced appreciation of the dangers of alkalinity for pediatric patients undergoing hypothermic bypass. By shifting back to the pH-stat strategy, choreoathetosis was essentially eliminated as a neurological complication of hypothermic bypass.

■ ■ Why Is the pH-Stat Strategy Not Used Routinely for Pediatric Bypass?

Adding carbon dioxide to the oxygenator sweep gas increases the complexity of managing perfusion for the perfusion technician. For perfusionists who mainly undertake adult perfusion, it can be intimidating to have to manage not only a smaller and modified circuit for pediatric perfusion but in addition having to manage blood gases in a different fashion. Furthermore there has been less use of hypothermia and particularly deep hypothermia than in the early years of pediatric bypass. At a mild degree of hypothermia such as 30–32 °C, there is very little difference between the pH-stat strategy and alpha-stat strategy. In fact some centers have eliminated the use of hypothermia altogether and undertake normothermic bypass (Corno 2007). So far there are no randomized prospective trials that have documented that there is any advantage in applying normothermic bypass.

■ **Fig. 7.8** Even a mild degree of hypothermia markedly reduces cerebral oxygen consumption. Thus, a lower flow rate safely supplies adequate substrate. Lower flow generates fewer emboli, reduces the inflammatory effects of bypass, and allows a lower reservoir level and hence less addition of blood products

7.3.3 Risks of Normothermic Bypass

Normothermic bypass requires a much higher flow rate than mildly hypothermic bypass (■ Fig. 7.8). There is a steep decline in the metabolic rate of the brain with even a mild degree of hypothermia. Thus, the safety margin with hypothermia is substantially increased, for example, in the event that a technical problem with the bypass circuit requires a temporary stop of cardiopulmonary bypass. The greater flow rate required for normothermia also results in increased delivery of microemboli and increased use of the cardiotomy suction system. This is where most of the blood injury occurs such as hemolysis and complement activation. Hypothermia per se reduces the inflammatory effects of cardiopulmonary bypass.

7.3.4 Hemodilution

In the earliest years of cardiopulmonary bypass in the 1950s, pure blood was used to prime the bypass circuit. No doubt this reflected the inefficiency of early disk and mesh oxygenators. A high hematocrit was required to achieve adequate oxygen delivery. However, by the 1960s it was possible to hemodilute the perfusate and maintain reasonable oxygen delivery (Neptune et al. 1960). Furthermore

it had been recognized by this time that the «homologous blood syndrome» was an important source of morbidity after cardiopulmonary bypass (Gadbois et al. 1962). During the 1980s with the discovery of HIV as well as hepatitis C and therefore increasing cost for testing and storing bank blood, there was increasing pressure from hospital blood banks for cardiac surgeons to reduce blood usage during cardiopulmonary bypass.

7.3.4.1 Safe Limits of Hemodilution

One of the most influential studies regarding the question of the safe limit of hemodilution was published by Kawashima (Kawashima et al. 1974). They used a noncardiopulmonary bypass dog model and determined that systemic oxygen consumption was maintained until the hematocrit fell to less than 20%. It is important to recognize that using a non-bypass model fails to take account of the fixed upper limit of perfusion flow rate that exists in the setting of cardiopulmonary bypass. In the nonbypass model, there is a compensatory increase in cardiac output that maintains oxygen delivery. Further studies were undertaken by Laver et al. (1975). They determined that in the setting of profound hypothermia and circulatory arrest, even extreme hemodilution to hematocrits below 15% appeared to be clinically well tolerated. Ott and Cooley extended the limits of hemodilution among Jehovah's Witness

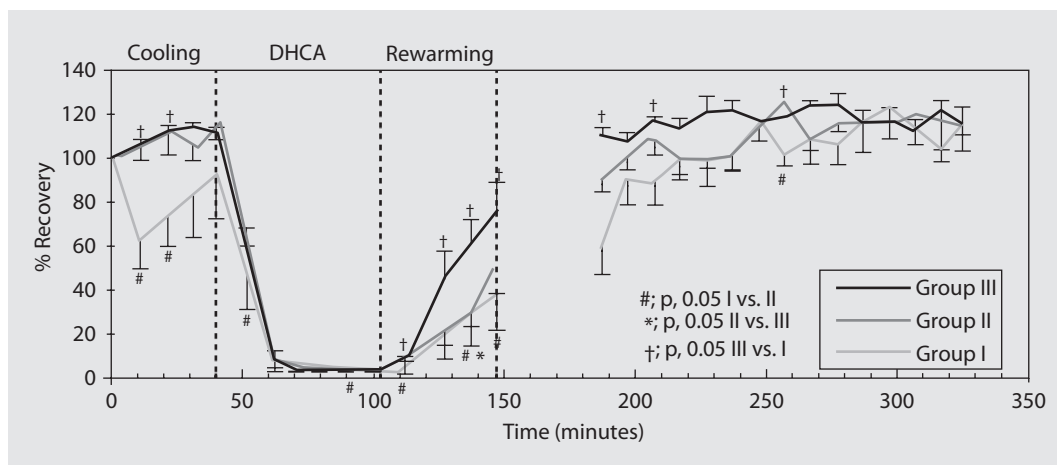

Fig. 7.9 Extreme hemodilution to a hematocrit of 10% (group I) was associated with a significant decline in cerebral phosphocreatine as measured by magnetic resonance spectroscopy in piglets undergoing cooling to deep hypothermia. Piglets with a hematocrit of 20% (group II) and 30% (group III) demonstrated a slight increase in phosphocreatine during cooling (From Shin'oka et al. 1996; used with permission)

patients. They reported in 1977 that they had performed 542 operations without blood transfusion (Ott and Cooley 1977). Work undertaken in the 1990s at the Mayo Clinic using a dog model with cardiopulmonary bypass also suggested that extreme hemodilution to a hematocrit of 12–15% was «safe» (Cook et al. 1997). The reduced perfusion pressure resulting from hemodilution was compensated for in this study by an increase in pump flow rate to double the normal flow.

7.3.4.2 Laboratory Studies of Hemodilution at Children's Hospital Boston

A piglet model of cardiopulmonary bypass was developed that employed simultaneous magnetic resonance spectroscopy and near-infrared spectroscopy as well as survival of the animals after 1 h of deep hypothermic circulatory arrest. An initial study compared hematocrits of 10, 20, and 30% (Shin'oka et al. 1996). It was found that there was a significantly more rapid recovery of high-energy phosphates after circulatory arrest with the highest hematocrit (■ Fig. 7.9). The cerebral oxyhemoglobin level measured by magnetic resonance spectroscopy was maintained at a significantly higher level with a higher hematocrit. The neurological deficit score was significantly improved in the highest hematocrit group relative to the other two groups.

In an extension of the initial laboratory study of hemodilution, the differential effects of oncotic pressure and oxygen delivery were analyzed (Shin'oka et al. 1998). Piglets were separated into

five different groups. Two of the groups had a relatively low hematocrit of 20%, but the colloid oncotic pressure was boosted by addition of either hetastarch or pentafraction. In another group modified ultrafiltration was undertaken at the conclusion of bypass. The conclusions of this study were that both higher hematocrit and higher colloid oncotic pressure with pentafraction improved cerebral recovery after deep hypothermic circulatory arrest. Higher hematocrit improved cerebral oxygen delivery but did not reduce total body edema. Modified ultrafiltration after cardiopulmonary bypass was less effective than having a higher initial prime hematocrit or colloid oncotic pressure.

7.3.4.3 Microcirculation During Deep Hypothermia

The concept that deep hypothermia was associated with disturbances of the microcirculation became increasingly entrenched in cardiac surgical texts from the 1970s onward (Messmer et al. 1972). It was felt that increased red cell rigidity and increased plasma viscosity resulted in occlusion of capillaries. Hemodilution was proposed as a method to counteract this microcirculatory disturbance.

7.3.4.4 Potential Disadvantages of Hemodilution

The most important risk of hemodilution is that it reduces oxygen carrying capacity. Below a hematocrit of 20%, the oxygen transport capacity of blood

declines quite rapidly. However, this is not the only risk of hemodilution. Hemodilution also results in a marked decrease in viscosity and therefore a reduction in perfusion pressure. While this is not of great significance for the pediatric patient, it is very important for the adult patient who may have a carotid or cerebrovascular stenosis. Furthermore cerebral blood flow must increase in order to maintain cerebral oxygen delivery. Thus, there is potential for greater delivery of both particulate and gaseous cerebral microemboli when hemodilution is employed.

7.3.4.5 A Study of Cerebral Microcirculation During Deep Hypothermia

In order to study the effects of hypothermia and hemodilution on the cerebral microcirculation, a new model using intravital microscopy in the pig was developed (Duebener et al. 2001). A burr hole was placed in the skull of a pig. The dura and arachnoid were removed from the surface of the brain. Using a scanning microscope, the microcirculation on the surface of the brain can be viewed. By administering fluorescent dyes, it is possible to label white cells and to label the plasma (FITC, fluorescein isothiocyanate) thereby allowing visualization of red cells. An initial study that was undertaken compared hemodilution to 10, 20, and 30% during cooling to deep hypothermia as well as before and after hypothermic circulatory arrest. It was found that the functional capillary density, a measure of capillaries perfused within a given area, was well maintained with an undiluted hematocrit of 30% at deep hypothermia and with full flow cardiopulmonary bypass. Hemodilution resulted in an increased flow rate relative to baseline confirming the risk of greater emboli delivery with hemodilution (Duebener et al. 2001).

Following deep hypothermic circulatory arrest, reperfusion occurred more rapidly and more evenly with a hematocrit of 30% relative to a hematocrit of 10%. Furthermore there was greater activation of white cells in the hemodilute group of 10%. These findings suggest that there is greater risk of endothelial injury during deep hypothermic and circulatory arrest if a severe degree of hemodilution is employed. It is possible that this is hypoxic endothelial injury that may result in a reduced ability to secrete nitric oxide. The endothelial activation also results in a greater number of rolling white cells that adhere to the activated endothelium.

The animals that were studied were tested for functional recovery after circulatory arrest. There was a significantly more rapid return to normal

■ Table 7.4 Randomized clinical trial of hematocrit

Eligible	Excluded
Planned two ventricle repair using CPB	Weight <2.3 kg
<9 months old	Genetic syndrome
	Major extracardiac anomalies
	Previous cardiac surgery
	Arch reconstruction
Children's Hospital Boston December 1996–December 2000	

neurological function with the hematocrit of 30% relative to the more hemodilute animals. Furthermore the histological score was significantly worse with a *p* value of 0.02 in animals that were subjected to hemodilution to 10%.

7.3.5 Clinical Studies of Hematocrit

An initial prospective randomized clinical trial of hemodilution was undertaken at Children's Hospital Boston between 1996 and 2000 (Jonas et al. 2003). The eligibility criteria are shown in ■ Table 7.4. All patients were less than 9 months of age at the time of surgery and were undergoing biventricular repair using cardiopulmonary bypass. Most patients did not undergo circulatory arrest. Patients were randomized to a hematocrit of either 20 or 30%. However, as shown in ■ Fig. 7.10, the hematocrits achieved were 27.8 ± 3.2 for the higher hematocrit group and 21.5 ± 2.9 for the lower hematocrit group. Thus, the spread of average hematocrit was only 6%. Seventy-three patients were randomized to the higher hematocrit group and 74 to the lower hematocrit group. The use of blood products was essentially identical between the two groups. This was achieved through conventional ultrafiltration and reduced prime volume circuits. There was 1 death among 147 patients for an overall mortality of 0.7%. The lactate level 1 h after bypass was significantly higher with the lower hematocrit. Whole-body edema measured by bioimpedance was significantly higher with the lower hematocrit. Interestingly the lowest cardiac index measured by thermodilution for the first 24 h postoperatively was significantly lower with the lower hematocrit. This was true for all subgroups including the transposition subgroup

Fig. 7.10 In a prospective randomized clinical trial of minimum hematocrit during neonatal and infant bypass, the target hematocrits were 20 and 30%. The figure illustrates the hematocrits that were actually achieved. By minimizing circuit volume and using hemofiltration, there was no difference in the volume of blood or blood product use between the two groups

who had the lowest cardiac index postoperatively as well as in the tetralogy/truncus subgroup which had the intermediate cardiac output and the VSD/complete AV canal group which had the highest cardiac output (■ Fig. 7.11).

Developmental testing was undertaken at 1 year of age. There was a significantly lower psychomotor development index, which assesses motor skills, among the lower hematocrit patients. A significantly higher percentage of patients in the lower hematocrit group scored below two standard deviations of normal ($p=0.01$). This resulted in the data and safety monitoring board of the NIH discontinuing the trial before its planned completion date. However, the trial was subsequently extended to compare a hematocrit of 25% vs. hematocrit of 35% (Newburger et al. 2008). The extension trial did not show any additional advantage in increasing the hematocrit to 35%. The data analysis of the combined trials suggested that there was a cut point at approximately 23.5% below which there was a higher probability of a low psychomotor development index score (Wypij et al. 2008).

7.3.5.1 Modifications to Clinical Practice as a Result of the Hematocrit Trial

Most centers have modified their hemodilution practice in response to the prospective randomized trials of hematocrit described above. Hematocrits

of less than 20% are now strenuously avoided although they used to be standard of care for deep hypothermia. In order to maintain a reasonable safety margin from the cut point of 23.5%, most centers use a hematocrit of at least 25% and during rewarming will use conventional ultrafiltration to hemoconcentrate up to a hematocrit of 30–35%. In patients who will be cyanotic after weaning from bypass, for example, patients with hypoplastic left heart syndrome undergoing the Norwood procedure, it is now common practice to hemoconcentrate up to a hematocrit of 40% for weaning from bypass.

7.3.6 Interaction of Flow Rate, pH, Hematocrit, Blood Temperature, and Brain Temperature

The cardiac surgeon should be acutely aware of the patient's brain temperature during cardiopulmonary bypass. Nasopharyngeal temperature and tympanic membrane temperature will give approximations as to the patient's brain temperature. When the brain is at normothermia, it is particularly important to avoid a «perfect storm» of limited oxygen delivery. The most typical perfect storm occurs when flow to the brain is reduced, for example, there is a fixed upper bypass flow rate (even at «full flow») and collaterals are stealing

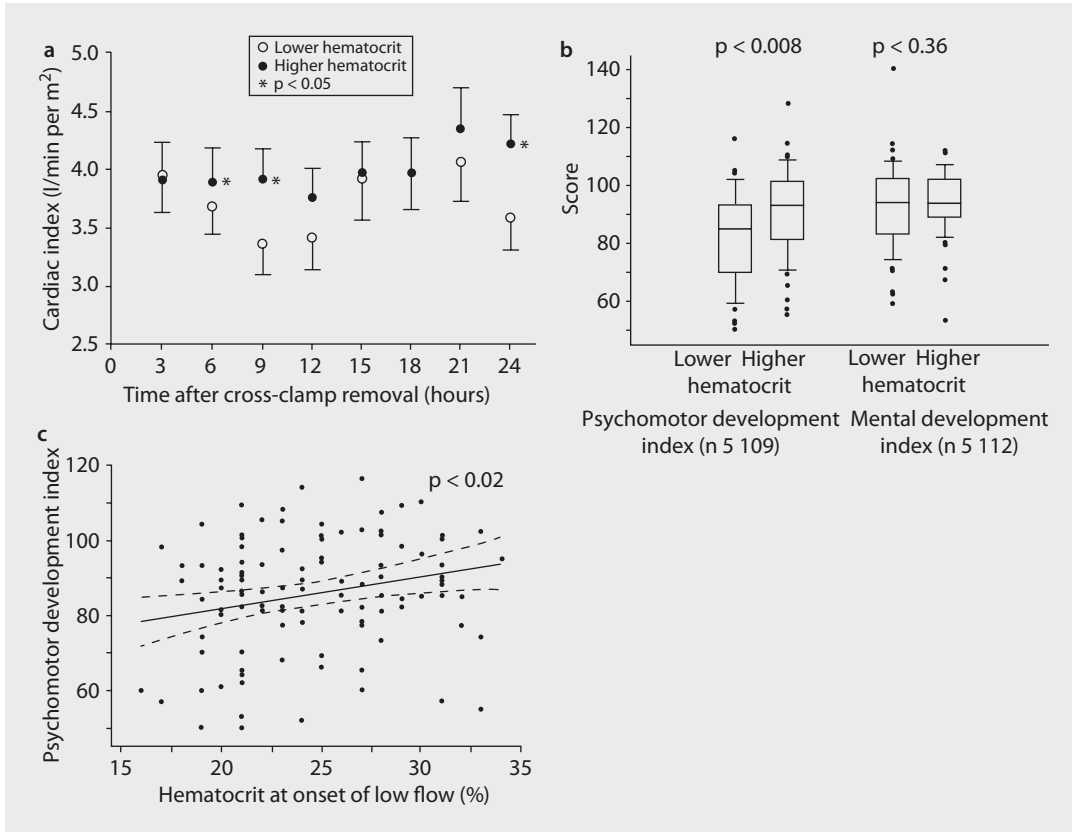

Fig. 7.11 Results of a randomized prospective clinical trial of lower hematocrit (21.5%) versus higher hematocrit (27.8%) at Children's Hospital Boston. **a** The use of a higher hematocrit (closed circles) was associated with a significantly higher cardiac index at 6 and 9 h after cross-clamp removal compared with lower hematocrit (open circles). **b** Developmental assessment at 1 year of age demonstrated a significantly higher psychomotor development index (a measure of motor skills) in patients managed with a higher hematocrit ($p = 0.008$). **c** Analysis using hematocrit as a continuous variable demonstrated a significant association between high Psychomotor Development Index at 1 year of age and higher hematocrit during cardiopulmonary bypass

from the systemic circulation (open shunt, collaterals, etc.) and the oxyhemoglobin dissociation curve is left shifted because of cold blood and alkalinity. Hemodilution will further exacerbate the limitation of oxygen delivery (Table 7.5). Thus, the early phase of cooling when the brain is warm (high metabolic rate) and the blood is cold and dilute (low oxygen availability) is the highest risk situation (Sakamoto et al. 2002). Monitoring venous oxygen saturation can be quite misleading because during the early cooling phase, venous oxygen saturation may be falsely elevated due to the hypothermic blood and leftward shift of oxyhemoglobin.

The rewarming phase is generally a less dangerous time because the brain is cool and the blood is warmer so that oxyhemoglobin dissociation has been shifted rightward and oxygen avail-

ability has been increased at a time when the brain metabolic rate is still low.

7.3.6.1 The Importance of Brain Temperature

The most critically important point for the cardiac surgeon and perfusionist to remember is that the brain metabolic rate is essentially exponential with respect to the effect of temperature. The hyperthermic brain that is above 37 °C is at exceedingly high risk of brain injury because of a markedly increased metabolic rate. On the other hand, a very mild degree of hypothermia, for example, to 32 or 34 °C, substantially decreases brain metabolic rate. It is also important to appreciate that temperature gradients exist within the brain. The cortex of the brain tends to be at a lower temperature than the deep brain structures

■ **Table 7.5** The probability of histologic injury after circulatory arrest increases with higher temperature, lower hematocrit, and more alkaline pH

Multivariate predictor				
Temperature	pH strategy	Hematocrit (%)	HCA (min)	Predicted total histologic score
15	pH	30	60	0.0
15	pH	20	60	0.5
15	Alpha	30	60	1.0
15	pH	30	80 or 100	1.5
15	Alpha	20	60	2.0
25	pH	30	60	2.5
15	Alpha	30	80 or 100	3.0
15	pH	20	80 or 100	3.0
25	pH	20	60	3.5
25	Alpha	30	60	4.0
15	Alpha	20	80 or 100	4.0
25	pH	30	80 or 100	4.5
25	Alpha	20	60	5.0
25	pH	20	80 or 100	6.0
25	Alpha	30	80 or 100	7.0
25	Alpha	20	80 or 100	8.0

such as the thalamus and basal ganglia. This temperature gradient can be magnified by the use of surface cooling techniques, for example, packing the head in ice.

7.3.7 Adjunctive Techniques for Brain Protection

Many innovative methods for maintaining brain perfusion have been developed including retrograde cerebral perfusion and antegrade cerebral perfusion. Studies of retrograde cerebral perfusion both in the lab and clinically have led to its complete discontinuation. There is still enthusiasm for various methods of antegrade cerebral perfusion though today the only clinical studies that have been undertaken have been disappointing and have if anything suggested a higher level of brain injury, particularly embolic injury, with this technique relative to deep hypothermic circulatory arrest (Goldberg et al. 2007).

7.4 Conclusion

Continuing refinement in the hardware and techniques of cardiopulmonary bypass specifically designed for neonates and infants will result in further reduction in the morbidity of cardiopulmonary bypass. However, it is critically important to remember at all times that cardiopulmonary bypass is not a physiological state so that expeditious and yet accurate surgery including minimization of the use of blood products will result in an optimal outcome.

8.1 Background

End-stage organ failure and tissue loss represent the most devastating and costly problems in modern medicine. Over the last years, many treatment options, i.e. tissue and organ transplantation as well as the development of advanced alloplastic prostheses and devices, have significantly improved patient outcome. However, due to a number of limiting factors, both these substitutional and reconstructive options are still imperfect. The most important factors are:

1. The increasing lack of donor organs for transplantation and associated second-line risks due to lifelong immunosuppressive therapy, which may induce the development of malignant tumors
2. The qualitative and quantitative shortage of usable donor tissues
3. An increased risk for infectious and thromboembolic complications, i.e. following the implantation of mechanical devices and alloplastic grafts
4. The disability of alloplastic prostheses to dynamically adapt to altered surroundings, e.g. an apparent infection

8.1.1 Aim of Discipline

Seeking for a method «*designed and constructed to meet the needs of each individual patient*» (Vacanti and Langer 1999) and to avoid or at least to reduce the above-mentioned limitations of currently used prostheses, the idea of (*cardiovascular*) «tissue engineering» was created in 1987 by members of the American Science Foundation (NSF) in Washington, DC. It describes the interdisciplinary approach to combine and apply principles and methods of engineering and life sciences towards the development of biological substitutes that restore, maintain and/or improve diminished tissue functions (Ferber 1999; Vacanti 1988; Vacanti and Langer 1999). The concept of *Cardiovascular Tissue Engineering* follows the bioartificial generation of solid cardiovascular tissue structures, such as the myocardium, heart valves and blood vessels as well as the application of cellular preparations, e.g. to treat arrhythmic disorders or myocardial infarction.

8.1.2 Basic Principles

Over the years, various methods and techniques to manufacture bioartificial tissues have been described. Although different in detail, almost all of these approaches can be categorized according to one of the following three superordinate concepts:

1. *Guided Tissue Regeneration*: (engineered) cell-free matrices of various origins—*biological, synthetic or combined*—are implanted into a recipient organism for in vivo cellular (re-) seeding, maturation and restoration. *Example: an in vitro decellularized biological blood vessel or heart valve of allogeneic or xenogeneic origin is implanted into a recipients organism and then regenerates under in vivo conditions in corpore.*
2. *Selective Cellular Transfer*: systemic or local application of cell preparations (*of autologous, allogeneic or xenogeneic origin*) to elevate the concentration of a specific cell type and to provide a defined cell-mix within a target tissue area, respectively. *Example: injection of a stem cell suspension into areas of myocardial infarction to induce regenerative processes and thus to improve tissue function*
3. *Tissue Engineering (classical sense)*: in vitro isolated, expanded and, sometimes, differentiated cells (*preferentially of autologous origin*) are seeded in vitro onto or into a matrix scaffold to form a living tissue or solid organ. *Example: endothelial cells isolated from an individual patient are expanded and seeded in vitro on the luminal surface of a tubular matrix scaffold to generate a bioartificial vascular prosthesis.*

Many different (*cardiovascular*) tissue structures have already been generated and larger 3D-tissue structures, e.g. bioartificial myocardium grown in vitro are beginning to take shape (Ferber 1999). However, many obstacles and challenges still remain. This chapter focuses on surgically implantable prostheses and thus predominantly reports on selected examples and concepts of grafts generated by methods of *guided tissue regeneration* and *tissue engineering* in the classical sense. Additionally, some historical background information as well as still existing limitations and prospective key activities in cardiovascular tissue generation are provided.

8.2 Components Necessary for Bioartificial Tissue Generation

Regardless of the desired tissue type, the successful generation of bioartificial tissue constructs relies on four superordinate components:

1. Tissue-specific cells which form, vitalize and establish the functionality of a desired tissue
2. Matrix scaffolds, which provide niches to accommodate these cells and direct their growth within a definite three-dimensional architecture
3. Stimulating signals (*chemical or physical*), which modulate cellular gene expressions and, thus, cellular differentiation and synthetic activity, e.g. extracellular matrix production
4. Cellular and humoral components of the recipient's immune system, which adjudicate on tissue integration or graft deterioration and destruction

The ideal characteristics of a bioartificial cardiovascular prosthesis are summarized in **Table 8.1**.

8.2.1 Cells

Cells are key components in cardiovascular tissue generation and regeneration. They (re-)vitalize

acellular or decellularized matrices and build-up extracellular matrix components through their proliferative activity and differentiation and thus regenerate, remodel and construct new tissues, respectively. A cell source should be easily accessible and ideally of autologous origin. The harvested cells should fast proliferate, be easily to differentiate into a desired cell type or—if already differentiated—should preserve their cellular phenotype and function. They may not transmit pathogens and should be none antigenic. Fibroblasts, keratinocytes and endothelial cells are examples for such already differentiated and highly proliferative cells and therefore are broadly applied in experimental as well as clinical settings of bioartificial skin, cartilage and cardiovascular graft generation/regeneration. However, other organ-specific cells, e.g. hepatocytes or cardiomyocytes, show no or only very limited and slow proliferation (Teebken et al. 2005).

In all these cases, embryonic and adult stem cells are of special interest. Embryonic stem cells are able to differentiate into structures of all three germinal sheets and thus are of high benefit—at least experimentally. Due to legislation and ethical concerns, its use is very limited or forbidden in most countries. In contrast, adult stem cells are only able to differentiate into a limited number of tissues, e.g. bone, cartilage, tendons and skeletal muscle. However, due to its legal harmlessness and good availability even in adult, old and multimorbid patients, these cells are an attractive alternative and object of intense research (Pittenger et al. 1999).

A third, relatively new approach is the emergence of so-called induced pluripotent stem cell (iPS cell) technology, which base in groundbreaking works of Yamanaka and colleagues (Takahashi and Yamanaka 2006) (**Fig. 8.1**). They demonstrated that the overexpression of four genes («Yamanaka factors»= Oct4, Sox2, Klf4, c-Myc) allow for re-programming of already differentiated somatic cells into the embryonic state and thus, at least in theory, the creation of a whole organism from one single somatic cell. Over the last years, many groups picked up this unique concept and, i.e. performed studies to simulate genetic cardiovascular disorders (Narsinh et al. 2011; Freund and Mummery 2009) or to develop and test drugs (Inoue and Yamanaka 2011; Wu and Hochedlinger 2011). Some researchers

Table 8.1 Properties of an ideal (bioartificial) cardiovascular prosthesis

Autologous origin
Resistance against infection
No transmission of pathogens
Non-carcinogenic
Non-teratogenic
High hemo- and biocompatibility
Lifelong durability
Ability to grow
Ability to integrate, regenerate and dynamically adapt to changing conditions
Good availability
Passable costs
Good surgical manageability

Fig. 8.1 **a, b** iPS-cell culture. Haase, Leibniz Research Laboratories for Biotechnology and Artificial Organs—LEBAO, Hannover Medical School, Hannover, Germany)

anticipate that this technique will close the gap between the advantages of pluripotent cells and legislation. Although many efforts have been undertaken to follow this concept and some working groups already reported on successful applications in experimental settings (Schmidt 2010; Rufaihah 2011), especially the development of methods to assess the risk for tumor induction, e.g. teratomas is still open.

8.2.2 Matrices

Another important prerequisite for the generation of tissues is a structural fundament—the matrix. Matrices are of biological, synthetic or combined (hybrid constructs) origin. They serve as structural backbone and provide guidance and anchorage for seeding cells. However, in contrast to construction materials in building industries, tissue matrices are non-static but prone to dynamic tissue remodeling in the sense of situation-adapted synthesis and degradation of its components and thus possess varying biomechanical properties. An ideal matrix scaffold should exhibit the following characteristics: it should be bio- and hemo-compatible non-antigenic and immunogenic supportive for cellular growth and (neo-) angiogenesis to provide sufficient cell- and matrix nutritionable to grow natural materials such as acellularized extracellular matrix components of allogeneic or xenogeneic origin are mostly applied for the generation of pre-defined anatomical structures, e.g. blood vessels or heart valves.

However, apart from this anatomic advantage, major disadvantages simultaneously lie in the fixed shape and size of these matrices as well as in its immunogenic/antigenic potential due to their allogeneic and xenogeneic origin.

Regarding the latter aspect, we recently analyzed decellularized equine carotid arteries (dEAC) with a low DNA content for residual cellular proteins. A detergent-based decellularization protocol including endonuclease treatment resulted in dEAC with 0.6 ± 0.15 ng DNA/mg dry weight representing 0.33 ± 0.14 % of native tissue DNA content. In contrast, when matrices were homogenized and extracted by high detergent concentrations Western blot analyses revealed cytosolic and cytoskeleton proteins like GAPDH and smooth muscle actin which were depleted to 4.1 ± 1.9 % and 13.8 ± 0.55 %, respectively. Also putative immunogenic MHC I complexes and the alpha-Gal epitope were reduced to only 14.8 ± 1.2 % and 15.1 ± 2.05 %, respectively. Mass spectrometry of matrix extracts identified 306 proteins belonging to cytosol, organelles, nucleus and cell membrane. Moreover, aqueous matrix extracts evoked a pronounced antibody formation when administered in mice and thus display high immunogenic potential. Our data indicated that an established decellularization protocol which results in acellular matrices evaluated by low DNA content reduces but not eliminates cellular components and thus may contribute to its immunogenic potential in vivo (Böer et al. 2011).

Synthetic matrices are artificial constructs often based on polymers, which are synthesized

out of biological, artificial or combined bioartificial materials. Shape and size of the resulting constructs are highly variable and arbitrary and the polymers applied in tissue engineering are often sprouts of polyhydroxy acid (PHA) of aliphatic polyesters, e.g. polyglycolic acid (PGA), polylactic acid (PLA) or copolymers (PGLA) of these materials. Polyhydroxyalkanoates (PHAs) are a class of natural occurring polymers and exhibit thermo-plastic properties. They are biocompatible, reabsorbable and highly flexible and induce only slight inflammatory reactions after implantation into a living organism. Because of these characteristics and its high tensile strength, these polymers are often applied for the bioartificial generation of blood vessels and heart valves, too (■ Table 8.2).

Regardless of the matrix material used, the most crucial and thus limiting factor of all currently undertaken approaches to generate living three-dimensional tissue structures remains thickness. Beyond a critical thickness, which

varies depending on the porosity of a certain matrix, tissues need vasa vasorum to ensure sufficient cell and matrix nutrition at lower dimensions by diffusion. Therefore, pivotal questions regarding cell-cell interactions and the in vitro induction of angiogenesis are as important as the matrix material itself. Referring to these aspects, porosity of a scaffold and its internal pore organization influences cell migration and plays a major role in its biodegradation dynamics, nutrient diffusion and mechanical stability. Thus, in order to control cell migration and cellular interactions within the scaffold, novel technologies capable to precisely produce predefined 3D structure designs are required as a first step. The two-photon polymerization (2PP) technique allows for the realization of those arbitrary 3D structures with submicron spatial resolution. We used this technique to generate highly porous 3D scaffolds made out of acrylated poly(ethylene glycol) (PEG) and seeded the resulting matrix

■ Table 8.2 Matrices and exemplary clinical applications

Matrix	Components	Example for clinical application
<i>Synthetic matrices</i>		
Non-biodegradable	Dacron (polyethyleneterephthalate), ePTFE, polyurethane	Vascular prostheses made out of dacron and ePTFE are routinely applied in the clinical setting; an autologous endothelialization of small-calibre prostheses and its subsequent clinical application as bypass or hemodialysis access has already been tried
Biodegradable	Derivatives of poly α -hydroxy acids of aliphatic polyesters, e.g. polyglycolic acid (PGA), polylactic acid (PLA) and copolymers thereof (PLGA), poly-epsilon-aminocaproic acid, poly-4-hydroxybutyrate (P4HB), polyglycolic acid (PGA), hyaff-11 (hyaluronic acid ester)	Suture material, vascular replacement therapy
<i>Biologic matrices</i>		
Primary acellular	Collagen	Vascular graft, heart valve, myocardial tissue
Secondary acellular	Native acellularized matrix scaffold of small intestinal submucosa (sis), bone, heart valves or blood vessels	Decellularized heart valve, venous valve out of sis
Non-acellularized	Native matrix scaffolds, e.g. human allograft/homograft prostheses	Cryopreserved human allograft prostheses for heart valve-, vascular- or skin-replacement therapy

According to Teebken et al. (2005)

scaffolds fully automated with cells by means of a technique called «laser-induced forward transfer (LIFT)». In this laser printing approach, a propulsive force, resulting from laser-induced shock wave, is used to propel individual cells or smaller cell groups from a donor substrate towards the receiver substrate. We could demonstrate that printing of multiple living cell types into 3D scaffolds to be possible using this technique (Ovsianikov et al. 2010).

To further evaluate survival and functionality of cells transferred by the LIFT method, we printed human adipose-derived stem cells (hASCs) in a free-scalable 3D grid pattern in a second step. Here, it was demonstrated that neither the proliferation ability nor the differentiation behavior of stem cells was affected by the LIFT procedure. The 3D grafts were differentiated down the adipogenic lineage pathway for 10 days, and finally we could verify by quantitative assessments of adipogenic markers that the 3D grafts resembled cell lineages present in natural adipose tissue. Additionally, we provided the proof that even pre-differentiated hASCs could be utilized for the generation of 3D-tissue grafts (Gruene et al. 2011a, b).

As mentioned above, the utilization of living cells for therapies in regenerative medicine requires a fundamental understanding of the interactions between different cells and their environment. Moreover, common models based on adherent two-dimensional cultures are not appropriate to simulate the complex interactions that occur in a three-dimensional cell microenvironment in vivo. Thus, using the LIFT technique, we printed spots of human adipose-derived stem cells (ASCs) and endothelial colony-forming cells (ECFCs) in a 3D array. We could demonstrate that (i) these cell spots can be arranged layer by layer in a 3D array; (ii) any cell-cell ratio, cell quantity, cell-type combination and spot spacing can be realized within this array; and (iii) the height of the 3D array is freely scalable. As a proof of concept, we printed separate spots of ASCs and ECFCs within a 3D array and observed cell-cell interactions in vascular endothelial growth factor-free medium and showed that direct cell-cell contacts trigger the development of stable capillary-like networks (Gruene et al. 2011a, b). Thus, these methods may help to study the complex and dynamic relationships between cells and their local environment and to standardize the in vitro generation of bioartificial (*cardiovascular*) tissue constructs.

8.2.3 Bioreactor Technologies

Initial bioartificial tissue generation is based on static in vitro cell and tissue expansion and the use of simple culture media. However, slowly it became clear that the development of living, structural and functional intact tissues strongly depends on a multitude of dynamically adapted environmental factors, which build up a physiologic and tissue-specific micro- and macrosphere. Individually constructed bioreactor systems, e.g. for the generation of blood vessels and heart valves, thus allow for a tailored mass transfer of nutritive factors, metabolites, regulatory molecules and gases and simulate parameters of physiologic hemodynamics, e.g. pH, blood flow velocity, shear stress and shear rate, temperature and blood pressure, which are crucial for the dynamic maturation of a specific tissue (Martin and Vermette 2005).

Studies comparing static and dynamic culture conditions during the generation of various cardiovascular constructs showed those tissues, cultured under pulsatile conditions, to exhibit significantly higher values for burst pressure, suture retention strength and collagen fiber content (Teebken and Haverich 2002; Niklason et al. 1999). More and above, it is known that the absence of physiologic stress leads to altered gene expression and may result in cellular apoptosis finally. All these findings demonstrate the complexity and plasticity of individual physiologic micro- and macrospheres, simultaneously underscoring the essential importance of bioreactor systems for the mimicry of tissue-specific culture conditions (■ Fig. 8.2).

8.3 Blood Vessels

Depending on its size and localization, blood vessels are made for blood conduction, supply/disposal of metabolic elements and/or thermoregulation and blood pressure regulation. However, the primary aim of all surgical and/or interventional vascular interventions is the sole restoration of blood flow within an impaired or destructed vascular area to warrant blood supply in downstream tissue areas or to assure adequate blood refuse via the venous system. The spectrum of possible techniques reaches from local reconstructive approaches, e.g. thromboendarterectomy

■ **Fig. 8.2** Complex bioreactor system. Bioreactor system for in vitro generation of **a** vascular and **b** cardiac valve grafts. The system shown in **c** allows for parallel generation of up to three vascular grafts and is housed in an incubator. A computer system controls all relevant parameters, e.g. media flow velocities, pressure and shear stress **d** and media flow is generated by **e** a centrifugal pump (Courtesy of Prof. M. Wilhelmi, Dept. of Cardiothoracic, Transplantation, and Vascular Surgery, Hannover Medical School, Hannover, Germany)

to complete substitution by biological (= *autologous*, *allogeneic* or *xenogeneic*), synthetic (= *alloplastic*) or hybrid vascular grafts.

8.3.1 Generation of Vascular Grafts Based on Biological Matrix Materials

Autologous vessel grafts harvested from an individual patient to substitute or reconstruct his own diseased vessels are used since the early eighteenth century (Goyanes 1906; Murphy 1897; Carrel 1902). The clinical application of allogeneic prostheses mainly harvested in the context of autopsies started in the 1940s and mainly based on works of Charles Hufnagel and Robert Gross

(Gross and Bill 1948; Gross et al. 1949). However, 3–5 years after implantation of these allogeneic grafts, severe calcifications visible on X-rays pointed to degenerative processes, which often resulted in complete and initially inexplicable graft loss (Dubost et al. 1952; Outdot and Beaconsfield 1953; Outdot 1951).

Addressing this observation, a first milestone in the history of biological grafts was laid by Rosenberg and co-workers, who tried to reduce the presumable underlying graft immunogenicity by impregnation. He used bovine carotid arteries and tried to improve its in vivo performance by impregnation with dialdehyde starch (Rosenberg and Henderson 1956; Rosenberg 1976) and anticipated that induced cross-linkings between extracellular matrix proteins of these vessels would

weaken immunological responses of the recipient while preserving graft structure/shape and prolonging its storage time. However, it emerged that dialdehyde starch was a bad choice. These grafts also demonstrated severe calcification and degradation. Subsequently, different chemical agent—glutaraldehyde—was discovered and found to be a much better choice. Many different tissues were impregnated very successfully with this agent and became readily available off the shelf.

In 1972, Dardik evaluated glutaraldehyde preserved human umbilical veins as an alternative biological bypass material, i.e. for lower extremity bypasses (Dardik and Dardik 1973). However, as already postulated by Kunlin in 1949, these grafts also failed in the long term, and the greater saphenous vein was found to be the most suitable graft in this anatomic area (Kunlin 1949).

Reviewing the underlying mechanisms of graft deterioration, two factors seem to play a particular role in this phenomenon: (i) immunological reactions in the sense of subliminal tissue rejection (Wilhelmi et al. 2003a, b), which seem to be induced by the antigenicity of resident allogeneic cells and (ii) the method of tissue preservation/fixation (glutaraldehyde) itself. As mentioned before, initially this latter agent was used to reduce the immunogenicity of tissues via the cross-linking of collagen fibers to prolong its durability. However, over the years it became clear that glutaraldehyde increases the risk for calcification, potentially amplifies immunological reactions and, most importantly, inhibits processes of in vivo regeneration (O'Brien et al. 1999). Today it is believed that histoincompatibilities are responsible for the induction of immunological responses and resulting tissue rejection. We could indeed show that even established decellularization protocols reduce but not eliminate all cellular components and thus may still contribute to immunogenic reactions in vivo (Böer et al. 2011).

The first vascular prosthesis completely generated on the basis of biological materials goes back to Weinberg and Bell (Weinberg and Bell 1986). They seeded smooth muscle cells in vitro on a collagen gel, which mimicked the lamina media, added fibroblasts to the outer surface of this construct and thus generated a bioartificial adventitia. Following 2 weeks of further in vitro culture, endothelial cells were added to the luminal surface to serve as an artificial lamina interna. Scanning electron microscopic (SEM) evaluations

revealed endothelial monolayers on the luminal surface of these grafts, which stained positive for von Willebrand factor. However, although histological data were very promising, biomechanical tests revealed that these constructs had only very limited structural stability so that Dacron nets had to be wrapped around the grafts to allow at least physiological pressure loads (Weinberg and Bell 1986). L'Heureux picked up the principle of this method, changed some culture conditions and noticed that it was possible to positively influence graft stability and pressure tolerance/burst strength by modification of environmental conditions (Edelman 1999; L'Heureux et al. 1998).

These two concepts rely on the principle of *tissue engineering in the classical sense*. Campbell and co-workers also imitated this basic concept but utilized on in vivo situation for graft generation (= *guided tissue regeneration*). They implanted silastic tubings into the peritoneal cavity of rats, and after 2 weeks they observed that fibroblasts and mesothelial cells seeded on the outer surface of these tubings. The resulting tubular tissue sheet was then dissected and everted so that the previously outer mesothelial cells subsequently built-up the inner surface and thus mimicked the lamina interna. In animal models these bioartificial vessel grafts showed physiological reactivity towards vasoactive agents and were patent for up to 4 months (Campbell et al. 1999). Another classical tissue engineering approach was used by a working group of Huynh. They used small intestinal submucosa (SIS) and bovine type-I collagen to generate a new kind of vascular prosthesis. After removal of all cellular components via hypotonic solutions, they tested autologous, allogeneic and xenogeneic grafts in large animal models and reported on excellent patency rates. In the histological analysis, they found these primary decellularized implanted grafts to spontaneously re-seed in vivo and thus obviously underwent regenerative processes (Huynh et al. 1999). However, in experiments using smaller animals such as rats, these small calibre vessel grafts were found to be occluded very early due to thrombus formation (Schmidt and Baier 2000).

Apart from the use of conventional matrix materials, e.g. just decellularized preformed vascular matrices of allogeneic or xenogeneic origin or the de novo synthesis of collagen fibers as suggested by L'Heureux, another interesting concept was developed based on the use of fibrinogen and

fibrin. Fibrin is known to facilitate matrix synthesis by seeded cells compared to other reconstituted proteins such as type I collagen. However, despite these promising attributes, fibrin gel alone possesses inadequate mechanical properties to withstand implantation in the vascular system.

Therefore, Tschoeke et al. (2008) developed an injection molding technique to completely integrate a non-biodegradable, high porous textile structure (pore size ~ 2 mm) into the vascular wall, which consists of an autologous fibrin gel scaffold as cell carrier for the vascular smooth muscle cells (Tschoeke et al. 2008). He hypothesized that the combination of a mesh and dynamic culture conditions allows for the generation of mechanically stable and implantable vascular grafts within a shorter cultivation period than traditional methods. He developed a two-step molding technique to integrate a polyvinylidene fluoride (PVDF) mesh (pore size: 1–2 mm) in the wall of a fibrin-based vascular graft (inner diameter 5 mm) seeded with carotid myofibroblasts. The graft was cultured under increasing physiological flow conditions for 2 weeks. Cell growth and tissue development were excellent within the fibrin gel matrix surrounding the PVDF fibers, and tissue structure demonstrated similarity to native tissue. The grafts were successfully subjected to physiological flow rates and pressure gradients from the outset, and mechanical properties were enhanced by the mesh structure. Mean suture retention strength of the graft tissue was 6.3 N and the burst strength was 236 mmHg, and thus small-calibre vascular grafts with good mechanical properties could be obtained within 14 days. In a next step, the non-biodegradable material was replaced by a midterm biodegrad-

able polylactide mesh structure (degradation time of 6–9 months), and again, after in vitro maturation, the graft was ready for implantation (Tschoeke et al. 2009), also shown by others (Aper et al. 2004) (■ Fig. 8.3).

8.3.2 Generation of Vascular Grafts Based on Alloplastic Matrix Materials

In 1952, Voorhees and co-workers identified an alloplastic material called Vinyon «N» (Voorhees et al. 1952). Vascular conduits made out of this material and tested in animal models revealed good initial functionality. However, soon it became clear that it was not possible to autoclave this material without severe deformation and pronounced shrinking. Even with these initially somewhat disappointing data, many scientific groups began to think about alloplastic materials, and soon another material—polyester (=Dacron)—was discovered and evaluated for its applicability as a vascular prosthesis. A new era in vascular surgery was heralded and the clinical introduction of these prostheses spread all over the world. More and above, a new medical speciality—*medical material engineering*—came up. Following the establishment of basic technical methods in the production of woven prostheses, it was tried to optimize material properties, e.g. compliance, manageability. The necessity to do so based on the observation that the first generation of these prostheses was very porous and therefore had to be pre-clotted with blood prior to implantation. Furthermore, they were very stiff and kinky and stenoses occurred when they

■ Fig. 8.3 Vascular graft made out of fibrin gel. Small-diameter vascular graft exclusively consisting of fibrin gel (Courtesy of Prof. M. Wilhelmi and Dr. Th. Aper, Dept. of Cardiothoracic, Transplantation, and Vascular Surgery, Hannover Medical School, Hannover, Germany)

were implanted in angles. Therefore, Sauvage introduced a crimped prosthesis to avoid those kinking-related stenoses (Sauvage et al. 1974). A further development in this sense was the application of external rings to prevent kinking and outer velour coverage for better integration of the prostheses into the surrounding tissue.

In 1954 another new material—«nylon»—was discovered (Shumacker and King 1954), and Edwards and Tapp constructed a new prosthesis out of this material (Edwards and Tapp 1955). However, in 1958 Harris observed that 100 days following implantation into the aorta, these prostheses lost their structural stability, whereas Teflon and Dacron did not. Thus, the era of nylon was terminated before it really began. In the 1970s another new material became available. It was a variant of Teflon, named expanded polytetrafluoroethylene (ePTFE). The microstructure of this material initially discovered by Eiseman is characterized by microscopic small knots and transversal fibers running between them. Because of the resulting huge internodal spaces, up to 80% of the prosthesial wall are simply made of nothing. The practical meaning of this characteristic is that these prostheses are primarily blood tight and thus do not require pre-clotting prior to implantation.

Deduced from further studies aiming to increase the impermeability of vascular prostheses, collagen, albumin and gelatin impregnations were discovered as useful tools. Importantly, it was observed that these modifications were not associated with loss of biomechanical stability or other characteristics relevant for clinical application. Further refinements comprise the binding of various effectors, e.g. fibrinolytic or antibiotic substances, anticoagulants or other effectors to minimize damaging influences and to optimize bio- and hemocompatibility of these prostheses (Sagnella et al. 2003, 2005; Murugesan et al. 2002; Lachapelle et al. 1994; Ginalska et al. 2005a, b), a concept today termed biofunctionalization.

In the clinical setting, alloplastic prostheses, i.e. those made out of Dacron and ePTFE, are primary used for reconstructive interventions of large calibre vessels such as the aorta and its side branches. The restriction of these implants to mainly large vessel areas (>6 mm) is explained by the clinical observation that autologous vessel grafts such as the greater saphenous vein still

reveal much better patency rates. However, in contrast to the assumption that the greater saphenous vein may represent a universally applicable vessel graft, it should be noticed that due to prior surgical interventions, varicoses or deep vein thrombosis, this vessel is not available in every patient. Furthermore, it belongs to the venous and thus low pressure part of the cardiovascular system, predisposing ectatic and degenerative deformations when exposed to arterial blood pressure load. Other autologous venous grafts, e.g. the femoral vein or those obtained from the upper extremity, exhibit the same structural disadvantages and are reported to be even less qualified than the greater saphenous vein. Based on these limitations, the search for tissue engineered grafts has intensified, especially for prostheses in the venous system and for small-diameter arterial grafts.

8.3.3 Generation of Vascular Grafts Based on Hybrid Matrix Materials

The basic idea for the generation of hybrid constructs combining biological and synthetic matrix materials was to profit from positive attributes of both these material groups. An early approach aiming to realize such a concept was the subcutaneous implantation of polyethylene, polyvinyl or silastic mandrains covered by a polyester net. The ratio behind this concept was that fibroblasts may spontaneously seed on these alloplastic nets to de novo synthesize a tissue sheet within a few weeks following the concept of guided tissue regeneration. Indeed, Sparks and co-workers demonstrated that it was possible to generate such a tubular structure but also reported on degenerative changes in the sense of aneurysm formation and resulting graft loss in the long term (Sparks 1973).

More and above, the application of alloplastic vascular prostheses with an inner diameter smaller than 5–6 mm was and still is often associated with early thrombotic occlusion and graft failure. Thus, one of the most important clinical issues in cardiovascular surgery was and is to identify materials, which allow for the generation of vascular grafts ≤ 5 mm. In early experiments it was tried to reduce the intrinsic thrombogenicity of alloplastic grafts by seeding autologous endothelial cells on their inner surface (Williams

1995). Miwa and Matsuda developed a prosthesis on polyurethane basis with an artificial lamina basalis composed of collagen type-I and dermatan sulfate on which an endothelial monolayer was transferred. Following *in vitro* culture, they implanted this construct in dogs and observed a primary patency rate of 75% without additional anticoagulative therapy (Miwa and Matsuda 1994).

Deutsch reported on a study in which endothelial cells seeded ePTFE prostheses were implanted as above the knee bypasses. He found a 9-year patency rate of 65% and thus comparable results to those obtained with greater saphenous vein bypass grafts. In contrast, non-seeded prostheses revealed only a patency rate of 16% (Deutsch et al. 1999). However, these good patency rates of seeded grafts could not be achieved when used for coronary revascularization (Laube et al. 2000). Thus, it was hypothesized that an increased intrinsic thrombogenicity might be responsible for this phenomenon. As a consequence, polyurethane matrices seeded with endothelial cells were coincubated with heparin and RGD groups to further increase endothelial cell adherence. Indeed, a 75% increase in endothelial surface coverage was observed.

Another, potentially disadvantageous issue with regard to *in vivo* graft performance might be the use of non-reabsorbable matrix materials for that they may prevent remodeling and regenerative processes (Seifalian et al. 2002). Alternative may be reabsorbable materials, which degenerate over time and in parallel to the bioartificial *in vivo* generation of a living graft. However, one essential prerequisite in this regard is that the initially implanted biodegradable material has to be biomechanically stable enough to withstand physiological hemodynamic stress load. Also, the bioartificially generated tissue has to develop in parallel to material degradation with subsequent biomechanical properties similar to those of a native vessel.

Over the last years, many polymers (degradable and non-degradable) were evaluated, but most of them were found to be highly thrombogenic, induced foreign body reactions, led to the formation of aneurysms and/or were reabsorbed too fast. Niklason, therefore, tried to combine biodegradable polymers with living cells (Niklason et al. 1999). Polyglycolic acid (PGA) matrices were seeded with smooth muscle cells

obtained from bovine aortas and cultivated under pulsatile culture conditions *in vitro*. After 8 weeks, endothelial cells were added at the luminal side and in the subsequent histological analysis up to 50% of all extracellular matrix components were identified as elastin and collagen proteins. Furthermore, scanning electron-microscopic analyses revealed homogeneous cellular monolayers on the luminal surface, which stained positive for CD31 (PECAM-1). In animal models, these prostheses were patent for up to 8 weeks and withstood a blood pressure load of more than 2,000 mmHg. Presently, many working groups try to identify, synthesize and characterize further biodegradable materials, which exhibit optimized properties for the realization of such hybrid concepts (Nerem 1992).

If other prospective approaches, e.g. gene therapies aiming to modulate crucial tissue characteristics, i.e. intrinsic thrombogenicity or further modified surgical methods and techniques will help to increase patency rates is uncertain (Kuo et al. 1998; Hubbell et al. 1991). However, a few positive effects could already be observed (Flinn et al. 1984; Tyrrell and Wolfe 1991; Taylor et al. 1992; Siegman 1979; Miller et al. 1984; Linton and Darling 1962; DeLaurentis and Friedmann 1972).

8.4 Cardiac Tissue Engineering

8.4.1 Heart Valves

Today heart valve replacement therapy comprises mechanical and bioprosthetic valves. Similar to small-calibre alloplastic vascular prostheses, mechanical valves incur high rates of thrombosis and thromboembolic complications. Oral anticoagulants, however, are associated with an increased risk for bleeding complications, but they significantly reduce the risk for thromboembolic complications (Cannegieter et al. 1994). The valve itself is prone to an elevated risk of infectious complications but nevertheless is expected to last a whole patient's life. Bioprosthetic valves fabricated from decellularized and preserved xenogeneic valves or pericardial tissues are relatively non-thrombogenic, and bleeding complications are rare due to the lack of lifelong anticoagulation. However, these valves tend to degenerate over time and have no or only limited

remodeling capacities. Nonetheless, nowadays these valves last for up to 20 years (Rahimtoola 2003; Marchand et al. 2001). Taken together, the need for the generation of bioartificial heart valves bases on the following arguments: (i) ability to remodel and grow (*application in infants*), (ii) reduced immunogenicity and thus reduced tissue deterioration/degradation (*lifelong durability*) and (iii) avoidance of (oral) anticoagulants (i.e. *in young, physical active and old, disabled patients*). Finally, tissue-engineered heart valves may exhibit anti-infectious properties, if complete inner and outer cellular coverage could be achieved.

Historically, Ross and Barret-Boyes were the first who used biological, allogeneic human heart valve prostheses in the clinical setting. Their primary thought was to identify an alternative to mechanical prostheses, i.e. because of the lack of distracting «click» noises and oral anticoagulation following implantation (Barratt-Boyes 1965; Ross 1967). However, initially, progressive degenerative changes occurred 8–10 years following implantation, which finally led to complete destruction and thus often necessitated redo operations. The underlying mechanisms were thought to base especially on two major factors: (i) immunological reactions in the sense of subliminal tissue rejection (Wilhelmi et al. 2003a, b), which seem to be induced by the antigenicity of resident allogeneic cells, and (ii) the method of tissue preservation/fixation by glutaraldehyde. Initially, this latter agent was used to reduce the immunogenicity of tissues via cross-link of collagen fibers to prolong its durability. With time, however, it became clear that actually the risk for calcification increases, immunological reactions are amplified and *in vivo* regeneration is hampered by this agent (O'Brien et al. 1999).

Trying to avoid the antigenic influence of resident cells, Gulbins seeded cryopreserved human allografts with autologous endothelial cells *in vitro* and implanted these prostheses in animals. However, the prostheses were not decellularized prior to the *in vitro* seeding, and thus the success was only moderate (Gulbins et al. 2003). The group of Wilson picked up the basic idea to use allogeneic cardiac valves but established a multistep decellularization protocol, which based on the use of hypo- and hypertonic solutions, detergents and enzymes to remove all cellular components within the allogeneic valvular tissue (Wilson et al. 1995). The valves were implanted in

the pulmonary position of dogs, and, following 1 month, no hints to inflammatory reactions or other immunological side effects could be observed—at least macroscopically.

Other groups who used similar *in vitro* decellularization protocols reported on comparable results, so that the first commercially available decellularized and cryopreserved xenogeneic valvular prostheses came up. It could be shown that decellularized valves exhibit reduced immunogenicity in comparison to native control groups. However, it was warned that even the application of these valves may lead to accelerated destruction, especially when used in infants (Simon et al. 2003). The presumptive reason for this phenomenon was an elevated activity of the infant immune system in combination with a physiologically increased calcium metabolism at this age.

As a logical consequence of the concept of exclusive decellularization, an additional step of *in vitro* autologous endothelial re-seeding was added, and following promising initial data in animal models, results in human patients are available already (*xenogeneic heart valves re-seeded with autologous human endothelial cells*) (Dohmen et al. 2002a, b). Another approach of autologous endothelial re-seeding of decellularized heart valve prostheses could be realized in Hannover in close collaboration with the university of Chisinau, Republic of Moldavia. Assuming that decellularized, xenogeneic matrix scaffolds may still induce immunological reactions due to interspecies differences, human allografts decellularized by using an elaborated protocol were re-seeded by autologous endothelial cells obtained as mononuclear cells isolated from individual blood probes. Positive stains for the von Willebrand factor, CD31 (PECAM-1) and flk-1 as observed in monolayers of cells cultivated and differentiated on the luminal surface of the scaffolds in a dynamic bioreactor system indicated the endothelial nature of these cells. The re-seeded valves were implanted in pulmonary position of two pediatric patients (age 13 and 11 years) with congenital pulmonary valve failure. Postoperatively, a mild pulmonary regurgitation was documented in both children.

Based on regular echocardiographic investigations, hemodynamic parameters and cardiac morphology changed in 3.5 years as follows: increase of the PV anulus diameter (18–22.5 mm

and 22–26 mm, respectively), decrease of valve regurgitation (trivial/mild and trivial, respectively), one decrease (16–9 mmHg) and one increase (8–9.5 mmHg) of the mean transvalvular gradient, one remaining (26 mm) and one decreasing (32–28 mm) right ventricular end-diastolic diameter. The body surface area increased (1.07–1.42 m² and 1.07–1.46 m², respectively), and no signs of valve degeneration were observed in both patients now 10 years after the procedure. Thus, it could be shown that the tissue engineering of heart valves using autologous endothelial progenitor cells is a feasible and safe method at least for pulmonary valve replacement. Furthermore, it was concluded that tissue engineered valves have the potential to remodel and grow according to the somatic growth of a child (Cebotari et al. 2002, 2006).

Another interesting approach of this group was the use of fresh decellularized pulmonary homografts (DPH) for pulmonary valve replacement. Thirty-eight patients with DPH in pulmonary position were consecutively evaluated during the follow-up (up to 5 years) including medical examination, echocardiography and MRI. Patients were matched according to age and pathology and compared with glutaraldehyde-fixed bovine jugular vein (BJV) ($n=38$) and cryopreserved homograft (CH) ($n=38$) recipients. In contrast to BJV and CH groups, echocardiography revealed no increase of transvalvular gradient, cusp thickening or aneurysmatic dilatation in DPH patients. Over time, DPH valve anulus diameters converge towards normal z -values. Five-year freedom from explantation was 100% for DPH and $86 \pm 8\%$ and $88 \pm 7\%$ for BJV and CH conduits, respectively. Additionally, MRI investigations in 17 DPH patients with follow-up time >2 years were compared with MRI data of 20 BJV recipients. Both patient groups (DPH and BJV) were at comparable ages (mean, 12.7 ± 6.1 versus 13.0 ± 3.0 years) and have comparable follow-up time (3.7 ± 1.0 versus 2.7 ± 0.9 years). In DPH patients, the mean transvalvular gradient was significantly ($P < 0.001$) lower (11 mmHg) compared with the BJV group (23.2 mmHg). Regurgitation fraction was $14 \pm 3\%$ and $4 \pm 5\%$ in DPH and BJV groups, respectively. In three DPH recipients, moderate regurgitation was documented after surgery and remained unchanged in follow-up.

Thus, in contrast to conventional homografts and xenografts, decellularized fresh allograft

valves showed improved freedom from explantation, provided low gradients in follow-up and exhibited adaptive growth (Cebotari et al. 2011) (■ Fig. 8.4). This concept has now been evaluated for experimental aortic valve replacement and is currently introduced in selected clinical cases (Baraki et al. 2009).

An alternative approach basing on alloplastic matrix materials was followed especially by Mayer and Vacanti. They used synthetic matrix scaffolds on polymer basis—polyglycolic acid (PGA) and polylactide (PLA), respectively (Hoerstrup et al. 1998). Following re-seeding of such matrices with autologous arterial vessel wall-specific cells, pulmonary valves and pulmonary artery segments were generated and tested in a sheep model (Shum-Tim et al. 1999; Shinoka et al. 1996, 1998). However, the initially experienced disadvantage of very high rigidity of polymer scaffolds led to the development of new polymers and copolymers, e.g. polyhydroxyalkanoate (PHA), poly-4-hydroxybutyrate (P4HB) and polyglycolic acid (PGA) (Sodian et al. 2000; Korecky et al. 1982; Hoerstrup et al. 2000). In contrast to the above-mentioned studies on DPH, till now none of these scaffold materials reached the clinical stage of development.

8.4.2 Myocardial Tissue

According to its typical three-layered architecture, the heart represents the largest «vascular» structure of the body. Thus, at the first glance, it may seem to be very simple to bioartificially construct a heart. Actually, the mimicry of this organ or even parts thereof still faces the scientific world with one of the most challenging tasks. The first, probably accidental event to develop a three-dimensional myocardial tissue dates back to the early 1950s, when Moscona and co-workers isolated embryonic chicken cardiac muscle cells and cultivated them under continuous rotation in an *in vitro* setting. After 18 h in culture, the cells spontaneously formed spheroid, three-dimensional and approximately 200 cells comprising aggregates, which most interestingly exhibited spontaneous contractile activity (Moscona 1959). Many other groups picked up this promising model and observed that these cellular aggregates resembled functional native cardiac tissue much more than any other two-dimensional cellular monolayer before (McDonald et al. 1972). Thus, this early observation demonstrated that embryonic cardiac cells grow even under *in vitro* culture conditions and tend to form spontaneous cellular aggregates. However, following longer times of *in vitro* culture and ongoing cell proliferation, it could be observed that: (i) the spontaneous contraction ceased, (ii) the whole tissue contracted and (iii) the cellular sheets loosened and started to float in the culture medium.

For a long time, insufficient culture conditions were accused to cause this phenomenon and many groups skipped to follow this experiment. However, Shimizu and co-workers regarded this phenomenon as a chance to harvest and staple the floating monolayers and thus to generate a 3D-tissue structure without the need for an additional matrix scaffold (Shimizu et al. 2002). According to the observation that free floating and thus mechanical nonloaded myocardial monolayers cease their contractile activity over time, Vandenburg and co-workers covered cultured muscle cells with type-1 collagen to further mechanically load and stimulate these cells (Vandenburg et al. 1988). And indeed, they observed that this method led to improved differentiation of myocytes so that this basic principle was transferable to other, non-

muscular cell types as well. The resulting data revealed that a 3D matrix architecture led to improved cellular differentiation of all kinds of evaluated cells and tissue generation.

Beside cellular composition and differentiation, living tissues and, i.e. functional myocardium are characterized by the orientation of its resident cells. Here, two factors seem to play a crucial role for the heart (i) mechanical stimuli and (ii) the geometric orientation of matrix components. Regarding the first point, electronically controlled bioreactors were developed, which provide, e.g. stretching forces to muscle cell cultures originating from the musculature and the heart. Using these devices, it could be shown that mechanical stimuli exhibit positive effects on differentiation and orientation of both types of muscular cells (Terracio et al. 1988; Chambard et al. 1981). Under conditions of continuous cyclic stress consisting of distension and relaxation, skeletal muscle cell cultures formed longitudinally orientated 3D muscle fibers, which began to form tendons as well (Vandenburg et al. 1991).

In another concept, collagen sponges were combined with a suspension of newborn rat cardiomyocytes in Matrigel and stimulated electrically (Radisic et al. 2004). This concept led to the formation of cardiac muscle structures with enhanced tissue morphology, contractile function and specific molecular marker expression. Thus, electrical stimuli seem to have similar effects as mechanical ones (Fink et al. 2000; Zimmermann et al. 2002). Furthermore, it could be observed that other parameters, e.g. strong magnetic fields, influence the orientation of fibroblasts and smooth muscle cells as well (Guido and Tranquillo 1993; Torbet and Ronzière 1984; Tranquillo et al. 1996).

Regarding the second influencing factor—the geometric orientation of matrix components—it was observed that the matrix scaffold itself has essential influence on tissue growth and cellular differentiation. One important example, which underscores this observation, was that cardiomyocytes obtained from newborn rats and seeded on a rill-shaped collagen type-1 matrix grew along these structures (Simpson et al. 1994).

Perhaps one of the most striking examples demonstrating the influence and importance of extracellular matrix components for the survival of injected cells was a study in which a whole rat heart was decellularized and subsequently

repopulated with neonatal cardiomyocytes, resulting in a beating heart (Ott et al. 2008). However, and as already mentioned above, the optimal matrix scaffold for the bioartificial generation of cardiac tissue is still unknown. The reasons for this fact are manifold and may be characterized as follows:

1. The necessity of high mechanical stability with coexistent high compliance
2. The helical and interweaved fiber structure of the cardiac muscle, which are mandatory for optimal pump function
3. Adequate tissue niches to host/retain tissue-specific cells, (iv) the guarantee of a sufficient supply of these key cells with oxygen and nutrients
4. The ability to completely integrate into the surrounding myocardial tissue

Today it is not clear, if it ever will be technically possible to generate materials, which completely mimic the complex structure of a living heart. Even if it should be possible, e.g. on basis of modern nanotechnologies, it has to be guaranteed that quantitatively enough niches are present within those matrices, so that specific cells can be nested within the scaffolds, connect with each other and build up a fully functioning electrical and mechanical syncytium. Whether strategies developed in Taylor's laboratory to decellularize and reseed an entire organ will proof successful has to be awaited (Badylak et al. 2011). At least, a matrix closest to native would be provided.

Another approach to bioartificially generate myocardial tissue, resulted from an *in vitro* model initially developed to evaluate embryonic fibroblasts (Kolodney and Elson 1993). Here, cardiomyocytes were cultured in a collagen-gel matrix (Chambard et al. 1981; Hall et al. 1982). The particular characteristic of an experimental setting established by Eschenhagen and co-workers was that the cell containing matrices were positioned between two rectangular positioned Velcro covered glass rods. Spontaneous muscle activities and forces generated by the resulting cellular aggregates adhering to these glass rods thus could be identified and quantified (Eschenhagen et al. 1997). Cardiomyocytes obtained from newborn rats and embedded in collagen type-1 gel exhibited no growth and differentiation until the addition of further extracellular matrix components

(Matrigel) (Zimmermann et al. 2000; Souren et al. 1992). However, the resulting contractile forces could be tripled by applying cyclic distension forces (Fink et al. 2000).

Two other, totally different approaches based on cell-matrix combinations consisting of polyglycolic acid (PGA) or a liquid gelatin matrix and cells, e.g. fetal rat cardiomyocytes (Langer and Vacanti 1993; Li et al. 1999; Carrier et al. 1999). Both these cell matrix composites exhibited spontaneous contractile activities—in *vitro* and *in vivo*. However, following implantation in infarcted myocardial tissue areas, only a very few of these cardiomyocytes could be detected histologically. In contrast, following implantation of alginate-based matrices seeded with fetal cardiac cells, Leor observed distinctive vascularization within these constructs. However, a real integration into the surrounding recipient's myocardium could not be observed either (Leor et al. 2000).

Apart from all matrix-based techniques mentioned above, Shimizu and co-workers presented a complete matrix-free approach. They used a culture flask coated by a thermosensitive surface on which cells of all kinds can be grown. However, in contrast to other known culture flasks, this specific setting allows cells to detach in reaction to changes in temperature (Shimizu et al. 2002). Thus, confluent monolayers of cardiac myocytes can be grown and subsequently piled up to 3D-connected cellular layers (up to 50–75 μm thickness). The advantages of this technique are the simplicity of the method and the independence from the use of potentially immunogenic, pathogenic or even toxic matrix scaffolds. The disadvantages comprise limitations with regard to geometric shapes, fragility and thus only limited mechanical load capacity. Meanwhile, various variations of this method have been described (Kofidis et al. 2002; Akins et al. 1999).

8.4.2.1 Vascularization and Cellular Composition

Over the last decade, various methods and techniques to bioartificially generate cardiovascular tissues have been described. However, as finds true for almost every other kind of 3D-tissue structure as well, one of the most essential and still unsolved problems is the limitation of the maximal achievable tissue thickness, which bases

on limited diffusion capacities for nutrients and oxygen. Studies evaluating the process of angiogenesis in tumors have shown that in the absence of capillary vessels and perfusion, the thickness of living tissues is restricted to a maximum of 2–4 mm (Folkman 1971). One crucial parameter in this regard is the individual and tissue-specific metabolic activity and the local concentration of cells, respectively. Contractile cardiac tissue contains a very number and high density of cellular components and thus exhibit a very high metabolic activity. Depending on the stage of development, a human heart contains between 2,400 and 3,300 capillaries per mm² area (Rakusan et al. 1992).

On the other side, it is known that embryonic rat hearts and adult frog hearts are completely avascular and are fed only by diffusion. The reason for this phenomenon lays in the structure of these tissues, which are characterized by a wide spread trabecular system composed of muscular struts (Sys et al. 1997; Ratajska et al. 2003). Regarding strategies for the bioartificial generation of tissues, this means that a physiological vascularization or an intensive trabecular systems with fibers not thicker than 50–75 μm has to be present. Some working groups tried to increase the transport capacity for oxygen and other nutrients by using specialized bioreactor systems or oxygen carriers, e.g. peroxy fluorocarbon (Radisic et al. 2005; Carrier et al. 2002). Actually it was possible to induce a positive effect on the cellular density as well as metabolic activity (Carrier et al. 2002); subsequently cardiac tissue with a clinical relevant tissue thickness of up to 500 μm could be generated (Radisic et al. 2005).

Other strategies based on data observed at newborn rat hearts. Here it was tried to generate single tissue struts, which than were woven to each other so that the resulting network was completely perfused and allowed for diffusion through the whole tissue structure. Alternatively it was tried to integrate bioartificially generated cardiac muscle constructs into native vascularized tissues (with or without additional pharmacological stimulation of angiogenic processes). Although it was observed that all these artificially generated heart muscle tissues exhibited a fast (re-)vascularization following implantation and that hypoxic periods during and early after

implantation seemed to be of only minor importance with regard to tissue fate, some essential questions could not be answered: (i) is the pre-existing vascularization sufficient for long-term survival, (ii) how many of the initially implanted cardiomyocytes survive over time, (iii) do these implanted cells functionally and structurally integrate into the recipient myocardium and (iv) does the implantation of those constructs really lead to an augmented cardiac function? In context of some in vitro studies, such as Langendorff models, it was observed that the cardiac function actually improved, higher pressure values were obtained (Li et al. 1999) and the fractional shortening was increased (Leor et al. 2000). However, these effects, overall, were not very pronounced and could be obtained in a similar way by the injection of different and, i.e. non-cardiomyocytic cells. In direct comparison of cellular suspensions and 3D bioartificially generated tissue grafts, the advantage of latter is not clear at present.

Another conceptual issue regarding the bioartificial generation of cardiac tissue refers to specific cellular components and sources to isolate or generate such cells, respectively. It is estimated that an adult human heart comprises 5×10^9 cardiomyocytes within the left ventricle alone (Beltrami et al. 1994). This means that approximately 40 million cardiomyocytes are present within 1 g of cardiac tissue or in other words that it is nearly impossible to harvest a sufficient cell count to generate a complete bioartificial heart, e.g. via cardiac biopsies. Scientific approaches with focus on adult stem cell research might represent a possible solution for this problem. Today it is known that all cells necessary to generate autologous cardiac tissues can be differentiated from (adult) stem cells, which can be harvested from, e.g. bone marrow aspirates (Makino et al. 1999; Orlic et al. 2001), peripheral blood probes (Asahara et al. 1997; Badorff et al. 2003), cord blood (Condorelli et al. 2001) or fatty tissue (Zuk et al. 2001).

Another potentially interesting alternative to generate higher quantities of suitable cells might be the induction of pluripotent stem cells (iPS cells) from somatic cells of an individual patient. Currently, the most common method of generating cardiomyocytes from iPS cells is the embryoid body differentiation system which coaxes the iPS

cells to differentiate into the cardiac lineage (Narsinh et al. 2011). However, although the resulting cells show many functional properties of normal human cardiomyocytes, some other aspects of these cells, including their morphology, remain relatively immature and «fetal-like». More and above, these pluripotent cells still run the risk to induce teratomas (Oh et al. 2012). Thus, all of the above-mentioned techniques and cellular sources have to be investigated intensely in the future.

8.5 Outlook

Shortcomings of all known alloplastic implant materials, namely, infectious and thromboembolic complications, blazed a trail for biological and bioartificial tissue substitutes in the cardiovascular system. However, although a huge variety of methods and techniques have been established to generate and evaluate bioartificial cardiovascular grafts, only two of these have found their way into clinical practice (■ Table 8.3), i.e. the following issues still have to be addressed and further evaluated:

- The development of dynamically (self-)adapting systems (*intelligent bioreactors*) for the (*automated*) in vitro generation of cardiovascular tissues
- The identification and establishment of micro- and nanotechnologies, which facilitate tissue/matrix (neo-)angiogenesis and thus allow for the generation of complex 3D-tissue structures
- The identification of suitable autologous cell sources and techniques for the isolation (*adult stem cells*) or generation (*iPS cells*) of high quantities of suitable key cells for matrix (re-)vitalization and functionalization
- The evaluation of residual immunological differences between donor tissue and the recipient immune system
- The development of strategies to avoid or minimize the immunological consequences
- The identification, formulation and implementation of standard operating procedures (SOP) for the bioartificial generation of cardiovascular grafts
- Formulation of nationally and internationally accepted uniform requirements for product licencing procedures

■ Table 8.3 State of the art of cardiovascular implants and grafts

Type of prosthesis	Matrices and cells	Application
Vascular replacement therapy: <i>with synthetic matrices</i>	Non-reabsorbable prostheses out of Dacron and ePTFE	Commercially available, clinical routine (Rahlf et al. 1986)
	Seeding of alloplastic prostheses with endothelial cells	Clinical studies (Vara et al. 2005)
	Seeding of biodegradable synthetic matrices	Clinical studies (Isomatsu et al. 2003)
	With different kinds of cells	
Vascular replacement therapy: <i>with biologic matrices</i>	Acellular vascular implants of brute origin	Commercially available, clinical routine
	Acellular vessel of human origin	Animal experiments (Schaner et al. 2004) and clinical case reports
	Acellular and re-seeded vessel grafts of human origin	Clinical case reports (Zehr et al. 2005)
	Tissue preparations of small intestinal submucosa (SIS)	Animal experiments (Tucker et al. 2002) Stent-based venous valves (Pavcnik et al. 2002)

■ **Table 8.3 (continued)**

Type of prosthesis	Matrices and cells	Application
Cardiac valve replacement therapy: <i>with synthetic matrices</i>	Seeding of biodegradable synthetic matrices with different kinds of cells	Animal experiments (Teebken et al. 2005)
Cardiac valve replacement therapy: <i>with biologic matrices</i>	Glutaraldehyde-preserved heart valves of brute origin	Commercially available, clinical routine
	Decellularized heart valves of brute origin	Clinical case reports (Goldstein et al. 2000)
	Cryopreserved human heart valves (<i>homografts</i>)	Clinical routine (Vogt et al. 1999)
	Decellularized cryopreserved human heart Valves (<i>homografts</i>)	Clinical studies (Zehr et al. 2005)
	Decellularized cryopreserved and autologous	Clinical case reports (Dohmen et al., 2002; Cebotari et al. 2006) and animal studies (Steinhoff et al. 2000)
	Re-seeded human heart valves (<i>homografts</i>)	Clinical study (Cebotari et al. 2011)
	Decellularized fresh human heart valves (<i>homografts</i>)	Stent-based pulmonary valve (Lutter et al. 2010; Metzner et al. 2010)
	Small intestinal submucosa (SIS)	
Myocardial regeneration	Combination of liquid matrix preparations With cardiomyocytes or stem cells	Animal experiments (Kofidis et al. 2005; Eschenhagen and Zimmermann 2005)
	Injection of cell suspension	Clinical case reports (Menasché et al. 2001)
Myocardial replacement therapy: <i>with synthetic matrices</i>	In vitro generated conduits	Animal experiments (Ozawa et al. 2004)
Myocardial replacement therapy: <i>with biologic matrices</i>	In vitro generated myocardial patches	In vitro generated myocardial patches (Leor et al. 2000)
	Autologous vascularized SIS	Hata et al. (2010), Tudorache et al. (2009)
	Constructs made out of cell sheets	Animal studies (Shimizu et al. 2006)

9.1 Introduction

The chapter will provide an overview of protocols and therapies in perioperative cardiac surgical intensive care. Due to its broad spectrum, cardiac surgical intensive care cannot be discussed in a single chapter. In this context suggested literature provides a more in-depth representation of the topic.

The chapter is written based on the clinical and chronological course of the patient. However, the hectic schedule of cardiac surgical intensive care unit (CSICU) will frequently alter the temporal schedule of a cardiac surgical intensivist. A seasoned intensivist will be able to make the appropriate decision despite limited time in obtaining information and diagnostics. The content of this chapter is aimed at supporting the cardiac surgical intensivist in this critical task.

9.2 Aims of Intensive Care

One of the basic goals of postoperative intensive care is maintain hemodynamic stability, hemostasis, and adequate oxygenation and ventilation leading to prompt extubation in order to move the patient quickly to the step-down unit.

In this process the patient should wake up neurologically intact, have adequate perfusion and hemodynamics, get extubated promptly, tolerate liquids and solid food, and have adequate pain control.

The prerequisite for this process is preoperative normal function of organ systems. Furthermore, it is expected that appropriate anesthesia induction and maintenance, as well as uncomplicated cardiac surgical operation, have been performed.

Here lay two further aims of intensive care: prevention of complications by appropriate preventive intervention and, in case of issues, efficient and quick treatment of complications.

The length of intensive care stay remains a surrogate for «complicated postoperative course» after open-heart operations. It can be assumed that approximately 75% of the cardiac surgical patients will have an uneventful postoperative course, while 25% will require a prolonged and complicated CSICU stay.

9.3 General Intensive Care

9.3.1 CSICU Admission

The monitored transport of the patient from the operating room to the CSICU has to be performed by the attending anesthesiologist and a member of cardiac surgical team. The report must be communicated directly to the CSICU physician on duty, and it must contain all relevant information about the operation to estimate the therapeutic milestones for the next 12–24 h.

The report should contain all necessary pre- and intraoperative information. A protocol involving standardized transfer reporting is advisable. Here are suggestions for the content of this report:

- Name
- Age
- Size and preoperative weight
- Medical history (comorbidities, risk factors)
- Preoperative medication (sedative agents, antibiotics, antihypertensive medication)
- Preoperative status (any type of complications, difficulties during intubation, abnormal baseline activated clotting time, and other abnormal laboratory values)
- Preoperative diagnosis and details of the surgery performed
- Anesthesia induction and intraoperative medication
- Ventilator settings and abnormalities in blood gas analysis
- Intraoperative course
- Any complications
- Any incomplete coronary revascularization or remaining valvular regurgitation after repair
- ECG findings (signs of ischemia)
- Bleeding tendency
- Number and location of drains and temporary pacemaker electrodes
- Transfused and any remaining blood products
- Intraoperative volume status and cardiac function after weaning off extracorporeal circulation (heart rate, systolic blood pressure, central venous pressure, cardiac output)
- Course of pharmacologic support, actual medication at transfer
- Intraoperative renal function and positive or negative fluid balance

In times of electronic health records, the CSICU admission report may be performed electronically. However, a complimentary verbal report is highly recommended to clarify any questions, issues, and inconsistencies. The verbal report may specifically enhance alertness to specific existing or upcoming potential problems!

9.3.2 Patient Assessment at CSICU Arrival

9.3.2.1 Physical Examination

The physical examination at the time of admission to the CSICU provides critical information that completes the clinical picture in combination with monitoring tools and laboratory and imaging results.

The physical examination at admission on the CSICU should be expeditious and is grossly performed in the form of inspection, palpation, and auscultation. The clinical exam findings at the time of admission are important indicators of the patients' clinical course.

After connecting the patient to the ventilator, both lungs are carefully auscultated, to ensure adequate and equal ventilation of each lung side. Furthermore the heart auscultation may detect any murmurs and rubs and will help in assessing the heart rhythm at admission. Due to opiate injection, bowel sounds are mostly quiet and of no diagnostic significance at this point. The correct position of the nasogastric tube should be confirmed by air insufflation into the tube and simultaneous auscultation of the epigastrium.

The inspection should include the following points: the light reflex of the pupils and the pupil status, any grimacing of the patient, the location and function of all venous and arterial lines and drains, the position of the endotracheal tube, the position of the extremities, dermal color (normal, cyanotic, or pale), evidence of increased jugular vein pressure, and the adequate perfusion of the visible mucous and extremities.

The palpation should include checking the skin turgor and edema, bilateral thorax excursion, the friction of the abdominal wall, and the pulse status of all extremities. To state the degree

of relative hypovolemia, hypothermia, or endogenous and exogenous catecholamine-mediated centralization, the extremities have to be examined equally from both sides from central to periphery, and the results have to be documented. Furthermore the patency of the chest tubes has to be ensured and any intraluminal clots removed.

Finally, the quality and quantity of chest tube drainages have to be analyzed, and the filling state of the pleura vacs on admission has to be documented.

9.3.2.2 Assessment of Anesthesia and Sedation

To appraise the depth of sedation, the intensivist should address the patient first. In case of no response, the patient may be touched on the forehead, for example, or an adequate pain stimulus can be given, as needed. During transportation to CSICU, the patient should preferably have a Ramsay score of 4–5 (■ Table 9.1). The neurological findings are always correlated with the administered drug levels (Ramsay et al. 1974).

■ **Table 9.1** The Ramsay Sedation Scale defines three awake levels 1–3, and three asleep levels 4–6, the latter depending on the patient's response to a light glabellar tap or loud auditory stimulus

Score value	Grade of sedation	Assessment
1	Patient anxious and agitated or restless or both	Mild, inadequate sedation
2	Patient co-operative, oriented, and tranquil	Adequate sedation, pt stable at CSICU
3	Patient responds to commands only	Adequate sedation, pt stable at CSICU
4	a brisk response	Desired level at transport to CSICU
5	a sluggish response	Desired level at transport to CSICU
6	no response	Sedation probably too deep

9.3.2.3 Neurological Status

Glasgow Coma Scale (GCS) is a useful tool in quantifying and monitoring the progress of patient's neurological status (■ Table 9.2). The Glasgow Coma Scale provides a score in the range of 3–15; patients with scores of 3–8 are usually said to be in a coma. The total score is the sum of the scores in three categories. However, the GCS has only a limited use in sedated and intubated patient. Since cerebral ischemia and intracerebral hemorrhage occur in 1–5% of patients undergoing cardiac surgery (Markewitz and Lante 2006), it is important to monitor the pupillary response, the position of the eyeballs, and the motor response of the extremities on CSICU admission and closely in the postoperative course. Frequent neurological exams are essen-

■ Table 9.2 Glasgow Coma Scale and Score

Reaction	Action	Score
Eye opening response	Spontaneous—open with blinking at baseline	4
	Opens to verbal command, speech, or shout	3
	Opens to pain, not applied to face	2
	None	1
Verbal response	Oriented	5
	Confused conversation, but able to answer questions	4
	Inappropriate responses, words discernible	3
	Incomprehensible speech	2
	None	1
Best motor response	Obeys commands for movement	6
	Purposeful movement to painful stimulus	5
	Withdraws from pain	4
	Abnormal (spastic) flexion, decorticate posture	3
	Extensor (rigid) response, decerebrate posture	2
	None	1

According to Teasdale and Jennett (1974), Jennett et al. (1977)

tial in early diagnosis along with prompt diagnostic tools (e.g., cranial computed tomography) to potentially minimize neurological deficit.

9.3.2.4 Volume Status, Centralization, and Body Temperature

The basic principles of postoperative cardiac surgical intensive care are hemodynamic monitoring and the differentiated management of intravascular volume and vasoactive substances, inotropic support, heart rate, and rhythm management. Therefore early on CSICU admission, the intensivist has to estimate patient's intravascular volume status and the degree of centralization or peripheral vasoconstriction. The volume status can be estimated by evaluating core body temperature, central venous pressure (correlated to «positive end-expiratory pressure» on the ventilator), and the undulation of the arterial pressure waveform, the heart rate, and blood pressure.

If there are no signs of volume overload (hypervolemia) at the time of CSICU admission (pulmonary edema, central congestion on the thoracic X-ray, right heart failure, insufficiency of the tricuspid valve), volume substitution should be considered to reduce hypotension due to rewarming and the concomitant loss of peripheral resistance.

9.3.2.5 Heart Rhythm and Heart Rate

To achieve an adequate cardiac output, a heart rate of 60–120 bpm with a cardiac output of >2.0 l/min/m² body surface has to be established. Regular atrial and ventricular function in sinus rhythm or under pacemaker sensing/pacing is helpful in maintaining adequate cardiac output. The frequent episodes of bradycardia or tachycardia after cardiac surgery require the continuous heart rate monitoring. Patient's abnormal rhythm should be correlated to invasive arterial blood pressure monitoring and the pulse oximetric curve. In case of discrepancies, and when the electronic measurement is not reliable, the pulse may be palpated.

9.3.2.6 Secure the Pacemaker Function

Depending on the operation and the occurrence of preoperative or intraoperative arrhythmias, the temporary pacemaker wires are attached to the right atrium and the right ventricle and, in special cases, also to the left ventricle. If heart rhythm

disturbances occur in the postoperative course, the cardiac output will be reduced, and this may require external electrical stimulation. Therefore the function of the pacemaker wires has to be tested and documented at the time of CSICU admission: proper capture and sensing is critical!

9.3.3 Basic Monitoring and Diagnostics

To assess all relevant parameters in cardiac surgery patients, various monitoring systems have to be intertwined.

Basic monitoring of CSICU patients includes (Carl et al. 2010):

- Continuous ECG and 12-lead ECG
- Invasive and noninvasive blood pressure measurement
- Measurement of central venous pressure
- Pulse oximetry
- Input and outputs (chest tube drainage, volume input, and urine output)
- Body core temperature measurement

If the postoperative course will be complicated, additional monitoring will be required. After CSICU admission and review of the basic monitoring tools, the diagnostic tools may be supplemented by:

- Mixed venous and arterial blood gas analysis
- Chest X-ray, a - p (lying and in inspiration)
- Routine laboratory diagnostics

9.3.3.1 ECG and 12-Lead ECG

To get a basic monitoring for arrhythmia and ischemia, continuous ECG monitoring is required on CSICU. In lead II the electrical axis is parallel to the sinus node and the AV node. Usually the P wave is clearly detectable in lead II, so supraventricular and ventricular rhythm disturbances can be differentiated. Lead V5 should be added on the monitor in patients with coronary artery disease to recognize any ischemia at the anterior and lateral wall. An ST-segment analysis is recommended for each ECG monitoring. In cardiac surgical patients, a 12-lead ECG should be performed routinely for any patient at CSICU admission and daily on the first three postoperative days. If patients stay longer on CSICU, indication for additional ECG depends on clinical status, especially if any ST-changes occur as seen on the monitor.

9.3.3.2 Invasive Blood Pressure Monitoring

The postoperative measurement of the arterial blood pressure is an essential part of CSICU monitoring. The acquisition of the arterial pressure can be carried out in two ways: a noninvasive method using a blood pressure cuff or an invasive method requiring cannulation of the radial or femoral artery. The noninvasive measurement is error prone and inadequate for a safe blood pressure monitoring. The invasive blood pressure measurement allows close pressure monitoring as well as assessment of the volume status of the patient due to respiratory undulation of the pressure curve. Furthermore during mechanical ventilation and under inotropic and vasopressor administration, arterial blood gas may be drawn from the arterial line for easy blood sample and laboratory analysis.

Possible errors occur if the pressure transducer is not correctly zeroed or if any air bubbles remain in the pressure lines. The air leads to a distortion of the pressure curve due to damping. The mean arterial pressure (MAP) is utilized routinely in CSICU. It can be calculated after measuring the systolic (AP_{syst}) and diastolic (AP_{diast}) blood pressure using the following formula:

$$\text{MAP [mm Hg]} = \text{AP diast} + 1/3(\text{AP syst} - \text{AP diast})$$

9.3.3.3 Measurement of Central Venous Pressure

The central venous pressure (CVP) is invasively measured in the upper caval vein in about 1–2 cm distance the right atrium. CVP correlates—in absence of an insufficiency of the tricuspid valve—with the end-diastolic pressure in the right ventricle. The CVP value depends on the intravascular volume, the peripheral vascular resistance, the right ventricular ejection fraction/compliance, the pulmonary artery resistance, and the intrathoracic pressure (PEEP ventilation/intrinsic PEEP).

The CVP is low in relative volume-deficient patients and elevated due to volume overload, right heart failure, pulmonary embolism, pericardial tamponade, tension pneumothorax, and in ventilated patient with high PEEP (CVP_{real} = CVP - PEEP).

The diagnostic value of the CVP is limited due to the high volume compliance of the venous system. However, if followed as a trend, the CVP provides useful information about the volume

status as well as the right ventricular preload and compliance. It is helpful to know the CVP value at the time of weaning from extracorporeal bypass and correlating cardiac function with corresponding right ventricular preload help assist as guideline for postoperative volume management.

9.3.3.4 Pulse Oximetry

The percutaneous spectrophotometric determination of oxygen saturation is a very useful and noninvasive and continuous approach to measure the peripheral arterial oxygen saturation (SaO_2). It is displayed as a pulse synchronous undulating curve. The SaO_2 is defined as percent of oxygenated hemoglobin denominated by the sum of oxygenated and deoxygenated hemoglobin. It can be compared in its diagnostic relevance to the partial pressure of oxygen (paO_2).

The respiratory monitoring allows the assessment of pulmonary oxygen uptake and allows, by knowing the actual hemoglobin concentration, the assessment of the arterial oxygen supply of the tissue. Additionally, the acquisition of the pulse curve shows the mechanical heart function.

Pulse oximetry cannot discriminate among oxygenated hemoglobin, carboxyhemoglobin, and methemoglobin. In these cases, the measured SaO_2 concentration is actually lower than displayed SaO_2 given concomitant dyshemoglobinemia in the bloodstream.

Estimated oxygen saturations (SaO_2) at 40 mmHg carbon dioxide, at a pH 7.4, and physiological body temperature are depicted in **Table 9.3**.

9.3.3.5 Fluid Balance

The postoperative fluid balance is close monitoring of fluid input and output (I&O) including urine output and chest tube and nasogastric drainage. In the first 24 h after operation, the hourly documentation of I&O may be useful. However, after the first postoperative day, the interval can be extended to every 4 h. Separate documentation of crystalloid versus colloid volume resuscitation in the postoperative phase has not been clinically useful and has fallen out of favor.

Table 9.3 Reference values for estimated oxygen partial pressure (paO_2) based on measured oxygen saturation (SaO_2) by pulse oximetry (see text)

Parameter	Values					
PaO_2 [mmHg]	26	35	40	60	90	150
SaO_2 [%]	50	66	75	90	95	100

9.3.3.6 Chest Tube Output

On admission, the filling state of the pleura vacs has to be documented. The chest tube output is an important indicator for postoperative bleeding in cardiac surgery. However, the chest tubes have to be frequently checked by active manipulation (gentle «milking» motion) for proper drainage. Breathing and pulse synchronous movements of the liquid level are also an indication for patency. In case of a pulmonary parenchymal injury, there will be breath-dependent air bubble leaking from the first fluid chamber.

The total chest tube output should ideally be less than 100 ml per hour. If the drainage is more than 100 ml per hour, it may be necessary to check one or more of these blood coagulation parameters:

- Activated clotting time
- Prothrombin time (PT)
- Partial thromboplastin time (PTT)
- Level of fibrinogen
- Platelet count
- Functional coagulation tests such as thromboelastogram

If the patient is stable without evidence of pericardial tamponade, the abnormal coagulation values should be normalized first. If a high chest tube is combined with a significant hemoglobin drop or a new pericardial effusion leading to atrial or ventricular collapse and circulatory instability, the patient should be taken back for mediastinal exploration and control of hemorrhage (see also **Section 9.5.3 «Bleeding Complications and Pericardial Tamponade»**).

9.3.3.7 Measurement of the Body Temperature

The body temperature should be measured continuously. Among others, it affects the values of the blood gas analysis. Furthermore, hypothermia can exacerbate bleeding tendencies in the early postoperative course. For this reason, the temperature should be collected at least to every arterial blood gas sample taking. Typically, a four-hourly interval is recommended. The temperature can be measured by using a Foley catheter with integrated temperature sensor or transesophageal or intravascular by the Swan-Ganz catheter or by infrared (middle ear temperature) approach.

The interpretation of body temperature is always intertwined with the clinical picture: while in the postoperative rewarming phase and peripheral vasoconstriction, the body temperature

can arise to 102 °F (39 °C) in 2–3 h and decreases to normal values after vasodilatation; a temperature rise combined with peripheral vasodilatation is rather a sign of prolonged systemic inflammatory response (SIRS) or septic event.

9.3.3.8 Blood Sample Analysis

A blood gas analysis should be performed immediately after CSICU admission. Furthermore, blood gas sampling should be repeated if cardiopulmonary instability occurs or if the ventilation settings have been changed (here with a time interval of 30 min after change). At an inspiratory oxygen fraction (FiO₂) of >0.6, a blood gas analysis is recommended every 4–8 h intervals.

To maintain an «oxygen reserve» during the transport from the OR to the CSICU, the patient is generally transferred with a FiO₂ of 1.0. Furthermore, manipulations like disconnection from the ventilator or other problems can be better managed, and the lung function can be estimated on CSICU admission. If a patient under controlled ventilation with an FiO₂ of 1.0 for transport have a body temperature-corrected PaO₂ of <200 mmHg (Horovitz quotient of <200, normal value in pulmonary healthy patients 350–450), a pulmonary problem can be expected (For Horovitz quotient see also ► paragraph Respiratory Failure in Sect. 9.5.4 Lung and Mechanical ventilation, p. 226). Then the need of special attention and close controls is necessary. In patients with opened pleural cavities, an initial PEEP of 8 cm H₂O is recommended to reduce atelectasis and may be weaned down prior to extubation.

Point-of-care laboratory tests using specialized blood gas-analyzing machines, prompt results can be obtained in the CSICU including determination of the acid-base balance, concentrations of electrolytes (especially potassium), and the hemoglobin and blood glucose values.

9.3.3.9 Chest X-Ray

Soon after the patient arrives and is situated in his bed, a chest X-ray is mandatory in order to judge the correct position of any indwelling catheters, endotracheal tube, and chest drains as well as proper lung expansion. The scan should be done in ventilatory inspiration. While acutely the chest X-ray checks for intrathoracic fluid accumulation (e.g., hemothorax) or pneumothorax as well as lung congestion in left heart failure, repeated daily chest X-rays for the first three postoperative days are an ideal follow-up tool to screen cardiopulmo-

nary status. Additional chest X-rays are only ordered for specific questions arising from changes in the clinical status of the patient.

9.3.3.10 Routine Laboratory Investigations

Cardiac surgical operations change important physiological processes: changes to the body temperature, full heparinization and reversal along with heparin rebound, intravascular fluid changes, electrolyte shifts, activation of inflammatory cascades, etc. During surgery only a few laboratory values are tested. Therefore, upon CSICU admission, checking the following parameters may be necessary:

- Blood count
- Activity of lactate dehydrogenase (LDH)
- Urea and creatinine
- PT value
- PTT
- Antithrombin III levels
- Activity of creatine kinase (CK) and CK-MB
- Troponin I levels
- Activity of aspartate transaminase (AST), also known as serum glutamic oxaloacetic transaminase (SGOT)
- Activity of alanine transaminase (ALT), also known as serum glutamic-pyruvic transaminase (SGPT)
- Concentration of C-reactive protein (CRP)
- Lactate
- Magnesium

In an uneventful course, a 12-h lab check interval should be adequate. Additionally, daily laboratory test may include the function of the liver, the lactate, and the total protein and albumin levels. The monitoring of blood glucose levels and electrolyte values is additionally measured with the periodic blood gas analysis. Other laboratory parameters are checked as indicated.

9.4 Objectives and Standard Procedures in CSICU

9.4.1 Objectives

Well-run CSICU should have a clear definition of primary end points of therapeutic regimen. This helps to identify patients with prolonged and complicated course that require an escalation of monitoring and/or an adjustment of the current therapy.

To recognize the optimal time point for adjusting the therapy, the objectives and therapeutic goals and their progress require a close monitoring and documentation (usually once per shift). The following criteria have to be achieved during the first 24 h of an uncomplicated postoperative course:

- Awake patient (Ramsay score of 2) with no evidence of neurological deficit
- Warm extremities without edema with even balance
- No abnormalities in the blood gas analysis compared to patient's baseline
- No evidence of bleeding or clotting disorder
- Hemoglobin concentration of >8 mg/dl
- SaO₂ of >92 % (peripheral)
- MAP of >65 mmHg
- Sinus rhythm with a heart rate of 60–90/min
- Adequate left and right ventricular function on echocardiogram
- CVP of 8–12 mmHg
- Stable urine output >0.5 ml/kg/h
- Normal lactate levels

With increased age and patient's comorbidities, there is increased risk for adverse events associated with complicated operative and postoperative course. The clinical experience shows that errors in the early postoperative period may lead to life-threatening complications, or at least a complicated course, requiring more costly expansion of monitoring, therapeutic arrangements, and longer ICU stay. In the following, we will discuss various therapeutic goals and regimens, some supported by published guidelines.

9.4.2 Sedation and Analgesia

For the patient with an uncomplicated course, a differentiated analgesia and sedation is suggested, aiming for antianxiety, analgesia, and vegetative protection. According to the current guidelines, various combinations of drugs are available for adequate analgesia and sedation. Preferably, the concept has to be adapted to the intraoperative anesthetic management to avoid unnecessary change of medication, possibly causing adverse interactions of various analgesics and sedatives due to different pharmacokinetics. ■ Table 9.4 provides a list of these medications.

To attenuate autonomic responses during weaning from mechanical ventilation and in association with the extubation, sedation can be complemented with clonidine (IV clonidine is not available in the USA):

- Objective of clonidine use: weaning
- Drug (active ingredient): clonidine
- Drip dosage: 1.5 mg/50 ml
- Concentration: 0.03 mg/ml
- Infusion rate: 1–4 ml/h/70 kg body weight

A deep sedation in cardiac surgery should only be used in special cases:

- Complicated long-term mechanical ventilation
- Abdominal positioning (usually for severe hypoxemia)
- Inadequate oxygen delivery to peripheral organs caused by sepsis or multi-organ dysfunction syndrome

■ Table 9.4 Overview of routinely used sedatives and their dosages

Duration of sedation	Drug	Drip dosage [mg/50 ml]	Concentration [mg/ml]	Infusion rate [ml/h/70 kg]
Up to 24 h	Propofol 1 %	500	10	3–10
	Remifentanyl	5	0.1	1–12
24–72 h	Midazolam	90	1.8	1–7
	Sufentanyl	0.5	0.01	1–10
More than 72 h or for unstable patients	Midazolam	90	1.8	1–7
	Ketamine	1250	25	2–10

Besides sedation and analgesia, peripheral analgesics are administered. For slight or moderate pain, the following nonopioid analgesics can be used:

- Acetaminophen: 1 g q6h per mouth or nasogastric tube (maximum dosage, 4 g/day)
- Ibuprofen: 600 mg q8h per mouth or nasogastric tube (maximum dosage, 2.4 g/day)
- Ketorolac: 30 mg q6h intravenous (maximum dosage, 120 mg/day)
- Tramadol: 50–100 mg q4–6h per mouth or nasogastric tube (maximum dosage, 300 mg/day)

These medications have to be adapted to the patient (allergies, age, renal function) and to the operation (ketorolac may cause increasing bleeding tendency in postoperative course) and should be given orally as soon as possible. Oral or parenteral opioids should be used complementary for severe pain. The goal is to maintain a pain score below 2–3 (0 meaning no pain, 10 being the worst pain) to allow adequate breathing and early ambulation.

9.4.3 Gastrointestinal Ulcer Prophylaxis

Physiologic stress associated with illness and hospitalization is known to result in gastrointestinal ulceration, especially among the critically ill. The complication of this stress-related mucosal disease could be prevented with appropriate application of pharmacologic prophylaxis. Stress-induced ulcer (SU) has decreased significantly in the last 25 years (less than 0.5%), but remains associated with significant morbidity and mortality. This can be reduced by early enteral nutrition. An ulcer prophylactic medication is generally recommended in CSICU, because cardiac surgical patients often presented with at least one risk factor for stress-induced ulcer. This is generally achieved with proton pump inhibitor (PPI) or H₂-receptor antagonist (H₂RA). PPI medications are preferred by some due to less interaction with other medications and better efficacy. Common drug regimen is esomeprazole 20–40 mg enteral or parenteral every day.

There are, however, no studies available, which have demonstrated a superiority of PPI over H₂RA

for SU prophylaxis. Additionally, PPIs have been associated with a risk of community-acquired *C. diff.* (Aseeri et al. 2008; Buendgens et al. 2014), osteoporosis (Yang et al. 2006), pneumonia (Laheij et al. 2004; Sarkar et al. 2008), and interstitial nephritis (Leonard et al. 2012). In centers preferring H₂RA as first-line medication for SU prophylaxis, PPI may still be used in those patients who had suffered from a more recent GI hemorrhage (Alhazzani et al. 2013; MacLaren and Campbell 2014).

9.4.4 Antibiotic Therapy

The importance of prophylactic antibiotics to reduce surgical site infections (SSI) has been clearly demonstrated in a number of placebo-controlled studies. SSIs and particularly sternal and mediastinal infections have implications for significantly increasing both morbidity and mortality. Based on availability and cost, it is reasonable to use cefazolin (a first-generation cephalosporin) for standard cardiac surgical prophylaxis, given the fact that most randomized trials could not discriminate between various cephalosporins.

Based on The Society of Thoracic Surgeons' guidelines, the duration of antibiotic prophylaxis should not be dependent on indwelling catheters such as chest tubes, as practiced in some centers. There is evidence indicating that antibiotic prophylaxis of 48-h duration is effective.

Edwards et al. recommend in a 2006 published guideline to continue the perioperative antibiotic therapy for a maximum of 48 h to avoid the development of antibiotic resistance (Edwards et al. 2006). In order to reduce multiresistance in the CSICU, the duration of antibiotics should be only prolonged for plausible and documented reasons.

In case of the occurrence of fever in combination with septic clinical picture within 48 h postoperatively, the perioperative antibiotic regime should not be continued, rather, changed and adapted.

9.4.5 Administration of Blood and Blood Products

The use of the extracorporeal circulation does significantly alter the primary and secondary

hemostasis and the coagulation system. Additionally, a high percentage of cardiac surgical patients are on dual antiplatelet medications, altering the coagulation profile as well. Therefore, many reference values for the coagulation profile are approximations. ■ Table 9.5 contains expected values and their development.

Even a significant abnormality in the coagulation profile may not require immediate therapeutic intervention. Before any values are treated, the clinical picture has to be taken into account for decision-making. Only the context of clinical presentation and laboratory extents should lead to a therapy—for example, an elevated blood loss from the chest tubes has to be treated—rather a deranged coagulation profile without any clinical evidence of bleeding. The necessity of blood products has to be checked in any case.

9.4.5.1 Packed Red Blood Cells (PRBC)

The cutoff for transfusion of PRBC has been controversial. There is more evidence supporting the fact that PRBC transfusion increases morbidity and mortality, along with increased local and systemic infectious complications (Engoren et al. 2002; Whitson et al. 2007). However, it is not clear whether the transfusion itself or the comorbidities of the patients requiring transfusions are the ultimate culprit.

STS guidelines from 2011 suggests three important preoperative risk factors are linked to bleeding and blood transfusion: (1) advanced age

(age >70 years), (2) low RBC volume either from preoperative anemia or from small body size or from both, and (3) urgent or complex operations usually associated with prolonged CPB time and non-CABG procedures.

The transfusion of PRBC in patients with a hemoglobin level less than 7 g/dL is reasonable, but it is based on good evidence (class IIb, level of evidence C), and the transfusion in patients with a hemoglobin more than 10 g/dL, trying to improve the oxygen transport, is not recommended (class III, level of evidence C) (Ferraris et al. 2011).

In clinical practice the transfusion of PRBC correlates to the patient's condition. Patients in life-threatening situation should receive blood even if the hemoglobin level is not under 7 g/dL. If a surgical problem (e.g., surgical site suture bleeding) is suspected, a re sternotomy has to be performed promptly.

Of particular concern are the side effects of blood and blood products:

- Hemolytic transfusion reaction of immediate type
- Hemolytic transfusion reaction of the delayed type
- Febrile, nonhemolytic transfusion reaction
- Allergic transfusion reaction
- Transfusion-related acute lung injury (TRALI)
- Transfusion reactions due to bacterial contamination
- Transfusion-associated infections

Transfusion-associated respiratory insufficiency may exacerbate the clinical picture in a multi-morbid patient, complicating the postoperative differential diagnosis and therapeutic approach.

9.4.5.2 Platelet Concentrates

The use of platelet concentrates in cardiac surgery is necessary due to platelet dysfunction after CPB. A platelet transfusion is necessary for unstable patients with active bleeding if the platelet count is <50/nl (<50.000/μl). In hemodynamically stable patients, even without bleeding, the threshold for transfusion is a platelet count of <10/nl (<10.000/μl). After transfusion of one unit of platelet concentrate, the expected raise of the platelet count will be approximately 30/nl (30.000/μl).

Furthermore, according to STS guidelines, the use of intraoperative platelet plasmapheresis is reasonable to assist with blood conservation

■ Table 9.5 Reference values for the coagulation profile on admission on the CSICU and their postoperative changes

Extent	On admission	Postoperative course
Activated clotting time (ACT)	Basic value	No change
Thrombocyte count	>50.000/μl	Increase
Prothrombin (PT) value	>50 %	Increase
Activated partial thromboplastin time (aPTT)	<40 s	Decrease
Antithrombin III level	>60 %	Increase

strategies as part of a multimodality program in high-risk patients if adequate platelets yield can be reliably obtained (Ferraris et al. 2011).

9.4.5.3 Fresh Frozen Plasma (FFP)

FFP contains all coagulation factors and their inactivators. Considered indications for transfusion of FFPs are the emergency treatment of a clinically relevant bleeding and an acute bleeding due to a complex coagulation disorder, expected after prolonged CPB, and the loss and/or a dilutional coagulopathy in patients with severe blood loss and extensive transfusions. In these cases and as rule of thumb, a unit of FFP is transfused for each four PRBC transfusions.

FFPs should not be given to expand volume. Here are further recommendations from STS guidelines for blood conservation (Ferraris et al. 2011):

1. Plasma transfusion is reasonable in patients with serious bleeding in context of multiple or single coagulation factor deficiencies when safer fractionated products are not available (class IIa, level of evidence B).
2. For urgent warfarin reversal, administration of prothrombin complex concentrate is preferred, but plasma transfusion is reasonable when adequate levels of factor VII are not present in prothrombin complex concentrate (class IIa, level of evidence B).
3. Transfusion of plasma may be considered as part of a massive transfusion algorithm in bleeding patients requiring substantial amounts of red blood cells (class IIb, level of evidence B).

9.4.5.4 Prothrombin Complex Concentrate

Prothrombin complex concentrates (PCCs) are hemostatic blood products containing four vitamin K-dependent clotting factors (II, VII, IX, and X), as well as the anticoagulant inhibitor proteins C, S, and Z (Ansell et al. 2004). They are a useful, reliable, and fast alternative to fresh frozen plasma for the reversal of the effects of oral anticoagulant treatments (vitamin K antagonists). The use of PCC rather than FFP is recommended for Coumadin reversal in patients with major bleeding (Baglin et al. 2006; Baglin et al. 2007). The use of PCC is not the first choice in bleeding complications, because PCC stems from a large pool of donors and puts the recipients at increased risk of anaphylactic shock, viral transmission, etc.

Recommended PCC dose is 25–30 IU/kg as initial bolus.

9.4.5.5 Recombinant Factor VIIa (rFVIIa)

The use of rFVIIa has a limited indication in high-risk patients as last resort. Recommended dose ranges vary from 11 to 200 µg/kg body weight. We use 90 µg/kg body weight to be administered within 2–5 min, preferably immediately after FFP transfusion. If the bleeding does not stop, a second infusion may be considered after 20–30 min. There are varying results in literature concerning thromboembolic side effects from 5% (Warren et al. 2007) to no increased risk (Kluger et al. 2007; Chapman et al. 2011). According to STS guidelines, rFVIIa concentrate may be considered for the management of intractable nonsurgical bleeding that is unresponsive to routine hemostatic therapy after cardiac procedures using CPB (class IIb, level of evidence B).

9.4.5.6 Antithrombin III (AT III)

Antithrombin III concentrates has a class I recommendation according to STS guidelines for blood conservation: AT III is indicated to reduce plasma transfusion in patients with antithrombin-mediated heparin resistance immediately before cardiopulmonary bypass (level of evidence A). In case of heparin resistance, and instead of FFP transfusion, it is strongly suggested to administer AT III to improve activated clotting time for the CPB.

Various dosing algorithm exists based on baseline antithrombin activity levels. If such levels are not available in the operating room, 1,000 IU is given parenterally, and the activated clotting time is remeasured.

9.4.6 Nutrition

Poor nutritional status can adversely affect thoracopulmonary function in spontaneously breathing and mechanically ventilated patients with respiratory disease by impairment of respiratory muscle function, ventilatory drive, and pulmonary defense mechanisms. The questions of whether, when, and how intensive care patients must be fed are essential in planning the nutrition plan at the CSICU. In critically ill patients, including cardiac surgical patients, an underfeeding is related with a poor outcome (Preiser et al. 2015). It is recommended to consider enteral feeding in patients who will not

have oral intake within the next 5 days. An enteral nutrition is preferable, unless the patient is on high-dose inotropes, making adequate gut perfusion unlikely, or there is an enteral passage malfunction due to injury or surgical operations. Enteral feeding is started after the position of jejunal nutrition tube has been confirmed on X-ray and with elevation of the upper part of the body. For patients with ventilator failure, it is recommended to avoid overfeeding, causing nutritionally associated hypercapnia. This may delay timely extubation.

It is important to provide patients with an estimated prolonged intubation time with additional calories, to be started within the first 24 h. The required amount of calories is 20–25 kcal/kg body weight/day (Kreymann et al. 2006). Controlling subsequent hyperglycemia, therefore reducing the risk of infection using insulin drip protocols, remains critical aspect in ICU nutrition (van den Berghe et al. 2001; Bhamidipati et al. 2011; Haga et al. 2011).

Optimal support would establish neutral or positive nitrogen balance, depending on the need for protein repletion. In the critically ill patient with renal function impairment, this can be accomplished by giving 1–3 g of protein/kg daily. Generally, this amounts to approximately 20% of total calories being administered as protein. While recommendations for an appropriate substrate mix of carbohydrates and fats vary, generally 60–70% carbohydrates are given with 20–30% fats.

9.4.7 Discharge from ICU

The decision whether the patient is ready to be transferred from CSICU should only focus on medical criteria. Most cardiovascular patients will be transferred to an EKG-monitored step-down unit for further recovery. Patients with ongoing organ support, hemodynamically unstable patients, patients with complex heart rhythm disturbances, or patients with a Ramsay score >3 have to stay in the CSICU.

It is common practice that the daily need for ICU capacities deforms the clinical picture of the patient to a better one. Unfortunately this may lead to higher readmission rate to the CSICU. If the readmission rate exceeds 5%, discharge criteria should be revisited.

9.5 Special CSICU Arrangements

9.5.1 Introduction

9.5.1.1 The Importance of Communication

Especially in critically ill patients, the importance of communication with the patient himself and his family, but also with the medical and nonmedical staff on the CSICU, is of great importance. The clinical situation of the patient as well as the medical course for the next 24 h has to be evaluated and discussed in this «family-and-CSICU-staff team.» It is important to create a mutual trust, especially if serious and final decisions have to be made. Additionally clerical or psychological support can be an important part of the family-and-staff team and should be consulted early, especially in a complicated course. The bulk of problems can be avoided using open communication and care, whereas poor communication skills and a lack of understanding may lead to complaints from patient, family members, or health-care providers.

9.5.1.2 Incidence of Organ Malfunction and Failure

To predict the incidence of organ malfunction and failure of CSICU patients, different scores can be used which take preoperative data into account. ■ Table 9.6 is a general overview of prevalence and mortality rates with multiple organ failure according to our own experience (Markewitz and Lante 2006).

One-fourth of patients will have a CSICU stay of more than 48 h. This is closely related to the

■ Table 9.6 Prevalence and mortality of multi-organ failure after cardiac surgery

Parameter	Organ complications/failure				
	Circulatory system	Lungs	Kidney	Intestine	Central nerve system
Prevalence (%)	4–7	3–9	1–5	1–3	1–5
Mortality (%)	38	20–25	40–80	10–100	20–25

From Markewitz and Lante (2006)

preoperative risk and an increased use of resources (Giakoumidakis et al. 2011). It is obvious that failure of one or more organ system will influence the physiological function of the other organ systems (Sealy and Christou 2000). Clinical practice shows that the right therapeutic strategy leads to a recovery of the malfunction organ, but the interactions between the different systems are still undiscovered. This lack of knowledge is one reason for the high mortality in organ failure. As the knowledge of these interactions grows, it might be possible to influence them, to decrease mortality. The mission of the intensivist is to define the therapeutic course as clearly as possible and adjust it, as needed.

9.5.2 Circulatory System

9.5.2.1 Postoperative Physiology and the Incidence of Its Failure

The postoperative cardiac physiology is modified depending preoperative cardiac anatomy and physiology and the type of index operation. For the postoperative CSICU therapy, the awareness and knowledge of prevalent postoperative temporarily impaired cardiac function are important. A reduced myocardial compliance leads to a stiffer ventricle with higher intracardiac filling pressures. Preoperative risk factors, such as advanced age, hypertension, decreased left ventricular ejection fraction (<30%), a left main stem stenosis, diabetes in combination with its vascular transformations, renal insufficiency, or pulmonary disease, as well as intraoperative complications, increase the risk of postoperative heart failure (St. André and DelRossi 2005). The treatment strategy should include preload optimization and administration of intravenous inotropes and vasopressors. High dosages of parenteral drugs are necessary in one-third of the patients (Vargas-Hein et al. 2006) and mechanical circulatory support in 4–5% (Vargas-Hein et al. 2006).

9.5.2.2 Goals of Postoperative Cardiovascular Therapy

The goal of postoperative cardiovascular therapy is defined to maintain a sufficient tissue perfusion and a normalization of the oxidative metabolism (Carl et al. 2010). The required blood oxygen saturation is directly associated with lung function, cardiac output, and intravascular volume.

Optimal ranges for postoperative cardiovascular parameter are:

- Mean arterial pressure (MAP) of >65 mmHg
- Central venous pressure (CVP) of 8–12 mmHg (in dependence on the ventilation)
- Diuresis of >0.5 ml/kg/h
- Lactate concentration of <3 mmol/L
- Central venous oxygen saturation (ScvO₂) of >70% and mixed venous oxygen saturation (SvO₂) >65%
- Cardiac index of >2.0 L/min/m²
- Pulmonary capillary wedge pressure (PCWP) of 12–15 mmHg
- Left ventricular end-diastolic area index (LVEDAI) of 6–9 cm²/m²
- Intrathoracic blood volume index (ITBVI) of 850–1,000 ml/m²
- Global end-diastolic volume index (GEDVI) of 640–800 ml/m²

The MAP as tissue perfusion pressure and the CVP as index for right ventricular preload are recommended as basic ICU pressure monitoring (Carl et al. 2010). Furthermore the hourly produced urine as a marker for a sufficient renal glomerular perfusion, the serum lactate level as a marker for a sufficient end-organ tissue perfusion and oxygenation, and the central venous oxygen saturation—as approximate mixed venous oxygen saturation—should be also considered as basic postoperative monitoring.

If the cardiac function is impaired, more cardiac parameters are required to refine the therapeutic course (extended monitoring). A Swan-Ganz catheter should be placed to monitor the mixed venous oxygen saturation and the pulmonary capillary wedge pressure. The left ventricular end-diastolic area index (an approximate for left ventricular preload) should be measured using transesophageal echocardiography. The intrathoracic blood volume index and the global end-diastolic volume index are also used to determine the left ventricular preload and are obtained analyzing the pulse curve contour.

9.5.2.3 Diagnostic Approaches in Postoperative Cardiovascular Therapy

The following findings are consistent with low cardiac output syndrome (LCOS), requiring prompt attention and therapeutics:

- MAP of <60 mmHg
- Urine excretion of <0.5 ml/kg/h for more than 1 h
- SvO₂ of <60% in a patient with SaO₂ of 98%
- Lactate concentration of >2.0 mmol/L
- Peripheral vasoconstriction with cold extremities as a sign of centralization

The immediate initiation of therapy for low cardiac output syndrome is critical and directly associated with outcome, similar to the septic patients (Polonen et al. 2000; Rivers et al. 2001).

9.5.2.4 Pathophysiology, Clinical Presentations, and Differential Diagnosis of the Postoperative Low Cardiac Output Syndrome (LCOS)

Usually the immediate therapy will solve the problem. Therefore the correct choice of the therapy is primarily dependent on the cause.

The most common causes of postoperative LCOS are:

- Volume deficiency (especially bleeding)
- Rhythm disturbances
- Pericardial tamponade
- Myocardial infarction
- Left heart failure
- Right heart failure
- Vasoplegic syndrome
- Maximum variant: cardiovascular arrest

A tension pneumothorax and a circulatory compromise due to unfavorable mechanical ventilation should be excluded as part of the differential diagnosis. In the first step, easily correctable problems should be eliminated, for example, lack of volume and arrhythmias.

■ ■ Lack of volume

A lack of volume will present as a low CVP and a respiratory undulation of the blood pressure curve. The main cause of a lack of volume is the postoperative blood loss, consistent with increased chest tube output, if the drains are not clogged.

The causal therapy is to optimize the preload by fluid administration. There are two different fluid solutions available: crystalloid solutions that serve as full electrolyte solutions and colloids, such as hydroxyethyl starch (HES, nonionic volume expander), succinylated gelatin solution, or human albumin. There is no reason not to use HES, and there is no new scientific literature on this issue.

From total crystalloid volume infusion, at least 25% stay in the intravascular space. In comparison to colloids, more crystalloids have to be administered to have an equivalent preload-increasing effect. Therefore colloid transfusion especially human albumin in 5 or 25% concentration is preferred in the CSICU. However, it is not clear whether any choice of fluid solutions will improve patient's survival.

The side effect of synthetic colloids is anaphylactic reaction especially after administration of gelatin products, whereas the succinylated forms are less reactive. Increased bleeding complications and renal function impairment after HES infusion have been documented, in particular in the high-molecular, high-substituted solutions. The complication rate of currently used low-molecular, low-substituted solutions is very low, keeping the daily dose limit of 50 ml/kg in mind. Albumin has anti-inflammatory effects, very helpful in patients with poor nutritional status or liver disease, and—in concentrated form and with increased osmolarity—may help reduce peripheral edema. However, there is a very small risk of infection, and therefore the use of albumin should be wisely considered. Last but not least, it is important to stress that blood and blood products are not appropriate for volume replacement therapy (Ferraris et al. 2011). Unless hemoglobin is low anyways, or blood is the volume missing, like in bleeding states.

■ ■ Rhythm disturbances

While evaluating the volume status, the heart rhythm should be analyzed, and obvious hemodynamically compromising rhythm disturbances have to be treated immediately. Details will be given in the following. If there is any evidence of LCOS after correction of preload and dysrhythmias, the extended monitoring has to be implemented to find the cause of the circulatory impairment.

■ ■ Pericardial tamponade

Pericardial tamponade is associated with elevated CVP, decrease of the urine production, and cold extremities, and it is a clinical diagnosis. The X-ray of the chest may show an enlarged mediastinum with a «tent sign.» A transesophageal echocardiography (TEE) should confirm the clinical diagnosis, with compressed atria or right ventricle as well as respiratory variation of

mitral valve inflow; however, a TEE comes rather late during this often rather rapid process. It is commonly associated with decreasing chest tube output after significant output just before, consistent with clogged drains. A sterile suction of chest tube may be attempted; however, if the drains cannot be reopened and bleeding is thought to be due to «hypoprolenemia» (slang for missing sutures), a rethoracotomy has to be performed promptly. If the patient is in an unstable condition, the tamponade has to be treated immediately at the CSICU. Having sternotomy carts, established protocols, and trained CSICU nurses can make this procedure more efficient and successful.

■ ■ Myocardial infarction

The occurrence of a perioperative myocardial infarction may be recognized in the ECG with typical ST elevation or echocardiogram findings of regional wall abnormalities. It is accompanied by rhythm disturbances, elevated myocardial markers in the serum such as troponin, CK, and CK-MB (understanding that these markers are frequently elevated without myocardial infarction), up to hemodynamically unstable patients. An upward trend in CK and CK-MB serum levels in sequential analyses is more disturbing than an isolated high value. If the patient is stable enough to be transported to the cath lab, an immediate coronary angiography should be performed. The cath result may mandate an interventional angioplasty or another cardiac operation. If the patient's condition is too critical or if there is no further intervention possible, the acute circulatory failure has to be treated medically using nitroglycerin, aspirin, β -blockers, an adequate analgesia, and heparin, or more advanced therapies such as balloon pump and ventricular assist and extracorporeal membrane oxygenation (Antman et al. 2004).

If myocardial infarction is excluded, it is important to take the following differential diagnosis into account: left heart failure, right heart failure, biventricular failure, or vasoplegic syndrome. To gain information the extended monitoring will be necessary.

■ ■ Left heart failure

The failure of the left ventricle is one of the major complications after cardiac surgery. Predisposing factors that cannot be influenced are:

- Advanced age
- The extent and severity of underlying heart disease, especially preexisting reduction of left ventricular ejection fraction
- Previous cardiac surgery
- Presence of peripheral vascular disease
- Urgency of index operation

Factors that can be influenced are the intraoperative factors, such as the cross clamp time, the quality of myocardial protection, and the degree of success in the operative approach. The main cause of the left heart failure is an excessive myocardial pressure and/or volume overload. Special forms are the «myocardial stunning» and the «hibernating myocardium.»

Usually the myocardial stunning is a completely reversible, mostly diastolic, prolonged myocardial dysfunction after a short period of myocardial ischemia. If appropriate and effective revascularization is performed, no permanent cell defects will remain; however, the contractility may be impaired over a prolonged period of time. The basic research is ongoing to explore the pathways of the «stunning.» It can occur after a regional ischemia, such as myocardial infarction, or after a global ischemia, triggered by a cardiac arrest.

In contrast, the «hibernating» myocardium is defined as an adaption of the myocardium to the reduced coronary perfusion. After a proper restoration of the perfusion, the contractility will get back to normal function, although on occasion a «stunned» situation can appear.

■ ■ Right heart failure

Diagnosis and treatment of right ventricular failure is challenging. Pulmonary hypertension and long-standing valvular disease are predisposing factors. Insufficient cardioplegia or intravascular volume overload may contribute to the disease. Additionally left heart failure, anaphylactic reaction to protamine administration, or an inflammatory response to the operation can acutely increase right ventricular afterload that can lead to myocardial damage. In echocardiography the right ventricle is enlarged and hypo- or akinetic with potentially normal left ventricular function. Often, new onset tricuspid regurgitation is remarkable.

■ ■ Vasoplegic syndrome

Reduced peripheral vascular resistance occurs in at least 20% of the patients after cardiac

surgery. The standard therapy is the administration of volume and norepinephrine (Carrel et al. 2000). In some patients there is a norepinephrine-resistant reduced peripheral vessel resistance (Levin et al. 2004). This is called a vasoplegic syndrome. A possible correlation to preoperatively administered ACE inhibitor therapy is discussed. Besides ruling out hypoadrenal syndrome, initiation of intravenous vasopressin therapy or methylene blue is recommended (Egi et al. 2007).

■ ■ Cardiac arrest

The worst case of a LCOS is the cardiac arrest that appears in 1–2% of cardiac surgery patients (European Resuscitation Council, Nolana et al. 2010). The most common causes of postoperative cardiac arrest are (modified after European Resuscitation Council, Truhlár et al. 2015):

- Myocardial ischemia
- Tension pneumothorax
- Pericardial tamponade
- Massive bleeding with hypovolemic shock
- Pacemaker dysfunction in patients with little or no intrinsic rhythm
- Electrolyte disturbances, especially in low or high levels of potassium

The cardiac arrest can be directly monitored by the minimal or missing peaks in the blood pressure curve. Ongoing ventricular fibrillation or cardiac arrest is displayed by the ECG. Therapy has to be started immediately. Obvious reasons can be treated easily: If a tension pneumothorax is present, the situation can be handled by deployment of a thoracic drain. If the pacemaker is not active or the connection is defective, it must be reconnected or replaced or a transvenous or transcutaneous pacer be placed. If the electrolyte situation is unbalanced, it has to be corrected.

A myocardial ischemia leading to ventricular fibrillation can be treated using a biphasic electric defibrillation shock with maximum energy. Additionally the ischemia has to be treated with a cardiopulmonary resuscitation. The resuscitation has to be performed according to ACLS protocol. If classical ACLS protocol does not resolve the cardiac arrest in CSICU, immediate opening of the chest is recommended, as last resort. This will alleviate tamponade and pneumothorax, will help diagnose significant bleeding, and will allow internal cardiac compression and defibrillation

(■ Fig. 9.1). Differences in Guidelines from the European Resuscitation Council and the American Heart Association are featured in a Critical Care Nurse article more recently (Ley 2015).

The survival rate of these patients is better than expected: overall 33% of patients in whom a rethoracotomy due to cardiac and circulatory arrest on the CSICU was performed will survive (Mackay et al. 2002), compared to 48% survival rate if the rethoracotomy was performed within the first 10 min after the arrest (Mackay et al. 2002).

9.5.2.5 Therapy of LCOS

■ ■ Pharmacological circulatory support

The therapy of LCOS is the continuous intravenous application of circulatory supportive medication that will be described in the following.

■ ■ Catecholamines

Dopamine acts directly and indirectly on α -adrenergic receptors as well as on β -adrenergic receptors, in addition to its affinity to dopamine receptors. The affinity to receptors is dose dependent: 0.5–3 $\mu\text{g}/\text{kg}/\text{min}$ leads to a vasodilatation of renal and abdominal vessels via dopamine receptors, 3–10 $\mu\text{g}/\text{kg}/\text{min}$ raises the heart rate and the cardiac output with increasing the arterial and pulmonary artery pressure via stimulation of the β -receptors, and a dosage of more than 10 $\mu\text{g}/\text{kg}/\text{min}$ increases the peripheral vascular resistance due to stimulation of the α -adrenergic receptors with additional release of norepinephrine. An increase in mean pulmonary artery pressure and the wedge pressure can be corrected using pulmonary vasodilators. Important side effects are suppression of the pituitary gland hormone, ischemia of gastrointestinal mucosa, and, as with all catecholamines, an increase of myocardial oxygen consumption. Important to mention that low-dose dopamine has not been shown to prevent renal failure (Lassnigg et al. 2000).

Epinephrine activates β_1 -, β_2 -, and α -adrenergic receptors. The receptor response is dose dependent: 0.02–0.05 $\mu\text{g}/\text{kg}/\text{min}$ increases the inotropic effect predominantly through the β_1 -receptors, 0.05–0.2 $\mu\text{g}/\text{kg}/\text{min}$ increases the inotropic effect and the peripheral vascular resistance by the β - and the α -receptors, and a dosage >0.2 $\mu\text{g}/\text{kg}/\text{min}$ will increase the peripheral vascular resistance by increasing effects on the

■ **Fig. 9.1** Therapeutic algorithm for cardio-circulatory arrest (Modified after European Resuscitation Council (2010)). VT ventricular tachycardia, ECG electrocardiogram

α -receptors. Important side effects are tachycardia, increase of the mean pulmonary artery pressure and the wedge pressure, ischemia of gastrointestinal mucosa, and an increase of myocardial oxygen consumption.

Norepinephrine activates α -adrenergic receptors, but also β_1 - and β_2 -receptors. Although there is increase in contractility, the cardiac output overall is not increased due to higher peripheral vascular resistance. The arterial vasoconstriction improves the perfusion pressure to all organs. Important side effects are tachycardia (less than epinephrine) and increase of mean pulmonary artery and pulmonary artery wedge pressure.

Norepinephrine is the first choice as vasoconstrictor and is recommended in two situations:

- In patients with low blood pressure due to low systemic vascular resistance, if this cannot be effectively treated by administration of volume or positive inotropic agents
- To compensate the initial blood pressure drop after starting a phosphodiesterase-III-inhibitor therapy such as milrinone

Dobutamine activates the β_1 -receptors and significantly β_2 - and α -adrenergic receptors. Dobutamine is a positive inotropic and lusitropic agent (improves myocardial relaxation in the diastole) and has also vasodilatory effect. This

improves the cardiac output. Most common relevant side effects are tachycardia and increased myocardial oxygen consumption.

Due to lack in increase of the mean pulmonary artery pressure and the wedge pressure and maintenance of perfusion of the visceral arteries, in our practice the use of dobutamine is the first choice in increasing cardiac output.

■ ■ Vasodilators

Phosphodiesterase-III inhibitors such as milrinone: In contrast to catecholamines, milrinone is an adrenoceptor-independent inotrope with vasodilatory characteristics. The administration leads to an increase of intracellular cAMP levels due to a blockade of cAMP depletion. This triggers the calcium influx into the cell and an increased release of calcium from the sarcoplasmic reticulum. Smooth muscle cells with an increased level of cAMP dilate. In addition milrinone may increase the heart rate by affecting the sinus node and increase the atrioventricular conduction transmission. In contrast to catecholamines, the myocardial oxygen consumption is not significantly augmented due to a simultaneous reduction of the pre- and afterload. In summary, milrinone has a positive inotropic effect with an increased cardiac output along with a drop of cardiac filling pressures and the pulmonary vascular resistance. Side effects are long half-life time with difficult dose adjustments, increased pulmonary shunting, and hypotension requiring vasoconstrictors. In clinical practice, milrinone is used when inotropic effect of dobutamine is reduced due to β -adrenergic receptor overregulation.

■ ■ Levosimendan

Levosimendan is used to prevent and to treat LCOS and acts as a calcium sensitizer. It is increasingly being used in Germany. Levosimendan is currently not available in the USA for clinical use. For further information see ► Chapter «[Critical Care in Pediatric Cardiac Surgery](#)», Sect. 10.3.2.4.

■ ■ Nitroglycerin

The administration of nitroglycerin leads to a dilatation of vessels, especially the venous and the coronary vessels and, in smaller amount, the arterial system. The primary use is the prophylaxis and the therapy of a myocardial ischemia.

Furthermore it can be used to reduce an elevated pulmonary artery pressure and in right heart failure. Important side effect is a hemodynamically relevant tachycardia with hypotension. Further, the inhibition of hypoxemia-triggered pulmonary vasoconstriction and an increased intrapulmonary right-left shunt can lead to decreased oxygenation. Finally, a high dosage can result in severe headaches, and prolonged applications will cause tolerance that mitigates the effect. Details of pharmacotherapy are discussed under treatment of arterial hypertension (► Sect. 9.5.2.6).

■ ■ Nitroprusside

Sodium nitroprusside decreases the afterload and the preload with consequent increase of cardiac output. Therefore, the myocardial oxygen consumption is decreased.

In severe LCOS the use of sodium nitroprusside is recommended to reduce systemic vascular resistance. Similar to nitroglycerine, the side effects are decreased oxygenation, and in our Los Angeles experience, we do not recommend it for aortic dissection, as there is evidence that nitroprusside may increase shear stress on the aortic wall. Some references, however, suggest to employ it combined with beta-blockers (Erbel et al. 2001; Tsai et al. 2005). The most dangerous side effect is cyanide intoxication. In order to avoid this side effect, nitroprusside medication should be accompanied by IV sodium thiosulfate infusion.

Details of pharmacotherapy of sodium nitroprusside are discussed under treatment of arterial hypertension (► Sect. 9.5.2.6).

■ ■ Inhalative Vasodilators

Inhaled vasodilators, such as nitric oxide (NO) are often used to treat a pulmonary hypertension. The mode of NO action is the activation of guanylate cyclase (cGMP) with a specific dilation of pulmonary vessels. The drop of the pulmonary resistance and the shift of blood flow through ventilated lung areas reduce the pulmonary pressure and improve the arterial oxygenation. In contact with hemoglobin, the NO is been deactivated. Therefore, the NO does not enter the systemic circulation. Important side effects are the methemoglobinemia due to prolonged use and an increased bleeding tendency, but the incidence is low by using the recommended dosage of <20 ppm.

An alternative for pulmonary vasodilatory effect is the phosphodiesterase-V inhibitor sildenafil. Sildenafil is available orally with the similar effects such as NO. There is a potential side effect of systemic hypotension with sildenafil.

■ ■ Vasopressors

Vasopressors are primarily used to increase the arterial perfusion pressure, in cases where the optimized volume status and positive inotropic response is inadequate for peripheral perfusion. Vasopressin as well as methylene blue belongs to the vasopressors.

■ ■ Vasopressin

Vasopressin activates the vasopressin-1 receptor with an increase of the intracellular calcium level. Vasopressin is very effective especially in the vasoplegic syndrome, unresponsive to maximal norepinephrine dosage. The side effect of vasopressin even in low dose is significant decrease of microcirculation. Therefore the use of vasopressin should be considered as second or third choice and preferably should be used in low dosage.

■ ■ Methylene blue

The effects, side effects, and indications for use of methylene blue are similar to vasopressin. Although there are promising reports, overall there is little data supporting routine use of methylene blue. Further details are given in ■ Table 9.7.

■ ■ Basic rules in pharmacological circulatory support

A LCOS has to be treated immediately according to the underlying reason. Therefore an algorithmic approach to pharmacological circulatory support is critical. The results of Swan-Ganz catheter and transthoracic echocardiography are frequently not available immediately, allowing for algorithmic approach recommended in ■ Figs. 9.2 and 9.3.

However, the basic circulatory monitoring will provide important information, allowing for following rules of thumb:

- In a patient with MAP <60 mmHg and a central venous pressure of >12 mmHg, treatment with positive inotropic agents should be considered.
- The worse the left ventricular function is in the patient, the earlier should these drugs be initiated.
- The worse the left ventricular function is in the patient, the more sensitive the heart may respond to volume administration, especially in an already preoperatively increased left and right ventricular preload.
- Initial drug of choice is dobutamine in combination with norepinephrine and/or epinephrine given the aforementioned advantages and side effects. Dobutamine reduces systemic and pulmonary vascular resistance along with inotropic effect. If the vasodilatory effects are too strong, norepinephrine or epinephrine may be used.

■ Table 9.7 Dosage of inotropes and vasopressors

Drug	Bolus	Dosage
Dopamine	None	<3 µg/kg/min: renal effect
		3–10 µg/kg/min: β-adrenergic effect
		>10 µg/kg/min: β- and α-adrenergic effect
Dobutamine	None	2–20 µg/kg/min: β-adrenergic effect
Adrenalin	During ACLS protocol	0.05–1.0 µg/kg/min
Noradrenalin	None	0.05–1.0 µg/kg/min
Milrinone	25–75 µg/kg over 20 min	0.25–0.75 µg/kg/min
Enoximone	0.25 bis 0.75 µg /kgKG	1.25 bis 7.5 µg/kg/min
Levosimendan [not available in the USA]	12 bis 24 µg/kgKG ^a	0.1 µg/kgKG/min (0.05 bis 0.2 µg/kgKG/min)

^aShould not be given as bolus in patients with hypotension

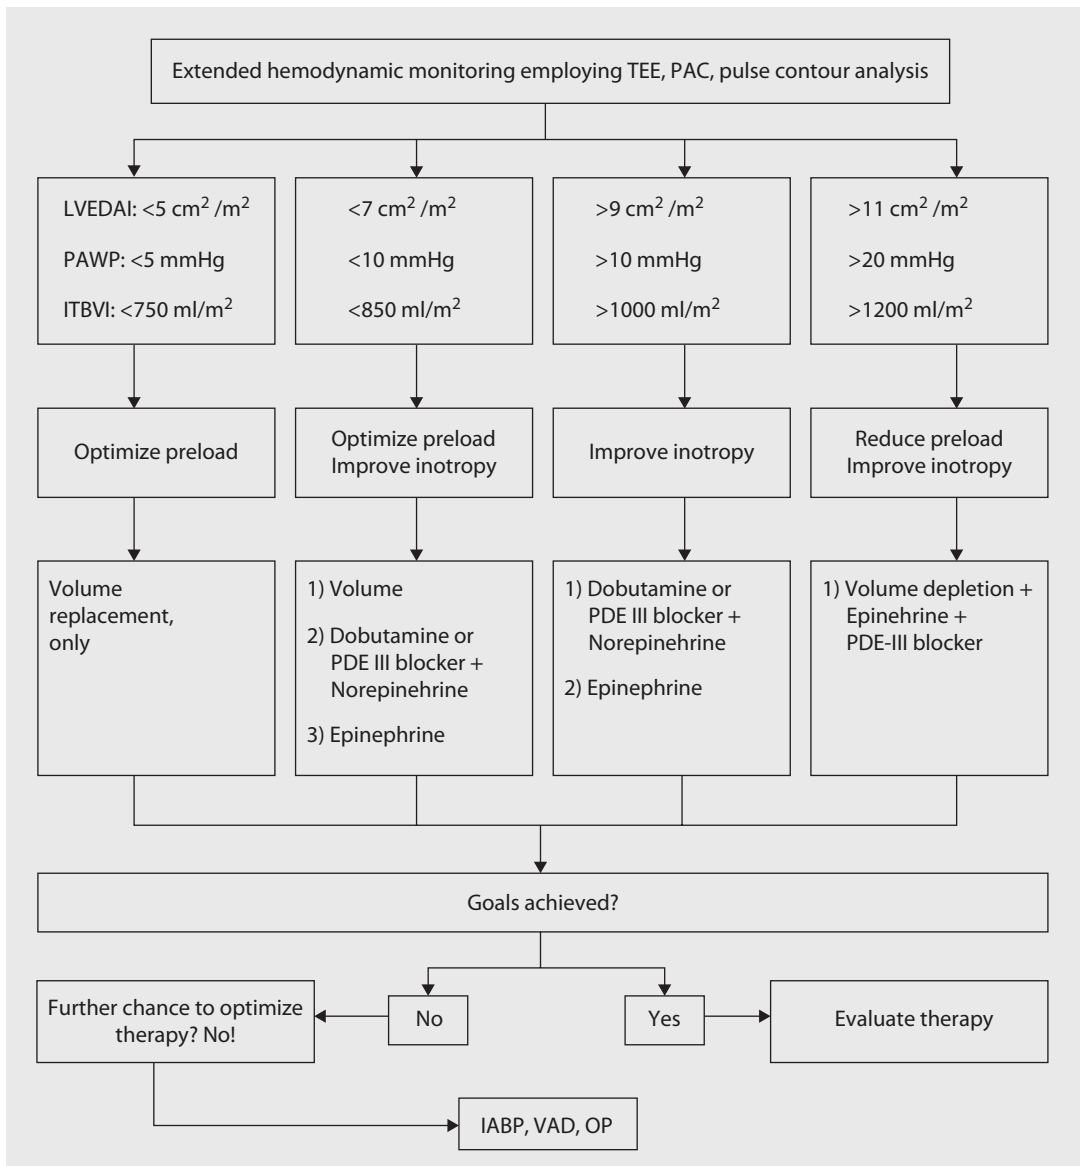

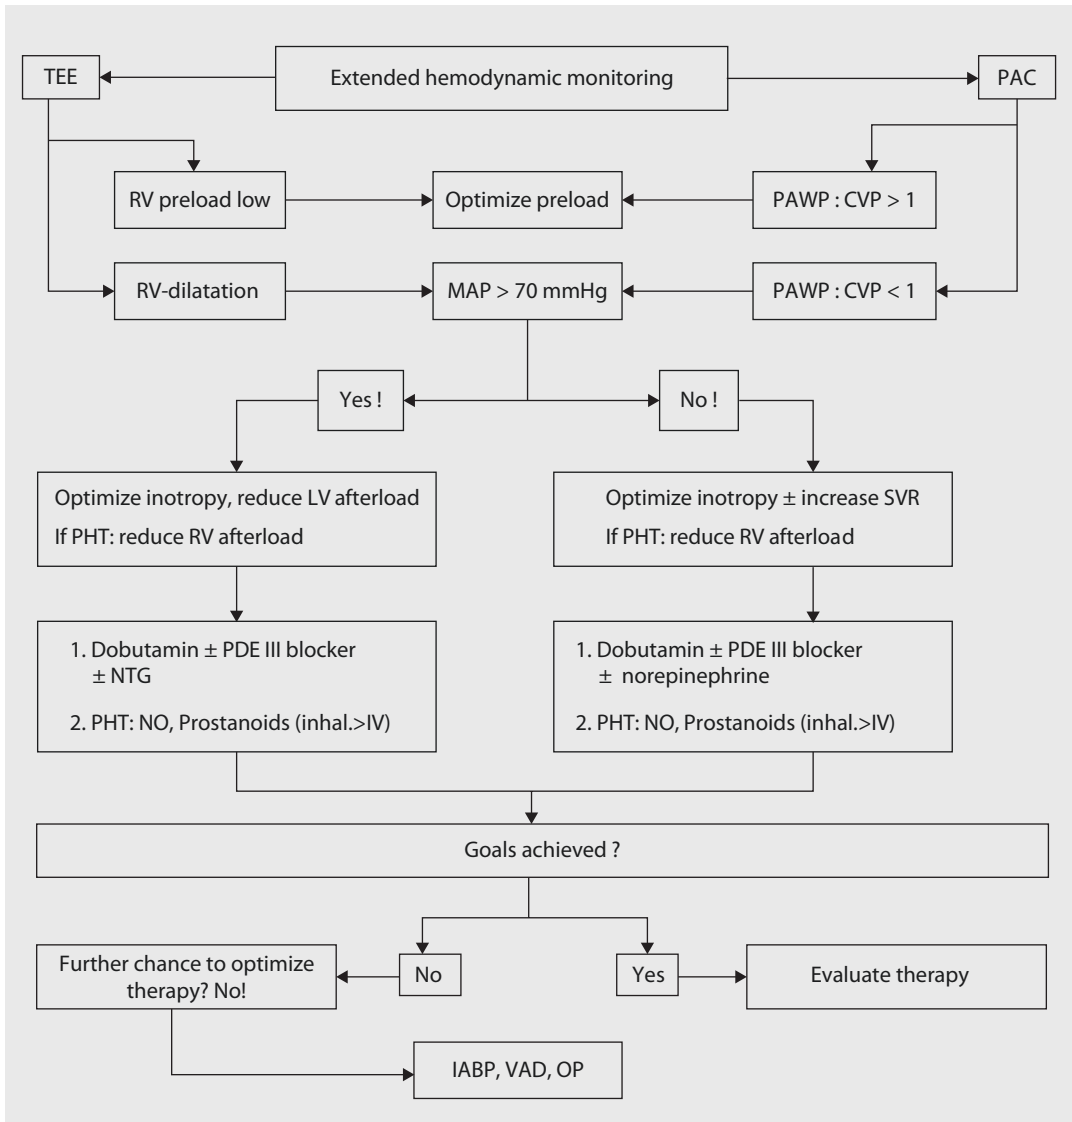

Fig. 9.2 Therapeutic algorithm for left heart failure according to results of extended monitoring. *IABP* intra-aortic balloon pump, *ITBVI* intrathoracic blood volume index, *LVEDAI* left ventricular end-diastolic area index, *OP* redo surgery, *PAC* pulmonary artery catheter, *PAWP* pulmonary artery wedge pressure, *PDE III* phosphodiesterase III, *TEE* transesophageal echocardiography, *VAD* ventricular assist device (Modified after Carl et al. (2010)). This is an open-access article distributed under the terms of the Creative Commons Attribution License (<http://creativecommons.org/licenses/by-nc-nd/3.0/deed.en>)

Alternatively milrinone/vasopressin combination is used especially in patients with high propensity of going into atrial fibrillation, causing further drop in cardiac output. Both drugs do not possess any adrenergic receptor response.

In case of intravascular volume overload or increase of the CVP without augmentation of

MAP, the intravascular volume has to be reduced. This can be assured using diuretics or renal replacement therapy. Furthermore, in the presence of right heart failure, right ventricular afterload reduction using nitroglycerine, milrinone, and inhaled NO may be necessary.

If hemodynamic stabilization cannot be achieved with pharmacotherapy, a prompt decision for mechanical circulatory support is

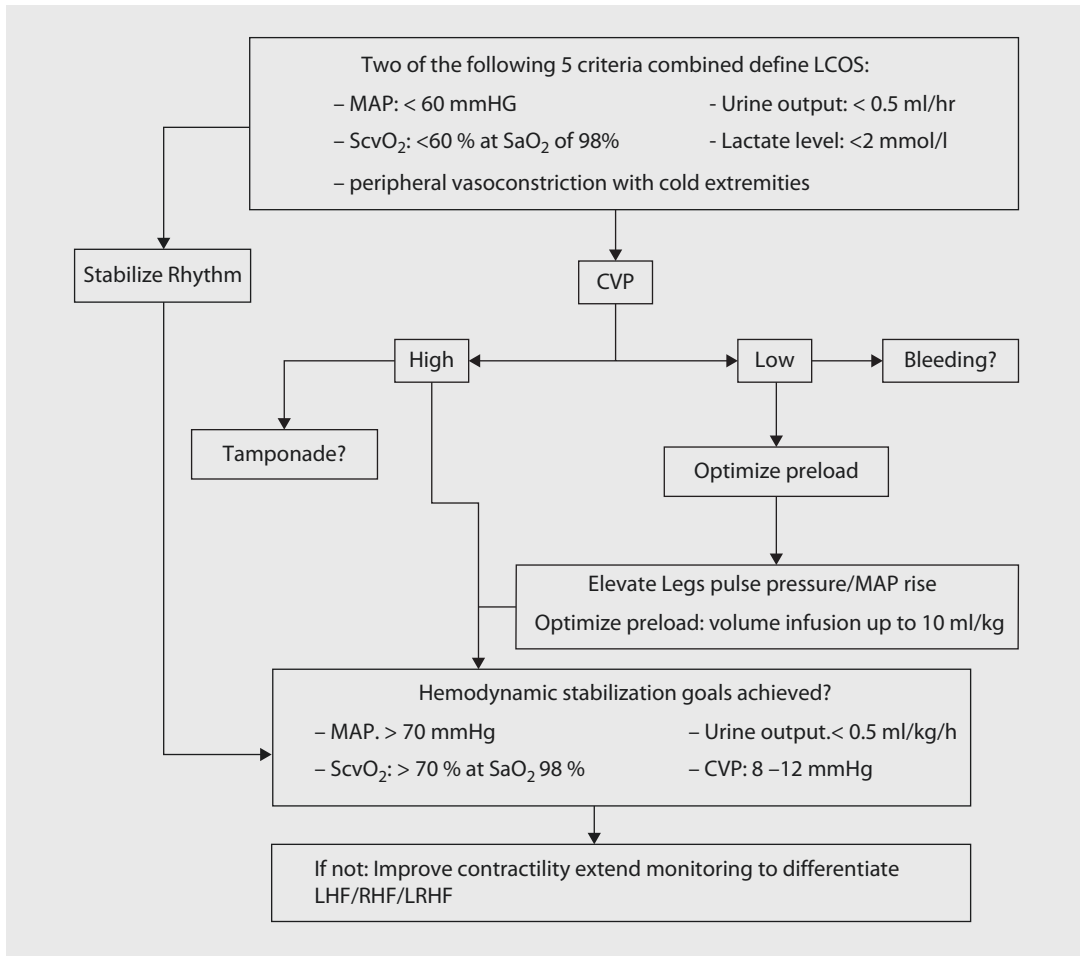

■ **Fig. 9.3** Therapeutic algorithm for right heart failure according to data from extended monitoring. *IABP* intra-aortic balloon pump, *OP* redo surgery, *PAC* pulmonary artery catheter, *PAWP* pulmonary artery wedge pressure, *PDE III* phosphodiesterase III, *TEE* transesophageal echocardiography, *VAD* ventricular assist device. *CVP* central venous pressure, *LV* left ventricular, *MAP* mean arterial pressure, *NO* nitric oxide, *NTG* nitroglycerin, *PHT* pulmonary hypertension, *RV* right ventricular, *SVR* systemic vascular resistance

required. Besides pharmacological or mechanical circulatory support, adequate therapy for the other organ systems must be provided, including:

- Adequate oxygenation
- Balanced acid-base balance, especially due to a poor response of adrenergic receptors to catecholamines in an acidic pH range
- Adequate blood sugar levels with a target of <180 mg/dl

■ ■ Mechanical Circulatory Support: Intra-aortic Balloon Pump

The intra-aortic balloon pump (IABP) is one of the mostly used mechanical circulatory support devices in cardiac surgery due to ease of transfemoral implantation into the descending aorta with relatively low risk and side effects (Robicsek et al. 2003). The main goal is the augmentation of the diastolic blood pressure by balloon inflation

■ **Fig. 9.4** Staged approach to therapy of postoperative low cardiac output syndrome (LCOS), stage I: CVP central venous pressure, LHF left heart failure, LRHF left and right heart failure, MAP mean arterial pressure, RHF right heart failure, SaO₂ oxygen saturation, ScvO₂ central venous oxygen saturation

and a decrease of the left ventricular afterload by well-timed balloon deflation. This leads to an enhancement of coronary perfusion and a relief of cardiac work with the result of an improved oxygen supply-demand ratio and a somewhat increased cardiac output.

The appropriate time of initiation of the IABP is as soon as possible (Baskett et al. 2002; Christenson et al. 2002; Ramnarine et al. 2005). It is frequently helpful for the treatment of LCOS and especially helpful for coronary patients during the weaning process from extracorporeal circulation. The exceed threshold of an epinephrine dose level of >0.2 µg/kg/min or a dobutamine dose level of >10 µg/kg/min should be the indication for IABP use. Preoperatively, IABP will be very useful in

patients with an impaired left ventricular ejection fraction, left main stem stenosis, unstable angina, or the need of a coronary reoperation to improve outcomes (Dunning and Prendergast 2003).

The useful effects of the IABP use can be immediately seen at the pressure curve after IABP is initiated: due to the reduced cardiac output, diminished first peak in the arterial pressure curve is frequently followed by a second higher peak as function of the preload reduction. Recovery of the left ventricular function leads usually to a conversion of the peaks—the first one overgrow the second one. This is an indication for removal of IABP, especially in face of significantly reduced pharmacological circulatory support. The IABP should be weaned from a 1:1

■ **Fig. 9.5** Staged approach to therapy of postoperative low cardiac output syndrome (LCOS), stage II: CVP central venous pressure, IABP intra-aortic balloon pump, LHF left heart failure, LRHF left and right heart failure, LV left ventricular, MAP mean arterial pressure, RHF right heart failure, RV right ventricular, SaO₂ arterial oxygen saturation, ScvO₂ central venous oxygen saturation

augmentation to 1:2, finally to 1:3, understanding that thrombus may form on the balloon surface at this rate. The complication rate should be below 10%, mostly related to vascular problems such as site bleeding, thromboembolic events, and ischemia of lower extremities.

The therapy success relates to the basic problem and its reversibility. While stunned myocardium should return to near-normal function, the scarred myocardium will not improve contractility despite IABP support. In patients with failed IABP support, mechanical circulatory support may have to be escalated to the next level using ventricular assist devices.

■ ■ Mechanical Circulatory Support: Ventricular Assist Devices (VADs)

There is a variety of ventricular assist devices available, some combined with an oxygenator, to treat both cardiac and lung failure in the short, mid, or long term postoperatively. The ventricular assist devices may be pulsatile or axial, uni- (LVAD or RVAD) or biventricular (BiVAD), and intra-, para-, or extracorporeal. There is also FDA-approved total artificial heart for intracorporeal biventricular assistance. Finally, the VADs may be considered as bridge to recovery, sole therapy, or bridge to heart transplant depending on patient's characteristics and medical history. Having an

■ Fig. 9.6 Staged approach to therapy of postoperative low cardiac output syndrome (LCOS), stage III: *BiVAD* biventricular assist device, *IABP* intra-aortic balloon pump, *LHF* left heart failure, *LVAD* left ventricular assist device, *MAP* mean arterial pressure, *RHF* right heart failure, *RVAD* right ventricular assist device, *SaO₂* arterial oxygen saturation, *ScvO₂* central venous oxygen saturation

on-site heart transplantation program can be very complementary for the latter group of patients.

Overall, the management of VAD patients consumes a lot of time, money, and resources. The adjudication and indications for use will be limited in the future to smaller cohort with best possible outcomes. This is important in today's increasing health-care cost environment (See also ► Chapter «Cardiac Assist Devices and Total Artificial Heart», Sects. 38.4–38.7). ■ Figs 9.4, 9.5, and 9.6 summarize graphically the key points of LCOS therapy.

9.5.2.6 Arterial Hypertension

The early postoperative blood pressure in cardiac surgical patients is more often rather too low than too high. The occasional presence of early postoperative arterial hypertension may become problematic especially in patients with fragile cardiac, aortic, and arterial tissue. An extreme case is perioperative care of patients with acute aortic syndrome such as aortic dissection (Khoynezhad and Plestis 2006). After pain has to be excluded as cause, the pressure has to be lowered using the following drugs—alone or in combination (Khoynezhad 2007).

Table 9.8 Review of approach to patients with acute aortic syndrome presenting with hypertension to the CSICU

1. Physician has a high index of suspicion for acute aortic dissection
 - (a) History:
 - (i) Severe, sudden onset, sharp or tearing back pain, chest pain, shoulder pain, or abdominal pain
 - (ii) 50 years or older, history of hypertension, aortic dissection or aortic aneurysm (of family history of such), previous cardiac surgery, connective tissue disorder (bicuspid aortic valve, Marfan syndrome, Ehlers-Danlos syndrome, Loeys-Dietz syndrome), or peripartum
 - (b) Physical examination:
 1. Blood pressure differential in various extremities (pulse deficit)
 2. Acute stroke, paraplegia, or paraparesis
 3. Abdominal pain, flank pain
2. General measures:
 - (a) Establish two large bore (18 gauge or bigger) IVs
 - (b) Supplemental oxygen by nasal cannula or mask
 - (c) Cardiac monitor
 - (d) Get an EKG, portable chest X-ray, place a Foley catheter
 - (e) Obtain CBC, chemistry panel, coagulation panel, UA, CK, Troponin, d-dimer
 - (f) Type and cross ten units packed red blood cells (PRBCs)
 - (g) Set up an arterial line
3. Diagnostic imaging:
 - (a) Computed tomography angiogram (CTA)
 - (b) Transesophageal echocardiogram
 - (c) Magnetic resonance angiogram (MRA)
 - (d) Intravascular ultrasound
4. Prompt cardiothoracic surgical consultation
5. Blood pressure, heart rate, and pain management
 - (a) First line: β -blockers
 - (i) Labetalol, bolus (15 mg) \pm a drip (5 mg/h)
 - (b) If hypertension persists, add:
 - (i) Nicardipine drip (starting dose: 5 mg/h)
 - (c) If tachycardia persists, add:
 - (i) Esmolol (loading 0.5 mg/kg over 2–5 min, followed by a drip of 10–20 μ g/kg/min)
 - (ii) Diltiazem drip (loading 0.25 mg/kg over 2–5 min, followed by a drip of 5 mg/h)
 - (d) Goals:
 - (i) Heart rate 60–80 beats/min
 - (ii) Systolic blood pressure 100 mmHg
 - (e) Morphine (for pain relief)
6. Hemodynamically unstable patients:
 - (a) Endotracheal intubation and mechanical ventilation
 - (b) Blood pressure support with crystalloid and colloid (PRBCs if rupture is suspected)
 - (c) TEE at bedside in the emergency department or in the OR
 - (d) Pericardiocentesis is not recommended (class III)

(From Tran and Khojnejzhad (2009); used with permission)

■ ■ Nitroprusside

Nitroprusside is a potent direct arterial and venous dilator, acting through release of nitric oxide. It has a rapid onset of action, with a half-life of seconds to <2 min and thus is given in the form of continuous infusion. Dose is 0.3 $\mu\text{g}/\text{Kg}/\text{min}$ IV infusion; with titration q2 min until desired response with maximum dose 10 $\mu\text{g}/\text{Kg}/\text{min}$. The hypotensive effects of nitroprusside can be unpredictable because it simultaneously causes potent venodilatation and peripheral arterial vasodilatation. This is especially the case for patients with severe left ventricular hypertrophy and preload-dependent diastolic dysfunction. It has been shown to cause coronary steal; it can cause a significant reflex tachycardia, causing increase in aortic shear stress (dp/dt). Therefore, especially when given in aortic dissection patients, it should be combined with beta-blocker therapy.

It is photosensitive, so it requires special handling. Its most serious adverse effect is in the form of cyanide toxicity, which occurs due to accumulation of its metabolites thiocyanate/cyanide, and its clinical presentation may vary leading to difficulty in diagnosis. Thus, it is recommended that this drug be used only when other intravenous antihypertensive agents are not available.

■ ■ Nitroglycerin

Nitroglycerin acts by release of nitric oxide causing vasodilation, especially of the coronary arteries. It is primarily a venodilator; however, at higher doses it also causes arterial vasodilation. It does not cause coronary steal. Initial dose is typically 5 $\mu\text{g}/\text{min}$ IV infusion with increments by 5 μg q3–5 min until desired response, with a maximum of 200 $\mu\text{g}/\text{min}$. A drawback is that it cannot be used for a prolonged duration as patients rapidly develop tolerance to it. Being predominantly a venodilator, it is subject to same hemodynamic issues such as nitroprusside. It may predispose to severe hypotension in patients with left ventricular hypertrophy and preload-dependent diastolic dysfunction.

■ ■ Nicardipine

Nicardipine is a short-acting calcium channel blocker belonging to the dihydropyridine class. It causes cerebral and coronary vasodilation with only minimal negative inotropic effect, has minimal effects on atrioventricular nodal conduction,

and has little effect on cardiac output or pulmonary artery wedge pressure. In contrast to nitroprusside, the pharmacodynamic properties of nicardipine are favorable. Nicardipine has a very long half-life; the β -half-life of nicardipine is approximately 40 min, whereas its γ -half-life is approximately 13 h. Because about 14% of the drug is eliminated during the γ -phase, the hypotensive effect can be prolonged. In a study comparing the effect of nicardipine to nitroprusside in patients with severe postoperative hypertension, the two drugs had equivalent efficacy, but only nicardipine reduced both cardiac and cerebral ischemia. Nicardipine is administered through a continuous infusion with starting dose at 5 mg/h infusion. It is titrated by 2.5 mg/h q5 mins with maximum of 15 mg/h. In cardiac surgical patients, nicardipine has been shown to decrease arterial BP acutely with no effects on ventricular preload or cardiac output, suggesting that it has a minimal negative inotropic action. With nicardipine, oxygen delivery to the cells is usually well maintained, and oxygen requirements are unchanged. Because nicardipine is metabolized primarily by the liver, it can be used in patients with renal insufficiency. However, there have been concerns with the use of calcium channel blockers in patients with coronary artery disease, possibly due to sympathetic activation, bleeding caused by inhibition of platelet aggregation, and pro-arrhythmic effects. There remains considerable debate about the role of calcium channel blockers as first-line therapy.

■ ■ β -blockers

In perioperative cardiac surgery, especially in caring of patients with aortic dissection and aortic aneurysm, integrity of arterial system depends not only on the absolute blood pressure but also on the velocity of left ventricular contraction (dp/dt). A vasodilator alone, instead of decreasing the heart rate, may even cause reflex tachycardia, thus causing propagation of the aortic dissection. Therefore, the optimum treatment involves a combination of a parenteral β -blocker and an arterial vasodilator, with heart rate targeted around 55–65 beats/min. The β -blocker of choice in this situation is generally esmolol and, alternatively, labetalol or metoprolol.

Esmolol is a β_1 -antagonist, while labetalol is a combined α_1 -, β_1 -, and β_2 -antagonist with an

alpha to beta-blocking ratio of 1:7. Both of them, by slowing down the heart rate, also reduce the myocardial oxygen demand. Esmolol reduces blood pressure by reducing cardiac output and inhibiting renin release, while labetalol decreases afterload directly and also inhibits renin release. Their disadvantage is in the form of their negative inotropic effect and possible reaction in patients with reactive airway disease. Half-life of esmolol is around 9 min, while that of labetalol is 5.5 h.

The hypotensive effect of labetalol begins within 2–5 min after its intravenous administration, reaching a peak at 5–15 min following administration and lasting for about 2–4 h. Labetalol may be administered as a loading dose of 20 mg, followed by repeated incremental doses of 20–80 mg at 10-min intervals until the desired BP is achieved. Alternatively, after the initial loading dose, an infusion commencing at 1–2 mg/min and titrated up to until the desired hypotensive effect is achieved is particularly effective. Bolus injections of 1–2 mg/kg have been reported to produce precipitous falls in BP and should therefore be avoided.

The onset of action of esmolol is within 60 s, with duration of action of 10–20 min. However, because it is metabolized by red blood cell (RBC) esterases, any condition that precipitates anemia will prolong its «short half-life.» The metabolism of esmolol is via rapid hydrolysis of ester linkages by RBC esterases and is not dependent on renal or hepatic function. Typically, the drug is administered as a 500–1,000 µg/kg loading dose over 1 min, followed by an infusion starting at 50 µg/kg/min and increasing up to 300 µg/kg/min as necessary.

■ Table 9.8 reviews approach to patients with acute aortic syndrome presenting with hypertension to the CSICU (Tran and Khojzeshad 2009).

9.5.2.7 Rhythm Disturbances

Rhythm disturbances can be categorized by their heart rate such as tachycardia and bradycardia, by hemodynamic situation, such as stable or unstable, and they also can be anatomically classified into being of supraventricular or ventricular origin.

■ ■ Bradycardia

Bradycardia after cardiac operations is often seen. The operated heart profits from an elevated heart rate for the first postoperative hours to days, to

ensure a sufficient cardiac output in combination with an increased diastolic myocardial perfusion.

Most cardiac surgical patients are pretreated with β-blockers due to their cardiac disease. This results in a sinus bradycardia after operation. For a sufficient weaning from extracorporeal circulation, a transient pacing of the heart is frequently necessary. In patients after valve operations, the anatomical relation to the atrioventricular conduction system has to be considered for possible irritation or damage with a resulting dysfunction. These rhythm disturbances require short-term external pacing via temporary pacing wires on the right atrium and the right ventricle.

Most patients with normal ventricular function do well with transient ventricular pacing. In patients with decreased left ventricular function, a more physiologic pacing, such as AV sequential pacing, is recommended—especially for hypertrophic and dilated hearts. The pacing should be at 80–100 bpm with an AV interval of 150 ± 25 ms. The power output should be at least double the lowest energy to stimulate the heart (stimulation threshold). If the patient does not have an adequate baseline rhythm, the output should be three times higher as the threshold. In the operating room, the sensing will be turned off due to interferences with the electrocautery. Before closing the chest, the pacemaker has to be recalibrated to detect any own rhythm and to work proper in the inhibited mode (Spotnitz 2005).

The role of temporary biventricular pacing in the perioperative setting is not well defined yet, although some data suggest a benefit in patients with poor left ventricular function. If it is tried, the position of the pacemaker wires on the left heart is important. The recommended site for the left ventricular wire is the posterior lateral position, near the first marginal artery. An anterior position is not recommended (Flynn et al. 2005).

■ ■ Supraventricular tachycardia

Supraventricular tachycardia occurs with an incidence of 50% after cardiac surgery. In general a low potassium and magnesium blood level is a frequent reason for supraventricular tachycardia, mostly an atrial fibrillation. Supraventricular extrasystole is harmless and can be treated by balancing the electrolyte blood levels. A postoperative atrial fibrillation is associated with an increased mortality. It is also associated with major adverse events, such as ventricular tachycardia, stroke, prolonged hospital stay, and

Table 9.9 Pharmacological therapy in atrial fibrillation

Drug	Rhythm control	Rate control	Prophylaxis
Flecainide	(+)	(+)	(+)

Electric cardioversion	+++	+++	–

– no therapeutic effect, (+) therapeutic effect controversially discussed, + therapeutic effect possible, ++ therapy effective, +++ therapy very effective

increased hospitalization costs (Dunning et al. 2006; European Resuscitation Council 2005; McKeown and Gutterman 2005).

The most important aspect of supraventricular tachycardia for the cardiac surgical patient is the hemodynamic relevance. If the patient's hemodynamics are unstable, the heart rate has to be immediately decreased to 80–100 bpm, usually in the form of electric cardioversion.

If the patient is hemodynamically stable, one has to decide whether heart rate control or rhythm control, namely, conversion into sinus rhythm, is the ultimate goal. In patients with history of atrial fibrillation or with high pretest probability for atrial fibrillation, such as large atrium or mitral valve operations, conversions may not be persistent. **Table 9.9** gives an overview about the drugs used in atrial fibrillation as well as their effects.

If atrial fibrillation is present, the following aspects have to be addressed additionally: pain-induced stress must be treated adequately, the potassium blood level should be more than 4.5 mmol/L, the oxygen saturation should be more than 92%, and the volume overload with atrial stretch should be avoided.

In the presence of atrial fibrillation over 24 h, a systemic anticoagulation with a PTT prolonga-

tion of 50–60 s is recommended. In patients with transient atrial fibrillation, it can be stopped after 24 h if stable sinus rhythm prevails.

If the diagnosis of tachycardia is unclear, administration of 6–12 mg adenosine may be diagnostic and—on rare occasion—therapeutic. Adenosine allows for cardiac pause due to bradycardia and complete AV block in patients with supraventricular tachycardia, in particular in AV-reentry pathology. In patients with ventricular tachycardia, adenosine remains without any response. In the following, less common supraventricular tachycardia forms will be presented.

Sinus tachycardia mostly appears if the patient suffers stress, such as pain or fear due to inadequate sedation. In some cases, β -blockers, digoxin, or verapamil will be recommended.

Atrial flutter: this rhythm disturbance shows up with a sawlike P wave configuration in the ECG. The goal is to overdrive the flutter with the pacemaker or to perform synchronized electric conversion. In some cases, vagus stimulation or pharmacological AV delay (i.e., with verapamil) will reduce the heart rate, but the rate of conversion is very low.

AV-reentry tachycardia can be influenced using adenosine or verapamil. β -blockers, flecainide, or propafenone are not very effective.

■ ■ Ventricular tachycardia

Intermittent ventricular extrasystoles are common after cardiac surgery and do not have to be treated in the majority of cases. The common causes are hypoxemia and unbalanced electrolytes. These have to be treated first. Sometimes the pharmacological effect of β -blocker or amiodarone can be helpful. If intermittent monomorphic extrasystoles occur, such as nonsustained ventricular tachycardia, the CSICU physician has to be cautioned, because these can lead to an ongoing ventricular tachycardia (VT).

A persisting ventricular tachycardia is, in most cases, hemodynamically compromising, especially with ventricular flutter or ventricular fibrillation. An immediate therapy is required: an electric r-peak triggered cardioversion (biphasic; 100 J \rightarrow 200 J) in ventricular flutter and an asynchronous defibrillation in the presence of ventricular fibrillation. In general, resuscitation due a relevant drop of the arterial pressure is required, too. A slow VT can be treated medically

Table 9.10 Survey of commonly used antiarrhythmic drugs

Class of drugs	Drug	Dosage	Indication
1 Sodium channel blocker			
1 A	Disopyramide	50–100 mg po	Atrial and ventricular tachycardia
1 B	Lidocaine	100–150 mg IV	Ventricular tachycardia
1 C	Flecainide	100–150 mg po	Prophylaxis of atrial fibrillation
	Propafenone	100–150 mg po	
2 (β -blocker)	Metoprolol	5–20 mg IV	Supraventricular and ventricular extrasystole, frequency control of atrial fibrillation
		25–100 mg po BID	
	Esmolol	25–50 mg IV	
3 (potassium channel blocker)	Amiodarone	5 mg/BW within 20 min IV	Ventricular tachycardia, atrial fibrillation
	Sotalol	20–100 mg IV	Atrial fibrillation
4 (calcium channel blocker)	Verapamil	5–10 mg IV	Atrial tachycardia, frequency control of atrial fibrillation
	Diltiazem	20–30 mg IV	
Others	Adenosine	6–18 mg	All kinds of atrial tachycardia (except atrial flutter), differential diagnosis for rhythm disturbances
	Digoxin	0.4–0.6 mg	Frequency control of atrial fibrillation

with lidocaine (100–150 mg) or amiodarone (300 mg) or with an overdrive pacing.

While **Table 9.10** gives an overview about commonly used antiarrhythmic drugs, **Fig. 9.7** shows our treatment algorithm for tachycardias.

According to their mode of action, the commonly used antiarrhythmic drugs can be divided into four classes and others. The four classes are:

1. Sodium channel blockers
2. β -blockers
3. Potassium channel blockers
4. Calcium channel blockers

9.5.3 Bleeding Complications and Pericardial Tamponade

9.5.3.1 Incidence, Cause and Diagnostic

Bleeding complications occur after cardiac surgery with an incidence of 1–3% (Mehta et al. 2009). The following table indicates general guide-

lines for tolerable chest tube outputs, which, however, do not apply to all patients (**Table 9.11**). The amount of chest tube output and its assumed cause are important for therapeutic decision-making. If the diagnosis is unsecure, a hematocrit check of chest tube drainage will establish the diagnosis.

After cardiac surgery employing extracorporeal circulation, function of the coagulation system is severely impaired. Reasons are full heparinization, reduced platelet function (preoperative antiplatelet therapy, perioperative hemodilution, hypothermia, and mechanical irritation), and lack of fibrinogen in combination with a hyperfibrinolysis (in close correlation to the duration of the extracorporeal circulation). Initially increased chest tube output is not unusual but has to be watched carefully.

On ICU admission, the surgeon will report any intraoperative bleeding complication and if there may be a surgical reason for the bleeding. If the deranged coagulation system is the presumed underlying cause, appropriate diagnostics should be run to guide therapeutics:

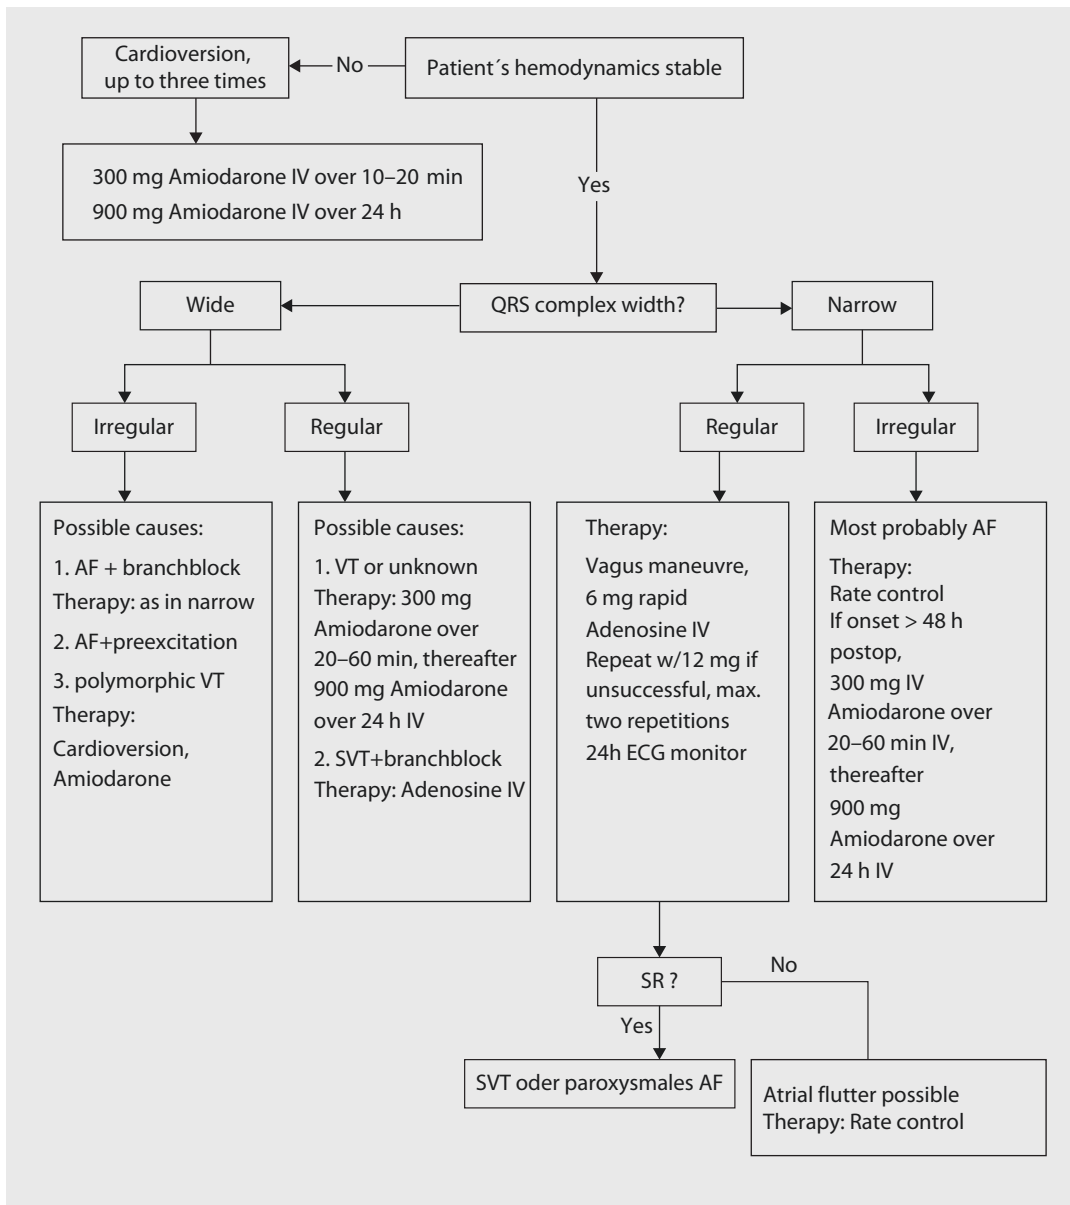

Fig. 9.7 Our management algorithm for tachycardia. AF atrial fibrillation, SR sinus rhythm, SVT supraventricular tachycardia, VT ventricular tachycardia

- Protamine administration to correct prolonged activated clotting time
- Administration of platelets in patients with platelet dysfunction or thrombopenic patients
- Administration of fresh frozen plasma or cryoprecipitate due to a lack of coagulation factors

The routine blood gas analysis will provide additionally the actual hemoglobin concentration

to detect any hemoglobin drop. Furthermore, hemoglobin sample from chest tubes, chest X-ray, and echocardiography can assist with diagnosis of bleeding and cardiac tamponade.

9.5.3.2 Prevention

The most important way to prevent bleeding complications is a careful chest closure. A famous quote in cardiac surgery puts it well: most common cause of significant postoperative bleeding is

Table 9.11 Limits for the postoperative blood drain loss in adult patients

Time after operation	Maximum amount of tolerable blood loss (ml)
First hour	400
Second hour	300
Third hour	250
Fourth hour and later	200

«hypoprolinemia,» insufficient use of suture material to avoid surgical site bleeding. Furthermore, antifibrinolytics such as ϵ -aminocaproic acid or tranexamic acid have shown to reduce postoperative bleeding and take backs for hemorrhagic complications.

The potential value of intraoperative monitoring of fibrinolysis, residual heparin content, or platelet function is not unequivocally established, yet.

9.5.3.3 Therapy

Disorders of the coagulation system have to be treated as already described. If there are bleedings from the sternal closure wires out of the bone, a temporarily increased PEEP to 10 mmHg may stop the bleeding. In case of a true blood loss above the limits given in **Table 9.11**, a prompt reexploration should be considered. The timing for take back is poor, if the patient requires new onset and/or increasing inotropic support. If the diagnosis is in doubt, a more aggressive approach toward operative exploration is warranted. Furthermore, sternal exploration in CSICU should be promptly done in acute hemodynamic compromise: simple bleeders can be treated immediately, and in more complex situations, the hemodynamics can be stabilized, allowing safe transfer of the patient to the OR. Principles of explorations in CSICU should be exercised as «dry run» with the nursing and allied health-care providers, allowing for smoother run in true emergencies. A re sternotomy kit should be fabricated, along with adequate lightening tools, improving visualization of surgical site in CSICU.

9.5.4 Lung and Mechanical Ventilation

The lungs in cardiac surgical patients are compromised due to various reasons. Therefore a short

period of mechanical ventilation is common. However, if other circulatory and pulmonary reasons are lacking, weaning from ventilator should be attempted at or before 4 h after operation. A long-term ventilation (more than 72 h) is only required in 5% of the patients after cardiac surgery (Murthy et al. 2007).

Generally, two different ventilation mechanisms are used: mandatory or assisted ventilation. The mandatory ventilation can be volume- or pressure-controlled, the latter being the mode of choice. The goal of mandatory ventilation mode is to improve the gas exchange by improving the ventilation-perfusion ratio, whereas the assisted ventilation aims toward reducing the work of breathing for the patient (**Table 9.12**).

9.5.4.1 Ventilation Parameters and Settings of the Ventilatory Machine

A series of parameters may be adjusted and regulated on the ventilator. In the following, important ventilation parameters are discussed briefly:

- The *inspiratory oxygen concentration* can be adjusted between 21% and 100%, corresponding to FiO_2 of 0.21–1.0.
- The *respiratory rate* is the adjustable frequency of breathing cycles on the ventilator and is usually between 8 and 14 per minute.
- The *tidal volume* is defined as the amount of air introduced during one breathing cycle. The physiological value is between 5 and 8 ml/kg BW.
- The *minute volume* is the product of respiratory rate and tidal volume. The physiological value is between 5 and 8 l/min.
- The *inspiratory flow* is the amount of airflow during inspiration compared to the time. The inspiration flow can be constant, decelerating, or accelerating. Generally the inspiration flow is chosen as short as possible and as high as necessary, mostly in decelerating fashion.
- The *maximum inspiratory pressure* is the guiding parameter in pressure-controlled ventilation. If the inspiratory pressure is not regulated, especially in volume-controlled ventilation, pulmonary complications may occur due to pulmonary barotrauma. Therefore the pressure-controlled ventilation has become the preferred mode of ventilation in the last years.
- The *relation of inspiration and expiration* should be 1:2 to ensure an almost complete

■ **Table 9.12** Summary of ventilation modes

Controlled ventilation	Assisted ventilation	Controlled and assisted ventilation
IPPV, intermittent positive pressure ventilation CPPV, continuous positive pressure ventilation VCV, volume controlled ventilation PCV, pressure controlled ventilation	SIMV, synchronized intermittent mandatory ventilation MMV, mandatory minute volume PSV, pressure support Ventilation ASB, assisted spontaneous breathing CPAP, continuous positive airway pressure	BIPAP, biphasic positive airway pressure

airway gas exchange. The *end-expiratory pressure* is the alveoli pressure at end of exhalation, and it is in the *spontaneous breathing* human ca. 4–5 cm H₂O. Ventilation with a positive end-expiratory pressure (PEEP) ensures patency of the alveoli, by reducing the alveolar collapse, which decreases the ventilation/perfusion interface.

To set the ventilator, size, weight, and clinical condition of the patient have to be considered, and there are certain limits that should not be exceeded. For example, an oxygen concentration of more than 60% for a prolonged time can cause lung trauma. Furthermore, high maximum inspiratory pressure as well as tidal volume of more than 12 ml/kg BW is associated with a poor outcome (Malhotra 2007; Wheeler and Bernard 2007). ■ Table 9.13 has suggested values for various ventilatory parameters. The settings of the ventilator are adjusted and corrected by blood gas analysis, pulse oximetry, end-tidal CO₂ monitoring, and intrapulmonary pressure curves on the ventilator.

■ **Table 9.13** Proposed ventilator settings

Extent	Setting
Inspiratory oxygen concentration, FiO ₂	<0.6
Respiratory rate	8–12/min
Inspiration-expiration relation	1:2
Positive end-expiratory pressure (PEEP)	5–8 cm H ₂ O
Maximum inspiration pressure	<30 mmHg
Tidal volume	5–8 ml/kg BW ^a

^aPredicted body weight (female, 45.5 + 0.91 × [height in cm – 152.4]; male, 50 + 0.91 × [height in cm – 152.4])

9.5.4.2 Weaning and Extubation

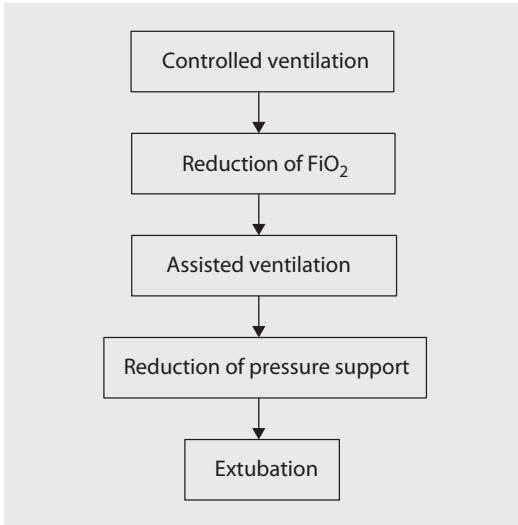

Generally, the patient arrives on the CSICU in mandatory ventilation mode until the cardiopulmonary situation is stable and the patient is normothermic. Weaning from ventilator should be performed in stepwise fashion. The mandatory ventilation mode may then be switched to assisted mode, if the acid-base balance and the oxygen level are stable at a FiO₂ 0.6 (pH 7.4 ± 0.5; arterial CO₂ partial pressure, 40–55 mmHg; HCO₃⁻ concentration, 20–28 mmol/L; base excess, 1.5 to 1.5). Controlled reduction of the ventilation pressure support to 3–5 mmHg over PEEP is the next step. ■ Figure 9.8 summarizes our approach for weaning patients from ventilation.

Extubation can be possible if the following extents are achieved:

- Adequate oxygenation under spontaneous breathing with a paO₂ >60–80 mmHg with a FiO₂ ≤0.5 and a peripheral SaO₂ ≥92%
- PEEP ≤8 cm H₂O
- Pressure support 3–5 mmHg over PEEP
- Tidal volume ≥5 ml/kg BW
- Breathing minute volume <20 L/min
- Respiratory rate 8–18 per min
- pH level 7.3–7.45 with a CO₂ arterial partial pressure of 40–55 mmHg

The clinical presentation of the patient before the extubation is important:

- The patient is awake, alert, and responds adequately.
- The patient can cough on command.
- The cardiac function is stable (heart rate 50–140 bpm, systolic blood pressure 90–180 mmHg, low-dose catecholamines, isovolemia, no pathological ECG changes to the preoperative ECG).
- Body temperature ≥96.8 °F (36 °C).
- Drainage loss ≤50–100 ml/h.
- Intact physiological reflexes.

■ **Fig. 9.8** Stepwise weaning from postoperative ventilation

An impaired renal function should not be a reason for prolonged ventilation. Some patients present with agitation and stress during the extubation process (respiratory rate >35 per min, increased blood pressure, and sweating). They should receive light anxiolytics and after ongoing ventilation a second trial of extubation. Only a small percentage of these patients will require reintubation.

9.5.4.3 Respiratory Failure

Acute respiratory failure is the most important pulmonary issue in critical care medicine. The following risk factors are known to increase the risk for an acute respiratory failure:

1. Preoperative risks
 - Emergency operation
 - Cardiac reoperation
 - Age >75 years
 - High level of urea
 - Low hematocrit level
 - Body mass index >30 kg/cm²
 - Pulmonary hypertension
 - Left ventricular ejection fraction <35 %
 - Cardiogenic shock
 - Chronic obstructive pulmonary disease
2. Intraoperative risks
 - More than 120 min of extracorporeal circulation

- Transfusion more than six units of PRBCs
- Cardiac arrest

3. Postoperative risks

- Serum albumin level <4 g/dl
- Low cardiac output requiring catecholamines
- Resternotomy for bleeding

Before an acute respiratory failure can be diagnosed, other causes of hypoxemia have to be corrected first:

- Occluded breathing tube
- Leaking ventilation system
- Improper ventilation mode
- Occluded bronchus with mucus or foreign bodies
- Hemothorax, pneumothorax
- Diaphragm malfunction due to phrenic injury
- Pleural effusion
- Atelectasis
- Significant right-left shunt
- Lung edema of cardiac origin

■ ■ Symptoms, findings, pathophysiology, causes, and diagnostic of respiratory failure

The most common symptom of respiratory insufficiency is dyspnea, often associated with tachypnea, along with cyanosis. It may have an acute onset. The X-ray displays diffuse, bilateral interstitial infiltrates that are not of cardiac origin. However, the differential diagnosis in cardiac surgical patients may be difficult, and per definition wedge pressure should be less than 18 mmHg.

In respiratory insufficiency oxygen saturation is less than 90 % on pulse oximetry, and the blood gas analysis is consistent with hypoxemia. If the $\text{paO}_2/\text{FiO}_2$ ratio (Horovitz quotient) is less than 300, a mild acute respiratory distress syndrome (ARDS) is present. If the quotient is less than 200 (e.g., $\text{paO}_2 < 100$ mmHg at $\text{FiO}_2 0.5$), it is defined as moderate ARDS. If it is below 100, the ARDS is classified as severe (The ARDS Definition Task Force 2012).

The causes for respiratory insufficiency after cardiac surgery are:

- Pneumonia
- Aspiration
- TRALI (Transfusion-related acute lung injury)

- Reperfusion injury after long-term extracorporeal circulation
- Pulmonary parenchymal hemorrhage
- Secondary involvement due to multi-organ failure

Based on the causes, the required diagnostics are:

- Bronchoscopy, combined with sampling for microbiological analysis
- Critical analysis of the pulmonary and perioperative history
- Chest X-ray
- CT scan

The pathophysiology of the acute respiratory failure is topic of many research endeavors and is discussed below in brief:

In the beginning of acute respiratory failure, the capillary endothelium is damaged by toxin that leads to hyperpermeability of the endothelium followed by an interstitial pulmonary edema. This increases the gas diffusion distance and causes collapse or narrowing of the alveoli. This process is enhanced by the loss of surfactant factor. Ventilation-perfusion mismatch occurs: the not ventilated lung parts are well perfused, whereas the ventilated lung parts are only insufficiently or not perfused. The thrombotic occlusion of pulmonary capillaries, hypoxemia-triggered vasoconstriction, the release of proinflammatory mediators, and the ventilation-perfusion mismatch worsens the pulmonary function. The ensuing hypoxemia deteriorates the function of other organ systems. Adequate oxygenation needs to be maintained, and the aggressive ventilation mode (FiO_2 1.0, high ventilation pressure) necessary for adequate oxygenation may enhance the structural damage of the alveoli and the lungs.

■ ■ Therapy

Treatment of acute respiratory failure consists of two basic principles: a causal and a symptomatic. The cause of ARDS must be treated promptly. The symptomatic treatment entails ensuring proper oxygenation of the patient. This includes adequate mechanical ventilation and other supportive care, such as special positioning of the patient. Noninvasive ventilation in patients developing acute respiratory failure after primary extubation has been advocated (Hill et al.

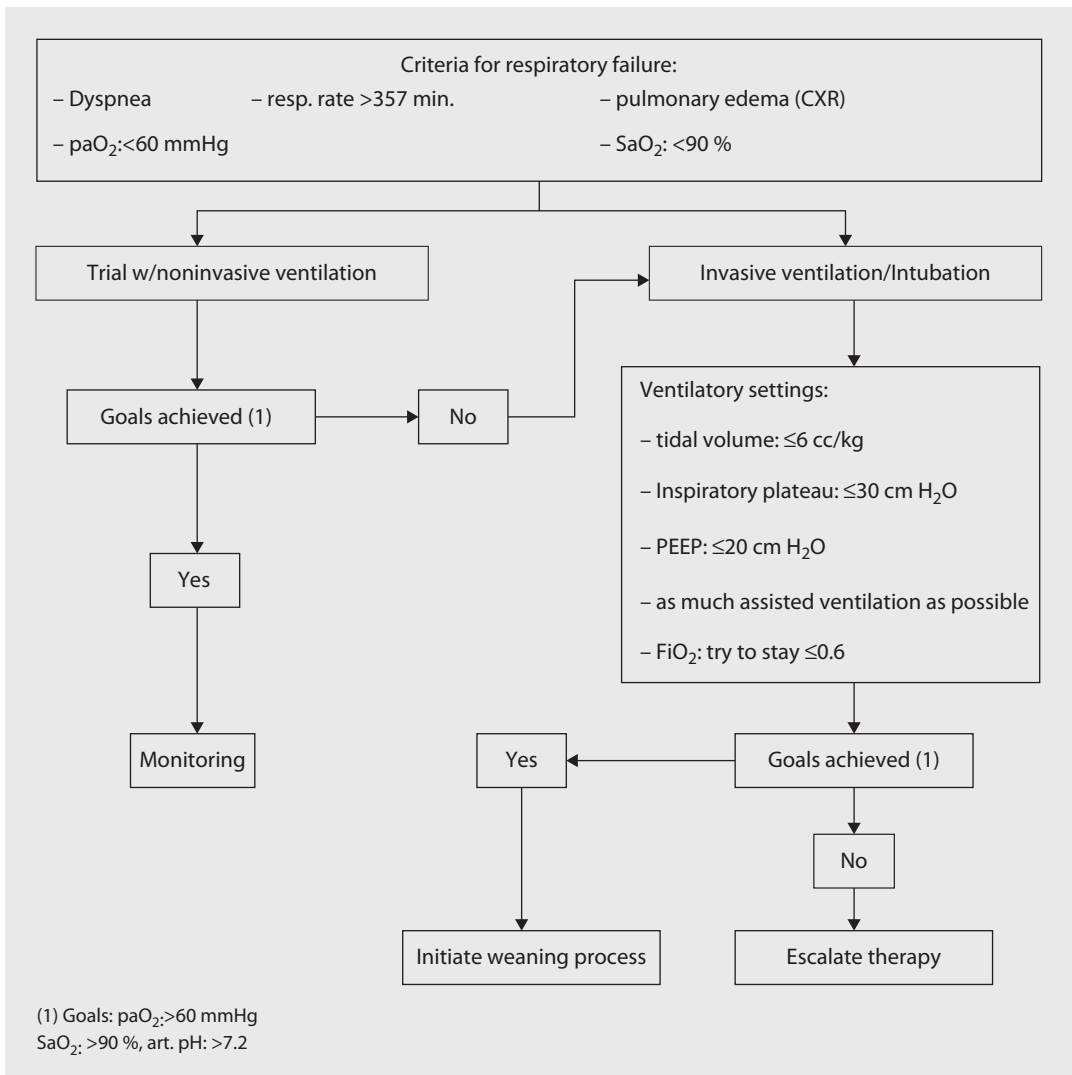

2007) and gained some interest more recently in cardiac patients, also (Guarracino and Ambrosino 2011; Cabrini et al. 2015), but it remains controversial.

■ ■ Ventilation in respiratory failure

Since only a portion of alveoli are sufficiently ventilated and perfused, the ventilation of patient with ARDS is challenging: The interstitial edema decreases the compliance of the lungs. Therefore the ventilation pressure is increased to maintain the effective minute volume, imposing additional stress to the alveoli and causing their further destruction. To reduce these deleterious effects, reduced tidal volume to 4–6 ml/kg has been shown to be associated with improved outcomes (The Acute Respiratory Distress Syndrome Network 2000). A possible side effect of this alveoli-protective strategy is an increased CO_2 partial pressure that can be tolerated upon 80 mmHg (permissive hypercapnia), unless the associated metabolic acidosis would be harming the patient.

In acute severe lung failure, high PEEP levels have to be used. The PEEP setting on the ventilator is usually 12–15 cm H_2O but may be increased to maximal 25 cm H_2O . To calculate the approximate required PEEP, the formula $\text{PEEP} \leq \text{FiO}_2/0.05$ can be useful. The exacter method is to adjust the PEEP to the pressure-volume curve, where the PEEP value has to be chosen right above the lower inflection point. The lower inflection point indicates the pressure limit that is necessary to open the alveolus. A PEEP right above this point ensure open alveolus (Hemmila and Napolitano 2006; Malhotra 2007; Wheeler and Bernard 2007). Adequate PEEP will prevent alveoli trauma caused by collapse and reopening. The effect of high PEEP to the circulatory system occurs only in patients with hypovolemia, but higher risk of pneumothorax has to be considered in all patients with sudden respiratory deterioration. It is important to mention that there is no data supporting improved outcome with high PEEP ventilation in respiratory failure. The strategy of a low tidal volume, permissive hypercapnia, and high PEEP is called the open lung concept.

In addition to high PEEP ventilation, recruitment maneuver is helpful in maintaining alveoli open: this includes brief gradual increase of

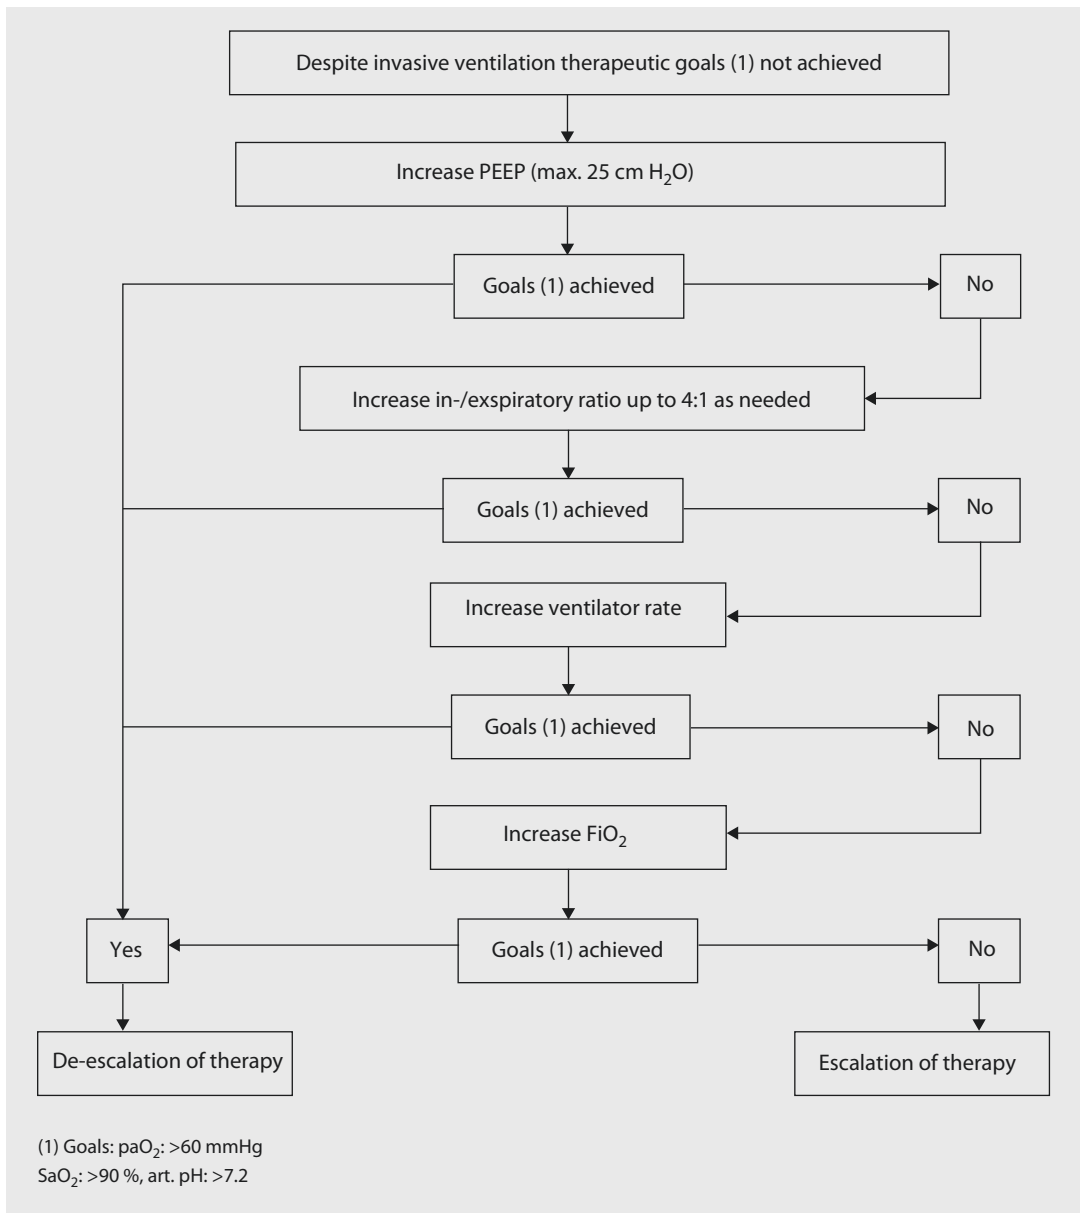

■ **Fig. 9.9** Our initial therapeutic approach in acute respiratory failure/acute pulmonary failure. FiO_2 inspired oxygen fraction, paO_2 arterial oxygen partial pressure, $PEEP$ positive end-expiratory pressure, CXR chest X-ray, SaO_2 arterial oxygen saturation

maximal ventilation pressure up to 40 cm H₂O to «recruit» (reopen) collapsed alveoli. After recruitment maneuver is finished, the maximal ventilation pressure is reduced slowly to lowest possible PEEP that keeps the alveolus open based on lower inflection point.

If the open lung concept with a low tidal volume and a high PEEP do not sufficiently improve oxygenation, inverted ratio ventilation may be tried: the inspiration-expiration ratio has to be changed to a prolonged inspiration time (2:1 up to 4:1), and the FiO_2 has to be maximally increased to 1.0. This is an effective approach in

hypoxemic patients, but usually requires paralyzing medication.

Yet another mode of ventilation that can be useful in patients with acute respiratory failure and maximal reduced lung compliance is the high-frequency oscillatory ventilation mode. A high ventilation frequency between 300 and 600/min reduces the tidal volume to 1–4 ml/kg and subsequently reduces stress to the alveoli (Hemmila and Napolitano 2006). The expiration is actively carried out by a vibrating membrane, in contrary to other forms of high-frequency ventilation (i.e., jet ventilation).

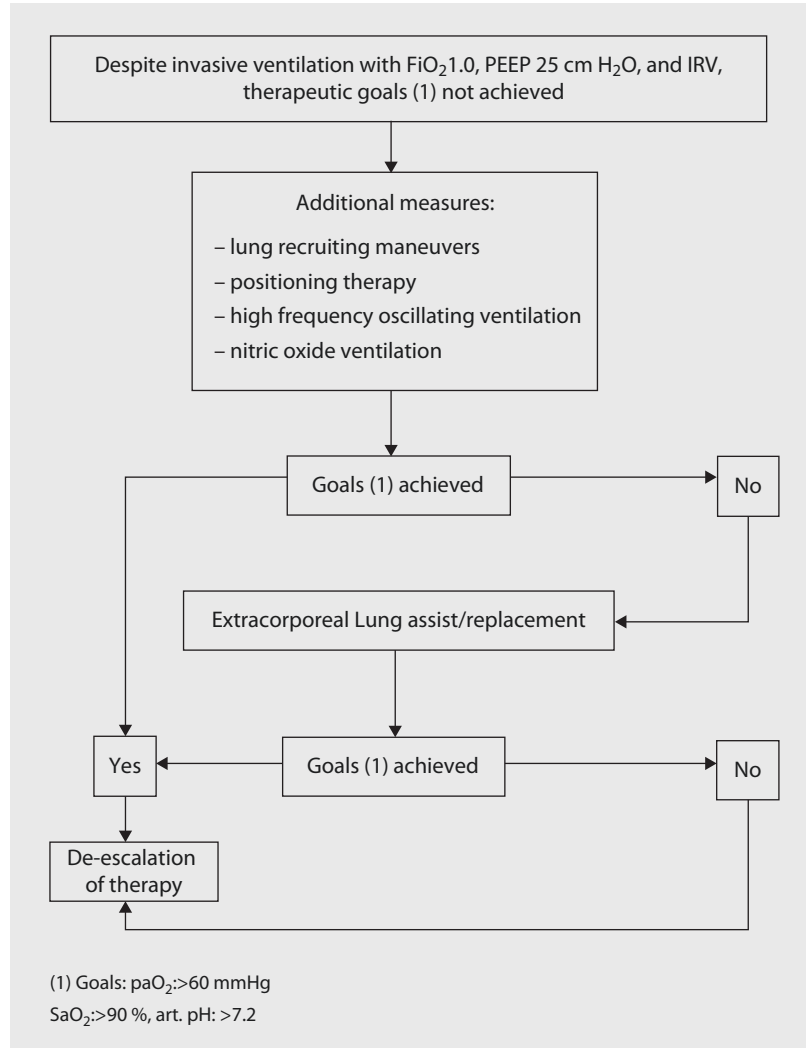

■ Fig. 9.10 Our approach for therapeutic escalation in acute respiratory distress syndrome: FiO_2 inspired oxygen fraction, paO_2 arterial oxygen partial pressure, $PEEP$ positive end-expiratory pressure, SaO_2 arterial oxygen saturation

■ ■ Other supportive Measures

The proper position of the patient can improve the oxygenation. Elevated upper body position (30–45°) supports the patient's breathing, by reducing pressure from the diaphragm caused by abdominal organs, and reduces silent aspiration. The most effective strategy for oxygenation is ventral positioning of the patient. This has a very

positive influence on oxygenation due to improved ventilation-perfusion ratio and homogenized ventilation. The frequency and the duration of this positioning are not strictly defined, but it should be adapted to the patient's clinical condition. The positioning maneuver requires increased logistic and personnel workforce, but the effects on the respiratory system are remarkable.

■ **Fig. 9.11** Our approach for further therapeutic escalation in acute respiratory distress syndrome: irresponsive to first stage escalation of therapy: FiO_2 inspired oxygen fraction, IVR inversed ratio ventilation, NO nitrogen oxide, paO_2 arterial oxygen partial pressure, $PEEP$ positive end-expiratory pressure, SaO_2 arterial oxygen saturation

The 135° positioning and special rotational beds are less effective than the true 180° positioning but certainly very helpful. To perform these maneuvers, the patient's hemodynamics has to be stable. This may not be the case early after open-heart cases.

The fluid management of the respiratory-impaired patient has to be restrictive to avoid any volume overload that results in an increase of the existing lung edema, worsened by cardiogenic pulmonary edema. However, intravascular hypervolemia has to be avoided given the high PEEP ventilation.

Furthermore, «sedation holiday» is an effective method in shortening ventilation

time and the CSICU stay. This entails daily brief disruption of the sedatives, until the patient is awake and more alert, before reinitiating the sedation.

The early initiation of enteral nutrition has shown a positive effect in reducing ventilator period in patients with mechanical ventilation more than 36 h, whereas the endotracheal surfactant therapy and the inhaled medications, such as prostacyclin or iloprost, have not proven to be efficacious.

Steroids improve blood pressure, the pulmonary oxygenation, and the duration of mechanical ventilation in ARDS but do not reduce the 60- or 180-day mortality.

If, despite maximal aforementioned efforts, adequate oxygenation is not secured, more invasive methods may be considered in appropriate patient cohort, understanding the significant cost involved: there are pump-driven systems, such as extracorporeal membrane oxygenation (ECMO) for heart and lung support, or pumpless systems that work due to the artery-venous pressure gradient. In both systems the blood oxygenation occurs with assistance of a gas exchange membrane oxygenator. The oxygenation is more effective using ECMO, but the pumpless systems are more often used in hypercapnic patients with hypoxemia responding to conventional measures.

Due to its pump drive, the ECMO is not dependent on the circulatory situation, whereas the pumpless systems require a stable or stabilized cardiocirculatory function. ECMO consumes significantly more CSICU resources (Bein et al. 2007).

■ Figures 9.9, 9.10, and 9.11 show treatment algorithms and therapeutic escalation in respiratory distress situations.

■ ■ Tracheotomy

Tracheotomy is a supportive measure providing the following advantages: secured airway, easier oral care, more comfort for the patient, and no larynx trauma. Weaning from mechanical ventilation is faster and less complicated in patients having tracheotomy (De Leyn et al. 2007). Reduced dead space ventilation by tracheotomy reduces the work of breathing for the patient. The procedure can be performed surgically or using percutaneous Seldinger approach in CSICU—dilatational tracheotomy—that can be done on bedside with bronchoscopy (Ciaglia et al. 1985).

The optimal timing for a tracheotomy is unclear yet (Young et al. 2013), but the positive effect of this treatment should encourage the intensivist to perform it earlier if prolonged mechanical ventilation is expected.

■ ■ Weaning from ventilation and extubation

Patients with more than 48 h of mechanical ventilation will have a more difficult course of extubation. The weaning actually starts already preoperatively with breath-exercising respiratory physiotherapy. The weaning process once

intubated and ventilated starts by reducing the sedation so far that the patient is stress-free and hemodynamically stable under assisted ventilation. Then the patient controls his breath rate, but the tidal volume is assisted by the ventilator. Subsequently the ventilation pressure is reduced stepwise, allowing the patient do most of the work of breathing. The blood gas analysis and the clinical situation should be stable within 30–60 min without evidence of respiratory fatigue.

Signs of respiratory fatigue are:

- Agitation
- Anxiety
- Sweating
- Tachycardia
- Blood pressure drop or rising
- Centralization (peripheral vasoconstriction)
- Inadequate ventilation time volume
- Inadequate tidal volume
- Breath rate of >35 per minute
- Peripheral oxygen saturation of <92 %
- Arterial oxygen partial pressure <60 mmHg

If the patient displays these symptoms, the extubation should be delayed for another 24 h, before a second extubation is attempted.

If the patient is stable and calm, the sedation should be ended. Just before extubation the patient should be totally awake, should push the hand on command, and should raise the head off the pillow. If a gastric tube is in place, it should be completely suctioned and removed before extubation.

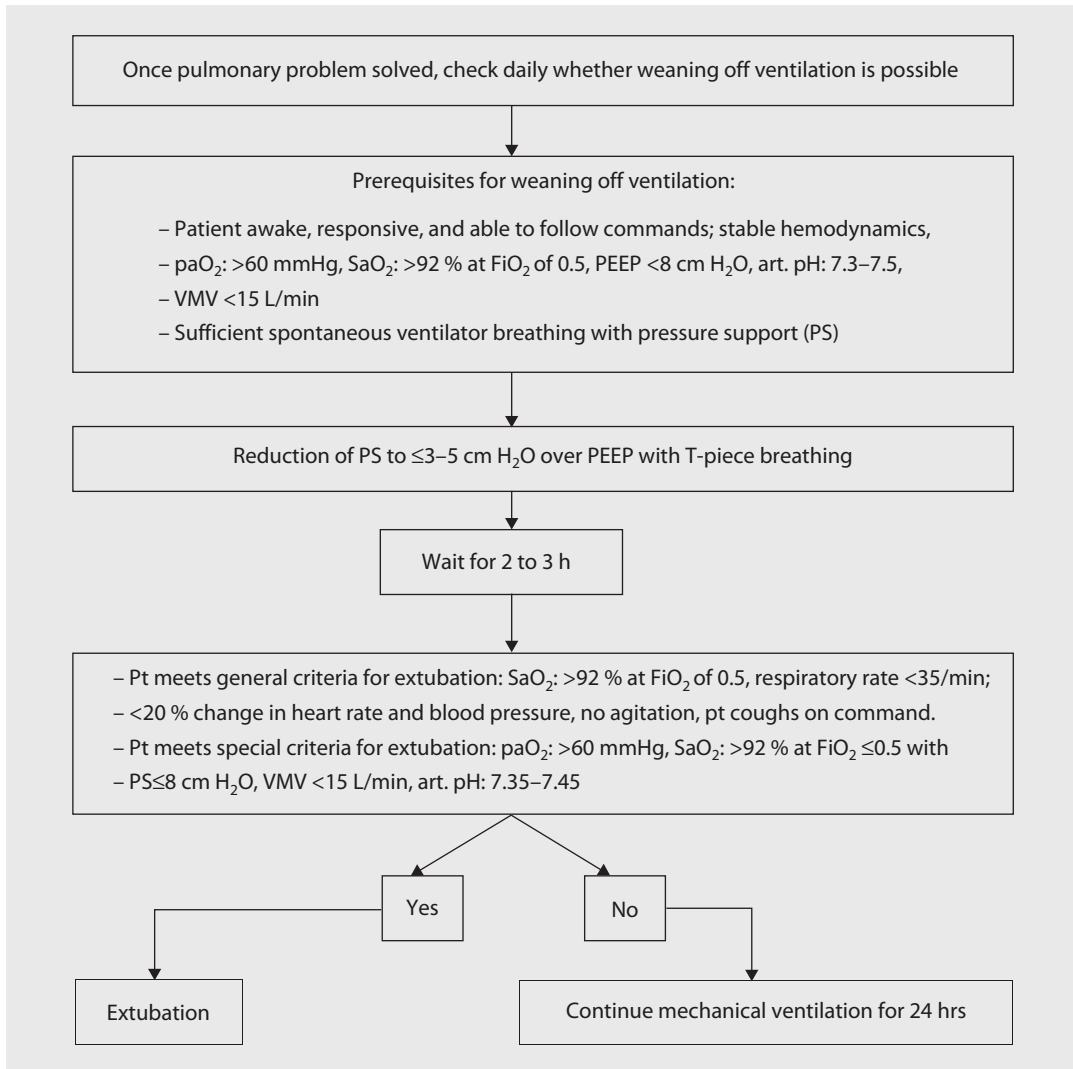

After extubation, the patients are positioned in sitting or with upper body elevated 30–45° to facilitate the work of breathing and reduce aspiration risk. The possibility of reintubation has to be considered in elderly, frail, malnourished patients, or those with poor mental status and prolonged ventilator support.

■ Figure 9.12 summarizes our approach to wean patients from ventilation after a complicated course.

■ ■ Side Effects and complications of mechanical ventilation

Possible side effects of the mechanical ventilation are:

- Increased intrathoracic pressure with a reduction of the cardiac filling

■ **Fig. 9.12** Our approach for weaning off mechanical ventilation. FiO_2 inspired oxygen fraction, paO_2 arterial oxygen partial pressure, PEEP positive end-expiratory pressure, PS pressure support, SaO_2 arterial oxygen saturation, VMV ventilator minute volume

- Decrease of renal blood flow with activation of the renin-angiotensin system
- Reduction of airway mucus clearance
- Damage to the surfactant monolayer by positive airway pressure-mediated shear stress
- Pulmonary trauma due to a high FiO_2
- Damages of the alveoli due to high tidal volume or a high airway pressure
- Barotrauma of the lungs with the risk of a pneumothorax
- Decubitus and thromboembolic complications due to immobilization

The following complications should be mentioned:

- Trauma to or edema of larynx, trachea, and bronchi
- Ventilator-associated pneumonia

While most side effects and complications may be self-limiting, the most deleterious effect on a patient with acute respiratory failure is from ventilator-associated pneumonia (VAP). VAP

develops 48 h or longer after mechanical ventilation is given by means of an endotracheal tube or tracheotomy and is associated with substantial mortality. VAP results from the invasion of the lower respiratory tract and lung parenchyma by microorganisms. Intubation compromises the integrity of the oropharynx and trachea and allows oral and gastric secretions to enter the lower airways. The prevention of any triggers is most important: sterile exchange of ventilator components, sterile endotracheal suction, positioning of the patient with aspiration precautions, and weaning according to established protocols.

9.5.5 Kidney

9.5.5.1 Incidence, Cause, and Diagnostic of Renal Complications

The perioperative acute renal failure occurs with an incidence 1.2–5.1% after cardiac surgery and is associated with 40–80% increased mortality (Markewitz and Lante 2006; Mehta et al. 2006).

The definition of renal failure has been somewhat empiric and vague in cardiac surgical literature; increased creatinine by certain value or percentage, reduced urine output, and other factors had been used in the past, making reliable comparison of literature impossible. The RIFLE classification (■ Table 9.14) as well as the more recent AKIN classification (Acute Kidney Injury Network) (■ Tables 9.15 and 9.16) can be used to quantify and qualify renal failure (Bellomo et al. 2004; Hoste et al. 2006; Kuitunen et al. 2006; Mehta et al. 2007). RIFLE, for example, classifies severity and outcomes, it proposes criteria for three grades of increasing severity: risk of acute renal dysfunction (*R*), injury to the kidney (*I*), and failure of kidney function (*F*), and two outcome classes: loss of kidney function (*L*) and end-stage kidney disease (*E*). The RIFLE classification based on estimated glomerular filtration rate (eGFR) and serum creatinine. eGFR is calculated with the abbreviated «Modification of Diet in Renal Disease formula», MDRD (Jin et al. 2008). Calculation of estimated glomerular filtration rate (eGFR) with the abbreviated «Modification of Diet in Renal Disease» formula: Chronic kidney

■ **Table 9.14** The RIFLE criteria according to Bellomo et al. (2004)

Class	GFR criteria
<i>Risk</i>	Plasma Cr increase 1.5 × baseline or GFR decline >25 %
<i>Injury</i>	Plasma Cr increase 2 × baseline or GFR decline >50 %
<i>Failure</i>	Plasma Cr increase 3 × baseline or GFR decline >75 % or acute plasma Cr > 4 mg/dL
<i>Loss</i>	Persistent ARF = complete loss of kidney function requiring dialysis for >4 weeks but <3 months
<i>End stage</i>	End-stage kidney disease requiring dialysis for >3 months

■ **Table 9.15** National Kidney Foundation classification of stages for chronic kidney disease

Stage	Description	GFR
1	Kidney damage with normal or ↑ GFR	>90 (with CKD risk factors)
2	Kidney damage with mild or ↓ GFR	60–89
3	Moderate ↓ GFR	30–59
4	Severe ↓ GFR	15–29
5	Kidney failure	<15 (or dialysis)

■ **Table 9.16** Grading for acute renal failure according to the consensus conference of the Acute Kidney Injury Network (AKIN)

Grade	Serum creatinine level	Urine output
1	Creatinine ↑ by ≥0.3 mg/dL or ↑ by >150–200 %	<0.5 cc/kg/h for 6 h
2	Creatinine ↑ by >200–300 %	<0.5 cc/kg/h for 12 h
3	Creatinine ↑ by >300 % or by 4 mg/dL or by ≥0.5 mg/dL acutely	<0.3 cc/kg/h for 24 h or anuria (<100 cc in 12 h)
3	Kidney replacement therapy necessary	

Mehta et al. (2007)

$$\left(\begin{aligned} \text{Estimated eGFR [ml/minute/1.73 m}^2\text{]} &= 186 \times [\text{serum creatinine}]^{-1.154} \times [\text{age}]^{-0.203} \\ &: [0.742 \text{ if female}] \times [1.210 \text{ if African - American}] \end{aligned} \right)$$

disease (CKD) is defined as a baseline eGFR ≤ 60 ml/min/1.73 m², while chronic renal failure (CRF) is defined as eGFR ≤ 30 ml/min/1.73 m² (stage III versus IV and V according to the Kidney Disease Outcome Quality Initiative) (National Kidney Foundation 2002).

In clinical practice, many cardiac surgical patients can be classified into RIFLE criteria «risk,» and some may correspond to the level «injury.» However, the recovery is the norm in majority of these patients.

Starting with the level «failure,» the treatment of the patients is going to be more complex and resource intensive. CSICU capacities are limited, and patients that require hemodialysis may occupy them for a prolonged period of time. The preoperative risk stratification of renal failure is not easy to perform, but the Society of Thoracic Surgeons (STS) provides a risk score for postoperative renal failure (Online STS Risk Calculator) (Table 9.17). Figure 9.13 shows how the results of the STS Risk Calculator translate into a probability for renal replacement therapy.

9.5.5.2 Prevention of Renal Complications

Prevention is the best therapy of renal failure. It is important to ensure an adequate hydration, oxygenation, and adequate mean arterial pressure. The perioperative administration of aspirin has proven to have a positive effect (Mangano et al.

2002); this not being the case with N-acetylcysteine or «renal-dose» dopamine. Avoiding any nephrotoxic function, such as aminoglycosides, and all prostaglandin-synthesizing blockers is important but not always possible.

9.5.5.3 Therapy of Renal Complications

During the first hours after cardiac operation, the urine production decreases in nearly all patients due to various causes. Once in a while, the urinary catheter may be clogged or kinked, or the mean arterial pressure is too low. These problems can be solved easily, and they have to be considered early in the evaluation of the patient. Generally diuretics, such as furosemide or torasemide or mannitol, are given to improve urine output, understanding that urine output per se does not imply extend of kidney function. Also, the maximum dose per day of diuretics has to be taken into account.

If urine output cannot be reactivated with the aforementioned methods, the decision for renal replacement therapy should be made within 24 h or less of oliguria or anuria. Options for renal replacement therapy such as intermittent or a continuous filtration mode does not influence the patient's outcome (Garwood 2004). Diuretic administration, however, should be stopped due to its contra-productive effect (Mehta et al. 2002), as up to 25 % of these patients will require long-term renal replacement therapy.

■ **Fig. 9.13** Probability to require renal replacement therapy after cardiac surgery in relation to preoperative risk factors (STS risk score acc. to Table. 9.17) Mehta et al. (2006)

Table 9.17 Parameters and corresponding points for risk assessment, if perioperative renal replacement therapy will be required

9.5.6 Gastrointestinal Tract

Severe complications of the gastrointestinal tract, such as bleeding, ulcer, prolonged ileus, pancreatitis, intestinal ischemia, or mesenteric artery thrombosis occur in about 3% of the patients undergoing open-heart surgery.

The outcome of patients with severe gastrointestinal complications is associated with high mortality (Markewitz and Lante 2006). Most common problems involved gastrointestinal bleeding, amenable to endoscopic treatment options, and associated with much better outcome. Ischemic bowel complications are associ-

ated with a mortality of 70–100%, and high index of suspicion is critical to promptly achieve the right diagnosis. The symptoms are usually unspecific, causing late diagnosis. Furthermore, there is no specific monitoring available, but increasing lactate and phosphate levels and persisting therapy refractory metabolic acidosis should increase index of suspicion, prompting diagnostic testing. The metabolic acidosis is usually accompanied by paralytic ileus and leukocytosis. The next step has to be taken very quickly to confirm the diagnosis: mesenteric arteriogram, but if there is no possibility for angiography, immediate laparotomy is requested to diagnose and possibly treat the issue

with superior mesenteric or celiac artery bypass operation. If a nonocclusive ischemia is present, the administration of local vasodilatory drugs such as papaverine is possible. Even with rapid decision taking, the mortality remains at 50%. When symptoms are present for more than 12 h survival is improbable.

A subtype of patients with acute type A or B aortic dissection may have or develop malperfusion to celiac or mesenteric artery during the index hospitalization (complicated aortic dissection). The malperfusion is usually due to dynamic (dissection flap occluding the orifice of the aortic branch vessels) or anatomic (dissection flap and hematoma in the orifice for the branch vessels). These patients have a treatment paradigm that has significantly changed in recent years, requiring further details here (Khoynezhad et al. 2009).

Prompt diagnosis and anti-impulsive treatment of patients with suspected complicated aortic dissection (CAD) is essential for improved outcome. Originally, the minor only available option used to be surgical fenestration of the membrane separating true and false lumen in order to perfuse both true and false lumen and reduce the pressure gradient that is the cause for the dynamic malperfusion. For anatomic obstructions, mesenteric bypass operation would be added. The endovascular treatment is, however, now the new standard to promptly restore intestinal blood flow. Diagnosis is confirmed with intravascular ultrasound and/or angiogram in the hybrid suite (See also ► Chapter «Endovascular Surgical Therapy of Thoracic and Thoracoabdominal Disease of the Aorta», Sect. 28.7.2).

9.5.7 Central and Peripheral Nervous System

9.5.7.1 Incidence of Neurological Complications

Depending on definitions and the diagnosing physician, incidence of neurological complications may vary. As minor as it may appear to be,

it can significantly reduce quality of life longterm and does increase early mortality. Neurological complications are classified into the following categories:

- Ischemic stroke
- ICU psychosis
- Critical illness polyneuropathy
- Other neurological complications such as neurocognitive deficits, neuropsychological complications, and peripheral nerve injuries

9.5.7.2 Ischemic Stroke

The incidence of an ischemic stroke after cardiac surgery is 2–10%, being between 1.4% and 3.8% in patients after coronary artery bypass grafting and up to 10% with multiple valve operations or total arch replacement (Selim 2007). The patient typically has hemiparesis and aphasia depending on the troubled brain hemisphere. CT scan will be able to show the infarcted area 2 h after stroke. The usual causes for an ischemic stroke are ruptured atherosclerotic plaques from the aorta, or calcific aortic valve, thrombotic material from the left atrium or the left ventricle, acute occlusion of a high-grade-stenosed internal carotid artery. Next to CT and duplex carotid, transesophageal echocardiography is ordered to exclude emboli source from the heart.

Therapeutic approach to thromboembolic ischemic stroke is parenteral lysis with recombinant tissue-type plasminogen activator. However, this therapeutics cannot be used for most cardiac surgical patients given the recent operation. In certain circumstances, super-selective intra-arterial lysis may be performed; however this has to be performed within 6 h of symptoms. In most cases the stroke occurs in patients under sedation, making any therapeutic intervention within that «window» impossible. Therefore the therapy of a stroke in cardiac surgical patients is mostly symptomatic:

- Increase of the blood pressure (160–180 mmHg systolic) as autoregulation in the stroke area may not be present any more
- Adequate oxygenation
- Blood glucose level <150 mg/dl
- Body temperature less than 99.5 °F (37.5 °C)

While systemic heparinization is not recommended, administration of aspirin (50–325 mg) daily as secondary prophylaxis is established.

The most feared complication is brain edema with increase of intracranial pressure. Therefore the monitoring has to be extended to check for signs of increased intracranial pressure and decreased consciousness. Recommended positioning is 30° elevated upper body, diuresis with mannitol, or administration of short-acting barbiturates, such as thiopental. While steroids are no longer recommended, the use of hyper-ventilation is controversial and may be used as short-term therapy until other measures are initiated. The last option in reducing intracranial pressure is surgical decompression with a craniotomy.

Furthermore, treatment of accompanying seizures may be necessary, along with all accompanying problems of immobilized and unconscious patients, such as aspiration pneumonia, thromboembolic complications, and decubitus ulcer.

The prognosis of survivors with stroke after cardiac surgery is rather grim; only 47% survive the first 5 years, half of them with permanent deficits requiring external support for daily living activities (Salazar et al. 2001). Early rehabilitation will help to restore the muscular coordination and improve functional outcome.

9.5.7.3 ICU Psychosis

ICU psychosis is a disorder in which hospitalized patients, especially in ICU, may experience anxiety, paranoia, hallucinations, disorientation, agitation, and even violence against nurses and doctors. The condition has been formally defined as «acute brain syndrome involving impaired intellectual functioning which occurs in ICU patients.» ICU psychosis is a form of delirium or acute brain failure, and some organic factors including dehydration, hypoxia, low cardiac output, infections, and drugs may contribute to its development. The postoperative delirium occurs relatively often in elderly and remains clinically challenging for many physicians, nursing staff, and the patient's family.

Mild form of delirium does not require therapy, especially in elderly, or in case of significant fluid loss (fever, sweating, diarrhea) or high ambient temperatures, making adequate

volume resuscitation necessary. In the individual case, especially in violent patients, administration of 2–10 mg haloperidol or clonidine IV (clonidine as an IV drug is not available in the USA) as well as the newer generation of atypical antipsychotic drugs may be considered. Only in extreme situations, endangering the patient and the CSICU staff, the sedation with propofol is recommended.

To further differentiate and quantify psychosis, the Richmond Agitation-Sedation Scale (Sessler et al. 2002), in conjunction with the Confusion Assessment Method, may be employed (Ely et al. 2003, 2004; Sessler et al. 2002). The physical fixation of the patient should only be performed in extreme situations; on the one hand, it is restricted by law and needs clear documentation, and on the other hand the symptoms can be exacerbated by physical fixation.

It is not uncommon that patients with ICU psychosis develop an instable sternum requiring surgical reintervention.

9.5.7.4 Critical Illness Polyneuropathy

The cause of this rare complication is not well understood, allowing for no treatment or prophylaxis. This polyneuropathy affects mainly the motor axons, occurring most commonly after sepsis and polytrauma. A correlation with systemic inflammatory reaction syndrome (SIRS), multi-organ failure, and various drugs is highly suggested. The main problem is to wean the patient from ventilator, as breathing muscles are commonly affected by critical illness polyneuropathy. After repeatedly failed extubation attempts, the critical illness polyneuropathy has to be taken into account. Early mortality is about 30%, another 50% of the patients recover between 6 weeks and a year, while 20% will have residual neuropathies (Kane and Dasta 2002).

9.5.7.5 Other Neurological Complications

Other complications, such as neurocognitive deficits, neuropsychological complications, and peripheral nerve lesions, are not specific to cardiac surgical patients. Peripheral nerve injuries are potentially preventable complications during anesthesia, requiring extra attention while positioning the patient.

9.5.8 Acid-Base Balance and Electrolytes

The laboratory values and the common causes for disorders of the acid-base balance are displayed in ■ Tables 9.18 and 9.19.

Metabolic acidosis is the most relevant acid-base disorder in the CSICU, as the underlying causes can be potentially fatal disorders. An insufficient oxygen supply, caused by LCOS or mesenteric ischemia, initiates a change from aerobic to anaerobic metabolism, releasing more acids in the bloodstream. Main goal is to treat the underlying cause of the acidosis, as sole treatment of the metabolic acidosis may not be enough. Clinical implications are reduced myocardial contractility and decreased effectiveness of catecholamines, clinically relevant in patients with pH below 7.2. The amount of NaHCO_3 to balance the acidosis can be calculated with the following formula:

$$\text{Negative base excess} \times 0.3 \\ \times \text{body weight (kg)} = \text{mval NaHCO}_3 \text{ (8.4\%)}$$

Administering large amounts of NaHCO_3 results in iatrogenic hyponatremia. If more bicarbonate buffer is needed in case of a sodium level more than 145 mmol/L, Tris (hydroxymethyl) amino-methane (THAM) may be used:

$$\text{Negative base excess} \times 0.1 \\ \times \text{body weight (kg)} = \text{ml tris buffer solution}$$

A metabolic alkalosis is often the result of an overtreated metabolic acidosis. A metabolic alkalosis can also cause a reduction of myocardial contractility and heart rhythm disturbances and will worsen the oxygen tissue supply by shifting the oxygen dissociation curve.

Electrolyte abnormalities will influence the heart function, especially the potassium level have the most clinical effect. The typical potassium level in the blood serum is 3.5–5 mmol/L. A low level of potassium associated with metabolic alkalosis is accompanied by extrasystoles, tachycardia, and ST interval decrease or a prolonged QT interval and will be treated by parenteral administration of KCl. If hyperkalemia is present, high peaks of the T waves can be seen as well as enlargement of QRS complex, branch blocks, arrhythmias, and cardiac arrest. To lower the serum potassium level, the administration of diuretics, NaHCO_3 , calcium, or glucose with insulin can be helpful. Diuretics will eliminate the potassium, but the other attempts only provide a potassium shift from extracellular to intracellular. Another effective method to reduce potassium levels is Sodium

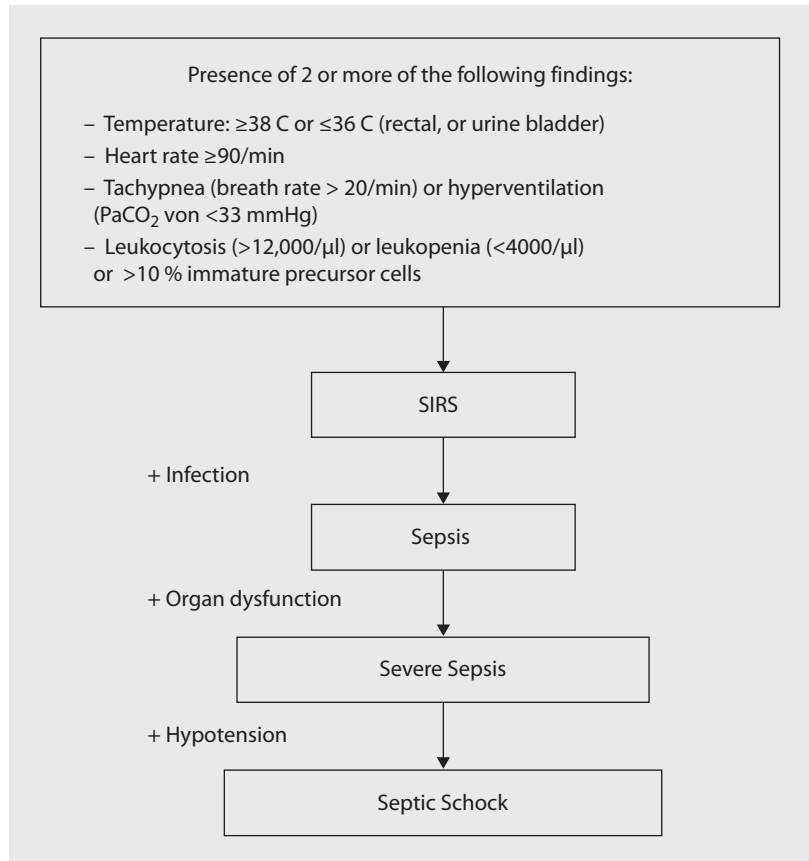

■ Table 9.18 Laboratory values in disorders of the acid-base balance

Disorder	pH level	CO ₂ partial pressure mmHg	Bicarbonate concentration mmol/L	Base excess mmol/L
Normal values	7.36–7.44	35–45	22–26	–2 to + 2
Respiratory acidosis	<7.36	>45	Normal	Normal
Respiratory alkalosis	>7.44	<35	Normal	Normal
Metabolic acidosis	<7.36	Normal	<22	Negative
Metabolic alkalosis	>7.44	Normal	>26	Positive

■ Table 9.19 Common causes for disorders of the acid-base balance

Disorder	Cause	Therapy
Respiratory acidosis	Hypoventilation	Increase respiratory rate or tidal volume
Respiratory alkalosis	Hyperventilation	Decrease respiratory rate or tidal volume
Metabolic acidosis	Anaerobic metabolism	Bicarbonate and correct the underlying cause
Metabolic alkalosis	Overcorrected acidosis	Acetazolamide and correct the underlying cause

■ **Fig. 9.14** Differential diagnosis and grading of severity of inflammatory reactions without and with infectious cause

Polystyrene Sulfonate Suspension, a cation-exchange resin administered orally or as an enema.

If the potassium level exceeds 6 mmol/L or patient is having active symptoms, extracorporeal filtration of potassium using renal replacement therapy may be indicated.

If high levels of sodium are present, the sodium intake has to be stopped immediately to prevent a hyperosmotic coma. All transfusion fluids should be sodium-free, such as glucose 5%. A hypernatremia due to fluid overload or sodium loss through the kidney or the gut (diarrhea) can be treated by administration of sodium-containing fluids.

9.5.9 Fever and Infection

The rise of the body temperature after cardiac surgical operations is not uncommon and does not require a treatment in the absence of any signs of infection. This is especially true in the first few days after index operation, commonly associated with body's systemic inflammatory

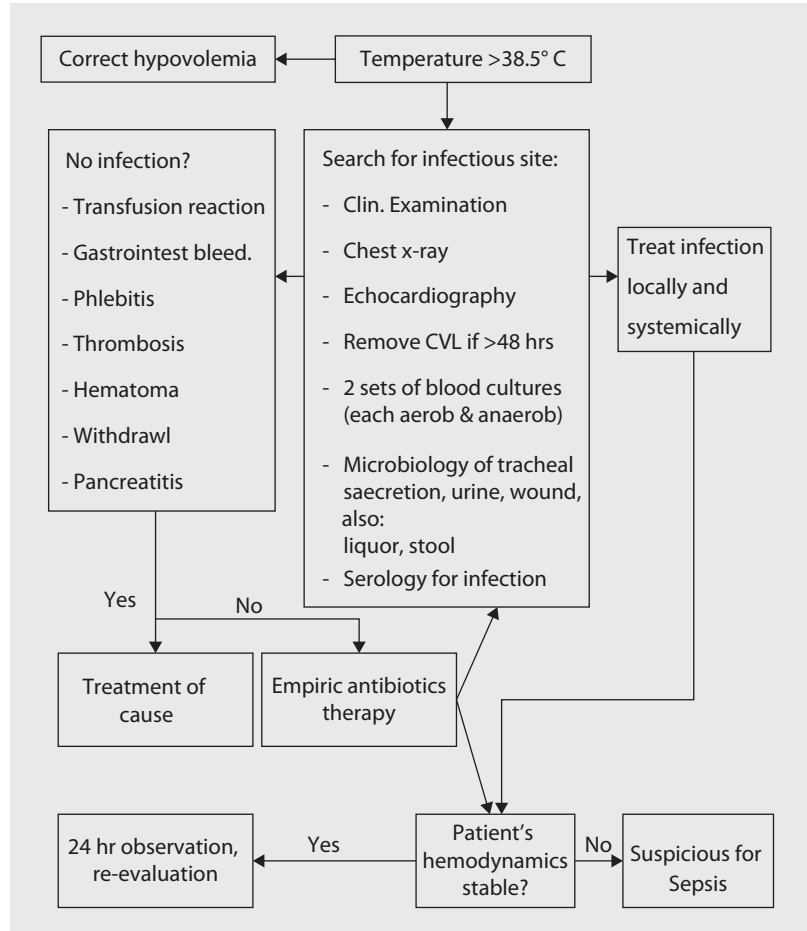

response syndrome or early postoperative atelectasis. The temperature course should be followed and does not require normalization if patient is not tachycardic or otherwise symptomatic. Exceptions to this rule are operations for infective endocarditis, or sternal wound infections. The challenge for the intensivist is to differentiate between physiological fever and brewing infection. ■ Figure 9.14 depicts and describes sequence and grading of differential diagnosis in inflammatory processes.

Infection is a clinical diagnosis or positive result in microbiology examination.

Organ dysfunction include:

- Acute encephalopathy with impaired vigilance, disorientation, restlessness, delirium
- Relative or absolute thrombocytopenia with a platelet drop >30 % within 24 h or a platelet count <100,000/μl in the absence of acute bleeding
- Arterial hypoxemia with $\text{paO}_2 < 75$ mmHg in room air, Horowitz quotient <250 (see ► Sect. 9.5.4.3, p. 229)

■ **Fig. 9.15** Our algorithm for diagnosis and therapy of postoperative fever. CXR chest X-ray examination, CVL central venous line

- Renal dysfunction, diuresis <0.5 cc/kg/h for more than 2 h despite adequate volume load or serum creatinine climbed to twice normal
- Metabolic acidosis, negative base excess exceeds -5 mmol/L or lactate increased more than 1.5 normal
- Hypotension with systolic arterial pressure <90 mmHg or mean arterial pressure <70 mmHg for at least 1 h despite volume replacement and IV vasopressor therapy

■ ■ Practical steps

Fever is defined as a body temperature with more than 100°F (in Europe $38.3^{\circ}\text{C} = 100.9^{\circ}\text{F}$). Initially hypovolemia should be corrected that may cause fever by itself. If the temperature is not dropping or another fever is coming up, a high index of suspicion for brewing infection should be maintained. The next step is the search for the infection focus.

Since postoperative cardiac surgical infections are associated with significantly increased mortality and cost, any signs of infection have to be evaluated carefully and promptly. If an infection is present, an appropriate and immediate treatment is recommended. This is especially true for patients with high pretest probability of infection such as immune suppressed, HIV-infected, or poorly controlled diabetic and obese patients

The search for infection after cardiac surgery should focus on:

- Pneumonia
- Urinary catheter infections
- Central vein catheter and peripheral line infections
- Surgical site infections

The first three types of infection occur usually after the fifth postoperative day, whereas surgical site infections appear mostly after more than

1–2 weeks depending on involved pathogen. These wound infections should be treated according to general surgical principles and accompanied by systemic antibiotics.

If bedside investigations, such as chest X-ray, urine, and respiratory cultures, remain negative for an infection, an antibiotic therapy should be started even without knowing the infectious organism. The typical organism described in the literature may be helpful, but it is more useful to know the hospital common organisms and their resistances. Furthermore, the initial antibiotic should be wide spectrum, reducing to more narrow antibiotics once sensitivities are back. If an infection focus is identified, removal of the focus with or without surgical excision should be performed immediately.

■ **Figure 9.15** illustrates our algorithm to evaluate postoperative fever.

If the infection progresses to a full-blown sepsis, the prognosis will be significantly worse. These four strategies have shown to improve severe sepsis or septic shock outcomes:

- Early support for normalized hemodynamic function (Rivers et al. 2001)
- Intensified insulin therapy (van den Berghe et al. 2001)
- Administration of human recombinant activated protein C (APC) (Bernard et al. 2001).
- Widening of antibiotic therapy including antifungal or antiviral in specific patient cohort

In the meantime, target levels for tight glycaemic control have been changed (Haga et al. 2011). Activated protein C (APC) has been removed from the market due to questionable benefit (Marti-Carvajal et al. 2012). This topic is rather comprehensive and complex and cannot be sufficiently handled in this chapter. Therefore, further detailed reading is suggested (Dellinger et al. 2013).

9.5.10 Decubitus

A decubitus is tissue damage caused by prolonged compression (Maklebust 2005; Thompson 2005). In clinical practice, decubitus is the short form for the historical term decubitus ulcer. As the word decubitus in Latin means lying down, although these damages can be caused in other positions

also, the more general term to describe these tissue damages would be pressure sore. This compression of the tissue reduces the blood supply, and the ensuing hypoxia may damage the nerves in this area within a few hours. If the patient cannot change the position, a permanent skin damage will occur.

Besides the hypoxia, compromised venous drainage is also important in accumulation of acid metabolism products in the skin. Furthermore, the acidic environment initiates vasodilatation with hyperemia, with subsequent exudate and transudate with possible tissue edema and blisters, and microthrombotic vascular changes. This acid environment stimulates usually the ambulatory human to move a little bit, preventing thereby any tissue damage in healthy individuals.

Frequently the decubitus is infected, prolonging the healing process. Body parts without a proper muscle or fat tissue are most vulnerable to decubitus.

The decubitus can be categorized in different depths and sizes and is commonly classified as follows:

Stage I is the most superficial and recoverable, characterized by nonblanchable redness that does not subside after finger pressure is relieved. This stage is visually similar to reactive hyperemia seen in the skin after prolonged application of pressure. Stage I pressure ulcers can be distinguished from reactive hyperemia in two ways: (a) reactive hyperemia resolves itself within three-fourth of the time pressure was applied and (b) reactive hyperemia blanches when pressure is applied, whereas a Stage I pressure ulcer does not. The skin may be hotter or cooler than normal, have an odd texture, or be painful. Although easy to identify on a light-skinned patient, ulcers on darker-skinned individuals may show up as shades of purple or blue in comparison to lighter skin tone.

Stage II is damage to the epidermis extending into, but no deeper than, the dermis. In this stage, the ulcer may be referred to as a blister or abrasion that can be infected.

Stage III involves the full-thickness damage of the skin and may extend into the subcutaneous tissue layer. This layer has a relatively poor blood supply and can be more difficult to heal. At this

stage, there may be undermining tissue damage that makes the decubitus much larger than it may seem on the skin level.

Stage IV is the deepest, extending into the muscle, tendon, or even bone.

The decubitus prophylaxis is the best therapy. The treatment of a fulminant decubitus is very complex and requires plenty of resources. For prophylaxis, the following aspects are very important:

- Tissue-protective patient exercise, positioning, and transfer
- Routine use of softgel or air-filled mattresses
- Continuous performance of prophylactic maneuvers

Local therapy of decubitus contains:

- Debridement
- Treatment of infection
- Moist wound treatment
- Wound conditioning
- Hyperbaric oxygen therapy and VAC wound treatment

The causal wound therapy is:

- Complete decompression of the damaged tissue
- Improvement of nutrition
- Adequate pain therapy
- Improving the general functional condition

Stage II decubitus ulcer or higher is a sign of poor nursing and patient care. It should be investigated if there was omission or human error associated with it. The incidence for decubitus on any ICU should be less than 1% per year.

9.5.11 Disturbances of the Coagulation System

Most common problems with coagulation system after cardiac surgery have been discussed (paragraph ► Sect. 9.5.3). In this section, heparin-induced thrombocytopenia (HIT) will be briefly described (Napolitano et al. 2006; Selleng et al. 2007). The incidence of HIT complications is 1–2% after cardiac surgery, being associated with an increased mortality (Kerendi et al. 2007).

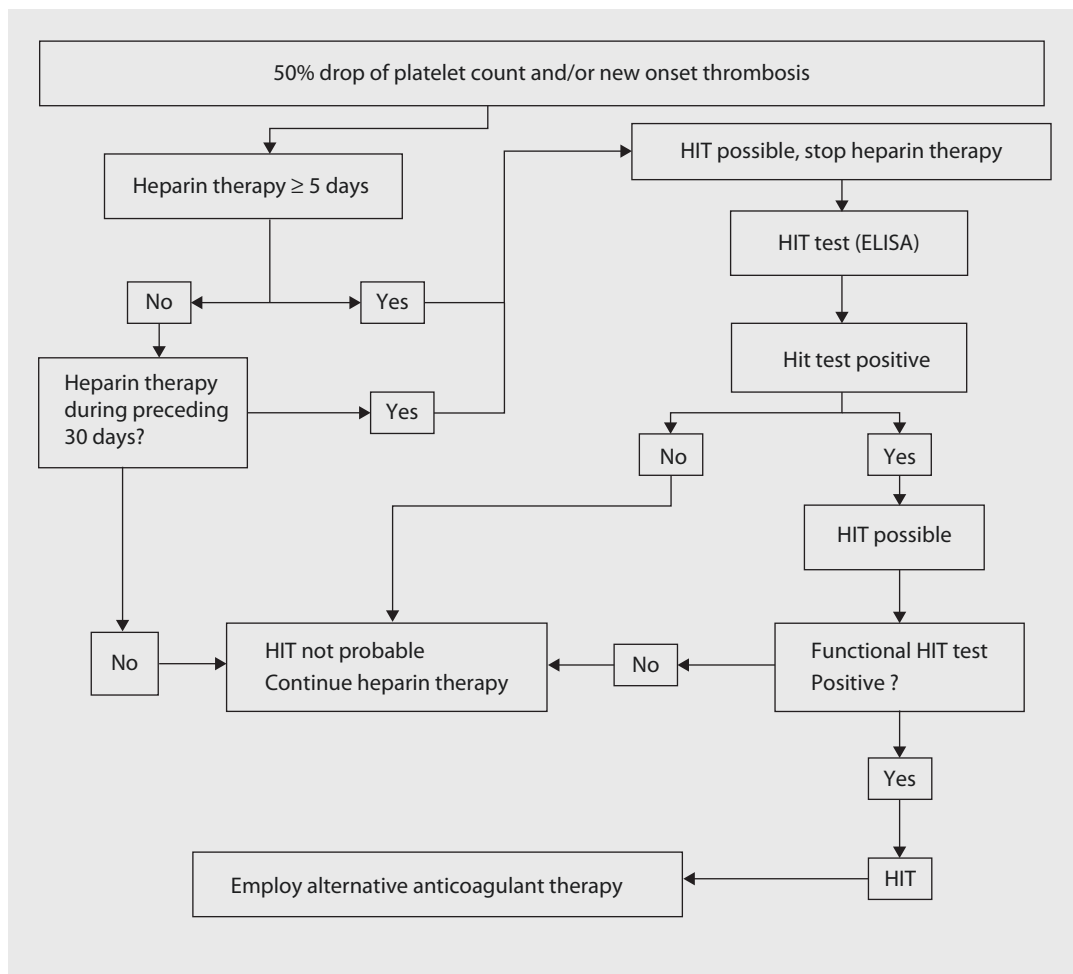

HIT is a prothrombotic disease triggered by an immune reaction against the platelet factor 4 heparin complex. The clinical signs are drop of the platelet count more than 50% and clinical thrombosis. Actual HIT tests are sensitive but less specific. Nearly half of cardiac surgery patients develop antibodies to heparin, whereas only 1–2% will have a clinically relevant HIT. Functional HIT tests, such as serotonin-released assays, are more accurate by measuring the platelet activation caused by heparin antibodies.

The prompt therapy is to stop any exposure to heparin and to change the anticoagulation to alternatives, such as lepirudin. Additionally, platelet infusions may have to be administered to remove the existing antibodies. ■ Figure 9.16 summarizes the approach to HIT.

9.5.12 Endocrine System

After intensified insulin therapy to achieve blood glucose levels less than 110 mg/dl had shown to decrease mortality and the incidence of postoperative infections, intensified insulin therapy was on protocols of most CSICUs (van den Berghe et al. 2001). Meanwhile, it could be demonstrated that moderate glycemic control with blood glucose levels less than 180 mg/dl is more advantageous in patients after cardiac surgery (Haga et al. 2011; Bhamidipati et al. 2011). With both protocols, the incidence of hypoglycemia is a concern, being increased up to sixfold. Furthermore, low potassium level can occur, contributing to dysrhythmias. A close monitoring of blood glucose level and potassium should be ensured through close monitoring. In critically sick patients, especially those on high-dose catecholamines, adequate blood glucose levels may be much harder to achieve.

T3 levels in patients after open-heart surgery are reduced. However, T3 supplement has failed to demonstrate any improved outcome (Ronald and Dunning 2006). Same principle applies to postoperative cortisol levels, making supplemental steroid administration useless and possibly deleterious due to effects on postoperative wound healing. In patients requiring perioperative steroids, such as adrenal insufficiency, vitamin A administration may counteract steroid effects on wound healing.

9.6 Scores and Quality Assurance

Both topics are subject for numerous publications of all kind. Their significance for clinical intensive care treatment in cardiac surgery has yet to be shown. There are, however, in various versions a vast number of intensive care medicine scores available (see also ► Chap. 2, «Risk Scores in Cardiac Surgery»), which all have been developed for different purposes, for example, APACHE (Acute Physiology and Chronic Health Evaluation), SAPS (Simplified Acute Physiology Score), or SOFA (Sequential Organ Failure Assessment). To assess the economic aspects of ICU treatment, scores like TISS 28 (Therapeutic Intervention Scoring System 28)

have been developed, also. Further scores are available in the internet (Société Française d'Anesthésie et de Réanimation 2008). In Germany, currently a combination of a modified SAPS II score and TISS 28 score is employed to evaluate the expenditure of an individual treatment course to be used for reimbursement—an example of how a potentially useful clinical instrument is used for purposes other than originally intended.

Quality assurance in intensive care medicine currently is only done on a voluntary basis. However, any intensive care unit should check its own quality of treatment at least by a minimal data set. An example for some parameters is given in ■ Table 9.20.

Table 9.20 General guidelines for quality improvement in ICU with goals and thresholds, which should not be surpassed

Parameter	Goal	Threshold
% of patients requiring early readmission to ICU	<3	5
% of patients with de novo decubitus (stage II and higher)	<1	2
% post-op extubation within 6 h	>75	50
% reintubation	<3	5

10.1 Introduction

Advances in outcomes for pediatric and congenital cardiac surgery cannot be attributed to advances in cardiac surgery alone; they rather have to be also attributed to advances in pediatric cardiology, pediatric cardiac anesthesia, and last but not least, postoperative pediatric cardiac intensive care management. Intraoperative care including myocardial protection, deep hypothermic cardiac arrest, ultrafiltration, and technical advances has contributed to an increasing postoperative survival rate especially for infants with complex congenital heart defects. The overall surgical 30-day mortality in childhood decreased to 2–4% and, today, nearly 90% of the children will reach adulthood. With even further reduction of the immediate postoperative surgical mortality, the focus is more directed on postoperative morbidity, sequelae of treatment, and residual defects that might compromise quality of life.

While primary corrective surgery for most biventricular congenital heart defects and neonatal palliation for complex multistage definitive surgery for univentricular lesions has been established, with the development of combined surgical/catheter interventional procedures, new therapeutic fields opened. Treatment now starts on one end of the spectrum with low and very low birthweight neonates and widens to an increasing number of adult patients with congenital heart defects palliated or operated upon during childhood requiring further surgical or catheter interventional therapy.

Therefore, management concepts for patients with congenital heart defects require interdisciplinary care including pediatric and congenital cardiac surgery, cardiac anesthesia, pediatric cardiac intensive care, pediatric and adult cardiology, and neonatology. Ideally, management starts with fetal echocardiography for prenatal counseling. Other subspecialties such as pulmonology, neurology, hematology, and/or hepatology are important to manage interacting problems with other organ systems.

Over the last years, pediatric cardiac intensive care has developed new management strategies for:

- Treatment of heart failure—including new pharmacologic agents, mechanical cardiopulmonary support with extracorporeal membrane oxygenation and ventricular assist devices, and heart and heart-lung transplantation

- Treatment of pulmonary hypertension
- Respiratory modalities such as high-frequency oscillatory ventilation
- Postoperative cardiac catheterization techniques with the option of using catheter interventional procedures
- Hybrid techniques which combine catheter intervention and surgery already as a primary treatment option (hybrid operating room or surgery in the cath lab).
- Treatment for cardiac dysrhythmia and pacing including epicardial/transvenous leads, resynchronization therapy, and intracardiac defibrillator ICD
- Management strategies for patients with functionally univentricular hearts such as hypoplastic left heart syndrome and balancing systemic and pulmonary vascular resistance

These management strategies are supported by complex perioperative monitoring with the availability of intraoperative transesophageal echocardiography even in neonates and routine sometimes frequent transthoracic echocardiography in the PCICU. Hemodynamics and tissue oxygenation are closely assessed in real time via intravascular catheters, sometimes with direct measurements of cardiac output. Thereby, significant complications (pleural and pericardial effusions, impaired ventricular function) and/or residual lesions can be picked up even before they lead to deleterious consequences. Neuromonitoring includes near-infrared spectroscopy, electroencephalogram, and transcranial Doppler ultrasound whenever indicated with the additional option of cranial magnetic resonance imaging.

Postoperative morbidity and mortality have a close relation to postoperative complications. Therapeutic strategies should be developed to anticipate or to avoid adverse events. The early identification of low cardiac output syndrome is one of the most important goals in the care for children after cardiac surgery. An essential element of successful pediatric intensive care is multidisciplinary collaboration with standard treatment concepts, however, with decisions individualized based on close clinical assessment. Continuum of service and a gradual transition in small steps during recovery and weaning are mandatory (Chang 2005).

10.2 Noninvasive and Invasive Monitoring

Comprehensive and detailed information about the diagnosis and the surgical procedure is of utmost importance for the continuum of management and to plan the therapeutic strategy in the intensive care unit. This information includes intraoperative parameters such as cardiopulmonary bypass time, aortic cross-clamp time and complications, hemodynamic and metabolic status, and anesthetic protocol, especially vasopressor and vasodilator medication (Diaz 2006; Beke et al. 2005; Ravishankar et al. 2003).

Standard *noninvasive monitoring* includes electrocardiogram (ECG), oscillometric blood pressure measurement, pulse oximetry, capillary refill time, temperature, and assessment of end-organ function such as urine output. For most surgical procedures adequate postoperative monitoring includes *invasive measurement* of arterial blood pressure to assess cardiac output and oxygen delivery for anticipation and early detection of low cardiac output syndrome. This is demonstrated by tachycardia, hypotension, poor end-organ perfusion, cool extremities, weak pulses prolonged capillary refill time, and oliguria or anuria.

Radial artery cannulation, or femoral artery access when radial cannulation is not possible or of limited diagnostic value such as in patients with coarctation or aortopulmonary shunt, allows continuous blood pressure monitoring and measurement of metabolic acid-base status. Neonates may arrive on a PCICU with an umbilical arterial line. Axillary artery cannulation for invasive blood measurement in our hands is only a third choice and rarely necessary. In rare cases intraoperatively, while the chest is still open, a percutaneous mammary artery pressure line can be inserted, which can be pulled later on with ties in place.

Double or triple lumen central venous catheters (via internal jugular vein, subclavian vein, or an umbilical venous catheter in neonates) allow for hemodynamic monitoring and application of inotropic agents, volume supplementation, correction of coagulation factors, and parenteral nutrition. Femoral vein catheters are only used when other options have failed. *Right atrial or central venous pressure* reflects systemic venous return, right ventricular preload and function, and intravascular volume load. Measurement of oxygen saturation excludes intracardiac/atrial shunting and provides information about oxygen extraction as a potential indicator of low cardiac output. The trend of serum lactate level is another surrogate parameter to judge cardiac output. Pressure traces will indicate arrhythmia such as atrial tachycardia or junctional rhythm. *Left atrial pressure* monitoring is not routinely performed, it reflects left ventricular function and compliance, and it is routinely used in children after mitral valve surgery or when abnormal values are expected, as in situations with poor preoperative left ventricular function and/or left heart surgery. *Pulmonary artery pressure* will be abnormally elevated in any mechanical airway obstruction, by hypoxia, acidosis, hypothermia, or pain. It is only monitored as systolic, diastolic, and mean pressure in special situations with known pre- and/or postoperative pulmonary hypertension or suspected risk for pulmonary hypertensive crisis.

Whenever myocardial function is compromised for a prolonged period of time postoperatively or if there is suspicion for relevant residual lesions, *cardiac catheterization* is indicated early in the postoperative period.

Measurement of cardiac output follows the Fick principle to calculate systemic (Qs) and pulmonary (Qp) blood flow (under the assumption of a constant oxygen consumption).

$$Q_s = \frac{\text{Oxygen consumption } VO_2}{\text{systemic arterial oxygen content} - \text{mixed venous oxygen content}}$$

$$Q_p = \frac{\text{Oxygen consumption } VO_2}{\text{pulmonary venous oxygen content} - \text{pulmonary arterial oxygen content}}$$

Intracardiac shunt calculation results from the ratio Qp/Qs.

The calculation of the vascular resistance *R* is made from the relation of mean pressure changes to blood flow across systemic or pulmonary circuit.

$$R_s = \frac{\text{mean aortic pressure} - \text{mean right atrial pressure}}{Q_s}$$

$$R_p = \frac{\text{mean pulmonary artery pressure} - \text{mean left atrial pressure}}{Q_p}$$

The pulmonary vascular resistance is expressed as mmHg/l/min (Wood units) and normally varies between 1 and 4 Wood units; the normal ratio R_p/R_s is <0.2 .

Arterial pulse wave analysis provides continuous monitoring of cardiac output, stroke volume, and systemic vascular resistance. Correlation between thermodilution cardiac output determination and calculation from pulse contour analysis could be demonstrated (Fakler et al. 2007; Proulx et al. 2011).

Transthoracic echocardiography is routinely used for quick monitoring of global systolic ventricular function, to judge atrioventricular and semilunar valve function, for early detection of pericardial and pleural effusion, and also for detailed evaluation of the surgical result. For early postoperative follow-up evaluation, cardiac output can be calculated using the velocity time integral across the aortic valve by pulsed wave Doppler and the cross-sectional area of the left ventricular outflow tract/aortic valve annulus. Right ventricular/pulmonary artery pressure can be calculated using the Doppler flow profile across the pulmonary artery or of the tricuspid valve regurgitation.

The *transesophageal echocardiography* is now used on a routine base intra- and perioperatively as it allows continuous hemodynamic assessment to exclude relevant residual lesions. In some places it is also used routinely to monitor weaning from cardiopulmonary bypass or hemodynamic changes during chest closure.

Monitoring of pulmonary function is possible by using the new ventilator systems; renal and gastrointestinal function is monitored biochemically and by ultrasound. Sedation and analgesia are monitored by various physiologic parameters and pain assessment tools. Potential neurologic sequelae are monitored by different modalities including electroencephalography, cranial ultrasound in infants, and transcranial Doppler sonography. To verify/rule out major cerebral complications like bleeding and/or infarction, magnetic resonance imaging (MRI) or computed tomography (CT) may be employed.

10.3 Myocardial Dysfunction: Low Cardiac Output Syndrome (LCOS)

10.3.1 Clinical Signs and Diagnosis

Low cardiac output syndrome (LCOS) is a serious postoperative complication that can be caused by a transient reduction in myocardial function after cardiac surgery in neonates, infants, and young children. It is observed in up to 25 % of children and occurs within the first 48 h, typically 6–18 h after operation. The temporary reduction in systemic perfusion leads to an inadequate oxygen supply of the end organs. It is associated with an increase in systemic and pulmonary vascular resistance of up to 25 % and 40 %, respectively. This results in longer mechanical ventilation and prolonged intensive care stay and increased mortality (Hoffmann et al. 2003; Wernovsky et al. 1995). Prevention and early recognition of LCOS became more important although evidence-based guidelines on diagnosis and treatment are not available.

The *risk* for development of LCOS is specifically high in young children who require complex cardiac surgery or redo procedures, in those who have preexisting cardiac and pulmonary dysfunction, and in those with coronary artery problems. Several factors can contribute to the development of LCOS: prolonged periods of myocardial ischemia with or without cardioplegia, hypothermia and reperfusion injury, activation of the inflammatory cascade by cardiopulmonary bypass, increase of systemic and pulmonary vascular resistance, impaired myocardial function and arrhythmia, capillary leakage, and pulmonary dysfunction. Residual defects (intracardiac shunts, valve insufficiency) or the need of a ventriculotomy also increases the risk of LCOS (Hoffmann et al. 2003; Nagashima et al. 2000; Ravinshankar et al. 2003; Li et al. 1998). LCOS can be diagnosed by its clinical features as tachycardia, impaired systemic perfusion, and decreased urine output or oliguria (normal urine output 1 ml/kg/h in infants, 0.5 ml/kg/h in older children and adults).

Signs of inadequate oxygen delivery and impaired systemic perfusion might precede clinical symptoms: difference of arterial and mixed venous oxygen saturation >30% (normal 20–25%) metabolic acidosis (BE > -5 mmol/l) which correlates with inadequate oxygenation and tissue perfusion and a lactate level rising >2 mmol/l in two consecutive blood samples. A lactate level >4.5–6 mmol/l was shown to be predictive for postoperative morbidity and mortality (Cheung et al. 2005; Hoffmann et al. 2002; Takami and Ina 2002). An increase of lactate level may be a typical sign for inadequate tissue perfusion, but it also rises with increased metabolic demand in the presence of hyperthermia or with muscular activity (shivering, seizures), glycogenolysis during catecholamine administration, and with compromised kidney or liver function leading to insufficient lactate elimination.

Therefore, prevention and early diagnosis of a developing LCOS need a close postoperative monitoring employing indirect judgment of cardiac output with clinical signs like slow capillary refill, cold extremities, and hypotension and the collection of directly measured parameters as mixed venous oxygen saturation, base deficit, and serum lactate. Direct monitoring of cardiac output with thermodilution technique and continuous monitoring of arterial saturation, however, are not routinely used (Hausdorf 2000; Ravinshankar et al. 2003; Stocker and Shekerdemian 2006).

As cardiac output is determined by heart rate and stroke volume which are influenced by preload, afterload, and contractility, the *continuous hemodynamic monitoring* includes heart rate, right atrial or central venous pressure (and with special indication the left atrial pressure), and arterial blood pressure. Tachycardia will indicate a compensatory mechanism to maintain cardiac output; intravascular volume depletion is indicated by central venous pressure; drop of arterial blood pressure is a late sign of reduced cardiac output. The intracardiac ECG allows detection and analysis of various dysrhythmias; echocardiography provides a quick assessment of ventricular function and cardiac output looking at the systemic ventricular outflow profile (VTI, velocity time integral). Right atrial or systemic venous pressure reflects the systemic venous return and right ventricular preload (■ Table 10.1).

10.3.2 Treatment

Postoperative treatment strategies for LCOS are:

- Limiting oxygen consumption
- Optimizing ventricular contractility
- Improvement of diastolic function
- Adequate ventricular preload
- Reduction of afterload

Heart rate should be normalized and cardiac rhythm converted into sinus rhythm; often atrial or sequential pacing is necessary to stabilize the early postoperative hemodynamics. Ventricular function should be monitored and residual anatomic lesions should be ruled out by echocardiography (transthoracic, transesophageal); cardiac catheterization should be performed early in any unclear or prolonged hemodynamically unstable situation.

Prevention, early diagnosis, and treatment of LCOS are the important measures to reduce morbidity and mortality in patients at risk for postoperative LCOS. With lack of evidence-based guidelines, different drug regimens and drug classes are used, with dosing and duration of drug administration showing a high variability (Vogt and Læer 2011).

10.3.2.1 Limiting Oxygen Consumption

This can be achieved by mechanical ventilation, adequate analgesia, and sedation provided. Normothermia is preferred except in those patients with specific tachyarrhythmia who need a controlled hypothermia. Drug therapy is chosen according to type of LCOS, like with elevated systemic vascular resistance, with low systemic vascular resistance, or with predominantly elevated pulmonary vascular resistance (Ravinshankar et al. 2003).

10.3.2.2 Optimizing Pre- and Afterload

The optimal ventricular filling pressure is determined by monitoring the right atrial/central venous (and left atrial) pressure, heart rate, and blood pressure. Extra fluid boluses (5–10 ml/kg) may become necessary to maintain adequate preload. This can be expected in patients after repair of tetralogy of Fallot and after Glenn or

Table 10.1 Causes for changes of right and/or left atrial and pulmonary artery pressures

Pressure changes	Causes
Decreased right atrial/systemic venous pressure and decreased left atrial pressure	Hypovolemia
	Systemic vasodilatation
	Bleeding
	Polyuria
Elevated right atrial/systemic venous pressure	Hypervolemia
	Tamponade
	Right ventricular dysfunction
	Increased afterload (elevated pulmonary vascular resistance)
	Dysrhythmia
	Inadequate analgesia and sedation
	Tricuspid/AV valve stenosis or insufficiency
Elevated right atrial/decreased left atrial pressure	Pulmonary hypertension
Elevated pulmonary artery pressure	Left ventricular dysfunction
	Primary/persistent pulmonary hypertension
	Peripheral pulmonary stenosis
	Hypoventilation/respiratory acidosis
	Mechanical airway obstruction (atelectasis, pneumothorax, pleural effusion)
	Inadequate analgesia and sedation
Decreased pulmonary artery pressure	Hypovolemia
	Reduced cardiac output
Elevated left atrial pressure	Hypervolemia
	Tamponade
	Left ventricular dysfunction
	Increased afterload (elevated systemic vascular resistance)
	Dysrhythmia
	Mitral/AV valve stenosis or insufficiency

Fontan procedure. Vasoactive drugs are administered to reduce preload by increasing vascular capacity.

Elevation of the systemic and pulmonary vascular resistance can be observed in patients with acidosis, hypoxemia, and inadequate analgesia and sedation. In patients with LCOS in the presence of elevated systemic vascular resistance, inodilators

are most often administered, sometimes in combination with epinephrine. Increased pulmonary vascular resistance requires sufficient mechanical ventilation, mild hyperventilation, and temporarily inhaled nitric oxide; sometimes prostacyclin derivatives are added, also. In patients with LCOS and low systemic vascular resistance, catecholamine support with dopamine or epinephrine

■ **Table 10.2** Receptor response in different catecholamines (Beke et al. 2005)

Catecholamine	α (Alpha)-receptor (inotropy, vasoconstriction)	β (Beta)1-receptor (inotropy, chronotropy)	β (Beta)2-receptor (vasodilatation)	Dopaminergic receptor (peripheral/renal vasodilatation)
Dopamine	0–3	2–3	1	3
Dobutamine	0–1	3	1	0
Epinephrine	3	3	3	0
Norepinephrine	3	3	1	0

(and norepinephrine) is preferred to maintain adequate cardiac output but also systemic vascular resistance and blood pressure.

- Increase of systemic vascular resistance and arterial hypertension
- Downregulation of β -adrenergic receptors

10.3.2.3 Improvement of Inotropy and Control of Afterload

After optimizing preload conditions, treatment of myocardial dysfunction is focused on improving inotropy and reducing afterload. In addition, heart rate has to be normalized related to age; sinus tachycardia up to 200/min can be tolerated for several hours in otherwise stable neonates as it helps to maintain cardiac output. In older children inadequate tachycardia will decrease cardiac output by shortening the ventricular filling period. Supraventricular tachycardia has to be controlled pharmacologically (adenosine, amiodarone) or in hemodynamically unstable patients by immediate cardioversion. Bradyarrhythmia should be avoided employing temporary external pacing; postoperative atrioventricular dyssynchrony as in junctional ectopic tachycardia, junctional escape rhythm, or third-degree atrioventricular block should be regulated by sequential pacing, either directly or after pharmacologic heart rate reduction.

Depending on the type of LCOS (elevated or low systolic/pulmonary vascular resistance), milrinone, dopamine, dobutamine, epinephrine, and norepinephrine are most commonly used (Vogt and Laer 2011). An improvement of ventricular contractility can be achieved by the administration of different catecholamines (■ Table 10.2). Their clinical effect is dose related with potentially unfavorable side effects with higher doses (Bailey et al. 1999; Chang et al. 1995; Penny et al. 2001):

- Increase in myocardial oxygen consumption
- Increase of heart rate
- Arrhythmia

Dopamine improves cerebral and abdominal/splanchnic perfusion (2–5 $\mu\text{g}/\text{kg}/\text{min}$). In higher dosages (5–10 $\mu\text{g}/\text{kg}/\text{min}$), dopamine stimulates myocardial β -receptors and increases contractility or induces peripheral vasoconstriction via α (alpha)-receptor stimulation (>10 $\mu\text{g}/\text{kg}/\text{min}$); there is an increased risk of cardiac arrhythmia. In addition the development of intrapulmonary shunts is described. During sepsis dopamine can have an unfavorable effect on intestinal perfusion (Dolye et al. 1995; Lee and Mason 2001).

Dobutamine (β (beta)-receptor stimulation) combines the pharmacological effects of chronotropy, contractility, and vasodilatation; it is potentially arrhythmogenic (low/high dosage, 5/20 $\mu\text{g}/\text{kg}/\text{min}$). During the early postoperative period, the perfusion pressure can drop and epinephrine might be more indicated. Combining dobutamine and milrinone, a synergistic effect increases cardiac output by increasing contractility while decreasing afterload (Berg et al. 1993; Hausdorf 2000; Leonhard et al. 1997).

Epinephrine (low dose 0.05–0.1 $\mu\text{g}/\text{kg}/\text{min}$, max. 1.0 $\mu\text{g}/\text{kg}/\text{min}$) with its α (alpha)- and β (beta)-receptor stimulation has a strong inotropic effect; the systemic vascular resistance will increase via α (alpha)-receptor stimulation. This bears the risk of renal failure if preload is inadequate. The chronotropic effect can be beneficial in neonates in whom cardiac output is heart rate dependent. In older children inadequate tachycardia predisposes to myocardial ischemia. Adverse effects related to daily dosages are comprise of diastolic ventricular function, increase of ventricular filling pressure and oxygen consumption

with lactate generation, and an increase of systemic and pulmonary vascular resistance (Chang et al. 1995; Wenvovsky and Hoffman 2001; Wessel 2001).

Milrinone is a phosphodiesterase III inhibitor that improves myocardial contractility by increasing the intracellular cAMP and calcium concentration; in addition to this the agent induces pulmonary and systemic vasodilatation via cGMP. Besides these inodilator properties, milrinone improves ventricular diastolic relaxation (lusotropic effect). It can be used in combination with other vasoactive drugs in preventing and managing LCOS. After an initial bolus (25/50 µg/kg over 15–60 min) and an infusion for maintenance (0.25–0.75–1.0 µg/kg/min), an increase in cardiac output and reduction of ventricular filling pressures can be documented. Arrhythmia, hypotension, and thrombocytopenia are rare and dose-dependent complications. Prophylactic administration of milrinone might reduce the risk for postoperative LCOS (Bailey et al. 1999; Chang et al. 1995; Duggal et al. 2005; Hoffman et al. 2002, 2003). After Fontan operation patients with high pulmonary vascular resistance and postoperatively impaired oxygenation will benefit from the combined use of milrinone and inhaled nitric oxide (Cai et al. 2008).

Enoximone is also a myocardial-specific phosphodiesterase III inhibitor and provides the same spectrum of indications; half-life is even longer and somewhat unpredictable compared to milrinone. It is not available in the USA.

Norepinephrine (0.01–1.0 µg/kg/min) predominantly stimulates the peripheral α(alpha)-receptors and has little inotropic effect limiting its use in LCOS patients. It might increase oxygen consumption and lactate generation. It is often used as first add-on drug in LCOS with low systemic vascular resistance and to maintain an adequate arterial perfusion pressure in sepsis or after an aortopulmonary shunt procedure to improve pulmonary blood flow.

Vasopressin (AVP) (and terlipressin [TP, not available in the USA]) may be used in hypotensive, catecholamine-refractory shock after cardiopulmonary bypass and depressed cardiac function. AVP significantly improves blood pressure, accompanied by heart rate decrease and reduction of required catecholamine support that lowers the risk for arrhythmia. Dosages start at a low level (AVP 0.0002–0.002 U/kg/min; TP

7–20 µg/kg/dose) (Dunser et al. 2003; Lechner et al. 2007; Matok et al. 2007, 2009). There is still debate on the indication and timing of initiation of AVP and also on dosage regimen as reflected by a wide range of starting doses.

Nonspecific vasodilators as nitroglycerin (glyceryl trinitrate) and nitroprusside are used for afterload reduction. Nitroglycerin (5–20 µg/kg/min) predominantly reduces preload with venous pooling. Nitroprusside (0.5–10 µg/kg/min) has the effect of relaxation of smooth muscles in arteries and veins leading to a decrease of preload, systemic, and pulmonary vascular resistance. This drug has a rapid onset and short half-life; dosages can be adjusted. Invasive monitoring is required. Prolonged periods of drug administration (>72–96 h) exceeding a total dosage of 0.5 mg/kg results in formation of thiocyanate and cyanide; in order to decrease cyanide, thiosulfate has to be given simultaneously in a ratio 10:1. Titrating the effective dosage can reduce the adverse side effects such as pulmonary vasodilation, intrapulmonary shunt opening, and reduction of cerebral vasodilatation (Wessel 2001).

Phentolamine is a nonselective α(alpha)-receptor blocker that works as a competitive antagonist for α(alpha)1 and α(alpha)2 adrenoreceptors. The drug can be administered peripherally in a dose of 2–6 µg/kg/min; it is a relatively long-acting drug that lowers the systemic vascular resistance. It is used to «balance» systemic and pulmonary blood flow in duct-dependent congenital heart disease, i.e., HLHS, and to manage infants after the Norwood procedure (Tweddell et al. 1999; Motta et al. 2005; Galal et al. 2005).

For the management and rescue treatment with *glucocorticoid*, see ► Sect. 10.4.

■ ■ Thyroid hormone

After cardiopulmonary bypass transient reduction of levels of triiodothyronine (T3) is known in pediatric and adult patients. Low levels of T3 can contribute to the development of LCOS and prolonged mechanical ventilation. They are associated with higher requirements of catecholamine support and longer stay on the ICU. A low thyroid hormone level may be caused by hemodilution, release of cytokines, and TNFα(alpha) and dopamine infusion that interfere with thyroid hormone levels, also (Murzi et al. 1995). T3 supplementation during the first 72 h improves cardiac output and systolic blood pressure,

decreases required vasoactive support, and improves renal perfusion and fluid balance (Mackie et al. 2005).

10.3.2.4 New Class of Agents

As stated above, ideal strategies to treat LCOS include:

- Systemic venous and arterial vasodilation
- Maintenance or decrease of myocardial oxygen consumption
- Control of heart rate, avoiding arrhythmia
- Control of neurohumoral activation
- Improving renal perfusion and fluid balance

Basic treatment strategies with inotropic support (i.e., dobutamine and milrinone) may induce or sustain elevated myocardial oxygen consumption and are potentially arrhythmogenic (Moffett and Chang 2006).

Nesiritide, a recombinant form of B-type natriuretic peptide, has a vasodilating effect on the venous, arterial, and coronary artery vascular system reducing pre- and afterload. Nesiritide can improve neurohumoral markers of heart failure; it decreases the autonomic stimulation by inhibiting the renin-angiotensin-aldosterone system (Behara et al. 2009; Jefferies et al. 2007; Simsic et al. 2006). The pharmacologic profile with a short half-life makes this drug attractive for the early postoperative period although more pediatric studies are necessary before routine use. The dosage used starts with a bolus of 1–2 µg/kg followed by a continuous infusion of 0.01–0.02 µg/kg/min for 24 h (Simsic et al. 2006).

Levosimendan—used to prevent and to treat LCOS—acts as a calcium sensitizer. Increasing the sensitivity of the contractile myofilaments to calcium results in inotropic support; via an ADP-associated process, potassium channels of vascular smooth muscles are opened resulting in decreased systemic and pulmonary vascular resistance and coronary dilatation. As the vasodilating effect precedes the inotropic effect, some continued catecholamine support should be considered. The myocardial oxygen consumption remains unchanged. Levosimendan acts via active metabolites, which explains the long duration of drug action. Levosimendan infusion starts usually after a loading dose of 12–24 µg/kg over 10 min followed by continuous infusion of 0.1–0.2 µg/kg/min for 24 h and in some patients up to 48 h (Osthaus et al. 2009;

Suominen et al. 2011; Momeni et al. 2011). Levosimendan is at least as efficacious as milrinone and was administered in combination with other vasoactive drugs as catecholamines, vasopressin, or inhaled nitric oxide (Follath et al. 2005; Stocker et al. 2007; Suominen et al. 2011). Levosimendan is currently not available in the USA for clinical use.

10.4 Systemic Inflammatory Response Syndrome (SIRS)

10.4.1 Clinical Manifestations of SIRS

Both cardiopulmonary bypass and deep hypothermia with or without circulatory arrest may induce an inflammatory process mediated by cellular activation and activation of pro- and anti-inflammatory cytokines and mediators. The inflammatory cascade and activation of leucocytes, endothelial cells, myocytes, and hepatocytes lead to the systemic inflammatory response syndrome (SIRS). The incidence for this potentially life-threatening complication is reported in 4–37% of patients on extracorporeal circulation during the operation. Clinical manifestations in the first (three to five) postoperative days begin with fever, fluid retention due to capillary leak syndrome, myocardial dysfunction with low cardiac output syndrome (LCOS), the need for initiation or increases in inotropic support, acute pulmonary dysfunction (acute respiratory distress syndrome, ARDS), renal dysfunction, neurologic symptoms, or rarely, multiorgan failure (Carvalho et al. 2001; Chang 2003). The activation of an immunologic response can be attributed to the surgical trauma, ischemia, reperfusion, or cellular activation by the artificial surface of extracorporeal circulation. Fever as the main symptom may be due to bacterial infection or a noninfectious origin such as SIRS; procalcitonin and C-reactive protein (CRP) kinetics can be useful markers in differentiating these conditions (Nahum et al. 2012; Arkader et al. 2004).

10.4.2 Clinical Criteria for SIRS (Cavadas et al. 2011)

- Fever
- Myocardial dysfunction, hemodynamic instability, and need for inotropic support

- Pulmonary dysfunction with increased FiO₂ and respiratory distress syndrome
- Renal dysfunction
- Endothelial dysfunction and fluid retention with weight gain

A few studies describe the molecular mechanism of the inflammatory cascade («postcardiopulmonary bypass inflammation,» «post pump syndrome») which seems to be age related and more severe in very young patients. In relation to their bodyweight and body surface area, neonates with complex cardiac surgery are exposed to the largest artificial surface area of cardiopulmonary bypass circuits. The most important mediators are interleukin (IL)-6, IL-8, and IL-10, tumor necrosis factor (TNF α (alpha)), and adhesion molecules like integrin and selectin; there is an increase in circulating complement fractions (Bronicki et al. 2000; Carvalho et al. 2001; Neuhof et al. 2003; Tarnok et al. 1999). The induced inflammatory processes are responsible for the capillary leak syndrome with extracardiac fluid retention, edema, and compromised organ function or multiorgan failure requiring delayed chest wall closure, longer period of mechanical ventilation and catecholamine support, higher risk of infection, and longer ICU stay (Casey 1993; Dickerson and Chang 2005). An isolated organ dysfunction can be observed as myocardial dysfunction and decrease in cardiac output (about 16%), pulmonary dysfunction (about 23%), or renal dysfunction (about 23%) (Cavadas et al. 2011).

Different factors including preoperative pulmonary hypertension, cardiac failure, or cyanosis have been assumed to increase the risk and clinical manifestation of SIRS. In addition genetic polymorphisms predisposing to systemic inflammatory response are discussed (Chang 2003; Mou et al. 2002). The pronounced complement activation in patients with lack of complement component C4 might trigger the inflammatory reaction and capillary leak syndrome (Zhang et al. 2005). Younger age, lower weight, longer cardiopulmonary bypass time, and longer duration of mechanical ventilation were identified as predisposing factors; about 22% of pediatric patients 3 years and younger presented with SIRS (Cavadas et al. 2011). SIRS and organ injury after pediatric open-heart surgery were not influenced by bypass temperature when moderate or mild hypothermia was employed (Stocker et al. 2011).

10.4.3 Treatment Options

Various strategies have been considered to affect and ameliorate the inflammatory cascade in SIRS. These include the use of heparin-coated bypass circuits, ultrafiltration during cardiopulmonary bypass procedures, and administration of steroids or intravenous immunoglobulin or leukocyte-endothelial blocking agents (Berdat et al. 2004; Bronicki et al. 2000; Chaney 2002; Checchia et al. 2003; Grossi et al. 2000; Lindberg et al. 2003; Thompson et al. 2001). Heparin-bonded bypass circuits seem to have some clinical benefit, but data on the relation to cytokine response is limited. Ultrafiltration techniques, either before, during, and/or after cardiopulmonary bypass, have become a standard method to remove surplus body water administered with the circuit prime volume during cardiopulmonary bypass procedures (Wang et al. 2012). In addition, long duration of bypass, deep hypothermia, and low weight increase the risk of water accumulation during bypass in infancy. Excess water removal will induce hemoconcentration, reduce myocardial edema, improve contractility, improve pulmonary gas exchange, and improve pulmonary ventilation. Low molecular weight substances such as inflammatory cytokines and complements will be removed during ultrafiltration; benefits for the early postoperative period and recovery are obvious (Huang et al. 2003; Mahmoud et al. 2005). Monitoring of the inflammatory response during cardiopulmonary bypass was considered; this would allow monitoring of the intensity of the inflammatory reaction. Combining conventional (during CPB) and modified ultrafiltration (after CPB) seems to be the most effective strategy, especially in neonates and infants who undergo complex cardiac surgery with long duration of extracorporeal circulation (Berdat et al. 2004; Gaynor 2003; Thompson et al. 2001).

The criteria for the use of *steroids* vary depending on the age of the patient or type and length of the cardiac surgery. There is a lack of standardization with regard to the type of corticosteroid, timing of administration (before, during, or after cardiopulmonary bypass or combined), and dosing regimens (Checchia et al. 2005; Dickerson and Chang 2005).

The probable mechanisms of steroids by which they may improve the hemodynamic situation in inotropic- and volume-resistant hypotension include (Bronicki et al. 2000; Chaney 2002; Seri et al. 2001; Shore et al. 2001):

- Limiting the capillary permeability and fluid retention
- Improving pulmonary compliance and oxygen delivery
- Preserving myocardial performance
- Reduction of inotropic requirements with adrenergic receptor induction

Stress doses of hydrocortisone given intra- and postoperatively can attenuate the SIRS by an immunomodulating effect with reduction of pro-inflammatory cytokines (e.g., IL-6 and IL-8), increases in anti-inflammatory cytokines (e.g., IL-10), and modulation of the IL-6-to-IL-10 ratio, which is associated with improved outcome after major cardiac surgery (Weis et al. 2009).

The combined pre- and intraoperative steroid administration seems to have the best anti-inflammatory effect. The peak effect of methylprednisolone occurs 1–4 h after application (Checchia et al. 2005; Lindberg et al. 2003). The recommendations for dosage vary from a dose equivalent of 1–30 mg/kg of methylprednisolone. Dexamethasone dosage is usually 1 mg/kg. There are no data on the effect of steroids during the period of reperfusion or early postoperative period. Steroids given postoperatively in hemodynamically compromised neonates with low cardiac output unresponsive to high doses of inotropic agents and fluid resuscitation turned out to be highly effective in improving the hemodynamic parameters and decreasing the inotropic requirements. In this «rescue protocol» hydrocortisone was administered using two dosing regimens (100 mg/m²/day for 2 days, 50 mg/m²/day for 2 days, and 25 mg/m²/day for 1 day or 100 mg/m²/day for 1 days, 50 mg/m²/day for 2 days, and 25 mg/m²/day for 2 day; Suominen et al. 2005). Adverse effects associated with steroid administration included hyperglycemia requiring insulin administration, infectious complications, or wound infections (Checchia et al. 2005; Heyn et al. 2011).

10.5 Postoperative Bleeding Complications and Anticoagulation

10.5.1 Causes of Postoperative Bleeding Complications

Cardiac surgery with extracorporeal circulation requires anticoagulation, as the blood contact

with artificial surfaces leads to activation of coagulation with thrombin generation, fibrinolysis, and an inflammatory reaction on humoral and cellular level. Coagulation and inflammatory system have multiple interactions in association with thrombin generation and proinflammatory state. Surgical trauma per se causes tissue factor activation, also followed by thrombin generation. The aim of anticoagulation is the suppression of thrombin formation and consumption of coagulation factors.

Bleeding complications after cardiac surgery are related to platelet dysfunction, thrombopenia, activation of the complement system, hemodilution, activation of the hemostasis, and fibrinolysis as well as consumption of coagulation factors (Chang 2005; Pychynska-Pokorska et al. 2004). During the neonatal period and infancy, additional aspects include the immaturity of the coagulation system; impaired heparin clearance; more significant hemodilution with reduction of clotting factors and thrombopenia; deep hypothermia and cardiac arrest with more profound inflammatory reaction associated with increased vascular permeability, platelet activation, and fibrinolysis; platelet dysfunction induced by preceding prostaglandin infusion or in association with asplenia or polysplenia; and immaturity or impairment of kidney and liver function. In cyanotic congenital heart disease with stimulation of erythropoiesis, platelet regeneration and survival time are often reduced. In children with preoperative hepatic congestion or right heart dysfunction, coagulation factor abnormalities for fibrinogen, antithrombin, factors II, V, VII, IX, and X, as well as proteins C and S have to be assumed (Bulutcu et al. 2005; Despotis et al. 2001; Williams et al. 1999).

Technical developments improving the CPB circuit are aimed at minimizing the activation of coagulation, inflammatory, and fibrinolytic systems. Reducing the size of the perfusion equipment and circuit volume seems to be beneficial. To enhance the biocompatibility of the CPB circuits, biopassive coatings have been developed and some promising pediatric studies could be published (Eaton et al. 2011).

10.5.2 Anticoagulation

During cardiopulmonary bypass high-dose *heparin* (unfractionated) is administered to

inhibit coagulation; however, some intravascular and intracircuit coagulation is still possible. Intraoperatively direct heparin level monitoring is available. The anticoagulant effects of heparin can be monitored with some limitations using the ACT (activated clotting time) (Easton and Iannoli 2011). The heparin response will depend on the concentration of AT III, which has a lower baseline concentration in infancy. At completion of cardiopulmonary bypass protamine is administered to reverse heparin partially or completely. Adverse effects after application of protamine include histamine-dependent vasodilation, anaphylaxis, or pulmonary hypertension.

The experience with direct thrombin inhibitors (argatroban, bivalirudin) is still very limited; guidelines for dosing and monitoring in children are not available (Riess et al. 2007).

10.5.3 Therapy of Bleeding Complications

Postoperative bleeding complications require extended laboratory testing including hemoglobin, platelet count, fibrinogen, fibrin degradation product, D-dimer, activated partial thromboplastin time (aPTT), and INR. Perioperative use of thromboelastography provides information on the coagulation system from clot generation to fibrinolysis and facilitates the treatment of perioperative bleeding complications (Moganasundram et al. 2010).

Replacement of *fresh frozen plasma* (10–15 ml/kg) and platelets (thrombopenia $<30,000/\mu\text{l}$) is a first-line measure. Transfusion of *packed red blood cells (PRBC)* should follow a transfusion algorithm as recommended in adult patients as long as the corrective surgery led to a noncyanotic state. *Surgical exploration* can be indicated, but allow to detect an etiology of bleeding only in less than 50%. This should be considered if blood loss via chest tube output exceeds 50–70 ml/h in infants or 60–100 ml/h in children less than 10 kg body weight and 160–270 ml/h in children with less than 25 kg body weight or 5–10 ml/kg/h (Kirklin and Barratt-Boyes 1993).

For restitution of hemostasis after cardiopulmonary bypass, *specific agents* are available. Aprotinin has been withdrawn from the market in 2008 because of specific adverse effects (Codispoli and Mankad 2000; Mossinger et al.

2003). Antifibrinolytic agents such as ϵ -aminocaproic acid and tranexamic acid have been used to decrease blood loss and substitution of coagulation factors by interfering with the plasmin binding to fibrin; variable dosing schemes exist for both agents (Despotis et al. 2001; Ririe et al. 2002; Martin et al. 2011). Desmopressin, which increases factor VIIIc and von Willebrand factor, can be applied for bleeding control with limited pediatric experience (Kenet et al. 2008).

If transfusion and optimization of coagulation factors and platelet counts cannot achieve normalization of hemostasis, *recombinant factor VII (rFVIIa)* can control a nonsurgical critical, otherwise intractable bleeding (Douri et al. 2000; Tobias et al. 2003). Experience in pediatric patients is still limited; besides control of bleeding, there is a risk of thrombotic complications in 4–25% (Stocker and Shekerdemian 2006; Tobias et al. 2003). rFVIIa improves platelet function and directly activates factors X and Xa supporting thrombin generation; it should only be administered after normalization of platelets and coagulation factors including fibrinogen (Monroe et al. 1997; Pychynska-Pokorska et al. 2004; Eaton et al. 2011).

10.6 Temporary Chest Wall Patch Plasty (TCWPP)

After complex cardiac surgery, especially in neonates, it may be lifesaving to leave the sternum split open and plan for a delayed sternal closure. Main indications for a primary delayed sternal closure were severe cardiomegaly due to myocardial edema or dilatation especially after RV to PA conduit implantation. Other reasons are reduced shunt flow due to pulmonary vascular resistance, significant nonsurgical bleeding, decreased lung compliance, and high ventilatory pressure to maintain acceptable ventilation and oxygenation (Samir et al. 2002; Tabbutt et al. 1997). The incidence for application of this technique may vary depending on surgical policy to perform TCWPP in all neonates or only in a hemodynamically unstable situation or after failure to close the sternum as indicated by heart rate and rhythm change, drop in arterial oxygen saturation and pressure, or drop in central venous saturation while the venous pressure rises.

Potential risk factors for delayed sternal closure were increased pulmonary vascular resistance due to primary cardiac diagnosis,

cardiopulmonary bypass time longer than 185 min, aortic clamping time above 98 min, central venous saturation below 51%, and age at operation less than 7 days (Samir et al. 2002). The incidence of TCWPP in neonates came up to 30%. After primary sternal closure, atypical tamponade or the tight mediastinal syndrome with low cardiac output, hypoxemia, acidosis, or increased systemic venous pressure can be signs to indicate a need for reopening. This was described in 6.7% of patients after primary chest closure (Samir et al. 2002). In this group the postoperative mortality rate was significantly higher (Ziemer et al. 1992).

The risk of infection during TCWPP turned out to be negligible as a routine antibiotic prophylaxis is given using a cephalosporin or vancomycin in combination with an aminoglycoside (Christenson et al. 1996; Tabbutt et al. 1997).

After 2–4 days with reduction of edema and hemodynamic stabilization, definite chest closure can be planned. Central venous pressure should be less than 10 mmHg, the coagulation parameters normalized, a negative total fluid balance documented, and hemodynamics should have been stable during the last 24 h. Close monitoring of hemodynamic parameters is necessary including heart rate, central venous (and left atrial) pressure, systemic arterial pressure, central venous saturation, and arterial blood gases. Delayed sternal closure is possible if after sternal wiring the central venous pressure increases less than 2 mmHg and the mean arterial blood pressure does not decrease more than 5 mmHg, comparable to the situation in the OR (Ziemer et al. 1992). To avoid hemodynamic instability by transferring the patient to the OR, we rather maintain the hemodynamic stability with the patient staying in his ICU bed and receiving definite chest closure almost always on the intensive care unit.

10.7 Postoperative Analgesia and Sedation

An appropriate individualized strategy for postoperative analgesia and sedation (narcotic analgesia) and potential muscle relaxation starts in the operating room and continues into the pediatric intensive care unit. The range includes the child after elective surgery for simple lesions and optional fast-track surgery extubated in the OR

on one end to the critically ill neonate after complex cardiac surgery in low cardiac output state with delayed sternal closure, with or without mechanical circulatory assist device on the other end. For the future the adult with congenital heart disease may become an additional important challenge with special requirements for neuroprotection and adequate management of pain and sedation (Beke et al. 2005; Chang 2005; Diaz 2006; Donald et al. 2007; Huber and Kretz 2005; Wolf and Jackman 2011).

Several tools are now available to assess pain and sedation from neonate to adult. Behavioral and self-reporting scales have been recommended, but difficulties still exist for neonates and infants, preverbal children, and developmentally delayed children. To reduce the risk of neurologic sequelae, multimodal neuromonitoring was developed including bispectral index (BIS) using data from the electroencephalogram, near-infrared spectroscopy to monitor regional cerebral oxygen index, or transcranial Doppler evaluation.

«Fast tracking» and early postoperative extubation need appropriate modification of the anesthetic technique using shorter-acting drugs; increasing the acceptance of regional anesthesia supports the goal of «fast tracking,» if desired. Long-term sedation and analgesia after complex cardiac repair can promote the development of tolerance and withdrawal phenomena. During the weaning process, a continuing balance of adequate analgesia without deep excessive sedation while maintaining sufficient respiratory function is required.

10.7.1 Analgesia

10.7.1.1 Intravenous Application

Morphine During the early postoperative period, all patients usually receive a *morphine* infusion (30–100 ug/kg/h; supplemental bolus, 50–100 ug/kg as required). Problematic side effects are respiratory depression, deep sedation, pruritus, vomiting and nausea (in awake patients), and infrequently hypotension and bradycardia. In neonates delayed recovery has to be considered; in renal insufficiency adequate dose reduction due to prevent accumulation of active

metabolites is mandatory to avoid excessive long-lasting sedation. In older children, patient-controlled analgesia (PCA) may be tried; otherwise nurse-controlled analgesia may be preferable. Pain scores and vital signs should be monitored continuously.

High-dose opioid administration is associated with reduced stress reaction, reduced nitrogen loss, and fewer postoperative complications providing better outcomes in critically ill infants and patients with low output and pulmonary hypertension.

Fentanyl provides rapid onset and offset (high lipid solubility) with intense analgesia. After prolonged infusion (days), long elimination half-life causes delayed recovery; there is a rapid development of tolerance. Analgesia can be achieved with infusion rates of 1–5 (–10) ug/kg/h. Bolus fentanyl of 5–10 ug/kg may be necessary for endotracheal suctioning, 10–50 ug/kg in pulmonary hypertensive episodes.

Remifentanyl (0.1–0.3 ug/kg/min) is a synthetic, ultrashort-acting opiate with potent analgesic effects and rapid onset and offset, largely dependent on infusion duration and age. It is metabolized by plasma and unaffected by renal or hepatic function. It is suitable for ventilated patients, but has to be combined with midazolam or a volatile anesthetic agent.

Non-opioid analgesics such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAID) as diclofenac and ibuprofen are used as co-analgesia mainly to reduce opioid side effects and to allow fast-track surgery (Maund et al. 2011). Ketorolac is a potent NSAID without respiratory depression but has some important side effects (bleeding complications, renal dysfunction, gastrointestinal complaints, or dyspepsia).

Ketamine (bolus 1–2 mg/kg; infusion 10–20 ug/kg/min) provides rapid onset with positive effect on arterial blood pressure and heart rate making it unsuitable for analgesia during delayed chest closure as it may obscure hemodynamic compromise of sternal adaptation acutely. Its use for narcosis for secondary chest closure violates the principle of hemodynamic stability in the sense of maintaining homeostasis around this procedure.

Analgesia in *fast-track pediatric patients* needs a multimodal pain management that facilitates rapid extubation and discharge from intensive care unit, beginning with a limited intraoperative

use of fentanyl (<20 ug/kg). Fast-track management is useful in selected non-neonatal patients with uncomplicated cardiac surgery, but needs effective pain management by specialized nurses (Iodice et al. 2011; Roediger et al. 2006). Short-acting opioids (as remifentanyl) and muscle relaxation (by rocuronium or vecuronium) are preferred. To promote early extubation after cardiac surgery, an epidural pain management strategy may provide stable analgesia in a steady state, but data are still limited with lack of large randomized controlled studies (Thammasitboon et al. 2010).

10.7.1.2 Oral Application

Oral opioid administration may be advantageous and reduces the infection risk.

Morphine is the standard opiate and is available for multiple routes of administration. Oral *morphine* needs a three- to sixfold higher dosage than the IV formulation. It is excreted by the kidneys, and its half-life may be prolonged in newborns. Careful titration with monitoring for adverse effects such as respiratory is required.

Oxycodone and hydrocodone are semisynthetic opioids with an onset of 20–30 min and a duration of 4–6 h. Oxycodone is 50% more potent than hydrocodone and is dosed at 0.05–0.15 mg/kg every 4–6 h. Hydrocodone is dosed 0.1–0.2 mg/kg every 4–6 h. Both are available as combination products with acetaminophen.

Codeine (0.5–1.0 mg/kg every 4–6 h) is a weak opioid receptor antagonist. It is available in combination with acetaminophen. Ten percent of the drug is metabolized to *morphine* by cytochrome P450 2D6, which does have high rates of genetic polymorphism.

Tramadol (1.0–2.0 mg/kg every 4–6 h) is an atypical opioid in that the majority of its opioid receptor activity is by its metabolite. It also centrally inhibits the reuptake of norepinephrine and serotonin. It has decreased risk of respiratory depression than other opioid analgesics but is associated with nausea and vomiting and an increased risk of seizures.

10.7.2 Sedation

Most of the analgesic drugs have some sedative properties also. For longer periods of postoperative mechanical ventilation, especially in patients

with cardiac failure, pulmonary hypertension, and lung or airway disease, additional sedation is recommended.

Benzodiazepines (midazolam, bolus 0.05–0.1 mg/kg; infusion 0.05–0.2 mg/kg/h) have an amnestic effect with a reduction in consciousness and help with seizure control but have the risk of withdrawal with prolonged use. Some drugs reduce consciousness and pain such as ketamine or clonidine.

Ketamine in addition to its analgesic properties has a sedative effect, also (see ► Sect. 10.7.1.1 «Intravenous Application»). It can cause hemodynamic compromise by increasing afterload in catecholamine-dependent patients. It has, however, on the other side, a catecholamine-sensitizing effect.

Chloral hydrate (oral/rectal 25–50 mg/kg) may be administered in addition to *morphine*/midazolam during weaning process and is well tolerated.

Haloperidol is used for delirium in agitated patients. It has the risk of extrapyramidal side effects. IV doses of 0.025–0.05 mg/kg/day divided in three to four doses have been used.

Propofol (normal infusion dose 50–200 µg/kg/min, max. 4 mg/kg/h) is used for short-term procedures; has a risk of hypotension and decrease in systemic vascular resistance, dysrhythmias, rising lactate, or acidosis; and may cause propofol infusion syndrome: acidosis, bradyarrhythmia, and rhabdomyolysis.

Dexmedetomidine (loading dose, 0.5 µg/kg over 15–30 min)—a selective α (alpha) 2 agonist—has a sympatholytic effect resulting in hypotension and bradycardia and a decrease in systemic vascular resistance without suppressing respiratory drive. These effects are thought to be beneficial in cardiac patients, especially for attenuating the hemodynamic and endocrinal response to cardiopulmonary bypass with an intraoperative infusion (Munoz and Berry 2005).

Methadone is a synthetic opioid with potent analgesic activity and a long half-life. Because of its half-life and good oral bioavailability, it has been used successfully to treat iatrogenic narcotic dependency or chronic pain.

Clonidine, an α (alpha)2 agonist, has less analgesic potency and can be used for longer sedation and withdrawal from opioids (oral, 2–5 µg/kg every 4 h; also available in transdermal application; IV preparation not available in the USA, dose 0.5–3 µg/kg/h).

Analgesia and sedation for many days can be followed by withdrawal symptoms such as sweating, tachycardia, hypertension agitation, vomiting, or diarrhea; this needs a special oral weaning regimen over 7–14 days using clonidine, an opioid, and/or benzodiazepine or haloperidol in older children.

10.7.3 Muscle Relaxation/Paralytics

Muscle relaxation has to be considered in special situations during the early postoperative period when low cardiac output is present. Muscle relaxants reduce oxygen demand, and by inducing chest wall relaxation, they have an indirect influence on pulmonary vascular resistance when remaining elevated in a hemodynamic unstable situation. For the same reasons they are applied in children with delayed chest closure or those who require hypothermia because of severe dysrhythmia (Playfor et al. 2007).

Pancuronium (0.1 mg/kg bolus) is a nondepolarizing neuromuscular blocking agent, which is long acting with vagolytic effects, resulting in tachycardia and hypertension.

Vecuronium (0.1 mg/kg bolus) has less unwanted side effects, but can accumulate in hepatic failure.

Rocuronium (0.6–1.2 mg/kg bolus) has a rapid onset of action, is useful for tracheal intubation, and turned out to have only minimal cardiovascular side effects (Reich et al. 2004).

Cisatracurium (0.1–0.2 mg/kg bolus IV) is an intermediate-acting neuromuscular blocking agent. It has no significant cardiovascular adverse events.

10.8 Perioperative Prophylaxis for Infectious Complications

The perioperative administration of antimicrobial agents is routinely used in pediatric cardiac surgery. While the onset of routine antimicrobial treatment is rather uniform, about 1 h to immediately before surgery, the duration of prophylaxis varies. Usually the antimicrobials are administered up to 24 or 48 h postoperatively. Longer durations may depend on the presence of central venous lines and chest tube drains that are handled following more local intensive care guidelines. Thus, antimicrobials for 6–9 days postoperatively seem to be common.

Nosocomial infections (NI) were found to occur in up to 15% with the consequence of longer intensive

care stay and increased mortality. The predominant organism was coagulase-negative *Staphylococcus* from skin flora, but also *Staphylococcus aureus*, gram-negative pathogens, and enterococci were found. Risk factors for NI include younger age/infancy, complex cardiac surgery, or open-chest procedure; NI sites are mainly bloodstream or lower respiratory tract or the urinary tract (Grisaru-Soen et al. 2009). An increased risk might also be present in pediatric patients with intracardiac right-to-left shunt (cerebral emboli, brain abscess) and after implantation of prosthetic material (valve prosthesis, conduits, patch material).

The *antimicrobial agent* used for prophylaxis should be effective against staphylococci like cephalosporins or penicillins combined with a β -lactamase inhibitor; limiting the duration of prophylactic administration will reduce the risk of the development of resistant pathogens. Glycopeptides such as vancomycin or teicoplanin were used in patients with high risk for methicillin-resistant *Staphylococcus aureus* (MRSA), especially in the neonatal period.

Kato et al. defined three potential groups of patients being at highest risk for postoperative MRSA infection:

1. Preoperative colonization with MRSA screened by sampling
2. Young children (<3 months) who had been in the hospital since birth
3. Infants and young children who had complex cardiac surgery

The risk of resistant pathogens such as vancomycin-resistant enterococci (VRE) has also to be considered (Kato et al. 2007; Finkelstein et al. 2002; Maher et al. 2002).

In patients with temporary chest wall patch plasty and secondary chest closure, the risk of infection or mediastinitis was low as a routine antibiotic prophylaxis is given using a cephalosporin or vancomycin in combination with an aminoglycoside (Christenson et al. 1996; Tabbutt et al. 1997). This also is our personal experience in over 25 years.

10.9 Arrhythmia

10.9.1 Causes and Hemodynamic Sequelae

Arrhythmias are quite frequent during the early postoperative period, predominantly during the

first 48 h after intracardiac surgery employing extracorporeal circulation. The reported *incidence* varies between 15 and 25%. They occur most often as sustained or non-sustained tachyarrhythmia (supraventricular tachycardia [SVT], atrial flutter [AF], junctional ectopic tachycardia [JET], ventricular tachycardia [VT]), or bradyarrhythmia (higher-degree AV block, sinus bradycardia). Predisposing risk factors are prolonged cardiopulmonary bypass time, cardiac arrest and deep hypothermia, younger age, myocardial ischemia, atrial or ventricular cardiomyotomy and placement of suture lines, hemodynamic impairment, electrolyte imbalance, or arrhythmogenic agents as catecholamines. Preoperative arrhythmia may recur postoperatively or persist (Batra et al. 2006; Beke et al. 2005; Craig et al. 2001; Hoffman et al. 2003; Ravinshankar et al. 2003).

Mechanisms of postoperative arrhythmia are abnormal automaticity as assumed for JET and VT; they are influenced by the autonomic nervous system and show a gradual onset and termination. Reentry mechanisms by anatomic or functional boundaries can develop at the atrial, AV nodal, atrioventricular, or ventricular level; they occur with rapid onset and sudden termination and may cause AF and VT. Triggered automaticity can develop in the presence of premature beats and is a reason for torsades de pointes or other polymorphic tachycardias.

Hemodynamic consequences depend on the heart defect and potential anatomic residua and are mainly characterized by loss of atrioventricular synchrony; the cardiac output decreases by nearly 10–20%. In addition, tachycardias reduce the cardiac output by shortening the diastolic filling phase, leading to a decreased stroke volume. Bradycardia can be compensated to a certain degree by increasing stroke volume, but the filling pressure may increase also, with an increase of ventricular volume.

10.9.2 Diagnostic Procedures

Monitoring heart rate variability is one of the diagnostic tools used to detect inadequate heart rate acceleration or arrhythmia; in addition, invasive monitoring by arterial and systemic venous lines is routinely available. An intracardiac ECG via the temporary epicardial pacemaker wires allows detailed rhythm analysis, identifying atrial and

ventricular spikes. Esophageal electrogram can identify atrial activity; as the catheter electrodes have sensing and pacing modes, atrial stimulation or overdrive pacing is possible in infants; the first choice epicardial wires allow for atrial stimulation or overdrive pacing in any age group. Cardiac catheterization should be considered if the arrhythmia may be related to surgical technique compromising coronary artery perfusion.

10.9.3 Management of Postoperative Arrhythmia

First of all, before specific and eventually complex treatment modalities are embarked on, disturbances of the electrolyte status or acid-base status have to be excluded. In addition, myocardial dysfunction or ischemia with acute increase in atrial or ventricular volume or pressures can initiate arrhythmia. Modification of the inotropic support by catecholamines has to be considered, also. Management of acute arrhythmia depends on the hemodynamic status and mechanism; treatment may be pharmacologic or electrical or a combination of both (Payne et al. 2011).

10.9.3.1 Treatment of Tachyarrhythmia

Supraventricular tachycardias result most often from intra-atrial reentry mechanisms. Depending on heart rate and hemodynamic situation, strategies comprise vagal maneuvers, overdrive pacing, or application of IV adenosine (initial 0.05–0.1 mg/kg IV, max. 0.3 mg/kg IV). Adenosine induces a short AV block terminating SVT which runs across the AV node. The short half-life of 7–10 s allows repeated applications. In situations of atrial flutter, adenosine will unmask the atrial activity during short AV block. Overdrive pacing choosing a heart rate 10–40 beats higher than SVT may interrupt the reentry tachycardia. If the patient is hemodynamically compromised or even in shock, synchronized cardioversion (0.25–1.0 J/kg) is used (Beke et al. 2005; Perry and Walsh 1998).

Atrial flutter (intra-atrial reentry mechanism) can be diagnosed in the classic form by a sawtooth p-wave pattern in the surface ECG with a p-wave rate of 300–600/min. More often, the p-wave morphology is irregular and the frequency varies, related to various locations of potentially surgically induced foci. Depending on the AV conduction, the ventricular rate varies;

most often there is a 2:1 or 3:1 conduction. If the patient is hemodynamically compromised, atrial overdrive pacing with 120% of the flutter frequency or cardioversion is indicated. Pharmacologic therapy is initiated to prevent recurrence (e.g., digoxin and β -blocker or class III agent sotalol or amiodarone).

Atrial fibrillation with an atrial rate of 400–700/min is less common, and it causes loss of mechanical atrial activity; the ventricular rate is irregular (absolute arrhythmia). It is treated along the decision lines and treatment options for atrial flutter; however, atrial overpacing is not possible.

Ectopic atrial tachycardia is rarely documented early postoperatively and may occur transiently triggered by abnormal automaticity. Treatment strategies include digoxin, reduction of catecholamine infusion, β -blocker (esmolol), and amiodarone to control ventricular rate.

Junctional ectopic tachycardia has become the most frequent postoperative tachyarrhythmia (incidence 6–11%). This arrhythmia can occur after any cardiac surgery but may be more commonly seen after surgery for tetralogy of Fallot, ventricular septal defect, atrioventricular septal defect, atrial switch operation, or Norwood procedure (Batra et al. 2006; Hoffman et al. 2003; Perry and Walsh 1998). Predisposing factors may be younger age at surgery (<6 months), prolonged bypass times, and catecholamine support; it is not necessarily surgery near the His bundle or hypomagnesemia (Batra et al. 2006; Dodge-Khatami et al. 2002; Hoffman et al. 2003). JET starts often during the first 24–48 h postoperatively and may be acutely life-threatening by loss of AV synchrony and rapid ventricular rates, but is often self-limiting after 2–8 days. Diagnosis is made from the surface or intracardiac ECG showing AV dissociation with an atrial rate lower than the ventricular (tachycardia with small QRS at a rate of 170–230/min). This causes a dramatic decrease in cardiac output and hypotension. Managing JET today includes a combination of hypothermia (surface cooling; 32–34 °C) and amiodarone (IV bolus 5 mg/kg, continuous infusion 10–15 mg/kg/day) to control the ventricular rate or restore sinus rhythm. Temporary atrial/DDD pacing with a heart rate just above the ectopic tachycardia induces AV synchrony (Janousek et al. 2000; Laird et al. 2003). Adequate analgesia, sedation, and paralysis are needed to tolerate surface cooling (Hoffman et al. 2003; Laird et al. 2003).

Ventricular tachycardias (VT) are uncommon in early childhood. They are potentially related to electrolyte or acid-base status, myocardial ischemia, myocarditis, or a low cardiac output state (LCOS). Patients with a damaged or scarred myocardium after surgery for tetralogy of Fallot, aortic valve procedures, or Ross procedure may develop ventricular tachycardia with widened (>0.09 s) QRS complexes of a single dominant morphology. AV dissociation, fusion beats, and intermittent sinus beats are other observed features.

The other types of VT show varying QRS morphology, twisting around the isoelectric baseline (*torsades de pointes*). This type of VT is at high risk for ventricular fibrillation (and in need of defibrillation with 2–4 J/kg). Treatment should be initiated immediately with synchronized cardioversion (1–2 J/kg). More hemodynamically stable patients can be treated pharmacologically with magnesium (25–50 mg/kg in 5–15 min), lidocaine (1 mg/kg; infusion 20–50 $\mu\text{g}/\text{kg}/\text{min}$), or amiodarone (Craig et al. 2001; Hanisch 2001). Detailed evaluation of the hemodynamic situation and electrophysiologic examination are usually initiated. For chronic prevention of symptomatic VT, medical treatment or implantation of an «automatic implantable cardioverter/defibrillator» is recommended (Kleinman et al. 2010).

10.9.3.2 Treatment of Bradyarrhythmia

Sinus bradycardia with slowing of the heart rate below the age-related normal rates postoperatively mainly results from various degrees of AV block. First-degree AV block becomes hemodynamically relevant only with extremely prolonged PQ duration. This can occur after complex atrial surgery or surgery around the AV node. Second-degree AV block with intermittently missing QRS complexes (Mobitz type II) can result in slow heart rates. Here, sequential pacing can be indicated or infusion of isoproterenol (continuous infusion 0.05–0.1 $\mu\text{g}/\text{kg}/\text{min}$) or atropine bolus (0.02 mg/kg). Third-degree AV block after routine surgery may be transient early postoperatively with return of conduction within a few days; however, there is an increased risk of delayed AV block. Surgeries with a risk of at least temporary postoperative AV block include correction of ventricular septal defect, atrioventricular septal defect, subaortic stenosis, tetralogy of

Fallot, or l-transposition of the great arteries. The incidence of advanced second-degree or third-degree AV block requiring pacemaker implantation is now less than 1%. All patients with a persistent higher-degree conduction block for more than 10–14 days should undergo permanent cardiac pacemaker implantation (VVI-VVIR or DDD system) (Gregorates et al. 2002; Lin et al. 2010).

Less often, sinus node dysfunction may be the cause of sinus bradycardia. It may follow atrial surgery like correction of sinus venosus defect, Mustard or Senning surgery (atrial switch) for transposition of the great arteries, or Fontan-type surgery. Permanent cardiac pacemaker implantation (AAI, AAIR, or DDD mode) is indicated when bradyarrhythmia causes symptoms or even reported syncope.

10.10 Respiratory Dysfunction and Mechanical Ventilation

10.10.1 Indication and Ventilation Modes

Prolonged respiratory dysfunction after pediatric cardiac surgery may have various reasons. The respiratory mechanics may be impaired by upper airway obstruction (subglottic stenosis, injury to the recurrent laryngeal nerve), interstitial edema from left-to-right shunt or inflammatory response after cardiopulmonary bypass (SIRS), parenchymal compromise by atelectasis or pneumonia, pleural effusion, diaphragmatic paralysis, chest wall edema, or abdominal compression by ascites. Insufficient ventilation can occur in association with deep sedation/analgesia, neuromuscular insufficiency after prolonged mechanical ventilation, or with advanced malnutrition. Pulmonary gas exchange is also impaired in situations with low cardiac output, ventilation-perfusion mismatch, or intrapulmonary shunts with the consequence of hypercapnia.

The *indication* for prolonged endotracheal intubation (or reintubation) and mechanical ventilation is given in situations with acute respiratory insufficiency and inadequate gas exchange with retention of carbon dioxide ($\text{pCO}_2 >50$ mmHg), hypoxemia ($\text{pO}_2 <70$ mmHg) and peripheral oxygen saturation $<93\%$, and/or respiratory acidosis. These limits have to be adapted to

the individual situation of the patient. Patients with right-to-left shunt are used to having lower oxygen saturations, the same as in patients with chronic hypercapnia.

In spontaneous respiration there is a synchronous active contraction of the diaphragm and intercostal muscles, inducing a negative intrathoracic pressure followed by a passive expiration. Invasive ventilation offers a positive pressure at inspiration; the pressure decrease at expiration can be modified by using positive end expiratory pressure (PEEP). This can be associated with a decrease in venous return, increase in pulmonary artery pressure and pulmonary vascular resistance, and reduction in pulmonary blood flow or cardiac output with the need for volume supplementation. These effects are «compensated» by improvement of oxygenation and consecutive reduction of the pulmonary vascular resistance. In patients with Fontan circulation, however, the passive pulmonary artery flow can be significantly compromised by inadequate positive pressure ventilation and PEEP.

The initial, conventional mode of mechanical ventilation is often pressure-regulated volume controlled; with the beginning of spontaneous breathing, the mode is switched to synchronized intermittent mandatory ventilation (SIMV) with pressure control. After complex cardiac surgery with prolonged cardiopulmonary bypass time, most patients remain under controlled ventilation for at least 24 h, especially in neonates and infants.

Principal ventilatory parameters for infants/children include a ventilator rate of 15–40/8–20 per minute, a tidal volume of 8–10–12 ml/kg, and an I:E ratio of 1:1.5–1:3. Elevation of mean airway pressure (by increase of PEEP, inspiratory time or flow) and inspired oxygen concentration will increase the oxygenation. Hypercapnia needs an increase ventilatory minute volume.

International guidelines for the variety of ventilation modes are still lacking; modes included pressure control, synchronized intermittent mandatory ventilation, pressure support, and pressure-regulated volume control.

The ventilation mode should take the underlying disease into account. Patients with pulmonary hyperperfusion may require pressure-controlled ventilation with increased PEEP and a lower ventilator rate. After univentricular palliation with Glenn- or Fontan-type surgery, mechanical ventilation is focused on optimal ventilation and

oxygenation with a low mean airway pressure. Here, the aim is more than in any other patient to extubate as early as possible in order to use the negative intrathoracic pressure under spontaneous respiration for improvement of passive pulmonary perfusion.

Modifications of mechanical ventilation have been introduced to reduce the ventilator-related lung injury, to improve the postoperative hemodynamic situation, and to facilitate gas exchange.

High-frequency oscillatory ventilation (HFOV) uses the combination of very small tidal volumes (1–3 ml/kg) and high-frequency oscillatory ventilation (2–15 Hz, 120–900/min). This allows for lung-protective ventilation with a reduced risk of barotrauma and atelectasis (Kneyber et al. 2012). It generates a continuous positive airway pressure system with small oscillations. It is mainly used as a rescue modality when hypoxemia and acidosis occur on conventional mechanical ventilation despite increasing alveolar ventilation. Oxygenation depends on FiO_2 and mean airway pressure, ventilation on frequency, and amplitude of oscillation. Early use of HFOV in pediatric cardiac surgery may be beneficial, and it can be used when there is evidence of pulmonary hypertension and right ventricular failure (Bojan et al. 2011). *High-frequency jet ventilation (HFJV)* uses rates of 60–600 per minute with tidal volumes of 2–5 ml/kg; this results in a lower mean airway pressure. *High-frequency positive pressure ventilation (HFPPV)* combines tidal volumes of 3–4 ml/kg with rates of 60–150 per minute.

Neurally adjusted ventilatory assist (NAVA) is the newest mode of mechanical ventilation that uses the electrical activity of the diaphragm to trigger the ventilator breath and to adjust the ventilatory assist to the patient's neural drive. First clinical data demonstrated a superior patient-ventilator synchrony, lung-protective mechanical ventilation mode, and efficient unloading of the respiratory muscles and suggested potential advantages for the weaning process after prolonged mechanical ventilation (Verbrugghe and Jorens 2011).

Noninvasive positive pressure ventilation (NPPV) provides mechanical respiratory support without the need for endotracheal intubation. It refers to continuous positive airway pressure (CPAP) or bilevel respiratory support including expiratory or inspiratory positive airway pressure or biphasic positive airway pressure (BIPAP).

It can be used in selected patients including circumstances with postoperative or postextubation respiratory failure, atelectasis, pneumonia, or ARDS. NPPV can facilitate weaning from mechanical ventilation reducing the risk of reintubation as it improves gas exchange and reduces work of breathing. Predictive factors for failure of NPPV are higher FiO_2 and hypercapnia on admission (Najaf-Zadeh and Leclerc 2011). Care has to be taken that the face mask used can be tolerated comfortably and does not cause pain. Tight masks leading to face hematomas have to be avoided.

In neonates and infants, some units prefer to apply high flow (4–8 l/min) air or oxygen via nasal prongs after extubation, as a substitute/alternative for CPAP. Care has to be taken to avoid skin breakdown from prolonged prong placement.

Following repair of tetralogy of Fallot, low cardiac output state secondary to restrictive right ventricular physiology, refractory to conventional measures, may be improved by using negative pressure ventilation (NPV). NPV can augment pulmonary blood flow and cardiac output in patients with restrictive right ventricular physiology and diastolic dysfunction (Shekerdemian et al. 2000). The use of negative pressure ventilation may also be beneficial in patients after Fontan operation with improvement of pulmonary blood flow and stroke volume (Shekerdemian et al. 1997).

The administration of *heliox*, a mixture of helium and oxygen, during mechanical ventilation decreases the work of breathing and diminishes respiratory distress. It facilitates gas exchange by improving oxygenation and eliminating carbon dioxide, making it a rescue strategy in patients with severe airway obstruction and respiratory failure (asthma, bronchiolitis, upper airway obstruction, cystic fibrosis, and congenital tracheal stenosis, postoperatively after tracheal surgery). Early experience made ventilation with *heliox* a promising strategy for children with various complex respiratory diseases (Gupta and Cheifetz 2005; Martín-Torres 2012).

10.10.2 Weaning and Extubation Readiness

Weaning off mechanical ventilation is a priority once postoperative hemodynamic stabilization is achieved. This may be already the case with the

patient arriving on the intensive care unit. He may, however, have already been extubated in the OR.

The weaning process begins with the onset of spontaneous breathing accompanied by a decrease in ventilator support. There is no standard strategy for the weaning process. Factors influencing weaning are level of sedation, fluid balance of the patient (lung compliance decreases with interstitial edema, chest wall edema), pulmonary hypertension (with the need for oxygen supplementation and special inhalation regimen), and function of the diaphragm. Steroids started 6–24 h before planned extubation after prolonged ventilation may be useful in reducing tracheal inflammation and subglottic edema (Newth et al. 2009).

Using indices to predict success of weaning and extubation is probably less reliable than clinical judgment and decision-making. A spontaneous breathing test or extubation readiness test consisting of a period of spontaneous breathing with $\text{FiO}_2 < 0.5$ failed to indicate extubation success (Newth et al. 2009).

The weaning process in infants and children employs SIMV (synchronized intermittent mandatory ventilation) or IMV mode with pressure support and gradual reduction of the ventilator support, i.e., ventilator rate. Comparing the effect of SIMV and BIPAP ventilation, the last mode allows more synchronization with the respirator. *Criteria for extubation* (extubation readiness) include spontaneous ventilation, stable hemodynamic parameters, and optimal cardiac output, normal cardiac rhythm/adequate pacing, intact airway reflexes with vigorous coughing, manageable airway secretion, adequate oxygenation on fraction of inspired oxygen < 0.4 , maintenance of a $\text{pH} > 7.35$ and $\text{PaCO}_2 < 45$ mmHG, adequate hemostasis, and sufficient consciousness. Extubation failure (need for reintubation within 24–72 h) is most often related to upper airway obstruction and is expected in nearly 6% of patients. The requirement to reintubate increases morbidity. Residual anatomic lesions have to be excluded as well as pulmonary causes of respiratory failure (i.e., pleural effusion, diaphragm paralysis, pneumothorax). These all, however, should have been excluded before extubation. Neurologic problems such as oversedation or neuromuscular blockade may lead to reintubation, also.

Prolonged mechanical ventilation (> 72 h) following cardiac surgery in neonates and infants

correlated with postoperative morbidity including nosocomial infections and pneumonia, low cardiac output syndrome, need for inotropic support and more fluid retention, delayed sternal closure, and extubation failure. Longer stay in the ICU and increased mortality may be the consequence. Risk factors associated with prolonged mechanical ventilation were younger age, more complex form of congenital heart disease, or pre-existing comorbidities such as chromosomal abnormalities, dystrophy/malnutrition, heart failure, pulmonary hypertension, and pulmonary disease (Szekely et al. 2006).

Early extubation after pediatric cardiac surgery (<8 h postoperatively) offers some benefits as reduction of pulmonary and nosocomial infections and lower use of sedation. An additional aspect is a shorter duration of intensive care stay with reduced financial costs (Davis et al. 2004). Fast-track pediatric anesthesia and cardiac surgery is a concept suitable for selected patients with uncomplicated cardiac defects (as ASD, VSD, partial AVSD, subaortic stenosis, a replacement of RV-PA conduits) and absence of relevant comorbidities such as pulmonary hypertension or heart failure. Effective pain management is one of the most important aspects of fast-track process (Howard et al. 2010; Iodice et al. 2011).

10.11 Postoperative Pulmonary Hypertension

10.11.1 Diagnosis and Specific Causes

During the last years, the incidence and severity of postoperative pulmonary hypertension (PH) have been reduced related to early surgical correction of congenital heart disease, associated with modification of cardiopulmonary bypass like using modified ultrafiltration, and changes in treatment of critically ill patients. PH is due to persistent increased pulmonary blood flow (L/R shunt) or elevated pulmonary vascular resistance (PVR). It is defined as a mean pulmonary artery pressure >25 mmHg at rest. An increased vascular reactivity and the development of hypertensive crisis postoperatively have to be anticipated in some cardiac lesions with long-standing preoperative increased pulmonary blood flow or pulmonary venous obstructive lesions with elevated

PVR. These are predominantly total anomalous pulmonary venous connection, truncus arteriosus communis, atrioventricular septal defects, nonrestrictive ventricular septal defect, transposition of the great arteries with ventricular septal defect or aortopulmonary window, and during the early postoperative period after cardiac transplantation.

Monitoring shows an increase of the systemic venous pressure accompanied by a decrease of cardiac output as well as arterial pressure and oxygen saturation. A pulmonary hypertensive crisis was defined as a pulmonary-to-systemic pressure ratio of more than 0.75, potentially leading to acute right heart failure. Postoperative PH is the result of endothelial damage, suppression of endogenous NO production, inflammatory processes, ischemic lesions, or reperfusion syndrome after cardiopulmonary bypass leading to an increased reactivity of the pulmonary vasculature. The pulmonary vascular endothelium produces endogenous vasoconstrictors (as endothelin-1) and vasodilators (as prostacyclin). Additional circumstances can promote a postoperative increase of PVR requiring a longer period of mechanical ventilation and stay on intensive care unit. These circumstances include pulmonary complications (atelectasis, pneumothorax, pleural effusion, bronchospasm), pulmonary vascular microemboli, pulmonary edema, inadequate ventilation with carbon dioxide retention, and inadequate high PEEP (Brown et al. 2003; Checchia and Bronicke 2012; Huddleston and Knoderer 2009; Schulze-Neick et al. 2001).

In postoperative situations with systemic-to-pulmonary connections as after aortopulmonary shunt procedures, especially in preoperative duct-dependent cardiac lesions as hypoplastic left heart syndrome, the relation of PVR to systemic vascular resistance may be rather low, as a result of severe pulmonary hypercirculation. Balancing the systemic and pulmonary circulation can be achieved by measures which either increase the PVR, like reduction of the inspired oxygen fraction, hypoventilation, and elevation of the mean airway pressure (e.g., with higher PEEP), or by lowering the systemic vascular resistance with specific agents as sodium nitroprusside or phentolamine.

In biventricular circulation, an abnormal increase of the right ventricular pressure—calculated by the trans-tricuspid Doppler velocity—can also be caused by residual anatomic lesions.

These may be right ventricular outflow tract obstructions, pulmonary valve stenosis, left heart obstructive lesions, or pulmonary venous obstruction. Right ventricular pressure overload shifts the interventricular septum toward the left ventricle, causing severe tricuspid regurgitation, arrhythmias, and left ventricular dysfunction, each of these sequelae leading to low output states. Primary treatment options beside the management of the PH are fluid management for adequate preload, control of arrhythmias, and inotropic support.

10.11.2 Treatment Options: Prevention First!

Management strategies in patients at risk for postoperative PH are mainly focused on preventing potential trigger mechanisms and by providing deep sedation, moderate hyperventilation (i.e., $p\text{CO}_2$ 30–35 mmHg), an increase of inspiratory oxygen fraction, and adequate PEEP ventilation. The application of pulmonary vasodilators needs a strong indication because of the potential side effects. Milrinone, a selective phosphodiesterase-3 inhibitor with inotropic and vasodilator effects, works as an unspecific pulmonary vasodilator with pronounced lowering of the systemic blood pressure and therefore has only limited indications in PH. Intravenous prostacyclin (epoprostenol, started with 1–2 ng/kg/min, titrated to 10–20 ng/kg/min) is an alternative option; however, dose-dependent systemic side effects such as systemic hypotension, headache, nausea, and vomiting may limit its use. Abrupt withdrawal may induce rebound pulmonary hypertension. Inhaled prostacyclin and the prostacyclin analog, iloprost, seem to be as effective as inhaled nitric oxide (Mulligan and Beghetti 2012; Rimensberger et al. 2001); the most common side effects are cough, headache, or flushing. Inhaled iloprost is often used in combination with other vasodilator drugs (sildenafil, bosentan).

Inhaled nitric oxide (iNO) is a potent vasodilator and now a standard of care for postoperative pulmonary hypertension; however, prophylactic administration in patients at risk for pulmonary hypertensive crisis is not recommended. Development of methemoglobinemia may limit its use. After abrupt reduction of NO, «rebound» pulmonary hypertension, because of downregulation

of endothelial NO, can complicate the weaning process (Atz et al. 1996; Miller et al. 2000). The recommended starting dose of NO is 20 ppm, but it may vary between 5 and 40 ppm (Journois et al. 2005; Stocker et al. 2003).

Sildenafil, a specific phosphodiesterase-5 inhibitor, allows for a more selective pulmonary vasodilation and is used for acute and chronic treatment of PH with lower risk of systemic arterial hypotension. The special effects in children after congenital heart surgery need further evaluation (Atz et al. 2002; Schulze-Neick et al. 2002). However, data suggest that oral sildenafil can facilitate the weaning of iNO (Huddleston and Knoderer 2009). As enteral absorption may be compromised during the early postoperative period, intravenous sildenafil is advantageous and was reported to reduce pulmonary artery pressure (Fraise et al. 2011). Preoperative sildenafil reduced postoperative pulmonary artery pressure and shortened length of stay in the intensive care unit (Palm et al. 2011).

Chronic treatment options include *bosentan*—an endothelin receptor antagonist; it was shown to be safe and improves functional capacity. Potential side effects described were (reversible) abnormalities in hepatic function tests (Galie et al. 2003). In combination with sildenafil, both a decrease of sildenafil and increase of bosentan concentration have to be considered; at present, no dose recommendations are available for this combined therapy. Dosing for bosentan monotherapy is weight related: for $5 \leq 10$ kg, 15.6 mg daily for 4 weeks and thereafter 15.6 mg twice daily; for weight 10–20 kg, 31.25 mg daily for 4 weeks and thereafter 31.25 mg twice a day; for 20–40 kg, 31.25 mg twice a day for 4 weeks and thereafter 62.5 mg twice a day; and for bodyweight >40 kg, 62.5 mg twice a day and thereafter 125 mg twice a day.

The degree of right ventricular failure must be determined, and treatment is aimed to reduce pulmonary vascular resistance, increase cardiac output, and resolve systemic hypotension. Dobutamine in doses up to 5 $\mu\text{g}/\text{kg}/\text{min}$ significantly decreased pulmonary vascular resistance and increased cardiac output especially when combined with iNO. Individualized therapy also may include the administration of norepinephrine and dopamine. In these patients modification of mechanical ventilation has to be considered as hyperinflation or inadequate PEEP ventilation

can fatally reduce cardiac output. In refractory right ventricular failure, atrial septectomy/septostomy or the use of mechanical right ventricular assist devices has to be discussed.

10.12 Kidney Injury and Renal Replacement Therapy

10.12.1 Definition, Risk Factors, and Staging of Acute Kidney Injury (AKI)

Acute kidney injury (AKI) in infants and children after heart surgery is a serious complication encountered in 11–30% (Sethi et al. 2011, Chiravuri et al. 2011). AKI requiring dialysis occurs in up to 5% of these patients. The mortality rate under these conditions might approach 40%. However, even after a period of dialysis, chronic renal impairment rarely develops (Skippen and Krahn 2005).

AKI can be *defined* as an abrupt (within 48 h) reduction in renal function with increase in serum creatinine of >0.3 mg/dl or a total increase in serum creatinine to >1.5-fold from baseline or reduction in urine output (<0.5 ml/kg/h for more than 6 h) (Sehti et al. 2011). Using the modified RIFLE (Risk, Injury, Failure, Loss of kidney function, and End-stage kidney disease.) criteria, a decrease of estimated creatinine clearance by 50% (resp. 75%) and reduction of urinary output <0.5 ml/kg/h for 16 h (resp. <0.3 ml/kg/h for 24 h) might indicate kidney injury (resp. failure) (Akcan-Arikan et al. 2007). Uniform standards for defining and staging of AKI were established in 2008 by the AKI Network (Mehta et al. 2008).

The risk for renal dysfunction is increased in:

- Children younger than 12 months
- Weight <10 kg
- Duration of cardiopulmonary bypass time >90 min
- Complex heart defect and cyanosis
- Postoperative LCOS and prolonged inotropic support
- Systemic inflammatory response syndrome with intraoperative activation of the immune system despite changes in CPB practice (hemofiltration, modified ultrafiltration) (Sethi et al. 2011; Picca et al. 2008; Beke et al. 2005; Chang 2003; Ravinshankar et al. 2003).

- Renal dysfunction has a multifactorial origin, *sometimes determined by preoperative events*:
- *Prerenal* (hypovolemia, hypotension, LCOS, sepsis, peripheral vasoconstriction, increased central venous pressure, mechanical ventilation, intra-abdominal pressure elevation, ascites, postoperative residual lesions)
- *Renal* (renal failure due to hypoxemia, acidosis, nephrotoxic agents, hemolysis with hemoglobinuria)
- *Neurohumoral* abnormalities (i.e., inadequate ADH secretion, increase of plasma-renin or aldosterone)
- *Postrenal* (preexisting/congenital renal anomalies or uropathy)

The diagnosis and classification of AKI can be made using the gold standard of serial creatinine measurements; biomarkers such as neutrophil gelatinase-associated lipocalin (NGAL), N-acetyl-β-(D)-glucosaminidase (NAG), interleukin-18, kidney injury molecule-1, and cystatin C, however, may allow for early rapid diagnosis of AKI as they precede the increase in serum creatinine by several hours. This might enable prevention and early modification of clinical management of AKI after cardiopulmonary bypass (Krawczeski et al. 2010, 2011; Parikh et al. 2011).

10.12.2 Management of AKI

Postoperatively compromised cardiac function and hemodynamics lead to decreased kidney perfusion. The clinical features of a low cardiac output syndrome include tachycardia, poor systemic perfusion and inadequate mean arterial pressure, increase in serum lactate, and decreased urinary output. Therapeutic options include inotropes, vasopressors, vasodilators, and diuretics to optimize cardiac function, renal and systemic perfusion, as well as pulmonary blood flow for oxygen supply. To balance systemic and pulmonary blood flow, ensuring adequate systemic organ perfusion, as well as sufficient oxygenation, medication, and drug dosing, has to be titrated continuously, accompanied by ventilatory adjustments.

■ ■ Dopamine

Dosages of 3–5 ug/kg/min improve renal perfusion and urinary output (dopamine receptor, also present

in the mesenteric vascular system), whereas dosages from 5 to 10 $\mu\text{g}/\text{kg}/\text{min}$ increase inotropy and chronotropy (β_1 -stimulation) and from 10 to 20 $\mu\text{g}/\text{kg}/\text{min}$ increase systemic vascular resistance (α (alpha)-receptor stimulation). High doses of dopamine for treatment of low cardiac output syndrome might induce peripheral and splanchnic vasoconstriction (Gajarski et al. 2003; Prins et al. 2001).

■ ■ Fenoldopam

It is a selective dopamine-1 receptor agonist which combines the effect of decreasing systemic vascular resistance while increasing renal blood flow, tubular sodium extraction, and urinary output. In contrast to dopamine, dopamine-2 and adrenergic receptors are not activated, and chronotropic and inotropic effects are not observed (Bove et al. 2005; Costello et al. 2006; Goldstein and Chang 2006). Pediatric experience is still limited.

■ ■ Epinephrine

Treatment of low cardiac output syndrome often includes epinephrine at a dose $>0.05 \mu\text{g}/\text{kg}/\text{min}$ for maintenance of adequate mean arterial pressure.

■ ■ Milrinone

It is a phosphodiesterase III inhibitor. Without the increase of myocardial oxygen consumption, it combines the effect of moderate inotropy after end diastolic relaxation with vasodilation of pulmonary and systemic circulation (Stocker and Shekerdemian 2006).

■ ■ Diuretics

Prevention of fluid overload, pulmonary edema, and elevated cardiac afterload is an important clinical goal in treatment of critically ill children after cardiac surgery. To support a net negative fluid balance from the start, diuretic therapy is introduced almost immediately postoperatively. Furosemide, a loop diuretic, is most often used either as a bolus (1 mg/kg every 6–8–12 h) or in a continuous infusion (4–8–10 $\text{mg}/\text{kg}/\text{day}$) as recommended in the hemodynamically unstable patient. Usually treatment is started with higher doses and adjusted based on urinary output (Ravishankar et al. 2003; Van der Vorst et al. 2001). In addition to furosemide, aminophylline (single bolus infusion 5–10 mg/kg) is an effective adjuvant for diuresis as is chlorothiazide (10–20 $\text{mg}/\text{kg}/\text{day}$, divided q6 h, or later 20 $\text{mg}/\text{kg}/\text{day}$ p.o.). Additionally ethacrynic

acid (IV 0.5–1 $\text{mg}/\text{kg}/\text{day}$, max. 2 $\text{mg}/\text{kg}/\text{day}$) may be administered early postoperatively. A more expensive alternative to furosemide is bumetanide in single doses of 0.05 mg/kg every 6–8–12 h or in a continuous infusion (0.2–0.4–0.5 $\text{mg}/\text{kg}/\text{day}$).

■ ■ Renal replacement therapy (RRT)

Renal replacement therapy may be required to be required in nearly up to 10% of children undergoing heart surgery. Acute peritoneal dialysis is most frequently used, as hemofiltration has the disadvantage of vessel access and systemic anticoagulation.

Indications for peritoneal dialysis (PD) are oliguria ($<0.5 \text{ ml}/\text{kg}/\text{h}$ for more than 4 h) or anuria (despite adjusted inotropic, vasodilator, and diuretic support), fluid overload, creatinine level $>1.2 \text{ mg}/\text{dl}$, hyperkalemia or electrolyte imbalances, or acidosis. Fluid overload may be an indication without acute renal failure (Chan et al. 2003; Ravishankar et al. 2003). As PD is easy and safe, it does not need any anticoagulation or vessel access and is well tolerated in the hemodynamically unstable infant, and early application is now recommended to avoid increasing fluid overload. Prophylactic placement of peritoneal catheters intraoperatively for routine early postoperative dialysis is expected to reduce the effects of systemic inflammatory response by removing inflammatory mediators and allows early fluid balance (Baskin et al. 2010; Dittrich et al. 2004).

10.13 Postoperative Nutrition

Early nutrition assessment in the postoperative period is necessary to avoid underfeeding or overfeeding; outcome and length of stay on the ICU can be affected. *The energy requirements* are difficult to estimate and will change during the postoperative course; nutritional needs may be calculated using preoperative anthropometric measurements or indirect calorimetry. Reasons for inadequate nutrition therapy can be based on fluid restriction, ceasing of enteral nutrition for diagnostic procedure, weaning process and extubation, or surgery, gastrointestinal intolerance with vomiting, abdominal distension, and disturbed motility. Overfeeding also has adverse metabolic effects with hepatic dysfunction.

Protein requirements are higher than in healthy children to yield a positive nitrogen balance; in critically ill children, protein breakdown will exceed protein synthesis leading to negative nitrogen balance, weight loss, and skeletal muscle wasting. BUN will increase and mimic renal failure for some! Depending on age protein intake varies between 2 and 4 g/kg/day until the age of 2 years and 1.5 g/kg/day above 13 years (Skillman and Mehta 2012). Protein malnutrition can cause higher risk of infections, wound healing problems, longer dependency on mechanical ventilation, and prolonged weaning.

Inadequate *carbohydrate* feeding can lead to an increase in insulin concentration, lipogenesis with an increase in CO₂ production, and steatosis and hepatic cellular injury (Hulst et al. 2006). Postoperative hyperglycemia is caused by the acute stress response, occurs in 90% of patients, and was found to resolve within 72 h (Moga et al. 2011).

To maintain normoglycemia monitoring and insulin therapy may be necessary as this strategy seems to lower postoperative morbidity and mortality by also reducing the risk of infection and liver dysfunction in pediatric patients (Hulst et al. 2006).

Adult data suggested in 2001 the preferable serum glucose level to be <110 mg/dl for reduced risk of wound complications; however, more recent data show the same effect for a glycemic control at levels <180 mg/dl (van den Berghe et al. 2001; Bhamidipati et al. 2011; Haga et al. 2011). See also ► Chapter «Cardiac Surgical Intensive Care», Sects. 9.5.7 and 9.5.12.

Enteral nutrition is always preferred, but has to be precluded in hemodynamically unstable patients receiving high-dose vasoactive medication, muscle relaxants, analgesia, and sedation, as well as in situations with increased risk for aspiration. Sometimes enteral nutrition is initiated using nasogastric tube or postpyloric tube. In patients with gastrointestinal intolerance, prokinetic medication should be considered.

Parenteral nutrition has the increased risk of infection from central venous lines and hepatic dysfunction and is thought to be generally initiated only if enteral nutrition is insufficient for at least 5 days (Mehta et al. 2009). Serial assessment of nutrition requirements is necessary and should be focused on protein balance and continuous glucose monitoring to avoid hyper- or, even more important, hypoglycemia.

Chylothorax after surgery is a complication that occurs with an incidence of 0.9–6%; newborn and infant patients with complex surgery are at highest risk. Possible reasons include surgical damage of the thoracic duct, central vein thrombosis, elevated systemic venous pressure, or damage of small lymphatic vessels at secondary chest closure (Biewer et al. 2010). Diagnosis is obvious in milky appearance of the pleural effusion once enteral feeds are initiated, lymphocytosis, elevated triglyceride concentration, and the presence of chylomicrons.

Treatment options are mainly based on nutritional supplementation with MCT diet for at least 10 days up to 30 days or even 6 weeks for lymphatic decompression; this was effective in more than 70% of patients. Alternatively, oral nutrition with low fat formula and additional intravenous lipid application might be possible. In cases of central vein thrombosis, lysis or interventional catheter should be considered. Persisting chylothorax for more than 10 or 14 days needs further diagnostic procedures to rule out elevated systemic venous pressure or otherwise impaired postoperative hemodynamics. More aggressive therapeutic regimens included total parenteral nutrition (TPN); however, in some series MCT feeding does not cause longer pleural drainage than TPN. Rarely octreotide therapy or pleurodesis has to be discussed. Prolonged intensive care stay, malnutrition, hypogammaglobulinemia, and lymphopenia with predominant T-cell depletion may result in a higher incidence of opportunistic infections and indication for prophylactic antimicrobials if not taken care of by meticulous monitoring and replacement therapy as necessary.

10.14 Perioperative Neurologic Injury and Neurologic Monitoring

Nearly 90% of children with congenital heart defects will survive into childhood, and many cardiac malformations are now corrected or palliated in the neonatal period or during infancy. Once mortality of surgery for congenital heart disease had improved significantly over the years, surgical modifications and changes in intra- and perioperative management are primarily focused on prevention of postoperative morbidity and long-term outcome. Reoperations or reinterventions,

either planned or not planned, severe arrhythmias, and exercise impairment are well known and seem to be typically associated with surgery for complex congenital heart disease. These sequelae, however, are less frequent than developmental delay or mental retardation, as well as behavioral and learning problems, which are often not recognized before childhood.

10.14.1 Preoperative Neurological Abnormalities and Risk Factors

Preoperative neurological abnormalities such as hypo- or hypertonia, motor asymmetries, feeding difficulties, and seizures have been described in more than 50% of the newborn with congenital heart defects. Sonographic brain abnormalities were found in up to 10% of infants before surgery including holoprosencephalopathy and agenesis of the corpus callosum (Kaltman et al. 2005). Microcephaly that can be followed into childhood may be present in more than 25%. Its causes are multifactorial, although special abnormalities of fetal hemodynamics, secondary to the specific cardiovascular pathoanatomy, might influence cerebral development (Limperoupolos et al. 2000; Shillingford et al. 2005). This aspect was discussed for infants with hypoplastic left heart syndrome, transposition of the great arteries, or tetralogy of Fallot and may be related to alterations in cerebrovascular resistance (Kaltman et al. 2005).

In addition, genetic syndromes with abnormal neurological development have to be considered such as trisomy 21, monosomy 22q11.1, velocardiofacial syndrome, associations of multiple congenital anomalies such as VACTERL or CHARGE syndromes, or Williams-Beuren syndrome.

In preterm neonates, after prolonged perinatal asphyxia or intracranial bleeding, in a hemodynamically unstable condition or in the presence of coagulopathies, it might be necessary to postpone the corrective surgical procedure or to switch to a palliative operation, like pulmonary artery banding in VSD or bilateral banding and ductus stenting in HLHS.

Preoperative magnet resonance imaging studies showed ischemic lesions, mainly periventricular leukomalacia, in up to 20% of all patients with congenital heart defects (Mahle et al. 2002), even more frequent in infants with hypoplastic left

heart syndrome. Postoperative findings describe new lesions or worsening of preoperative lesions in more than 66%. Isolated risk factors such as the use of deep hypothermic cardiac arrest or duration of cardiopulmonary bypass time were not identified; other factors as compromised pre-, intra-, and postoperative hemodynamics, especially pronounced low cardiac output syndrome, may be more important (Bellinger et al. 1999; Galli et al. 2004). Resolution of mild periventricular leukomalacia can be assumed; ventriculomegaly and cerebral atrophy are very rare.

10.14.2 Peri-, Intra-, and Postoperative Neurologic Injury

Perioperative factors related to the risk of neurologic injury include preoperative prostaglandin infusion, mechanical ventilation, placement of central venous lines, or catheter intervention such as balloon atrial septostomy or balloon valvuloplasty. Cerebral pressure autoregulation in children with congenital heart disease may be impaired; autoregulatory limits are expected to vary with type of defect and age and are not clearly defined.

Intraoperatively many risk factors can be identified which might cause neurological abnormalities: cardiac arrest, deep hypothermic circulatory arrest, hemodilution (hematocrit should be above 30%), reperfusion injury, inflammatory reaction, or hyperglycemia (Bellinger et al. 2001). Pharmacologic management or bypass flow rates to maintain mean arterial pressure intraoperatively carry the risk of brain injury by ischemia or hyperperfusion (Scheers et al. 2006).

Prolonged and uninterrupted periods of deep hypothermic circulatory arrest in neonates and infants may have adverse effects on late neurologic outcome (Clancy et al. 2003; Forbess et al. 2002). The effects of duration of circulatory arrest on later neurodevelopmental parameters are nonlinear; a «safe» duration of total circulatory arrest cannot be given as effects of cardiopulmonary bypass are also influenced by diagnosis, age at operation, and other perioperative variables (Wernovsky 2006; Wypij et al. 2003). Strategies with continuous cerebral perfusion during cardiopulmonary bypass are frequently preferred these days, although data on long-term neurologic outcome for this approach

are lacking. A long-term follow-up study in children with transposition of the great arteries undergoing neonatal arterial switch surgery revealed worse results in motor and speech functioning for infants after predominantly deep hypothermic circulatory arrest; however, after low-flow cardiopulmonary bypass (initiated to reduce the risk of ischemic cerebral injury), a higher proportion of patients with behavioral difficulties was described. The entire study group, regardless of bypass strategy, presented with difficulties in sustained attention, speech, and learning abilities or developmental delay (Bellinger et al. 1999; Skaryak et al. 1996). Animal studies could demonstrate that low-flow cardiopulmonary bypass may induce a greater inflammatory response with nonneurologic morbidity; the intermittent perfusion during deep hypothermic circulatory arrest seems to have a neuroprotective effect resulting in normal cerebral metabolic and ultrastructural recovery (Langley et al. 1999).

Postoperative risk factors for cerebral injury include invasive monitoring, mechanical ventilation, pharmacologic management in a hemodynamically unstable patient, risk of cerebral emboli, post-bypass cerebral edema related to inflammation, reperfusion injury or microemboli, and hyperthermia with increase cerebral oxygen requirements. The duration of postoperative intensive care unit length of stay in the newborn period was associated with worse developmental outcome (Newberger et al. 2003). During the early postoperative period, the first 24–48 h after cardiopulmonary bypass, the systemic blood flow and oxygen delivery are decreased, and the cerebral pressure autoregulation is impaired, implying the high risk for localized ischemic or global hypoxic injury of the central nervous system (Bassan et al. 2005; Wernovsky 2006).

The occurrence of *seizures* in the immediate postoperative period after repair or palliation of congenital heart defects was defined as a marker of early central nervous system injury. Continuous electroencephalographic monitoring demonstrated seizures in 10–20% of neonates and infants and was thought to be a surrogate marker for long-term neurologic outcomes in early studies, while more recent data could not prove the negative predictive value (Gaynor et al. 2006; Clancy et al. 2003; Rappaport et al. 1998). Postoperative seizures were more often identified after prolonged duration of deep hypothermia

and circulatory arrest and in infants with coexisting abnormalities of the central nervous system (Gaynor et al. 2006; Clancy et al. 2003).

Thromboembolic events may occur intraoperatively (contact of blood with artificial surfaces of extracorporeal circulation, air embolism) or early postoperatively (venous stasis, clotting factor imbalance, residual lesions, artificial patches, and tubes). Due to postoperative sedation and pharmacologic paralysis, this injury may be recognized only days later. Screening for coagulopathies (primary prophylaxis) and appropriate treatment reduce the risk at the original surgery. Secondary prophylaxis means to prevent recurrence.

Postoperative dyskinesias, most often described as choreoathetosis, have an incidence of 0.5%; they usually become evident clinically after several days. They are assumed to be secondary to hypoxic-ischemic injuries related to a special vulnerability of the basal ganglia during extracorporeal circulation. They occur more often after surgery for cyanotic lesions, especially with high pulmonary and consecutively less cerebral flow during extracorporeal circulation. There is recovery; however, in most cases, it is not complete.

10.14.3 Neuromonitoring Techniques

A standard for continuous intraoperative and early postoperative cerebral monitoring that allows for immediate detection of potential brain damage has not been defined. Maintaining cerebral oxygenation and cerebral autoregulation is most important in preventing brain injury during cardiopulmonary bypass and when employing deep hypothermic circulatory arrest. Noninvasive monitoring techniques include cranial near-infrared spectroscopy (NIRS), electroencephalogram (EEG), transcranial Doppler ultrasound (TCD), and bispectral index monitoring (BIS).

NIRS uses near-infrared light signals to monitor nonpulsatile signal component reflecting tissue (arteriolar (25%), capillary (5%), venous (70%)) circulation and measures oxygenation regionally in the frontal cerebral cortex. Tissue oxygenation measured by NIRS showed a good correlation to mixed venous saturation used as an indicator for cardiac output (Nagdyman et al. 2005; Tortoriello et al. 2005). This correlation, however, is best for children weighing less than 10 kg. As studies revealed that it may not be

possible to predict absolute mixed venous saturation, NIRS can be used for indicating trends (Mittnacht 2010). In cyanotic patients, NIRS baseline values may vary between 40 and 60 %; in acyanotic patients they reach approximately 70 %. Trends during cardiopulmonary bypass are similar in infants and children, but they showed a wide inter-patient variability and an absence of normal values.

Postoperative EEG monitoring allows detection of (subclinical) seizures in patients under sedation und neuromuscular blockade.

TCD measures the blood flow velocity in the anterior and/or middle cerebral arteries; patient's baseline measurement can be compared with the actual intra- or postoperative measurements. Age-specific normal values can be provided and allows the detection of decreased Doppler velocities related to hemodynamic instability, general anesthesia, or low temperature (Zimmermann et al. 1997; Andropoulos et al. 2003).

BIS as a simplified processed EEG can correlate brain wave activity with awareness or depth of sedation; it was found to indicate changes in cerebral activity in the presence of acute hypotension causing cerebral hypoperfusion. The BIS monitor may indicate by burst suppression pattern the adequate cooling before initiating deep hypothermic circulatory arrest (Hayashida et al. 2003).

10.15 Postoperative Extracorporeal Life Support (ECLS)

Low cardiac output syndrome secondary to myocardial failure remains a serious problem in pediatric cardiac intensive care management. Cardiac failure and indication for mechanical circulatory support may be related to congenital heart disease with or without immediately preceding cardiac surgery. Other reasons include myocarditis and cardiomyopathy, intractable arrhythmias, postcardiopulmonary resuscitation, pulmonary hypertension, or respiratory failure. Predominantly two forms of extracorporeal life support (ECLS) are used: extracorporeal membrane oxygenation (ECMO) for short-term cardiopulmonary support and ventricular assist device (VAD) as a long-term bridge to cardiac recovery or heart transplantation. The use of an intra-aortic balloon pump is still limited to older children (if children at all), adolescents, and adults. Being the most frequent

form of ECLS in pediatrics, the largest experience is now available for ECMO.

10.15.1 Indications

The indication for ECLS connected with cardiac surgery may exist for:

- Any unstable postoperative state after complex congenital heart surgery, predominantly connected with Bland-White-Garland (Anomalous Left Coronary Artery from the Pulmonary Artery (ALCAPA)) syndrome, transposition of the great arteries, total anomalous pulmonary venous drainage, and hypoplastic left heart syndrome
- Inability to wean from cardiopulmonary bypass; postoperative myocardial dysfunction (LCOS)
- Occasional preoperative stabilization (i.e., cardiogenic shock, after clinical deterioration or even resuscitation, pulmonary hypertension refractory to medical therapy; in rare exceptions for patients with obstructive total anomalous pulmonary venous drainage or Ebstein's anomaly)
- Severe hypercapnia after tracheal resection in pulmonary artery sling surgery not amenable to Heliox treatment (see ► Sect. 10.10)

Indications for ECLS primarily not connected to cardiac surgery are:

- Acute myocarditis
- Bridging to transplantation in patients with cardiomyopathy or («end stage») congenital heart disease
- Arrhythmia refractory to medication with hemodynamic compromise (supraventricular tachycardia, junctional ectopic tachycardia, ventricular dysrhythmias)
- Pulmonary hypertension
- «Acute respiratory distress syndrome,» severe upper airway obstruction, respiratory failure in parenchymal lung disease
- Any cardiopulmonary arrest as extracorporeal cardiopulmonary resuscitation

Prerequisites for initiation of ECLS are:

- Principally reversible situation of cardiopulmonary deterioration
- High mortality rate with continued optimal medical treatment

- Exclusion of relevant residual lesions and surgical bleeding
- Neurological integrity
- Upper limit of pharmacologic treatment

Clinical findings mirror a low cardiac output constellation with inadequate organ perfusion with low mean arterial blood pressure, reduced ejection fraction (<25%) and cardiac index (<2 l/min/m²), limited diuresis (<1 ml/kg/h), central venous pressure >15 mmHg or left atrial pressure >18 mmHg, and increasing lactate level. The criteria to start with ECLS are variable. Nearly 1–5% of pediatric patients need mechanical circulatory support after corrective surgery for complex congenital heart defects (Duncan et al. 1998; Morris et al. 2004; Walker et al. 2003).

10.15.2 Extracorporeal Membrane Oxygenation (ECMO) and Ventricular Assist Devices (VAD)

For pediatric patients two forms of mechanical life support are available: the ECMO system for critically ill children who require acute or short-term circulatory support and the VAD for long-term support in children with cardiac failure who need longer time for recovery or bridging to transplant. Obviously, VAD implantation requires a sufficient pulmonary function. The decision for one or the other system also depends on anatomy (uni- or biventricular circulation), pathophysiology, cannulation, emergent resuscitation, and local experience.

For cardiac support ECMO *cannulation* usually requires venoarterial access (transthoracic, right atrium-ascending aorta; cervical, jugular vein-carotid artery). More than 70% of venous return can be passed to the membrane oxygenator bypassing the heart. Respiratory failure in isolated parenchymal lung disease with sufficient cardiac function can be managed by venovenous ECMO, usually via a transjugular double lumen catheter.

With increasing experience, ECMO indication was extended to *functionally univentricular circulation*, requiring some modification in the technical management (e.g., increased flow because of the runoff by the systemic-to-pulmonary shunt). It can be lifesaving in acute shunt thrombosis, deterioration of ventricular

function, and inability to wean from cardiopulmonary bypass (Hintz et al. 2005; Ravinshankar et al. 2003). Some centers have recommended routine mechanical ventricular support to stabilize the early postoperative period after Norwood I procedure coining it NOMOVAD («no membrane oxygenator ventricular assist device») (Shen and Ungerleider 2004). The known difficulties in resuscitating patients after Glenn or Fontan procedure, with limitations to achieve effective pulmonary blood flow and oxygenation to start with, continue with technical difficulties of cannulation for ECMO in this challenging patient group. Experience is very limited in the literature, most probably due to individual poor outcome in these cases.

The principal *management* includes monitoring of the systemic perfusion (acid-base status, mixed venous oxygen saturation, serum lactate, urine output), providing afterload reduction (i.e., vasodilators as nitroprusside or milrinone), modifying ventilator settings, assessment of the neurologic state (including daily cranial ultrasound examination) and organ function, as well as exclusion of infections. Fluid retention and total body edema formation can require hemofiltration. Heparin is used for anticoagulation (400–1000 IU/kg/day) monitored by the «activated clotting time» (ACT, target 180–220 s). When using heparinized tubings, the ACT can be kept lower, around 150 s for centrifugal pump VADs and 180 s for centrifugal pump ECMOs. The hematocrit should be optimized to 40–50%, the platelet count >100,000/μl (Cooper et al. 2007, Coskun et al. 2011). Weaning from ECMO requires inotropic support, monitoring of cardiac output and filling pressures, and stepwise reduction of flow. Usually mechanical support is required for 2–3 days; if myocardial recovery is limited or needs more than 3–5 days, VAD should be considered in cases of good pulmonary function. Poor prognosis is associated with an ECMO period of longer than 8–10 days (Coskun et al. 2011).

Bleeding is one of the major complications during ECMO. It often is associated with the need for extensive replacement of blood products; subsequent re-exploration of the mediastinum might be indicated. Other complications comprise thromboembolic events, hemolysis, air embolism, infections, cerebral bleeding, and stroke. Finally, multiorgan failure after repeat transfusions or

major technical problems can complicate the ECMO period even more (Montgomery et al. 2000; Sorof et al. 1999). Thus, management of an ECMO patient requires an experienced interdisciplinary team.

The *advantages* of ECMO include the option of biventricular support as well as respiratory support. It can readily be applied in emergent resuscitation, it offers the possibility of peripheral cannulation, and it is suitable for newborn babies. Disadvantages are patient immobilization and the need for anticoagulation with the risk for bleeding complications. Pulmonary blood flow may be critically diminished especially with nonpulsatile flow dynamics in two ventricle hearts.

ECMO has become the routine system for short-term circulatory support. Bridging to recovery or cardiac transplantation can be offered by VAD. This long-term mechanical support is now also available for children weighing less than 5 kg. For long-term use pulsatile devices are used for univentricular and biventricular support (e.g., Berlin Heart VAD, MEDOS VAD; Reinhartz et al. 2002). Indications include myocarditis, dilated cardiomyopathy, and postsurgical complex congenital heart disease.

Advantages of VAD include mobilization if no mechanical ventilation is required, lower-level anticoagulation, less trauma and alteration of blood cells, and lower risk for infections (Aharon et al. 2001; Mehta et al. 2000; Cooper et al. 2007; Fan et al. 2011; Morales et al. 2010).

As VAD provides only cardiac support, its effectiveness requires sufficient pulmonary function, which may be listed as a *disadvantage* in comparison with ECMO.

The *survival* for children with complex congenital heart defects after ECMO support varies from 30% to 60% and is determined also by the timing of initiating ECLS (intraoperatively, after a period of being successfully weaned, emergent resuscitation, or after resuscitation), age, and accompanying renal and hepatic dysfunction. With increasing duration of ECMO, the prognosis will decrease as myocardial dysfunction persists, renal and hepatic dysfunction might develop, and the risk for additional complications of mechanical circulatory support increases (Hintz et al. 2005; Kolovos et al. 2003; Morris et al. 2004). The survival rate after VAD is different as the children are usually older and nearly 50% were subsequently transplanted; mortality rate while being

on VAD is supposed to be as high as 25% (Cooper et al. 2007). Neurological impairment has been described in up to 20% after VAD and more than 60% after ECMO, which, however, is more often used in critically ill infants with complex surgical procedures.

11.1 Introduction

Pediatric cardiac surgery began with Dr. Gross's first successful ligation of a patent ductus arteriosus (an extracardiac lesion) on August 8, 1938, at the Children's Hospital in Boston. The beginnings of open heart surgery for repair of congenital malformations, aside from Gibbon's first successful closure in Philadelphia of an atrial septal defect using an artificial heart–lung machine, can be traced to members of the Department of Surgery at the University of Minnesota during the 1950s and 1960s of the twentieth century. This story will be told as well as other advances will be discussed, some of which also carry the imprint of the Minnesota surgical training program, with its heavy emphasis on research.

11.2 Comments

Primary morphogenesis of the human heart is completed 60 days after conception. The embryonic heart, initially a tubular structure includes the truncus, conus, bulbo cordis, ventricle (left), and atria. Obeying genetic commands, the heart undergoes looping (more commonly dextro-looping) to become, after 2 months, the final four-chambered, four-valved organ. The original left ventricle is the primary pump of the phylum Chordata, while the right ventricle makes its first appearance in reptiles, hence in landlocked animals that depend on a pulmonary circuit. Amphibians still have only one ventricle (the left ventricle), while reptiles have two atria and two ventricles, albeit still interconnected. Cardiac ontogenesis seems to recapitulate phylogenesis.

According to more recent information, single genes can cause single cardiac malformations, and mutation in a single locus may demonstrate different penetration, expression, and hence phenotype, while mutations in different loci may induce the same phenotype. Genetecists now believe that at least 75% of congenital cardiac malformations have a genetic origin. The earlier the «insult» during embryogenesis, the more complex the malformations. During the remaining 7 months of intrauterine existence and in the presence of an important

primary defect, additional in utero acquired cardiac pathology may significantly complicate the primary congenital cardiac lesion.

One of the first depictions of a congenital cardiac defect was by Leonardo da Vinci who clearly drew a partial anomalous pulmonary venous connection of the right pulmonary veins to the right atrium (Da Vinci 1979). The first successful operation for correction of an extracardiac lesion, namely ligation of a patent ductus arteriosus was accomplished by R. E. Gross on August 8, 1938, at the Children's Hospital in Boston (Gross and Hubbard 1939). This epic operation ushered in the era of pediatric cardiovascular surgery. Six years later on October 10, 1944, C. Crafoord (Crafoord and Nylin 1945), at the Karolinska Hospital in Sweden, repaired successfully a coarctation of the aorta. On November 9 of the same year, Blalock and Taussig (1945) carried out the first subclavian artery to pulmonary artery anastomosis to palliate cyanosis producing malformations, particularly tetralogy of Fallot.

In 1952 Muller and Dammann (1952) introduced pulmonary artery banding to protect the pulmonary arterioles from developing pulmonary vascular obstructive lesions, a consequence of increased intravascular pressure and shear stress. The more those indications were diagnosed, the more it became apparent that most congenital cardiac defects were indeed intracardiac. The challenge during the late 1940s and early 1950s was how to gain access to the interior of the heart. Several ingenious half measures were proposed including Gross's atrial well technique (Gross et al. 1953). Although useful in some patients, this and similar makeshift attempts proved too limiting and inadequate for the repair of most intracardiac defects. Clearly, surgeons needed to be able to see how to carry out the repair inside the heart. Haecker in 1907, using normothermic superior and inferior vena cava occlusion, learned that dogs did not tolerate circulatory occlusion for more than 3 min; beyond that time dogs either died or exhibited central nervous system damage (Haecker 1907). Using this background information, surgeons started to experiment with ways to prolong these 3 min.

Boerema et al. in Amsterdam (1951), Bigelow et al. in Toronto (1950), and John F. Lewis at the

University of Minnesota (Lewis and Taufic 1953) began to use total body hypothermia, both moderate at 28 °C and profound at 18 °C. Their purpose was to lower metabolic demands particularly of the CNS, hoping to consequently allow for longer and safer period of caval occlusion. When the University of Minnesota team convinced themselves that at 28 °C the CNS was sufficiently protected to withstand 10 min of circulatory arrest and that a simple ostium secundum defect could be closed within less than 10 min, John F. Lewis and collaborators succeeded on September 2, 1952, in closing an atrial septal defect in a 5-year-old girl, under direct vision using moderate hypothermia and caval inflow occlusion (Lewis and Taufic 1953).

This operation was soon adopted by other surgeons principally by Swan in Denver (Swan et al. 1953) and Derra in Düsseldorf, Germany (Derra et al. 1965). Although this technique represented an important advance, it was nevertheless far from ideal. Clearly a system was needed that would substitute both the pumping function of the heart and the respiratory function of the lungs. In 1933 John Gibbon, at that time a surgical resident at Jefferson University, while on a clinical rotation at the Massachusetts General Hospital (MGH) in Boston, witnessed the death of a young woman from a pulmonary embolus. Gibbon recognized that removal of the saddle embolus could have saved the life of this otherwise healthy young woman. Despite little support from the senior staff at the MGH, Gibbon obstinately persisted in developing an artificial heart–lung machine.

Twenty years later and after many research trials, Gibbon succeeded on May 9, 1953, to close an atrial septal defect in a young woman using a screen oxygenator of his own design and a roller pump (Gibbon 1954). Unfortunately, a previous attempt at closing a ventricular septal defect in an infant and four other open heart operations after the successful second patient ended in death of all five patients. Gibbon became so discouraged by his results and those of other surgeons, obtained between 1951 and 1954 (■ Table 11.1), that he offered to lead a move to ban, for an unforeseeable time, other attempts at open heart procedures in the United States. The generalized pessimism that affected the cardiologic community was based on the conviction that the sick or malformed heart simply could not withstand surgical manipulations.

■ Table 11.1 Early attempts at open heart surgery with a heart–lung machine

Name	Year	No.	Outcome
Dennis	1952	2/2	Died
Gibbon	1953	5/6	Died
Helmsworth	1953	1/1	Died
Dodrill	1953	2/2	Died
Clowes	1954	2/2	Died
Mustard	1954	5/5	Died
	Total	17/18 (94.5%)	Died

Fortunately, a group of young, aggressive, and scientifically trained surgeons at the University of Minnesota did not share these pessimistic predictions. The story of the ingenious and daring «controlled cross circulation» experience by C. W. Lillehei is extensively outlined in G.W. Miller's book *King of Hearts: The true story of the maverick who pioneered open heart surgery* (Miller 2000). Although the hospital mortality was high, Lillehei and his team definitely proved that the heart (and the patient) could and did indeed withstand the repair of even very complex congenital cardiac malformations, including tetralogy of Fallot and complete AV canal (Lillehei et al. 1955). Controlled cross circulation served a most important and opportune historical purpose; it dispelled the prevailing pessimism about the feasibility and future potential of open heart surgery. Still, the need for subjecting a healthy donor to the risks of anesthesia, anticoagulation, and cannulation of important veins and arteries with the added threat of possible air embolism made this technique less than practical for routine use.

What were the circumstances that authorized at the University of Minnesota the first open heart operations under direct vision, using moderate hypothermia and caval inflow occlusion and also the daring controlled cross circulation experience as well as some other firsts? One reason was Dr. Owen H. Wangensteen, the Chief of the Department of Surgery, who fostered at the University of Minnesota a very special intellectual environment, stimulated scientific curiosity, and

provided through the various research and Ph.D. opportunities, the tools to pursue new knowledge. The cardiac surgical leadership at that time also included Dr. Richard L. Varco, a very erudite individual, intellectually versatile with a deductive intelligence, a synthesizer of knowledge, and a masterful surgeon. C. Walton Lillehei was a visionary surgeon, innovative, an unrelenting pioneer, emotionally hardy, an iconoclast, and outwardly flamboyant. Clearly the controlled cross-circulatory idea carried his imaginative seal. John Kirklin accompanied by Mr. Richard Jones, an engineer also from the Mayo Clinic, paid a visit to Gibbon's laboratory to study in detail his heart–lung machine. Kirklin and Jones succeeded in improving and simplifying Gibbon's screen oxygenator, called from then on the Mayo–Gibbon pump oxygenator. Kirklin using this machine in early 1955 inaugurated the outstanding accomplishments in cardiac surgery of the Mayo Clinic Group (Kirklin et al. 1955).

The first patient was a child with a ventricular septal defect. In the meantime Richard de Wall at the University of Minnesota developed a very simple, easy to assemble and use, bubble oxygenator (DeWall 1956). For nearly 2 years, all open heart operations in the world were carried out in Minnesota in two institutions located 70 miles apart. Subsequently, and in great measure thanks to the simplicity and low cost of the de Wall bubble oxygenator, open heart centers spread rapidly, first in the United States and then throughout the world. Note also that at the beginning all open heart operations were indicated for repair of congenital cardiac lesions. During the 1950s and 1960s, the prevailing impression was that open heart operations were poorly tolerated by the very young, as demonstrated by the cross circulation experience and other sporadic attempts at open heart repair in infancy. Therefore, symptomatic neonates and infants were first subjected to palliative procedures, while intracardiac repair was delayed until age 5–7 years.

This therapeutic policy presented serious disadvantages, including:

1. The need for two operations.
2. The palliative operation did not always accomplish its purpose.
3. Iatrogenic damage was not uncommonly produced by the palliative procedure itself.

4. The emotional burden placed on child and parents living with the threat of another operation.
5. The increased cost of two operations.

In the late 1960s and early 1970s, Horiuchi et al. (1963) and Hikasa et al. (1967) in Japan and Barrat-Boyes et al. in New Zealand (1972) started to obtain good results with primary repair in infants. In 1972, at Boston Children's Hospital, we followed this lead and accumulated as well a large and satisfactory experience with open heart operations in infancy (Castañeda et al. 1974). However, review of our data from the New England Infant Cardiac Program (Report of the New England Regional Infant Cardiac Program 1980) showed that deaths from complex congenital cardiac defects occurred mostly during the first few weeks of life.

Based on this information and also after reviewing our midterm and late results with the atrial switch operations (Senning and Mustard) for transposition of the great arteries (TGA), we became convinced that complex cardiac lesions should, by preference, be repaired during the neonatal period in order to reduce early deaths and to minimize secondary organ damage, including the heart, lungs, and CNS. This early approach would also allow normal postnatal development, such as physiologic myocardial hyperplasia/hypertrophy, coronary angiogenesis, and pulmonary angio- and alveologenesis. Also preliminary laboratory experiments in 2-kg puppies subjected to 2 h of cardiopulmonary bypass convinced us that the effects of this 2-h period of extracorporeal bypass on both the formed elements of blood and the lungs (air and fluid static volume–pressure measurements as well as alveolar bubble stabilizations) revealed only minor, transitory, and rapidly reversible changes that were well tolerated by these very young animals (Visudh-Arom et al. 1970).

Consequently, on January 2, 1983, we performed our first arterial switch operation (ASO–Jatene) in an 11-day-old neonate with TGA and an intact ventricular septum (Castañeda et al. 1984). The operation consists of first transecting both great arteries that arise anomalously, the aorta from the right ventricle and the pulmonary artery from the left ventricle. Then, both left and right coronary arteries are explanted from the proximal aorta, now the neopulmonary artery, and are reimplanted

into the proximal neoarteria. The operation is completed by anastomosing the proximal neoarteria, with its implanted coronaries, to the distal ascending aorta and the proximal neopulmonary artery to the distal main pulmonary artery. The interatrial communication, mostly enlarged by a balloon atrial septostomy (Rashkind procedure) and that permitted early postnatal survival and also serves to decompress the pulmonary circuit, is closed as is a ventricular septal defect, if present.

The results both early and late of the ASO in the neonate have been very satisfactory (Castañeda et al. 1994) (■ Table 11.2). We had established to our satisfaction that optimal management of dextro-transposition of the great arteries with an intact ventricular septum was achieved by an ASO, performed ideally within the first 2 weeks of life. However, a substantial number of patients were referred to our institution for an ASO beyond the first month of life for various reasons, including sickness or late referral by parents or physicians. Experimental work related to left ventricular hypertrophy had shown that LV muscle mass increased very rapidly following experimental coarctation of the aorta in rats. In fact within 7 days, the LV muscle mass increased by more than 40%. Beyond that time there was no appreciable continued increase in hypertrophy. This rapid response of the myocytes proved to be due to a fivefold increase in *c-fos* and *c-myc* myosin heavy chain mRNA and HSP 70 within 1–3 h after the applied pressure stimulus (Izumo et al. 1988).

Based on these experimental data, we initiated a clinical series in which the preparatory first-stage operation consisted of pulmonary artery banding and a modified Blalock–Taussig shunt.

■ Table 11.2 Transposition of the great arteries: arterial switch operation 1983–1997

Type lesion	No. patients	Hospital mortality
Interventricular septum (IVS)	522	15 (2.8%)
Ventricular septal defects (VSD)	261	9 (3.4%)
Tubercular meningitis (TBM)	29	3 (10.0%)
	812	27 (3.3%)

Postoperatively these patients were kept in the pediatric cardiac care unit for 7–8 days in order to undergo the second-stage operation that included removal of the pulmonary artery band, closure of the shunt, and an arterial switch operation. During this week-long interval, serial two-dimensional echocardiography showed that LV mass increased similar to the rat by a mean of over 50%, and cardiac catheterization revealed a mean left ventricular–right ventricular pressure ratio increase from 0.5 ± 0.08 before to 1.04 ± 0.29 7 days after the first stage. Of the first 49 patients subjected to this two-stage approach, there was one death after the first stage and one more death after the second stage (Jonas et al. 1989).

The obvious advantages of this rapid two-stage approach are the following:

1. That a larger group of patients with dextro-transposition and an intact ventricular septum can be offered this option beyond the first month of life.
2. Both stages can be performed at one hospitalization and offer also important psychological, logistic, and financial advantages.

Clearly, there are many other important areas of development within pediatric cardiac surgery over these last 66 years, which within the limitations of this chapter cannot all be mentioned, but they will in part be dealt with in the specific chapters of this book.

In ■ Table 11.3 these important areas are enumerated. Finally, outlined in ■ Table 11.4 are the

■ Table 11.3 Additional areas of important developments in pediatric cardiac surgery

The dispensable right ventricle (Fontan)
Conduits: valved and nonvalved
Perioperative care
Deep hypothermia ± circulatory arrest
Preservation of the «immature» myocardium
Mechanical ventricular assistance
Pulmonary vascular obstructive disease
Electrophysiology
Interventional cardiology–surgery collaboration

Table 11.4 Hospital mortality according to age and years

Age (years)	Hospital mortality	
	1954–1960	1995–2000
<1	4%	2.5%
1 < 5	21%	1.5%
5 < 12	20%	2.5%
<12	24%	3.5%

impressive decreases achieved in operative mortality between the years 1953–1960 and 1995–2000. Not shown but equally dramatic are the improvements in functional results after early primary repair of most complex congenital cardiac malformations.

11.3 Conclusions

Pediatric cardiac surgery has made much progress since Dr. Gross's epic operation, in 1938. The transition from early palliation and elective repair at preschool age to the eventual aggressive primary repair in the neonate has led to a worldwide substantial reduction in operative risk and improved long-term results. The clinical application of the concept of the «dispensable RV» originally accomplished by Fontan has allowed an impressive expansion of the surgical armamentarium, including for such extreme lesions as the hypoplastic left heart syndrome and other complex single-ventricle lesions. Although a palliative procedure, the various modifications of the original Fontan procedure have allowed many otherwise doomed children to enjoy a very reasonable lifestyle.

To become a well-trained and competent pediatric cardiac surgeon, it is important to include at least 6–12 months additional specialized training in an institution with a large volume of children with complex cardiac pathology. Also, future pediatric cardiac surgeon interested in an academic career should ideally include a research experience either in molecular cardiology/biology, genetics, biophysics (tissue engineering), immunobiology (xenotransplantation), pharmacology, neurobiology (CNS protection), or ethics.

Past efforts of pediatric cardiac surgeons and of pediatric cardiologists, anesthesiologists, intensivists, perfusionists, and pathologists, all concerned with the diagnosis and treatment of congenital cardiac malformations, have produced impressive advances over these many years. I am convinced that the most exciting advances of our specialty are still before us.

12.1 Anomalies of the Atria

12.1.1 Isolated Atrial Septal Defects

12.1.1.1 Definition of the Disease Entity and Aim of Operation

Secundum atrial septal defect (ASD II) is one of the most common congenital heart defects.

ASD II occurs in about 1 in 1,500 live births or in approximately 7% of the children with congenital heart disease. The male to female ratio is 3:2. While an ASD II allows for a bidirectional shunt, an open foramen ovale with functioning valve, as present in 15–20% of healthy adults, can only lead to a right-to-left shunt, elevated right-sided pressures provided.

In the Western countries, ASD-related mortality is very low, less than 1%. Morbidity secondary to ASD is also rare but can occur in infants with very large left-to-right shunt and associated defects and in adults with high pulmonary hypertension and/or arrhythmias, usually in the form of atrial fibrillation or flutter. Abnormal ventricular compliance may contribute to the development of congestive heart failure in some patients (Park et al. 2011).

In adult patients there is the risk of cerebrovascular events caused by paradoxical systemic embolism through the ASD or open foramen ovale and of the development of atrial arrhythmias (Gatzoulis et al. 1996; Mas et al. 2001).

The clinical effect of an isolated secundum ASD is related to left-to-right shunting. The magnitude of shunt depends on the size of the defect, its location, the cardiac chamber compliance, and the pulmonary vascular resistance. The majority of children with isolated ASD are clinically asymptomatic. The diagnosis is usually made after the discovery of a cardiac murmur during routine examination and echocardiography. If clinical signs suggest high pulmonary arterial pressure, cardiac catheterization may be indicated to establish the degree of pulmonary hypertension.

12.1.1.2 History

Secundum atrial septal defect was among the first anomalies amenable to operative treatment. Before the advent of whole-body hypothermia and

total cardiopulmonary bypass, several ingenious closed surgical techniques were developed and used (Alexi-Meskishvili and Konstantinov 2003). Despite good results in the experimental laboratory, these techniques did not always secure complete closure of large atrial septal defects. Robert Edward Gross of Boston described the atrial well semi-open technique (Gross 1952). Although many surgeons of that time successfully used Gross' method, it did not always enable complete closure of defects, especially of those not centrally located in the atrial septum. On September 2, 1951, F. John Lewis, with his first assistant Richard Varco and further assistants Mansur Taufic and Walton Lillehei, operated on a 5-year-old girl with ASD II under general hypothermia and inflow occlusion. This operation was the world's first successful operation on the open human heart under direct vision (Lewis and Taufic 1952). It marked the beginning of the era of open-heart surgery. In 1955, for the first time in Europe, Ernst Derra in Düsseldorf operated successfully on patients with secundum ASD employing surface hypothermia and inflow occlusion (Derra et al. 1955).

The world's first successful operation with cardiopulmonary bypass was a direct closure of an ASD II in an 18-year-old patient on May 6, 1953, performed by John Heysham Gibbon in Philadelphia, USA (Gibbon 1954). Operations on the atrial septum paved the road to modern open-heart surgery.

12.1.1.3 Embryology of the Atrial Septum

In histology specimen, cardiac tissues are first detectable on day 18 or 19 of fetal life. Cardiac development continues for the next several weeks. The atrial septum begins to form during the 4th week and is complete by the end of the 15th week of gestation.

In the early embryo heart, the atria comprise a common chamber. As the atria enlarge, the septum primum forms and grows from the roof of this chamber toward the developing atrioventricular canal area, which is later divided by the superior and inferior endocardial cushions. These cushions fuse and bend with their convexity toward the atria, thereby approaching the downgrowing septum primum. This process continually narrows the passageway between the atria, which is then defined as the ostium primum.

The ostium primum closes completely, but, before this occurs, a central perforation appears in

the septum primum, allowing continuous unrestricted flow from the right atrium to the left atrium. This perforation, the second opening in the septum primum, is called the ostium secundum. As the atria expand to either side of the truncus arteriosus, a fold is produced in the roof of the atria just to the right of the septum primum. This passively formed fold is the septum secundum. The lower edge of the septum secundum is crescent shaped and forms the upper edge of the foramen ovale. It comes to overlay the ostium secundum but does not interfere with blood flow from right to left through the foramen ovale. After birth, with the increase of pulmonary blood flow and elevation of the left atrial pressure, the septum primum is pushed against the septum secundum, effectively closing the atrial septum.

Fusion of the septum primum and the septum secundum closes the foramen ovale. Complete closure occurs in most individuals. In 25–30% of normal adult hearts, however, a probe can be passed from the right atrium to the left atrium via the foramen ovale. This patent foramen ovale

allows a tiny left-to-right shunt that can be detected by sensitive techniques, such as color Doppler echocardiography, in 15–20% of healthy adults.

The tissue of the fossa ovalis acts as a valve when it is superimposed on to the left side of the crescent-shaped septum due to the elevated left-sided pressure. When the right atrial pressure increases, this valve can open the path for a right-to-left shunt and also for paradoxical embolization.

12.1.1.4 Anatomy of the Atrial Septum

Knowing the anatomy of the atrial septum is important to avoid specific complications during surgery, especially the inducement of rhythm disturbances (■ Fig. 12.1).

The right atrium is the chamber of the heart that normally receives systemic blood from the caval veins and from the coronary sinus. Morphological characteristics of the right atrium are the presence

■ Fig. 12.1 Anatomy of the atrial septum

of the limbus of the fossa ovalis, which surrounds the valve of the fossa ovalis (septum primum) superiorly, anteriorly, and posteriorly; the broad-based atrial appendage; the Eustachian valve at the orifice of the inferior vena cava; the Thebesian valve at the orifice of the coronary sinus; the muscle band known as the crista terminalis, which separates the trabeculated from the nontrabeculated portion of the atrium; and the ostium of the tricuspid valve.

It has been suggested that there are three internodal tracts in the right atrium connecting the sinus node and the atrioventricular node: an anterior, middle, and posterior bundle (James 1963; Sealy et al. 1969). This is a controversial issue. According to Anderson and Becker (1980), there are parallel and closely packed bundles of working myocardium in the crista terminalis and in the anterior limb of the fossa ovalis, which could be the morphological counterpart of the preferential pathways demonstrated by the electrophysiologists. However, it has not been possible to identify any such bundles in the muscular bands (Wilcox et al. 2004). Experimentally it was shown that damage to the crista terminalis can be a substrate for the development of atrial arrhythmias (Gandhi et al. 1996).

12.1.1.5 Forms of Atrial Septal Defect

Atrial septal defects occur at several sites within the atrial septum, but only atrial communications occurring in the region of the fossa ovalis or so-called secundum defects—as related to the embryonic ostium secundum—are true ASDs because the interatrial septum is only slightly larger than the fossa ovalis itself (Silverman 1997; Wilcox et al. 2004).

Many classifications for atrial septal defects have been suggested. In the classification of Edwards, the following types of ASD are recognized (Edwards 1953):

- Secundum type within the fossa ovalis (60 % of cases)
- Sinus venosus type, often associated with anomalous return of the right pulmonary vein(s) (10 %)
- Ostium primum defects below the fossa ovalis (today part of AV septal defects)
- Raghb-type ASD (with absent coronary sinus in the presence of a persistent left superior vena cava, thereby connecting to the left atrium)
- Multiple coalescent defects, essentially forming a common atrium

A more recent classification of ASD suggested by the Congenital Heart Surgery Nomenclature and Database Project (■ Fig. 12.2) identifies the

■ Fig. 12.2 Common types of atrial septal defects according to the Congenital Heart Surgery Nomenclature and Database Project. CS coronary sinus, FO fossa ovalis, IVC inferior vena cava, RAA right atrial appendage, RLPV right lower pulmonary vein, RUPV right upper pulmonary vein, SV sinus venosus, SVC superior vena cava, TV tricuspid valve

following main types of atrial septal defects (Jacobs et al. 2000b):

- Common atrium (single atrium): complete absence of the intra-atrial septum. The term «single atrium» is applied to defects with completely normal atrioventricular valves and «common atrium» to defects accompanied by malformation of the atrioventricular valves.
- Coronary sinus ASD (synonym: «unroofed coronary sinus») defines a defect of the wall separating the left atrium from the coronary sinus, often allowing blood to drain from the left atrium via the coronary sinus and the coronary sinus ostium to the right atrium. Coronary sinus defects make up a small subset of ASDs and are often associated with a persistent left superior vena cava draining anatomically into the coronary sinus, here functionally into the left atrium, leading to cyanosis if ASD is closed.
- ASD, patent foramen ovale: a small interatrial communication in the region of the foramen ovale characterized by no absence of septal tissue of the septum primum or septum secundum.
- ASD, primum: a usually crescent-shaped ASD in the inferior portion of the atrial septum directly above the AV valve level.
- ASD, secundum: an ASD confined to the area of the fossa ovalis. It is not necessarily to be distinguished from a wide-open foramen ovale («stretched foramen»). The most common etiology is a defect of the septum primum, but an absence of tissue of the septum secundum may also contribute. An ostium secundum defect may be associated with an aneurysm of the interatrial septum. This is thought to be due to excess tissue of the fossa ovalis valve. It may be accompanied by mitral valve prolapse or atrial arrhythmias.
- ASD, sinus venosus: an interatrial communication in the region of the right horn of the sinus venosus, usually in the area of the cranial sinoatrial junction close to the superior vena cava orifice, but more rarely posterior to the fossa ovalis and without a connection to a cava orifice or in the region of the caudal sinoatrial junction near the inferior vena cava orifice. The superior sinus venosus defect is usually associated with anomalous drainage of the right upper and occasionally also of other pulmonary veins into the right atrium.

The exact nature of the development of sinus venosus defects remains controversial.

This type of ASD would more properly be termed a «sinus venosus defect» because the lesion represents an intra-atrial communication rather than a defect of atrial septal tissue. Anderson and colleagues suggested that the superior sinus venosus defect results from a failure of infolding of the atrial walls between the superior vena cava and the right pulmonary vein (Al Zaghaf and Anderson 1998; Anderson et al. 1995). Van Praagh et al., however, postulated that sinus venosus defects result from a deficiency in the common muscular wall that normally separates the right pulmonary veins from the superior vena cava, resulting in «unroofing» of the right pulmonary veins allowing them to drain into the superior vena cava or the right atrium (Van Praagh et al. 1994).

12.1.1.6 Surgical Indications

Although the presence of an ASD does not represent a life-threatening condition, there is a danger of complications and chronic sequelae developing with time, and it is generally accepted that all ASDs should be closed either surgically or by an interventional procedure before the patients reach school age.

Today candidates for surgical closure are the patients with large secundum ASDs deemed not amenable to transcatheter closure, patients with sinus venosus and coronary sinus defects (LSVC), and those with primum-type ASD as well as common atrium.

This recommendation of closure of ASD before school age includes asymptomatic ASD. Early ASD closure is indicated to avoid atrial fibrillation, pulmonary hypertension, chronic right ventricular overload, mitral valve incompetence, and the risk of paradox systemic embolization (Cheng et al. 1994; Mas et al. 2001). Cardiac catheterization is rarely necessary. Echocardiographic evidence of right atrial and in particular right ventricular enlargement is usually considered sufficient evidence of a clinically significant left-to-right shunt representing an indication for surgical closure of the ASD. Surgery is ideally performed in children aged 2–4 years, when the surgical risk is very low. However, if symptoms of congestive heart failure occur and cannot be effectively controlled, the operation may be indicated even in early infancy. In adult patients closure of ASDs results in clear clinical improvement because of the reduction in the volume load of the chambers (Thilén and Persson 2006). For example, it has shown that mitral

valve prolapse was reduced or eliminated in 80% of patients because of normalization of the left ventricular geometry (Schreiber et al. 1989). In adult patients with an ASD and atrial fibrillation, closure of the ASD should be combined with antiarrhythmic surgery (atrial ablation).

12.1.1.7 Surgical Procedure

Today, the operation is normally performed with normothermia and using the heart–lung machine. Among the surgical approaches to the heart, the median sternotomy is the classical method (Julian et al. 1957). To achieve better cosmetic results, limited access techniques have been developed, as there are lower partial sternotomy, anterior submammary incision, anterolateral thoracotomy, and limited or posterior thoracotomy (Del Nido and Bichell 1998). In prepubescent female patients, a submammary thoracotomy should be avoided in view of the risk of impaired breast development, and other surgical approaches, such as a right posterior thoracotomy or lower partial sternotomy, should be followed (Bleiziffer et al. 2004). These techniques are ideally suited for closure of a simple secundum-type ASD since, in addition to the cosmetic advantage, they probably also decrease the duration of hospital stay (Barbero-Marcial et al. 1998; Bauer et al. 2000a; Black and Freedom 1998; Del Nido and Bichell 1998; Gundry et al. 1998). These limited access techniques require considerable expertise in pediatric cardiac surgery since the view of the operative field is limited and difficulties may occur in de-airing the heart after the chambers have been closed (Cooley 1998). Small incisions do offer a sufficient visualization but not the same as standard incisions. The surgeon can see only certain areas, but the entire heart, which means that there is a loss of operative control (Mavroudis et al. 2005). Although diagnostic procedures have improved over the past decade, they have not become 100% accurate, yet. Contrary to limited skin incisions, full median longitudinal sternotomy enables the surgeon easier access to the systemic venous return, which is of particular advantage in the case of persistent left superior vena cava or other anomalies of the venous return. With lateral or partial thoracotomy at our institution, we use aortic and bicaval cannulation to connect the heart–lung machine and avoid cannulation of the femoral artery or femoral vein (Bauer et al. 2000a, b). Because of the risk of air embolism that attends all open-heart operations and to reduce this risk, we employ continuous insufflation of carbon dioxide into the operative field during cardiomy as previously suggested

(Barnard and Speake 2004; Olinger 1995; Svenarud et al. 2003). More recently, however, in a double-blind, randomized clinical trial of neurocognitive effects, a benefit of carbon dioxide insufflation in open-chamber cardiac surgery could not be shown in an adult population (Chaudhuri et al. 2012).

■ Access and general surgical technique

After the standard median sternotomy is performed, the pericardium is opened longitudinally, and pericardial stay sutures are placed. To avoid oversized resection of the pericardium, we prefer not to harvest the autologous pericardial strip until after the atrial septum has been inspected. Direct superior vena cava cannulation is important especially in patients with superior sinus venosus defects and provides optimal exposure. After direct cannulation of the superior vena cava, transatrial cannulation of the inferior vena cava near its entry into right atrium is performed, the aorta is cannulated, and cardiopulmonary bypass is instituted under normothermic conditions. Tourniquets are applied to the venae cavae and snared. After cardiac fibrillation has been induced, the ascending aorta is clamped, and cardioplegic solution is infused proximal to the aortic clamp through a separate cannula to induce cardiac arrest. Some surgeons use the electrically induced ventricular fibrillation for the operation without interrupting blood flow into the coronary arteries by clamping. This is an acceptable method, but there is a risk of air embolism from the left heart chamber if spontaneous defibrillation occurs. The right atrium is opened by means of a longitudinal incision from the atrial appendage toward the inferior vena cava, and stay sutures are placed on the anterior and posterior edges of the atrial incision (■ Fig. 12.3).

The area of the sinus node and crista terminalis leading from it are avoided during atriotomy to reduce the risk of postoperative atrial arrhythmias. First of all

■ Fig. 12.3 Surgical access

the anatomy is carefully inspected to recognize any additional fenestrations or defects in the atrial septum and to determine the location of all four pulmonary veins and their orifices and the position of the mitral valve and coronary sinus. Usually a part of the septum with multiple fenestrations is resected to obtain a single ASD. Only small defects can be closed by means of direct suturing, since the tension on the tissue must be kept to a minimum to prevent the recurrence of ASDs (■ Fig. 12.4).

In cases of small defects, which nowadays are, however, rarely treated surgically, we use the continuous double-suture technique. The suture starts at the inferior edge of the defect (■ Fig. 12.5).

When placing sutures on the lower aspect of the defect, care must be taken to avoid tissue near the coronary sinus that contains the conduction system (■ Fig. 12.6).

■ Fig. 12.4 Closure of a small defect by direct suture

■ Fig. 12.6 Positioning of the sutures at the lower part of the defect

■ Fig. 12.5 a, b Continuous double-suture technique for the closure of small defects

The best way to avoid residual air remaining in the left side of the heart is to prevent it from getting there by avoiding suction from the left atrium to start with. With filling the left atrium carefully with blood before the closing suture is tightened and the anesthetist vigorously ventilating the lungs, accidental left-sided air can be completely removed. Before taking off the aortic cross-clamp, the patient is placed in the Trendelenburg position. At this stage additional antegrade de-airing through the ascending aorta via a small incision or the cardioplegia infusion site is very helpful.

We recommend closing all types of atrial septal defect with an untreated autologous pericardial patch and a nonabsorbable suture (■ Fig. 12.7).

In large secundum ASDs, care must be taken to accurately identify the lower margin of the defect and to avoid mischanneling of the inferior

■ Fig. 12.7 a, b Closure with untreated autologous pericardium and nonabsorbable sutures

■ Fig. 12.8 a, b Closure of a large secundum defect

vena cava into the left atrium (■ Fig. 12.8) (Gaynor 2006).

Sinus venosus defects are not atrial septal defects but interatrial communications outside the boundaries of the atrial septum (Van Praagh et al. 1994). The superior type is located above and outside the fossa ovalis, usually adjacent to the superior vena cava and the right upper pulmonary vein. The inferior type, which is extremely rare, is located near the orifice of the inferior vena cava and the right lower pulmonary vein (Banka et al. 2011). Sinus venosus defects must always be closed with a pericardial patch. In the case of superior sinus venosus defects, the orifice of the right superior pulmonary vein is visualized, and the suture line is placed between it and the orifice of the superior vena cava and then around the rim of the defect.

After the defect has been closed, the atrial incision is closed with a continuous suture. Before the suture is knotted, the tourniquets around the lower and upper vena cava are released, and the venous line is slightly compressed to fill the right

atrium with venous blood. The patient is placed in the Trendelenburg position, the lung is vigorously ventilated, routine de-airing procedures are performed, and the aortic clamp is removed. When adequate cardiac function has been restored, the cardiopulmonary bypass is terminated. Once the venous cannulas are removed and protamine is given, transesophageal contrast echocardiography may be employed to check the surgical result. As contrast medium we use cardioplegic solution (hydroxyethyl starch), which is injected into the right upper pulmonary and in both the superior and inferior venae cavae. This does not only exclude residual shunt defects but also an anomalous drainage of the inferior vena cava. Thereafter surgery is completed in the routine manner.

■ Alternative approaches

In all the approaches described below, we do not use special or custom-made instruments. We only use those available in the standard surgical instrumentarium.

■ ■ Limited right-sided posterolateral thoracotomy

The patient is placed in the left lateral decubitus position with the ipsilateral arm suspended. A posterolateral thoracotomy incision is made on the right. The anterior end of the skin incision is restricted so as not to cross over the anterior axillary line. The chest is opened in the fourth intercostal space, the lung is retracted in dorsal direction, and the pericardium is opened 1 cm anterior to the phrenic nerve. Pericardial stay sutures are placed, with two caudal pericardial stay sutures placed through the costal cartilage to elevate the ascending aorta into the operative field. After heparin has been given, the aorta is cannulated, and bicaval venous cannulation is performed. The cannula for the inferior vena cava is placed through a separate skin incision, which is later used for chest tube placement. After clamping of the aorta with a straight clamp and cardioplegia administration, the intracardiac repair is performed.

■ ■ Right-sided anterolateral thoracotomy

This approach is only recommended for young female patients when breast development is complete (Schreiber 2013). For optimal surgical exposure, single-lung ventilation is helpful in larger patients, but not necessary. The patient is positioned with the right side of the body elevated by 35° achieved with an inflatable airbag under the shoulder. The right arm is fixed at the elbow and wrist and suspended from a frame positioned at the head end of the operation table. The skin incision is made below the breast, about 1 cm caudal to the submammary skinfold, and the pleural cavity is opened through the fourth intercostal space. Next, the pericardium is opened anterior to the phrenic nerve, and following the conventional cannulation and induction of cardioplegic cardiac arrest, intracardiac repair is carried out.

■ ■ Limited inferior sternotomy

A limited skin incision (maximal length 5–7 cm) is made, starting from the lower pole of the corpus sterni (excluding the xiphoid process) and proceeding in the direction of the neck. The subcutaneous tissue is mobilized to prevent undue tension on the soft tissue. The lower part of the sternal body is exposed and the sternum is partially split down the middle, limited to the bor-

ders of the corpus sterni. A small sternal retractor is used to gradually splay the two halves of the partially split sternum. Rapid and vigorous splaying must be avoided to prevent sternal fracture. The thymus tissue is displaced in the direction of the neck or more or less resected, and following the pericardiectomy, pericardial stay sutures are placed and the ascending aorta is cannulated, for example, by the Seldinger method. Traction of the aorta in caudal direction with small forceps enables complete exposure of the ascending aorta. The inferior vena cava is cannulated directly and the superior vena cava through the right atrial appendage. After the ASD closure is completed, the air is carefully removed from the left side of the heart. Totally thoracoscopic closure of ASD in children was recently reported (Wang et al. 2011).

■ ■ Technical considerations

Although ASD closure is generally considered to be a simple operation, exact preoperative diagnosis is critical to avoid intraoperative and postoperative complications. This is especially important if there is limited experience with thoracotomies. The lower edge of ostium secundum defects may be difficult to identify if the inferior vena cava cannula is placed too high. Also the Eustachian valve may be mistaken for the lower edge, in which case incorrect defect closure would result in diversion of blood from the inferior vena cava into the left atrium, leading to cyanosis. An unusual kind of interatrial shunting is caused by the «partially unroofed coronary sinus» which allows left atrial blood to enter the right atrium through the coronary sinus. To expose the defect in the roof of the coronary sinus, an incision in the interatrial septum is necessary.

The surgical mortality is low in patients with uncomplicated ASDs. In experienced pediatric centers, the mortality rate should be much less than 1%.

Postoperative morbidity after ASD surgery consists almost exclusively of the formation of pericardial effusion (postpericardiectomy syndrome), which occurs in approximately one third of patients. If tamponade occurs, pericardiocentesis is necessary. Pericardial effusion should be suspected in any pediatric patient who has undergone surgical repair of an ASD and who presents with chest pain, fever, shortness of breath, or general

malaise. In young children, symptoms may be nonspecific and include irritability and decreased appetite.

■ ■ Interventional closure of atrial septal defects

The transcatheter approach to ASD closure has gained acceptance for both pediatric and adult patients (Berger et al. 1999). Benefits of the transcatheter approach include its minimal invasiveness, the avoidance of both thoracotomy and cardiopulmonary bypass, and the relatively short recovery time. Potential drawbacks are residual shunting around the device and displacement of the device requiring surgical intervention (Bohm et al. 1997). Interventional closure is not suitable when the rim of the defect is not large enough to properly seat the device. Further, long-term safety concerns have been raised, and there is a need for specific technical expertise and equipment.

Secundum ASDs are currently the only subtype of ASD that are amenable to this type of treatment, which can be performed in the catheterization laboratory without fluoroscopy and with echocardiographic monitoring alone (Ewert and Berger 2003).

12.1.2 Partial Anomalous Pulmonary Venous Drainage

12.1.2.1 General Comments

Partial anomalous pulmonary venous drainage (PAPVD) may occur as an isolated anomaly in patients with intact atrial septum or in patients with ASD. In patients with upper sinus venosus defects, the pulmonary vein is often connected high on the superior vena cava. Sinus venosus

defects are, strictly speaking, not a form of ASD because they occur outside the boundaries of the atrial septum and are thus interatrial communications but not true ASD. Operating on a sinus venosus defect with anomalous pulmonary venous drainage obliges the surgeon to reform the entire superior cavoatrial junction, taking the utmost care to avoid damage to the sinus node and thus postoperative arrhythmic sequelae (Anderson et al. 1983).

12.1.2.2 Isolated Partial Anomalous Pulmonary Venous Drainage

The superior vena cava cannula must be placed cranial to the anomalous connection of the right superior pulmonary vein. After atriotomy, the atrial septum, namely, the cranial part of the septum primum in the fossa ovalis, is resected. The edges of the created ASD caudally and the cranial circumference of the abnormal right upper pulmonary vein must be incorporated into the patch closing suture so that, during defect closure with a pericardial patch, correction of the anomaly and redirection of the right superior pulmonary vein into the left atrium are achieved (■ Fig. 12.9).

It is often assumed that nonendothelialized edges of the created ASD can lead to thrombus formation and systemic embolization. However, experience from the field of heart transplantation contradicts this assumption.

12.1.2.3 Partial Anomalous Pulmonary Venous Drainage and Sinus Venosus Defect

On rare occasions the sinus venosus defect is so small that there will not be free drainage of the superior pulmonary vein after closure of the defect. In such cases the defect is enlarged by an incision into the atrial septum toward the fossa ovalis, and then a patch is placed. There are different methods

■ Fig. 12.9 a–c Pericardial patch closure of the atrial septal defect created and redirection of right upper pulmonary vein in isolated partial anomalous pulmonary venous drainage

■ **Fig. 12.10** a–c Redirection of the pulmonary veins in large sinus venosus defect

of correcting a sinus venosus defect and partial anomalous pulmonary venous drainage:

- Simple patch closure of the defect (primary or enlarged defect)
- Patch closure of the defect and second patch for augmentation of the superior vena cava—right atrial junction
- Patch closure of the defect incorporating the SVC orifice with distal superior vena cava reimplantation into the right atrium (Warden technique)
- Transcaval closure

The choice of the method depends on the individual anatomy of the patient. There is little data on the long-term functional outcomes following repair of these defects.

If the superior vena cava is large, the right atrium is opened in the usual manner. The opening of the pulmonary veins into the superior vena cava is visualized, and the veins are completely redirected into the left atrium by roofing the pulmonary vein, namely, closing the interatrial communication using an autologous pericardial patch (■ Fig. 12.10).

Incision through the cavoatrial junction must be avoided because the sinus node and its arterial supply may be compromised during repair (Anderson et al. 1979a, b, 1983; Buz et al. 2008). If for the atriotomy an incision in the cranial area is selected that runs parallel to the course of the superior vena cava directly anterior to the anomalously connected pulmonary veins, no sinus node arteries can be damaged (R. Van Praagh personal communication).

In the case of a smaller superior vena cava and rather distant anomalous pulmonary venous drainage into the SVC, placement of the patch to divert the pulmonary venous blood into the left atrium may result in significant stenosis of the

cavoatrial junction or even both the caval and pulmonary venous pathways. In such cases, after transection and reimplantation of the superior vena cava, a cavoatrial anastomosis can be created by patching the sinus venosus defect and the orifice of the SVC. This represents a very useful technique (Gustafson and Warden 1995; DiBardino et al. 2004; Agarwall et al. 2011; Warden et al. 1984) and was originally proposed by John Lewis in 1958 (Benvenuto and Lewis 1959; Ehrenhaft et al. 1958; Groves 1967). The superior vena cava is mobilized to make room for the anastomosis to the right atrial appendage and is transected above the insertion of the uppermost pulmonary vein; its cardiac end is then closed with a continuous suture. The orifices of azygos vein and abnormal pulmonary veins have clearly to be distinguished, the azygos vein usually closed and divided for better mobilization. Prior to completing this anastomosis, it is critically important to identify and resect any potentially obstructive trabeculae carneae of the pectinate muscles within the right atrial appendage (DiBardino et al. 2004). The sinus venosus defect is closed with a pericardial patch in such a way that the stump of the superior vena cava and the pulmonary veins can drain into the left atrium in an unobstructed manner (■ Figs. 12.11 and 12.12). Caval division techniques (Said et al. 2011), a transcaval technique (Nassar et al. 2012), and a pulmonary vein reimplantation technique (Aramendi et al. 2011) were also reported.

12.1.2.4 Scimitar Syndrome

Complete or partial drainage of the right pulmonary veins into the inferior vena cava (scimitar syndrome) is a rare anomaly, first described in 1836 (Cooper 1836). Scimitar syndrome is often associated with aplasia of parts or the whole of the right lung. In scimitar syndrome drainage, the right pulmonary veins can also drain into the

Fig. 12.11 a–c Warden's technique for sinus venosus defect repair. **a** Anomalous pulmonary venous connection to the superior vena cava (SVC) well above the cavoatrial junction. An associated high sinus venosus defect is shown by the *dashed lines*. **b** First stage of repair: a superficial purse-string suture is placed around the cephalad SVC, and partial cardiopulmonary bypass is instituted with venous return from the inferior vena cava (IVC) only. The SVC is mobilized, the azygos vein transected. **c** Total cardiopulmonary bypass is established by introducing a cannula through the lateral wall of the right atrium and the tip of the right atrial appendage into the SVC. The SVC is transected, the caudal stump is oversewn, and anastomosis of the cephalad end of the SVC to the right atrial appendage is begun. It often requires patch enlargement

portal vein or into the hepatic veins. An ASD is present in 25–50% of the patients. In some patients anomalous lung segments are supplied with arterial blood from the descending aorta by small pulmonary arteries. The scimitar vein (SV) is typically single, runs anterior to the hilum of the lung, and pierces the diaphragm en route to the inferior vena cava, where it enters just above, behind, or lateral to the right hepatic vein orifice. Considerable variations of this anatomy have been noted: the SV may run behind the hilum or may be present as a double vein, with the anomalous entry point being as far away as the right hepatic vein and the azygos vein. In addition, the scimitar vein may be stenotic at or just distal to its junction with the inferior vena cava or right atrium; this occurs in 10–20% of cases.

In descending order of frequency, the following anomalies are associated with the scimitar vein:

- Anomalous right lung sequestration and right lung hypoplasia (virtually 100%, with widely varying degrees of hypoplasia)
- Dextroposition of the heart
- Hypoplasia of the right pulmonary artery (60%)
- Systemic arterial blood supply to the right lower lung from the infradiaphragmatic aorta (60%)
- Atrial septal defect of the secundum type (40% overall, 80–90% in the infantile variant)
- Right-sided diaphragmatic hernia (15%)
- Horseshoe lung (parenchymal continuity between the right and left lung behind the heart and anterior to the esophagus)

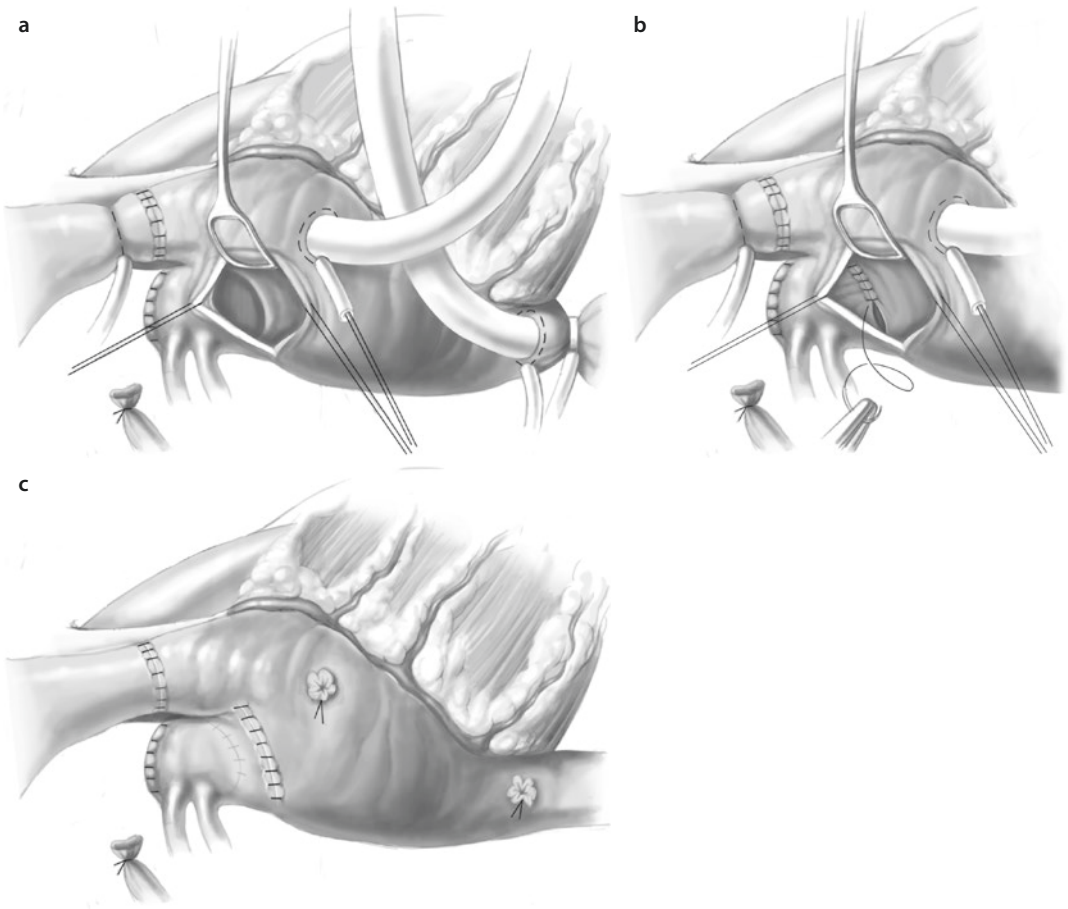

Fig. 12.12 a–c Warden's technique for sinus venosus defect repair (continued). **a** The cavoatrial anastomosis is complete. The right atriotomy exposes the sinus venosus defect. **b** The inferior margin of the defect is sutured to the anterior and lateral margins of the intracardiac SVC orifice. **c** Completed repair. Anomalous pulmonary venous flow has been directed through the proximal SVC and across the septal defect into the left atrium. Flow from the SVC into the right atrium is reconstructed by the cavoatrial anastomosis (Warden et al. 1984)

The infantile scimitar syndrome, in addition to its high incidence of ASD, is associated with a large number of further cardiovascular anomalies (Brown et al. 2003):

- Ventricular septal defect
- Patent ductus arteriosus Botalli
- Hypoplastic aortic arch
- Aortic isthmus stenosis
- Tetralogy of Fallot
- Anomalous origin of the left coronary artery
- Truncus arteriosus communis

There are two forms of scimitar syndrome that are clearly distinguishable in terms of clinical presentation (Gudjonsson and Brown 2006):

- An infantile syndrome associated with significant mortality

- A milder form presenting in late childhood or adulthood that is frequently asymptomatic, with diagnosis often being made incidentally because of radiographic abnormalities

Surgery for scimitar syndrome was first performed in 1950 by Drake and Lynch (1950). In a patient with recurrent right-sided pneumonia and a scimitar vein draining the bronchiectatic lower right lung, they resected the right lower lung lobe, with good results.

The first corrective surgical procedure in a patient with scimitar syndrome and an ASD was performed in 1956 by Kirklin using cardiopulmonary bypass (Kirklin et al. 1956). The scimitar vein was anastomosed to the right atrium in proximity to the ASD, and this portion of the

Fig. 12.13 a, b Correction of scimitar syndrome. **a** Correction by reimplantation of the scimitar vein into the right atrium and redirection by creation of a tunnel by suturing of a short baffle. **b** Correction by creation of a tunnel from the inferior vena cava to the ASD by suturing of a long baffle

right atrial wall was then sutured to the margin of the ASD, closing the ASD and rerouting the blood flow from the scimitar vein to the left atrium.

Classical repair of scimitar syndrome consists in redirection of the anomalous pulmonary veins leading to the inferior vena cava through the atrial septal defect into the left atrium by means of a pericardial baffle (■ Fig. 12.13).

In small children this method results in a high incidence of obstruction of the tunnel. The method of choice in these patients is therefore direct anastomosis of the right pulmonary veins with the lateral wall of the left atrium (■ Fig. 12.14).

In an adult patient, the procedure can be performed through a right posterolateral thoracotomy and without cardiopulmonary bypass (Brown et al. 2003). In small children cardiopulmonary bypass is obligatory. In infants and small children, direct implantation of the scimitar vein into the left atrium can be technically difficult because the left atrium is small. In such cases the scimitar vein can be implanted into the right atrium, and the flow can then be redirected via an existing or created ASD using a pericardial patch (Brown et al. 2003; Gudjonsson and Brown 2006; ■ Fig. 12.15). To prevent tension or kinking of the

Fig. 12.14 Scimitar syndrome repair via right thoracotomy without the use of cardiopulmonary bypass in adults (Adapted from Brown et al. 2003). The repair is complete and the clamp is about to be removed from the left atrium

scimitar vein in small children, the interposition of a graft as an extension between the anomalous vein and the left atrium has been reported (Lam et al. 2007).

In patients with scimitar syndrome and right lung sequestration, ligation of collaterals to the affected lung segment is generally recommended, and the segment(s) may remain in place. Right pneumonectomy is indicated in patients with intractable

■ **Fig. 12.15** a Isolated anomalous drainage of the left pulmonary veins into the innominate vein. b Anastomosis of the anomalously draining left pulmonary veins with the left atrial appendage

pulmonary sequestrations (persistent infections) or if the attempt at correction has failed (Huddleston et al. 1999; Thibault et al. 1995; Torres and Ca 1993).

12.1.2.5 Anomalous Drainage of the Left Pulmonary Veins into the Innominate Vein

In its isolated form, this anomaly is very rare (see ■ Fig. 12.15a). Partial left drainage of a small upper lobe vein into the innominate vein may be left uncorrected, but if all the left pulmonary veins drain abnormally and create similar hemodynamic consequences to those of an ASD, surgical correction is indicated. In asymptomatic infants and small children, the operation can be postponed to grow into a size with less postoperative risk of stenosis of the anastomosis between the left pulmonary veins and the left atrial appendage.

The operation is conducted using cardiopulmonary bypass and cardioplegic cardiac arrest. The phase of cardioplegia is important to obtain a bloodless operative field, which facilitates the creation of a wide, nonconstrictive anastomosis between the left pulmonary venous stem and the left atrial appendage.

The persisting left upper caval vein should be doubly ligated and may be transected at its

entrance into the innominate vein to create a long tunnel for the anastomosis to the left atrium. The pulmonary venous stem is opened longitudinally to receive an anastomosis with large lumen. The left atrial appendage is amputated, and the anastomosis is carried out with a continuous 7/0 or 6/0 monofilament suture (see ■ Fig. 12.15). In some cases patch enlargement of this anastomosis with autologous pericardium is necessary.

12.1.3 Anomalous Drainage of the Caval Veins

12.1.3.1 Definition and General Comments

Anomalies of the systemic venous return that drains to the heart may occur in isolation or in association with other congenital heart defects (DeLeval et al. 1975; Gandy and Hanley 2006). Many of the common defects are clinically of minor significance when found in isolation. There are many rare anomalies that may or may not become clinically significant. However, systemic venous anomalies are of great importance in patients with the different forms of a univentricular heart and may complicate the creation of cavopulmonary connections as well as the later Fontan completion.

The presence of a systemic venous anomaly may necessitate modifications of the implantation techniques for heart transplantation or combined heart and lung transplantation. The classification of these anomalies is primarily descriptive (Gaynor et al. 2000; ■ Figs. 12.16, 12.17, and 12.18).

12.1.3.2 Anatomy

Isolated anomalies of the caval veins are overall rare, but they are frequently associated with other congenital heart defects, especially in the presence of heterotaxy and isomerism.

In situs solitus a left superior vena cava is connected to the coronary sinus, and, in the absence of other cardiac defects, this has no functional impact. Its importance for surgery is that it must be taken into consideration in the technique of venous cannulation or intermittent occlusion and causes difficulties if minimally invasive surgical approaches are used.

The most common malformation of clinical significance is drainage of the left superior vena cava into the left atrium. In the Raghbir-type ASD (Raghbir et al. 1965), the coronary sinus roof is completely or

■ Fig. 12.16 Anomalies of the superior vena cava. *Top row:* right superior vena cava to right atrium (*left*); right superior vena cava through the coronary sinus to left atrium (*center*); right-sided superior vena cava to left atrium (*right*). *Middle row:* Left superior vena cava to left-sided atrium (completely unroofed coronary sinus; *left*); left superior vena cava through the coronary sinus to right atrium (*center*); left vena cava to right atrium (*right*). *Bottom row:* bilateral superior vena cava: right superior vena cava to right atrium, left superior vena cava to left atrium (completely unroofed coronary sinus; *left*), bilateral superior vena cava: right upper vena cava to right atrium, left superior vena cava through the coronary sinus to right atrium (*center*), bilateral superior vena cava: right upper vena cava through the coronary sinus to left atrium, left superior vena cava to left atrium (*right*)

partially absent, resulting in venoarterial shunt at the left atrial level, clinically compensated by the large left-to-right shunt through the ASD. Clinical symptoms occur, however, after closure of the ASD without having taken care of the anomalous LSCV drainage. Combinations with other congenital heart defects have also been described (Abbattista et al. 1994; Cherian and Rao 1994; DeLeval et al. 1975; Liang et al. 1996; Quarti et al. 2005).

Other less common anomalies of systemic venous return to the left atrium include drainage of the inferior vena cava into the left atrium or in separate drainage of the hepatic veins into the left atrium.

This can, if not recognized, lead to inadequate total cavopulmonary connection during performance of the Fontan operation or ASD closure, with resulting residual or de novo right-to-left shunt.

12.1.3.3 Surgical Technique

Anomalous drainage of the left superior vena cava to the coronary sinus without unroofed coronary sinus needs no surgical intervention. If surgery for other cardiac anomalies is required, direct cannulation of an isolated left superior vena cava is necessary, to obtain a dry operative field. Cannulation must be performed after the cardiopulmonary bypass is started up, to prevent hemodynamic disturbances. Cannulation itself can be performed in the usual manner. In bilateral superior venae cavae with a sufficiently large connection between the left and right superior caval veins through the innominate vein, the left superior vena cava can be temporarily clamped using a tourniquet of hemoclip, which needs to be removed after the heart chambers are closed. Alternatively, in infants and small children, the left superior vena cava can be transected in preparation for a Fontan operation.

Interruption of the inferior vena cava is a very rare vascular anomaly. In such cases all venous blood from the bottom half of the body drains into the superior vena cava through the azygos vein or else into the left superior vena cava through the hemiazygos vein. This anomaly necessitates special care when performing the superior cavopulmonary connection, during the Fontan operation and in atrial switch operations in patients with transposition of the great arteries. With anomalous drainage of the systemic veins into the left atrium, the surgical management of an unroofed coronary sinus presents technical challenges. Different surgical options exist to correct this anomaly (Gandy and Hanley 2006; Quaegebeur et al. 1979; Reddy and McElhinney 1997; Van Son et al. 1998a, b, c):

■ ■ Anomalous drainage of the superior vena cava into the left atrium

Ligation of the left superior vena cava can be performed if there is a good connection between the right and left caval vein via the innominate vein (Liang et al. 1996). If the innominate vein is absent, ligation is possible in exceptional cases if, after clamping of the left superior vena cava,

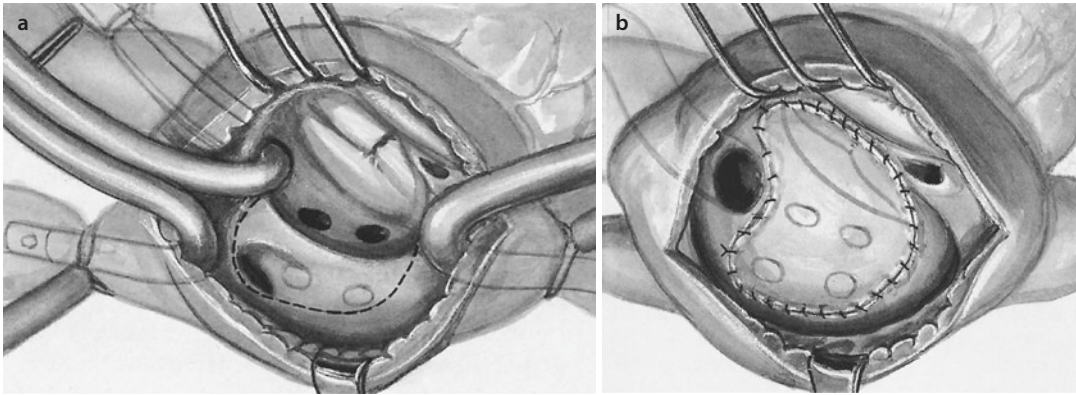

■ **Fig. 12.18** Anomalies of the hepatic veins. *Upper row:* right lower vena cava and separate entry of hepatic veins into left atrium (*left*); right inferior vena cava and separate entry of hepatic veins into right atrium (*center*); right inferior vena cava and separate entry of hepatic veins into coronary sinus (*right*). *Middle row:* left inferior vena cava into the left atrium and separate entry of hepatic veins into right atrium (*left*); left inferior vena cava and separate entry of hepatic veins into coronary sinus both into the left atrium (*center*); left inferior vena cava and separate entry of hepatic veins into coronary sinus both into the left atrium (*right*). *Bottom row:* interrupted right lower vena cava with azygos continuation into right upper vena cava and separate entry of hepatic veins into right atrium (*left*); interrupted right inferior vena cava with azygos continuation into right upper vena cava and separate entry of hepatic veins into left atrium (*second from left*); interrupted left inferior vena cava with hemiazygos continuation into left superior and separate entry of hepatic veins into left atrium (*second from right*); interrupted left inferior vena cava with hemiazygos continuation into left superior vena cava and separate entry of hepatic veins into right atrium (*right*)

venous pressure does not exceed 15 mmHg and the coronary sinus and the pulmonary venous drainage are not compromised (Laks 1994). In cases of hypoplastic innominate vein, enlargement of the innominate vein between the right brachiocephalic vein and the left jugular vein with a pericardial patch and ligation of the left superior vena cava can be successfully performed (Van Son

et al. 1998a, b, c); in some cases spontaneous enlargement, actually caused by elevated LSVC pressures after ligation, may be expected.

Reimplantation of the left superior vena cava into the right atrium or the pulmonary artery is practiced successfully (Gandy and Hanley 2006; Liang et al. 1996; Quarti et al. 2005). There are, however, concerns about the potential early

■ **Fig. 12.19** a, b Procedure for intra-atrial redirection of anomalous LSVC to left atrial connection

stenosis of the anastomosis and thrombus formation and the possibility of reverse flow in the case of elevated pulmonary arterial pressure at rest or during physical exertion in the later course.

Intra-atrial redirection of the left superior vena cava is the preferred option. There are two possible techniques (Gandy and Hanley 2006; Quaegebeur et al. 1979):

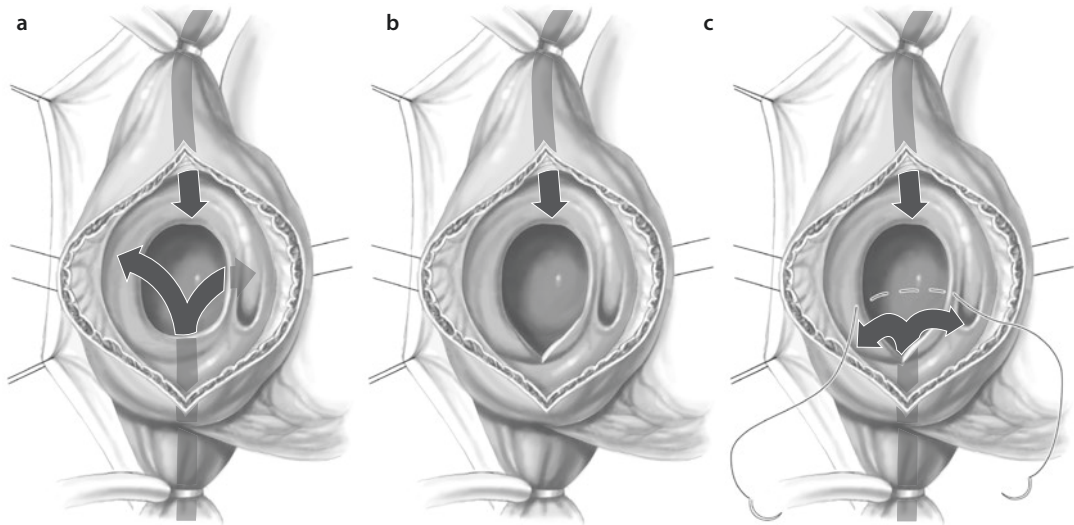

- **Roofing procedure.** This operation can be recommended if the roof of the coronary sinus is absent. After the establishment of cardiopulmonary bypass and cardioplegic cardiac arrest, the right atrial incision is performed. A separate cannula is introduced into the innominate vein orifice through the coronary sinus orifice. If there is no additional ASD, the interatrial septum is incised. The repair is started at the point of entrance of the left superior vena cava into the left atrium. A pericardial patch is used to cover the defect of the coronary sinus roof. With a separate pericardial patch, the ASD is then closed.
- **Intra-atrial baffle procedure.** Because of the risk of obstruction of the left pulmonary veins and the mitral valve and also the risk of creating too small a tunnel, the preferred method is the intra-atrial redirection, which is carried out in such a fashion that the anomalous vein drains into the right atrium. If there is a secundum ASD, the patch is inserted between the two atrioventricular valves on the rim of the atrial septum or, with an ostium primum defect, along the anulus of one of the atrioventricular valves. The suture line is then carried down toward the posteroinferior corner of the left atrium and around the entrance of the left

superior vena cava, so as to redirect the blood from the anomalously draining left superior vena cava to the front side of the patch. The suture line then runs further to the roof of the left atrium and reaches the rim of the atrial septum laterally, thus completely separating the systemic venous return (■ Fig. 12.19).

■ ■ Anomalous drainage of the inferior vena cava into the left atrium

As an isolated anomaly, this defect occurs very rarely (Zenker et al. 1965) and usually presents in patients with heterotaxy syndrome and atrial isomerism (Rubino et al. 1995; Yun et al. 2006a). To connect the heart–lung machine, separate cannulation of the anomalous vein is necessary. For the Fontan operation, these veins can be connected to total cavopulmonary connection to prevent the development of pulmonary arteriovenous fistulas (Shah et al. 1997). If an extracardiac tunnel is created during the Fontan operation, the hepatic veins can be incorporated into the cavopulmonary connection using the atrial flap technique (Shah et al. 1997) or separately connected to the extracardiac conduit using an additional tube graft (Lee et al. 2002). If an intracardiac lateral tunnel operation is performed, these veins can be incorporated in the created lateral canal (Gandy and Hanley 2006; Shah et al. 1997).

In isolated cases repair consists of redirecting the direct hepatic veins or the inferior vena cava into the right atrium by creating an intracardiac tunnel. If there is an ASD, the pericardial patch must be inserted in such way that the blood flow leads into the right atrium (Derra et al. 1965; ■ Fig. 12.20).

■ Fig. 12.20 a–c Redirection of the blood flow into the right atrium for anomalous IVC or hepatic veins to left atrial connections

■ ■ Combined anomalous drainage of the vena cava and pulmonary veins

There are various forms of this combined anomalous drainage of the vena cava and pulmonary veins. Often, and particularly in patients with heterotaxy, these anomalies are associated with other complex congenital heart defects.

Surgical therapy in such cases must be tailored to the individual anatomy to achieve satisfactory hemodynamic results. Surgical mortality in patients with heterotaxy and combined systemic and pulmonary venous anomalies is high and in recent series approaches 50% (Friesen et al. 2005; Gaynor et al. 1999; Hashmi et al. 1998; Rubino et al. 1995; Yun et al. 2005, 2006a, b).

12.1.4 Cor Triatriatum Dextrum

12.1.4.1 Definition and General Comments

Cor triatriatum dextrum is defined as a separation of the right atrium by remnants of the right sinus venous valve (Abdulla et al. 2004). The extent of failure of sinus venosus valve (aka Eustachian valve) regression varies from a small mobile atrial septation of the right atrium called Chiari's network to complete septation of the right atrium (cor triatriatum dexter). Cor triatriatum dextrum can present as an isolated anomaly or as part of a complex malformation of the right side of the heart (Eroglu et al. 2004).

12.1.4.2 Surgical Technique

The operation is performed using cardiopulmonary bypass and cardioplegic arrest. Excision of the obstructive membrane and closure of a coexisting ASD leads to complete disappearance of the symptoms. In rare cases cor triatriatum dextrum is combined with cor triatriatum sinistrum (Steen et al. 2007; Wedemeyer et al. 1970). Resection of both membranes and closure of the ASD achieved complete correction in the case described (Wedemeyer et al. 1970).

12.1.5 Atrioventricular Septal Defects

12.1.5.1 Definition of the Anomaly and Surgical Aims

The term «atrioventricular septal defects» (AVSD) covers a group of congenital malformations of the atrioventricular septum and atrioventricular valves of differing degrees of severity. These anomalies have been, and continue to be, referred to in the literature by different names, for example, endocardial cushion defect, atrioventricular canal defect, and persisting atrioventricular canal defect (Becker and Anderson 1982; Bharati and Lev 1973; Dubost and Blondeau 1959; Litwin et al. 2007; Van Mierop and Alley 1966).

Since the absence of the atrioventricular septum is common to all forms of these defects, the term suggested by Becker and Anderson (1982),

«atrioventricular septal defect,» is anatomically correct and therefore seems to be the most appropriate, although surgical writing often uses the designation «atrioventricular canal defect» (Backer et al. 2007).

AVSDs represent a spectrum of cardiac malformations that can be divided into the partial AVSD, an intermediate AVSD type, and the complete AVSD (Jacobs et al. 2000a, b).

In the opinion of Anderson and Ho (1989), the division of the aortic leaflet of the left-sided AV valve found with AVSD, which used to be known as a cleft, is more appropriately viewed as a commissure of a tri-leaflet valve. Carpentier (1978) regarded, on the basis of such a view, cleft closure as unnecessary. Since then other authors have disagreed (Alexi-Meskishvili et al. 1996, 1997; Capoua et al. 1992; Crawford 2007; Pozzi et al. 1991).

In accordance with the varying degree of the two features, septal defect and AV valve malformation (others are described in the section «Surgical Anatomy»), three subgroups of AVSD may be identified (Jacobs et al. 2000a):

- Partial AVSD, in which there is an interatrial connection of the ostium primum defect type (ASD I) and two atrioventricular valve ostia with intact ventricular septum and a cleft in the anterior leaflet of the left AV valve (this type also includes the isolated ostium primum defect and the isolated «mitral» cleft)
- Total AVSD, characterized by a common atrioventricular valve orifice and the absence of the membranous and muscular portion of the atrioventricular septum
- The intermediate form (here the AVSD consists of only a small, depressed, restrictive ventricular septal defect exclusively between the superior and inferior leaflet portions, being «open» only in ventricular diastole, in which the crest of the interventricular septum can be seen from the atrial side)

All three groups have in common the presence of left-to-right shunt, with a tendency toward early development of high pulmonary resistance pressures (with the total defect more often than with the partial type). Therefore, the aim of the operation is the early, complete removal of the left-to-right shunt by closure of the defects while preserving—or achieving—normal AV valve

function. In 60–70% of cases, total AVSD is associated with Down syndrome.

12.1.5.2 Historical Comments

The first descriptions of these defects were from Peacock (1846), Rokitsansky (1875), and Abbott (1936). However, Rogers and Edwards (1948) were the first to describe the morphological similarity between the ostium primum defect and the common AV canal defect. Wakai and Edwards (1956, 1958) introduced the term «partial and complete atrioventricular canal defect.» Subsequently, other authors contributed to knowledge of the anatomy of the defects, among them were Lev (1958), who described the topography of the AV node and the His bundle; Bharati and Lev (1973), who introduced the concept of the intermediate AV canal; and Van Mierop who supplied an overview of the pathology and pathogenesis of endocardial cushion defects (Van Mierop and Alley 1966). In 1966 Rastelli and colleagues presented a division into types A, B, and C (Rastelli et al. 1966), which for a long time provided orientation for the surgical procedure, although different variants of a spectrum existed.

The first successful repair of an AVSD was reported by C. Walton Lillehei. He used cross circulation and direct suture of the atrial rim of the septal defect to the crest of the ventricular septum (Lillehei et al. 1955). In the late 1950s and early 1960s, Lillehei, McGoon and Kirklin, and Cooley converted the use of cardiopulmonary bypass and used two synthetic patches to close the atrial and ventricular components of the defect separately (Cooley 1960; Lillehei et al. 1955; McGoon et al. 1959). Maloney reported the use of a single-patch technique for direct closure (Maloney et al. 1962). Dwight McGoon described the double-patch technique (McGoon et al. 1959).

Wilcox and Nicholson each independently reported a «simplified» or «modified» single-patch technique for repair of AVSD (Nicholson et al. 1999; Wilcox et al. 2004). Each technique has strong advocates, but it is not clear that any of them is superior to the other two (Crawford 2007). Recently, Aramendi described a technique for repair of a complete AVSD without a patch (Aramendi et al. 2006).

Mair and McGoon (1977) reported successful correction of the AVSD during the first year of

life. They stressed the importance of taking enough tissue from the tricuspid valve to create an adequate left AV valve.

The most controversial issue in the surgical treatment of the complete AVSD was whether it is necessary to close a so-called mitral cleft. The issue remains controversial for patients with parachute «mitral valve» (Sharma et al. 2013). This so-called mitral cleft (better referred to as a cleft of the left AV valve) is referred to by some authors as the «zone of apposition» (Wetter et al. 2000). The opinion that the cleft should be left intact is not new and was proposed for patients with incomplete AVSD many years ago (Dubost and Blondeau 1959; Van Mierop and Alley 1966). In the late 1970s, the concept of the tri-leaflet mitral valve was introduced by Carpentier, Becker and Anderson (Becker and Anderson 1982; Carpentier 1978). Carpentier believed that the left AV valve functions best when reconstructed as a tri-leaflet valve (Carpentier 1987). This led some surgeons to leave the cleft open during total repair of the complete AVSD (McGrath and Gonzales-Lavin 1987; Ross et al. 1991).

At the same time, some proponents of the tri-leaflet mitral valve concept maintained that although it was impossible to produce a bileaflet valve which structurally approximated the mitral valve of a normal heart, «closure of the 'cleft' in some cases may be the only way to produce a competent atrioventricular valve» (Becker and Anderson 1982).

The left AV valve reconstructed during repair of AVSD is not a mitral valve.

The main goal of left AV valve reconstruction in patients with complete AVSD is to produce a competent and nonstenotic systemic atrioventricular valve. Criticism of the tri-leaflet concept has increased over the past 25 years as surgeons have noted that the high rate of reoperations necessitated by late AV valve insufficiency after total correction of complete AVSD could be mainly attributed to nonclosure or incomplete closure of the cleft or avulsion of the suture used to close the cleft (Alexi-Meskishvili et al. 1996, 1997; Ten Harkel et al. 2005; Wetter et al. 2000).

From the surgical point of view, we do not consider the question of whether the cleft found with complete AVSD is a normal commissure to be of great importance. It is far more important to note that a partially or completely open cleft is the main cause of subsequent valve incompetence and that cleft closure represents the only means for achieving long-term valve competence in such cases. The incidence of late operation for late severe left AV valve incompetence in patients with nonclosed cleft was 14–26% (McGrath and Gonzales-Lavin 1987; Pozzi et al. 1991; Ross et al. 1991). Nowadays surgeons must be advised always to close a left AV valve cleft to approximate to the age-related normal diameter of the mitral valve (Crawford 2007; Litwin et al. 2007; Nunn 2007; Wetter et al. 2000). It should be remembered that closure of the zone of apposition (cleft) does not create a leaflet comparable to the aortic leaflet of the normal mitral valve (Wilcox et al. 2004).

From the end of the 1960s and the beginning of the 1970s, the surgical indication for AVSD repair was extended to include children in the first year of life (Bailey et al. 1976; Barratt-Boyes 1973). Since then the age at which complete AVSD is electively corrected has dropped. In many centers the mean age of patients at the time of complete AVSD repair is around 4 months (Backer et al. 2007; Singh et al. 2006). More recent recommendations are based on operating before pneumonia occurs and before the development of irreversible pulmonary hypertension and the complications of congestive heart failure and AV valve insufficiency. The ability to perform safe surgery in early infancy has been facilitated by improvements in anesthesia, cardiopulmonary bypass, and postoperative management. In most centers the preoperative diagnosis is made on the basis of transthoracic echocardiography only. Cardiac catheterization is rarely used. The ideal age for the correction of complete AVSD appears to be between 3 and 6 months (Backer et al. 2007). The ideal age for correction of an incomplete, non-complicated AVSD is about 2 years.

If patients with a partial AVSD present with symptoms very early in life, complex anatomy should be suspected, including multilevel left-sided hypoplasias, which may pose a significant challenge to management and suggest a poor prognosis (Giamberti et al. 1996; Manning 2007).

12.1.5.3 Surgical Anatomy

Knowledge of the main anatomic characteristics of AV septal defects is essential not only to define the diagnosis but also for the surgical treatment. These characteristics are (Anderson and Ho 1989; Piccoli et al. 1979; Wilcox et al. 2004):

- The absence of the atrioventricular septum
- The absence of the normal «wedging» of the aorta between the mitral valve and the tricuspid valve, which is partially responsible for the presence of a common atrioventricular valve
- Abnormal relationship between the left ventricular outflow tract (LVOT) and the «unwedged» aortic valve
- Abnormal relationship between the inflow and outflow tract of the left ventricle in favor of the outflow tract, which results from the above features
- Posterior displacement of the conduction system due to the absence of the atrioventricular septum

To successfully reach the goals of surgery, secure defect closure without AV block, and competent AV valves, the pathomorphology of the AV valves and the anatomical course of the conduction system are of utmost importance (■ Fig. 12.21).

There are significant differences between the AV valves of a normal heart and of a heart with partial or total AVSD (see ■ Fig. 12.21a–c). As in the normal heart (see ■ Fig. 12.21a), the heart with a partial AVSD has two distinct AV valve orifices, while the individual leaflets of these AV valves differ: both the tricuspid valve and the mitral valve are not to be regarded as such in the presence of an AVSD but rather as right and left AV valves. In principle these are double-leaflet valves with the corresponding commissures (Anderson and Ho 1989). The resulting six leaflets are named according to their position: for the right AV valve, right superior (RS), right lateral (RL), and right inferior (RIS), and for the left AV valve, left superior (LS), left lateral (LL), and left inferior (LIS) (see ■ Fig. 12.21b). When a complete AVSD is present, there is a single common AV valve ostium (see ■ Fig. 12.21c). This common AV valve usually consists of five leaflets, rarely of six, and their nomenclature corresponds to that used with a partial AVSD.

It was recognized that the classification of total AVSD into types A, B, and C by Rastelli et al. (1966) did not exactly reflect the actual anatomic features, but for surgical purposes the detailed description of the individual morphology in terms of this classification has proven its worth. Assuming that the inferior portions of the left and right AV valve usually form a

common posterior leaflet, the Rastelli classification is applied to the behavior of the superior leaflets only: if they are divided from each other, type A is present; if there is a so-called common superior leaflet without attachments to the interventricular septum, the type is C. With type B, which is extremely rare, tendinous threads attached to the left superior leaflet lead to an anomalous papillary muscle in the right ventricle.

In line with modern concepts (Anderson et al. 1985; Wilcox et al. 2004), the common anterior (or superior) and posterior (or inferior) leaflets are to be seen as «bridging leaflets» that override the ventricular septal defect to a greater (type C) or lesser (type A) extent. The greater variance is in the relationship of the anterior (superior) leaflet to the bridged septum, so that the classification is largely made in this respect.

The size of the interventricular communication, the *ventricular septal* defect, is also very variable. Sometimes there is only a small gap between the left superior and inferior leaflet. Frequently, however, the defect reaches over the whole extent of the superior leaflet, up to the aortic valve, just as it can extend below the inferior leaflet.

In addition to the variants described so far, we should also mention those that result from the relative position of the common AV valve in relation to the ventricular septum. As well as a balanced form (similar size right and left ventricle with the common AV valve lying centrally above them), a right-dominant form is found, which is defined by an enlarged right ventricle, small left, and displacement of the AV valve to the right. By analogy the left-dominant form has the opposite features.

Owing to the absence of the atrioventricular septum, hearts with AVSD show displacement of the conduction system in comparison with normal hearts. This concerns first and foremost the AV node, which is normally situated in the apex of the Koch triangle but in the heart with an AVSD is displaced in posterior direction and is found between the insertion line of the posterior (inferior) common leaflet and the anterior area of the coronary sinus (■ Fig. 12.22).

In comparison with the normal heart (see ■ Fig. 12.22a), the crest of the ventricular septum and also the entire axis of the conduction system is, like the AV node, displaced in posterior direction (see ■ Fig. 12.22b; Mitchell et al. 2007). Surgical view of conduction system is presented on ■ Fig. 12.22c, d.

AVSDs occur not only in isolation but also in combination with other heart defects, e.g., with

tetralogy of Fallot, transposition of the great arteries, and total anomalous pulmonary venous drainage. The surgical procedure must be tailored to addressing both malformations. In such combinations the interventricular communication is particularly large, so that the patch used for closure must be large enough and must be cut to correspond to the particular form.

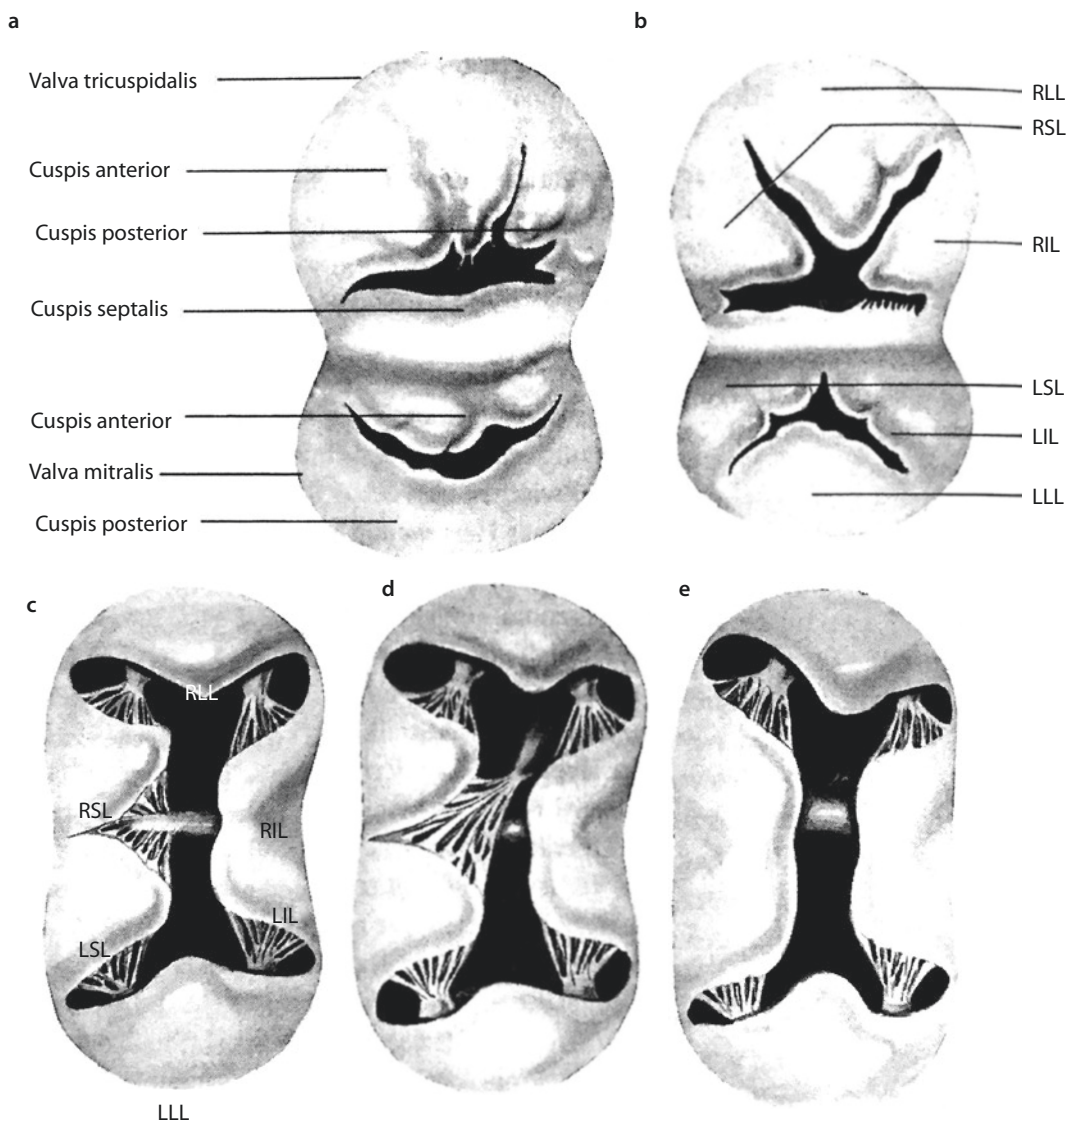

■ ■ Specifics of extracorporeal circulation

Today intracardiac correction procedures are performed using cardiopulmonary bypass in moder-

ate hypothermia and with cardioplegic heart arrest to protect the myocardium (Crawford 2007; Litwin et al. 2007; Manning 2007). For operations on infants, deep hypothermic cardiac arrest with or without cardioplegia is an option.

■ ■ Access and general surgical technique

The standard access is by median longitudinal sternotomy. In large patients the right-sided anterolateral thoracotomy in the fourth or fifth intercostal space may be selected. Today the limited lower sternotomy and the posterolateral

■ Fig. 12.21 a–e Morphology of the AV valves and course of the conduction system. *LIL* left inferior leaflet, *LLL* left lateral leaflet, *LSL* left superior leaflet, *RIL* right inferior leaflet, *RLL* right lateral leaflet, *RSL* right superior leaflet. **a** Normal heart with tricuspid and mitral valve. **b** Partial AVSD, **c** total AVSD (Rastelli type A), **d** total AVSD (Rastelli type B), and **e** total AVSD (Rastelli type C)

■ **Fig. 12.22** a–d Displacement of the conduction system. **a** Diagram of normal configuration, **b** diagram of posterior displacement, and **c**, **d** diagrammatic view of surgical situs

right-sided thoracotomy are also used. At a few places, more recently a trans-axillary approach is suggested also (German Heart Center Munich, Mt. Sinai Hospital, New York, NY)

12.1.5.4 Surgery for Partial Atrioventricular Septal Defect

After access has been gained, a patch of autologous pericardium is harvested, keeping an adequate distance from the phrenic nerve. The patch can be pretreated with glutaraldehyde (0.1–0.6%) according to the surgeon's preference. Aortic and bicaval cannulation is performed. If there is a persistent left superior vena cava, this is cannulated separately or temporarily closed with a tourniquet.

We usually perform the correction on high-flow cardiopulmonary bypass with hemodilution and normothermia or moderate hypothermia to (28–32 °C). Myocardial protection is provided by antegrade application of cold crystalloid or warm blood cardioplegic solution.

The right atriotomy is made from the base of the right atrial appendage to just above the inferior vena cava (■ **Fig. 12.23**).

After right atriotomy has been performed, the remains of the septum secundum and primum are

■ **Fig. 12.23** Right atriotomy

incised up to the atrial wall (Sondergaard's groove, interatrial groove) to prevent extreme pull-up and deformation of the mitral valve and to ensure optimal suspension and mobility of the reconstructed valve (Alexi-Meskishvili et al. 1996). Sometimes there is, in addition to the ostium primum defect, an atrial septal defect of secundum type, which is divided from the primum defect by a muscle bridge. A small sucker is placed through the atrial septal defect into the left atrium to keep the operative field bloodless. We prefer to continuously direct carbon dioxide into the operative field with flow of 3–6 l/min.

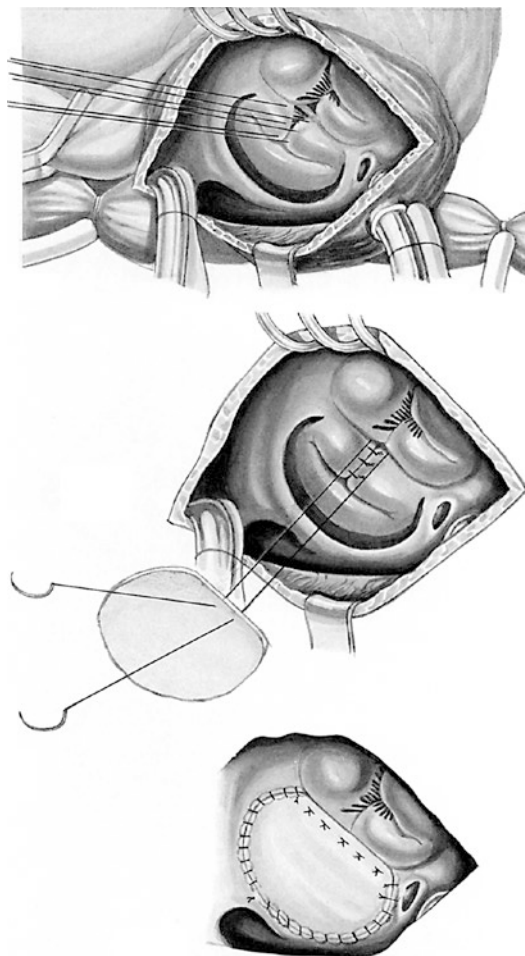

The anatomy of the AV valves is carefully inspected, and the degree of regurgitation is tested by injecting cold normal saline solution into the left and right ventricles.

It is important to assess the adequacy of the lateral commissures and to measure the orifice of the left AV valve, which will be left after closure of the zone of apposition (cleft).

The septal commissural cleft is identified and closed with interrupted, nonabsorbable sutures that may be reinforced with pericardial pledgets to prevent suture dehiscence. During cleft closure the minimal acceptable mitral valve diameter is determined according to the patient's body surface area (Rowlatt et al. 1963). In cases where the medial and lateral commissures are fused and cleft closure would produce a stenotic orifice, the cleft is only partially closed or is left completely open. Competency of the atrioventricular valves is reassessed, and in some cases anuloplasty or commissuroplasty is required to establish best possible apposition of the valve leaflets to achieve acceptable valve function.

Next, the atrial septal defect is closed. A pericardial patch is sutured close to the junction of the atrioventricular valves, adjacent to the tricuspid valve, using monofilament nonabsorbable mattress sutures. Alternatively a continuous suture may be used (Sadeghi et al. 1997). Multiple small careful bites are taken from the posterolateral leaflet of the tricuspid valve and anchored close to the anulus, to prevent residual atrial septal defects. Initially this suturing is continued toward the coronary sinus. We routinely allow the coronary sinus to drain into the right atrium by carrying the suture line along the left atrial side of the septum and the anterior lip of the coronary sinus away from the Koch triangle. The suture line continues to the dome of the right atrium. Another suture starts at the anterior edge of the atrial septal defect and joins the posterior suture; after the air has been evacuated from the left side of the heart, the two sutures are knotted together (■ Fig. 12.24).

After closure of the atrial septum, the right atrium is closed with a continuous suture. Special attention is given to de-airing both the left and right sides of the heart using forced ventilation of the lungs and continuous aspiration of blood from the ascending aorta. In all patients transesophageal echocardiography is performed after

■ Fig. 12.24 Closure of a partial atrioventricular septal defect

separation from the heart–lung machine to assess valve function and identify any residual defect.

12.1.5.5 Surgery for Intermediate Atrioventricular Septal Defect

In the presence of an intermediate AVSD (■ Fig. 12.25a), it is possible to suture the edge of the small, basin-like central ventricular septal defect directly with the midline of the AV valve apparatus, which is then slightly lowered. To this end double-armed sutures are placed as individual U-sutures that pierce the right-sided portion of the ventricular septum as superficially as possible, taking care to preserve the heart structures, in particular the right bundle. The sutures enter the tissue about 6 mm from the upper rim of the defect, exit 2–3 mm further away, and are then led in the direction of the atrium through the border

■ Fig. 12.25 a, b Closure of an intermediate atrioventricular septal defect

of the AV valves. To prevent the sutures being transected by the septum muscle, we use synthetic reinforcement, i.e., either small Teflon tubes or Teflon pledgets. Placement of the sutures begins on both sides in the outer edges of the defect and proceeds toward the center, so that the last of these sutures can be used as the first suture for adaptation of the corners of the left superior and left inferior leaflet in the area of the marking suture. Thus, the same sutures can then be passed through the lower edge of the pericardial patch that serves to close the ostium primum defect and then be knotted (■ Fig. 12.25b).

In rare cases of intermediate AVSD, it can be necessary, in the interests of secure closure of the interventricular communication, to use a synthetic patch, namely, when only a very delicate, fragile membrane is present below the AV valves. Alternatively, the complete AV valve level can be lowered onto the septal crest (see also below: modified single-patch technique for total AVSD repair).

12.1.5.6 Surgery for Complete Atrioventricular Septal Defect

■ ■ Repair of complete AVSD with double-patch technique

When compared to single-patch and modified single-patch techniques, double-patch repair may offer practical and theoretical advantages: there is no need to incise the bridging leaflet, which is necessary with the single-patch technique. This avoids the risk of leaflet dehiscence and the shortening of the mitral valve leaflets that may occur with the single-patch technique (Fortuna et al. 2004; Litwin et al. 2007).

Correction of the complete atrioventricular septal defect should maintain the anatomically correct position of the atrioventricular valve leaflets at end systole, to avoid leaflet distortion, which can result in mitral valve incompetence or to narrowing of the left ventricular outflow tract and the development of a subaortic stenosis.

We perform the operation through a complete or partial median sternotomy. The heart–lung machine is connected via aortic and bicaval cannulation, and the procedure is carried out in moderate hypothermia and with myocardial protection by means of crystalloid cardioplegia solution. To obtain optimal exposure, the superior caval cannula is placed directly in the superior vena cava and the inferior cannula near the entrance of the inferior vena cava into the right atrium.

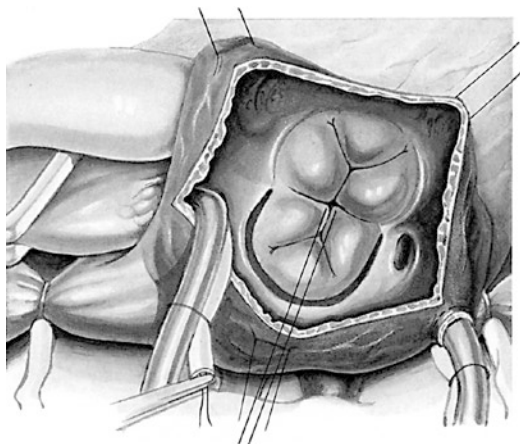

The right atrium is opened in the same manner as described for the correction of partial AVSDs. Following right atriotomy, four stay sutures are placed on the anterior and posterior edges of the atrial incision, and a small vent catheter is placed in the left atrium so that the anatomy can be evaluated. Next, the VSD is visualized, including the anterior and posterior VSD–annulus relations, to identify the extent of VSD repair necessary. The common atrioventricular valve is evaluated after injection of cold sterile saline solution into the left ventricle to recognize the ideal coaptation of the left components of the anterior and posterior bridging leaflet. To anticipate the cleft closure, a marking suture is placed at the base of

the cleft. Asymmetric apposition of the leaflets should be avoided because this can lead to postoperative incompetence of the left AV valve. The deepest part of the cleft at the valve leaflet free margin is identified by bringing together the bridging leaflets at the point of the first chordal attachments to the free margins. The extent of the cleft closure is indicated by marking sutures placed along the facing margins of the anterior and posterior bridging leaflet (■ Fig. 12.26).

When the leaflets are undivided, an attempt is made to place more leaflet tissue on the side of the left AV valve. If leaflets are naturally divided, this usually determines the size of the new anterior left AV valve leaflet (■ Fig. 12.27a).

When the leaflet anatomy has been identified and marking sutures have been placed on the base point of the AV valve cleft, the ventricular septal defect is closed with multiple interrupted felted mattress sutures or with continuous sutures placed on the right ventricular side of the VSD. Usually six to eight single sutures are necessary (■ Fig. 12.27b). These sutures should be placed further from the crest at the posterior end of the VSD to avoid injury to the conduction tissue. A scalloped Dacron patch (or alternatively a pericardial or Gore-Tex patch) is trimmed to make it slightly smaller than the VSD. This reduces the size of the dilated anulus and therefore may help to reduce the incidence of AV valve incompetence newly occurring after the repair (Suzuki and Fukuda 2002).

When fashioning the VSD patch, the height should be chosen to maintain the valve leaflets

■ Fig. 12.26 Closure of a total atrioventricular septal defect using a double-patch technique

close to their native and systole position and so that they are separated from the left ventricular outflow tract by the short anterior end of the patch (Van Arsdell et al. 1995). The stitches are pulled tight so that the right side of the patch is firmly fixed to the ventricular septum.

After the VSD patch is secured, 6-0 or 5-0 monofilament nonabsorbable sutures are passed through the upper rim of the VSD patch and then through the adjacent AV valve leaflets using the previously placed marking sutures as a guide. Thus, the separation is achieved, enabling a left and right AV valve to be formed (■ Fig. 12.27c, d). The cleft in the new anterior left AV valve leaflet is closed completely up to the insertion point of the primary chordae at the leaflets edges, using interrupted fine monofilament nonabsorbable sutures. The valve size is measured with a Hegar dilator and compared with the age-dependent normal diameter to avoid AV valve stenosis (Rowlatt et al. 1963). If the newly created orifice is too small, a few of the sutures at the free margin of the valve that were placed for cleft closure can be removed, although we consider a diameter of 1–2 mm smaller than the normal age-related orifice diameter to be acceptable (Rowlatt et al. 1963). Valve competence is tested by filling the left ventricle with saline. If there is residual insufficiency, additional anuloplasty sutures are necessary, with the position of the anuloplasty determined by the direction of the insufficiency jet (Spray 2004). It may be necessary to tolerate slight residual insufficiency. Although incomplete cleft closure has to be tolerated in cases of small orifices with complete closure, these patients are at a higher risk for reoperation for left AV valve regurgitation in medium-term follow-up (Alexi-Meskishvili et al. 1997).

Next, the ASD is closed according to the technique described in the section on partial AVSDs (■ Fig. 12.27e). The right atrium is then closed and after de-airing of the heart the aortic clamp is released.

Only in patients with a risk of developing a critical elevation of pulmonary vascular resistance postoperatively do we place a left atrial pressure measurement catheter through the sulcus interatrialis at the level of the right upper pulmonary vein and a pulmonary arterial pressure measurement catheter through the right ventricular outflow tract. Others routinely place left atrial catheters postoperatively in any AVSD patient.

Transesophageal contrast echocardiography is performed to evaluate cardiac function, residual shunt flow, and atrioventricular valve function. Using careful intracardiac evaluation

and meticulous technical repair, it is, in our experience, rarely necessary to reestablish extracorporeal circulation to perform a further correction.

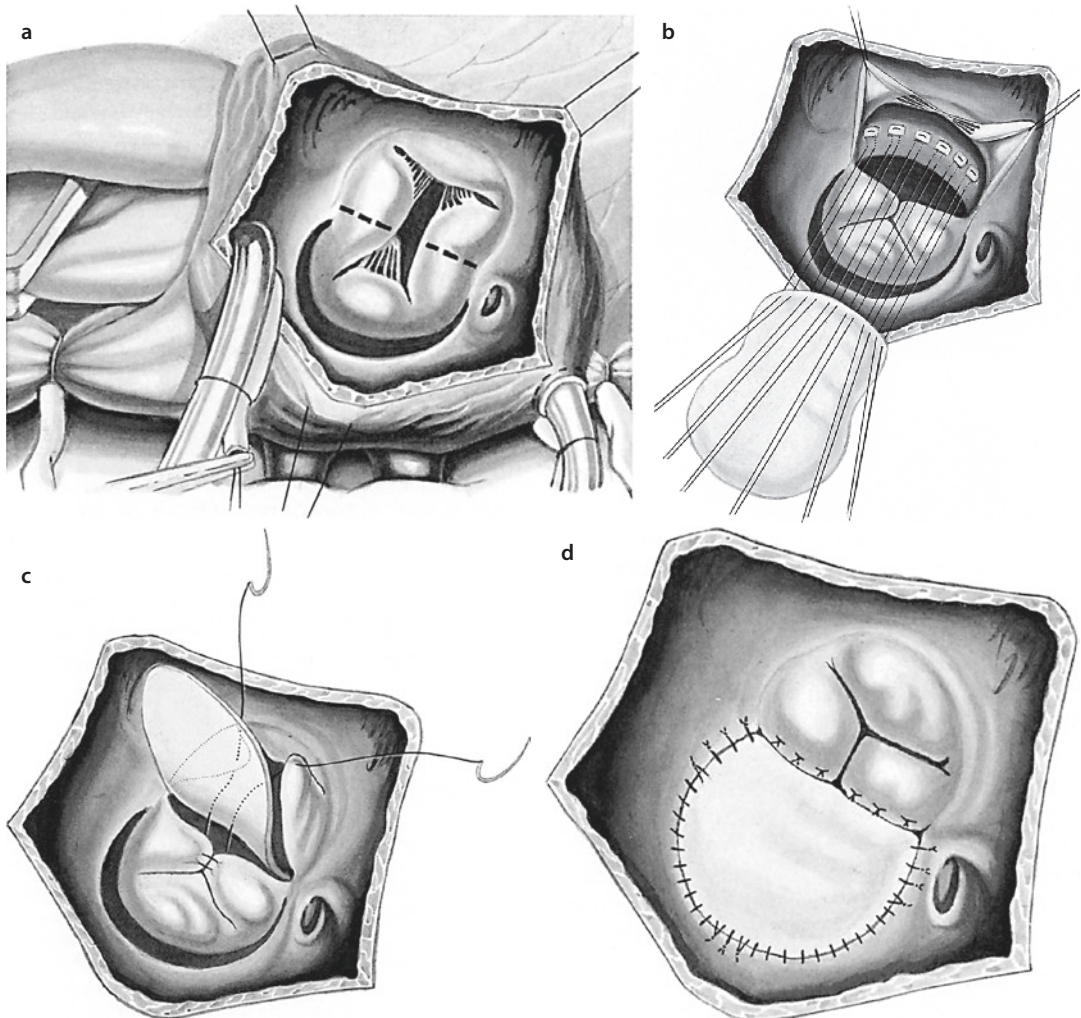

■ Fig. 12.27 Closure of a total atrioventricular septal defect using a double-patch technique

■ ■ Repair of complete AVSD with single-patch technique

The original single-patch technique for correction of the total AVSD was described by the group from Mayo Clinic (Rastelli et al. 1968a). This technique was favored by Aldo Castaneda also and found again more recent appreciation (Crawford 2007; Reddy and McElhinney 1997). It is described shortly below (■ Fig. 12.28).

A single pericardial patch, harvested at the beginning of surgery and fixed in glutaraldehyde (0.1–0.6%), is used to repair the entire septal defect. After aortic cross-clamping and cardioplegia administration, the right atriotomy is performed as described above. The valve leaflets are inspected after infusion of 20-mm cold saline into

the left ventricle with a small catheter. Because the superior and inferior bridging leaflets of the common AV valve must be completely divided in the single-patch technique, it is very important that the point of apposition of these leaflets be identified and marked with fine stay sutures. Once the line of division has been planned, the superior and inferior bridging leaflets are divided, therefore becoming part of the left and right AV valves. After division of the leaflets, the underlying ventricular septal defect can be seen. All chordae tendineae attaching to the free edge of the leaflets should be preserved as far as possible. The interventricular component of the defect is first closed with interrupted pledget-supported 5-0 nonabsorbable sutures or continuous 5-0 polypropylene sutures.

■ Fig. 12.28 a–d Closure of an atrioventricular septal defect using single-patch technique

When the level of the AV valve orifice is reached, the divided valve leaflets are sewn to the patch with interrupted nonabsorbable doubly pledget-supported sutures. The level of reattachment of the leaflets to the patch should be chosen rather lower than too high. Closure of the cleft in the newly created left AV valve is performed with interrupted 5-0, 6-0, or 7-0 polypropylene sutures, which are placed up to the first-order chordae tendineae when closure is complete. The cleft can be also closed before reattachment of the leaflets to the patch. It can even be closed before the superior leaflet is divided for this technique. In circumstances in which complete closure would result in a restrictive valve orifice, fewer sutures are placed (partial closure). The newly created left AV valve is tested by injecting saline into the left ventricle. If necessary, anuloplasty is performed. After resuspension and adjustment of the leaflets, the pericardial patch is used to close the atrial component of the septal defect (including the secundum defect, when present) with a running 5-0 polypropylene suture so that the coronary sinus orifice comes to lie in the right atrium. The right atrium is closed and the operation is completed in the usual manner.

■ ■ Repair of complete AVSD with modified single-patch technique

When the modified single-patch technique is used (Bender et al. 1982; Nicholson et al. 1999; Wilcox et al. 2004), the VSD is closed directly using multiple interrupted mattress sutures. Teflon-butressed 5-0 sutures are placed from the right side of the interventricular septal crest and passed through the bridging leaflet of the common AV valve, through one edge of the autologous pericardial patch—to close the atrial septal defect—and finally through a thin strip of Dacron or pericardium. These sutures are then tied down to close the ventricular septal defect. The length of Dacron or pericardial strip must be shorter than the septal crest, so that suture tying results in a central anuloplasty of the common orifice and ensures that adequate leaflet tissue is available for coaptation of the leaflets. If the central leaflets are naturally divided rather than bridging, the sutures are passed from the septal crest through the edge of the leaflets on each side of the septum (creating a bridging leaflet) and then through pericardium or Dacron as described above (Nunn 2007). The remainder of the AVSD repair is conducted as described for single-patch repair.

12.1.5.7 Important Technical Comments for AVSD repair

To avoid injury to the conduction system, some surgeons used alternative techniques for ASD closure. The suture line can be placed outside the coronary sinus so that this opens under the patch into the left atrium leading to a mandatory right-to-left shunt. If a left upper vena cava leading into the coronary sinus is present, this technique cannot be used. If the coronary sinus is unroofed, the defect should be closed through the left atrium. If there is a prominent left upper vena cava leading into the coronary sinus, patch closure of the ASD by the technique described above means that the coronary sinus and the left upper vena cava lead into the right atrium. A left upper vena cava is treated in the manner described in the section on anomalies of the caval veins (12.1.3).

In about 10% of partial, intermediate, or total AVSD, additional AV valve abnormalities may complicate the surgical procedure. Most often a double orifice of the left AV valve («double-orifice mitral valve») and a potential parachute valve, which is caused by fusion of the papillary muscles to form a single papillary muscle, are found (Ilbawi et al. 1983). In addition to a left open cleft or a reopening cleft, these additional abnormalities lead to postoperative incompetence of the AV valve and result in the need for reoperation following AVSD correction (Alexi-Meskishvili et al. 1996, 1997; Nakano et al. 2002). Sometimes there is more than one additional anomaly of a valve (Bano-Rodriges et al. 1988). If there is a double-orifice valve, the main orifice is often associated with a cleft formation supported by both papillary muscles, while the second orifice, which lies in the posteromedial portion of the left AV valve, is usually supported by only one papillary muscle. This prevents the normal excursion of the leaflet during the diastole (Manning 2007). Separation of the bridging leaflet tissue must be avoided to prevent floating and prolapsing of the central segment of the valve, which would lead to severe postcorrection valve insufficiency (Lee et al. 1985; Manning 2007). If there is a cleft in the true orifice, it should be closed up to the point on the edge of the leaflet where the chordae tendineae support the leaflet. In patients with a narrow mural valve portion and when complete cleft closure would significantly reduce the true opening area, closure of the cleft must remain partial. In such situations some surgeons accept a true

opening area of a minimum of 80 % of the normal value (Nakano et al. 2002; Rowlatt et al. 1963). When an accessory mitral valve orifice is well supported by chordae and does not cause incompetence, it may be left as it is (Lee et al. 1985; Nakano et al. 2002; Schaff 1982). In these cases, the cleft of the true opening may be completely closed to achieve complete valve competence, even if now the true orifice becomes stenotic. The second, double orifice would compensate for this.

When there is only a single left ventricular papillary muscle, this potentially leads to a stenotic parachute valve, which represents a considerable challenge for the AVSD correction procedure. This situation should be distinguished from pathologies in which one of the papillary muscles is hyperplastic. In single papillary muscle, anatomical complete closure of the cleft carries the risk of producing a significant mitral valve stenosis. In such situations the division of a single papillary muscle and partial cleft closure, without creating a stenosis, represent an acceptable compromise (David et al. 1982; Litwin et al. 2007; Manning 2007).

If tetralogy of Fallot is present, the anterior edge of the patch used to close the VSD must be much wider and reach far enough to the right to completely subsume the overriding aortic root and prevent narrowing of the subaortic area (Ilbawi et al. 1990). When applying a single-patch technique for complete AVSD repair in TOF, the superior bridging leaflet has to be divided more anteriorly to prevent subaortic stenosis and/or increased risk for patch dehiscence.

12.1.5.8 Patients with AVSD and Small Left Ventricle

Surgical correction of a partial or complete AVSD in patients with a preoperatively identified small left ventricle poses a challenge for cardiac surgeons, in particular in terms of the choice of surgical strategy (Apitz et al. 2009). There are as yet no proven guidelines for deciding between biventricular correction and univentricular palliation (Cohen and Stevenson 2007). These authors reported on a large group of patients with unbalanced AVSD, in whom they used echocardiographic measurement of the atrioventricular valve index (AVVI). This parameter is the left valve area divided by the right valve area. The authors suggested that only patients with AVVI >0.67 (symmetrical) can safely undergo biventricular repair. Further, it

was hypothesized that right ventricle volume overload results in right-to-left septal bowing and contributes to the presence of a hypoplastic left ventricle, which can actually accommodate a greater potential volume (Phoon and Silverman 1997). Hence, surgical decision-making depends not only on the AVVI but also on the absolute left ventricular volume and the potentially tolerated total volume. However, the definition of ventricular hypoplasia to be determined preoperatively remains unclear, since the main criteria used so far apply to small left ventricles in other clinical conditions (Phoon and Silverman 1997; Van Son et al. 1997).

At our institution we have developed a guideline for the choice of surgical strategy based on the relationship between the long axis of the left ventricle and the long axis of the right ventricle (LV/RV long axis ratio) (Delmo Walter et al. 2008). A small left ventricle is defined on the basis of angiographic measurements when the LV/RV long axis ratio is smaller than 1.1. The ventricular axis lengths were measured in the plane in which the left and right AV valve reach a position in one plane with their respective apices during ventriculography (■ Fig. 12.29).

In our experience, 16 patients with an LV/RV value of >0.65 (mean 0.80 ± 11) underwent successful biventricular correction of the defect. In two out of three patients with severe left ventricular hypoplasia (LV/RV value of 0.45, 0.60, and 0.62, respectively), weaning from cardiopulmonary bypass was not possible. Two of them (LV/RV value of 0.45 and 0.60) died on the 8th and 11th postoperative day, respectively, despite mechanical circulatory support. The third patient (LV/RV of 0.62) needed postoperative extracorporeal membrane oxygenation due to myocardial failure and successfully underwent heart transplantation on the 21st postoperative day.

Our experience demonstrates that the size of the left ventricle in total AVSD should not be considered absolute and that the left ventricle has the potential to increase to a size sufficient to support the systemic circulation. In this regard it was surprising that preoperatively the volume-overloaded right ventricle can compress the already small left ventricle. Further, it was notable that after surgical correction of the total AVSD, primarily because of reversal of septal deviation, the left ventricle is allowed to attain its full status as a ventricle.

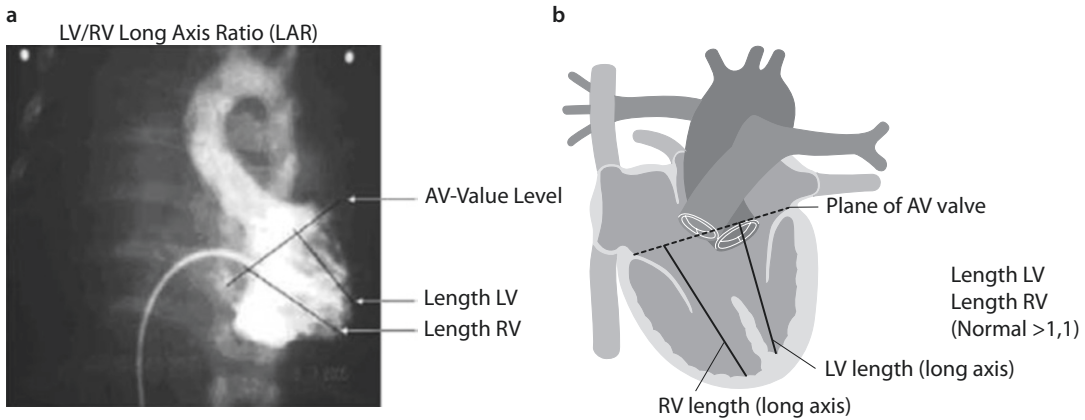

Fig. 12.29 a, b Measurements of LV-to-RV long axis ratio (LAR) where ventricular lengths were obtained by measuring the distance in the plane in which the left AV valve and right AV valve are on the same level as their respective apices. The relation of the left to the right side is determined (normal: >1.1)

The presence of a small left ventricle (with LV/RV value of as low as 0.66) did not preclude successful biventricular repair. However, a value of under 0.65 in the preoperative angiogram was clearly a predictor of myocardial failure. In such a case a univentricular surgical strategy should be followed (Drinkwater and Laks 1997).

Although our findings cannot be compared directly with those of Cohen and Rychik (1999), we agree that the true LV size may be misleading. Our series suggest that the size of the left ventricle may be influenced by surgical manipulation. The key parameter is the relationship between the long axes, since this value is independent of septal deviation. Further, this parameter is not only simple to obtain but probably also far better than volumetry with its complex measurements.

12.1.5.9 Results of AVSD Repair

Complete correction of a complete AVSD remains a challenging operation (Kaza et al. 2011). In recent years there have been many modifications in the surgical technique and different approaches to the AV valve, and many centers have reported low early and late postoperative mortality. Nevertheless, left AV valve incompetence remains the main cause of postoperative mortality and morbidity and is the most frequent indication for reoperations, which are necessary in 10% of cases (Ando and Takahashi 2011; Patel et al. 2012; Permut and Mehta 1997). The incidence of severe preoperative left AV valve incompetence is rare. However, in some series a higher incidence of preoperative left AV incompetence was noted

in patients with partial AVSD than in those with complete AVSD. This phenomenon can partially be explained by the fact that a higher incidence of additional anomalies of the left AV valve morphology is observed in patients with partial AVSD than in patients with complete AVSD.

Han and colleagues (1995) found that the overall increase of valve incompetence in patients after correction of partial AVSD correlated to an increase in mild regurgitation. There is a tendency toward an increase in moderate regurgitation and no change in the group with severe regurgitation. The incidence of reoperations for significant left AV valve incompetence after correction of various types of AVSD ranges between 8 and 20% and seems to be higher in patients with unsutured cleft or additional valve anomalies (Alexi-Meskishvili et al. 1997; Nakano et al. 2002; Hooehenkerk et al. 2012).

There is no single or ideal procedure for correcting residual AV valve incompetence if the cause is other than open cleft. Various surgical techniques have been suggested, among others cleft closure or valve perforation suturing with or without different types of anuloplasty, triangular or quadrangular leaflet resection, chordal shortening, or resection of secondary chords and plication of redundant leaflets; the number of variations reflects the complexity of the problem.

Valve replacement during initial surgery for AVSD is rarely necessary, although the presence of severe valve anomalies increases risk of recurrent valve incompetence and the subsequent need for valve replacement. Mitral valve replacement can be performed safely in adult patients, but in

infants and small children it can be a challenging procedure. Drawbacks of prosthetic valve replacement in children include the requirement of long-term anticoagulation, the potential of compromising annual growth and the necessity of repeat valve replacement as the child grows. Proposed techniques of valve replacement in small children include supra-anular implantation in cases of severe anular hypoplasia and enlargement of the mitral valve annulus after incision of the ventricular septal patch (Ando and Fraser 2001).

A further potential danger after AVSD repair is the development of an obstruction of the left ventricular outflow tract, which is observed in 2–10% of patients operated upon (Crawford 2007; Nunn 2007). The causes of this complication are intrinsic abnormalities of the left ventricular outflow tract. Elongation, anterior rightward displacement, and stenosis of the left ventricular outflow tract are present in most hearts with an AVSD and represent the anatomic cause of the «gooseneck» deformity. When these features are pronounced, tubular stenosis may occur. Excrescences of fibrous tissue related to the left AV valve and thickening of the fibrous tissue in the membranous portion of the septum may produce a discrete ridge within the left ventricular outflow tract. Other causes of obstruction include abnormal insertion of papillary muscles or chordae tendineae into the infundibular septum and dynamic obstruction by systolic anterior motion of the left AV valve into the left ventricular outflow tract (Shiokawa and Becker 1997). Significant left ventricular outflow tract obstruction after AVSD correction is regarded as present when the pressure gradient at rest is >40 mmHg, which then is considered an indication for reoperation (Permut and Mehta 1997).

Management of this complication must often incorporate a number of techniques (Van Arsdell et al. 1995). There are several basic surgical options to treat this complication (DeLeon et al. 1991; Starr and Hovaguimian 1994; Van Son et al. 1997):

- Resection of fibromuscular tissue
- Modified Konno procedure
- Detachment and resuspension of the left AV valve
- Implantation of an apico-aortic valve-bearing conduit

The choice of procedure depends on the specific etiology of the obstruction. The most frequent form of subaortic stenosis, which may occur many years after AVSD correction, remains, however, the typical fibromuscular («membranous») form, which generally does not cause more technical difficulties than any other fibromuscular SAS in the absence of AVSD.

12.1.5.10 Atrium commune

The term «common atrium» is used for malformations with complete absence of the atrial septum accompanied by anomalies of the atrioventricular valves and can be considered a variant of the AVSD (Jacobs et al. 2000a). In these cases surgical treatment consists of complete creation of the atrial septum with autologous pericardium or a synthetic patch. If coexisting anomalies of the caval or pulmonary veins are present, they are also treated appropriately. The term «single atrium» is reserved for atrial septal defects resulting virtually in one atrium; however, there are no anomalies of the atrioventricular valves present.

12.2 Congenital Heart Defects with Obstruction of the Left Ventricular Inflow Tract

12.2.1 Overview

This group of congenital heart defects functionally has an obstruction of the blood flow from the lung into the heart and embryologically shows anomalous drainage of the pulmonary veins into the true left atrium. These defects are classified according to their localization:

- Stenosis and atresia of one or more pulmonary veins
- Total anomalous pulmonary venous connection to the systemic venous system with or without obstruction
- Cor triatriatum

In addition to these developmentally related anomalies, the following also belong to the congenital heart defects with obstruction of the left ventricular inflow tract:

- Congenital mitral valve defects
- Supravalvular stenotic mitral ring

- Left atrial cardiac tumor, which mainly occurs as an atrial myxoma (see ► Chapter «Cardiac Tumors and Pericardial Diseases», Sect. 31.1.2.1).

The clinical symptoms presented by these heart defects are extremely similar. Two-dimensional echocardiography should be able to establish the diagnosis. Cardiac catheterization and cardio-angiography could help in determining the actual hemodynamics if desired.

In the interests of completeness and less to aid differential diagnosis, congenital diverticulum of the left atrium is included in this section.

12.2.2 Congenital Pulmonary Vein Stenosis

12.2.2.1 Introduction

Congenital pulmonary vein (PV) stenosis is a rare anomaly, accounting for only 0.4–0.6% of all congenital cardiac anomalies (Edwards 1960; Park et al. 1974; Aleksi-Meskishvili 1977; Latson and Prieto 2007). It may involve any or all pulmonary veins. The term pulmonary vein stenosis describes a variety of entities with variable clinical courses. The basic pathological process is fibrous intimal thickening, which can gradually cause obliteration of the lumen of the pulmonary veins at the atrial junction. In its most severe form, congenital pulmonary vein stenosis is a progressive disease with rapid development of pulmonary hypertension and rare survival beyond the first year of life. It may not be found immediately after birth but develops within the first 6 months of life to clinical significance. Surgical intervention has not been successful in this group. Other forms of pulmonary vein stenosis, including unilateral types associated with further congenital heart defects, may be managed by various surgical procedures or in some cases by pneumonectomy. The pulmonary venous stenosis that can develop following radio-frequency ablation to correct atrial fibrillation is an iatrogenic complication (Saad et al. 2003).

Although multiple direct surgical techniques have been described for the repair of congenital pulmonary vein stenosis, the «sutureless» techniques are also important (Caldarone et al. 1998; Lacour-Gayet et al. 1996).

Often coexisting congenital pulmonary venous stenosis is an incidental finding during correction

of other congenital anomalies (Ito et al. 2001). Different surgical techniques have been used to correct congenital or acquired pulmonary vein stenosis in pediatric patients, but the success of the treatment was limited (Sakamoto et al. 1995; Spray and Bridges 1999). The problem with the proposed techniques of patch repair in small children and infants is partially related to the fact that minor geometric changes in small patients can have critical effects on the low-pressure system, in which the flow is high, resulting in turbulence, intimal hyperplasia, or kinking of the patch repair causing additional venous obstruction. Sutureless techniques proposed in the late 1990s, on the other hand, allow hemodynamically optimal correction (Azakie et al. 2011; Caldarone et al. 1998; Lacour-Gayet et al. 1996, 1999; Yanagawa et al. 2011). The patients with involvement of all pulmonary veins have a uniformly poor prognosis due to progressive pulmonary vascular disease and are candidates for heart–lung transplantation (Mendelhof et al. 1995; Spray and Bridges 1999).

Clearly no single-treatment algorithm can be applied in all cases. Congenital pulmonary venous stenosis is often an isolated lesion, but it may coexist with total anomalous pulmonary vein connection, complete transposition of the great arteries, a ventricular septal defect, or other anomalies (Van Son et al. 1995a).

12.2.2.2 Embryology

Congenital pulmonary venous stenosis has an embryologic relation with total anomalous pulmonary vein connection and cor triatriatum. Despite this embryologic relation, co-occurrence of congenital pulmonary venous stenosis and cor triatriatum is extremely rare (Sade et al. 1974). In the 3-mm large embryo, a diverticulum has formed that in the future will develop into the left atrial portion of the sinoatrial region. The diverticulum, or common pulmonary vein, grows toward the developing lungs and ultimately connects with the pulmonary veins, which have already formed. When this drainage pathway is established, the early connection between the splanchnic plexus and the umbilicovitelline and cardinal venous systems becomes of secondary importance and is largely lost. As the left atrium rapidly grows, the common pulmonary vein is absorbed into the posterior atrial wall, and the pulmonary veins enter the left atrium individually. A variety of obstructive lesions of the pulmonary venous drainage may

occur, depending upon the stage at which normal embryogenesis is interrupted. If atresia of the common pulmonary vein occurs very early, a major drainage route can be established through either the umbilical or cardinal venous system and lead to total anomalous pulmonary vein connection of the infracardiac or supracardiac type. If the stenosis occurs at a later stage, the result may be stenosis of the common pulmonary vein (cor triatriatum). If stenosis occurs at a very late stage, after absorption of the common pulmonary vein into the posterior left atrial wall, the result will be stenosis or atresia of an individual pulmonary vein. Further, pulmonary vein stenosis may occur on a physiological basis in patients with cor triatriatum due to restriction of flow from the chamber containing the pulmonary veins to the chamber containing the mitral valve.

12.2.2.3 Clinical Presentation

The clinical presentation of congenital pulmonary venous stenosis resembles that seen with all the other lesions that produce *pulmonary venous hypertension*. The prognosis is poor, particularly if all pulmonary veins are affected. Although progression of symptoms may be less rapid if only one or two pulmonary veins are involved, progression to bilateral pulmonary vascular disease leading to death is usually the rule, even in initially less severe cases (Edwards 1960; Lacour-Gayet 2006; Sade et al. 1974; Spray and Bridges 1999). Two-dimensional echocardiography with pulse Doppler examination and color-coded flow imaging provides a reliable method for identifying and localizing the pulmonary venous obstruction and determining its degree (Van Son et al. 1995a, b).

12.2.2.4 History

The first surgical correction of congenital pulmonary stenosis was reported by Kawashima in 1971 (Kawashima et al. 1971). Correction later in the life may be successful in removing a localized venous obstruction (Binet et al. 1972; Kawashima et al. 1971). In subsequent studies, high early and late mortality rates have been reported (Binet et al. 1972; Pacifico et al. 1985).

12.2.2.5 Surgical Procedures

The surgical approach to pulmonary vein stenosis must be flexible, and the correctional technique will depend on the local anatomy of each lesion. Those of the membranous type, as

described in a report on pulmonary vein stenosis after TAPVD repair, can be treated effectively by excision of the obstruction (Lacour-Gayet 2006). Initially, increase of the vein caliber can be effectively achieved by patch angioplasty. Whenever possible the use of artificial or allograft patches should be avoided, as they may induce neointimal formation with increased need for reoperation (Van Son et al. 1995a, b). When segmental stenosis or atresia is present, the technique described by Pacifico for the removal of pulmonary venous obstructions using either atrial wall or atrial septal tissue may be useful (Pacifico et al. 1985).

The surgical method of treatment for congenital and acquired pulmonary venous stenosis is described in detail in the section dedicated to total anomalous pulmonary venous drainage.

Histologically, the membrane that may be removed from the orifices of the pulmonary veins shows intimal fibrous thickening without cell infiltration and therefore no evidence of active inflammation (Reye 1951).

12.2.3 Cor Triatriatum Sinistrum

12.2.3.1 Introduction

Cor triatriatum is a rare congenital cardiac anomaly and represents 0.1% of all congenital cardiac malformations. It is associated with other cardiac defects in up to 50% of cases, for example, with (Löffler 1949; Marin-Garcia et al. 1975; Cooley and Murphy 1990; Masayaoshi et al. 2001; Oelert et al. 1973; Oglietti et al. 1983; Pirc et al. 1996; Richardson et al. 1981; Rodefeld et al. 1990; Sethia et al. 1988):

- Transposition of the great arteries
- Tetralogy of Fallot
- Atrioventricular canal defects
- Anomalous pulmonary venous drainage
- Tricuspid atresia
- Aortic isthmus stenosis
- Ebstein's anomaly
- Persistent ductus arteriosus Botalli

Surgery is the treatment of choice. Indications for emergency surgery in small infants are signs of cardiac failure with pulmonary and systemic congestion. In older children and adults, surgery is performed electively.

12.2.3.2 History

While the classical pathoanatomical features were already described in detail by Church 1867/1868, it was Max Borst in 1905 who presented a specimen using the term *cor triatriatum* (Borst 1905). The first anatomical classification, proposed by Löffler in 1949, was extended by Edwards in 1960. *Cor triatriatum* was successfully corrected for the first time by Lillehei in 1955 (Jorgensen et al. 1967; Vineberg and Gialloreto 1956).

12.2.3.3 Surgical Anatomy

Embryologically this condition arises through defective incorporation of the four pulmonary veins into the posterior left atrial wall (Steen et al. 2007). In its most common form, *cor triatriatum sinister*, the left atrium is divided into a proximal and a distal chamber. The two chambers are separated by a diaphragm with one or more restrictive ostia. The pulmonary veins drain into the proximal chamber, and when the openings are small, functional pulmonary venous stenosis results.

Variable types of subtotal *cor triatriatum* also exist, with only one right or one left pulmonary vein draining into the proximal chamber (■ Fig. 12.30) (Van Praagh and Corsini 1969). The clinical course of untreated *cor triatriatum sinister* depends on the effective opening area in the diaphragm and on the presence and location of an ASD as a decompression outlet for the left atrium. Three quarters of patients with severe obstruction die in infancy (Brown and Hanish 2003).

The *location of the atrial appendage* is a key characteristic of this congenital malformation and differentiates *cor triatriatum* from a similar condition, supralvalvular mitral valve stenosis. In *cor triatriatum*, the left atrial appendage is invariably found in the same chamber as the mitral valve ring, proximal to the dividing atrial membrane, i.e., in the «low-pressure» compartment. The classification by Lucas et al. (1961) includes eight main types of *cor triatriatum sinister* and is based on the relation of obstructive membrane to the atria and the atrial septal defects.

■ Fig. 12.30 a–f Types of *cor triatriatum sinister* with the different connections between the atria: intracardial a–e and extracardial f

12.2.3.4 Clinical Presentation

The degree of severity of the disease depends on the number and size of the orifices in the membrane between the upper and lower atrial portion. Whereas a severe obstruction unavoidably leads to pulmonary hypertension and right-sided heart failure, the anomaly may be accompanied by only moderate or even absent pressure gradients and a lack of clinical symptoms, and it may even be discovered only by chance. The clinical presentation of cor triatriatum is characterized by blood congestion in the pulmonary circulation, which is deceptively similar to that of congenital mitral valve stenosis. The final diagnosis is made by echocardiography. Additional cardiac catheterization is indicated at least beyond infancy to evaluate secondary pulmonary vascular obstructive disease.

12.2.3.5 Surgical Techniques

■ ■ Introduction

Symptomatic patients and patients with elevated pulmonary artery pressure need their obstruction to be taken care of. Although interventional catheterization techniques have been developed and have been used successfully in some patients (Huang et al. 2002), open surgical correction is currently preferred. In asymptomatic patients with normal pulmonary arterial pressure routine, echocardiographic observation is recommended (Alphonso et al. 2005; Steen et al. 2007). The procedure is performed on cardiopulmonary bypass and in cardioplegic cardiac arrest. Deep hypothermic circulatory arrest may be used in neonates and small infants. First successful operative treatment was performed by Vineberg on July 15, 1954 (Vineberg and Gialoreto 1956). Surgery offers good early and long-term results both for the isolated anomaly and also for those occurring in association with other congenital heart defects (Alexi-Meskishvili et al. 2000; Alphonso et al. 2005; Croti et al. 2003).

The surgical treatment involves *complete resection of the obstructive membrane* between the distal and proximal chambers in the left atrium performed through the atrial septal defect, which is enlarged for the purpose by an incision in the atrial septum. All pulmonary veins should be carefully identified. The atrial septal defect is closed with a pericardial patch. Alternatively, in older patients with a dilated left atrium, a left

atriotomy can be used. In some cases of coexisting complex cardiac anomalies, deep hypothermia and circulatory arrest can be used to allow complete repair (Alphonso et al. 2005).

■ ■ Operation through the right atrium and the atrial septum

Transatrioseptal access through the right atrium is suitable mainly in infants and small children and in older patients when there is, in addition, a large atrial septal defect. Cannulation of the upper and lower vena cava is performed in such a manner that a broad portion of the atrial wall remains free for the atriotomy. Opening of the right atrium is performed parallel and close to the atrioventricular groove: the retractor is positioned in the atrial wall, and the atrial septum is incised from the upper edge of the interatrial communication in the direction of the right upper pulmonary vein (■ Fig. 12.31a). Then the direction of incision is reversed, and the caudal atrial septum is opened, which exposes not only the actual left atrium but also the insertion edge of the separating membrane at the atrial septum. The retractor is switched to the atrial septum, and the relationship of the membrane to the mitral valve, on the one hand, and to the left pulmonary veins, on the other hand, is evaluated. After the surgeon has checked that all four pulmonary veins drain normally, the membrane is excised directly along the attachment margin (■ Fig. 12.31b). Direct vision of the entire mitral valve is not always possible from the beginning. However, as the membrane resection continues, the valve becomes more easily visible, which is particularly important where the membrane runs very close to the valve, in posterolateral direction (■ Fig. 12.31c).

Resection of the triatrial membrane in trans-right-atrial approach begins at the septal attachment and proceeds in anterior and posterior direction. The resection may be most difficult along the lateral left atrial wall, where it is vital to ensure that neither the mitral valve nor the entry of the left lower pulmonary vein into the left atrium is injured. In this area the depth of the excision is also difficult to gauge, and occasionally perforation of the free posterior wall of the left atrium or the coronary sinus may occur. Sometimes such injuries, which have to be sutured, are not to be avoided, when through complete excision of the membrane unhindered blood flow from the

pulmonary veins to the mitral valve needs to be guaranteed. Once it has been established that the left atrial wall and the mitral valve are intact, the atrial septum is closed by direct suturing or by implantation of a pericardial or synthetic patch that is anchored with a continuous suture (4-0 polypropylene) (■ Fig. 12.31d). In patch closure the suture begins at the lowest point of the atrial septal defect. From there it is taken in clockwise direction along the right lateral edge and then anticlockwise along the left lateral edge of the atrial septum in cranial direction and is knotted at the meeting point below the upper vena cava entry. Finally, the right atrial incision is directly closed with a continuous suture (4-0 polypropylene). The heart is routinely de-aired under partial bypass, and the aortic cross-clamp is released to restore coronary perfusion. Once normothermia has been reached, the patient is weaned from the extracorporeal circulation as per usual.

■ ■ Operation through the left atrium

In older children and adults, the intra-atrial membrane in cor triatriatum may alternatively be accessed through the pulmonary vein sinus, i.e., through the cranially positioned accessory left atrium. The incision is made to the right of and posterior to the interatrial sulcus. After broad opening a small hook is inserted into the atrial wall so that the membrane, with its usually central perforation, can be seen. Only the four entries of the pulmonary veins are visible, whereas the atrial appendage, which is normally visible in the left atrium, and the mitral valve cannot be seen. This lack of information concerning the exact position of the true left atrium and its demarcation in relation to the interatrial membrane as well as the interatrial septum is a serious disadvantage of this access approach. A possibly present atrial communication is not always to be seen from this approach.

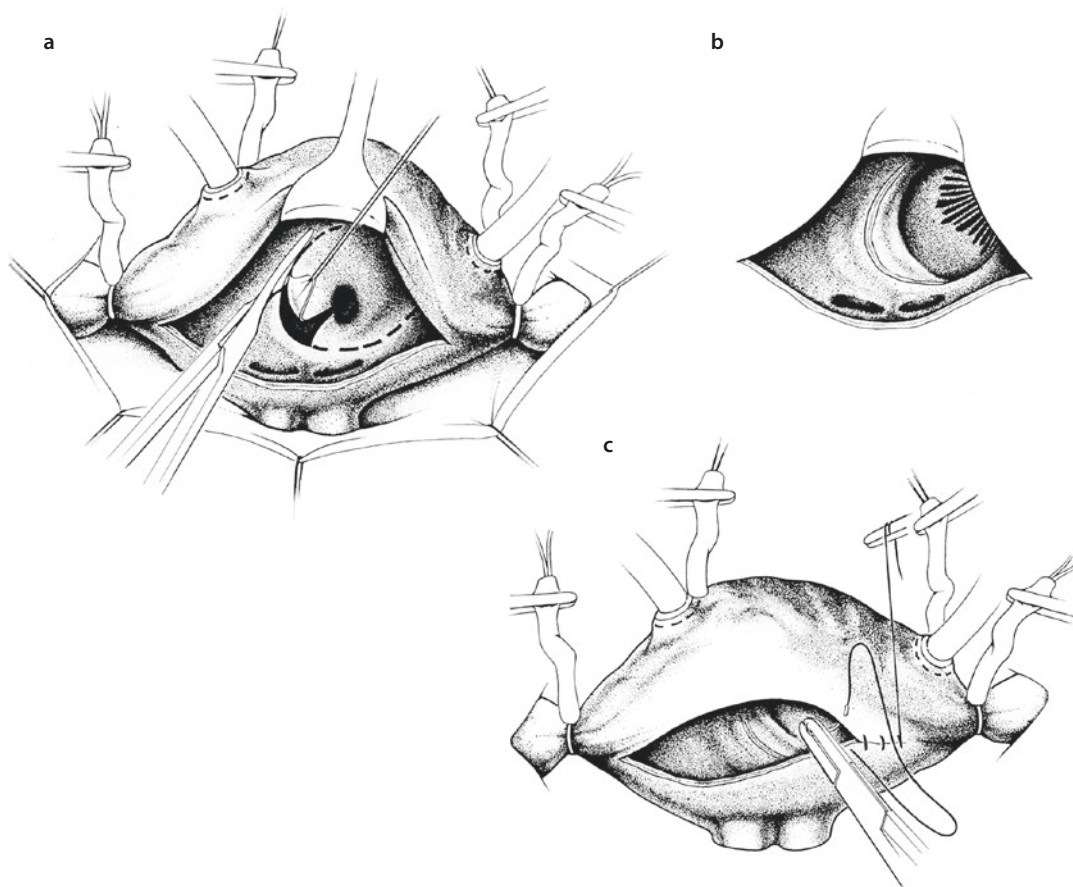

■ Fig. 12.31 a–d Cor triatriatum: operation through the right atrium and the atrial septum. a Incision of the atrial septum along the upper edge of the foramen ovale in the direction of the right upper pulmonary vein. b After visual inspection of both atrial portions, membrane excision is begun along the upper and posterior attachment margin. c Once the membrane is excised, the mitral valve becomes visible and is inspected to make sure it is intact. d Closure of the remaining communication between the atria with a synthetic or pericardial patch

The left transatrial access should be used only in large hearts in which it does not negatively affect the success of the corrective procedure.

Resection of the membrane through a left atrial incision should only be performed on the relaxed cardioplegic heart. It begins with an incision leading from the perforation opening to the right upper pulmonary vein (■ Fig. 12.32a). As soon as the incised membrane can be retracted to reveal the mitral valve, the resection may be continued without major risk. At the left attachment margin, it is necessary to take into consideration the close proximity of the left pulmonary vein to the mitral valve. As excision of the membrane continues,

perforation of the free wall of the left atrium between these two structures is to be avoided. If such an injury appears, it must be closed by direct suture. Not until the membrane is completely excised is the unobstructed connection between the pulmonary veins and the mitral valve, which is usually normally developed, completed (■ Fig. 12.32b). If present, the atrial septal defect is corrected through the same access before the operation is completed by closure of the atrial incision with a continuous over-and-over suture (■ Fig. 12.32c). The suture begins at the caudal incision edge, taking in the anterior atrial flap, tangentially the endocardium below the incision, and lastly the posterior atrial flap, and, after knotting, continues in cranial direction to the middle of the incision. A similar suture is placed from the upper incision edge in the opposite direction and,

■ Fig. 12.32 a–c Cor triatriatum sinistrum: operation through the left atrium. a Excision of the membrane dividing the left atrium starting from the central perforation and proceeding along the attachment margin. b After complete membrane excision, the two parts of the left atrium are connected, and blood flow to the mitral valve is unhindered. c Direct closure of the left atrium by continuous suture

after de-airing of the atrium by inflation of the lung, is knotted with the lower row of sutures. Release of the aortic cross-clamp after de-airing of the heart and weaning of the patient from the heart–lung machine in normothermia are then routine procedures.

■ ■ Operation for complete division of the left atrium

If the accessory left atrium is completely divided from the actual left atrium by an unperforated membrane (see ■ Fig. 12.30d) but has a connection to the right atrium, the correction is best performed by transatrioseptal access through the right atrium. Here the membrane is also excised, beginning at its caudal edge, which is attached to the inferior rim of the atrial septal defect. To enable visual inspection, the atrial septal defect is first enlarged in caudal direction (see ■ Fig. 12.31a). At the same time, this also opens the actual left atrium and allows the surgeon to assess the extent of the membrane. This is then entirely excised (see ■ Fig. 12.31b, c), and finally the remaining large atrial septal defect is closed with a pericardial or synthetic patch (see ■ Fig. 12.31d). The procedure is completed by direct closure of the right atrial incision with a continuous monofilament suture.

12.2.3.6 Complications and Their Avoidance

The most frequent complication is *injury to the posterior left atrial wall* between the mitral valve and the entry of the left lower pulmonary vein. Such injury cannot always be avoided during complete excision of the triatrial membrane and in principle is not dangerous as long as it is recognized and the damage is repaired by direct suturing.

When operated upon timely, surgical results are very good. Persistent *pulmonary hypertension*—especially in the early postoperative period—can negatively affect, especially prolong, the postoperative course.

12.2.4 Supravalvular Stenotic Mitral Ring

12.2.4.1 Introduction

This defect is formed by a circular ridge of endocardial tissue that is attached to the anterior leaflet of the mitral valve below its insertion on the anulus. Varying degrees of stenosis exist,

depending on the diameter of the ring. Usually the valve itself is abnormal, and frequently it is stenotic or hypoplastic. In many cases this lesion is associated with other *stenotic lesions* such as:

- Parachute valve
- Hammock valve
- Papillary muscle fusion
- Double-orifice mitral valve

Supravalvar, or subvalvar where applicable mitral ring must be differentiated from cor triatriatum. In both cor triatriatum and supravalvar mitral ring, the left atrium is divided into two compartments. In cor triatriatum, the distal, posterior compartment contains the pulmonary veins, while the anterior compartment contains the left atrial appendage and the mitral valve orifice. In supravalvular mitral ring, the posterior compartment contains the pulmonary veins *and* the left atrial appendage, while the anterior compartment contains only the mitral valve orifice.

12.2.4.2 History

The first case was described by Fisher (Cassano 1964; Fisher 1902). Shone and Edwards described a developmental complex of left-sided obstructions, consisting of a supravalvar mitral ring and a parachute mitral valve in addition to subaortic stenosis, ventricular septal defect, and coarctation of the aorta (Shone et al. 1963). Combinations with other congenital heart defects, mostly with coarctation of the aorta and a ventricular septal defect, have been reported (Srinivasan et al. 1980; Sullivan et al. 1986; Watraida et al. 1997). A parachute mitral valve is often associated with a supravalvular mitral ring (Banerjee et al. 1995). The first successful surgical correction was reported by Lynch and colleagues in 1962 in a 10-year-old girl with a coexisting ventricular septal defect (Lynch et al. 1962).

12.2.4.3 Surgical Procedure

Resection of the fibrous tissue taking care not to damage the anterior mitral valve leaflet is the procedure of choice. The ring is usually easily separated from the valve with the resection begun posteriorly and extended anteriorly. Only rarely is mitral valve replacement necessary. The operation is performed through a median sternotomy with standard extracorporeal circulation and cardiac arrest. The obstructive membrane/ring can be

■ **Fig. 12.33** a–c Supramitral ring. **a** Horseshoe-shaped supravalyvular mitral valve ring. Only in the area of the anterior commissure the stenotic effect of the membrane is less evident. **b** Excision of the supravalyvular stenotic mitral ring along its margin of attachment to the mitral annulus. **c** After total removal of the stenotic ring, the (usually intact) mitral valve is freely visible

resected through the left or right atrium after incision of the atrial septum.

12.2.4.4 Surgical Techniques

The operation always requires cardiopulmonary bypass and consists of complete resection of the supramitral ring, regardless of whether it consists of a ridge, a ring, or a membrane. Access is gained either through the right atrium and the atrial septum (especially when further intracardiac anomalies are present) or directly through the enlarged left atrium. Resection begins with incision of the superfluous anterosuperior tissue, which can then be relatively easily separated from the mitral annulus (■ Fig. 12.33). It should be possible to avoid injury to the mitral valve. Coexisting heart defects must be corrected at the same time. If the defect arose from acquired endocardial fibrosis and the mitral valve is therefore insufficient, the valve will need to be reconstructed so that the insufficiency does not increase postoperatively.

12.2.5 Total Anomalous Pulmonary Venous Connection

12.2.5.1 Introduction

The diagnosis of total anomalous pulmonary venous connection is made when all four pulmonary veins drain anomalously to the right atrium or to a tributary of the caval veins. This malformation is present in between 1 and 1.5% of all children with congenital heart disease. Although total anomalous pulmonary venous connection

(TAPVC) can be associated with other heart defects, especially in children with polysplenia, asplenia, or heterotaxy syndrome, we will mainly address isolated total anomalous pulmonary venous connection and its combination with other minor anomalies, such as patent ductus arteriosus Botalli or atrial septal defect.

12.2.5.2 Surgical Anatomy

Knowledge of the normal development of the pulmonary veins facilitates an understanding of how the various types of anomalous pulmonary venous drainage occur. Failure of the common pulmonary vein to connect with the pulmonary venous plexus leads to persistence of one or more venous connections to the right superior vena cava, to the left vertical vein/innominate vein, or to the umbilicovitaline vein/portal vein. Failure of the septum primum to form normally or abnormal septation of the sinus venosus can lead to direct connection of the pulmonary veins to the right atrium. Late obstruction of the common pulmonary vein after earlier venous channels have disappeared can lead to isolated pulmonary vein atresia, a rare and usually fatal condition. If incorporation of the common pulmonary vein does not take place, left atrial division may occur, or a cor triatriatum membrane may form, leading to stenosis of the common pulmonary vein.

TAPVC is divided into four broad categories defined by the site of entry of the anomalous connection to the systemic venous circulation (Herlong et al. 2000).

Darling proposed the most commonly used classification system for TAPVC (which he called TAPVD: total anomalous pulmonary venous

■ **Fig. 12.34** a–e Anatomic forms of total anomalous pulmonary venous connection: **a** type I supracardiac connection of all pulmonary veins to a left superior vena cava; **b** type I supracardiac connection of all pulmonary veins to the right superior vena cava; **c** type II (cardiac connection) with drainage of the pulmonary veins into the right atrium; **d** type II (cardiac connection) with drainage of all pulmonary veins into the coronary sinus; and **e** type III (infracardiac/infradiaphragmatic) with drainage of all pulmonary veins into the portal venous system or directly into the inferior vena cava

drainage) based on the site of pulmonary venous drainage (Darling et al. 1957; ■ Fig. 12.34):

- Type I or supracardiac connection (■ Fig. 12.34a, b) is the most common form and is seen in 51 % of cases. The four pulmonary veins drain via a common vein into the right superior vena cava, left superior vena cava, or their tributaries. In supracardiac connections, a stenosis may occur at the origin of the ascending vertical vein or at its attachment to the innominate vein, or the vertical vein may be stenosed where it crosses the left pulmonary artery and the left bronchus.
- Type II or cardiac connection accounts for 28 % of cases (■ Fig. 12.34c, d). The pulmonary veins connect directly to the right side of the heart, for example, to the coronary sinus or directly to the right atrium. In this anomalous connection, obstructions are rare but may occur at the junction between the common vein and the coronary sinus.
- Type III or infracardiac connection is found in 14 % of cases (■ Fig. 12.34e). Here the common pulmonary vein travels down anterior to the esophagus through the diaphragm to connect to the portal vein. Infradiaphragmatic connections have to be considered in almost every case: either because they drain through a still wide-open ductus venosus into the portal vein which acts stenotic due to its inherent elevated pressure or severe stenoses of the common pulmonary vein may almost inhibit the pulmonary venous flow when the ductus venosus constricts shortly after birth.
- Type IV or mixed connection is rare and accounts for only 7 % of cases. The right and left pulmonary veins drain to different sites (e.g., the left pulmonary vein into the left vertical vein and this in turn into the left innominate vein, with separate anomalous drainage of the right pulmonary vein) (Berdat et al. 2001).

■ **Table 12.1** Total anomalous pulmonary venous connection: distribution of the different forms reported by Hammon and Bender (1983)

Type	n	%
Type I: supracardiac total anomalous pulmonary venous connection	284	51
Type II: cardiac total anomalous pulmonary venous connection	156	28
Type III: infracardiac total anomalous pulmonary venous connection	79	14
Type IV: mixed forms	40	7
Total	559	100

In all types, stenosis may also occur because of restrictive atrial septal defect size and the small left atrium. Incidence of different forms of TAPVC is shown in ■ Table 12.1.

Pulmonary venous obstruction may occur in all types of anomalous connections, and in all cases clinicians must identify all sites of stenosis so that they can be treated at the time of surgical repair.

Children with obstructed TAPVC often show respiratory problems, hypoxia, or even low cardiac output syndrome. Pulmonary artery hypertension may also be present.

In children with obstructed TAPVC, urgent correction is required, if necessary as an emergency procedure, whereas in those with unobstructed TAPVC, the operation can be performed electively.

12.2.5.3 Patients with Pulmonary Venous Obstruction

Pulmonary venous obstruction occurs either functionally or even anatomically in virtually all patients with infradiaphragmatic drainage and in approximately 50% of patients with supracardiac drainage. Patients with an obstruction develop symptoms early, usually at age 24–36 h. These *symptoms* include tachypnea, tachycardia, and cyanosis. Occasionally, newborns with obstructed TAPVC are treated with extracorporeal membrane oxygenation (ECMO) for respiratory failure or pulmonary hypertension prior to corrective surgery (Ishino et al. 1997; Meadows et al. 2007). Signs of pulmonary hypertension progress due to decreasing

pulmonary blood flow resulting in worsening cyanosis. If the condition remains untreated, the course is characterized by progressive clinical deterioration and early death in the first week or month of life, depending on the degree of pulmonary venous obstruction (Hammon et al. 1980).

Patients with symptomatic obstructed total anomalous pulmonary venous connection may need immediate attention and emergency operation.

Some anatomic subtypes of supracardiac connection are more prone to obstruction. If the anomalous confluens vein drains directly into the right superior vena cava, partial obstruction occurs in approximately 65% of cases. Almost all patients with drainage into the azygos vein show pulmonary vein obstruction. The diagnosis is made by echocardiography.

Preoperative angiography in children with symptoms of obstruction may provoke a clinically relevant deterioration (Serraf et al. 1991).

Physical examination findings include severe cyanosis with threatening respiratory failure. The apical heart beat is prominent, but usually the heart is not clinically enlarged. The pulmonary component of the second heart sound appears louder, and a persistent splitting of the sound may be heard. A typical sound is usually lacking. Sometimes a systolic murmur over the pulmonary area or a tricuspid insufficiency murmur at the mid- or lower sternum may be heard. The peripheral pulses usually appear normal directly after birth but decrease as heart failure progresses. The chest X-ray shows a small heart with pulmonary congestion, which is occasionally interpreted as a severe pulmonary infection. Hepatomegaly commonly occurs, especially in TAPVC type III with infradiaphragmatic drainage. Although definitive correction is not possible by catheter intervention, atrial septostomy is performed in some patients when the foramen ovale is the site of the obstruction or when stenting of the narrowed vertical vein is able to bridge the time until corrective surgery if this has to be delayed for some reason (Kanter 2006).

12.2.5.4 Patients Without Pulmonary Venous Obstruction

TAPVC patients with unobstructed pulmonary venous flow present with symptoms similar to those of a large atrial septal defect. Mild failure to thrive with greater respiratory effort than normal during exertion and recurrent pulmonary infections may be present. Often, chest radiographs in these patients with an increased incidence of respiratory infections reveal significant cardiac enlargement.

Physical examination findings suggest right ventricular volume overloading with an increase in right ventricular pulsation, a widely split second heart sound, usually with normal-intensity pulmonary closure, and a pulmonary outflow murmur with or without a diastolic tricuspid murmur. Cyanosis does not necessarily occur in the first year of life. If a restriction develops at the level of the foramen ovale, the probability of the development of pulmonary hypertension and its severity are increased. In this case there is earlier onset of tachypnea, louder pulmonary valve closure sound, more prominent right ventricular pulsation, and a greater likelihood of systemic and pulmonary venous congestion.

Diagnosis of TAPVC is usually made by echocardiography. Only rarely is cardiac catheterization now necessary; it is typically reserved for patients with coexisting complex malformations requiring further definition and patients with forms of mixed pulmonary vein connection in whom the individual pulmonary veins cannot be clearly delineated by echocardiography alone.

12.2.5.5 Surgical Procedures

The goal of surgery is to redirect pulmonary vein flow entirely and directly to the left atrium.

The first surgical correction is attributed to Muller and colleagues at the University of California in Los Angeles. Without the aid of cardiopulmonary bypass, the left atrial appendage was anastomosed to the pulmonary venous confluence (Muller 1951). The first complete correction as an open-heart procedure was performed by Lewis and Varco at the University of Minnesota in 1956, using the technique of moderate hypothermia and caval inflow occlusion (Lewis et al. 1956).

The first TAPVC repair on cardiopulmonary bypass was performed by Kirklin at the Mayo Clinic on May 26, 1955 (Burroughs and Kirklin 1956; Kirklin 1973). Since the 1960s, TAPVC cor-

rection was usually performed using profound hypothermia and circulatory arrest, although in older children it can be performed with bicaval cannulation and low-flow hypothermic perfusion. Circulatory arrest has the advantage of allowing a bloodless surgical field with excellent exposure of the pulmonary venous confluence and without unnecessary manipulation or clamping of the pulmonary veins which can cause the later development of pulmonary vein stenosis. We tend to use bicaval cannulation in all children, including the smallest of neonates (body weight <2 kg). Standard metal-tipped right-angled cannulas are introduced directly into the inferior vena cava just above the diaphragm and into the superior vena cava near the junction with the innominate vein. In children with supracardiac TAPVC, the superior vena cava is considerably larger than normal since it receives additional blood flow from the anomalously draining pulmonary veins, and this facilitates direct cannulation. In those rare cases of supracardiac TAPVC with anomalous drainage into the azygos vein, it is better to place a bulldog clamp below the azygos vein (but at a distance from the sinus node) than to place a tourniquet around the superior vena cava. This enables decompression of the pulmonary veins through the superior vena cava during cooling (Kanter 2006). An alternative for decompression of pulmonary veins would be to open the confluens right away with going on bypass.

With bicaval cannulation, in our hands, the cannulas are not in the way during the correction, and one is able to achieve excellent exposure of the pulmonary venous confluence, especially in the phase of cardioplegic arrest. On occasion, it is helpful to introduce brief periods of circulatory arrest during the most critical parts of the operation to optimize surgical exposure in a bloodless field. However, with bicaval cannulation and low-flow hypothermic perfusion, this is rarely necessary. When cannulating and decannulating are meticulously done, no complications of direct caval cannulation such as superior vena cava thrombosis or postoperative chylothorax are to be expected.

12.2.5.6 Surgical Techniques

With TAPVC draining to the coronary sinus or directly into the right atrium (type II or cardiac connection), the correction is performed by simply enlarging the existing atrial septal defect or

patent foramen ovale and completely unroofing the coronary sinus until all four pulmonary veins are adequately visualized. The enlarged atrial septal defect is then closed with a patch of pericardium or other material incorporating and redirecting the pulmonary veins to the left atrium (■ Figs. 12.35 and 12.36). Care must be taken to avoid the conduction pathways.

The mere unroofing of the large coronary sinus when all pulmonary veins are draining into it was described by Van Praagh (Van Praagh et al. 1972). The right atrium is opened longitudinally,

■ Fig. 12.35 Correction of anomalous pulmonary venous connection to the coronary sinus (cardiac type) by opening the residual atrial septum between patent foramen ovale and coronary sinus and further resecting the anterior wall of the coronary sinus («unroofing») followed by closure of the atrial communication

and then the foramen ovale is enlarged to enable a better view into the left atrium. Next, a curved instrument is introduced into the enlarged coronary sinus, and its anterior wall, which at the same time is the posterior wall of the left atrium, is levered upward. The taut membrane thus brought into view is incised and cut out so that a defect with a diameter of at least 1.5–2 cm results. The creation of such a large opening far below the opening of the coronary sinus largely excludes injury to the atrial conduction pathways and the AV node. The opening of the coronary sinus into the right atrium is closed with individual sutures or a continuous suture placed 4–5 mm inside the coronary sinus. In these cases the interatrial communication, which had to be enlarged for visualization of the roof of the coronary sinus, can now also be closed by direct suture or with a patch.

Many techniques have been described for the correction of the supracardiac form of TAPVC. Commonly, once the patient is on extracorporeal circulation, the pulmonary veins are exposed in the posterior pericardial space by dividing the pericardial fold between the right atrium and the pulmonary venous confluence (Kirklin 1973). An incision is made in the common pulmonary veins—the confluence, which is typically oriented in a transverse direction. In cardioplegic arrest, with the aorta cross-clamped, an appropriately large incision is made in the posterior wall of the left atrium, corresponding

■ Fig. 12.36 a The wall dividing the coronary sinus from the left atrium is deeply incised and excised as much as possible. b The pericardial or synthetic patch closing the atrial septal defect is anchored into the anterior wall of the coronary sinus so that the coronary sinus itself drains into the left atrium together with the previously anomalously draining pulmonary veins

to the course of the incision into the confluents before. The incision is started near the atrial septum and then directed toward the base of the left atrial appendage, making a transverse incision in the left atrial back wall that corresponds to the incision in the pulmonary venous confluence. Next, a direct anastomosis, which should be as large as possible, is made between these two incisions using a continuous 7-0 or 6-0 absorbable suture (■ Fig. 12.37). The anastomosis can be augmented by dividing the left-sided vertical vein as far superiorly as possible at its entry into the innominate vein. An incision is made on the right medial aspect of the vertical vein down to where it enters the pulmonary venous confluence. This vein is then flapped down medially on to the superior aspect of the anastomosis

between the pulmonary venous confluence and the back wall of the left atrium. This pedicled flap of autologous vein wall serves to strengthen the anastomosis and to increase the effective volume of the left atrium. The vertical vein is usually ligated/clipped or transected (Kumar et al. 2001; Spray 2001).

An alternative technique for the correction of supracardiac TAPVC is to use a biatrial transverse incision (Shumacker and King 1961). This consists of making a transverse right atrial incision across the crista terminalis and then through the posterior wall of the left atrium. Under direct vision, the posterior wall of the left atrium can then be directly anastomosed to the pulmonary venous confluence. For the last portion of the anastomosis, an interrupted suture

■ Fig. 12.37 a Horizontal incision of the left atrium in line with the pulmonary venous confluence (*dashed line*); b anastomosis of the pulmonary venous confluence and the left atrium with a running absorbable suture; c schematic representation of the completed correction with broad anastomosis between pulmonary venous confluence and left atrium; and transection of the left ascending superior vena cava venous confluence drainage between two ligatures

technique can be used. The atrial septal defect is typically closed with a piece of pericardium or other patch material. The incision in the right atrium is closed directly or with a separate patch if necessary. This technique has the advantage of enhanced exposure of the pulmonary veins. However, it requires more suture lines on the atrium, which potentially increases the risk of postoperative atrial arrhythmias (■ Figs. 12.38 and 12.39).

Cobanoglu and Menashe described a technique of repair in supracardiac or infracardiac TAPVC performing the anastomosis from the left side of the operating table with the apex of the heart tipped up and to the right (Cobanoglu and Menashe 1993). The anastomosis starts at the right side, and the surgeon works toward himself or herself to the base of the left atrial appendage, connecting the common pulmonary vein to the left atrium close to the left upper pulmonary vein (■ Fig. 12.40).

The persisting foramen ovale is then closed directly or, if there is concern about impingement on the pulmonary vein anastomosis, with a patch. Then the vertical vein is typically ligated (■ Fig. 12.41). The heart is closed and the child is rewarmed and weaned from the cardiopulmonary bypass.

If there is concern about postoperative pulmonary artery hypertension and subsequent right ventricular failure, a life-saving technique can be to leave the persisting foramen ovale partially open to allow decompression of the right side through the atrial septum with right-to-left shunting, at the expense of some systemic arterial desaturation.

Hawkins et al. described a direct approach to the anastomosis between the left atrium and the common pulmonary vein in which the fossa ovalis is first excised through the right atrium (Hawkins et al. 1983). A generous transverse incision is made in the back wall of the left atrium, and a corresponding incision is made in the pulmonary venous confluence. The common pulmonary vein is now anastomosed to the back wall of the left atrium directly through the fossa ovalis,

which is then closed with a pericardial patch. The authors postulate that this technique eliminates the possibility of distortion of the anastomosis because it is performed with the heart in the anatomically correct position.

Surgical correction for the *infracardiac type* of TAPVC is very similar to that described for supracardiac TAPVC. Often, however, the pulmonary venous confluence is oriented vertically in the common pulmonary vein so that the incision in the common pulmonary vein is more hockey-stick shaped, running vertically and then on to the left upper pulmonary vein to correspond with a similar incision on the back wall of the left atrium from the medial to the inferior side of the left atrial appendage (■ Fig. 12.42).

It is not necessary to ligate the common pulmonary vein below the diaphragm, and, in fact, some authors have advocated routinely leaving this vein open in patients who show symptoms of an obstruction (Cope et al. 1997). The advantage of leaving the vertical vein unligated is that, theoretically at least, it can allow decompression of the pulmonary venous channel through the sinus venosus in the early postoperative phase, particularly when the left atrium is small and poorly compliant (Cheung et al. 2005; Ishino et al. 1997). On the other hand, if the left atrium is quite small, it can be helpful to divide the vertical vein and use the remnant as an onlay patch to augment to the size of the left atrium. This technique involves wide mobilization of the pulmonary veins and pulmonary confluence. The correction is completed with the apex of the heart tipped up and to the right. After the vertical vein has been divided at the diaphragm, it is divided longitudinally. A parallel incision is made in the back of the left atrium extending into the left atrial appendage. The venoatrial anastomosis begins at the upper end of the pulmonary venous confluence and the base of the left atriotomy. The anastomosis proceeds along both sides until the inferior side of the confluence (the divided vertical vein) is anastomosed to the tip of the left atrial appendage (■ Fig. 12.42c). The surgical management of *mixed forms* of TAPVC varies according to the particular anatomy of each patient (Imoto et al. 1998). A single anomalous pulmonary vein can be occasionally left uncorrected if the other three veins are satisfactorily reconstructed and correctly connected. However, close observation is required

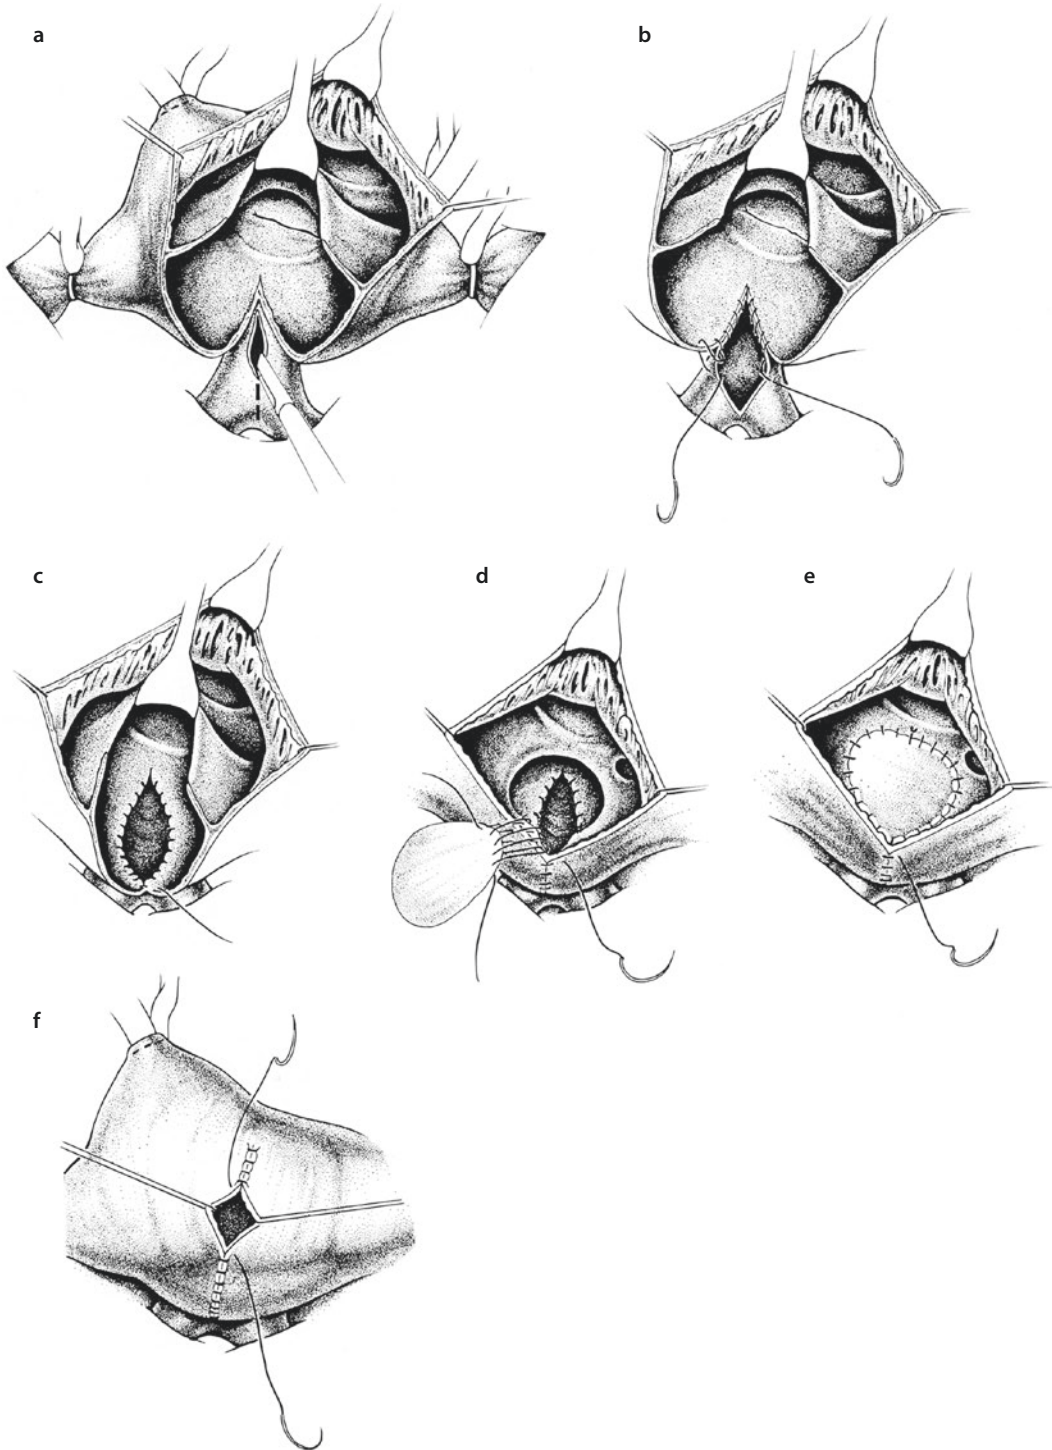

Fig. 12.38 a Right atrium, atrial septum, and left atrium have been opened horizontally. The opposite pulmonary vein confluence is incised in parallel. b Anastomosis between pulmonary vein confluence and posterior wall of the left atrium is performed with continuous absorbable suture. c Anastomosis between left atrium and pulmonary vein confluence is complete. d To enlarge the left atrium and enable unobstructed drainage from the pulmonary veins into the left ventricle, the atrial septal defect is closed not directly but with a synthetic patch. e The patch used to close the atrial septal defect is anchored with a continuous suture. Closure of the right atrial incision begins with a continuous suture at the remaining anterior incision edge. f Closure of the right atrial incision is performed with a continuous resorbable over-and-over suture, if necessary by sliding technique. At times an additional patch may be required to enlarge the posterior lateral wall of the right atrium also

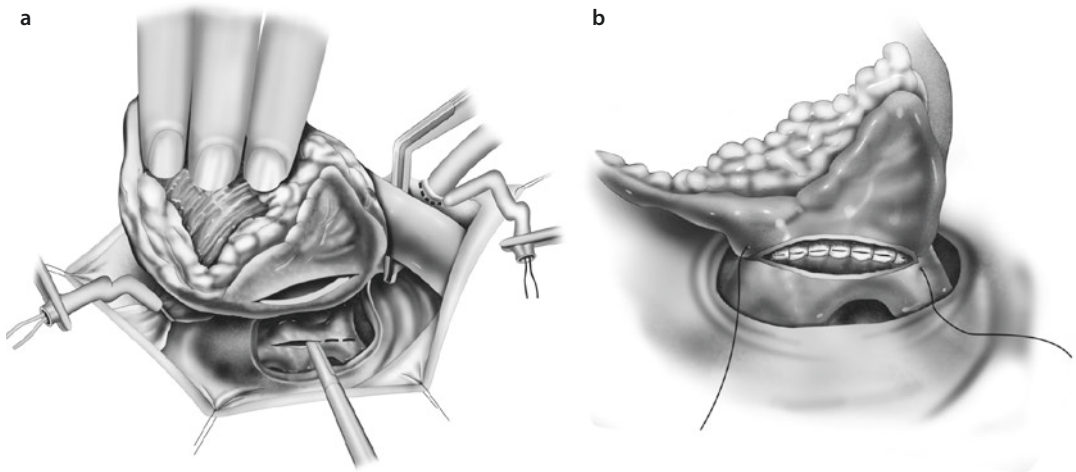

Fig. 12.39 **a** In some cases of infradiaphragmatic TAPVD, the anastomosis between the left atrium and the pulmonary vein confluence is created from the left, the heart being held out of the thorax to the right. The incision runs to the right, horizontally along the posterior wall of the left atrium and, in parallel, along the anterior wall of the pulmonary vein confluence. **b** The anastomosis between the opened pulmonary vein confluence and the left atrium is performed with a continuous over-and-over resorbable suture. The foramen ovale/ASD II has already been closed by direct suturing from the right atrium. The infradiaphragmatic connection is divided

Fig. 12.40 **a, b** The Cobanoglu technique

during the postoperative follow-up so that a significant left-to-right shunt or the onset of pulmonary vascular hypertension can be identified early.

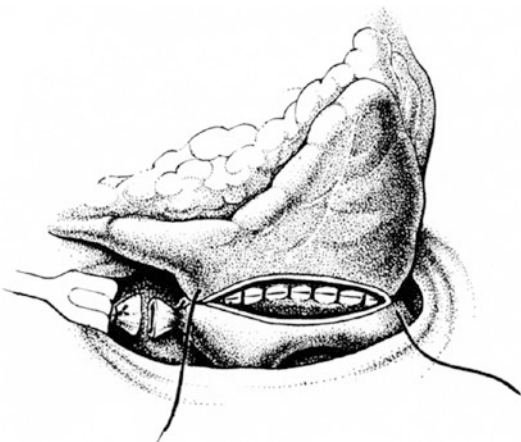

12.2.5.7 Postoperative Complications and Their Avoidance

Postoperatively, these children can present pulmonary artery hypertension, particularly those who had suffered from the symptoms of pulmonary vein obstruction. In fact, as noted above, some

may have been misdiagnosed as having persistent fetal circulation with pulmonary artery hypertension and may need continuing extracorporeal membrane oxygenation (ECMO) support. If the pulmonary artery pressure has risen following the correction, continuous measurement of the pulmonary artery pressure may be helpful to guide appropriate management (Imoto et al. 1998). Occasionally, children with persistent pulmonary artery hypertension will require nitric oxide

■ **Fig. 12.41** a Access from the right side in infracardiac total anomalous pulmonary venous connection. The incision is sometimes made vertically along the course of the draining vein in caudal direction, an orientation the confluents in infradiaphragmatic TAPVC often reveals. The corresponding incision in the left atrium runs parallel to it. b The incision openings are connected by a continuous suture. c Halfway across the opening, the suture ends are pulled tight. d The anastomosis between the pulmonary vein confluence and the left atrium is completed, and the drainage vein is transected between the two ligatures

■ **Fig. 12.42** Surgical correction for the infracardiac type of TAPVC

treatment or ECMO in addition to the standard measures of hyperventilation, adequate oxygenation, and sedation. Before purely embarking on treatment of persistent pulmonary hypertension, an anastomotic obstruction of the newly connected pulmonary veins has to be ruled out or being taken care of surgically.

Both in the operating room and in the early postoperative period, the left ventricle can be partially noncompliant and show a restricted stroke volume. These children will be very sensitive to volume overload. They seem to have a fixed stroke volume and can often compensate for the decreased stroke volume by an increase in heart rate until the compliance of the ventricle has improved. The use of milrinone to improve the

ventricular compliance and at the same time reduce the pulmonary vascular resistance may be helpful. Volume overload has to be avoided. In these very critical patients, temporary chest wall patch plasty with secondary sternal closure is a further expedient strategy (Alexi-Meskishvili et al. 1995).

A particularly challenging group of patients with total anomalous pulmonary venous connection are those with single left ventricle morphology. In these children the maintenance of adequate pulmonary blood flow is difficult since they develop pulmonary artery hypertension early on, particularly if they need either a systemic to pulmonary artery shunt or pulmonary artery banding. What appears to be adequate pulmonary blood flow in the operating room can later mean excessive blood flow through the pulmonary vessels when the pulmonary vascular resistance drops and becomes normal. It may be necessary to readjust the source of the pulmonary blood flow to these changes. Even in the best of hands, these children are problematical. A report from the Children's Hospital of Philadelphia published in 1999 showed a 1-year survival in this group of children with TAPVC and single-ventricle physiology of only 37% (Gaynor et al. 1999). The early mortality was 58% if the TAPVC was corrected during the first operation. More than half of the survivors later developed a pulmonary vein stenosis. Hashmi and associates from the Hospital for Sick Children in Toronto reported a 95% early mortality in 20 children with right atrial isomerism in whom TAPVC correction was performed either alone or in combination with other procedures (Hashmi et al. 1998).

12.2.5.8 Pulmonary Vein Stenosis After Correction of Total Anomalous Pulmonary Venous Connection

The major complication and the main cause of reoperation following surgery for TAPVC is the occurrence of pulmonary vein stenosis. Pulmonary venous stenotic disease is a poorly understood phenomenon associated with congenital pulmonary vein hypoplasia and carries a very poor prognosis (Ando et al. 2004). The causal mechanism is not well understood but may be related to endothelial trauma in the pulmonary vein during the initial operation or to pericardial adhesions. Pathological examination of the pulmonary venous obstruction following

TAPVC surgery shows fibrous intimal hyperplasia associated with some media hypertrophy. There is increasing severity in the spectrum of lesions from anastomotic strictures to ostial and diffuse pulmonary vein stenoses. In the case of an anastomotic lesion, revision of the left atrial anastomosis with patch enlargement plasty brings about good results. On the other hand, conventional techniques for treating an ostial pulmonary vein stenosis are of no use and have shown very poor results. The sutureless correction technique introduced in 1996 provides better midterm results than any other technique and improved the freedom from mortality and recurrence of the stenosis from 65 to 90% (Lacour-Gayet 2006; Lacour-Gayet et al. 1966).

When pulmonary venous stenosis occurs immediately after surgery or during the first postoperative days, it is the result of a primary restrictive anastomosis, a technical problem. More commonly, however, the stenosis occurs after a delay varying from two to several months, frequently after a large anastomosis repair and uneventful postoperative course.

Complex forms of TAPVR are associated with a significantly higher risk of pulmonary vein stenosis. A 20–50% incidence of postoperative pulmonary venous stenosis has been reported after repair of TAPVR associated with single-ventricle and right atrial isomerism. The mixed type of drainage, aberrant pulmonary venous drainage, association with scimitar syndrome, presence of genetic syndromes, and boy weight of less than 2.5 kg are all associated with increased occurrence of a secondary pulmonary vein stenosis (Lacour-Gayet 2006). The common denominator of most complex TAPVR is *hypoplasia of the pulmonary venous confluence*. The Toronto group introduced sutureless repair as the initial procedure in patients with hypoplasia of the pulmonary venous confluents (Yun et al. 2005). The critical element of this technique is to perform the atrial anastomosis directly to the pericardium around the incised common pulmonary vein, which should not have been further dissected out of its connective tissue surroundings.

The diagnosis of ostial pulmonary vein stenosis is based on Doppler echocardiography showing continuous flow with a velocity of >1.5 mm/s at the pulmonary vein ostium.

Magnetic resonance imaging is also, at least partially, helpful here. It is the only imaging

procedure able to visualize intact portions of the pulmonary veins in the case of ostial atresia. A pulmonary artery pressure of >50 mmHg is an indication for surgery (Lacour-Gayet 2006).

Growing severity of pulmonary venous obstruction after repair of TAPVC can be evaluated according to the score proposed by Lacour-Gayet (2006):

1. Anastomotic stenosis between the pulmonary vein confluence and the left atrium without individual ostial stenosis
2. Right pulmonary vein ostial stenosis involving the upper and/or the lower vein (a single pulmonary vein stenosis is usually well tolerated)
3. Left pulmonary vein ostial stenosis involving the upper and/or lower vein
4. Bilateral pulmonary vein stenosis involving two, three, or four individual pulmonary venous ostia
5. Diffuse hypoplasia of one or several pulmonary veins
6. Total atresia of several pulmonary vein ostia

Yun and associates proposed another score for the evaluation of pulmonary vein stenosis:

- 0—no stenosis
- 1—mild stenosis
- 2—severe stenosis
- 3—occluded pulmonary vein

The higher the score, the greater is the risk of the need for reoperation or death (Yun et al. 2005).

12.2.5.9 Standard Techniques

For each patient, the operative technique is selected on the basis of the specific anatomy of the stenosis.

In patients with isolated anastomotic stenosis, who in most cases present in the first days after original repair, revision of the left atrial anastomosis is performed by patch enlargement using a transseptal approach. The anterior aspect of the previous anastomosis between the common pulmonary venous trunk and the left atrial wall is incised. A polytetrafluorethylene (PTFE) patch is used to enlarge the anastomosis.

Ostial stenosis is sometimes associated with this lesion. Conventional repair of an individual pulmonary vein stenosis by either endarterec-

tomy of scar tissue or patch venoplasty (using either pericardium, living atrial tissue, or PTFE) has been associated with a high risk of recurrence (Ricci et al. 2003).

In these cases, which present usually much later than the cases of isolated anastomotic stenosis, the anterior aspect of the previous anastomosis between the common pulmonary venous trunk and the left atrial wall is incised to start with, also. Exposure is usually achieved via a right atriotomy and transseptal approach (■ Fig. 12.43a–c). The stenotic communication between the left atrium and the pulmonary vein confluens can be relieved by making a series of five or six radial incisions (■ Fig. 12.43d, e).

Resection of a portion of the stenotic rim is sometimes necessary to further enlarge the pulmonary vein orifice (Devaney et al. 2006a, b).

Patch enlargement of a left pulmonary venous stenosis using left atrial appendage tissue is an alternative technique (Pacífico et al. 1985).

12.2.5.10 Sutureless Correction of Postoperative Pulmonary Vein Stenoses with Pericardium

This technique was described by Lacour-Gayet in 1996 (Lacour-Gayet et al. 1996). The procedure is based on complete resection of the stenotic scar tissue of the pulmonary vein, creating an opening in the left atrial wall that is left open. For the operation it is necessary to leave intact the adhesions between the posterior left atrial wall, the venae cavae, and the pericardium. Posteriorly a minimal dissection is performed. While the use of total circulatory arrest is simpler, bicaval cannulation with full-flow CPB is our preferred technique. The superior vena cava is directly cannulated and snared in as high a position as possible. The inferior vena cava cannula is cannulated in low position and is not snared, which allows drainage of most of the return flow through the inferior vena cava. The left atrium is approached through a transseptal incision. The stenotic pulmonary venous ostia are identified. They can be reduced to the size of pinheads and are therefore often difficult to identify. The stenotic tissue of the right pulmonary vein is totally resected from inside the left atrium and also from the outside below the interatrial groove. This resection creates a large opening in the left atrial wall that is left open.

Fig. 12.43 Correction of anastomotic pulmonary vein stenosis via a right atriotomy **a** and transeptal incision **b** which exposes the narrowed anastomosis between left atrium and pulmonary vein confluents **c**. A series of five or six radial incisions can be made **d** resulting in a wide-open communication **e**

The stenotic pulmonary vein scar tissue is excised to the level of the pericardial reflection, until normal pulmonary vein tissue is reached (■ Figs. 12.44 and 12.45).

■ Fig. 12.44 Resection and sutureless correction (*right side*). This technique is based on total resection of the stenotic scar tissue in the pulmonary vein. A small incision is required posteriorly. The left atrium is approached through a transeptal incision. The stenotic tissue of the right pulmonary vein is totally resected. This resection creates a large opening in the left atrial wall that is left open

■ Fig. 12.45 Resection and sutureless correction (*right side*). The stenotic scar tissue of the pulmonary vein has been removed to the level of the pericardial reflection, so that normal pulmonary vein tissue can be recognized

The interatrial septum is closed, as is the right atrial wall. The fenestration between the left atrium and the pericardium is left wide open. The further course of the operation using this technique differs for the right and left side.

For *right-sided pulmonary vein lesions*, the right pericardial tissue is anastomosed around and in some distance to the atrial wall, above the left atrial fenestration, creating a left neo-atrial pouch made by the pericardial sac. The pericardial sac is dorsally kept closed by the pericardial adhesions from the previous operation. The patent right pulmonary vein leads freely into the pouch, and the blood drains through the opening in the left atrial wall (■ Figs. 12.45 and 12.46).

For *left-sided pulmonary vein lesions*, the correction can be conducted through the left atrial cavity (■ Figs. 12.47, 12.48, and 12.49).

The portion of the left atrial tissue surrounding the stenotic scar tissue is excised. This creates a large opening in the left atrial wall. The left pulmonary veins are dissected out to the left pericardium and transected once normal pulmonary vein tissue is reached beyond the stenotic segment. In the presence of sufficient pericardial adhesions left in place, no suturing is necessary (■ Fig. 12.48).

The blood from the left pulmonary veins is allowed to drain passively into the left atrium through the posterior pericardial cavity, which is

■ Fig. 12.46 Resection and sutureless correction (*right side*). For right-sided pulmonary vein lesions, the right pericardial tissue is anastomosed around and in some distance to the right atrial wall above the left atrial fenestration. Thus, a neo-atrial pouch made by the pericardial sac is created, through which the open right pulmonary vein drains freely into the opening in the left atrial wall. The phrenic nerve is located below the anastomotic suture line in front of the pulmonary veins

■ **Fig. 12.47** Resection and sutureless correction (*left side, from inside*). For left-sided pulmonary vein lesions, the correction is made through the left atrial cavity. A portion of left atrial tissue around the stenotic scar tissue has been excised, creating a large opening in the left atrial wall

■ **Fig. 12.48** Resection and sutureless correction (*left side, from inside*). The left pulmonary veins have been dissected and transected and longitudinally incised across the stenotic segment into normal pulmonary vein tissue. In the presence of sufficient pericardial adhesions, no suturing is necessary. Blood from the left pulmonary veins is allowed to drain passively into the left atrium through the posterior pericardial cavity maintained as a closed space by the pericardial adhesions

■ **Fig. 12.49** Resection and «sutureless» correction (*left side, from inside*). In the absence of sufficient pericardial adhesions, it is necessary to perform an atrio-pericardial anastomosis around and in some distance from either inside (as shown here) or outside

■ **Fig. 12.50** Resection and «sutureless» correction (*left side, from outside*). The atrio-pericardial anastomosis can also be performed from outside by elevating the heart

maintained as a closed space by the pericardial adhesions. In the absence of sufficient pericardial adhesions or in cases of congenital pulmonary vein stenosis without pericardial adhesions, it is necessary to perform an atrio-pericardial anastomosis either from inside the left atrium or from the outside by elevating the heart (see ■ Figs. 12.48, 12.49, and 12.50). The suture line is placed on the

pericardium, distant to the pulmonary venous ostia. The left phrenic nerve is located anterior to the pulmonary veins and outside the anastomotic suture line (■ Fig. 12.51).

In 1998, Caldarone and associates described a similar technique in which the stenotic tissue is left in place, but the obstructed pulmonary venous lesions are incised longitudinally (Caldarone and Behrendt 2000; Caldarone et al. 1998; ■ Figs. 12.52 and 12.53; Najm et al. 1998).

■ Fig. 12.51 Resection and sutureless correction (left side, from outside). Note that the suture line in the pericardium is placed at a distance from the pulmonary vein tissue. The course of left phrenic nerve is located anterior to the veins. Its actual position has to be known and checked for

12.2.5.11 Pulmonary Vein Stenting and Balloon Angioplasty

The results of stenting for pulmonary vein stenosis have been disappointing. The tendency of the pulmonary veins to develop significant intimal proliferation makes the stenting procedure hazardous. Nevertheless, this therapy option may be seen as an ultima ratio solution if stenosis has recurred again after several operations. Leaving an atrial fenestration to allow angioplasty is preferable. New generations of stent systems, such as the drug-eluting stents used for coronary artery interventions, may be more effective in the future. Knowing the tendency of the pulmonary venous endothelium to restenose after any manipulation, it is unlikely that the pulmonary veins will stay open for more than a few months (Bingler et al. 2012).

12.2.5.12 Prevention of Pulmonary Vein Obstruction Using a «No-Touch» Technique

Since Lacour-Gayet modified the surgical technique for correction of TAPVR in 1995 so that only minimal incisions of the pulmonary veins are made using total circulatory arrest, the rate of pulmonary vein obstruction has significantly decreased. Although the reasons are not entirely clear, there is no doubt that the neonatal pulmonary venous tissue is very sensitive and had a tendency to inflammatory stenotic processes. A «no-touch» technique (as far as the pulmonary venous ostia are concerned) is therefore advisable, using total circulatory arrest, dissecting the pulmonary veins only minimally, strictly limiting an

■ Fig. 12.52 a–c Right-sided marsupialization is performed for right pulmonary vein stenosis by making a left atrial incision a that is extended into each stenotic vein and across the area of narrowing. A posteriorly based flap of pericardium is mobilized b and reflected onto itself and the left atrium c, which avoids the need to directly suture the veins. The right phrenic nerve has to be watched out for

Fig. 12.53 a–c Left-sided marsupialization is accomplished in an analogous fashion to the right. Here elevation of the apex of the heart is necessary to facilitate exposure. A left atrial incision is made **a** and extended into each stenotic vein. A pericardial flap is cut out **b** and the marsupialization is completed **c**. The left phrenic nerve has to be watched out for

opening incision to the pulmonary vein confluence, and staying well away from the individual pulmonary vein ostia (Kanter 2006). A further precaution is to use resorbable sutures of polydioxanone for the anastomosis (Lacour-Gayet 2006).

12.2.6 Congenital Diverticula and Aneurysms of the Left Atrium

12.2.6.1 Historical Background

Congenital aneurysms of the left atrium belong to the very rare congenital anomalies. They were first described by Semans and Taussig (1938). Two variants of this anomaly are recognized: those with intact pericardium and those with partial absence of the pericardium. In the latter case, it is possible that the left atrial appendage protrudes through the pericardial defect rather than there being an aneurysm in the strict sense (Bukharin and Aleksii-Meskishvili 1969). Gold collected reports of 48 patients from the international literature (Gold et al. 1996). Since then, many new cases have been reported (Kiaii et al. 2004; Pome et al. 2000; Tanoue et al. 2004).

12.2.6.2 Surgical Anatomy

A true left atrial aneurysm must fulfill the following *criteria* (Foale et al. 1982; Huang et al. 1993; Stone et al. 1990):

- There is a normal atrium.
- There is direct continuity of the blood flow through the atrium itself.

- There is no evidence of a pericardial defect.
- Distortion of the left ventricular free wall by the aneurysm is present.

Very rare are multiple small aneurysms of both atria; these often become symptomatic through atrial tachycardia (Bokeria et al. 1989; Miyamura et al. 1990; Varghese 1969).

12.2.6.3 Clinical Picture

In asymptomatic patients, the diagnosis can be suspected if the heart silhouette in the chest X-ray is enlarged.

Despite its congenital etiology, manifestations usually do not arise until about the second decade of life, with a mean age of first presentation of 26 years. Atrial fibrillation is observed in 40% of these patients, and stroke occurs in 18% (Gold et al. 1996). Strokes have been reported even in infants (Sands et al. 2003). Typical chest pain can be caused by compression of the left coronary artery (Pomerantzeff et al. 2002). Congestive heart failure in the neonate may be related to an anatomic obstruction of the pulmonary venous drainage (Stone et al. 1990) or to displacement of the mediastinum or airway obstruction (Morales et al. 2001). Cardiac tamponade due to restricted diastolic expansion of the left ventricle has been described (Dimond et al. 1960). In the presence of multiple biatrial aneurysms, atrial tachycardia can occur in infants and small children (Bokeria et al. 1989; Miyamura et al. 1990). Diagnosis is easily established with echocardiography and magnetic resonance imaging.

■ **Fig. 12.54** a–c Left atrial aneurysm as a saculation of the left atrium along the posterior wall of the left ventricle. **a** View from anterior direction; **b** view from posterior direction; **c** closure of the left atrium with a direct, continuous over-and-over suture following resection of the aneurysm

Because of the risk of life-threatening complications, including tamponade, tachyarrhythmia, systemic embolization, heart failure, and potentially, at least, of heart rupture, surgery is recommended even in asymptomatic patients of any age (Fontain-Dommer et al. 2000; Gold et al. 1996; Morales et al. 2001; Pomerantzeff et al. 2002).

12.2.6.4 Surgical Techniques

Surgery to correct this anomaly may be performed through a left thoracotomy with or without cardiopulmonary bypass (McGuinness et al. 2007; Vagefi et al. 2007; Victor and Nayak 2001), using stapling devices (Burke et al. 1992) or even with a minimally invasive, endoscopic approach (Kiaii et al. 2004). Median sternotomy, however, is the favored approach because, particularly in the case of large structures, adequate exposure through a lateral thoracotomy is not possible. Using cardiopulmonary bypass also provides a motionless operative field, which helps to avoid embolization caused by manipulation (Gold et al. 1996; Tanoue et al. 2004; ■ Fig. 12.54). It is important to correctly assess the relationship between the neck of the aneurysm and the posterior mitral commissure of the mitral valve because if the aneurysm extends into the commissure, partial anuloplasty may be necessary to reestablish mitral valve competence (Stone et al. 1990). Mitral valve replacement has also been reported to be necessary if the attempt to reconstruct the deformed mitral valve

fails (Morales et al. 2001). The outcome is usually good, and the symptoms disappear (Gold et al. 1996; Pomerantzeff et al. 2002).

12.3 Congenital Mitral Valve Anomalies

12.3.1 Introduction

Pediatric mitral valve anomalies present complex management challenges to the surgeon, who has to choose between valve reconstruction and replacement. Frequently not only the mitral valve must be addressed but there are other associated congenital malformations also requiring correction. *Mitral valve reconstruction* is the preferred technique for any kind of mitral valve malformation in newborns, infants, and small children as well as in older children and adolescents. Valve reconstruction allows for valve growth with increasing age, does not necessitate anticoagulation, and carries very little risk of thrombus formation. It also entirely avoids the difficulty that there is a complete lack of prostheses suitable for this age group, and especially for small children. Even when the result of primary reconstruction is not optimal, the time until a repeat correction and until the patient reaches adulthood and/or can receive an adult-size prosthesis can be bridged. The best results of valve reconstruction are

achieved when the whole variety of reconstructive techniques are available, the technique is selected on an individual basis, and the use of any kind of prosthetic material is avoided. Valve replacement must be reserved only for patients with definitively irreparable mitral valves.

12.3.2 Historical Comments

Mitral valve surgery has a long tradition (Böttcher and Hübler 2006; Murray et al. 1938). The first closed mitral commissurotomy in a child was reported in 1952 by Mannheimer (Mannheimer et al. 1952). Young and Robinson (1964) reported the first successful mitral valve replacement in an infant with congenital mitral valve stenosis. During the past three decades, mitral valve surgery in infants and children has become an important part of pediatric cardiac surgery (Carpentier et al. 1976; Dunn 1998; Lamberti and Kriett 2007; Wood et al. 2004).

12.3.3 Incidence of Congenital Mitral Valve Anomalies

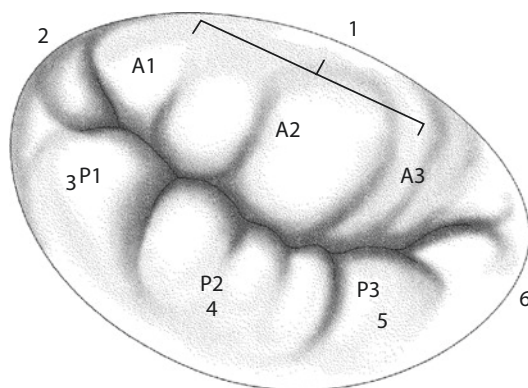

A congenitally abnormal mitral valve affects less than 1% of all infants born with a normal-sized left ventricle. Patients born with the different types of atrioventricular canal defects, single ventricle, and congenitally corrected transposition do not have a mitral valve in the anatomic sense of a systemic atrioventricular valve. In up to 60% of cases, congenital anomalies of the mitral valve occur in association with other cardiac lesions, and often more than one component of the mitral apparatus is involved (Wilcox and Anderson 1985).

12.3.4 Normal Mitral Valve Anatomy

The mitral valve consists of the anulus, leaflets, chordae tendineae, and papillary muscles. The mitral anulus is an integral part of the fibrous skeleton of the heart. Normally the mitral valve has two leaflets, anterior and posterior. The larger, anterior (septal or aortic) leaflet attaches to 150° of the anulus and is squat and trapezoid in shape. As a consequence of being in fibrous continuity with the aortic valve, it forms the posterior boundary of the left ventricular out-

flow tract. Both ends of the fibrous continuity of the aortic and mitral valve are anchored in the short axis of the left ventricle. Toward the ventricular musculature, the fibrous tissue is thickened to form right and left fibrous trigones (Wilcox et al. 2004). The scalloped posterior (mural) leaflet is narrower and its attachments occupy 210° of the anulus. Controversy remains regarding the most accurate terminology for the mitral valve leaflets. While some authors favor the terms «aortic leaflet» and «mural leaflet» (Ho and Anderson 1988; Wilcox et al. 2004), usually the leaflets are defined as an anterior and posterior mitral leaflet (Carpentier and Brizard 2006; Zias et al. 1998). The two mitral valve leaflets are separated by the anterolateral and posteromedial commissures. Close to the commissures lie two corresponding papillary muscles, which are extensions of the subendocardial myocardium. Chordae tendineae of the papillary muscles insert on both sides of the opposite commissure, so that each valve leaflet receives chordae from both papillary muscles. The chordae support the leaflets and connect them either to the free and rough side of the papillary muscles or directly to the ventricular wall, as so-called basal cords (Wilcox et al. 2004). The mitral valve leaflets are segmented in six components (scallops): three anterior (A1–A3) and three posterior (P1–P3) scallops (Carpentier and Brizard 2006; Kumar et al. 1995; ■ Fig. 12.55).

The relationship between the mitral valve ring and the coronary arteries depends on the dominance type of the coronary artery supply. When the left coronary artery is dominant, the entire attachment of the mural leaflet is

■ Fig. 12.55 Components (scallops) of the mitral valve (After Kumar et al. 1995). A anterior, P posterior

■ **Fig. 12.56** Important surgical structures of the mitral valve as viewed by the surgeon (After Wilcox et al. 2004)

intimately related to the coronary artery and its branch to the atrioventricular node. In the case of dominant right coronary artery, the posterior leaflet is encircled by the circumflex coronary artery, with the branch running below and to the left to the mitral ring as viewed by the surgeon (■ Fig. 12.56).

12.3.5 Classification of Congenital Mitral Valve Anomalies in Children

12.3.5.1 Introduction

The *Carpentier nomenclature* is most commonly used to classify congenital mitral valve anomalies (Carpentier and Brizard 2006; Carpentier et al. 1976). Carpentier defined a systematic classification based on an objective assessment of the valve function.

According to the Carpentier classification, lesions with normal leaflet motion and lesions with leaflet prolapse produce mitral valve insufficiency, whereas lesions with restricted leaflet motion lead to mitral valve stenosis.

This classification is based on a functional analysis of the mitral valve leaflet mobility:

- *Type I*: In this lesion there is typically normal leaflet motion. The regurgitation results from a lack of coaptation between the leaflets. This anomaly is subdivided

into annular dilatation, cleft leaflet, and partial leaflet agenesis (Chauvaud et al. 1997b).

- *Type II*: Leaflet prolapse. The free edge of one or both of the leaflets overrides the plane of the valve orifice during systole. These defects are subdivided into chordal elongation, papillary muscle elongation, and chordal agenesis.
- *Type III*: Restricted leaflet motion. The motion of one or both of the leaflets is limited, which usually results in mitral valve stenosis, although in some cases valve insufficiency is observed. Stenosis results from commissural fusion, imperforation, and thickening or shortening of the subvalvar apparatus.

There are two subtypes with further divisions:

- *Type III-1*: restricted leaflet motion with normal papillary muscles:
 1. With fused commissures of the papillary muscles
 2. With shortened chordae

Also included in this last group are anomalies with excessive leaflet tissue, the supra-annular mitral ring and annular hypoplasia.

- *Type III-2*: restricted leaflet motion with abnormal papillary muscles:
 1. Parachute mitral valve
 2. Hammock mitral valve
 3. Papillary muscle hypoplasia

There are two limitations to this classification that can lead to its being applied differently by different investigators and therefore to inconsistencies in data reporting. Firstly, a purely stenotic or insufficient valvular lesion is rarely observed. Secondly, the surgical literature has generally divided and evaluated the risk attached to congenital mitral valve lesions based on stenosis versus insufficiency, not leaflet function. In addition, the Carpentier classification was developed before two-dimensional echocardiography was routinely available. Individual interpretations of the functional anatomy introduce variability, which makes the classification less reliable and reproducible (Mitruka and Lamberti 2000).

Mitruka and Lamberti proposed a unifying anatomic classification for congenital abnormalities

of the mitral valve based on the consideration of whether the valve is stenotic or insufficient. When numerous defects of the valve apparatus are present, the predominant defect causing the functional deficit will direct the classification of the lesion. The many forms of mitral valve pathology can be coded in a hierarchical system by selecting the predominant lesion as the first diagnosis and each additional lesion as a subsequent diagnosis in decreasing order of importance. Using this rule the division of congenital mitral valve defects is as follows: type 1 lesions are supra-annular and type 2 lesions valvular, with type 2 subdivided into group A (annular defects) and group B (leaflet defects). Type 3 lesions are subvalvular, with group A involving abnormalities of the chordae tendineae and group B defects of the papillary muscles. Type 4 lesions are mixed lesions. The authors anticipate that adoption of their classification would minimize observer variability in the diagnosis and that the valve function can be described as a consequence of the valve anatomy. This, in turn, allows a segmental and systematic approach that is useful in selecting the best therapeutic options (Mitruka and Lamberti 2000).

Mitral valve reconstruction is the preferred technique for any kind of mitral valve disease in infants, children, and adolescents. This avoids the need for valve replacement with all its drawbacks, which is particularly important in infants and small children in the face of the complete lack of a prosthesis suitable for this age group. Even when an optimal result of primary reconstruction cannot be achieved, time is gained so that later a definitive adult-size prosthesis can be implanted. We are convinced that reconstruction allows valve growth without a need for anticoagulation. This is best achieved when the whole spectrum of reconstruction techniques are available and can be applied individually, avoiding the implantation of any prosthetic material.

Replacement of the mitral valve should be reserved for patients with truly irreparable valve damage (Hetzer et al. 2008).

12.3.5.2 Classification of Congenital Mitral Valve Stenosis

Congenital mitral valve stenosis is a very rare congenital heart defect, affecting less than 4 out of 1,000 infants with congenital heart disease (Keith et al. 1967). Infants with congenital mitral stenosis have a mortality rate approaching 40% after 2 years, regardless of the treatment applied (Moore et al. 1994).

Based on postmortem analyses of 49 children with mitral valve stenosis, Ruckman and Van Praagh (1978) proposed a division of mitral valve stenosis into four types, which is widely accepted:

- *Type A*: abnormalities of the mitral valve commonly seen in biventricular hearts. These lesions are subdivided into groups with short chordae, with abnormal mitral valve attachments, and with loss of interpapillary distance.
- *Type B*: lesions found in patients with a hypoplastic left ventricle.
- *Type C*: lesions found with the supra-annular mitral ring.
- *Type D*: the parachute mitral valve. This is a mitral valve abnormality in which all chordae tendineae of the mitral valve, which may itself be shortened and thickened, insert into a single, abnormal papillary muscle, usually causing mitral stenosis. The parachute mitral valve may be part of Shone's complex (1963). A congenital mitral valve stenosis associated with left ventricular outflow tract obstruction, Shone's complex, and age <3 months at operation are significant risk factors for early mortality (Serraf et al. 2000)

12.3.5.3 The Hammock Valve

The hammock valve is similar to the parachute mitral valve; however, the chordae are shortened or absent, and the thickened mitral valve leaflets insert directly into the rudimentary papillary muscle. Mitral valve excursion is limited and this results in mitral valve stenosis. The hammock valve is extremely rare; transitional forms between the hammock valve and parachute valve are possible.

12.3.5.4 Shone's Complex

Shone and colleagues described a developmental complex consisting of obstructions at many levels of the heart (Shone et al. 1963). This complex has four components:

- Parachute mitral valve
- Supra-anular mitral ring
- Subaortic stenosis
- Coarctation of the aorta

All four classical components were found in 19 out of 30 patients in one of the largest series reported (Bolling et al. 1990). *The abnormalities of the mitral valve* include fusion of the papillary muscles, fusion of the papillary muscle with the ventricular wall, and true parachute mitral valve with only one papillary muscle and fused chordae. A pressure gradient of >8 mmHg across mitral valve is regarded as significant. The aortic valve is usually bicuspid. Mitral valve stenosis or obstruction by the supra-anular ring was the main intracardiac lesion, causing early presentation, in 8 out of 27 patients with Shone's complex reported by Brown et al. (2005). These patients showed severe and progressive left ventricular outflow tract obstruction and suffered from pulmonary hypertension (Bolling et al. 1990). In practice there is a broad spectrum of manifestations of this complex, ranging from mild lesions to severely obstructive or hypoplastic left heart anatomy that necessitates single-ventricle palliation (see also ► Chapter «Surgery for Aortic Atresia, Hypoplastic Left Heart Syndrome, and Hypoplastic Left Heart Complex», Sect. 17.1 and Sect. 17.6.8).

Surgical treatment of Shone's anomaly must be tailored to the individual patients since the anatomical features are very variable. Anomalies causing hemodynamic problems must be addressed first. Many patients need multiple operations, particularly when the mitral valve is involved. In three large series, hospital mortality ranged from zero to 16% and late mortality from 10 to 24% (Bolling et al. 1990; Brauner et al. 1997; Brown et al. 2005). Late outcome in Shone's anomaly correlates with the severity of the mitral valve obstruction and the degree of pulmonary hypertension (Bolling et al. 1990; Brauner et al. 1997; Cavigelli-Brunner et al. 2012).

12.3.5.5 Congenital Mitral Valve Incompetence

Infants and children presenting with congenital atrioventricular valve incompetence represent a significant surgical problem. A congenitally abnormal valve may develop progressive insufficiency during early childhood. Anatomic reasons for congenital mitral insufficiency may be variable and can present in combination (Berguis et al. 1964; Davachi et al. 1971; Noren et al. 1964; Ohno et al. 1999):

- Cleft in the anterior or posterior leaflet
- Shortened leaflets
- Elongated chordae
- Hypoplastic leaflets
- Accessory orifice (double-orifice mitral valve)
- Ring dilatation
- Ischemic damage of the papillary muscles, as in patients with anomalous origin of the left coronary artery from the pulmonary artery (Bland–White–Garland syndrome)
- Direct leaflet–papillary muscle attachment
- Short or absent chordae
- Solitary papillary muscle

Connective tissue disorders such as Marfan's syndrome, mitral valve prolapse, or myxomatous mitral valve degeneration can also result in symptomatic mitral valve insufficiency in early childhood.

Surgical methods for the treatment of congenital mitral insufficiency are variable and must be tailored according to the individual anatomy in each patient. Segmental analysis of the insufficient mitral valve leads to a correction designed to optimize the function of the leaflets, the chordae, or the papillary muscles (Lamberti and Kriett 2007). The surgical methods include (Carpentier and Brizard 2006; Ohno et al. 1999; Okita et al. 1988; Lamberti and Kriett 2007):

- Plication of the commissures
- Plication of redundant leaflet portions
- Cleft closure by additional anuloplasty
- Leaflet resection, shortening, and replacement
- Creation of two orifices
- Chordal shortening or replacement

Often it is necessary to combine different methods to achieve optimal reconstruction of the insufficient valve. When mitral valve replacement cannot be avoided, a mechanical valve prosthesis is

usually appropriate. Bioprosthetic valves and homografts tend to degenerate rapidly in infants and children. Experience with the Ross–Kabbani operation (autologous transplantation of the pulmonary valve into mitral position) in infants is very limited, and long-term results in children are not available (Frigiolla et al. 2005; Mitchell et al. 2001).

12.3.5.6 Ischemic Mitral Valve Incompetence

This type of mitral valve incompetence usually occurs in patients with anomalous origin of the left coronary artery from the pulmonary artery (Bland–White–Garland syndrome, see ► Chapter «Congenital Anomalies of the Coronary Arteries and Coronary Diseases of Children and Adolescents», Sect. 20.2.1) and is the result of a combination of papillary muscle ischemia, dyskinesia of the free left ventricular wall, and left ventricular dilatation (Michielon et al. 2003; Noren et al. 1964). Mitral valve surgery in such patients is controversial (Dodge-Khatami et al. 2002). In patients with mild or moderate mitral valve incompetence, it has been shown that correction of the coronary system alone may lead to an improvement in mitral valve insufficiency. By normalizing the left ventricular end-diastolic diameter, the mitral valve insufficiency gradually decreases, but will not completely disappear. Although patients show an improvement in global ventricular function, they may be not free of symptoms because of this residual mitral valve incompetence (Huddleston et al. 2001; Michielon et al. 2003).

Persistence or recurrence of significant mitral valve regurgitation after correction of Bland–White–Garland syndrome should lead one to suspect a problem with the reimplanted coronary artery (Huddleston et al. 2001).

Our experience with this anomaly in 20 pediatric patients shows that simultaneous correction of severe mitral valve incompetence in the form of a mitral valve anuloplasty, performed in five patients, was able to prevent an aggravation of hemodynamic instability after the operation (Alexi-Meskishvili and Hetzer 2001; Alexi-Meskishvili et al. 1994).

12.3.6 Diagnostic Modalities

Accurate and thorough preoperative echocardiography is mandatory to define lesions based on

leaflet motion and to select the appropriate reconstruction technique (Chauvaud et al. 1997a, b). Visualization of the leaflet function by preoperative transthoracic two-dimensional echocardiography and by cardiac catheterization may differ (Banerjee et al. 1995; Freedom and Smallhorn 1988). Preoperative cardiac catheterization helps to evaluate the degree of pulmonary hypertension and define the anatomy of associated intracardiac and extracardiac defects (Brown et al. 2005).

12.3.7 Surgical Indications

Often infants and children are referred for mitral valve operation in the absence of manifest symptoms. Gross cardiomegaly and dilatation of the left atrium in a seemingly asymptomatic child may provide an adequate basis for operation if the preoperative echocardiographic analysis suggests that the valve is amenable to repair. In symptomatic children surgical intervention is considered anyways, especially if there is intractable heart failure, severe pulmonary hypertension, or a combination of both or when symptoms become severe or when exercise limitations become unacceptable (Mitruka and Lamberti 2000; Uva et al. 1995). In patients with a markedly abnormal valve or in those who have previously undergone reconstruction, mitral valve replacement may be the only remaining option.

12.3.8 Surgical Approaches to the Mitral Valve in Children

In the biventricular heart, the mitral valve can be approached through a variety of incisions. For small children without significant dilatation of the left atrium, the transeptal approach provides optimal exposure of a defective septal leaflet. If the incision is extended into the dome of the left atrium (the superior transeptal approach), ideal exposure of the mitral valve and its apparatus is possible, even in the smallest patients (Aharon et al. 1994; Lamberti and Kriett 2007). In older patients, an incision posterior to the intra-atrial sulcus is usually the most suitable. Transapical access through the left ventricular apical has also been described (Barbero-Marcial et al. 1993). The use of deep retractors may push the mitral annulus away from the surgeon and interfere with direct vision of and the approach to the valve. Plenty of

time should be devoted to inspection of the valve. Testing of the valve with gentle cold isotonic saline flushed into the left ventricle helps to assess apposition of the leaflets. All valve components should be systemically evaluated (■ Table 12.2):

- Supravalvular area
- Valve anulus
- Valve leaflets
- Chordae
- Papillary muscles

■ **Table 12.2** Systematic classification of congenital mitral valve anomalies

Type I: supravalvar
A: Supravalvar ring
Type II: valvar
A: Anulus
1: Midvalvar ring
2: Hypoplasia
3: Dilatation
4: Deformation
B: Leaflet
5: Hypoplasia/agenesis
6: Cleft
7: Excessive tissue
8: Double-orifice mitral valve
Type III: subvalvar
A: Chordae tendineae
1: Agenesis
2: Shortened-funnel valve
3: Elongated
B: Papillary muscle
4: Hypoplasia/agenesis
5: Shortened
6: Elongated
7: Single—parachute valve
8: Multiple—hammock valve
Type IV: mixed
All possible combinations of types I–III
Modified from Mitruka and Lamberti (2000)

Intraoperatively the valve diameter after reconstruction must be comparable with the normal size calculated according to body surface area (■ Table 12.3). For this purpose Carpentier published a correlation between normal valve diameter and body surface area in 1983. Since he gives «Rowlatt et al. (1963)» as the source, we assume that the circumferences given in that publication were converted by Carpentier to valve diameter measurements.

During lateral or posterior anuloplasty, great care must be taken not to produce kinking of the circumflex coronary artery (■ Fig. 12.57).

■ **Table 12.3** Heart valve diameters calculated in relation to body surface area (BSA) according to Rowlatt et al. (1963)

Body surface area [m ²]	Valve diameter [mm]			
	Mitral valve	Tricuspid valve	Aortic valve	Pulmonary valve
0.25	11.2	13.4	7.4	8.4
0.30	12.6	14.9	8.1	9.3
0.35	13.6	16.2	8.9	10.1
0.40	14.4	17.3	9.5	10.7
0.45	15.2	18.2	10.1	11.3
0.50	15.8	19.2	10.7	11.9
0.60	16.9	20.7	11.5	12.8
0.70	17.9	21.9	12.3	13.5
0.80	18.8	23.0	13.0	14.2
0.90	19.7	24.0	13.4	14.8
1.00	20.2	24.9	14.0	15.3
1.20	21.4	26.2	14.8	16.2
1.40	22.3	27.7	15.5	17.0
1.60	23.1	28.9	16.1	17.6
1.80	23.8	29.1	16.5	18.2
2.00	24.2	30.0	17.2	19.0

Modified according to Carpentier (1983)
 Approximated standard deviations for the mitral valve are 1.9 mm (BSA <0.3 m²) and 1.6 mm (BSA >0.3 m²)

Fig. 12.57 Danger of coronary kinking in **a** lateral anuloplasty and **b** posterior Gerbode anuloplasty

The use of synthetic pledgets should be avoided, especially in small children, as they can lead to hemolysis. We do not use synthetic rings at all in children because they fix the annulus and eliminate the possibility of its growth (Aharon et al. 1994). As suture pledgets and reinforcing material for anuloplasty, we prefer to use autologous nontreated pericardium which is excellently suited as a reconstruction material, allows growth, and at the same time remains stable. In patients with congenital mitral valve stenosis, aggressive commissurotomy may produce significant valve incompetence.

An exemption for using a prosthetic mitral valve ring may be the rare congenital Marfan's patient who may present already in early childhood with a severely dilated mitral annulus, which after reduction and improvement of valve function may still have (almost) normal adult dimensions.

Once the reconstruction is completed, the heart is de-aired, and the results may be evaluated with transesophageal echocardiography. Reinstitution of cardiopulmonary bypass and revision of the reconstruction are necessary in some patients when the results of the reconstruction are not yet satisfactory (Lamberti and Kriett 2007). This may have been already suspected from hemodynamic data once having come off bypass.

12.3.9 Cardiopulmonary Bypass and Myocardial Protection

The operation is performed through a full median sternotomy. For cosmetic reasons in female patients with fully developed breasts, a right submammary incision may be used. A conventional

heart–lung machine with a small priming volume is used, with aortic and bicaval cannulation. The superior vena cava is cannulated directly for better mitral valve exposure. In most cases we operate in moderate hypothermia of 32 °C. The patient's core body temperature can be further lowered depending on the complexity of the procedure. Myocardial protection is achieved with antegrade crystalloid or blood cardioplegia, and topical cooling with slush ice may be added. We repeat cardioplegia administration every 20 min. When the intracardiac procedure has been finished, the heart is de-aired by applying gentle atrial and ventricular massage and aspiration through the cardioplegia cannulas. We still believe in preventing air embolism by carbon dioxide insufflation into the operative field, although more recently no advantage could be shown in an adult population (Chaudhuri et al. 2012).

12.3.10 Treatment Options for Congenital Mitral Valve Anomalies

Mitral valve surgery in infants and children is less well established and less standardized than in adults. Reasons for this are the greater complexity of the defects, a broad variety of reconstruction techniques, the prospect of multiple repeat operations, and the lack of suitable prostheses (Lamberti and Kriett 2007). The limitations of replacing the mitral valve with a mechanical valve in infants and children are well recognized. Techniques for reconstruction of the mitral valve have become increasingly sophisticated in recent years, so that the interval before unavoidable valve replacement

has been considerably extended (Baird et al. 2012; Hetzer et al. 2008; Mitruka and Lamberti 2000). The surgical techniques consist of dilatation, reduction or plication of the anulus, the implantation of different types of ring, closure of clefts, sliding plasty, and many other alternatives (Pritisanic et al. 2005).

Valve replacement is the last option to be followed (Alsoufi et al. 2011; Brown et al. 2012; Hetzer and Drews 1999; Sim et al. 2012). Although replacement of the mitral valve in children with cryopreserved mitral valve homografts provided satisfactory early postoperative results (Plunkett et al. 1998), this technique must be considered investigational at the present time because the homograft valves degenerate rapidly in children (Revuelta 1998).

The *Ross-Kabbani operation*: Replacement of the mitral valve with the autologous pulmonary valve (Kabbani et al. 1999, 2001) represents a further alternative option, although long-term results in children are not yet available (Brown et al. 2006). In individual case reports, this operation was recommended for very small infants when valve reconstruction is impossible or a previously implanted mechanical prosthesis develops thrombosis despite adequate anticoagulatory treatment (Frigiolla et al. 2005; Mitchell et al. 2001).

More recently, on the AATS Mitral Conclave in New York, NY, in May 2013, Quiñonez et al. from the Boston Children's Hospital presented his early experience with catheter deployable valve for mitral valve replacement in seven neonates and infants with a mitral diameter of <12 mm (range 8–12 mm). He modified an externally stented bovine jugular vein graft (Melody™ valve) for open-heart surgical implantation in this cohort. His group hypothesized that the valve can be expanded in the catheterization laboratory as the child grows. There was one early death in a salvage patient. Two patients have undergone subsequent transcatheter balloon expansion of the prosthesis (to 12 mm) at 3 and 4 months postoperatively, both with ongoing mild regurgitation (Quiñonez et al. 2013). Experience with isolated *balloon dilatation* for congenital mitral stenosis is very limited, and there are only few reports about the long-term results of this procedure (Alday et al. 1994). This procedure should be considered before mitral valve replacement in young patients (less than 5 years old) and in those with hypoplas-

tic mitral anulus in whom valve replacement would be problematical (Spevak et al. 1990). Application of this procedure is limited by the lack of decisive functional improvement in response to balloon dilatation and the risk of it precipitating acute and severe mitral valve insufficiency.

Although balloon dilatation can significantly reduce the transmitral pressure gradient in the majority of patients, this effect persists in only about 40% of cases (Moore et al. 1994). The best result is observed in patients with pure stenosis and flexible leaflets. The worst results have been seen in children who had anomalies of the papillary muscles in addition to the congenital mitral valve stenosis. Many patients need further procedures to treat either recurrent mitral valve stenosis or mitral valve regurgitation resulting from dilatation-related disruption of the mitral valve apparatus (McElhinney et al. 2005).

12.3.11 Surgical Treatment

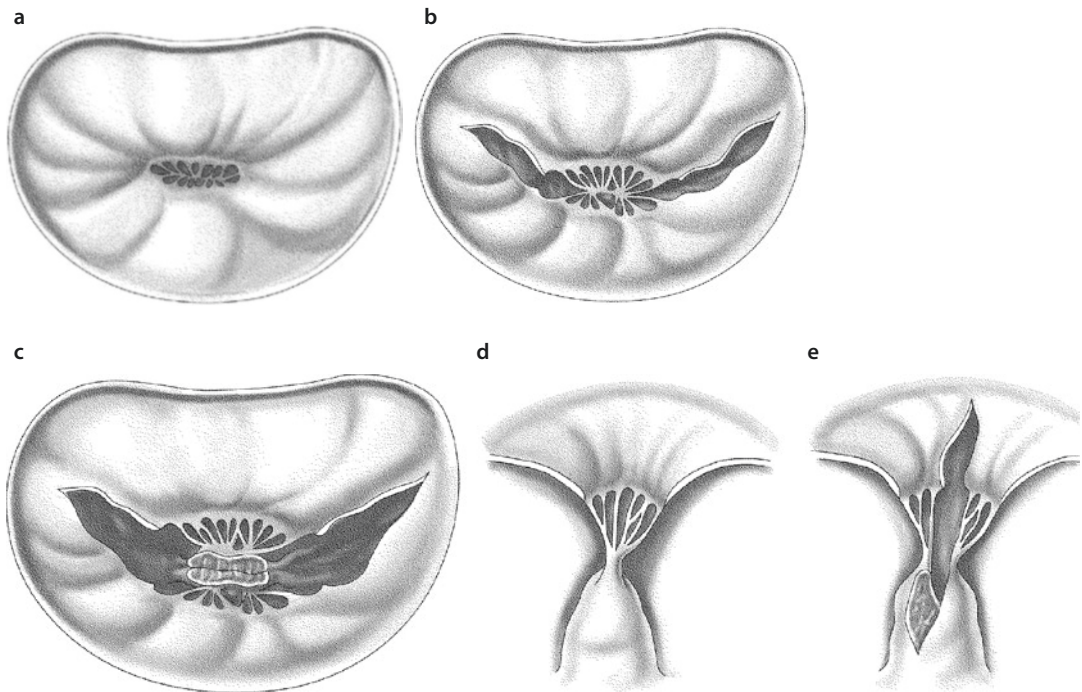

12.3.11.1 Surgery for Stenotic Anomalies of the Mitral Valve

■ ■ Supravalvar mitral ring

Resection of the fibrous tissue taking care not to damage the anterior leaflet is the procedure of choice. While the ring has to be cut off the anulus, it is usually bluntly separated from the valve leaflets with the resection begun posteriorly and extended anteriorly. Only rarely is mitral valve replacement necessary (Sullivan et al. 1986).

■ ■ Single papillary muscle—parachute mitral valve

Fenestration of the papillary muscle (split into anterior and posterior) with fenestration of the interchordal leaflet spaces typically releases the subvalvar stenosis. The most appropriate site for leaflet-splitting incisions is on both sides of the common papillary muscle toward the trigones (■ Fig. 12.58a, b). These incisions are extended into the body of the papillary muscle which is split toward its base, ensuring sufficient thickness of both «new» papillary muscles (■ Fig. 12.58c–e). Valve incompetence can be treated by leaflet suturing or anulus remodeling. As would be expected, the success rate of this procedure increases with the age and size of the patients.

■ Fig. 12.58 a–e Surgical procedure for single papillary muscle (parachute mitral valve). a, b Incisions to split the leaflets; c–e extension of the incisions deep into the body of the papillary muscle

■ ■ Hammock mitral valve

This lesion is one of the most difficult mitral anomalies to correct, since the muscular mass found beneath the leaflets impinges on the left ventricular outflow tract (Stellin et al. 2000).

Ideally the hammock valve is treated by excision of the excess papillary muscle beneath the mural leaflet, fenestration of the interchordal spaces, cleft suturing, or anular remodeling.

If the papillary muscles are not attached to the free edges of the leaflets, a suitably thick part of the posterior left ventricular wall carrying the rudimentary papillary muscle and the chordae is carved out of the wall (■ Fig. 12.59a, b). It must be ensured that both the remaining wall of the left ventricle and the «new» papillary muscle maintain—or obtain—sufficient muscle thickness to fulfill their respective functions (■ Fig. 12.59c). Valve replacement is often necessary (Uva et al. 1995).

Hammock mitral valve is a strong predictor of a high incidence of reoperations (Prifti et al. 2002).

12.3.11.2 Surgery for Mitral Valve Incompetence

■ ■ Dilatation of the valve anulus

The treatment for this disorder is typically a form of *anuloplasty*. In children less than 10 years of age, rectangular resection of the mural leaflet, anular plication, and suturing of the leaflet edges will usually reduce regurgitation and allow for future anular growth. The Kay–Whooler (eccentric) anuloplasty (Kay et al. 1961; Whooler et al. 1962) involves reduction of the dilated posterior mitral anulus by two sutures pledgeted with autologous pericardium placed anterior to each commissure and running at a varying distance along the mural anulus. When using the Kay–Whooler technique, it is essential for long-term stability that the sutures go through the fibrous trigones. Tightening the sutures narrows the anulus (■ Fig. 12.60).

The modified Paneth anuloplasty, published by his group (Burr et al. 1977), is used mostly in children and adolescents with severe anulus dilatation of any origin. This technique involves a reduction of the circumference of the posterior anulus by the placement of horizontal polypropylene mattress sutures that are anchored to the trigones with

■ Fig. 12.59 a–c Excision of a portion of the ventricular wall in hammock mitral valve correction

■ Fig. 12.60 a, b Kay-Whooler technique in dilated mitral valve annulus

■ Fig. 12.61 a–c Modified Paneth anuloplasty

pledgets of untreated autologous pericardium and placed in such a manner that they tauten the posterior annulus (■ Fig. 12.61a). The degree or extent of shortening is chosen so that the leaflets coapt well, and normal valve size according to the calculated body surface area is maintained (Carpentier 1983; Rowlatt et al. 1963; see ■ Table 12.2). The shortened posterior annulus is then stabilized with an untreated autologous pericardial strip (■ Fig. 12.61b, c). The pericardial strip can also be already primarily reinforcing the annulus with the shortening sutures.

■ Prolapse of the anterior leaflet

When all three segments of the anterior leaflet are prolapsed and there is no adequate chordal support, results of triangular resection are unsatisfactory (Mantovani et al. 2005). In children it seems to be more effective to shorten the chordae in combination with placing an autologous pericardial strip to strengthen the annulus and treat anular dilatation (Aharon et al. 1994). The main technical problem with artificial chordae is determining their correct length, especially given the fact that e-polytetrafluoroethylene

sutures are very slippery and the knots may slide when tied. In adults David (2004) recommends using the lateral commissure as a reference for correct chordal length estimation. In children it is much more difficult to estimate the correct length. The zone of apposition along the length of the healthy, nonelongated native chordae (attached to the nonprolapsing part of the valve) may serve as a reference (Boon et al. 2007; Minami et al. 2005).

■ ■ Leaflet hypoplasia or agenesis

Treatment for leaflet agenesis consists of a rectangular resection with suturing of the free edges of the leaflet remnants after a sliding valvuloplasty of the remnants has been performed. A defect in the anterior leaflet may be treated by direct suturing or by application of an autologous pericardial patch depending on its size (Aharon et al. 1994; Chauvaud et al. 1997a).

■ ■ Isolated leaflet cleft

The optimal treatment consists of closure of the leaflet cleft (Zias et al. 1998). Anterior leaflet clefts are repaired by direct suture technique. Care must be taken to avoid extending the suture line beyond the site of primary chordal insertion, as this would limit the valve opening. Posterior leaflet clefts may be treated by quadrangular resection or simple closure. In the case of a three-leaflet mitral valve, commissuroplasties at the anterolateral and posteromedial commissures are indicated. Suturing of the free edges of a cleft in the posterior leaflet and plication of the annulus also offer good palliation. If there is associated annular dilatation, an anuloplasty is performed concurrently (Perier and Clausnizer 1995). In rare cases the mitral cleft is a part of an anomaly of the ventriculo-arterial connection and is addressed during and after the complex corrective procedure (Fraise et al. 2002; Menahem and Anderson 2004; Photiadis et al. 1995).

■ ■ Double-orifice mitral valve

There are two strategies in treating the mitral valve with two orifices: the accessory orifice can be left intact if it is competent (Carpentier and Brizard 2006) or it can be oversewn and obliterated if it is incompetent and the main orifice is of adequate diameter (Baño-Rodrigo et al. 1988). If the valve is stenotic, the treatment is more complicated, as transection of the bridging tissue will

often render the valve incompetent, necessitating extensive reconstruction or valve replacement. Up to one half of the posterior leaflet is amenable to resection, but only a small wedge of the anterior leaflet can be safely resected. Larger areas of the unsupported anterior leaflet can be treated by chordal shortening, transfer, or replacement. Due to the consequential disparity between the mitral valve opening area and the leaflet size after leaflet resection, concomitant anuloplasty is usually necessary. Occasionally valve replacement is unavoidable.

■ ■ Chordae tendineae agenesis and rupture

The absence or rupture of the primary chordae of the central posterior scallop is most effectively dealt with by rectangular leaflet resection and direct suturing. Modified Gerbode plication plasty is the technique we use for ruptured chordae of the central scallop of the posterior leaflet (Gerbode et al. 1962) (■ Fig. 12.62a). The flail leaflet segment is plicated toward the ventricle with a V-shaped suture line of polypropylene interrupted mattress sutures pledgeted with untreated autologous pericardium (■ Fig. 12.62b, c). When valve competence is assured, the posterior annulus is stabilized with a strip of untreated autologous pericardium which is anchored to both trigones with separate pledgeted mattress sutures (■ Fig. 12.62d, e).

The use of artificial chordae of expanded polytetrafluoroethylene sutures in neonates and children has been reported (Anagnostopoulos et al. 2007; Kawahira et al. 1999; Matsumoto et al. 1999). Some authors suppose that, when this technique is combined with other conservative methods of mitral valve reconstruction in children, it delays and possibly entirely avoids the need for implantation of a mechanical prosthesis (Murakami et al. 1998). Valvular restriction by artificial chordae has so far not been observed in the midterm follow-up in growing children (Boon et al. 2007; Kawahira et al. 1999; Minami et al. 2005). However, the long-term results could not yet be observed (Matsumoto et al. 1999). The latest report with a mean follow-up of 8.3 years during a 17-year experience showed satisfactory results with mitral valve repair with artificial chordae in infants and children (Oda et al. 2013). Defects of the secondary chordal defects are addressed by suturing the free edges of the leaflet to the secondary chordae.

■ Fig. 12.62 a–e Procedure followed when chordae tendineae are ruptured or absent: modified Gerbode plasty

■ ■ **Elongated chordae tendineae, hypoplastic and shortened or ruptured papillary muscles, and mixed lesions**

Treatment of these anomalies must address the individual anatomy and anular remodeling. Often, valve replacement is the only viable option. A combination of different methods of valve reconstruction is necessary:

- Chordal shortening by splitting the papillary muscle and suturing the chordae in the depth of the papillary muscle stalk
- Resection and suturing of the prolapsed portion of the leaflet
- Quadrangular resection of the opposing segment of the posterior leaflet
- Transfer of the primary chordae by suturing the segment to the atrial surface of the anterior leaflet
- Fenestration of the interchordal spaces

When leaflet mobility is limited by abnormally short chordae or malformed papillary muscles (as in parachute or hammock valves), splitting the papillary muscles may improve leaflet excursion. Persistence of interchordal tissue can impede left ventricular inflow. Removal of the tissue between the chordae and resection of secondary chordae can increase the effective orifice area. Replacement of

chordae by expanded polytetrafluoroethylene sutures is an option, with limited but spreading use in children (Matsumoto et al. 1999; Oda et al. 2013).

■ ■ **Treatment of systolic anterior motion in patients with hypertrophic obstructive cardiomyopathy**

In patients with hypertrophic obstructive cardiomyopathy (HOCM), no distinct abnormalities of the chordae tendineae and papillary muscles are apparent. Valve reconstruction is guided by careful transesophageal echocardiographic assessment of the septal anatomy and thickness, mitral valve function and anatomy, and mobility of the subvalvular apparatus. The segments of the anterior leaflet closest to the trigones are sutured to the corresponding posterior anulus with interrupted polypropylene mattress sutures pledgeted with untreated autologous pericardium. Sutures are passed through the coaptation line of the anterior leaflet and the corresponding posterior anulus (■ Fig. 12.63a, b), Hetzer technique (Hetzer et al. 2008).

In this manner mobility of the anterior leaflet in the segments near the trigones is limited, and the development of systolic anterior motion (the SAM phenomenon) resulting in mitral valve insufficiency is prevented (■ Fig. 12.63c, d).

■ **Fig. 12.63** a Anterior leaflet retention plasty for systolic anterior motion (SAM) in hypertrophic obstructive cardiomyopathy (Hetzer technique); b completed repair (view from the atrium); c depiction of mitral valve insufficiency in hypertrophic and obstructive cardiomyopathy with SAM, longitudinal cross-sectional view; d the mitral valve regurgitant jet is diverted into the LVOT after septal myectomy and the retention plasty of the anterior leaflet; site of septal myectomy as viewed through the aortic valve. Opposite the anterior mitral valve leaflet (the *broken line* marks the incision in the myocardial septum; Hetzer technique) (Delmo Walter et al. 2010; Hetzer and Delmo Walter 2013) ph

Intraoperative measurement of the mitral valve opening area uses Hegar dilators. It is important to ensure that the age-related minimal normal valve diameter is reached, to avoid mitral valve stenosis. In addition to the retention plasty of the anterior mitral valve leaflet, Morrow-type subaortic myectomy through transaortic access should always be performed. Left ventricular and aortic pressure is measured directly and simultaneously. As the gradient across the left ventricular outflow tract may be low (30 mmHg) because of anesthesia, isoproterenol is administered, or premature ventricular contractions are induced to determine the maximal pressure gradient.

An oblique aortotomy is made, leading rightward into the noncoronary sinus in the direction of the aortic anulus. The aortic valve is inspected and the subvalvular region exposed. We make parallel incisions in the septum directly opposite the anterior mitral leaflet and resect long blocks of septal myocardium between the two incisions, which start directly below the aortic anulus at the right coronary sinus and at the commissure

between the right and the left coronary sinuses (Hetzer et al. 2008; ■ Fig. 12.63e). The incisions should be continued apically beyond the point of mitral–septal contact, which is usually marked by a fibrous band. This wide incision beneath the aortic valve improves exposure of the important area toward the apex.

After septal myectomy and anterior leaflet retention plasty, the aortic and mitral valves must be inspected to ensure that they have not been injured. Pressures in the left ventricle and aorta must be remeasured, and the transesophageal echocardiographic evaluation is repeated after weaning from the cardiopulmonary bypass. Myectomy has been successful when there is little or no residual LVOT gradient, absence of SAM, and no mitral valve stenosis.

■ Mitral valve reconstruction for endocarditis

The vital principle consists of adequate debridement of the infected tissue and meticulous flushing of all affected areas with povidone–iodine solution, regardless of whether purulence or

vegetations were present or not. Further, meticulous removal of vegetations, when present, and anatomic reconstruction using sutures reinforced with untreated autologous pericardial pledgets or pericardial strips are necessary.

Mitral valve reconstruction is performed using either anterior commissuroplasty (our modified Kay-Whooler technique; see ■ Fig. 12.60a, b), posterior commissuroplasty with leaflet resection (see ■ Fig. 12.61a), or posterior commissuroplasty with pericardial strip reinforcement as in our modification (see ■ Fig. 12.61b, c). Chordal rupture can be corrected by chordal reimplantation or replacement.

12.3.11.3 Atrioventricular Valve Reconstruction in Patients with Single Ventricle

Significant atrioventricular (AV) valve insufficiency has been reported in up to one third of patients with single ventricle who undergo palliation (Imai et al. 1999; Sallehuddin et al. 2004). This is considered a significant preoperative risk factor as well as a reason for the worsening in late results after bidirectional cavopulmonary shunt (BCPS) and after Fontan operation (Scheurer et al. 2008). We therefore prefer to correct significant AV valve insufficiency when performing BCPS. This provides a better background, avoids the need for additional intracardiac repair when the Fontan operation follows, and improves the results. Common reasons for AV valve insufficiency in patients with single ventricle are annular dilatation, elongation of the chordae, and the presence of clefts. To achieve valve competence, it is often necessary to combine valve reconstruction with anuloplasty. Although there are techniques that improve AV valve function, such as anuloplasty, bi-valvation of the common atrioventricular valve, cleft closure, chordal elongation or shortening, and the suturing of pericardial patches (Lamberti and Kriett 2007; Oku et al. 1994), there are still a number of patients who require AV valve replacement due to progressive valve insufficiency that is not amenable to reconstruction. To maintain ventricular function, it is important to preserve the chordae and the papillary muscles. Chordal attachments must be divided only if they obstruct the ventricular outflow tract (Mahle et al. 2001). The development of postoperative total AV block is common.

In patients with hypoplastic left or right ventricle and hypoplastic, insufficient corresponding valves not amenable to reconstruction, the insufficient valve can be closed with a pericardial patch, thus converting heart failure to mitral valve or tricuspid valve atresia. The creation or enlargement of an atrial septal defect is important in these circumstances to prevent atrial congestion.

12.3.11.4 Mitral Valve Replacement

At present there is no ideal valve prosthesis available for mitral valve replacement in children, particularly in early childhood and infancy (Alexiou et al. 2001). In children every possible effort should be made to preserve the native valve. It is our policy to attempt mitral valve reconstruction in every child, even when less than optimal results of the reconstruction must be accepted and reoperations after some time must be planned. The philosophy behind this concept is to bring every child—if necessary by repeated operations—up to an age when a prosthesis that will last for a lifetime can be implanted (Hetzer and Drews 1999; Hetzer et al. 2008). If reconstruction for mitral valve stenosis is attempted, mitral valve insufficiency often remains, partly due to defects of the subvalvar apparatus (such as parachute and hammock deformities). In this situation valve replacement is often the only remaining option (Beierlein et al. 2007; Günter et al. 2000; Kadoba et al. 1999). However, in small children whenever it is possible we prefer to implant a mechanical or biological aortic valve prosthesis in upside-down position. Most mechanical mitral valves are only available in sizes 25 and larger. Therefore, for smaller sizes, mechanical aortic valves, implanted in upside-down position, have to be used. The risk that arises after implantation of a mitral valve prosthesis that is too large is far greater than if elective second mitral valve replacement is performed after the child has grown (Caldarone et al. 2001).

Small prosthetic valves can lead to patient-prosthesis mismatch in the course of somatic growth of the patient (Vohra et al. 2006). The supra-annular implantation technique allows the mitral valve to be replaced with a prosthesis which is larger than the natural mitral valve ring (Kanter et al. 2011). After 15 years, all children with prosthesis of <23 mm have outgrown their valves, but mitral valve re-replacement with a larger size prosthesis is always possible, and the operative risk is low (Beierlein et al. 2007). In a large

multicenter study, the risk of developing total AV block was found to be between 8 and 30% (Caldarone et al. 2001; Kanter et al. 2005).

With the wide array of techniques currently available, satisfactory repair of congenitally anomalous mitral valves is possible in 80% of cases (Baird et al. 2012). Preservation of the chordal attachments is important in preserving ventricular function but is often not possible in infants and small children. When the anulus is too small to place the prosthesis in orthotopic position, the valve prosthesis may be implanted in supra-anular position in the left atrium (Tierney et al. 2008; Kanter et al. 2013; Rocafort et al. 2013). The most appropriate prosthesis for mitral valve replacement in older children is a low-profile mechanical bileaflet prosthesis (Alexiou et al. 2001; Alsoufi et al. 2011; Günter et al. 2000; Sim et al. 2012). In the not so distant past, the perioperative mortality for valve replacement in infants and children was 30–50% (Kadoba et al. 1999; Zweng et al. 1989). However, with improved myocardial preservation techniques, better valve prostheses, tighter control of postoperative anticoagulation, and improved postoperative intensive care unit management, the operative mortality for mitral valve replacement in children decreased to 3.5–11% (Alexiou et al. 2001; Günter et al. 2000; Brown et al. 2012), although valve replacement in the smallest children continues to carry a high early mortality of up to 20% (Beierlein et al. 2007; Serraf et al. 2000; Vohra et al. 2006). Repeat valve replacement is necessary in half of the cases within 3 years (Kanter et al. 2005). Long-term survival in small children remains poor, with an actuarial survival rate after 10–20 years of approximately 50–61% (Alexiou et al. 1999; Günter et al. 2000; Kadoba et al. 1999).

In a large multicenter study, the main reasons for second mitral valve replacement in 102 children operated on at age of less than 5 years were prosthetic valve stenosis and prosthetic endocarditis. In detail the following reasons for second mitral valve replacement were given:

- Stenosis of the original valve prosthesis (24 children, 83%)
- Thrombosis of the original valve prosthesis (4 children, 14%)
- Prosthetic valve endocarditis (1 child, 3%)

The second implanted prosthesis was always larger, which underlines the factor of continuing

growth of the anulus (Raghuveer et al. 2003). Children with mechanical valve prostheses must be placed on an anticoagulation regimen to maintain an international normalized ratio (INR) of between 2.5 and 3.5 (Günter et al. 2000). Long-term anticoagulation is usually well tolerated (Beierlein et al. 2007; Caldarone et al. 2001; Sachweh et al. 2007).

12.3.11.5 Implantation of the Extracardiac Valved Conduit for Mitral Valve Stenosis

In cases when the stenotic mitral valve is irreparable and valve replacement is not feasible due to anular hypoplasia in the setting of a normal-sized left ventricle, an extracardiac conduit with a porcine valve may be implanted (Amodeo et al. 1990). The operation is performed through a left thoracotomy or a median sternotomy (Laks et al. 1980). The prosthesis is attached to the left atrium by making an incision between the base of the left atrial appendage and the pulmonary veins. The distal end of the prosthesis is sutured to the apex of the left ventricle. Rapid calcification of the bioprosthesis in children is the main concern (Mazzerà et al. 1989; Serraf et al. 2000). The more recently published innovative surgical technique of implanting an individually modified transcatheter valve under direct vision with the option of stepwise dilatation during further follow-up (Quiñonez et al. 2013) may be applicable in these cases where earlier an atrioventricular conduit was thought of.

12.3.12 Results of Repairing Congenital Mitral Valve Anomalies

Results of mitral valve repair in pediatric patients have significantly improved in recent years (Hetzler et al. 2008; Delmo Walter et al. 2010). The reasons for this trend lie in better understanding of valve pathology, improved surgical techniques, changes in myocardial protection and extracorporeal circulation, and intraoperative use of transesophageal echocardiography. Mortality rates reported in different studies are difficult to compare because there are differences in the disease complexity, ages of the patients at operation, description of the mitral valve anomalies, and surgical methods used (Pritisanac et al. 2005; Seccombe 1999). Late results

are dependent on the age at operation, clinical presentation, presence or absence of valve insufficiency or stenosis, and other associated cardiac anomalies (Aharon et al. 1994). In general, higher mortality with reconstruction is to be expected when the mitral valve anomaly is associated with other additional heart defects (Wood et al. 2004). Best midterm and long-term results are achieved in patients with isolated mitral valve insufficiency because of annular dilatation or with the presence of a cleft (Zias et al. 1998). Results are suboptimal in patients with absent chordae (Sugita et al. 2001). In patients with mitral valve stenosis, the results are less satisfactory since there is greater complexity and variability in the pathology (Lorier et al. 2001). Many patients with mitral valve stenosis later need repeat operations and even mitral valve replacement (Uva et al. 1995; Serraf et al. 2000; Alghamadi et al. 2011; Remenyi et al. 2012; Jiang et al. 2013).

12.4 Ebstein's Anomaly

12.4.1 Introduction

Ebstein's anomaly is a rare, complex congenital malformation of the tricuspid valve and the right ventricle with very variable anatomy. The anomaly involves abnormal attachments of the tricuspid valve leaflets to the valve annulus. Marked variability exists in the degree of displacement of the septal and posterior leaflets into the cavity of the right ventricle. This may result in a right ventricle that is divided into an atrialized portion of the right ventricle above the valve leaflets and a remaining, more or less, hypoplastic ventricular portion below the valve leaflets. The lesion was first described in 1866 by the German pathologist Wilhelm Ebstein (1866) and was first referred to as Ebstein's disease in 1927 (Arstein 1927). The first diagnosis of Ebstein's anomaly in a living patient was made by Tournaire and associates (Tournaire et al. 1949).

The *incidence* of Ebstein's anomaly of the tricuspid valve is approximately 1:20,000 live births, accounting for less than 1% of all congenital heart defects. Male and female children are affected equally. In a large cardiac surgical center, Ebstein's anomaly accounts for less than 1% of all cardiovascular procedures for congenital heart disease (Hetzler and Pasic 2004).

Hemodynamic consequences of this lesion are directly related to the severity of the leaflet dis-

placement and the resultant tricuspid valve regurgitation. In the case of mild displacement and mild valve regurgitation, the patient may remain asymptomatic for many years. If, however, leaflet displacement and tricuspid valve regurgitation are severe, the pulmonary blood flow is decreased, the right atrium becomes dilated, and the blood is shunted from right to left through an atrial septal defect or more often a patent foramen ovale. The patient becomes cyanotic. The signs of heart failure may also develop secondary to a functional small right ventricle and decreased right ventricular compliance.

12.4.2 Mortality and Morbidity

Intrauterine mortality with this lesion is as high as 85%. Mortality after birth is related to the severity of cyanosis, the tricuspid valve deformation, and the lack of antegrade flow through the pulmonary valve (McElhiney et al. 2005). Newborns with cyanosis have a mortality rate of up to 70% compared to 15% for newborns without cyanosis (Arizmendi et al. 2004). Death is precipitated by heart failure or postoperative complications or occurs as sudden cardiac death. Actuarial survival among live-born patients has been reported to be 67% for the first year and 59% for the first 10 years (Giuliani et al. 1979).

Severity of the leaflet displacement and the degree of associated right ventricular outflow tract obstruction determine the age at which the patient develops symptoms. In large-scale investigations of Ebstein's anomaly, 81% of the patients were diagnosed during their first week of life, 6% when aged 1–4 weeks, 11% at the age of 5–25 weeks, and 2% when older than 25 weeks (Arizmendi et al. 2004; Correa-Villasenor et al. 1994; Kumar et al. 1971). After the first 6 months, the prognosis in infancy is approximately the same as that in childhood and adolescence (Arizmendi et al. 2004; Davidson et al. 1995; Davies et al. 2013; Yu et al. 2013).

12.4.3 History of Surgical Treatment

The surgical treatment of Ebstein's anomaly, the associated tricuspid valve incompetence, and the significant sequela remained controversial for a long time with regard to the surgical indication,

the most suitable operative technique (valve replacement or repair), the appropriate type of repair, and the optimal timing of the procedure. Reconstruction of the tricuspid valve in Ebstein's anomaly was not generally accepted, firstly because of the immense variety of pathological manifestations of the anomaly that makes the development of a standardized reconstruction concept difficult. Further, few surgeons have the opportunity to gain sufficient experience in the management of this defect since it so rarely occurs. Many surgeons favored tricuspid valve replacement, which is technically the most straightforward procedure, particularly after the first successful replacement was reported in 1963 by Barnard and Schrire (1963). Although some patients do well for many years after tricuspid valve replacement, prosthetic valve replacement exposes the patient to the well-known potential problems of prosthetic valve dysfunction, thromboembolism, endocarditis, and patient–prosthesis mismatch as a result of somatic growth of the patient. For these reasons a reparative plasty of the tricuspid valve should always be preferred to valve replacement, whenever it is possible. In cases where the tricuspid valve is completely absent so that no chordae or papillary muscles are recognizable or where the free edges of the leaflet are attached to the ventricular wall, reconstruction is not possible, and there is no alternative to prosthetic replacement in an older child or adult.

Hunter and Lillehei described the concept of *valve reconstruction* for the first time in 1958 (Hunter and Lillehei 1958). This technique was applied with clinical success by Hardy (Hardy et al. 1964) and was further modified by Danielson who has been credited with popularization of valve repair in Ebstein's anomaly in a large series of patients (Danielson et al. 1979a, b, c). In addition to reconstruction of the tricuspid valve, this technique includes transverse plication of the so-called atrialized chamber. In 1988, Carpentier introduced a technique of valve reconstruction with longitudinal (instead of transverse) plication of the atrialized chamber (Carpentier et al. 1988). This technique was further developed by Quaegebeur (Quaegebeur and Sreeram 1991). In contrast to these techniques, Hetzer in 1998 introduced a concept of tricuspid valve reconstruction in which the atrialized chamber can remain untouched (Hetzer et al. 1998).

In 2004 da Silva described a new technique for repair of Ebstein's anomaly (da Silva et al. 2004) which uses some principles of the Carpentier technique, but reconstructs the tricuspid valve in a significantly different way (da Silva et al. 2004, 2007; Dearani et al. 2008). According to da Silva (da Silva et al. 2007; da Silva and da Fonseca 2012), the surgical goal of the technique is to create a cone-like structure from the available tricuspid valve tissue, covering the right atrioventricular orifice and allowing leaflet-to-leaflet coaptation. This cone reconstruction technique was used successfully for primary correction of all forms of Ebstein's malformation (da Silva et al. 2007; da Silva and da Fonseca 2012; Vogel et al. 2012; Liu et al. 2011; Dearani et al. 2013a) and for re-repair due to residual severe tricuspid valve incompetence (Dearani et al. 2013b).

In neonates and infants, two different surgical strategies can be applied: valve reconstruction (Knott-Craig et al. 2000; Boston et al. 2011) or the univentricular approach known as the Starnes procedure (Starnes et al. 1991).

12.4.4 Anatomy

Ebstein's malformation of the tricuspid valve is characterized by three features:

- Adherence of the septal and posterior leaflets to the underlying myocardium with downward (apical) displacement of the functional anulus and so-called atrialization of the affected portion of the right ventricle
- Redundancy and fenestration of the anterior leaflet
- Dilatation of the right atrioventricular junction (i.e., the true tricuspid anulus)

Because each of these features may be manifested to different extents, the morphological appearance of the tricuspid valve in Ebstein's anomaly is also highly variable (Anderson and Lie 1979; Chauvaud et al. 2003; Chen et al. 2004).

Apical displacement always affects the septal leaflet, but it may also involve the posterior leaflet, and large parts of the affected leaflets are usually adhered firmly to the right ventricular wall (Becker 1995). The anterior leaflet is usually enlarged and resembles a billowed sail, but it is always attached to the anulus at the normal position (Becker 1995). Although the anterior leaflet

is not usually displaced, it is almost always anatomically abnormal. This leaflet may also have multiple chordal attachments to the ventricular wall. The displacement of the septal and posterior valve components in the direction of the apex of the right ventricular cavity divides the right ventricle into a supraventricular portion that is known as the atrialized chambers and a finally smaller subvalvular portion of the ventricle, the so-called true right ventricle. The true anulus of the tricuspid valve at the anatomic atrioventricular junction, the right atrium, and the functional tricuspid valve anulus are always dilated, and the tricuspid valve itself is usually incompetent. Dilatation of the right ventricle is associated not only with thinning of the right ventricular wall but also with an absolute decrease in the myocardial fiber count in the right ventricular myocardium (Anderson and Lie 1979). Significant fibrosis of the left ventricular myocardium in deceased neonates was also described (Celermajer et al. 1992b).

12.4.5 Associated Anomalies

An atrial septal defect or persistent foramen ovale is present in 90 % of the patients (Celermajer et al. 1992a; Watson 1974). In neonates with Ebstein's anomaly, the incidence of important *associated cardiac anomalies* is higher, 20–25 % (Arizmendi et al. 2004; Celermajer et al. 1992a, 1994; Kumar et al. 1971):

- Ventricular septal defects
- Transposition of the great arteries
- Tetralogy of Fallot
- Anomalous pulmonary venous drainage
- Aortic isthmus stenosis
- Atrioventricular septal defects

Abnormalities of the mitral valve in the form of fibrosis and prolapse were reported in 21 % of the patients (Cabin and Roberts 1981; Gerlis et al. 1993). Additional significant problems in these patients include an paroxysmal supraventricular tachycardia, which occurs in 25–50 %. Between 5 and 20 % of these patients have Wolff–Parkinson–White syndrome (Arizmendi et al. 2004; Giuliani et al. 1979). Other important complications of Ebstein's anomaly are cerebral abscesses and paradoxical emboli (Genton and Blount 1967; Mathews et al. 1983).

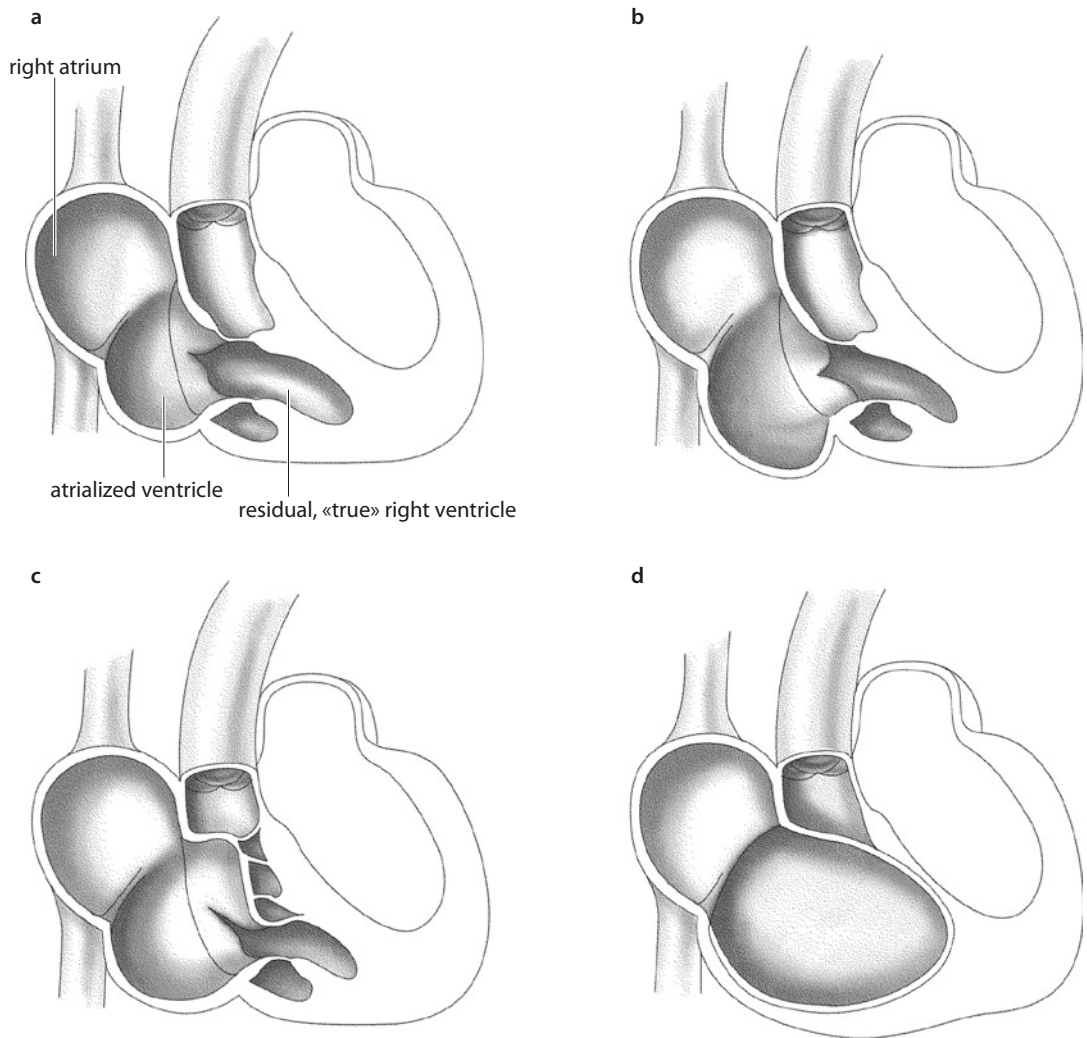

12.4.6 Classification

Carpentier's surgical classification of Ebstein's anomaly is valuable for making surgical decisions as to the most appropriate procedure and for estimating individual surgical risk (Carpentier et al. 1988; ■ Fig. 12.64): In type A (minimal disease), the septal and posterior leaflet origins are only moderately displaced into the right ventricle. The atrialized chamber is small, and a relatively large trabecularized right ventricular cavity is preserved. The anterior leaflet is large and mobile. The volume of true right ventricle is adequate (■ Fig. 12.64a). In type B (intermediate disease), the relationship between the volume of the atrialized chamber and true right ventricle is reversed: a large atrialized chamber and a smaller contracting ventricle are both present. The anterior leaflet is also large and mobile (■ Fig. 12.64b). In type C (severe disease), the anterior leaflet is restricted in motion by its adherence to the endocardium of the anterior right ventricular wall by a fibrous band or abnormal chordae tendineae. This restriction may cause significant stenosis of the right ventricular outflow tract (■ Fig. 12.64c). In type D (lesion of the tricuspid valve sac), the entire right ventricle is lined by broad adherent fibrous leaflet structures and is almost completely atrialized, with the exception of a small infundibular portion. Thus, the entire right ventricle forms a so-called tricuspid valve sac (■ Fig. 12.64d).

12.4.7 Preoperative Assessment and Preparation

12.4.7.1 Preliminary Comments

Patients with Ebstein's anomaly become symptomatic depending on the severity of the anomaly. Neonates who are highly symptomatic have massive cardiac enlargement, severe cyanosis, and metabolic acidosis; they require urgent surgery (Knott-Craig et al. 2002; Pflaumer et al. 2004; Reemtsen et al. 2006). In these patients, physiological pulmonary atresia is present due to inability of the right ventricle to produce sufficient pressure to open the pulmonary valve. This situation causes a right-to-left shunt through an interatrial communication, which leads to systemic arterial desaturation and cyanosis and, if not treated, to high mortality. The rate of survival

■ Fig. 12.64 a–d Carpentier's surgical classification of forms of the Ebstein's anomaly

up to the age of 30 years is 65% (Arizmendi et al. 2004). Some adult patients may show symptoms of chronic heart insufficiency with progressive cyanosis, paradoxical embolization, cerebral abscess, and atrial or ventricular arrhythmias. Paroxysmal atrial tachycardias may cause progressive heart failure or worsening of cyanosis and may even cause syncope. In the current era, application of the right-sided or biatrial maze procedure is a routine part of our corrective technique when atrial arrhythmias are present.

Some patients with the mild form of Ebstein's anomaly may be oligosymptomatic or even asymptomatic up to adulthood. Only rarely do patients survive in the long term without an intervention. However, unusual cases of patients who

reached the age of 80 years have been reported (Lillehei et al. 1967; Seward et al. 1979). In these patients, the diagnosis is usually made by echocardiographic examination after cardiac enlargement has been detected.

Patients with Ebstein's anomaly and severe cardiac failure who are not candidates for surgery are treated with standard heart failure therapy, including administration of diuretics and digoxin (Attenhofer et al. 2007).

12.4.7.2 Typical Radiological Findings

The chest X-ray of the adult patient is characterized by massive enlargement of the right atrium, resulting in a triangular heart silhouette with a broad basis sitting symmetrically on the

diaphragm. The pulmonary arteries and the aorta are usually narrow, and the pulmonary artery vasculature is rarefied.

12.4.7.3 Typical Echocardiographic Findings

The most important diagnostic procedure for Ebstein's anomaly is echocardiography with Doppler evaluation of the regurgitant tricuspid flow, the interatrial shunt, and the characteristic Ebstein's anatomy. Echocardiographic analysis focuses on the degree of tricuspid regurgitation and the size of the right atrium, the atrialized chamber, and the «true» right ventricle, the latter being the most decisive for the risk and the outcome of surgical repair. Also of great importance are the size and mobility of the predominant tricuspid valve leaflet, which is usually the anterior leaflet. Furthermore, determination of the shape, size, and function of the usually distorted left ventricle is important. These attributes may be further impaired by repair techniques with plication of the atrialized chamber. The location and size of an interatrial communication and the degree of shunt can be well determined by echocardiography.

Celermajer and associates devised the Great Ormond Street Echo grading system (GOSE; ■ Fig. 12.65) for severity of Ebstein's anomaly. In this system the ratio is calculated between the combined area of the right atrium and atrialized right ventricle to the combined area of the functional right ventricle, left atrium, and left ventricle in the four-chamber view at end-diastole. This scoring system has been shown to be the best independent predictor of death in neonates with Ebstein's anomaly and permits prognostic stratification (Celermajer et al. 1992a).

The ratio is used to define four grades of increasing severity (Celermajer et al. 1992a):

- Grade 1—ratio less than 0.5
- Grade 2—ratio between 0.5 and 0.99
- Grade 3—ratio between 1 and 1.49
- Grade 4—ratio greater than 1.49

Predictors of death are cardiothoracic ratio greater than 0.85, GOSE score of 4, or a combination of echocardiography scores 3 and 4, cyanosis, and severe tricuspid regurgitation (Celermajer et al. 1992a; Knott-Craig et al. 2000).

Area of (RA + aRV)

Area of (RA + LV + LA)

Grade 1:<0,5

Grade 2:0,5-1,0

Grade 3:1,1-1,4

Grade 4:>1,5

■ Fig. 12.65 GOSE scoring system (GOSE Great Ormond Street Echo score). aRV atrialized part of the right ventricle, RV right ventricle, LA left atrium, LV left ventricle, RA right atrium

Cyanosis in combination with a GOSE score of 3 or 4 in neonates and infants corresponds to a mortality rate of 100%. Grade 3 alone carries a risk of 45% for mortality in the later course (Knott-Craig et al. 2007). Robertson and Silverman defined further echocardiographic features that are highly predictive of death by 3 months of age. These parameters assess the degree of distal attachment of the anterosuperior tricuspid leaflet and the degree of right ventricular dysplasia and dyskinesia and left ventricular compression caused by right heart dilatation (Robertson and Silverman 1989).

Magnetic resonance tomography may be used to assess ventricular volumes and ventricular function when echocardiographic quality is inadequate (Attenhofer et al. 2007).

12.4.7.4 Typical Findings of Cardiac Catheterization

Cardiac catheterization is desirable only when it is necessary to detect anatomy of associated complex cardiac anomalies and cardiovascular disease, such as an anomaly of the coronary arteries, which is extremely rare in adult patients.

A further indication is the need to clarify pre-operative arrhythmias by electrophysiological evaluation. Electrophysiological mapping serves to locate and ablate accessory conduction pathways (Hebe 2000). Intracardiac pressure recording and oximetric determination of intracardiac shunts may be useful when it is necessary to verify the echocardiographic findings. However, cardiac catheterization is not without risk. Tachyarrhythmias associated with the procedure are relatively frequent (Davidson et al. 1995). In the early 1960s uncontrollable, malignant supra-ventricular arrhythmias in patients with Ebstein's anomaly were reported (Watson 1974).

12.4.7.5 Indications for Surgical Treatment

The management of patients with Ebstein's anomaly is aimed at preventing and treating complications. In general medical management is recommended only for patients with mild symptoms. This approach concentrates on medication for heart failure, arrhythmias, and anticoagulation. The classic indication for operative treatment is the presence of severe, chronic heart failure with symptoms of functional New York Heart Association (NYHA) class III or IV. However, based on favorable results of surgical treatment, the indications for operation have been considerably extended. Currently, most patients beyond the early infancy can be operated upon with good results (Davies et al. 2013; Yu et al. 2013). The extended indications for surgical treatment include the following (Hetzer and Pasic 2004):

- Less symptomatic patients with functional NYHA class II and progression of symptoms
- Increasing cyanosis
- Deterioration of exercise tolerance
- Retardation of growth curve in children
- Paradoxical embolization and cerebral abscesses
- Atrial and/or ventricular arrhythmias
- Increase in cardiac size
- Worsening of the echocardiographic findings, such as an increase in tricuspid valve regurgitation
- Enlargement of the right atrium and right ventricle
- Deterioration of right ventricular function

These indications mostly apply for older children and adult patients.

In symptomatic neonates and small infants, a delay in surgical treatment usually results in very high mortality (Knott-Craig et al. 2002). In this group of patients, two different surgical strategies have been applied: valve reconstruction (Knott-Craig et al. 2000, 2007) or the univentricular approach and the Starnes technique (Reemtsen et al. 2006; Starnes et al. 1991). Experience with both techniques is limited, and further experience is necessary to establish which of these approaches is superior.

12.4.7.6 Contraindications

There are no specific contraindications to reconstructive surgical treatment in Ebstein's anomaly per se. The contraindications include general contraindications for open-heart surgery and the assessment that a surgical intervention would not improve the patient's quality of life or life expectancy.

Relative contraindications to the cone operation include age above 50 years, moderately elevated pulmonary arterial pressure, reduced ejection fraction (less than 30%), significant delamination of the anterior leaflet and complete failure of delamination of the septal and inferior leaflets, severe right ventricular dilatation, and severe dilatation of true tricuspid anulus (Dearani et al. 2008).

12.4.8 Surgical Treatment Options

12.4.8.1 Introduction

There is still controversy surrounding the best type of tricuspid valve repair; indications for valve replacement, whether and how plication of the atrialized part of the right ventricle should be performed; and the surgical strategies to follow in neonates (Boston et al. 2006; Chauvaud et al. 2003; Chen et al. 2004; da Silva et al. 2007; Dearani 2007; Friesen et al. 2004; Hetzer and Pasic 2004; Knott-Craig et al. 2007; Reemtsen et al. 2006; Sano et al. 2002; Ullmann et al. 2004; Yun et al. 2006a, b). It is of great importance to note that every patient with Ebstein's anomaly is different and that different reconstruction techniques need to be available and to be applied in each individual situation (Dearani 2007).

Reconstruction of the tricuspid valve is preferable to valve replacement to avoid the well-known problems of valve prosthesis dysfunction and anticoagulation and the need for repeat valve reconstruction procedures in line with the growth of child patients. In view of the excellent results, it seems justifiable to extend valve reconstruction to include patients who

would previously have been treated by valve replacement. In line with the hospital-specific guidelines, valvuloplasty is possible in 40–98% of patients, with a reoperation rate of 3–15%. Numerous surgical techniques and modifications have been suggested. The five most important reconstruction techniques are those developed by the following authors: Hardy, Danielson, Carpentier, Quaegebeur, Hetzer, and da Silva. Depending on whether and how plication of the atrialized chamber is performed, the *techniques* can be regarded as falling into three groups:

- Transverse plication (Danielson et al. 1992; Hardy et al. 1964) (■ Fig. 12.68)
- Longitudinal plication (Carpentier et al. 1988; Quaegebeur and Sreeram 1991) (■ Fig. 12.69, ■ Fig. 12.70)
- Without plication (Augustin and Schmidt-Habelmann 1997; Hetzer et al. 1998; Ullmann et al. 2004; daSilva et al. 2004, 2007) (■ Fig. 12.71, ■ Fig. 12.72, ■ Fig. 12.74)

12.4.8.2 Surgical Options for Very Severe Anomalies (Types C and D of Carpentier's Classification)

In severely sick patients with the most unfavorable anomalies, any of the techniques described above carry a high operative risk. In adult patients and children, a combination of tricuspid valve reconstruction and a bidirectional cavopulmonary anastomosis can be applied (Carpentier et al. 1988; Chauvaud et al. 1998a, b). The bidirectional cavopulmonary shunt should be used selectively when the right ventricle is functioning poorly and there is difficulty in weaning the patient from the cardiopulmonary bypass. Among 169 patients with Ebstein's anomaly, Quiñonez and associates used additional bidirectional cavopulmonary shunt in 14 patients with decreased right ventricular function (Quiñonez et al. 2007). In high-risk patients with Ebstein's anomaly, an associated bidirectional cavopulmonary shunt seems to offer several distinct advantages including decreased operative mortality and better tolerance of the residual tricuspid valve dysfunction. Bidirectional cavopulmonary shunt may be considered as a planned procedure, as an intraoperative salvage maneuver, or as an alternative to cardiac transplantation in selected patients (Chauvaud et al. 1998b; Quiñonez et al. 2007).

The mechanism of improvement of the bidirectional cavopulmonary shunt may be due to an

energy-saving effect on the right ventricle during systole. The key point for the preoperative decision to create an additional cavopulmonary shunt during repair of Ebstein's anomaly is the assessment of the right ventricular function. Unfortunately, in Ebstein's anomaly there is no reliable method to measure the right ventricular wall stress, ejection fraction, and shortening fraction in the deformed right ventricle.

In order for the bidirectional Glenn shunt to be considered a potential adjunct to the operation, it is important that there should be good left ventricular function and low left atrial pressure, which is not always the case in advanced cases of Ebstein's anomaly.

Because concomitant left ventricular dysfunction may be present when the right ventricle fails, it is important to document by direct pressure measurements that the left atrial and pulmonary arterial pressures are low; otherwise, the shunt will not be effective.

In newborns and small infants, the Starnes technique may be indicated. Here a fenestrated tricuspid valve closure is combined with a central aortopulmonary anastomosis and an atrial septectomy (Starnes et al. 1991; Van Son et al. 1998a, b, c). Alternatively primary orthotopic heart transplantation can be considered.

■ Fig. 12.66 The right atrium can be opened in three alternative ways: an arched incision *a*, an oblique incision from the right atrial appendage to the inferior vena cava, *b* or a straight incision parallel to the interatrial groove *c*

12.4.8.3 Importance of the Atrialized Chamber

Plication of the atrialized part of the right ventricle is a controversial issue (Augustin and Schmidt-Habelmann 1997; Boston et al. 2006; Dearani 2007; Friesen et al. 2004; Hetzer et al. 1998; Ullmann et al. 2004; Vargas et al. 1998).

The main question is the *significance of the atrialized chamber*. Hardy, Danielson, Carpentier, and Quaegerbeur consider it necessary to obliterate this chamber or at least to reduce its size, for different reasons. On the one hand, this chamber, when subjected to the right ventricular pressure, can have a similarly negative effect on the energy system of the right ventricle as a left ventricular aneurysm can have on the left ventricle. Further, the formation of thrombi caused by low flow and stasis in a noncontracting sac is possible. Thus, plication of the atrialized chamber can improve the right ventricular function and prevent characteristic arrhythmias. On the other hand, transverse plication may, at least in the serious forms B and C in the Carpentier classification, transfer great tension to the plication sutures and the tissue. This may possibly have unknown negative influences on the already abnormal septum and the left ventricle. The longitudinal plication causes no distortion of the ventricular geometry and preserves the positional relationship between the apex and floor of the left ventricle. Most surgeons who favor tricuspid valve replacement leave the atrialized chamber untouched and no negative effects have been reported. In a similar fashion, the Hetzer technique does not close or reduce the chamber and has also not led to further enlargement of the right ventricle or to other unwanted effects (Hetzer et al. 2008). In addition, incorporation of the atrialized chamber into the contracting right ventricle may positively affect the ventricular filling during diastole. This can lead to stimulation of the remaining muscle tissue in the wall of the atrialized chamber and even to hypertrophy, which in some cases contributes to an improvement in right ventricular contraction. This interesting concept requires further investigation.

In his original technique, Danielson routinely plicated the atrialized ventricle as part of the repair (Danielson et al. 1979a, 1992). This approach was modified in that plication or resection is performed by the Mayo Clinic group now only when the atrialized part of the right ventricle wall consists of thinned, transparent wall, particularly in the inferior segments, since the current repair technique is

typically performed at the level of the functional tricuspid anulus. This is in contrast to the original reconstruction procedure, in which the functional anulus was brought up to the true anulus, which by definition results in plication of the right ventricle. The original plication technique was very effective in decreasing the size of the heart and in establishing good long-term durability results of the valve reconstruction. However, due in part to suture lines in the plicated ventricle and/or interruption of narrow branches of the right coronary artery, ventricular arrhythmias can be provoked. Since adoption of the newer technique in the mid-1980s, the incidence of perioperative ventricular arrhythmias is no longer of relevance (Attenhofer et al. 2007; Boston et al. 2006; Dearani 2007).

12.4.8.4 Anesthesia

The principles for anesthesia follow those that are relevant for all open-heart surgery. There are no specific requirements for the perioperative anesthesia for this procedure. In our institution the standard anesthesia protocol provides for induction with etomidate and fentanyl, and pancuronium is given as a muscle relaxant. The anesthesia is maintained by propofol infusion.

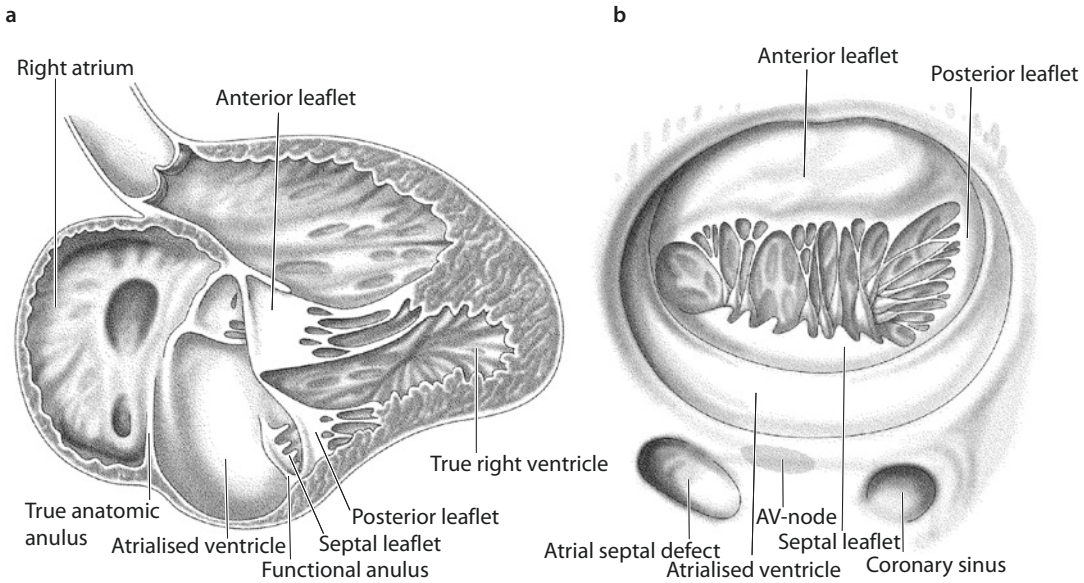

12.4.9 Operation

12.4.9.1 General Procedure Before Valve Reconstruction

The operation is performed via a complete or partial median sternotomy. After the pericardium is opened (■ Fig. 12.66), a piece of pericardium is harvested and fixed as patch material in glutaraldehyde (0.6%) or left unfixed. Next, the surgical site is inspected (■ Fig. 12.67). Typically the right atrium is enormously enlarged, and the right ventricle appears to be dilated, as far as both the atrialized chamber and the remaining part of the right ventricle are concerned. The atrialized chamber can be easily delineated at the acute margin of the heart and along its the inferior side. The left ventricle is displaced to the left and lies around the right ventricle like a curved cucumber.

12.4.9.2 Cardiopulmonary Bypass

After the aorta has been cannulated and separate bicaval cannulation has been performed, the patient is placed on extracorporeal circulation,

■ **Fig. 12.67** a, b The intracardiac situs. In this complex anomaly, the pathological intracardiac anatomy differs greatly between patients, and no one case is the same as others in all aspects. Certainly the characteristic findings of Ebstein's anomaly are easily identified in all patients. The anatomic anulus of the tricuspid valve is greatly dilated, and the origin of the septal leaflet lies in the chamber of the right ventricle. The posterior and anterior leaflets show broad variations. The attachment of the posterior leaflet to the anulus is also displaced in apical direction and leads to the formation of the so-called atrialized chamber, the size of which can greatly vary (see ► Sect. 12.4.6). In most cases the anterior leaflet is the largest. This leaflet may be entirely mobile or may be partially or even completely fixed to the neighboring free right ventricular wall by a varying number of fibrous bands. In this case the leaflet mobility is reduced. In some patients the posterior leaflet is strong and mobile and of about the same size as the anterior leaflet or even larger. The anterior leaflet can show a cleft or fenestration. Rarely one finds a fourth small accessory leaflet originating from the anterosseptal commissure

which provides total cardiopulmonary bypass, and moderate hypothermia of 30 °C is selected. The aorta is clamped and cardioplegic solution is given.

12.4.9.3 Myocardial Protection

Myocardial protection is given in accordance with our internal cardiac surgery guidelines. At our institution cardioplegia is induced by infusion of crystalloid cardioplegia into the aortic root. The myocardial protection is maintained by repeated infusion of cold hydroxyethyl starch solution.

12.4.9.4 Tricuspid Valve Reconstruction

■ Tricuspid valve reconstruction with transverse plication (techniques of Hardy and Danielson)

Reconstruction of the tricuspid valve by this technique (Danielson et al. 1979a, 1992; Hardy et al. 1964) uses the mobility of the anterior leaflet as a closing mechanism for the valve

(■ Fig. 12.68). In this procedure the displaced septal and posterior leaflets are transposed to the normal anatomical anulus level of the valve. Thus, the atrialized chamber is plicated and closed at the transverse level, i.e., parallel to the true tricuspid valve anulus. This leads the anterior leaflet body to the true tricuspid valve anulus and forms the coaptation of the anterior leaflet with the atrialized septum. Danielson modified this technique by performing an additional posterior anuloplasty to reduce the diameter of the tricuspid valve anulus.

Some modifications of the original Danielson reconstruction were reported by the Mayo Clinic group (Attenhofer et al. 2007; Boston et al. 2006; Dearani 2007). A patent foramen ovale is closed by direct suture, and larger atrial septal defects are closed with an autologous pericardial patch. Right reduction atrioplasty is routinely performed for an enlarged right atrium. The original technique of tricuspid valve reconstruction brought the

functional tricuspid annulus up toward the true anatomical tricuspid annulus; thus, it effectively plicated the atrialized part of the right ventricle (■ Fig. 12.68). At present valve reconstruction is performed at the level of the functional tricuspid annulus. In addition, contrary to early experience, plication of the atrialized portion is not performed unless the wall is severely thinned. A right-sided maze procedure is performed in patients with a history of intermittent or chronic atrial flutter or atrial fibrillation. Left-sided maze procedure usually is not applied.

■ ■ Tricuspid valve repair with longitudinal plication (techniques of Carpentier and Quaegebeur)

Carpentier's method of reconstruction (Carpentier et al. 1988; ■ Fig. 12.69) consists of separating the anterior and/or posterior leaflet from their hinge points at the annulus, transecting the connective tissue bands between the leaflets and the right ventricular wall, longitudinal plication of the atrialized chamber, and reinsertion of the leaflets into the true annulus above the plicated chamber. In addition the leaflets are displaced in clockwise direction toward the posterior part of the septal annulus. To reduce the tension on the new leaflet attachment line, transection and reattachment of the papillary muscle to the anterior leaflet may be necessary, particularly in the anterior portion. It is highly recommended that this new valve annulus is stabilized with a prosthetic ring, as originally suggested by Carpentier's group (Carpentier et al. 1988; Chauvaud et al. 1996).

Quaegebeur modified the Carpentier technique in two respects (■ Fig. 12.70): instead of suturing a ring to keep the annulus in a particular form and to reduce its size, he placed the reduction plasty along the posterior leaflet by using a suture that additionally reduces the annulus size. The second modification consisted of not applying separation and reimplantation of the papillary muscles of the anterior leaflet.

Since Jan Quaegebeur's original report of experience with his technique (Quaegebeur and Sreeram 1991), various alterations have taken place. We still believe that vertical plication of the right ventricle restores the normal inlet configuration of the right ventricle, reduces the tricuspid valve annulus, and supports the subvalvular apparatus. In addition, the plication itself likely helps to maintain a more normal ventricular geometry

and can thereby promote remodeling. Unlike the Danielson technique, in which a monocusp valve is created, this procedure creates a bileaflet valve (at least when a posterior leaflet, albeit morphologically abnormal, is present). In general, we do not consider atrial reduction a necessary part of the procedure. Finally, annular reinforcing sutures or artificial polytetrafluoroethylene (Gore-Tex™) chords have been placed only in a small number of cases (Chen et al. 2004).

■ ■ Tricuspid valve repair without plication (technique of Hetzer)

This technique as suggested by Roland Hetzer restores the valve mechanism on the plane of the true tricuspid valve annulus by using the most mobile leaflet for valve closure, without plicating the atrialized ventricle (■ Figs. 12.71 and 12.72). It provides sufficient reconstruction, even in cases where only the posterior leaflet or parts of the anterior leaflet can be remodeled and used for valve closure (Hetzer and Pasic 2004; Hetzer et al. 1998).

The technique introduced by us, making the atrialized chamber part of the right ventricle without any plication, may be employed in two ways: (1) either doing a posterior plication of the annulus, i.e., partial closure of the «true» ostium (see ■ Fig. 12.71), or (2) the creation of a «double-orifice valve» by suturing of the anterior annulus to the «true» septal annulus (see ■ Fig. 12.72). The decision in favor of posterior annulus plication is made when the posterior leaflet of the posterior portion of the anterior leaflet is not mobile and not capable of coaptation. We prefer the double-orifice valve when both the anterior and posterior leaflet segments, or at least the anterior leaflet, are present, mobile, and capable of coapting with the newly created ostia. Division of the ostium by an annulus suture is carried out when the anterior leaflet has a deep fissure.

To stabilize the ostium division suture, we regularly add the so-called Sebening stitch. This stitch tacks a papillary muscle or a strong fibrous chorda out of center of the anterior leaflet to the septum, usually to the fibrous tissue of the rudimentary, displaced septal leaflet (■ Fig. 12.73).

12.4.9.5 Cone Reconstruction of Ebstein's Anomaly

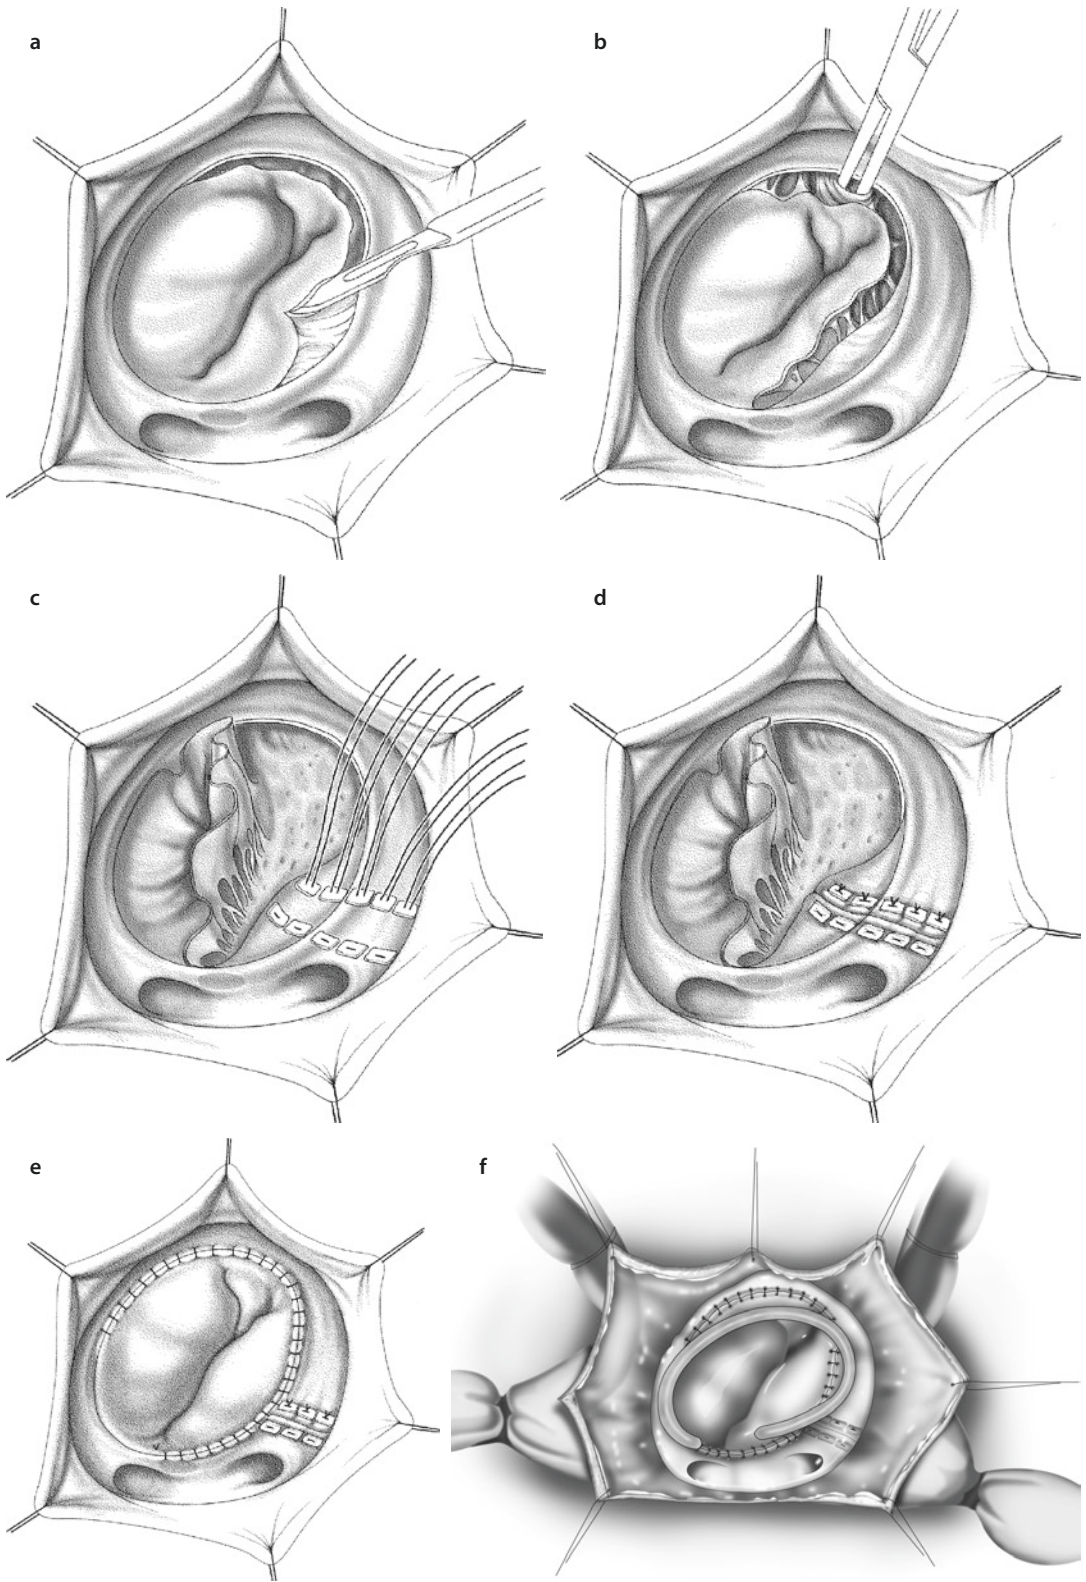

As described by da Silva (da Silva et al. 2004, 2007, da Silva and da Fonseca 2012), «After establishment of cardiopulmonary bypass and

■ **Fig. 12.68** a–c Tricuspid valve reconstruction with plication of the atrialized chamber (Danielson technique). **a** Apicobasal transverse ventricular plication sutures are placed. Teflon-pledgeted single-button sutures pierce the edge of the atrialized chamber in ventricular direction and exit at the true tricuspid valve anulus. **b** Transverse plication of the atrialized chamber is performed. The plication sutures are pulled tight, so that the posterior and the septal leaflet are pulled in the direction of the true anulus and the atrialized chamber is closed in a transverse plane, parallel to the true tricuspid valve anulus. **c** The valve anulus is reduced by a posterior anuloplasty, using Teflon-pledgeted polypropylene (3/0) mattress sutures. The sutures of the posterior anuloplasty are placed in a plane with the sinus coronarius to avoid injury of the cardiac conduction system. The tricuspid valve is tested for competence by instilling cold isotonic saline solution into the right ventricle. After the correction the tricuspid valve functions as a monocuspid valve

cardioplegia, right atriotomy is performed» (■ Fig. 12.74a). When creating a component tricuspid valve by the cone technique, it is very important to perform extensive mobilization of the displaced or tethered leaflets. The abnormal

papillary muscles and other tissues between the individual leaflets and the corresponding right ventricular wall areas are divided, taking particular care to preserve the right ventricular apex attachments.

■ **Fig. 12.70** Quaegebeur technique. A posterior anulo-plasty of the tricuspid valve anulus is performed. In this modified form of the Carpentier technique, no prosthetic ring is used to reinforce the anulus. The anulus diameter is reduced by a posterior anulo-plasty with a 3/0 polypropylene mattress suture reinforced with Teflon-felt pledgets. Unlike in the Carpentier technique, the newly inserted leaflets are not subjected to excessive tension so that transection and translocation of the papillary muscle are not necessary. The posterior anulo-plasty is performed close to the coronary sinus, and it is important to avoid injury to the conduction pathways

Division of fused papillary muscles, fenestration of obliterated interchordal spaces, and triangular resections on the leaflet distal third are required to improve subsequent right ventricular inflow. Afterward the septal edge of the anterior leaflet is carefully mobilized by freeing its connections to the interventricular septum. Only the normal attachment of the anterior leaflet to the tricuspid anulus and proper subvalvular apparatus are left in place (■ Fig. 12.74b). Then the free edge of the posterior leaflet is rotated clockwise and sutured to the anterior leaflet septal edge, forming a new tricuspid valve resembling a cone. The new valvular anulus is constructed at the anatomically correct level by means of plication of the true tricuspid anulus to match the proximal circumference of the constructed anulus (■ Fig. 12.74c). If the septal leaflet is too short to reach the true tricuspid anulus, longitudinal elongation is achieved by plicating its proximal edge toward the center. On completion of these preparatory steps, the anterior edge of the septal leaflet is sutured to the septal edge of the anterior leaflet. The atrialized RV is usually longitudinally plicated to exclude its thin part. Endocardial placement of this suture avoids damage to the coronary arteries. Atrial septal defect or open foramen ovale is

■ **Fig. 12.69** a–f Valve reconstruction with longitudinal plication of the atrialized chamber—Carpentier technique. **a, b** The anterior and posterior leaflets are mobilized. The anterior leaflet and the adjacent part of the posterior leaflet are separated from their anchorage along the anulus. The incision begins at the anterior commissure. The anchorage of the anterior leaflet at the anteroseptal commissure should, however, remain untouched. The released leaflets are further mobilized by transecting accessory trabeculae, fibrous bands, and adhesions to the ventricular wall. The interchordal spaces are enlarged by fenestration if they are narrowed. The accompanying papillary muscle is also entirely mobilized by transecting the muscle band that inserts at the lateral wall of the right ventricle. If the muscle is insufficiently mobilized, the leaflet coaptation may be unsatisfactory when there is excessive tension on the leaflets. **c, d** Longitudinal plication of the atrialized chamber is performed. The chamber is closed by placing sutures vertically to the true tricuspid valve anulus. For plication either Teflon-pledgeted single-button sutures or a continuous suture reinforced with several single-button sutures is used. It is important to ensure that the ventricular wall is not perforated or the coronary arteries injured. Plication of the atrialized chamber reduces the diameter of the tricuspid valve anulus. **e** The mobilized leaflets are rotated and refixed. The anterior and posterior leaflets are turned in clockwise direction and then attached to the new, narrower anulus with a continuous 5/0 polypropylene suture. The sutures should be placed at a distance from the atrioventricular node to avoid atrioventricular block. The danger zone lies in the septal portion of the anulus and close to the opening of the coronary sinus. For this reason the suture should end here. After the mobilized anterior leaflet has been attached, it covers the whole valve opening area, and the valve functions as a monocuspid valve. In this manner the tricuspid valve anulus is reduced by the size of the plicated atrialized chamber, and the anterior leaflet is swung in clockwise direction to cover the whole anulus portion of the anterior and posterior leaflet. The valve is then tested for competence by instilling cold isotonic saline solution into the right ventricle. After the correction the tricuspid valve functions as a monocuspid valve by virtue of the anterior leaflet. If the leaflet coaptation is not competent due to insufficient mobilization of the papillary muscle, the muscle can be detached from the lateral ventricular wall and refixed at a higher point on the ventricular septum. **f** The tricuspid valve anulus is reinforced. To stabilize the anulus, an anulo-plasty ring is implanted. This ring reduces the diameter of the dilated tricuspid valve anulus, thus enlarging the coaptation area of the leaflet and improving the valve competence. The ring should not be used in children; in patients with form A according to the Carpentier classification, it should not necessarily be applied

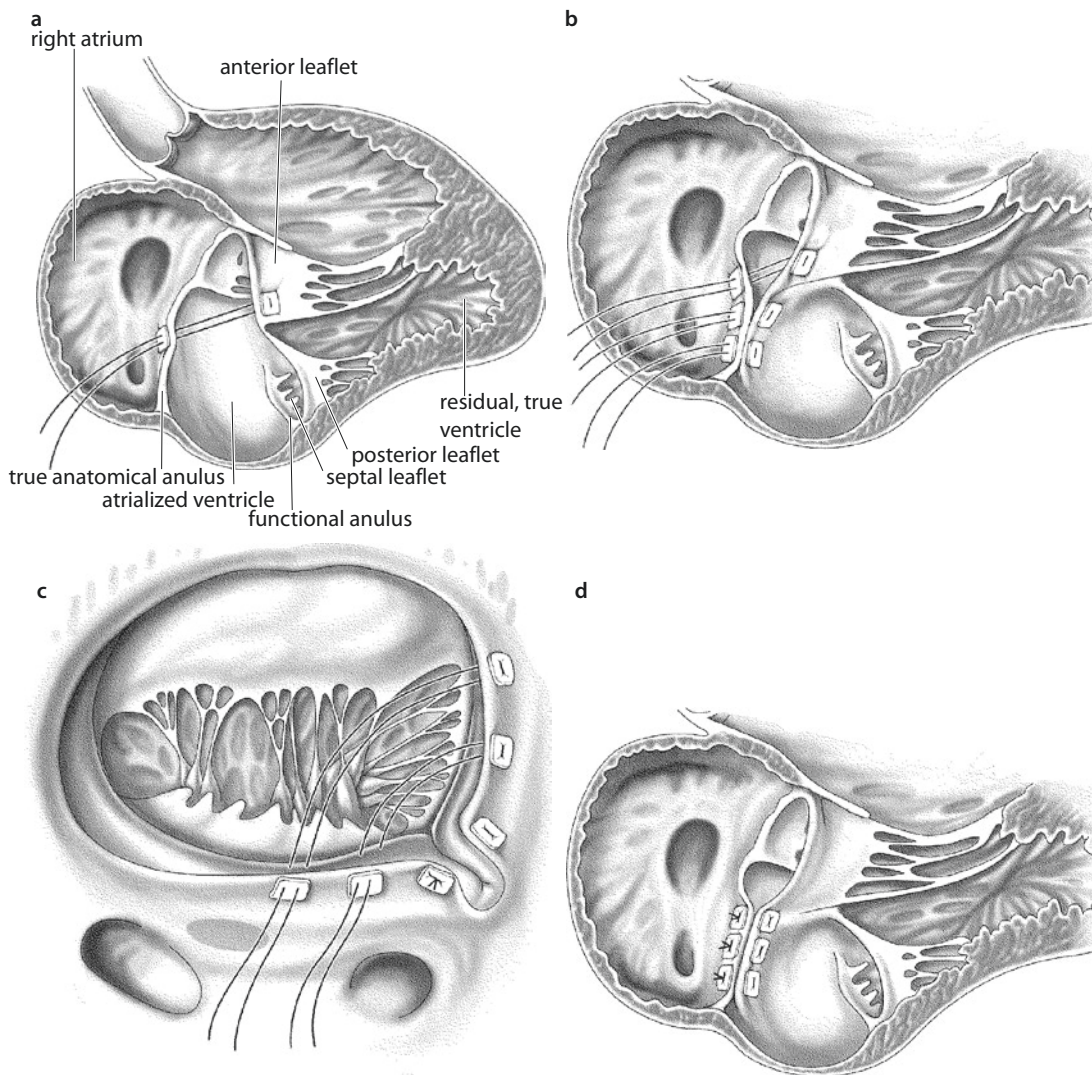

Fig. 12.71 a–h Hetzer technique: reconstruction of the valve without plication of the atrialized chamber—applied in a patient with a large and intact anterior leaflet. a–c The leaflet is mobilized and the sutures placed. First the anterior leaflet is assessed for mobility. If there are fibrous bands between the leaflet and the right ventricular wall, they are transected to improve leaflet mobility. The original valve opening is reduced in size by closing the posterior portion of the valve opening with four to six individual mattress sutures of 3/0 polypropylene, reinforced with autologous pericardium or Teflon pledgets. The diameter of the newly created tricuspid valve opening should be at least 2.5 cm. So that this size is reached, the first suture is placed as a trial suture. The suture runs through the true annulus at the area of the anterior leaflet and then through the opposite point on the septum. Thus, the suture divides the original valve opening into two parts. The anterior portion becomes the new valve opening and the posterior portion is closed. The valve is then tested by instilling cold isotonic saline solution into the chamber of the right ventricle to show that the anterior leaflet can effectively close the new valve opening. The remaining sutures are placed consecutively, to close the posterior portion of the tricuspid valve orifice. The suture line is placed in the plane of the true tricuspid valve annulus, leaving out the septal region. To avoid injury to the atrioventricular node in this area, the suture line is placed in the muscular part of the atrialized chamber, just below the real annulus. The atrialized chamber is not plicated. d, e The posterior portion of the annulus is closed. The pre-laid sutures are pulled tight, closing the posterior part of the original valve orifice. Thus, the anterior annulus is brought closer to the septum. f, g Next, the valve is tested for competence by filling the right ventricle with isotonic saline solution so that the anterior leaflet coapts with the atrialized septum. The atrialized chamber is thereby included in the chamber of the contracting ventricle. h Rarely is it necessary to correct the valve opening by additional narrowing of the anterosseptal commissure if residual valve insufficiency is present

■ Fig. 12.71 (continued)

usually valve closed which permits the flow of blood in one direction only (■ Fig. 12.74d).

Because of suture dehiscence at the septal and posterior part of new tricuspid annulus in some of their patients, da Silva suggested the need to reinforce the new tricuspid valve ring with additional interrupted sutures in children or with an anuloplasty ring in adult patients (da Silva and da Silva 2012).

12.4.9.6 Tricuspid Valve Replacement

In general TV repair is preferable to valve replacement whenever it is feasible. Depending on the experience of the groups concerned, the rate of valve replacement differs greatly, between 2 and 50%. A clear indication for tricuspid valve replacement is given when the valve tissue is not present or in the case of a Type D lesion according

Fig. 12.72 a–d Hetzer technique: reconstruction of the valve without plication of the atrialized chamber—when the anterior leaflet is divided by a cleft or fissure. **a** The anterior leaflet is inspected and mobilized. Here it is divided by a cleft and deep fissures. Several chordae adhesions to the right ventricular wall are transected. **b** The sutures are placed. Two polypropylene mattress sutures reinforced with autologous pericardium or Teflon-felt pledgets pierce the middle section of the anulus in the area of the cleft and the opposite part of the atrialized septum, just below the septal anulus. **c** A new valve morphology is created. The pre-laid sutures are pulled tight and the anterior anulus is drawn toward the septum. Thus, the valve receives two openings. The two individual parts of the anterior leaflet coapt with the opposite septum. **d** Competence of the valve closure is tested by filling the right ventricle with isotonic saline. Both valve openings are closed by both parts of the anterior leaflet. Thus, the atrialized chamber is incorporated into the contracting right ventricle

to the Carpentier classification («tricuspid valve sac»; Boston et al. 2006).

The prosthesis can be implanted by the standard procedure with insertion of the prosthetic suture ring into the true tricuspid anulus or in a slightly modified procedure, which was recommended by Barnard and Schrire (1963) (■ Figs. 12.75, 12.76, and 12.77). In their classic work, they described how the valve prosthesis is placed at the atrial side of the coronary sinus, to reduce the risk of complete atrioventricular block.

This allows the coronary sinus to drain into the right ventricle. However, complete AV block cannot always be avoided, and some patients need cardiac pacemaker implantation. The standard procedure for prosthetic valve implantation may or may not be accompanied by plication of the atrialized chamber. If the atrialized chamber is excessively dilated and the volume of the functional, true right ventricle is normal, plication of the atrialized chamber may be performed during the valve implantation. There is no consensus

■ **Fig. 12.73** a–c The Sebening stitch stabilizes the ostium dividing suture in Ebstein's reconstruction

on which prosthesis type—mechanical or biological prosthesis—should be implanted. The decision is made together with the patient, who is first informed of the advantages and disadvantages of the different prostheses.

Moderate or severe residual tricuspid regurgitation early after reconstruction surgery in Ebstein's anomaly is a significant risk factor for reoperation (Boston et al. 2006).

Freedom from reoperation for tricuspid valve dysfunction 10 years after initial valve repair in a report from the Mayo Clinic was $79.6 \pm 6.5\%$ (Boston et al. 2006). This compares favorably with the 72% freedom from reoperation for bioprosthesis dysfunction 10 years after initial valve replacement with a porcine bioprosthesis in a similar pediatric population (Kiziltan et al. 1998).

12.4.9.7 General Procedures Following Valve Reconstruction

■ ■ Closure of an interatrial connection

A persistent foramen ovale is closed using a continuous suture. Large atrial septal defects should be closed with a patch of impermeable material such as autologous pericardium or polytetrafluoroethylene.

■ ■ Correction of additional congenital anomalies

Further associated anomalies—ventricular septal defects, atrioventricular canal defects, mitral valve disease, and valvular or subvalvular pulmonary valve stenoses—are normally treated either before or after the tricuspid valve reconstruction.

■ ■ Treatment of atrial arrhythmias

Ablation for AV node reentry tachycardia or ablation of an accessory conduction path in Wolff–Parkinson–White syndrome can be performed as part of the surgical treatment. The Cox maze procedure (typically a biatrial maze procedure or isolated left or right atrial maze) can be performed at the same time as the valve reconstruction, to control chronic or paroxysmal atrial fibrillation or atrial flutter. The maze procedure is performed either surgically or through an incision/suture sequence or using high-frequency ablation equipment.

■ ■ Right-sided atrial reduction plasty and closure of the atriotomy

Closure of the right atriotomy can be performed in such a way that the gigantic right atrium is

Fig. 12.74 a–d Operative steps for Ebstein's anomaly repair using cone reconstruction. **a** Opened right atrium showing displacement of the tricuspid valve. *TTA* true tricuspid anulus, *ASD* atrial septal defect, *CS* coronary sinus. **b** Detached part of the anterior and posterior leaflet forming a single piece. **c** Clockwise rotation of the posterior leaflet edge to be sutured to the anterior leaflet septal edge and plication of the true tricuspid anulus. **d** Complete valve attachment to the true tricuspid anulus and valve closure of the atrial septal defect (From da Silva et al. 2007; used with permission)

significantly reduced in size. A substantial part of the dilated and redundant wall can be excised or incorporated into the suture line. The right atrium is closed with a continuous 4/0 polypropylene suture.

■ ■ De-airing of the heart

Cardiac de-airing is carried out in the manner normal in our hospital. To avoid air embolism, we employ carbon dioxide insufflation into the pericardium during the operation. More recently, however, it could be shown elsewhere that this has no impact on postoperative neurocognitive function (Chaudhuri et al. 2012).

■ ■ Intraoperative echocardiographic assessment

After the heart has been closed and is beating, the function of the tricuspid valve is evaluated, and the valve openings are measured by transesophageal echocardiography. In addition possible residual shunts are investigated and the left and right ventricular function analyzed.

■ ■ Perioperative monitoring and weaning from cardiopulmonary bypass

Temporary atrial and ventricular epicardial leads for early postoperative pacemaker stimulation are placed. Under monitoring of the left and right

■ **Fig. 12.75** a–c Tricuspid valve replacement: standard implantation without plication of the atrialized chamber. The leaflets and chordae attachments remain in situ, to support right ventricular function. When a right ventricular outflow tract obstruction is caused by leaflet tissue, commissurotomy-like radial incisions are made in the leaflet tissue to open the outflow tract. If necessary, single mattress sutures with Teflon-pledgeted reinforcement are placed so that they pierce the tissue of the true tricuspid valve annulus and then the prosthetic ring. It is important to carefully avoid the His bundle by placing the sutures in the septum, at least between the coronary sinus and the tricuspid valve annulus. A prosthesis, which should normally measure 31–33 mm, is positioned in the annulus. When the sutures are pulled tight, the suture ring of the prosthesis comes to rest on the anatomic tricuspid valve annulus. The atrialized chamber has not been plicated and its position is now below the prosthesis

atrial filling pressure, the patient is weaned from extracorporeal circulation.

■ ■ Perioperative and postoperative care

For weaning from extracorporeal circulation, inotropic support may be necessary and, in rarer cases, mechanical circulatory support, for example, in the form of intra-aortic balloon coun-

terpulsation. Nitric oxide can be added to the ventilator air to reduce the pulmonary vascular resistance if the pulmonary artery pressure is elevated; the indication should be made generously to relieve the right ventricular workload. Otherwise, the general institutional principles applied in patients after open-heart surgery are followed.

■ **Fig. 12.76** Tricuspid valve replacement: standard implantation with plication of the atrialized chamber. If the atrialized chamber is extremely dilated and the volume of the functional right ventricle is normal, atrialized chamber plication may be performed in addition to the prosthesis implantation. Individual Teflon-reinforced mattress sutures are placed close together through the false anulus, at the insertion line of the posterior and septal leaflet, through the true anulus and finally through the suture ring of the prosthesis. Once the sutures are pulled tight, the atrialized chamber is put out of action. The tricuspid valve leaflets are not excised

■ **Fig. 12.77** Tricuspid valve replacement: classic technique as described by Barnard and Schrire in (1963). The suture line is placed posterior to the AV node and around the coronary sinus, to avoid injuring the conduction system. In this way the valve prosthesis lies on the atrial side of the coronary sinus, which thus drains into the low-pressure right ventricle. The atrialized chamber is not plicated. If, however, plication of the atrialized chamber is desired, an additional suture line must be placed to avoid constriction of the coronary sinus

12.4.9.8 Specific Surgical Complications

The specific complications possibly arising from this operation are complete AV block, injury to the right coronary artery, acute heart failure, and failure of myocardial pumping, which can make the implantation of a mechanical circulatory assist system necessary. Further, persistent atrial or ventricular arrhythmia and tricuspid valve regurgitation or stenosis can occur after the reconstructive operation or following failure of the prosthesis to function correctly.

12.4.9.9 Postoperative Care

All patients should be monitored postoperatively in the standard manner. After discharge from hospital, the patient should receive routine cardiology follow-up with emphasis on heart rhythm and ventricular function.

12.4.10 Surgical Treatment in Neonates and Small Infants

12.4.10.1 Introduction

Neonates with symptomatic Ebstein's anomaly continue to represent a difficult management problem. They have a high perioperative and early mortality rate, and those surviving the first month of life remain at high risk of hemodynamic deterioration and sudden cardiac death (Celermajer et al. 1992a). All surgical attempts in these children, including palliative shunt procedures, were generally unsuccessful until Starnes developed a procedure in 1991 that included closure of the tricuspid orifice, enlargement of the interatrial communication, and a central shunt. In this manner the neonatal Ebstein's malformation is converted into functional tricuspid and pulmonary valve atresia. In infants with mild-to-moderate tricuspid regurgitation

■ **Fig. 12.78** a, b Starnes' procedure. a A glutaraldehyde-fixed autologous pericardial patch is sewn into the anatomic tricuspid valve annulus. b A fenestration is created in the patch using a 4-mm coronary punching device. The coronary sinus still drains on the right atrial side of the patch

and severe right ventricular outflow tract obstruction, a systemic artery-to-pulmonary artery shunt is created in addition to the interatrial communication being enlarged (Starnes et al. 1991) (■ Fig. 12.78).

12.4.10.2 Cardiopulmonary Bypass and Right Atriotomy

After median sternotomy a piece of pericardium is harvested as patch material. Cardiopulmonary bypass is established using standard aortic and bicaval cannulation, and under moderate hypothermia (28 °C), the heart is arrested with cardioplegic solution. Through an oblique right atriotomy, the tricuspid valve is inspected and evaluated for possible reconstruction. The relation in size between the atrialized chamber and the trabeculated (functional) right ventricle is determined, and then the leaflet tissue is addressed. It is very important to analyze the possibility of mobilizing the anterior leaflet. This leaflet must be able to cover the main part of the new tricuspid valve orifice. Therefore, the remnants of the small tethered septal and posterior leaflets are also assessed for their ability to be integrated in the reconstruction plasty. The right ventricular outflow tract is investigated. If the ventricle is tripartite and tricuspid valve tissue is adequate, reconstruction of the valve is undertaken by the Danielson or Hetzer method.

Experience with *biventricular correction* of Ebstein's anomaly in newborns and small infants is very limited. Only one surgical team from the

University of Oklahoma reported for the first time successful biventricular Ebstein's anomaly correction in three cyanotic neonates with severe tricuspid valve regurgitation (Knott-Craig et al. 2000). The surgical techniques included reconstruction of the tricuspid valve as a monocuspid valve, right-sided ventricular plication, subtotal closure of the atrial septal defect, and correction of associated heart defects (■ Fig. 12.79) (Knott-Craig and Goldberg 2007). A large and mobile anterior leaflet was present in all three patients, and this was used in the valve repair, which was very similar to that described by Danielson (Danielson et al. 1992).

If the tricuspid valve is not amenable to repair or the remaining functional portion of the right ventricle is inadequate or there is a right ventricular outflow tract obstruction that cannot reasonably be corrected, then right ventricular exclusion—the univentricular strategy—is undertaken (the Starnes procedure ■ Fig. 12.78; Starnes et al. 1991). This is performed by patching the tricuspid valve with a glutaraldehyde-fixed autologous pericardial patch or Gore-Tex patch sewn at the anatomic level of the tricuspid annulus. A 4-mm fenestration of the patch is then made with a coronary punch. The coronary sinus is left on the right atrial side of the patch, contrary to the original Starnes technique (Reemtsen et al. 2006; Starnes et al. 1991). The opening in the interatrial septal opening is enlarged. A right atrial reduction plasty is carried out and, depending on the size of the atrialized portion,

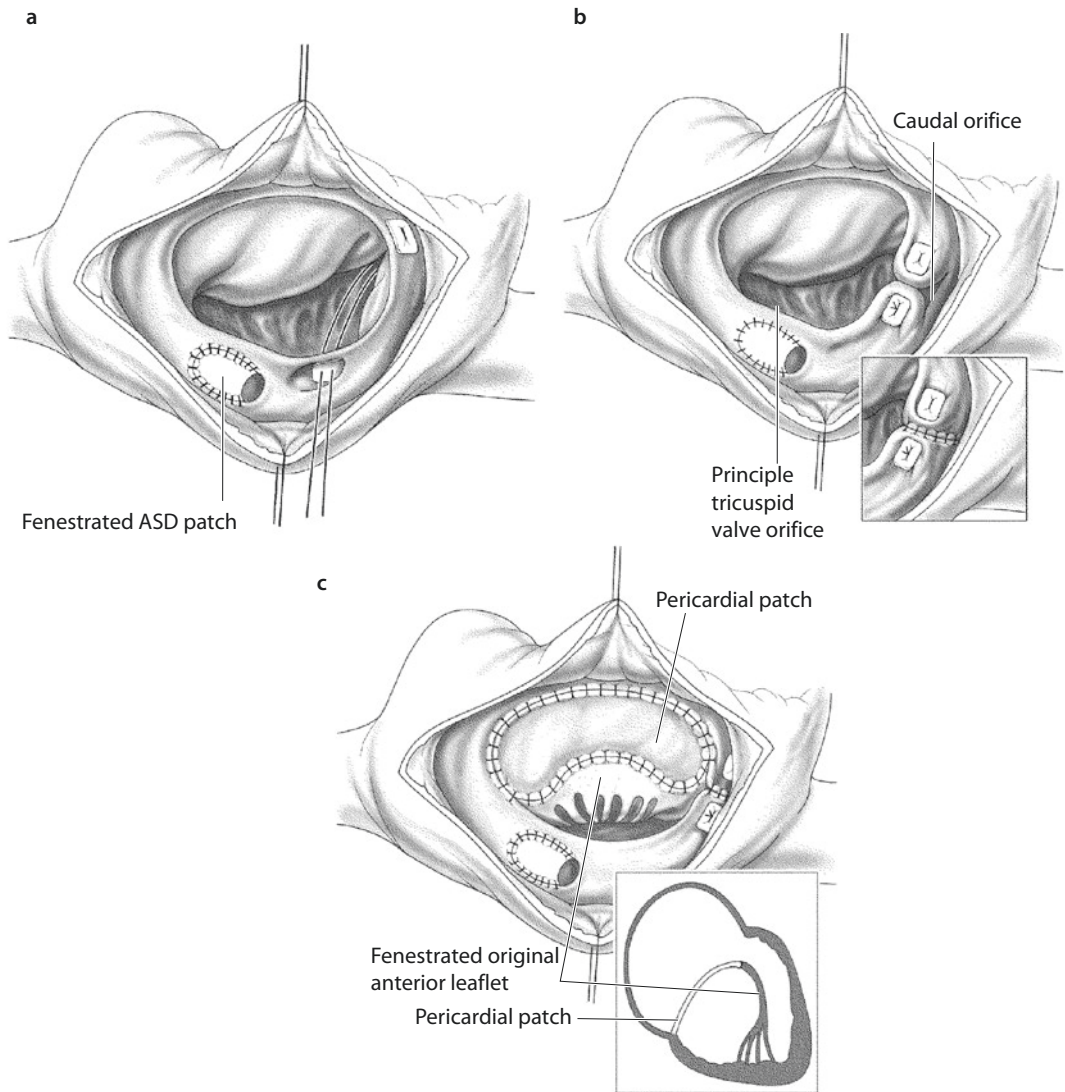

Fig. 12.79 a–c Knott-Craig's technique for correction of Ebstein's anomaly in neonates. **a** The atrial septal defect is closed with a fenestrated patch. For the anuloplasty a suture is placed so that its one pledgeted end is in the coronary sinus and the other pledgeted end comes to rest between the anterior and posterior leaflet. **b** The orifice of the tricuspid valve is divided into two openings by pulling tight the pre-placed suture. **Insert b** Once the valve has been shown to be sufficiently competent, the caudal orifice is closed and the atrialized part of the right ventricle is thus plicated. **c** A competent monocuspid valve is created by detaching the anterior leaflet from the annulus. The native leaflet is fenestrated and enlarged with a pericardial patch. **Insert c** Cross-sectional schematic view of extended anterior leaflet, fenestrated in its native component

right ventricular plication. Care must be taken to avoid kinking of the right coronary artery (see **Fig. 12.78**).

Next, the right ventricular outflow tract is addressed. To correct pulmonary valve insufficiency, the pulmonary trunk is interrupted and oversewn (Reemtsen et al. 2006; Van Son et al.

1998a, b, c). Finally, pulmonary blood flow is provided by a modified Blalock–Taussig shunt (5–4 mm). The atriotomy is closed. Usually the sternum is electively left open and closed 2–3 days after the operation (Reemtsen et al. 2006).

At about 6 months of age, a bidirectional superior vena cava-to-pulmonary artery anastomosis

■ **Fig. 12.80** Exclusion of the right ventricle by the Sano technique

and shunt takedown are performed. Fontan completion (inferior vena cava-to-pulmonary artery anastomosis) is usually performed when the patient is aged 2–4 years.

There are diverse modifications of the original Starnes procedure. Sano and colleagues developed a procedure for complete *exclusion of the right ventricle* in which also a part of the right ventricle is resected to reduce its size (Sano et al. 2002; ■ Fig. 12.80). A further modification was published by Yun's group (Yun et al. 2006b).

12.4.11 Results of Surgery for Ebstein's Anomaly

Many early studies found a 25–30% hospital mortality rate. Late results are influenced by arrhythmias, problems with artificial valve prostheses, and intrinsic primary myocardial disease.

Recent reports show decreased mortality and morbidity, compared with the early reports, but there is still controversy surrounding the question of whether to recommend early surgery in asymptomatic patients. It has been shown that some of these patients remain symptom free or have only mild symptoms for many years.

Stulak and colleagues from the Mayo Clinic (Stulak et al. 2007) published the results of biven-

tricular correction of Ebstein's anomaly in 524 consecutive patients. Tricuspid valve reconstruction was performed in 189 patients and valve replacement in 335 patients, most of whom received a bio-prosthesis. Antiarrhythmic surgery was carried out in 108 patients. The authors replaced the valve only when it was not possible to entirely detach the anterior leaflet and when strong linear adhesions or numerous thread-like connections were present between the free end and the myocardium below it. Since 1999 the early mortality has been 2.4%. The rate of freedom from reoperation due to tricuspid valve regurgitation after 5, 10, and 15 years was 91%, 80%, and 68%, respectively. There were no significant differences in probability of reoperation between patients with valve reconstruction and those with valve replacement. Moderate or severe tricuspid valve insufficiency on hospital discharge was a significant risk factor for reoperation only in the group of patients who received valve reconstruction.

Chauvaud and associates from France (Chauvaud et al. 2003) reported on 191 patients who were operated on using the technique of mobilization of the anterior leaflet introduced in 1988 by Carpentier (Carpentier et al. 1988). Conservative surgery was possible in 187 patients (98%) and included mobilization of the anterior leaflet, longitudinal plication of the atrialized right ventricle, and prosthetic anuloplasty with a prosthetic ring in adults. A bidirectional cavopulmonary shunt had to be performed in 60 patients. Four patients had valve replacement. Hospital mortality occurred in 18 patients (9%) and in nine patients due to right ventricular failure. Actuarial survival during the mean follow-up of 6.4 years was 82% at 20 years. Tricuspid valve insufficiency was of grade I or II in 80% of the cases. Reoperation was necessary in 8% (16 patients). The second procedure was successful in ten patients. Electron beam computerized tomography (in 20 patients) demonstrated that left ventricular ejection fraction improved from 56 to 66% ($p < 0.05$). The number of patients with supraventricular tachycardia and preexcitation syndromes was reduced from 23 to 5.

Chen from Jan Quaegebeur's group at Columbia University reported on 25 patients (19 children and 6 adults) who underwent valve reconstruction using the Quaegebeur technique, which involved vertical plication of the atrialized ventricle and reimplantation of the

valve leaflet after clockwise rotation (Chen et al. 2004). The average age at the time of operation was 14.2 ± 15.9 years, and the average follow-up was 4.1 ± 3.4 years. Three patients required reoperation for right ventricular overload (one child) and progressive severe tricuspid regurgitation (two adults). Both adults received tricuspid valve replacements, one at 4 years and the other at 8 years postoperatively. Three patients had radiofrequency ablation procedures performed intraoperatively. Ten patients (40%) had moderate-to-severe tricuspid regurgitation perioperatively. However, 18 children (95%) and 5 adults (83%) demonstrated significant improvement in exercise capacity late postoperatively. Two children died suddenly 11 months and 4 years after the corrective procedure.

The group from the German Heart Center in Munich reported results of a technique of Ebstein's anomaly repair in 23 patients by which a predominantly monocuspid valve is created, with simultaneous ventricularization of the atrialized right ventricular chamber (Augustin and Schmidt-Habelmann 1997; Ullmann et al. 2004). Mortality was 4% (one patient). Valvuloplasty consisted of creating a predominantly monocuspid valve at the level of the anatomical atrioventricular junction resulting in ventricularization of the atrialized chamber. Important recurrent atrioventricular valve regurgitation developed in three patients (13%). The cause was rupture of the fixation suture. Reoperation was necessary: two patients underwent repeat valvuloplasty and one patient tricuspid valve replacement. One patient presenting with hypoplastic right ventricle and subsequent right heart failure underwent creation of a total cavopulmonary connection. During a follow-up of 4.6 (0.5–10.9) years, all patients were doing well and showed significant improvement of right atrioventricular valve regurgitation and favorable development of the right ventricular geometry and function, as documented by serial echocardiographic examination. The authors concluded that their technique of Ebstein's anomaly repair with ventricularization of the atrialized chamber provides excellent results regarding right atrioventricular valve function and leads to favorable restoration of RV geometry and function (Ullmann et al. 2004).

George Sarris reported the results of a multicentric study by the European Congenital

Heart Surgeons Association in 2006 investigating the surgical treatment of Ebstein's anomaly in 150 patients. The surgical procedures ($n=179$) included 60 valve replacements, 49 valve reconstructions, 46 one-and-a-half ventricle reconstructions, 13 palliative shunts, and 11 other complex procedures. There were 20 hospital deaths (perioperative mortality 13.3%). Perioperative mortality did not differ significantly among repair, replacement, and one-and-a-half ventricle repair but was higher in patients with severe forms of the disease who underwent palliative procedures early in life. Young age seemed to be the only independent predictor of perioperative mortality (Sarris et al. 2006).

A conic reconstruction of the tricuspid valve and longitudinal plication of the atrialized part of the right ventricle was suggested by da Silva and associates (2007). They reported the results of repair of Ebstein's anomaly in 40 patients. An atrial septal defect, if present, was closed with a patch. There was 2.5% mortality. Two patients later required tricuspid valve reconstruction. No atrioventricular block occurred nor was a tricuspid valve replacement necessary at any time during the mean follow-up time of 4 years.

Boston and associates from the Mayo Clinic published the results of their surgical treatment of Ebstein's anomaly in 186 children aged <13 years (Boston et al. 2006). A total of 117 patients received tricuspid valve replacement. Tricuspid valve reconstruction and anuloplasty were carried out in 52 patients with Ebstein's anomaly of forms A and B according to the Carpentier classification (1988). The authors applied valve-preserving reconstruction techniques only in cases in which at least 50% of the anterior leaflet could be detached and the anterior end was not fixed to the endocardium. The early mortality rate in the reconstruction group was 5.8%; for the last 25 years, since 1981 (31 patients), there had been no deaths. The risk factors were age <2.5 years and weight of <10.7 kg. Morbidity consisted of transient arrhythmias of atrial and ventricular origin and the need for early reoperation ($n=3$). No patient required a permanent pacemaker. Actuarial survival following tricuspid valve reconstruction after 5, 10, and 15 years was 92.3%, 89.9%, and 89.9%, respectively. The

rate of freedom from reoperation at 5, 10, and 15 years was 91.0%, 76.9%, and 61.4%. Moderate-to-severe tricuspid valve regurgitation before hospital discharge was the only risk factor for reoperation. Tricuspid valve stenosis did not occur in any of the patients. In the long-term follow-up, 89% of the patients were in NYHA classes I and II.

A recent survey of a total of 595 patients with Ebstein's anomaly showed an overall in-hospital mortality of 5.9%. Mortality among the neonatal population was between 22.7 and 26.9% depending on need for multiple operations. Mortality in infants was 4.1% and in children and adults 0.7% and 1.1%, respectively (Davies et al. 2013). Fetal distress and pulmonary atresia/stenosis are significant predictors of mortality in neonates with Ebstein's anomaly (Yu et al. 2013).

In 2006 Starnes' group reported having treated 14 patients with his procedure, with total mortality of 30%. Survival was improved within that series, after a 4-mm fenestration of the tricuspid valve patch was introduced to avoid right ventricular distention and after the coronary sinus was retained on the right atrial side of the tricuspid valve patch (Reemtsen et al. 2006).

Knott-Craig described biventricular repair of Ebstein's anomaly in a consecutive series of 20 neonates and four young infants, with a survival rate of 70%. Three patients needed tricuspid valve replacement during the median follow-up period of 4.5 years (Knott-Craig et al. 2007).

12.5 Overriding and Straddling Atrioventricular Valves

12.5.1 Introduction

Overriding and straddling phenomena of the atrioventricular valves are rare: their rate of occurrence in relation to all congenital heart defects is between 0.3 and 3%. Then it is particularly the tricuspid valve and hearts with discordant atrioventricular connection that are affected (Liberthson et al. 1971; Milo et al. 1979; Reddy and McElhinney 1997; Jacobs and Mayer 2000; Güeven et al. 2003; Kiraly et al. 2007).

The phenomena of straddlings were described probably for the first time by Lambert (1951) and later analyzed in detail in univentricular hearts by

Van Praagh et al. (1964). Rastelli and colleagues (Rastelli et al. 1968a, b) identified the malalignment between the atrial and ventricular septum as a characteristic feature of hearts with overriding valves and described the straddling phenomenon of the tricuspid valve in cases of atrioventricular septal defects.

Straddling and overriding are often observed in combination with other complex congenital heart defects and are always associated with the presence of a ventricular septal defect or a common ventricle (Huhta et al. 1982a, b; Khairy et al. 2007; Liberthson et al. 1971; Reddy and McElhinney 1997; Serraff et al. 1996; Tabry et al. 1979; Van Son et al. 1998).

Since the introduction of echocardiography, this anomaly has been more frequently recognized and can be exactly described in patients with complex congenital heart disease. On the other hand, angiography plays only an inferior role (Delius et al. 1996; Freedom and Van Arsdell 1998; Freedom et al. 1978; Güeven et al. 2003; Huhta et al. 1982b; Seward et al. 1975; Yoshida et al. 1977).

Knowledge of the straddling phenomenon in one of the atrioventricular valves is particularly important for the choice of surgical strategy (univentricular or biventricular correction), which depends on the type of straddling and on whether correction is possible without producing valve incompetence or total atrioventricular block. The presence of such an anomaly can, in some patients with transposition of the great vessels and a ventricular septal defect and other complex heart defects, mitigate against a Rastelli correction, particularly when the closure of the ventricular septal defect would lead to AV valve dysfunction (Anderson and Ho 1998; Freedom and van Arsdell 1998; Huhta et al. 1982b; Khairy et al. 2007; Russo et al. 1988; van Arsdell 2006).

12.5.2 Definitions

An atrioventricular (AV) valve consists of the anulus, leaflets, and subvalvular apparatus. Normally each AV valve has a morphological relationship to a corresponding ventricle. This means that the valve anulus with its leaflets is entirely above this ventricle, and the subvalvular apparatus is anchored in this ventricle.

Straddling of an AV valve arises when the subvalvular apparatus originates from both sides of the ventricular septum, so that the opening usually comes to lie above both ventricular chambers. Straddling often occurs above a ventricular septal defect of the inlet septum. Using this definition a common AV valve almost always shows straddling. However, there is no consensus on whether in this case one should speak of a straddling phenomenon (Liberthson et al. 1971; Milo et al. 1979) or whether the concept «straddling» should be reserved for describing either the mitral or tricuspid valve when its papillary muscles are connected to both sides of the septum.

In overriding valves, the subvalvular apparatus originates entirely in the original chamber, but the AV valve anulus «rides» above a ventricular septal defect so that there is a communication with both ventricles.

The origin of the overriding and straddling phenomena lies in the malalignment between the anterior edge of the atrial septum and the crest of the muscular septum (Anderson and Shirali 2009; Rastelli et al. 1968a, b).

The chamber in which the whole tensor apparatus of an AV valve and parts of the tensor apparatus of the contralateral AV valve insert is known as the primary chamber (Anderson et al. 1981) or as the dominant ventricle. The chamber in which only one part of the tensor apparatus of the straddling AV valve inserts is regarded as the secondary chamber or «incomplete ventricle.» The latter chamber is typically much smaller or even hypoplastic.

Overriding and straddling phenomena are found both with distinct right and left AV valves and with a common AV valve (AV septal defect anomalies). Further, they have been observed to be independent of the atrial site (solitus, inversus, or ambiguous) and from the type of atrioventricular connection (concordant, discordant, or univentricular) (Güeven et al. 2003).

Overriding and straddling of an AV valve usually occur together. Very rarely they are found with two AV valves. However, both straddling and overriding can occur in isolation (■ Fig. 12.81).

Both overriding and straddling of AV valves are observed in different forms. When the overriding applies to more than 50% of the cross section of the valve, i.e., the larger part of the AV valve counts as part of the dominant ventricle, the phenomenon is known as «double-inlet» ventricle with a univentricular atrio-

ventricular connection (univentricular heart). In hearts with less than 50% overriding of an AV valve, i.e., if the larger part of the valve section is related to the corresponding chamber (the secondary chamber; Anderson et al. 1981), it is known as a biventricular atrioventricular connection (biventricular heart). The different forms of straddling depend on determination of the atrioventricular connection.

12.5.3 Surgical Anatomy

The phenomenon of overriding AV valves suggests, in addition to the valve anomaly, abnormalities of the atrial and ventricular septum (malalignment, ventricular septal defect), the ventricular conduction system, and the ventricular morphology.

12.5.3.1 AV Valves

Only AV valves can show the straddling phenomenon, since arterial valves have no tensor apparatus (Anderson and Shirali 2009). Only one AV valve can override in a heart. There are *four possible forms of AV valve overriding*: overriding mitral or tricuspid valve each in atrioventricular concordance or discordance (Anderson 1997; Güeven et al. 2003; Ho 2003; Jacobs and Mayer 2000; Khairy et al. 2007). Independently of the type of atrioventricular connection and the extent of the overriding, an overriding tricuspid valve is practically always above the posterior portion of the interventricular septum. In the area of the overriding, there is malalignment between the atrial and ventricular septum, and the ventricular septum is not developed as far as the crux cordis in posterior direction. In the contrary case of the mitral valve, the anteromedial portions are usually affected by overriding and straddling so that the valve rides above the anterior interventricular septum. In this situation the septum is developed up to the crux cordis (Anderson 1997; Anderson et al. 1981; Becker et al. 1980; Ho 2003).

The straddling of parts of the subvalvar apparatus of an AV valve can be slight, moderate, or severe. That is to say that the chordae tendineae that cross the ventricular septal defect may insert at the contralateral side of the septum very close to the ventricular septal defect or 2–3 cm away from it or crossing the cavum of the contralateral

■ **Fig. 12.81** a, b Illustration of the concepts of overriding and straddling. a A straddling valve has its subvalvar apparatus originating in both ventricles. Its valvular orifice overrides the septum in all cases. b Isolated overriding occurs with a subvalvar apparatus originating entirely and exclusively in one ventricle

ventricle and inserting at its free wall. In accordance with these variants, Seward et al. (1975) and Tabry and associates (Tabry et al. 1979) suggested classification into types A, B, and C (■ Fig. 12.82). The opening area of the abnormal AV valve is normally relatively large; the contralateral valve is smaller or frequently even hypoplastic (Milo et al. 1979).

When straddling of the morphological tricuspid valve is present, creating a double-inlet connection, the dominant ventricle always shows the morphology of a left ventricle. The rudimentary and incomplete right ventricle can be on the right or left side. In this form the straddling and overriding is extreme, and the tensor apparatus is almost always attached to the parietal wall of the dominant left ventricle (Anderson and Shirali 2009).

12.5.3.2 Ventricular Septal Defect (VSD)

All opinions published so far confirm that a large ventricular septal defect (VSD) is a necessary part of straddling anomalies of the AV valves.

In all cases of overriding/straddling tricuspid valve, there is malalignment between the atrium and chamber inlet septum. The VSD is in posterior position, and the overriding phenomenon concerns the posteroseptal valve portions. The VSD extends to the crux cordis (marginal perimembranous VSD, juxtacru VSD; Milo et al. 1979) and «prevents» the (inlet) septum from being formed. It is important to distinguish this

type of malalignment VSD with an overriding tricuspid valve from defect of the AV canal type (AV septal defect) (Anderson 1997). The malalignment defect with overriding tricuspid valve is not an AV septum defect: the difference is that in AV septum defects the septum, although deficient, is developed up to the crux cordis (Anderson 1997).

With an overriding/straddling mitral valve, the anteromedial valve portions are normally involved in the overriding or straddling process, so that here there is often a VSD in posterior position. The posterior parts of the septum are intact. The focus of the anomaly on the anterior septum also explains the frequent combination with defects such as the double outlet right ventricle and the subpulmonary VSD (Taussig–Bing anomaly) or transposition of the great arteries (Anderson et al. 1981; Freedom et al. 1978; Milo et al. 1979; Niinami et al. 1995; Ostermeyer et al. 1980; Serraff et al. 1996).

12.5.3.3 Conduction System

The position and the course of the specific conduction structures (AV node, «penetrating» His bundle, ventricular bundle branches) depend on the type of atrioventricular connection (concordant or discordant) and the anatomy of the posterior atrioventricular junction (alignment or malalignment of the septa). When there is no malalignment between the atrial and ventricular septum, i.e. the ventricular septum

■ **Fig. 12.82** a–c Classification for AV-valve straddling according to the site of insertion of the papillary muscle in the opposite ventricle by Tabry et al. (1979). **a** Type A: insertion at the other side of the ventricular septum or at the edge of the ventricular septal defect; **b** type B: insertion at the opposite side of the ventricular septum and removal from the rim of the ventricular septal defect; **c** type C: insertion at the opposite free wall of the ventricular chamber

is developed in posterior direction up to the crux cordis and also atrioventricular concordance is present, the position and course of the conduction system can be expected to be normal, with a regular AV node in the Koch triangle and posterior course of the His bundle with normal branching. These relations are found only in hearts with atrioventricular concordance. In those with overriding tricuspid valve (malalignment between the atrial and ventricular septum, juxtacruX VSD), an anomalous position of the AV valve and an abnormal course of the His bundle are to be expected. Milo and colleagues reported that the conduction path tissue does not originate from the regular AV node and that, in biventricular hearts with normal AV junction, the crux is derived from the conduction path tissue» (Milo et al. 1979). In the case of atrioventricular discordance (isolated ventricle inversion, corrected transposition of the great arteries), the ventricular conduction system originates from an AV node in anterolateral position, independently of the VSD position and of which AV valve is overriding, and takes its course in the area of the anterior circumference of the VSD (Anderson 1997). Here the determining factor of the position of the specific musculature is the atrioventricular discordance.

In hearts with atrioventricular concordance and overriding tricuspid valve, the criteria for the formation of a conduction path system are also not fulfilled due to the malalignment between the atrial and ventricular septum and the VSD that extends to the crux cordis (Anderson et al. 1981;

Milo et al. 1979). The AV node is found lateral to the atrial septum in a position directly below the point at which the ventricular inlet septum reaches the tricuspid anulus (Milo et al. 1979). The course of the His bundle is in the area of the posterior rim of the VSD. Although Serraf and colleagues (1996) assumed that the conduction system in biventricular heart with a VSD was similar to that in hearts with a simple VSD, this thesis has not been supported by anatomical evidence (Anderson 1997).

12.5.3.4 Ventricular Morphology

Apart from atypically inserted chordae tendineae and papillary muscles, the ventricles frequently show differences in size. Almost always there is hypoplasia of the secondary chamber (incomplete ventricle) and a relatively larger primary chamber, which still communicates more or less with the overriding contralateral valve in addition to the corresponding AV valve (Anderson et al. 1981; Corno 2005; Hanley 1999; Milo et al. 1979; Muster et al. 1979; Seward et al. 1975; Van Praagh et al. 1964).

12.5.4 Surgical Treatment

The corrective procedure for atrioventricular valves with the straddling phenomenon was first described in 1979 (Pacifico et al. 1979; Tabry et al. 1979). The surgical considerations arising from the overriding phenomenon of the AV valve have found attention in a number of publications in recent years (Aeba et al. 2000; Anderson 1997; Danielson et al. 1979a, b; Niinami et al. 1995;

Planche et al. 1982; Russo et al. 1988; Serraff et al. 1996; Tabry et al. 1979; Van Son et al. 1998a, b, c). These show that the operative strategy always depends on the hemodynamically most relevant anomaly and that the real surgical problem with the straddling AV valve lies in the need to close the always coexisting VSD without impairing the AV valve function, without producing AV block due to the positional anomalies of the specific muscles, and without the secondary chamber being too small after VSD closure.

Overriding of the AV valves, as discussed above, represents a whole spectrum of anomalies, with broad variability in position and size of the VSD and in the location and course of the specific conduction structures and the ventricular geometry. For these reasons it appears not to be useful to describe the surgical procedure in detail and, so to speak, «suture by suture» for an arbitrarily selected straddling situation, which would probably not be feasible with a different variant on the spectrum of anomalies. Instead we describe in the following the principle options for a surgical procedure, taking into account the different types of anomaly.

The straddling phenomenon remains a great challenge for the cardiologist and pediatric cardiac surgeon (Delius et al. 1996; Kiraly et al. 2007; Tabry et al. 1979). In patients with well-developed ventricles, an attempt should always be made to perform *biventricular correction* rather than univentricular correction; in doing so it is important to avoid traumatic AV block (Anderson 1997). Biventricular correction in valves with straddling phenomena carries the potential risk of causing dysfunction of the mitral and tricuspid valve, since dividing the chambers or placing the suture line for VSD closure can often mechanically distort or injure the tensor apparatus of the AV valves directly below the VSD. In addition, displacement of the suture line to the left or right in patents with the straddling phenomenon may lead to obstruction of the left or right ventricular outflow tract (Delius et al. 1996; Serraff et al. 1996). Variable valve morphology means that the valves in patients with functionally single ventricle are susceptible to developing insufficiency in the long-term course (Kiraly et al. 2007).

A further problem is the high risk of developing total AV block (Anderson 1997; Anderson and Ho 1998; Serraff et al. 1996). To avoid this, Planche and colleagues (1982) developed a technique that uses the leaflet tissue of the overriding tricuspid valve

components to strengthen the sutures in the areas where the suture line crosses the AV conduction path. The sutures are placed at a distance from the septum edge but in right ventricular or atrial tissue; the straddling components remain in the left ventricle (Planche et al. 1982). Damage to the penetrating AV bundle can be avoided by placing the sutures at the left side of the septum edge (Serraff et al. 1996).

Bob Anderson is of the opinion that surgical injury to the conduction path system can be avoided by having exact knowledge of the anatomy of the valves with the straddling phenomenon and the associated ventricular connection (Anderson 1997). However, in many patients a high incidence of postoperative complete AV block has been observed (Pacifico et al. 1979; Reddy and McElhinney 1997; Tabry et al. 1979).

Different surgical techniques in patients with straddling of the tricuspid and mitral valve who underwent biventricular correction have been described.

12.5.4.1 Transection of Tendinous Fibers

When straddling affects only individual chordae that play no part in the closure mechanism of the AV valve, these can be transected without risk. The VSD closure can then be performed in the usual manner. The possibility of proceeding in this way is definitely given when the crossing chordae in slight or moderate straddling (type A or B) insert at an isolated papillary muscle in the contralateral ventricle.

12.5.4.2 Slitting of the VSD Patch and Division of the VSD Patch Suture Line

In rare cases of type A and type B straddling, the crossing tendinous fibers could be brought through a slit in the VSD patch. To avoid a residual defect, the slit is sutured after VSD closure (Aeba et al. 2000; Pacifico et al. 1979). This technique should only be applied when the crossing chordae are not an important part of the mechanism of valve closure since the valve mobility would be reduced (Aeba et al. 2000; Danielson et al. 1979b; Tabry et al. 1979; ■ Fig. 12.83).

12.5.4.3 Papillary Muscle Re-implantation

With slight or moderate straddling (type A or B), if the crossing chordae insert at an isolated papillary muscle in the contralateral ventricle and this papillary muscle has no connections to the other

■ **Fig. 12.83** a, b Illustration looking into the right ventricle in a patient with transposition of the great arteries and ventricular septal defect. **a** At the papillary muscle of the mitral valve with straddling phenomenon, the suture line has been interrupted. **b** After completion of the VSD patch insertion, the straddling papillary muscles of the subvalvular apparatus of the mitral valve come to rest between the ventricular septum and the VSD patch. The cranial part of the VSD patch has been flipped over, allowing a free view of the aortic valve (Following Aeba et al. 2000)

AV valve, this muscle can be transected at its base and later be reimplemented in the septum of the corresponding ventricle during VSD closure (Niinami et al. 1995; Reddy and McElhinney 1997; Van Son et al. 1998a, b, c). Whether this method can produce undisturbed valve function remains questionable. Technically the procedure can only be performed when reimplantation is possible in the ventricle through which the operation is performed, usually only for a tricuspid valve in typical *trans*-right-atrial VSD patch closure.

12.5.4.4 Pseudoseptation

The patch selected to close the VSD is clearly larger and is placed in the primary chamber around the base points of the crossing chordae so that the entire subvalvar apparatus of the former straddling valve lies within the newly created ventricular cavum—a procedure that is particularly to be considered with type A straddling. This is technically relatively simple when the chords cross into the ventricle through which the surgeon works, mainly with straddling of the left AV valve into the right-position ventricle. However, it is in principle also possible with straddling of the right AV valve into the left-position ventricle (Pacifico et al. 1979; ■ Fig. 12.84).

12.5.4.5 Myocardial Conal Flap Methods

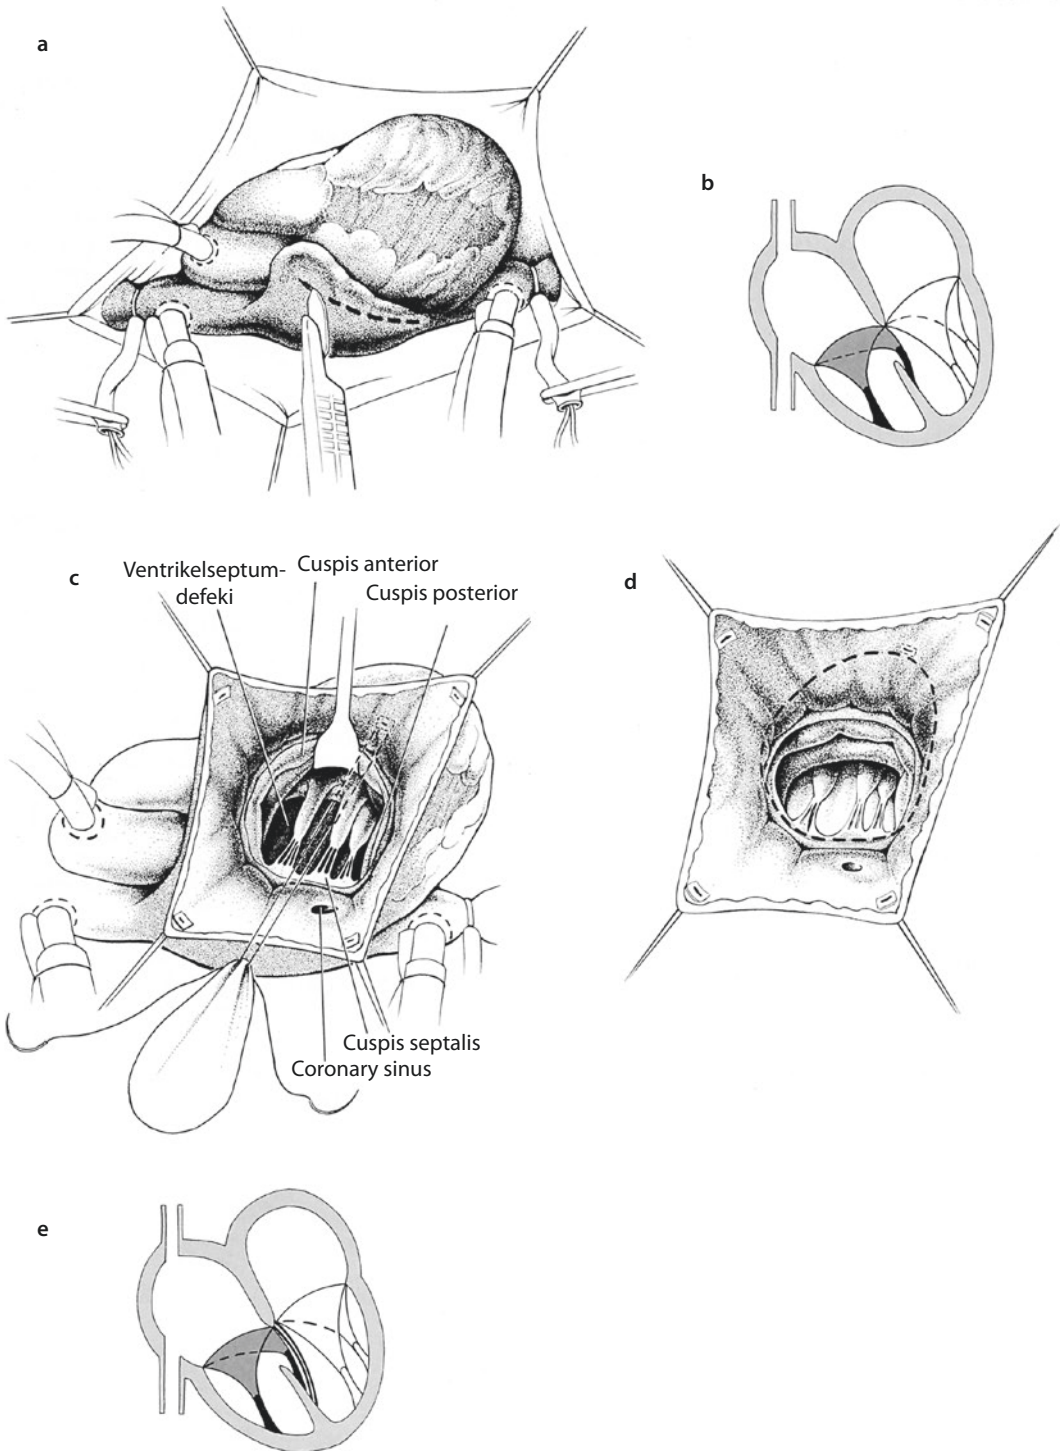

Trimming of a conal myocardial flap to be used to correct abnormal attachment of the tricuspid valve to the outflow tract septum and its fixation to the intracardiac tunnel in a patient with double outlet ventricle are shown in ■ Fig. 12.85 (Niinami et al. 1995; Serraff et al. 1996).

12.5.4.6 Retraction of the Chordae or the Papillary Muscle

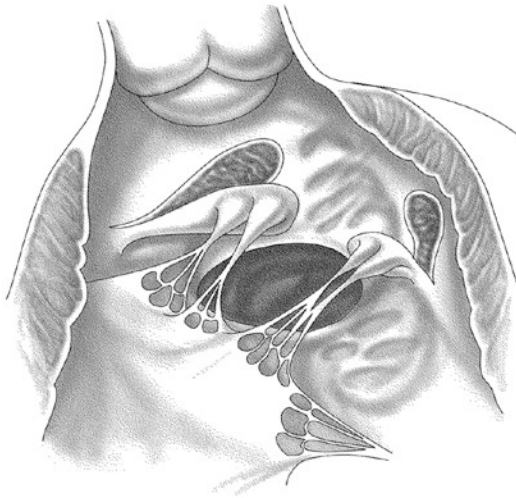

■ Fig. 12.85 illustrates retraction of the chordae or the papillary muscle of a tricuspid or mitral valve with straddling into the left ventricle through the native aortic valve (■ Fig. 12.85) or the pulmonary valve (■ Fig. 12.86) in a patient with dextrotransposition of the great vessels (Serraff et al. 1996).

12.5.4.7 AV-Valve Replacement

When an overriding or straddling AV valve is primarily incompetent, which is extremely rare, or when valve-preserving measures are not possible in type C straddling, valve replacement must be considered. However, the well-known disadvantages of valve replacement in children give rise to serious concerns (Tabry et al. 1979). If a malalignment VSD (straddling tricuspid valve) is present,

■ **Fig. 12.84** a–e Pseudoseptation of a perimembranous malalignment (juxtacru) ventricular septal defect in an overriding and straddling tricuspid valve in a patient with situs solitus and normal atrioventricular connections. **a** Access through an oblique incision in the right atrium. **b** The chordae of the septal tricuspid leaflet cross the ventricular septal defect to insert at papillary muscles of the left ventricle. The tricuspid valve annulus overrides by 10–20%. **c** Closure of the ventricular septal defect is performed transatrially. To preserve the tricuspid valve integrity, the patch is placed on the left side of the septum in such a manner that the whole subvalvar apparatus remains to the right of the Dacron patch. **d, e** Completed closure of the ventricular septal defect (Modified from Pacifico et al. 1979)

■ **Fig. 12.85** Surgical technique for trimming a myocardial flap to the correct size to operate on a tricuspid valve with anomalous attachment to the septum of the outflow tract and fixation to the intracardiac tunnel in a case of double outlet ventricle (After Serraff et al. 1996)

the artificial valve must normally be fixed to the septal VSD patch, which makes the use of a low-profile prosthesis seem advisable.

12.5.4.8 Alternative Methods

If it is highly likely that these intracardiac corrective operations will give rise to total AV block, a secondary ventricle that is too small and/or a restriction in AV valve function (e.g., with primary stenosis of the non-straddling valve), the following alternatives should be considered instead.

■ ■ Fontan operation

Patients with a giant papillary muscle and anomalous insertion of the tricuspid valve cannot be treated by biventricular correction, since this would cause obstruction of the left ventricular outflow tract and AV valve dysfunction (Aeba et al. 2000). Curtain-like tricuspid valve chordae with anomalous origin remain a contraindication to biventricular correction in patients with double

■ **Fig. 12.86** **a** Surgical technique for the intraoperative management of a tricuspid valve with straddling with transposition of the great arteries. The papillary muscle chordae are pulled toward the right ventricle using a hook that is entered through the native aortic valve. The ventricular septal defect is closed with access either through the native aortic valve or through the pulmonary artery in the normal fashion. Occasionally it is necessary to complete the procedure through the right atrium. **b** Surgical technique for the intraoperative handling of a straddling mitral valve with transposition of the great arteries. The chordae of the papillary muscles are pulled with a hook in the direction of the left ventricle through the pulmonary artery. The ventricular septal defect is then closed through the native aortic valve or through a right ventriculotomy. Sometimes the procedure must be completed through the right atrium (After Serraff et al. 1996)

outlet right ventricle, transposition of the great vessels, or severe right ventricular hypoplasia. Occasionally anomalies of the tricuspid valve or anomalies of the papillary muscle origin around the rim of the VSD in patients with double outlet ventricle make the creation of a satisfactory intracardiac rerouting difficult or even impossible.

As long as the general criteria for a modified Fontan operation are fulfilled, this could be the method of choice for patients with type B or type C straddling and clear hypoplasia of the secondary ventricle.

In such situation it is assumed that univentricular correction in the form of an extracardiac or intracardiac lateral tunnel as part of the Fontan operation is superior to biventricular correction (Anderson and Ho 1998; Delius et al. 1996; Freedom and Van Arsdell 1998; Hanley 1999; Marino 2002; Pacifico et al. 1979; Russo et al. 1988; van Arsdell 2006).

Therefore, exact preoperative diagnostic procedures are obligatory in valves with straddling and all surgical options should be carefully considered before the decision in favor of biventricular or univentricular correction is made. In patients with slightly hypoplastic right ventricle, the method of «one-and-a-half ventricle repair» may be applied (Hanley 1999; Serraff et al. 1996).

■ ■ Palliation

In infants and small children, especially when preoperative examinations have detected type B or type C straddling, one of the «classical» palliative operations (pulmonary artery banding, systemic–pulmonary arterial shunt) can be considered to optimize pulmonary perfusion.

■ ■ Heart transplantation

Heart transplantation should be reserved for patients with very severe myocardial dysfunction. For this reason it is never primarily indicated in cases of overriding or straddling AV valves.

12.5.5 Results

There are only few reports of midterm and long-term results of surgical treatment of straddling valves; moreover, the groups of patients reported on are very small.

Serraff and colleagues (1996) reported their experience with 34 patients with double outlet right ventricle and AV valves with the straddling

phenomenon. In four patients the switch to univentricular correction was made. There were four deaths after biventricular correction (13.3%), and six reoperations were necessary due to a subaortic stenosis, AV valve insufficiency, and the need for pacemaker implantation.

Reddy and colleagues (1997) described five patients with straddling of the AV valves in whom the technique of chordal translocation and reinsertion was used during the biventricular correction. None of the patients died, but three developed total AV block necessitating permanent pacemaker implantation.

For patients with type A straddling and without overriding, the results are clearly more favorable (Aeba et al. 2000; Niinami et al. 1995).

13.1 Introduction

The treatment of newborns and small children, who do not have two well-developed ventricles, presents one of the biggest challenges in therapy of congenital heart defects. In addition, the classification of this group of heart defects is difficult since there are a large number of heart defects, which can be accompanied by hypoplasia of one of the ventricles. These hearts are often described as ‘single ventricle’ or ‘univentricular heart’. However, these terms are not precise. It is extremely rare that these hearts actually consist of only one ventricle. In most of the cases, one ventricle is fully developed, while the other chamber is hypoplastic, not completely developed or rudimentary. Therefore, the term ‘functional single ventricle’ has been used in recent times to describe all heart defects, in which separation of the ventricles is not possible.

In presence of a functional single ventricle, the systemic and the pulmonary circulation are arranged in a parallel circuit. This is contrary to the serial arrangement in the normal circulation. Without a surgical intervention, this condition leads to a very unfavorable prognosis. The development of surgical strategies for these patients to separate the systemic from the pulmonary circulation has led to a significant improvement of life expectancy and quality of life.

13.2 Nomenclature and Classification

The terms ‘single ventricle’ and ‘univentricular heart’ were characterized by Abbott (1936), Taussig (1939), Edwards (1960), and Lev (1953). The term ‘functional single ventricle’ was established by van Praagh’s ‘Segmental anatomy approach’ (van Praagh et al. 1979) and Anderson’s ‘System of sequential chamber localization’ (Anderson et al. 1975). According to van Praagh, a functional single ventricle is connected with the atria through a mitral, tricuspid or common atrioventricular valve. Anderson’s nomenclature is also based on the atrioventricular connection. According to Anderson, in a functional single ventricle, all atrioventricular connections lead to just one ventricle. The other ventricle has no atrioventricular connection, and it is rudimentary. Anderson’s functional single ventricle can also be named as ‘univentricular atrioventricular connection’.

The surgeon needs a structured nomenclature, including all congenital heart defects with a functional single ventricle and including all additional heart malformations, which are important for planning of the surgical strategy. Such a nomenclature was developed by the ‘Society of thoracic surgeons international congenital heart surgery database project’ (Jacobs and Mayer 2000). Accordingly, the functional single ventricles are divided into the following subgroups:

- Hearts with double-inlet atrioventricular connection
- Hearts in which one atrioventricular connection is absent
- Hearts with common atrioventricular connection, where only one ventricle is normally developed
- Hearts with one normally developed ventricle in the presence of heterotaxy syndrome
- Very rare heart defects, which cannot be classified in the aforementioned categories

The common ground of all these hearts is the functional single ventricle physiology, regardless of the specific morphology. In most cases, a biventricular repair is impossible in the presence of a functional single ventricle physiology. Therefore in these patients, a univentricular palliation is performed in order to separate the systemic and pulmonary circulation. The basic strategy of univentricular palliation is similar, regardless of the specific morphology. Therefore, this chapter will describe all operations which are necessary to complete the univentricular palliation. The final step of separating the pulmonary and systemic circulation is named ‘Fontan operation’ after the surgeon, who first successfully performed this surgical principle (Fontan et al. 1971). The resulting circulation, which consists of one pumping chamber, is referred to as ‘Fontan circulation’.

13.3 Anatomy

13.3.1 Hearts with Double-Inlet Atrioventricular Connection

Double-inlet atrioventricular connection depicts a morphology, where both atria connect to only one ventricle through either two separate or one single atrioventricular valve. In most cases, the atria are connected with one fully developed chamber. The cases in which only one ventricle is present are,

however, very rare. A second, rudimentary or hypoplastic chamber is usually present. Either the hypoplastic ventricle has no atrioventricular connection or the common atrioventricular valve opens partially in the hypoplastic chamber, in terms of an override. The diagnosis of a 'double-inlet ventricle' is made, when more than 50% of the overriding valve lies over the dominant chamber.

The dominant ventricle can morphologically more or less resemble the right or the left chamber of a normal heart. Only rarely the morphology cannot be classified. The size of the dominant ventricle correlates with pulmonary blood flow. In the presence of pulmonary stenosis, the ventricle is smaller than in the cases with an unrestrictive pulmonary blood flow (Shimazaki et al. 1980). The morphology of the rudimentary ventricle is always complementary to the morphology of the dominant one. Usually, these chambers lack a part of the inflow tract. Sometimes, the outflow tract is also non-existent, and the ventricle consists only from the trabeculized part. The hypoplastic chamber is connected to the dominant ventricle through the bulboventricular foramen.

The position of the atria is variable. Normally positioned atria are found in most hearts with a double-inlet left ventricle, whereas only in half of the hearts with a double-inlet right ventricle. In the other half of the patients, isomerism (usually right) is present.

In general, two atrioventricular valves are present and both open in the dominant ventricle. These valves usually do not correlate to the morphological tricuspid or mitral valve. Therefore, it is advisable to refer to these valves as right and left atrioventricular valve (Restivo et al. 1982). A common atrioventricular valve is rarely present and mostly has a high grade of insufficiency (Soto et al. 1979). In approximately 20% of the patients, one of the atrioventricular valves is overriding the ventricular septum and a part of the chordal apparatus is going through the interventricular communication, which is known as straddling of the valve.

13.3.2 Hearts in Which One Atrioventricular Connection Is Absent

13.3.2.1 Tricuspid Atresia

The term 'tricuspid atresia' describes the hearts with an absent right atrioventricular connection. As a result, univentricular atrioventricular connection is present and consists of a left atrioventricular connection

between the left atrium and the left ventricle. An atrial septal defect is present in all cases, at least in a form of a non-restrictive foramen ovale. A bulboventricular foramen is present in most cases. The ventriculoarterial connection may be concordant or discordant.

Kühne, who also defined two basic forms of this heart defect, first described tricuspid atresia in 1906 as 'atresia of ostium venosum dextrum' (Kühne 1906). Edwards and Burchell in 1949 (Edwards and Burchell 1949), Keith in 1958 (Keith et al. 1958) and Tandon and Edwards in 1974 (Tandon and Edwards 1974) did further differentiation. Bellet and Steward in 1933 (Bellet and Steward 1933) and Taussig in 1936 (Taussig 1936) described the clinical picture.

Tricuspid atresia is complete in most cases, and the bottom part of the right atrium consists of muscles (Anderson et al. 1977). Membranous atresia is less common and has three different types. The first type is a tricuspid atresia with imperforated valve membrane. An impermeable membrane which resembles a valve, and sometimes chordae on the ventricular side, is present in this type (Anderson and Rigby 1987). The second type includes a tricuspid valve, which resembles the Ebstein anomaly, with completely fused leaflets (Anderson et al. 1977). In the third, rarest group, a complete atrioventricular septal defect is present, in which the right part of the common atrioventricular valve does not open in the right ventricle (Ottenkamp and Wenink 1989).

The right atrium can be dilated in the presence of tricuspid atresia, and the wall is mostly thickened. An atrial septal defect, which is mostly secundum type, represents the only outlet from the right atrium. The left atrium is dilated due to intraatrial shunt but usually shows normal morphology.

The mitral valve and the left ventricle are larger than normal. The left ventricle is enlarged due to volume overload. The right ventricle is connected to the left ventricle through a bulboventricular foramen, which always has muscular borders. The right ventricle is rudimentary and does not have an inlet component. The size of the trabeculized part and the size of the outflow tract of the right ventricle are dependent on the size of the bulboventricular foramen and the type of the ventriculoarterial connection.

Usually, a normal coronary pattern is present. The systemic veins are also usually normally connected, except for the persistent left superior

vena cava, which is present in up to 15% of these hearts. The position of the sinus node is normal; the AV node is on the right hand side of the central fibrous skeleton. The course of the ventricular bundles depends on the position of the bulboventricular foramen but are mostly positioned posterior and inferior of the defect.

Two further groups can be distinguished based on the type of the ventriculoarterial connection: ventriculoarterial concordance (normal position of the great arteries) and ventriculoarterial discordance (transposition of the great arteries) (Rosenthal and Dick 1983). According to the size of the bulboventricular foramen and the grade of the pulmonary stenosis, three more subgroups can be recognized:

Group I (ventriculoarterial concordance, 60–70% of the cases)

- Ia: no bulboventricular foramen and pulmonary atresia

- Ib: restrictive bulboventricular foramen and/or pulmonary stenosis
- Ic: unrestrictive bulboventricular foramen, no pulmonary stenosis

Group II (ventriculoarterial discordance, 30–40% of the cases) (Edwards and Burchell 1949; Anecchino et al. 1980):

- IIa: no bulboventricular foramen and pulmonary atresia
- IIb: restrictive bulboventricular foramen and pulmonary stenosis
- IIc: unrestrictive bulboventricular foramen, no pulmonary stenosis

Double outlet from the right or left ventricle is rare (Anderson et al. 1977), while other forms are even more uncommon. Altogether, 80% of the patients can be assigned to the aforementioned groups (Anderson and Rigby 1987; Forrest et al. 1987). ■ Figure 13.1 illustrates the classification according to Edwards and

■ Fig. 13.1 Most common forms of tricuspid atresia in a simplified categorization according to Rosenthal and Dick (1983) (Description in text)

Burchell (1949) in a simplified categorization according to Rosenthal and Dick (1983).

13.3.2.2 Mitral Atresia

In analogy to the absence of the right atrioventricular connection, the absence of the left atrioventricular connection can be accompanied with a number of different heart defects. The classical example of the mitral atresia is a functional single ventricle with a morphological right chamber and an absence of the left atrioventricular connection. Just like in the cases of tricuspid atresia, mitral atresia can be accompanied by an impermeable valve on which chordae may still be identifiable. However, a membrane consisting of connective and fat tissue is found more often (Thiene et al. 1981). When mitral and aortic atresia is present, the heart defect is classified as a part of the hypoplastic left heart syndrome (see ► chapter «Surgery for Aortic Atresia, Hypoplastic Left Heart Syndrome, and Hypoplastic Left Heart Complex», Sect. 17.1). This is also the case in different combinations of mitral atresia/stenosis and aortic atresia/stenosis. Borderline cases are sometimes difficult to classify, which is why the term hypoplastic left heart syndrome should always be used when there is no possibility of biventricular correction and where a definitive palliation leading to Fontan circulation must be undertaken (Kouchoukos et al. 2003a). For these borderline cases, also the term hypoplastic left heart complex is used (Tchervenkov et al. 1998) see also ► chapter «Surgery for Aortic Atresia, Hypoplastic Left Heart Syndrome, and Hypoplastic Left Heart Complex», Sect. 17.6.8.

Most of these hearts have normally positioned atria, d-loop of the ventricles, a dominant right ventricle which is connected to the right atrium through the tricuspid valve, and a hypoplastic left ventricle positioned left and posterior. In the cases with ventriculoarterial concordance and an existent connection between the dominant and the hypoplastic ventricle, the size of the aorta ascendens and the aortic arch is determined through the size of the bulboventricular foramen. When the foramen is restrictive, the ascending aorta and the arch are hypoplastic. In some cases, the aortic isthmus is also stenotic, and rarely, there is an interrupted aortic arch (Jacobs 2003).

Mitral atresia with ventriculoarterial discordance is very rare. More frequent are the cases with double outlet from the right ventricle. The left ventricle is in these cases a blind pouch which is connected only to the right ventricle.

13.3.3 Hearts with Common Atrioventricular Connection Where Only One Ventricle Is Normally Developed

Functional single ventricles with a malformation based on a defect of endocardial cushion are included in this rare subgroup. Unlike the hypoplastic ventricles in other groups described in this chapter, the chambers in this subgroup are not rudimentary since the inlet part of the ventricle is developed. They are however hypoplastic since the blood flow through the common atrioventricular valve is preferentially directed in the dominant ventricle. The underlying pathology is the imbalance between the components (right/left) of the atrioventricular valve and the two ventricles (right/left). The dimension of this imbalance determines the degree of hypoplasia and the dominance of the ventricle.

In the right-dominant type, the right ventricle is large, the left ventricle is smaller than normal and the blood flow from the atria in the ventricles is preferentially directed into the right ventricle due to displacement of the common atrioventricular valve towards the right. In left-dominant type, the left ventricle is large, the right ventricle is smaller than normal and the blood flow from the atria into the ventricles is preferentially directed into the left ventricle due to displacement of the common atrioventricular valve towards the left. In the cases with left dominance, there is a notable hypoplasia of the right ventricle. However, it is sometimes very difficult to separate the right-dominant type with a real dominance of the right ventricle, and the hypoplasia of the left ventricle from the common cases of atrioventricular septum defect with balanced ventricles, where the right ventricle is larger due to volume overload (Jacobs 2003).

It is very important to determine the degree of hypoplasia of the smaller ventricle in order to decide on surgical strategy. The atrioventricular valve index, introduced by Cohen et al. (1996), has proven to be helpful in deciding which patient is suitable for biventricular repair and in which univentricular palliation is necessary.

Hypoplasia of the aortic arch, or aortic isthmus stenosis, as well as a prominent pulmonary artery is relatively common in patients with right dominance of the common atrioventricular connection. On the other hand, the aortic arch and the pulmonary artery are usually normally developed in the left-dominant cases (Jacobs 2003).

13.3.4 Hearts with Only One Normally Developed Ventricle in the Presence of Heterotaxy Syndrome

Heterotaxy syndrome is characterized by a specific pattern of arrangement of thoracic and abdominal organs. Unpaired organs are usually positioned in the median line of the body, while the paired organs (e.g. lung lobes) or paired parts of organs (e.g. atria) pose a mirror image on each side. Hence, an atrial isomerism (more accurately an isomerism of atrial appendages) was described by Wilcox et al. (Becker and Anderson 1981). Since the spleen is typically absent in the patients with right atrial isomerism, and there is typically accessory spleen tissue in the patients with left atrial isomerism, the terms ‘asplenie’ and ‘poly-splenie’ are also appropriate (Van Mirop and Wigglesworth 1962; Becker and Anderson 1981).

A functional single ventricle is often found in patients with a heterotaxy syndrome. In addition, there are often anomalies in the systemic and pulmonary venous connections. Intracardial anatomy usually includes defects of the endocardial cushion and pulmonary stenosis.

More than half of the patients with right isomerism have a functional single ventricle. Typically, there is a dominant right ventricle (42%) with double outlet from the right ventricle (82%), pulmonary stenosis or atresia (96%), bilateral superior vena cava (71%) and a common atrioventricular valve (93%). Bilateral sinus nodes are present. Coronary sinus is absent. Total anomalous pulmonary venous connection is common (Rubino et al. 1995). The inferior vena cava and the liver veins drain separately in the atrium. Both lungs consist of three lobes (Jacobs 2003.)

Less than half of the patients with left isomerism have a functional single ventricle. Two thirds of them have a dominant right ventricle. There is no rudimentary chamber. Bilateral superior vena cava is common, as well as an interrupted inferior vena cava in the infrahepatic part, with azygos continuity (80%). Liver veins often drain bilaterally in the atria, while the pulmonary veins usually connect to the atrium located on the right hand side. In comparison to the hearts with right isomerism, pulmonary atresia is uncommon. Sinus node can be abnormally positioned or even completely absent. Both lungs consist of two lobes (Jacobs 2003).

Heart defects with a hypoplastic or rudimentary ventricle, which however do not include an atretic atrioventricular connection, double-inlet ventricle or an overriding of the atrioventricular valve in the presence of a complete atrioventricular septal defect, are according to this classification not defined as ‘functional single ventricle’. However, the underlying pathology of these defects can prevent a biventricular repair. Hence, practically the same surgical strategy must be applied, as in the cases of functional single ventricles. This subgroup of heart defects includes the extreme form of Ebstein disease, extreme forms of pulmonary atresia with intact ventricular septum, the isolated stenosis of tricuspid valve with intact ventricular septum and the isolated hypoplasia of the myocardium of the right ventricle (Uhl 1952).

13.4 Natural History

Tricuspid atresia is the most common form of a functional single ventricle. It represents 1–3% of all congenital heart defects (Kouchoukos et al. 2003b). The early natural course is determined by the amount of pulmonary blood flow (pulmonary stenosis, restrictive bulboventricular foramen). The further course of the disease is affected by cardiomyopathy, caused by the volume overload of the functional single ventricle in face of cyanosis.

Since the introduction of palliative surgical interventions to control pulmonary blood flow, the life expectancy of the patients with functional single ventricle has remarkably increased. At the present time, it is not possible to make any certain statements about the further course (‘unnatural history’) of these patients. Moddie et al. (1984) reported a survival of 50% at 14 years after primary diagnosis of functional single ventricle, with no surgical intervention. The main causes of death were terminal heart insufficiency and rhythm disturbances. In a group of patients with double-inlet left ventricle, from which some were palliated (there were no patients in whom a separation of systemic and pulmonary circulation was performed), a survival of 42% at 10 years was reported (Franklin et al. 1991).

The combination of atresia of the left atrioventricular valve with a restrictive interatrial communication has a very unfavorable course, due to obstruction of pulmonary venous return.

These children often pass away in the first few days after delivery due to acidosis following hypoxia (Jacobs 2003).

One of the most important morphological factors, which influences mortality, is a stenosis of the systemic outflow tract. This is especially pronounced when the aorta is connected to a hypoplastic ventricle. The morphological substrate is a restrictive bulboventricular foramen, through which the complete cardiac output has to be ejected. When this communication is prenatally restrictive, the findings of hypoplastic aortic arch and aortic isthmus stenosis or even interrupted aortic arch is common. A narrowing of the inter-ventricular connection may occur in the postnatal period, even in the absence of prenatal restriction (Rao 1983). In this context, pulmonary artery banding can exacerbate the course of the disease (Freedom et al. 1986). Donofrio et al. (1995) showed that all palliative measures, which lead to volume unloading of the functional single ventricle, changed the geometry of the ventricle. Mass-volume ratio changes, the wall thickness increases and the bulboventricular foramen gets smaller.

The natural history of the patients with tricuspid atresia is dependent on the pulmonary flow and is variable, just like in other patients with functional single ventricle. In the presence of ventriculoarterial concordance, there is usually limited pulmonary blood flow, due to restrictive bulboventricular foramen or infundibulum stenosis. Due to further reduction in the size of bulboventricular foramen, and further reduction of the pulmonary blood flow, 90% of these patients die due to hypoxemia in the first year of life without surgical intervention (Rao 1977). In rare cases, the hemodynamics are balanced without excessive pulmonary flow, and only mild cyanosis is present. However, 90% of these patients die due to hypoxemia within 10 years of life due to development of pulmonary stenosis (Rao 1977, 1983). The few patients who survive until the second or third decade of life pass away due to chronic obstructive pulmonary vasculopathy or due to chronic heart insufficiency based on high volume overload of the left ventricle.

Patients with tricuspid atresia and ventriculoarterial discordance have a worse prognosis. Unrestrictive pulmonary blood flow leads to heart failure and death within the first year of life. The presence of subaortic stenosis worsens the prognosis even further, since the pulmonary circula-

tion increases, while the systemic circulation continues to decline. In patients with hypoplastic aortic arch, or aortic isthmus stenosis, the systemic circulation is dependent on the ductal flow. The majority of these patients die within the first few weeks of life when the ductus arteriosus obliterates (Kouchoukos et al. 2003b).

Another factor, which determines the prognosis of the children with functional single ventricle, is the presence of total anomalous pulmonary venous return. Although the abnormal connection of the pulmonary veins can be seen in any patient with functional single ventricle, it is seen more often in patients with right atrial isomerism. The prognosis of these patients depends not only on the degree of restriction of the anterograde flow from the functional single ventricle in the pulmonary arteries but also on the presence and the degree of pulmonary vein stenosis. Altogether, these children have a very poor prognosis—44% die within 6 months, even with surgical intervention (Gaynor et al. 1999).

13.5 History of Surgical Treatment of Patients with Functional Single Ventricle

13.5.1 Palliative Operations

Shortly after palliative operations to either increase or limit pulmonary blood flow were described, surgeons started using these palliative techniques in children with tricuspid atresia. The Blalock-Taussig shunt (Blalock and Taussig 1945) treated cyanosis, the pulmonary artery band (Mueller and Dammann 1952) heart failure secondary to pulmonary overcirculation. During those times, these palliative measures were the only means to improve the quality of life and increase the life expectancy of the children suffering from their heart disease. Later, these early palliations became part of a staged approach for finally more complex definitive palliative procedures.

13.5.2 Septation of the Functional Single Ventricle

The septation of the functional single ventricle had the purpose of dividing the ventricle into separate subaortic and subpulmonary parts. All of

the first published operative techniques include a ventriculotomy (Sakakibara et al. 1972; Edie et al. 1973). In 1979, Doty et al. (1979) first described a transatrial approach for septation. However, the hospital mortality approached 50% (McKay et al. 1982). Restrictive bulboventricular foramen and a smaller ventricle were identified as risk factors. The surgeons were hoping that the hypoplastic ventricle would grow after implantation of a shunt between the systemic and pulmonary circulation. However, the early mortality remained high (Stefanelli et al. 1984). Stricter criteria for the selection of patients scheduled for septation exclude most of the patients with functional single ventricle. These criteria include the morphology and the function of the atrioventricular valve, and the hypoplastic ventricle, as well as the presence and the degree of subaortic and pulmonary stenosis (Pacífico et al. 1985). Ebert et al. (Ebert 1984) performed successful first-stage palliation for two-stage septations (temporary ventricular septal defect), in a limited patient group with rare indications. Although the concept seemed ingenious, the final results for these patients after potential second-stage surgery, however, were not reported. Since the introduction of the definitive palliation (Fontan circulation) in 1968, the prognosis of these patients improved significantly. When comparing the results of the septation operation to the results of Fontan operations, there seems to be almost no indication for septation of a functional single ventricle in the present time.

13.5.3 Cavopulmonary Anastomosis

In 1958, Glenn reported on the first clinical palliation, which included end-to-end anastomosis of the superior vena cava with the distal right pulmonary artery (Glenn anastomosis) (Glenn 1958). Independent of Glenn's work, Bakulev and Kolesnikov (1959) developed the same therapeutic concept, which Meshalkin introduced in the clinical practice in 1956. The first bidirectional Glenn anastomosis was introduced by Azzolina et al. in 1974 (Azzolina et al. 1972) and was further modified by Hopkins et al. in 1984 (Hopkins et al. 1985). The superior vena cava was connected end-to-side with the right pulmonary artery, which was not divided prior to the procedure (Azzolina et al. 1972; Hopkins et al. 1985).

13.5.4 Fontan Operation and Modifications

The first successful definitive palliation of a patient with tricuspid atresia by complete separation of the systemic and pulmonary circulation was performed in 1968 and published in 1971 (Fontan and Baudet 1971; Fontan et al. 1971). These operations included the Glenn anastomosis and a direct anastomosis between the right atrial appendage and the proximal end of the divided right pulmonary artery. The main pulmonary artery was ligated, the atrial septal defect was closed and a homograft valve was implanted in the ostium of the inferior vena cava. In the following two patients, a homograft valve was implanted between the right atrium and the pulmonary artery. Kreutzer et al. (1973) published a simpler method, in which the autologous pulmonary valve was used as a conduit between the right atrium and the pulmonary valve. In this way, the division of the right pulmonary artery and the implantation of a valve in the inferior vena cava became unnecessary (■ Fig. 13.2).

In the following years, the Fontan operation was modified by Fontan himself (Fontan et al. 1983) as well as numerous other authors. Although some of these operative techniques are no longer in clinical practice, the more common ones will be

■ Fig. 13.2 Atriopulmonary anastomosis with interposition of the autologous pulmonary valve according to Kreutzer et al. (1973). AOA ascending aorta, LA left atrium, LV left ventricle, PA pulmonary artery, RA right atrium, RV right ventricle, VCS superior caval vein

described at this point. The surgeons today might encounter the patients with different Fontan modifications during Fontan conversions, or other reoperations. In 1979, Bjork et al. (1979) described a direct connection between the atrium and the right ventricular outflow tract using a pericardial patch, in patients with preserved pulmonary valve (■ Fig. 13.3). The modification by Lins et al. (1981), which described a direct anastomosis of the atrium and the pulmonary artery, was the most commonly performed one in the 1980s (■ Fig. 13.4).

In tricuspid atresia, these Fontan modifications have in common that the complete right atrium is in the subpulmonary position. In the long term, this leads to significant dilatation of the right atrium and displacement of the reconstructed interatrial septum towards the left. This can possibly further lead to an obstruction of the inflow of the left atrio-ventricular valve and dilatation of the right atrium with unfavorable flow characteristics from both vena cava towards the pulmonary artery, with consequent arrhythmias and thromboses. Based on this, some surgeons decided on partition of the right atrium, through which most of the cavum of the right atrium was separated from the intraatrial cavopulmonary part. Unobstructed flow towards the pulmonary artery was modeled by implantation of a patch or by folding of the atrial wall ana-

logue to the Senning operation (Puga et al. 1987; Jonas and Castaneda 1988; DeLeon et al. 1989). Leval et al. (1988) proved that the flow through this 'lateral tunnel' leads to a smaller loss of energy in hemodynamic studies in vitro. Leval also introduced the term 'total cavopulmonary connection' for this Fontan modification (■ Fig. 13.5).

■ Fig. 13.4 Direct anastomosis of the right atrium and the pulmonary artery according to Lins et al. (1981)

■ Fig. 13.3 Direct anastomosis between the right atrium and the right ventricular outflow tract using a pericardial patch, in patients with a normal pulmonary valve, according to Bjork et al. (1979). RVOT right ventricular outflow tract

■ Fig. 13.5 Intracardiac total cavopulmonary connection ('lateral tunnel'). NeoAO neo-aorta

■ Fig. 13.6 Extracardiac cavopulmonary connection. RPA right pulmonary artery

The next logical step was to avoid using the atrial tissue at all for the construction of the cavopulmonary tunnel. Danielson and Norwood achieved this by implantation of a conduit between the inferior vena cava and the pulmonary artery (Jacobs 2003). Based on the report from Marcelletti et al. (1990) who used this conduit outside of the heart, first extracardiac cavopulmonary connection was introduced (■ Fig. 13.6). Using the modifications of the intracardiac and extracardiac cavopulmonary connection, it became possible to complete the Fontan circulation in almost all patients with functional single ventricle.

The Fontan operation is the endpoint for all patients in whom a biventricular repair is unachievable due to intracardiac anatomy. The objective of all Fontan modifications is to passively divert the blood from the vena cavas (in some modifications—from the coronary sinus as well) into to lungs and to use the functional single ventricle as the only pumping chamber for the newly constructed serial systemic pulmonary circulation. This also explains the term ‘definitive palliation.’ Different Fontan modifications, which are still being performed today, have both potential advantages and disadvantages and will therefore be presented in the following paragraphs. The

operation techniques, which are used less frequently, and which have special indications, as well as more controversial treatment strategies, will be discussed in ► Sects. 13.7.4 and 13.7.5.

13.5.5 Staged Therapy for Completing the Fontan Circulation

Most of the patients with functional single ventricle require a palliative operation, which enables the control over the pulmonary blood flow within the first days of life. This often resulted in a stable situation over the next couple of years and enabled patients to maintain good ventricular function and low pulmonary resistance until the Fontan operation. Nevertheless, the postoperative course after Fontan operation was commonly complicated through high central venous pressure, pleural effusions, ascites, and a low-output syndrome. It was noticed that the conversion of the ‘mixed’ circulation in a Fontan circulation results in an immediate volume unloading of the ventricle. However, due to a slower regression of the ventricle mass, there is a systolic and a diastolic dysfunction of the single ventricle. Accordingly, Kirklin et al. (1986) identified an older age at the time of Fontan circulation and ventricular hypertrophy as risk factors for mortality. Francois et al. (2005) showed that younger age at Fontan operation has beneficial influence on major complications and outcome. Schreiber et al. (2007) showed that completion of the Fontan circulation is feasible with very low mortality at an age of 16–48 months.

This led to a hypothesis that dividing the Fontan operation in two operations would lead to earlier volume unloading and possibly reduce the hypertrophy of the ventricle. Norwood et al. (Norwood and Jacobs 1993) introduced a ‘hemi-Fontan’ operation in 1989, as a middle stage on a way of completing the Fontan circulation. (Norwood and Jacobs 1993). Physiologically, this operation was similar to the bidirectional Glenn. The difference is that this operation is a part of the treatment strategy towards completing the Fontan circulation. A connection between the superior vena cava and the right pulmonary artery is established, just like in the bidirectional Glenn anastomosis. The continuity between the superior vena cava and the right atrium is however left in place and closed with a patch. At

the time of Fontan operation, this patch is removed to complete the intraatrial total cavopulmonary connection. The introduction of this additional operation as the second stage in Fontan completion has significantly improved the probability of survival of the patients with functional single ventricle (Attanavanich et al. 2007).

Other associated heart defects as pulmonary artery stenosis, subaortic stenosis, and insufficiency of an atrioventricular valve may be addressed at the time of hemi-Fontan operation. The main pulmonary artery is divided from the heart at the level of the valve. This step simplifies the Fontan operation, during which the patch between the superior vena cava and the right atrium is removed in order to establish the continuity between the superior and the inferior vena cava, in terms of formation of the lateral tunnel. Some surgeons prefer the bidirectional Glenn anastomosis over the hemi-Fontan operation and tend to complete the Fontan circulation through an implantation of an extracardial conduit between the inferior vena cava and the right pulmonary artery.

13.6 Indications for Definitive Palliation and Fontan Circulation

Definitive palliation and construction of Fontan circulation has to be considered in all patients with a functional single ventricle, which possesses a sufficient size and function, in order to provide a serial connection of the pulmonary and systemic circulation. This is usually the case in patients with an absent atrioventricular connection, double inlet in the dominant ventricle or an unbalanced atrioventricular septal defect.

The Fontan operation also has to be performed in some cases where a normally functioning but morphologically underdeveloped ventricle is connected to the pulmonary circulation. This is the case in extreme forms of Ebstein anomaly and in the presence of pulmonary atresia with intact ventricular septum (Alboliras et al. 1987). Finally, there are heart defects, in which two normally developed chambers are present, but a biventricular repair is very difficult due to complex ventricle position, abnormal position of the great vessels or multiple ventricular septal defects. In some of these complex cases, the Fontan circulation might provide better early results as the biventricular correction (Russo et al. 1988; Hraska et al. 2005).

13.7 Surgical Techniques

13.7.1 Stage I Palliation: Controlling the Pulmonary Blood Flow

The purpose of neonatal palliation of patients with all forms of functional single ventricle is balancing the systemic and pulmonary blood flow. In addition, an unrestrictive blood flow from the systemic and pulmonary veins has to be secured at the atrial level. All stenoses of the systemic outflow tract of the functional single ventricle as well as central pulmonary artery stenoses have to be addressed and corrected, also.

13.7.1.1 Systemic-to-Pulmonary Artery Shunt

Reduced pulmonary blood flow is typically found in the presence of tricuspid atresia with ventriculoarterial concordance. The cause for this may be pulmonary stenosis, infundibulum stenosis or a restrictive bulboventricular foramen. In some cases, a ductus-dependent pulmonary circulation is present. In all these patients, lung perfusion has to be secured through creation of a shunt between the aorta and one of its branches to the pulmonary artery. Another large group of patients with functional single ventricle who need a shunt are the patients with an obstruction in the outflow tract towards the systemic circulation and the aortic arch. In order to correct these stenoses, the main pulmonary artery is used to bypass the obstruction (Stansel anastomosis (Damus 1975; Kaye 1975; Stansel 1975)) as in modified Norwood operation. As a result, there is no continuity between the functional single ventricle and the pulmonary artery, which prompts for a shunt implantation.

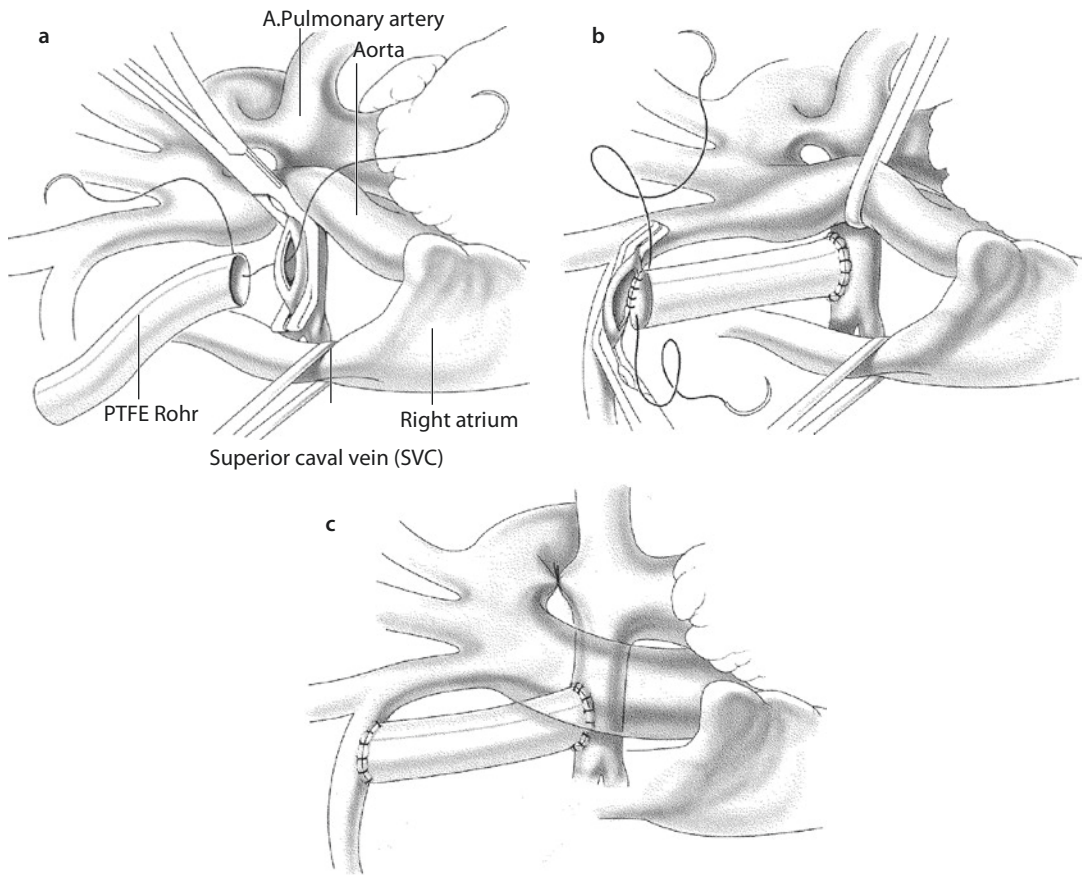

Sternotomy is the preferred approach, since it enables the surgeon to have a better exposition of all relevant structures, and it secures a quick connection to the heart-lung machine in case of hemodynamic instability. The shunt can be placed more centrally than through a thoracotomy, which can reduce the incidence of upper lobe artery stenosis, while a possible main pulmonary artery stenosis can easily be reconstructed using a patch. The duct can be safely divided, and an atrioseptectomy can easily be performed if indicated. The only disadvantage of this approach is the formation of adhesions in the area of ventricle and atria, the extent of which can be reduced by limiting the pericardial incision to the part above the great arteries.

A further advantage of avoiding lateral thoracotomy in staged palliation of single ventricle circulations is the impression that later development of rather significant aortopulmonary collateral perfusion of the lungs is clearly pronounced on the side of previous thoracotomies.

■ ■ Modified Blalock-Taussig shunt

In the next step, at least the right side of the thymus is subtotally resected. We prefer subtotal thymus resection at the first surgery as this facilitates

the following operations. The brachiocephalic trunk is mobilized up to the bifurcation of the right carotid and subclavian artery. Heparin is given at a dose of 3 mg/kg and a vascular clamp is placed on the brachiocephalic trunk proximal to the carotid artery, so that the vessel is excluded. A longitudinal incision is made in the vessel (■ Fig. 13.7). Care has to be taken not to incise the back wall of the vessel, also. An elastic polytetrafluorethylene tube with a diameter of 3.5 or 4 mm is usually used for newborns and infants. The

■ Fig. 13.7 a–c Construction of a right-sided modified Blalock-Taussig shunt through a median sternotomy, without cardiopulmonary bypass. The thymus is subtotally resected, and the truncus brachiocephalicus mobilized up to the bifurcation of the right carotid and subclavian artery. Either the proximal or the distal anastomosis can be performed as a first step. In the described case, the anastomosis with the pulmonary artery is completed first. The right pulmonary artery is partially occluded with a vascular clamp and longitudinally incised. The anastomosis with polytetrafluorethylene tube is performed using a non-resorbable monofilament suture 6/0 or 7/0. The posterior circumference of the anastomosis is performed at the beginning a. After completion of the anastomosis, the vascular clamp is removed from the right pulmonary artery, and the shunt occluded. In this way, the distal anastomosis is free from rotating forces and the correct length of the shunt can be easily determined. The length of the shunt is of utmost importance, since a shunt which is too long as well as a shunt which is too short can lead to torsion and stenosis of the pulmonary artery. After trimming of the shunt to the correct length, a vascular clamp is placed on the truncus brachiocephalicus proximal to the right subclavian artery, and the vessel is longitudinally incised b. The anastomosis with polytetrafluorethylene tube is performed using a non-resorbable monofilament suture 6/0 or 7/0. Special attention has to be paid to the angle between the artery and the shunt. After completion of the anastomosis, the vascular clamp is removed. At the end, the ductus arteriosus is encircled with a non-resorbable suture 5/0 and ligated c

anastomosis is performed using a non-resorbable monofilament suture 6/0 or 7/0. Special attention has to be paid to the angle between the artery and the shunt. After completion of the anastomosis, the vascular clamp is removed, and the shunt occluded. In this way, the proximal anastomosis is free from pulling and rotating forces and the correct length of the shunt can be easily determined. The length of the shunt is of utmost importance, since a shunt which is too long as well as a shunt which is too short can lead to a torsion, kinking and stenosis of the shunt itself or of the pulmonary artery. After trimming of the shunt to the correct length, the right pulmonary artery is occluded with a vascular clamp and longitudinally incised. The anastomosis is done with continuous 6/0 or 7/0 non-resorbable monofilament suture. The vascular clamp is then removed. Basically, either the proximal or the distal anastomosis can be made first. We prefer to perform the proximal anastomosis first, since the access to the innominate artery is more difficult compared to the access to the pulmonary artery.

Before opening the shunt, the ductus arteriosus is encircled with vessel loop and temporarily occluded. The hemodynamic situation is monitored after opening of the shunt. The saturation should be between 75 and 85%. If the saturation is lower than 75%, the shunt might be too small or one or both of the anastomoses may be stenotic. Oxygen saturations higher than 85% and a diastolic blood pressure lower than 30 mmHg can point to an oversized shunt. In all these cases, shunt revision should be considered. In the presence of stable hemodynamics, the ductus now should be permanently occluded to avoid competitive flow if it would reopen.

■ ■ Central aortopulmonary shunt

There are many possible positions for an aortopulmonary shunt, both on the aortic and the pulmonary side. The decision of the exact place for shunt implantation depends on the individual anatomy. In patients with small pulmonary arteries, it might be an advantage to place the shunt on the main pulmonary artery (■ Fig. 13.8). The proximal anastomosis is then usually placed in the ascending aorta. In some cases, the central pulmonary artery has to be augmented, and the shunt can be placed in an incision in the patch. In these cases, the distal anastomosis should be performed first. Central aortopulmonary shunts are usually shorter

than the modified Blalock-Taussig shunts. Furthermore, the proximal diameter of the brachiocephalic trunk in modified Blalock-Taussig shunt adds to flow restriction or even is a major cause for flow reduction. Therefore, the diameter of the tube in aortopulmonary shunts should be proportionally smaller. The smallest polytetrafluoroethylene tube has a diameter of 3 mm. If this tube is too large for the patient, a surgeon can try to place a longer shunt with proximal anastomosis in the aortic arch. Flow reduction through partially shunt clipping (at least when smaller tubes are used) leads to premature cyanosis requiring treatment. Interventional balloon dilatation may be used to widen a partially clipped shunt to the normal size. The potential risk of shunt tearing at the site of clip application when balloon dilated should be taken into account by the interventionalist.

13.7.1.2 Pulmonary Artery Banding

Increased pulmonary blood flow is typically found in the presence of tricuspid atresia with discordant ventriculoarterial connection. Since the aorta rises from a hypoplastic ventricle, it is usually underdeveloped. Many patients also have an aortic isthmus stenosis with isthmus hypoplasia and a hypoplastic aortic arch. In these cases, pulmonary artery banding is often done concomitantly with the resection of the aortic isthmus stenosis (Rodefeld et al. 2005). In cases where the aortic valve and the ascending aorta are hypoplastic, a modified Norwood operation with placement of a systemic-to-pulmonary shunt is performed.

A sternotomy is the preferred approach for the same reasons described in the previous paragraphs. After resection of the left part or all of the thymus, the pericardium is opened above the great arteries. A midpoint between the sinotubular junction of the pulmonary artery and the right pulmonary artery is noted. The tissue between aorta and the main pulmonary artery is dissected in this limited area, and the two arteries are separated from each other (■ Fig. 13.9). The band should not be too narrow to avoid erosions of the pulmonary artery, and the material should induce as few adhesions as possible. A 5–8 mm cut open segment of a PTFE tube or a band cut out of Dacron net-reinforced silastic sheeting provide ideal banding material.

After placing of the band around the pulmonary artery, the two free ends of the tape are fixed. The gradient over the banding is slowly adjusted,

Fig. 13.8 a–d Construction of a central aortopulmonary shunt through a median sternotomy, with cardiopulmonary bypass. The thymus is subtotally resected, and the ascending aorta, pulmonary trunk and both pulmonary arteries mobilized a. After cannulation of the ascending aorta (on the opposite side of truncus brachiocephalicus) and the right atrium, the pulmonary arteries are occluded. The pulmonary trunk is longitudinally incised at the bifurcation. The shunt can be first connected with a polytetrafluorethylene or homograft patch on which a central round excision was performed. This patch is then used for widening the pulmonary trunk b. The anastomosis is performed using a non-resorbable monofilament suture 7/0. After trimming of the shunt to the correct length, an appropriate place on the ascending aorta is identified. The aorta is partially occluded and incised c. The anastomosis of the shunt with aorta is performed using a non-resorbable monofilament suture 7/0. The shunt is correctly positioned when it is not kinking and when the pulmonary artery is not pushed dorsally or pulled anteriorly d

under strict control of the pressure in pulmonary artery distal from the banding and the systemic pressure. The banding tape is constricted in a step-wise fashion, using metal clips or stitches in order to increase the gradient over the banding. The arterial saturation is monitored during this procedure. A gradient of 30–60 mmHg and arterial saturation of 75–85% are acceptable, as long as the systemic arterial pressure corresponds to the normal pressure in a spontaneously breathing newborn. When the banding is in the definitive position, the tape is fixed to the proximal part of the pulmonary artery

in order to avoid dislocation and possible stenosis of the pulmonary bifurcation. Alternatively, the ‘Trusler formula’ can be used: the length of the band is calculated for each patient. It should be $2 \text{ cm} + 1 \text{ mm/kg}$ of body weight in patients with normally positioned great vessels, and $2,2 \text{ cm} + 1 \text{ mm/kg}$ of body weight in patients with transposition of the great arteries. The calculated length of the band may require adjustments according to the arterial saturation, as described before. Pulmonary artery pressure is usually not measured when employing this formula.

■ **Fig. 13.9** a–c Pulmonary artery banding. After resection of the left part of the thymus, the pericardium is opened above the great arteries. A midpoint between the sinotubular junction of the pulmonary artery and the right pulmonary artery is noted. The tissue between aorta and the main pulmonary artery is dissected in this limited area, and the two arteries are separated from each other **a**. Further resection should be avoided in order to prevent the dislocation of the banding tape. After placing of the banding tape around the pulmonary artery, the two free ends of the tape are fixed **b**. The gradient over the banding is slowly adjusted, under strict control of the pressure in pulmonary artery distal from the banding and the systemic pressure. The banding tape is constricted in a stepwise fashion using metal clips or sutures, in order to increase the gradient over the banding. The arterial saturation is monitored during this procedure. A gradient of 30–60 mmHg and arterial saturation of 75–85% are acceptable, as long as the systemic arterial pressure corresponds to the normal pressure in a spontaneously breathing newborn. When the banding is in the definitive position, the tape is fixed to the proximal part of the pulmonary artery in order to avoid dislocation and possible stenosis of the pulmonary bifurcation **c**

13.7.2 Stage II Palliation: Improving the Efficiency of Shunt-Dependent Circulation

The second stage of the three-stage palliation strategy should be performed as soon as possible in order to reduce the volume overload of the functional single ventricle and therefore improve the efficiency of the shunt-dependent circulation. All additional heart pathology should be addressed concomitantly. In newborns, in whom the pulmonary and systemic circulations are balanced within the first 3–6 months of life without a need for systemic-to-pulmonary shunt or banding of the pulmonary artery, stage II palliation is performed as the primary operation.

Volume unloading for the systemic ventricle is achieved by partial separation of the pulmonary and systemic circulation. Desaturated blood from the superior vena cava is directly led into the pulmonary artery. The flow of the blood through a systemic-to-pulmonary shunt may be reduced or even removed. As a result, workload of the functional single ventricle is reduced (Allgood et al. 1994; Jacobs et al. 1996 **b**) providing myocardial protection in the long term (Schwartz et al. 1996; Mahle et al. 1999). This is of utmost importance since poor ventricular function

leads to higher mortality and morbidity (Fontan et al. 1990; Parikh et al. 1991). In preoperatively severely cyanotic patients, stage II results in both volume unloading and increased saturation.

Considering the hemodynamic advantages of the upper cavopulmonary anastomosis over the shunt-dependent circulation, it is beneficial to perform the second-stage palliation as soon as possible. The current consensus is that the cavopulmonary anastomosis is performed at the age of 2–5 months, when the pulmonary resistance reaches a normal level (Chang et al. 1993; Slavik et al. 1995; Bradley et al. 1996). The contraindications are as follows:

- Age of less than 6 weeks
- Lung resistance of more than 4 Wood
- Pulmonary artery pressure of more than 30 mmHg
- Stenoses in pulmonary veins

The second reason for performing this ‘intermediate’-stage operation is a possibility to correct those accompanying defects, which are new or could not have been addressed during stage I. This includes pulmonary artery plasty, resection of subaortic stenosis, correction of a hypoplastic aortic arch, widening of a restrictive interatrial communication and surgery for atrioventricular

valve insufficiency. Addressing all of the above-mentioned problems can preserve good function of the functional single ventricle and make the patient a better candidate for a Fontan operation.

Two surgical techniques are used as stage II palliation, both resulting in partial separation of the pulmonary and systemic circulation through redirecting the desaturated blood from the superior vena cava to the pulmonary artery: bidirectional superior cavopulmonary anastomosis (bidirectional Glenn anastomosis) and the hemi-Fontan operation.

13.7.2.1 Bidirectional Superior Cavopulmonary Anastomosis (Bidirectional Glenn Anastomosis)

Superior cavopulmonary anastomosis may be performed with or without extracorporeal circulation. The precondition for not using cardiopulmonary bypass is the presence of a source of pulmonary blood flow aside from the site of the planned Glenn anastomosis. This chapter will describe the operation using the heart-lung machine (■ Fig. 13.10). Cardiopulmonary bypass is initiated after cannulation of the aorta, the right atrium and the superior vena cava at the junction of the left brachiocephalic vein. All systemic-to-pulmonary shunts have to be controlled at this point. If there is no need for additional pulmonary

flow, the shunt can be divided. In the presence of an antegrade flow through the pulmonary valve, one may decide to divide the pulmonary artery after securing the vessel with two vascular clamps and placing hemostatic sutures. If there is a need for additional pulmonary blood flow, the shunts may be temporarily occluded. In these cases, the pulmonary artery banding is left in place. In case of division of the main pulmonary artery, it is recommended to close the proximal pulmonary stump at the levels of the pulmonary valve, avoiding a blind pouch which could become source of systemic thromboemboli.

The azygos vein is divided in order to prevent blood flow from the superior to the inferior vena cava after the Glenn anastomosis is accomplished. If there is interruption of the inferior vena cava with azygos continuation, the azygos vein must be kept patent. This is often the case in patients with heterotaxy syndrome with left isomerism. The Glenn anastomosis in face of an azygos continuum is referred to as Kawashima operation leading comparatively high oxygen saturations up to 90% and more (Matsuda et al. 1986) (See also ► 13.7.5.2.).

In simple Glenn anastomosis, a vascular clamp is applied immediately above the cavoatrial junction. The position of the sinus node must be noted. The superior vena cava is transected, and the

■ Fig. 13.10 a, b Superior cavopulmonary anastomosis. The right pulmonary artery is clamped near the bifurcation, on the right side of the aorta. Superior vena cava, the right pulmonary artery and the upper lobe artery are snared. The azygos vein is ligated and divided. The superior vena cava is divided from the right atrium, and the cardiac end is oversewn a. The right pulmonary artery is partially excluded, and an incision is made on the superior wall. The anastomosis between the superior vena cava and the pulmonary artery is carried out with a running resorbable monofilament suture 6/0 or 7/0. The anastomosis should extend until the right upper lobe artery b

cardiac end is oversewn. The right pulmonary artery is clamped either proximally or distally or a C-clamp is used. A long incision is made on the superior wall of the RPA. The cavopulmonary anastomosis is then carried out with a running resorbable monofilament suture. Cardiopulmonary bypass is discontinued while carefully observing the pressure in the right atrium, in the superior vena cava, the systemic pressure and the arterial saturation. A transpulmonary gradient of 8 mmHg and a pressure of less than 18 mmHg in the superior vena cava are acceptable. The arterial saturation should be approximately 80%.

13.7.2.2 Hemi-Fontan Operation

The physiology following a hemi-Fontan operation is equivalent to the state after bidirectional superior cavopulmonary anastomosis. There are however basic differences in the operation technique. The hemi-Fontan operation always is an open-heart procedure and must therefore be performed using extracorporeal circulation (■ Fig. 13.11).

Following aortic and bicaval cannulation, and initiation of the cardiopulmonary bypass, the caval veins are snared, the aorta is cross-clamped and cardioplegic solution is infused in the aortic root. The main pulmonary artery is then divided,

■ **Fig. 13.11** a–d Hemi-Fontan operation. The hemi-Fontan operation must be performed using the heart-lung machine and requires cardioplegia and cross-clamping of the aorta. Following aortic and bicaval cannulation, and initiation of the cardiopulmonary bypass, the caval veins are snared, the aorta is cross-clamped and cardioplegic solution is infused in the aortic root. The main pulmonary artery is then divided, and both ends are oversewn. The pulmonary arteries are fully mobilized and controlled with snares. An incision is made in the dome of the right atrium and spirally extended towards the medial wall of superior vena cava. An incision is made in the right pulmonary artery immediately adjacent to the incision line in the right atrium **a**. The dorsal walls of the incision are connected with a running resorbable monofilament suture **b**. The anterior anastomosis is completed by patch augmentation **c**. The junction of the superior vena cava and the right atrium is closed using a patch, through a separate incision in the right atrium to direct the blood from the superior caval vein to the pulmonary artery **d**

and both ends are oversewn, avoiding creation of a proximal blind pouch (see ► 13.7.2.1). The pulmonary arteries are fully mobilized and controlled with snares. An incision is made in the dome of the right atrium and spirally extended towards the medial wall of superior vena cava. An incision is made in the right pulmonary artery immediately adjacent to the incision line in the right atrium. The dorsal walls of the incision are connected with a running resorbable monofilament suture. The anterior anastomosis is completed by patch augmentation in order to achieve a wide connection and an unobstructed blood flow between the superior vena cava and the pulmonary arteries.

The incised junction of the superior vena cava and the right atrium is closed using a patch from inside the right atrium, employing a separate incision in the right atrium. Consequently, the blood flow from the superior vena cava into the pulmonary arteries is separated from the blood flow from the inferior vena cava and the coronary sinus into the ventricle. Cardiopulmonary bypass is discontinued in the same way as during the bidirectional superior cavopulmonary anastomosis.

13.7.3 Stage III Palliation: Completion of Fontan Circulation

In the present time, most of the candidates for the Fontan operation have undergone bidirectional superior cavopulmonary anastomosis or hemi-Fontan operation. The purpose of the Fontan operation in this stage III setting is to complete the separation of pulmonary and systemic circulation by diverting the blood from the inferior vena cava into the pulmonary arteries. Therefore, the term ‘completion Fontan’ is also applied in this situation. Following the operation, only the pulmonary veins and the blood from the coronary sinus drain in the common atrium and therefore in the functional single ventricle. Therefore, separation of the pulmonary and systemic circulation is almost complete through stage III palliation.

The correction of any additional or residual heart defect, such as pulmonary artery stenosis, valve regurgitation or stenosis in systemic outflow tract, should be performed at this time. Two surgical techniques are used for completion of Fontan circulation: connection of the inferior vena cava with the pulmonary arteries using an extracardiac conduit (‘extracardiac

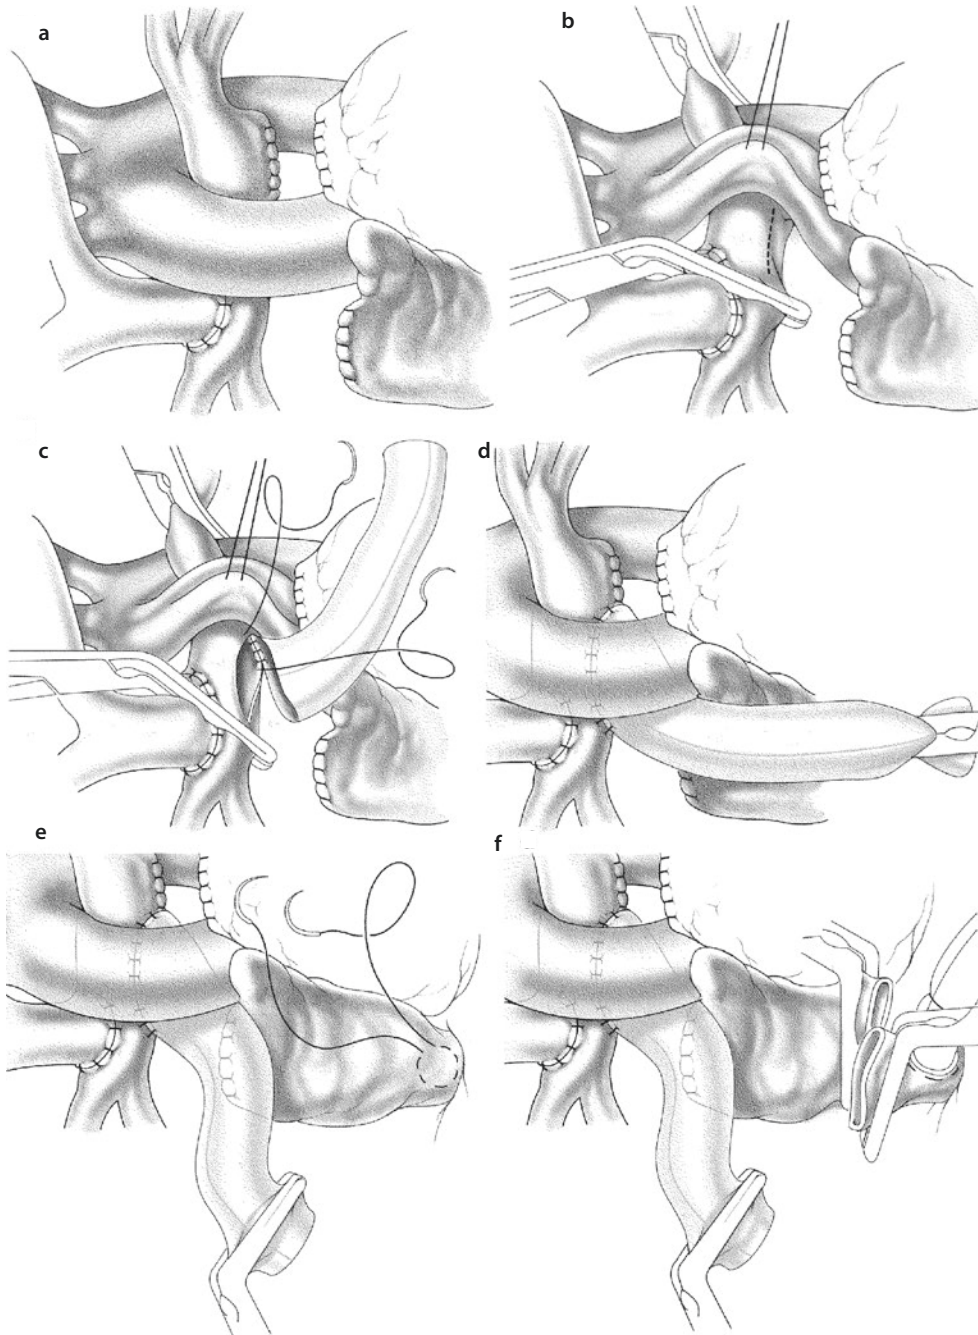

total cavopulmonary connection’) and a creation of an intraatrial lateral tunnel (‘intracardiac total cavopulmonary connection’).

13.7.3.1 Extracardiac Total Cavopulmonary Connection

The surgical technique performed in patients with tricuspid atresia, in whom a bidirectional superior cavopulmonary anastomosis was previously performed, will be described in this paragraph (► Fig. 13.12). The technique described can basically be performed in all patients with functional single ventricle, including patients who were not operated previously. In some cases, as for example atrial isomerism, situs inversus or interruption of the inferior vena cava, the operative technique has to be modified according to the specific anatomy. In patients who were previously not operated, and in patients in whom only stage I palliation was performed, the extracardiac total cavopulmonary anastomosis is preceded by bidirectional superior cavopulmonary anastomosis. After previous hemi-Fontan surgery, completion of the Fontan circulation is preferably accomplished by an intracardiac total cavopulmonary connection.

Following midline sternotomy, cardiopulmonary bypass is initiated after cannulation of the aorta and the superior and the inferior vena cava. Inferior vena cava should be cannulated as distally as possible, immediately superior to the diaphragm. It is advisable to use a right-angled cannula for the venous drainage. The right pulmonary artery is dissected from the right upper lobe branch across the midline posterior to aorta. Superior vena cava and the superior cavopulmonary connection are dissected. The adhesions around the right atrium and the right pulmonary veins have to be thoroughly dissected, in order to achieve correct position of the conduit.

The right pulmonary artery is cross-clamped immediately next to the right upper lobe artery, and the main pulmonary artery is cross-clamped on either side of the ascending aorta. The superior vena cava is then snared and the pulmonary artery is therefore completely isolated from blood flow. Alternatively, in order to avoid the dissection of the posterior wall of the aorta, a suction vent may be placed in the right pulmonary artery towards the left side of the body instead of using a cross-clamp. This might help reduce the risk of severe bleeding complications in patients with previous aortic arch reconstruction.

■ **Fig. 13.12** a–h Extracardiac total cavopulmonary connection. Superior cavopulmonary anastomosis was performed previously **a**. The right pulmonary artery is obliquely clamped on the medial side of the superior cavopulmonary anastomosis, so that blood can still flow from the superior vena cava into the pulmonary artery. The second clamp can be positioned on the left side from the ascending aorta. In this way, the central pulmonary artery is isolated and can be opened on the inferior wall **b**. The anastomosis is carried out with a non-resorbable monofilament suture 5/0 or 6/0 **c**. The conduit is then cross-clamped and the snares and clamps are removed from the pulmonary arteries and the superior vena cava **d**. Inferior vena cava is cannulated as distally as possible, immediately superior to the diaphragm. It is advisable to use a right-angled cannula for the venous drainage **e**. A vascular clamp is then applied immediately above the cavoatrial junction and the inferior vena cava is snared. The inferior vena cava is divided from the right atrium, and the cardiac end is oversewn using non-resorbable monofilament 4/0 suture **f**. After cutting the conduit in the appropriate length, the anastomosis to the inferior vena cava is carried out with a running non-resorbable monofilament 5/0 suture **g, h**

■ Fig. 13.12 (continued)

An incision is made on the inferior wall of the pulmonary artery which corresponds to the length of an obliquely cut conduit. The conduit should have a diameter of at least 18 mm. A conduit of this size may be implanted in children presenting with a body weight of at least 10 kg. The anastomosis is performed with a running non-resorbable monofilament 5/0 or 6/0 suture. The conduit is then cross-clamped and the snares and clamps are removed from the pulmonary arteries and the superior vena cava. A vascular clamp is then applied immediately above the cavoatrial junction and the inferior vena cava is snared. The inferior vena cava is divided from the right atrium, and the cardiac end is oversewn using non-resorbable monofilament 4/0 suture. After cutting the conduit in the appropriate length, the anastomosis to the inferior vena cava is carried out with a running non-resorbable monofilament 5/0 suture. Alternative techniques, described in ► Sects. 7.4 and 7.5, can be used to perform this operation without cardiopulmonary bypass.

Cardiopulmonary bypass is discontinued while measuring the pressure in the common atrium and the superior and inferior venae cavae and determining cardiac filling pressure, prepulmonary pressure and the transpulmonary gradient. A transpulmonary gradient of less than 8 mmHg and a pressure of 16 mmHg in both vena cava are ideal. Pressures up to 20 mmHg in the cava are acceptable. The blood pressure should be the same in the superior and the inferior vena cava. Placement of a temporary transcatheter line in the common atrium (functional 'left atrial' line) should be considered to monitor ventricular preload and transpulmonary gradient. This can be helpful for both diagnostic and thera-

peutic procedures. It also provides a possibility of volume substitution and catecholamine therapy without primary passage through the lungs.

13.7.3.2 Intracardiac Total Cavopulmonary Connection

Intracardiac total cavopulmonary connection can be planned after stage II bidirectional Glenn or preferably after hemi-Fontan surgery. Following midline sternotomy, cardiopulmonary bypass is initiated after cannulation of the aorta and the superior and the inferior vena cava (■ Fig. 13.13). The aorta is then cross-clamped and cardioplegic solution is infused in the aortic root in moderate systemic hypothermia. Alternatively, the operation is performed in hypothermic circulatory arrest.

All systemic-to-pulmonary shunts are divided and the pulmonary arteries are dissected until the upper lobe arteries. If there is a connection between the ventricle and the pulmonary artery, it should be closed at this point. In these cases, the main pulmonary artery is then divided close to the pulmonary valve, and both ends are oversewn taking the pulmonary valve into the proximal suture line. An incision is made in the anterior wall of the atrium, leaving enough of atrial tissue laterally for the formation of the lateral tunnel.

The superior vena cava is then snared, and a suction vent is placed in the pulmonary artery through the right atrial appendage after the patch, which was placed between the superior vena cava and the atrium during the hemi-Fontan operation is removed. Prior to the creation of the lateral tunnel, the lateral wall of the atrium is freed from any thick trabeculas. In cases where

■ **Fig. 13.13** Intracardiac total cavopulmonary connection. The hemi-Fontan operation was performed previously. Following midline sternotomy, cardiopulmonary bypass is initiated after cannulation of the aorta and the superior and the inferior vena cava. The aorta is then cross-clamped and cardioplegic solution is infused in the aortic root in moderate systemic hypothermia. The pulmonary arteries are dissected until the upper lobe arteries. An incision is made in the anterior wall of the atrium, leaving enough of atrial tissue laterally for the formation of the lateral tunnel **a**. The superior vena cava is then snared, and a suction vent is placed in the pulmonary artery through the right atrial appendage. The patch, which was placed between the superior vena cava and the atrium during hemi-Fontan operation, is removed. Prior to the creation of the lateral tunnel, the lateral wall of the atrium is freed from any thick trabeculas. A polytetrafluorethylene patch is cut into an appropriate shape and implanted. The continuous suture is started between the coronary sinus and the junction of the inferior vena cava and extended medially along the atrial septal defect towards the medial aspect of the junction of the superior vena cava. In the lateral direction, the suture is placed anterior to the junction of the inferior vena cava and extended along the lateral atrial wall, ending superior and anterior to the junction of the superior vena cava **b**

the inflow into the dominant ventricle mainly flows through a right atrioventricular valve, it is important to check for unobstructed pulmonary venous and coronary sinus blood flow. Coronary sinus unroofing may be performed in order to achieve this. A polytetrafluorethylene patch is cut into an appropriate shape and implanted. To cut a patch out of a large PTFE, prosthesis may be advantageous for its preshaped curvature. The continuous suture is started between the coronary sinus and the junction of the inferior vena cava and extended medially along the atrial septal defect towards the medial aspect of the junction of the superior vena cava. In the lateral direction, the suture is placed anterior to the junction of the inferior vena cava and extended along the lateral atrial wall, ending superior and anterior to the junction of the superior vena cava. The atriotomy is then closed using a running suture. When chosen appropriately, the atriotomy could be closed with the anterior patch suture limiting the number of atrial suture lines.

Cardiopulmonary bypass is discontinued in the same way as during the extracardiac total cavopulmonary anastomosis.

13.7.4 Special Surgical Techniques

13.7.4.1 Other Techniques of Systemic-to-Pulmonary Artery Shunt

Nowadays, a direct anastomosis of the ascending aorta and the right pulmonary artery (Waterson shunt) and a direct anastomosis of the descending aorta and the left pulmonary artery (Potts shunt) are obsolete. Both of them are characterized by uncontrollable shunt flow. In addition, closure of Waterson and Potts shunts during the next step operations is more difficult and rather complex compared to closure of a modified Blalock-Taussig or a central shunt. The classic Blalock-Taussig shunt, with end-to-end anastomosis of the subclavian artery and the

ipsilateral pulmonary artery, is rarely performed, in order to preserve upper extremity circulation. However, it may still be an option in special circumstances in very small patients (less than 2 kg).

13.7.4.2 Anastomosis of the Proximal Pulmonary Artery and the Ascending Aorta, with Aortic Arch Reconstruction

The pericardium is opened following midline sternotomy and subtotal thymectomy. The aortic cannula is placed as far distal as possible. In cases of interrupted aortic arch, the arterial duct needs to be cannulated via the pulmonary artery as well. Once the cannula is introduced into the duct, the duct can be snared around it. A single venous cannula is inserted through the right atrial appendage. After institution of cardiopulmonary bypass, the patient's core temperature is reduced to 18 °C. Temperatures should be measured in the rectum or urinary bladder and in esophagus or nasopharynx. During this cooling phase, the ascending aorta, the aortic arch, the supraaortic branches and the descending aorta distal to the isthmus are exposed. The main, right and left pulmonary arteries and the arterial duct are dissected as well. When the arterial cannula is placed in aorta, the arterial duct may be occluded. If it was only possible to cannulate the main pulmonary artery in interrupted arch, the right and the left pulmonary artery should be temporarily occluded at this point. Obviously, in this situation, the duct needs to be open for initial perfusion.

When the desired temperature is reached, the aorta is then cross-clamped, and cardioplegic solution is infused in the aortic root. The circulation is then arrested and the arterial cannula removed. The arterial duct is transected, and the pulmonary part is oversewn. All ductal tissue is resected together with the aortic isthmus completely. Alternatively, all ductal tissue is resected from the aortic isthmus, and the continuity of the aorta is left in place. An incision is made in the inner curvature of the aortic arch towards the ascending aorta and if necessary towards the descending aorta. When the continuity of the distal aorta was interrupted, the distal posterior wall is connected with the descending aorta with a resorbable monofilament 7/0 suture.

The pulmonary artery is divided immediately above the sinotubular junction. Many techniques are used for connecting the main pulmonary

artery to the ascending aorta. Using the following technique might help avoid stenosis or pulmonary valve insufficiency: an incision is made in the wall of the ascending aorta which is adjacent to the main pulmonary artery. An end-to-side anastomosis is then made between the main pulmonary artery and the incised part of the ascending aorta with a resorbable monofilament 7/0 suture. The rest of the defect is closed with a patch with a non-resorbable monofilament 7/0 suture.

In the presence of a restrictive interatrial communication, an atrioseptectomy should be performed through an incision in the right atrium. As soon as the atriotomy is closed, the cardiopulmonary bypass may be restarted, and the patient may slowly be rewarmed.

Finally, the pulmonary circulation must be restored. In most cases, the distal part of the main pulmonary artery has to be closed with a patch in order to avoid stenosis. The distal anastomosis of the modified Blalock-Taussig or central shunt may be positioned in the middle of this patch. In the literature, these techniques of dealing with a subaortic stenosis are connected to Damus, Kaye, Stansel and Lamberti (Damus 1975; Kaye 1975; Stansel 1975; Lamberti et al. 1991).

13.7.4.3 Modified Norwood Operation

The anastomosis of the proximal pulmonary artery and the ascending aorta, with aortic arch reconstruction procedure (► Sect. 13.7.4.2), follows the same principles as the Norwood operation for hypoplastic left heart syndrome. It can therefore be referred to as a modified Norwood operation. However, the position and the size of the great arteries may differ significantly from the typical patient presenting with hypoplastic left heart syndrome. The modified Norwood operation is performed in cases of tricuspid atresia with ventriculoarterial discordance or double-inlet left ventricle with ventricular L-loop and ventriculoarterial discordance. The variable morphology must be considered when constructing the neo-aortic arch. The dimension and orientation of the patch, used for reconstruction of the aortic arch, must be adjusted according to the specific anatomy and position of the great arteries.

13.7.4.4 Resection of Subaortic Stenosis

The technique to resect a subaortic stenosis (SAS) in patients with univentricular circulation is similar for very different anatomic settings, as the point of obstruction always is the interventricular

connection rather than a typical SAS in otherwise normal biventricular hearts. This is true for tricuspid atresia, ventriculoarterial discordance and a restrictive bulboventricular foramen. The same technique can be applied in cases of functional univentricular heart with univentricular atrioventricular connection, in which the aorta rises from the hypoplastic chamber, in cases of double-inlet left ventricle with ventriculoarterial discordance and in cases of mitral atresia with concordant atrioventricular connection.

The chest is entered through midline sternotomy, taking care of the aorta which lies directly behind the sternum due to its anterior placement. The cardiopulmonary bypass is initiated after aortic and bicaval cannulation. The aorta is then cross-clamped, and cardioplegic solution is infused in the aortic root. The bulboventricular foramen is exposed through an incision in the outflow chamber (Cheung et al. 1990). Alternatively, a transatrial or transaortic approach may be considered, keeping in mind that the small size of the aortic valve can compromise a good exposure (Newfeld and Nikaidoh 1987; Smolinsky et al. 1988). The conduction system is on the posterior-inferior ridge of the defect. This is also true for the double-inlet left ventricle with ventriculoarterial discordance. Therefore, the defect can be enlarged through an incision in the anterior superior ridge. Subvalvular muscle bundles should be resected, taking care of the aortic valve. The incision in the hypoplastic chamber is then closed with a patch.

13.7.4.5 Bidirectional Superior Cavopulmonary Anastomosis Without Cardiopulmonary Bypass

Bidirectional superior cavopulmonary connection can be performed without cardiopulmonary bypass in the presence of additional pulmonary artery blood source. When only one superior vena cava is present, the venous drainage of the upper body through a cannula is essential when the venous cross-clamp time is longer than 20 min. In the presence of bilateral superior vena cava, the venous drainage is usually not necessary. In these cases, the anastomosis is first done on the opposite side of the systemic-to-pulmonary artery shunt. During this time, the lung perfusion is ensured over the shunt. Following the first anastomosis, which provides a new path of lung perfusion, the shunt may be resected, and the second

anastomosis is performed (Lamberti et al. 1990). A unilateral left cavopulmonary anastomosis in the cases of situs solitus frequently requires cardiopulmonary bypass since manipulation of the heart for exposure leads to circulatory instability.

13.7.4.6 Fenestration of Total Cavopulmonary Connection

The surgical technique is different in cases of prior intracardiac versus prior extracardiac total cavopulmonary connections. Fenestration may be indicated in cases of high central venous pressure and low filling pressure of the heart following total cavopulmonary connection. In these cases, the fenestration can usually be performed without cardiopulmonary bypass. One clamp is placed on the atrium and another on the adjacent part of the extracardiac conduit. A defect is made in the conduit, a larger part of the atrium is excised and the two defects are connected. In order to prevent stenosis, the suture line must be placed at the ridge of the defect in the atrium, and with a distance away from the ridge of the defect in the conduit, similar to the principle of 'sutureless' pulmonary vein repair.

The simplest technique to fenestrate a lateral tunnel is to perforate the intraatrial patch. The size of the fenestration should be 4 mm in patients weighting less than 12 kg, 5 mm in the patients between 12 and 30 kg and 6 mm in patients over 30 kg (Kopf et al. 1992). Alternative techniques include performing a fenestration in a way that the opening can be controlled and later transcatheterously closed (Laks et al. 1991).

13.7.4.7 Extracardiac Total Cavopulmonary Anastomosis Without Cardiopulmonary Bypass, in the Presence of Superior Cavopulmonary Anastomosis

It is not necessary to cannulate the superior vena cava when the extracardiac total cavopulmonary anastomosis is performed without cardiopulmonary bypass. The right pulmonary artery is obliquely cross-clamped medially from the superior vena cava, so that the blood flow from the superior vena cava in the right pulmonary artery remains unobstructed. The left pulmonary artery can be cross-clamped on the left side of the ascending aorta. The main pulmonary artery is completely isolated, and its inferior wall can be incised for the anastomosis with the extracardiac conduit.

Prior to completing the anastomosis between the conduit and the inferior vena cava, the venous blood from the lower body must be drained. The inferior vena cava is cannulated immediately above the diaphragm, the second cannula is placed in the right atrium and the two cannulas are connected making sure no air is trapped in the system (Uemura et al. 1998). In the presence of collateral flow between the superior and the inferior vena cava through the azygos vein, the anastomosis can be performed with cross-clamping of the inferior vena cava, without connecting it to the atrium (Shiraishi et al. 2005; Shinkawa et al. 2011). It is important to avoid even temporary obstruction of the liver veins.

13.7.5 Controversial Treatment Strategies

13.7.5.1 Fontan Operation Versus Septation Operation

In some cases where the underlying anatomy may make the biventricular correction feasible, it might however be advisable to choose the univentricular palliation. This is the case when an extremely complex operation is necessary to achieve biventricular correction and when it is not certain if the hypoplastic ventricle will be able to support the systemic circulation. In the following circumstances, the univentricular palliation might be preferred over the biventricular correction:

- Unbalanced atrioventricular septal defect
- Moderate hypoplasia of the right ventricle
- Moderate hypoplasia of the left ventricle
- Double-outlet right ventricle combined with non-committed ventricular septal defect
- Tricuspid atresia with ventricular septal defect and moderate hypoplasia of the right ventricle
- Pulmonary atresia with ventricular septal defect, accompanied by moderate hypoplasia of the right ventricle with a moderately reduced function
- Ebstein anomaly with moderate hypoplasia and moderately reduced function of the right ventricle
- Significant straddling of one of the atrioventricular valves in the presence of ventriculoarterial concordance or discordance, ventricular septal defect and pulmonary stenosis

‘*One and a half ventricle correction*’ is a third alternative to Fontan operation, and biventricular operation in patients with hypoplastic right ventricle, whose volume is less than 30% of the normal (Muster et al. 1993; Hanley 1999). There are however no clear criteria to decide between the different strategies on an individual patient basis (DeLeon et al. 1989). Some reports present good results of the biventricular repair (Ebert 1984); others report better results following univentricular palliation (Delius et al. 1996; Hraska et al. 2005). Long-term results are still pending in both patient collectives, which, however, are always difficult to exactly compare.

13.7.5.2 Pro and Contra: Additional Pulmonary Blood Source Following Bidirectional Superior Cavopulmonary Connection

Additional pulmonary blood flow besides the superior cavopulmonary anastomosis, either in the form of a pre-existing shunt or an open pulmonary valve, has both advantages and disadvantages. One advantage is improvement of the systemic oxygen saturation (Webber et al. 1995). In addition, it may promote growth of the pulmonary arteries. This is very important because growth of the pulmonary arteries is not proportional to somatic growth in patients with functional single ventricle (Mendelsohn et al. 1994; Slavik et al. 1995; Tatum et al. 2006). However, even additional pulmonary blood flow following partial cavopulmonary connection does not lead to normal development of the pulmonary arteries (Berdat et al. 2004; Yoshida et al. 2005).

Another advantage is that the lungs will be supplied with blood containing angiotensin inhibitor of the liver (Clement et al. 1999). The formation of arteriovenous fistulas can be promoted in patients without an additional pulmonary blood flow due to absence of endostatin and angiostatin in the pulmonary vessels. The right-to-left shunt through the fistulas leads to a decrease in the systemic saturation. Arteriovenous fistulas are found in the ipsilateral lung of patients with unilateral Glenn anastomosis (McFaul et al. 1977) and in both lungs of patients with bidirectional partial cavopulmonary anastomosis (Srivastava et al. 1995). Even in patients with azygos continuity, the arteriovenous fistulas can be found following the bidirectional cavopulmonary

connection—Kawashima operation (Matsuda et al. 1986). The formation of these fistulas may be, however, reversible after completion of the Fontan circulation (Knight and Mee 1995; Srivastava et al. 1995; Praus et al. 2008).

The disadvantage of the increased lung perfusion in patients with an additional pulmonary blood flow is volume overload of the functional single ventricle. The aim of early staging by partial cavopulmonary connection is normalization of the workload of the functional single ventricle (Allgood et al. 1994; Jacobs et al. 1996a, b) and protection of the cardiac muscle in the long term (Schwartz et al. 1996). In addition, higher pressure in the pulmonary artery can lead to an increase in vascular resistance in the lungs. The increased pulmonary resistance was recognized as a risk factor for mortality after the Fontan operation (Boruchow et al. 1970; Fontan et al. 1989; Bartmus et al. 1990; Driscoll et al. 1992; Knott-Craig et al. 1995). A comparative study of patients with and without an additional pulmonary blood flow showed better results for patients without an additional pulmonary blood flow (Mainwaring et al. 1995).

The bidirectional partial cavopulmonary anastomosis with an additional pulmonary blood source provides very poor results as a definitive palliation without Fontan completion (Gerelli et al. 2012). These patients have a survival rate of 75% in the first 5 years after the operation. A late Fontan operation due to cyanosis or functional deterioration in these patients yields a perioperative mortality of more than 50% (Yamada et al. 2000). In most of these patients, elevated pulmonary artery pressure is the reason for delayed completion of the Fontan circulation and the related poor results. Gerelli et al. (2012) confirm that bidirectional partial cavopulmonary anastomosis with an additional pulmonary blood source fails as a strategy for definitive palliation. However, the authors observed that the additional blood flow may delay the long-term deleterious consequences of Fontan circulation and that it does not preclude a successful Fontan completion.

13.7.5.3 Pro and Contra: Bidirectional Superior Cavopulmonary Connection Without Cardiopulmonary Bypass

The decision to perform a bidirectional superior cavopulmonary connection with or without cardiopulmonary bypass is based on the anatomy of

the patient and the preference of the surgeon. The anastomosis can usually be performed without cardiopulmonary bypass with or without placement of a shunt between the superior vena cava and the right atrium (Murthy et al. 1999). Cardiopulmonary bypass is necessary when the pulmonary circulation is exclusively shunt dependent and the shunt has to be removed for the superior cavopulmonary anastomosis. This is usually the case with a right superior vena cava and a right-sided modified Blalock-Taussig shunt.

Off pump surgery avoids the disadvantage of hemodilution. This might lead to lower early mortality (Hussain et al. 2007). When the superior cavopulmonary connection is performed using cardiopulmonary bypass, it is recommended to perform modified ultrafiltration after discontinuing cardiopulmonary bypass. This procedure will possibly reduce the creation of edema and pulmonary effusions.

13.7.5.4 Bidirectional Superior Cavopulmonary Connection Versus Hemi-Fontan Operation

The choice between a bidirectional superior cavopulmonary connection and a hemi-Fontan operation depends on the technique of Fontan completion. If the surgeon prefers to perform an extracardiac total cavopulmonary connection, the bidirectional superior cavopulmonary connection should be performed as the second-stage operation. If the surgeon prefers to perform an intracardiac lateral tunnel, both the hemi-Fontan operation and the bidirectional superior cavopulmonary connection are an adequate second-stage procedure.

The largest disadvantage of hemi-Fontan operation is the fact that it is an intracardiac operation, which usually requires cardioplegia and cross-clamping of the aorta. Unlike the bidirectional superior cavopulmonary anastomosis, the hemi-Fontan operation always requires cardiopulmonary bypass.

13.7.5.5 Pro and Contra: Fenestration of the Total Cavopulmonary Connection

Performing an incomplete separation of the pulmonary and the systemic circulation by creation of a communication between the Fontan tunnel

and the systemic atrium can have advantages in certain situations. In the late 1980s, this concept was used in the treatment of high-risk patients during conversion of a shunt-dependent circulation into a Fontan circulation. In the following years, many publications suggested performing fenestration in all patients undergoing Fontan operation (Cochrane et al. 1997; Gentles et al. 1997b; Bando et al. 2000; Gaynor et al. 2002; Kumar et al. 2003; Gupta et al. 2004). However, this topic is still part of controversial discussions. Fontan operation without routine Fenestration can also be performed with low mortality and morbidity (Thompson et al. 1999; Schreiber et al. 2007; Salazar et al. 2011).

Fenestration of the total cavopulmonary anastomosis should be considered in patients with increased pulmonary resistance of 2–4 Wood units. The resulting right-to-left shunt in these circumstances provides the necessary preload of the systemic ventricle and therefore prevents a postoperative low-output syndrome. In addition, it prevents increased blood pressure in the caval veins and the pulmonary arteries. All this may result in fewer pulmonary effusions and a shorter hospital stay. However, it also leads to a reduced systemic oxygen saturation. Publications have shown no significant differences in the early or late mortality. However, in the long term, fenestration leads to a higher cardiac output and lower rate of arrhythmias (Ono et al. 2006). Atz et al. observed spontaneous closure of surgical fenestrations in 40% of the patients at 8 ± 3 years after the Fontan operation (Atz et al. 2011). There is evidence that subjects with a current fenestration are taking more medications (Atz et al. 2011) and have lower resting oxygen saturation (Atz et al. 2011; Imielski et al. 2013). Patients with fenestration require platelet aggregation inhibitors or anticoagulants in order to prevent thromboembolic events.

13.7.5.6 Pro and Contra: Intracardiac or Extracardiac Total Cavopulmonary Connection

There are still no long-term data, which show an advantage of either intracardiac or extracardiac total cavopulmonary connection. Both techniques provide a laminar flow in the tunnel, which is superior to an atriopulmonary connection (Alphonso et al. 2005). Theoretically, the flow dynamics are better in

the extracardiac conduit than in the intracardiac tunnel (Lardo et al. 1999).

One of the disadvantages of an intracardiac tunnel is the inevitable cross-clamp time and open-heart surgery. On the other hand, the extracardiac conduit can be placed on cardiopulmonary bypass with beating heart, which prevents the potential deteriorating effect of cardioplegia on the ventricular function (Schreiber et al. 2007). However, a very low mortality rate after performing an intracardiac lateral tunnel in hypothermic circulatory arrest was also reported (Jacobs et al. 2008).

The extracardiac total cavopulmonary connection can be performed without cardiopulmonary bypass (Uemura et al. 1998) avoiding the temporary increase in pulmonary artery resistance through the effects of cardiopulmonary bypass and hypothermia. Performing the operation without cardiopulmonary bypass may result in better postoperative hemodynamics, lower rate of secondary fenestration and lower rate of thrombosis (Petrossian et al. 2006). In addition, almost no atrial manipulation is necessary during implantation of the extracardiac conduit. This may result in lower rate of sinus node dysfunction (Petrossian et al. 2006; Lee et al. 2007), which could not principally be confirmed (Kumar et al. 2003). The extracardiac total cavopulmonary connection can also be performed in malpositioned hearts with apicocaval juxtaposition (Sakurai et al. 2010).

Lack of growth potential is the main disadvantage of the extracardiac conduit. This is however not an argument against using the extracardiac conduit or the reason to delay the completion of the Fontan circulation. An 18 mm conduit may be implanted in children with 10 kg of body weight (Schreiber et al. 2007), without the need for replacement in the future. The growth potential of the conduit may be preserved, by using patient's atrium for the extracardiac completion of the Fontan circulation (Lemler et al. 2006). However, there is no clear answer which of the two techniques of performing the total cavopulmonary connection is superior. Both techniques are characterized by low mortality and complication rates (Meyer et al. 2006; Fiore et al. 2007; Schreiber et al. 2007; Jacobs et al. 2008). Multicenter data suggest that in current use, the lateral atrial tunnel Fontan may be associated with superior early outcomes (Stewart et al. 2012).

13.8 Results

13.8.1 Mortality

13.8.1.1 Stage I Palliation

Early mortality of patients with tricuspid atresia, following a systemic-to-pulmonary shunt operation, is similar to the mortality of patients with tetralogy of Fallot (Kouchoukos et al. 2003a, b). Early mortality of patients following a modified Blalock-Taussig shunt operation for any indication declined during the last 60 years from 16% in the first half of this time period to 9% in the second half (Williams et al. 2007). This significant early mortality rate is accompanied by a high interstage mortality, which ranges between 14 and 26% (Fermanis et al. 1992; Fenton et al. 2003; Li et al. 2007). Shunt thrombosis is the main cause of death in the interstage period (Cholette et al. 2007).

In older publications, the early mortality of patients after pulmonary artery banding ranges between 25 and 35% (LeBlanc et al. 1987; Horowitz et al. 1989). Patients with non-restrictive pulmonary blood flow, who required pulmonary artery banding, often present with stenosis in the systemic outflow tract. The obstruction may be localized at the level of the ventricle or in the aortic arch. Obstruction at both localizations increases mortality (Lee et al. 2003). Patients who required pulmonary artery banding, without aortic arch enlargement, have a lower early mortality (<5%) (Cleveland et al. 1984; Stefanelli et al. 1984).

Early mortality of 35% is reported for patients after connection of the proximal pulmonary artery to ascending aorta and concomitant aortic arch reconstruction (Rychik et al. 1991). With increasing experience with the Norwood procedure in patients with hypoplastic left heart syndrome, a modified Norwood operation can be performed in patients with tricuspid atresia and ventriculoarterial discordance with improved results. Due to heterogeneity of the underlying anatomy, it is hard to estimate the results after resection of subaortic stenosis. Early mortality of 11% was reported for a small collective (Cheung et al. 1990). It is sometimes difficult to assess whether a widening of bulboventricular foramen is sufficient or a modified Norwood operation has to be performed.

13.8.1.2 Stage II Palliation

Early mortality following the bidirectional superior cavopulmonary connection or the hemi-Fontan operation ranges between 0 and 10% (Lamberti et al. 1990; Chang et al. 1993; Reddy et al. 1995; Bradley et al. 1996; Hussain et al. 2007). Associated anomalies and the type of concomitant procedures determine outcome. Risk factors are increased pulmonary artery pressure, dominant right ventricle, total anomalous pulmonary venous return, heterotaxy syndrome, atrioventricular valve insufficiency and very young age (Alejos et al. 1995; Reddy et al. 1995; Scheurer et al. 2007; Nakata et al. 2010). However, the bidirectional superior cavopulmonary connection has also been performed in patients as young as 2 months of age, with early and late mortality equivalent to that seen in older patients (Petrucci et al. 2010). Avoiding cardiopulmonary bypass might have a positive influence on early survival (Hussain et al. 2007). Bidirectional cavopulmonary anastomosis with additional source of pulmonary blood flow, as a definitive palliation without a planned completion of Fontan circulation, has an unfavorable prognosis (Yamada et al. 2000).

13.8.1.3 Stage III Palliation

Hospital mortality decreased from >20% in the first Fontan operations to <5% in the present time (Anecchino et al. 1988; Fontan et al. 1989, 1990; Bartmus et al. 1990; Myers et al. 1990; Stein et al. 1991; Driscoll et al. 1992; Mavroudis et al. 1992; Mayer et al. 1992; Day et al. 1994; Jacobs et al. 1995b; Knott-Craig et al. 1995; Cetta et al. 1996; Laschinger et al. 1996; Cochrane et al. 1997; Iemura et al. 1997; Petrossian et al. 2006; d'Udekem et al. 2007; Hosein et al. 2007; Ocello et al. 2007; Schreiber et al. 2007). In the recent years, early mortality is reported to be fewer than 2% (Meyer et al. 2006; Nakano et al. 2007; Schreiber et al. 2007; Jacobs et al. 2008).

Multivariate analysis of potential risk factors for early failure of Fontan circulation could identify the following factors (Gentles et al. 1997b; Wallace et al. 2011):

- Preoperative pulmonary artery pressure >19 mmHg
- Younger age at the time of the operation
- Weight-for-age z-score less than -2
- Heterotaxy syndrome
- Tricuspid valve as the dominant atrioventricular valve
- Stenosis of the pulmonary arteries

- Fontan modifications with atriopulmonary connection through an atrial appendage
- Total cavopulmonary connection without fenestration.

Increased pulmonary artery pressure and heterotaxy syndrome were confirmed as risk factors by many authors (Kirklin et al. 1986; Fontan et al. 1989; Bartmus et al. 1990; Myers et al. 1990; Driscoll et al. 1992; Pizarro et al. 2006). Since the introduction of staged palliation, younger age and shorter time between stage II and stage III palliation are connected to lower rate of complications and lower early mortality (Kirklin et al. 1986; Francois et al. 2005; Schreiber et al. 2007).

The long-term results show the palliative character of the Fontan circulation. Follow-up of patients, who were operated in 70s and 80s show 70% survival after 5 years, 65% after 10 years and 50% after 15 years (de Brux et al. 1983; Williams et al. 1984; Fontan et al. 1989; Tam et al. 1989; Earing et al. 2005).

Risk factors for late mortality are still not clearly identified. The results of older studies with long follow-up cannot be applied to the current patients. Improvement of the operative technique and the introduction of the staged approach, leading to an early unloading of the ventricle, are expected to yield better long-term results. Survival of patients after an ‘ideal’ Fontan operation was calculated through a mathematical model, eliminating the ‘avoidable’ risk factors (Fontan et al. 1990). The predicted survival was calculated to be 73% after 15 years, with low constant mortality risk afterward. Older age at the time of Fontan operation was the only recognized risk factor for late mortality. However, the modern concept of staged therapy was not followed in this patient collective. Ten-year survival rates of patients, who were treated according to the staged concept and received total cavopulmonary connection, are reported to be over 90% (Driscoll 2007; Lee et al. 2007; Nakano et al. 2007).

13.8.2 Functional Status

Physical endurance improves significantly after the Fontan operation. The cyanosis is usually resolved after the Fontan operation in patients in whom no fenestration was performed (Ovroutski et al. 2003). Although the cardiac index of patients

with Fontan circulation is practically the same as the one in healthy children (Peterson et al. 1984), most studies showed that they have worse hemodynamic parameters (Anecchino et al. 1988; Chin et al. 1993; Harrison et al. 1995). Only few patients are capable of reaching expected values in stress tests—their heart rate rises, but the stroke volume remains the same (Shachar et al. 1982).

NYHA classification status of the patients deteriorates in time. One year after the operation, 90% of the patients are in NYHA I class, while 20 years afterwards only 56% are in NYHA I class (Fontan et al. 1990; Gentles et al. 1997a).

Children with functional single ventricle do not have normal body growth (Ono et al. 2007; Vogt et al. 2007). Early volume unloading by partial cavopulmonary anastomosis has a positive effect on body growth (Ono et al. 2007; Vogt et al. 2007) and the functional status of the patients (Mahle et al. 1999). Patients who have a fenestrated Fontan tunnel have a higher cardiac index than the patients in whom the pulmonary circulation is completely separated from the systemic circulation (Ono et al. 2006).

13.8.3 Neurological Status

Neurological development of the children with functional single ventricle is the same as the development of healthy children (Uzark et al. 1998; Goldberg et al. 2000). Their school performance is also normal (Mitchell et al. 2006). The incidence of apoplexy is 3–9% in long-term follow-up (du Plessis et al. 1995; Barker et al. 2005; Chowdhury et al. 2005). The risk of cerebrovascular incidents is significantly reduced by acetylsalicylic acid therapy. The presence of the ligated pulmonary artery stump may place patients at risk for embolic stroke. The surgical approaches should avoid leaving any pulmonary pouch when ligating or disconnecting the pulmonary artery (Koide et al. 1999; Oski et al. 1996).

13.8.4 Right-Sided Thromboembolic Complications

Thrombosis can occur in the right atrium, Fontan tunnel, extracardiac prosthesis, in the venae cavae or in the pulmonary arteries. Half of the cases of thrombosis occur immediately after the operation, while the other half occurs in the long-term follow-up

(Dobell et al. 1986; Putnam et al. 1988). Embolization of the thrombotic material can lead to serious complications and might result in death of the patient (Cromme-Dijkhuis et al. 1990). The formation of thrombi is multifactorial. The aggravating factors are (Jacobs and Pourmoghadam 2007):

- Stasis in venous circulation
- Synthetic material
- Atrial arrhythmias
- Prothrombotic state

Prophylactic therapy with vitamin K antagonists or antiplatelet aggregation therapy can reduce the incidence of thromboembolic events. Special care should be taken to treat the atrial arrhythmias and a potential prothrombotic status. Optimal flow dynamics in the venous pathway should be achieved (Kaulitz et al. 2005).

13.8.5 Rhythm Disturbances

Tachycardic as well as bradycardic arrhythmias may occur in patients presenting with functional single ventricle after Fontan-type palliation. The following factors are potential causes for development of rhythm disturbances:

- Iatrogenic injury of the sinus node or its blood supply
- Long incisions and suture lines in atrium
- Effect of high pressure on the atrial tissue
- Congenital anomalies of the conductive system
- Consequence of a valve insufficiency

The incidence of arrhythmia in the long term is reported to be more than 50% (Deal et al. 2007). The following parameters were identified as risk factors for (Durongpisitkul et al. 1998; Alphonso et al. 2005; Chowdhury et al. 2005; Ono et al. 2006):

- Heterotaxy syndrome
- Poor ventricular function
- Anomalies of the pulmonary veins
- Glenn anastomosis
- Insufficiency of an atrioventricular valve
- Preoperative atrial fibrillation
- Atriopulmonary Fontan modification
- Older age at the time of Fontan operation

The influence of the type of total cavopulmonary connection (intracardiac vs. extracardiac) on the dysfunction of the sinus node is discussed controversial (Kumar et al. 2003;

Petrosian et al. 2006; Lee et al. 2007). Surgical treatment of rhythm disturbances include MAZE operation and its variations and a conversion of an atriopulmonary Fontan modification into either intra- or extracardiac cavopulmonary connection (Deal et al. 2007).

13.8.6 Protein-Losing Enteropathy

Protein-losing enteropathy is characterized by low serum albumin concentration, it results in pleural effusions and ascites. The underlying causes are not completely understood. High diastolic atrial pressure in the systemic atrium, pathological resistance in the mesenterial vessels and inflammatory reactions are discussed as possible causes (Hess et al. 1984; Ostrow et al. 2006). The prevalence reaches 13% at 10 years after Fontan operation (Feldt et al. 1996; Mertens et al. 1998). Only 50% of patients are alive 5 years after this complication was first diagnosed. In patients with sinus node dysfunction, an improvement may be achieved through pacemaker stimulation (Cohen et al. 2001). In certain cases, fenestration of the Fontan tunnel might reduce pleural effusions and ascites (Jacobs et al. 1996a; Warnes et al. 1996). Other surgical options include Fontan conversion and heart transplantation. The results of these operations are discussed in the following paragraph.

13.8.7 Reoperations

A stenoses in the venous pathway is the most common indication for reoperations following Fontan palliation (Girod et al. 1987; Mavroudis et al. 2005). Freedom of obstruction in venous pathways, 15 years following the operation, was 50% in a study with heterogeneous operation techniques (Fernandez et al. 1989). The incidence of reoperations is 2% after direct atriopulmonary connection and 13% after interpositions of a conduit (Fontan et al. 1989). Hospital mortality following these reoperations is reported to be 24% in older series (Fontan et al. 1989). The incidence of stenoses in venous pathways might decrease after the introduction of the lateral tunnel and the extracardiac total cavopulmonary connection. However, there is limited data available beyond 10 years of follow-up in these patients.

The following complications following an atrio-pulmonary Fontan operation may be indications for Fontan conversion:

- Large right atrium with unfavorable flow dynamics
- Rhythm disturbances
- Thrombosis
- Stenoses in venous pathways
- Protein-losing enteropathy

The Fontan conversion operation includes construction of a lateral tunnel or an extracardiac cavopulmonary anastomosis, removal of thrombotic material, reduction of the atrium and MAZE procedure (Kreutzer et al. 1996; McElhinney et al. 1996; Marcelletti et al. 2000). The operation has lower hospital mortality in patients with preserved functional status. The patients benefit from conversion to a cavopulmonary connection in terms of reduced effusion and lower incidence of arrhythmias (Kim et al. 2005; Ereik et al. 2006). Good results can be achieved by intracardiac as well as extracardiac total cavopulmonary anastomosis (Morales et al. 2005). Concomitant arrhythmia surgery effectively resolves the refractory atrial arrhythmias and may improve early survival (Sridhar et al. 2011).

Further indications for a reoperation are stenosis in the systemic outflow tract and insufficiency of the atrioventricular valve. Subaortic stenosis can develop at any point in treatment of patients with functional single ventricle (Rao 1983). The reoperations for subaortic stenosis are usually not required in cases where an anastomosis between the pulmonary artery and the ascending aorta was performed at the time of stage I or stage II palliation (Jonas et al. 1985; Jacobs et al. 1995a). Insufficiency of a single or a dominant atrioventricular valve can lead to a deterioration of the functional status. It may be beneficial to address the insufficiency prior to functional deterioration of the ventricle. The results of mitral valve repair are better than the results of tricuspid valve repair. However, any valve repair should be carefully considered since the longer aortic cross-clamp time, needed for reconstruction of an atrioventricular valve, is connected to a higher early mortality rate (Mavroudis et al. 2005).

Heart transplantation is the last surgical option in the treatment of patients with single ventricle (Pereira and Shirali 2005; Huddleston 2007). The expected 5-year survival of children (<18 years of age) with functional single ventricle

is 68% after heart transplantation (Jayakumar et al. 2004). This survival is lower than the survival of children with other congenital or acquired heart defects (Bernstein et al. 2006). The functional status of the patients improves significantly after the transplantation. The symptoms of protein-losing enteropathy usually improve as well (Bernstein et al. 2006).

13.9 Conclusions

The intracardiac and extracardiac total cavopulmonary connection are currently the best therapy option for most of the patients with functional single ventricle. The staged approach with early volume unloading of the systemic ventricle is an important element of the modern therapy concept. After the diagnosis of a functional single ventricle, a complete treatment plan, aiming at completion of the Fontan circulation, should be determined and followed. In spite of significant improvements in the therapy of patients with functional single ventricle, it is questionable whether the new therapeutical and surgical approaches will reduce the rates of known late complications. The Fontan operation most likely remains a palliative therapy.

14.1 Classification and Localizations

A ventricular septal defect (VSD) is defined as a communication between the left and the right ventricular chamber in the area of the interventricular septum. It may be isolated or can occur in association with other cardiac or vascular malformations. This chapter deals primarily with the treatment of isolated VSD which accounts for 20–25 % of all congenital heart disease.

As is so often encountered in terminology, several classifications for VSD exist, each with its own particular emphasis reflected in the literature. In this chapter, the recommendation by van Praagh (van Praagh et al. 1989) is followed, but the classifications according to Kirklin (Kirklin et al. 1957) and Anderson and Becker (Becker and Anderson 1982) are also common usage. All classifications share the description of the localization of the defect orientating themselves at features of

the right ventricle, as surgical access is usually from the right side (■ Fig. 14.1).

During the complex embryonic cardiogenesis (Goor and Lillehei 1975), normally a complete separation of both ventricular chambers is formed by the development of a partition consisting mainly of muscle (muscular septum) and a small membranous part (membranous septum). The latter is positioned toward the outflow tract with its cranial portion connecting to the septum of the former truncus arteriosus which is separating the two great arteries (conus septum or conotruncal septum).

The right ventricle is subdivided into an inlet, a trabeculated, and an outlet part. Following the blood flow one would encounter the different defects in the following order and frequency:

- Inlet VSD (6%)
- Muscular VSD (10%)
- Conoventricular VSD (80%)
- Conus VSD (4%)

■ Fig. 14.1 a, b Anatomy and nomenclature of VSDs. a Classification of the septum: membranous septum; muscular septum: inlet-, trabecular and outlet septum. b Localization of inlet, muscular, conoventricular (perimembranous) and conus defects

14.1.1 Defect of the Inlet Septum (Inlet VSD)

This defect lies directly behind the septal leaflet of the tricuspid valve and corresponds to the ventricular part of an atrioventricular septal defect or AV canal. Accordingly, it is often found in association with trisomy 21. The fact that some also call it an «AV canal-type VSD» is the cause of an ongoing morphological debate between the various schools of cardiac pathology (Spicer et al. 2013). Upstream its border is the tricuspid valve annulus. The conduction system usually lies rather superficial within the caudad muscular border. Chordae and papillary muscles of the sometimes atypically configured right-sided atrioventricular valve may obscure the overview from the right atrium. This can necessitate the detachment of a leaflet for secure closure (see below, ► Sect. 14.3.1).

14.1.2 Muscular VSD

Such a VSD is circumferentially bordered by muscle. It can occur in any area of the trabeculated part of the right ventricle. The view from the right ventricle with its crossing trabeculations can simulate multiple defects. Hence, the true arrangement can be judged much better from the smooth left ventricular side. Defects located anteriorly toward the apex are also known as «apical» VSDs. They are usually multiple and reflect an incomplete differentiation of the muscular septum. Spontaneous closure within the first months of life is therefore seen frequently.

The primarily netlike structure of the inter-ventricular partition with numerous communications explains the commonly encountered multitude of defects. Whereas this is often only an illusion in the midmuscular part, apical VSDs are multiple as a rule. A prominent disruption of the myocardial differentiation of the septum is colloquially called a «Swiss-cheese-type.» Apart from a conoventricular VSD a separate muscular defect may coexist, the relevance of which often only becomes evident if it is overlooked or deliberately not closed at surgery for the leading defect.

14.1.3 Conoventricular VSD

This defect is situated between the true ventricular and the conus septum. The conus septum may deviate anteriorly (RVOT narrowing, embryogen-

esis of tetralogy of Fallot) or rarely posteriorly (LVOT narrowing in interrupted aortic arch). An isolated conoventricular VSD is the result of an insufficient development of the membranous septum and is therefore often also called a «membranous» VSD. Because of the usual extension into the muscular part, «perimembranous VSD» may be the better term. This localization is the most frequent one by far (>80%).

There is a close relation to the tricuspid valve in the area of the commissure between the septal and the anterosuperior leaflet. The conduction system lies within the posteroinferior border. If the membranous septum is missing completely, the superior border of the VSD reaches the base of the right/noncoronary cusps of the aortic valve. Various extensions posteroinferiorly (muscular septum, inlet portion) or anterosuperiorly (conus septum, Fallot type) can occur and may impede orientation.

If there is only a small perforation of the membranous septum, the defect will be hemodynamically insignificant. The development of a sometimes quite impressive bulge of the membranous part may occasionally lead to subpulmonary obstruction. The impression of such a so-called aneurysm VSD is, however, more often created by an associated dysplasia of the tricuspid valve leaflet next to the defect which may be attached to its crest with several chordae. Septal and anterosseptal leaflet tissue can form a tunnel and direct blood from the left ventricle directly into the right atrium (Gerbode defect; Gerbode et al. 1958).

14.1.4 Conus VSD

This VSD is characterized by an incomplete closure of the conus septum between the two great arteries and is sometimes also called «subpulmonary» or «outlet» VSD. With the upper rim being outlined by the pulmonary valve, its caudad border is muscular. The conduction system and the tricuspid valve are far away. For embryological reasons, this defect is frequently seen with a common arterial trunk, the isolated form being very rare.

14.2 Natural Course and Indications for Operation

The natural course depends on the size and localization of the VSD. According to the shunted volume and the pulmonary vascular congestion

resulting therefrom, restrictive and nonrestrictive defects are differentiated. In the latter, right ventricular systolic pressure equals the left ventricular one. The degree of pulmonary vascular congestion is dependent on the variable of pulmonary vascular resistance (R_p). As this is physiologically increased early postnatally, the true hemodynamic significance often becomes apparent only with its decrease over several weeks of life. If the relation between pulmonary blood flow and systemic blood flow ($Q_p:Q_s$) is less than 1.5:1, a VSD is considered small and restrictive. Nonrestrictive VSDs often show a $Q_p:Q_s$ ratio of more than 3:1. A left-to-right shunt of such dimensions soon causes cardiac failure, which in the infant manifests itself with tachypnea, sweating and feeding difficulties, leading to failure to thrive. This development determines the timing of the operation. Closure of a VSD should be performed before manifestation of cardiac failure, independent of age.

Chronic pulmonary arterial hypertension in untreated VSD stimulates remodeling of the pulmonary vasculature, which eventually becomes irreversible and causes a massive increase in pulmonary vascular resistance. When the relation of the resistances $R_p:R_s$ (R_s = systemic vascular resistance) becomes greater than 1.0, the shunt flow is reversed to right to left, causing cyanosis. This phenomenon is known as «Eisenmenger's syndrome.» Because of the destruction of the pulmonary vasculature, the only «therapeutic» option may be combined heart-lung transplantation (HLT_x). It should be mentioned that one of the first two successful HLT_x in the world, performed by Bruce Reitz in 1981, was done for that very reason. The natural course of smaller defects is variable. Apical muscular defects show a tendency to close during ongoing myocardial differentiation within the first year of life. In the membranous septum such a spontaneous closure is often pretended by an increasing prolapse of accessory connective tissue («aneurysm VSD»). The development of a subaortic ridge at the left ventricular surface of the lower rim of an untreated conoventricular/perimembranous VSD is seen in about 6% of cases. Upon closing the VSD, this must be resected to avoid leaving behind a subaortic stenosis which may become more prominent over time (Eroglu et al. 2003; Kidd et al. 1993; Kleinman et al. 2007).

Leaving a VSD with a load of the right ventricle untreated for years may cause the development

of a trabecular hypertrophy up to an infundibular outflow tract stenosis («double-chambered right ventricle,» DCRV). During closure of the VSD this must be additionally corrected. A DCRV without VSD is extremely rare.

A direct relation of a high-positioned VSD with the aortic valve may cause prolapse of the right coronary, sometimes the non-coronary cusp into the VSD. The creation of a low-pressure zone at the border of an accelerated fluid is known as the «Venturi effect.» The acceleration of blood flow at the rim of a small VSD causes such traction on the affected valve cusps that an aortic valve insufficiency can result. The dynamics of this phenomenon have been repeatedly studied. The latest point in time to close such a high VSD is the appearance of valve regurgitation (see below, ► Sects. 14.6.2; Jian-Jun et al. 2006; Kostolny et al. 2006; Saleeb et al. 2007; Tatsuno et al. 1973; Tomita et al. 2004). Interestingly, such defects are more frequently encountered in patients of East Asian origin, which may be regarded as a hint to genetic disposition of the localization of VSDs.

Even a very small VSD must be feared to increase the risk of endocarditis because of the turbulence it creates on the endothelial surface. This is a weighty argument in favor of closure of defects which are barely or not hemodynamically significant (Backer et al. 1993).

It should be mentioned that a VSD may constitute a cardiac malformation in the context of a more complex genetic syndrome such as chromosome 22q11 deletion. Genetic investigations of these causes may help to further explain the mechanisms of cardiogenesis.

14.3 Cardiac Access

Median sternotomy is considered standard access for VSD closure. With the constant development of so-called minimally invasive techniques reports about alternative incisions such as partial inferior sternotomy, right anterolateral thoracotomy, or axillary thoracotomy are increasing (Kadner et al. 2006; Mavroudis et al. 2005). These do compromise visualization, however, and their use should be limited to groups with a particular experience and to older patients. They are favored for hybrid approaches (see below, ► Sect. 14.6.6; Mo et al. 2011; Schreiber et al. 2012; Xing et al. 2011). For open repair the mainly cosmetically advantageous

considerations must by no means compromise established security standards, e.g., direct suture instead of patch closure, or induced ventricular fibrillation instead of aortic cross clamping and cardioplegic arrest. Cannulation of a child's femoral or iliac vessels remains highly controversial because of its long-term side effects.

When using a standard median sternotomy, arterial cannulation is via the distal ascending aorta, the venous one bicaval with snaring of both veins. This is followed by the induction of cardioplegic arrest under aortic cross clamping.

Depending upon its localization, the VSD is then approached through a cardiac incision.

14.3.1 Transatrial Access

For transatrial access the right atrium is incised longitudinally, starting from the base of the right auricle. This can be extended if necessitated by poor exposure. A left atrial vent is placed through the foramen ovale or a small stab incision in the fossa ovalis. The anterosuperior leaflet of the tricuspid valve is then retracted with a blunt retractor. It may be helpful to additionally elevate the septal leaflet, too. This can be achieved with stay sutures. Through the tricuspid valve orifice one can then see the right ventricular aspect of the interventricular septum and all conoventricular (perimembranous) defects. The superior rim of the VSD may be difficult to visualize nevertheless. Sometimes it is then appropriate to partially detach the anterosuperior tricuspid leaflet. Confusing anatomy of chordae or papillary muscles sometimes need detaching of the septal leaflet. The leaflet in question is incised close and parallel to its fibrous anulus and reattached after VSD closure with a fine monofilament suture. A limited radial incision has also been described to provide very good exposure (Russell et al. 2011).

14.3.2 Transventricular Access

A routine approach through the right ventricle must be regarded as historical. In case of a localization in or extension into the conus septum, a limited infundibulotomy may facilitate exposure. Care must be taken to spare the coronary artery branches, which may be quite prominent in the conal area. Apart from that, a right ventriculotomy

is very rarely used for closure of anterior muscular VSDs. A conus VSD, however, can be approached through an oblique infundibulotomy.

In apical VSDs in the trabecular portion («Swiss-cheese-type»; see below, ► Sect. 14.6.4) a left ventriculotomy offers the theoretical advantage of unobstructed overview due to the lack of trabeculations. If done at all, the incision should be made at the very apex and to the right of the left anterior descending coronary artery. Closure of the ventricle usually requires fortification with buttressed sutures (e.g., with Teflon felt strips). Severe left ventricular dysfunction and arrhythmias were observed during long-term follow-up, making this approach almost obsolete (Hanna et al. 1991). If it comes into consideration at all, an alternative option should be discussed (see below, ► Sect. 14.6.6).

Access to defects close to the apex is often possible through an apical right ventricular incision. Obstructing trabeculations, however, must then be severed. Firm anchoring of the patch at the cranial rim may prove difficult (Myhre et al. 2004).

14.3.3 Transvalvular Access

Conotruncal defects immediately adjacent to the pulmonary or aortic valve can be reached through the respective valve orifice. Visualization of the interventricular septum remains limited. This approach is therefore reserved for smaller or recurrent defects in this area. In associated aortic valve insufficiency (see below, ► Sect. 14.6.2) or an aneurysm of the sinus of Valsalva (see below, ► Sect. 14.6.5), an aortotomy is obligatory and enables the precise exposure of the superior rim of any defect bordering the aortic valve.

14.4 Closure Techniques

The techniques for VSD closure described in the following paragraphs exclusively imply the use of patch material (Dacron, polytetrafluorethylene [PTFE], autologous or xeno-pericardium, tissue-engineered matrix). The suture techniques used are urgently recommended. Individual expertise, however, allows for the routine use of alternative techniques: e.g., «always» running sutures, or «always» interrupted sutures with or without buttressing material (Teflon felt, pericardium).

■ **Fig. 14.2** Transatrial closure of a VSD. Exposure of the VSD through the right atrium and the tricuspid valve. Shown is the partial detachment of the septal tricuspid valve leaflet at the anulus to expose the superior rim of the defect. VSD sutures in U-stitch technique

14.4.1 Conoventricular VSD

Almost all of these defects can be closed through a transatrial/transtricuspid approach. Initially, the upper rim is often obscured. Before starting any closure, however, the complete anatomy must be visualized unequivocally. It is also to be determined if the rim of the defect reaches the anulus of the tricuspid valve directly, or if a muscular ridge is present. If borderline structures remain obscured by valve tissue, detachment of the respective tricuspid valve leaflet directly above its anulus may be required.

For anchoring of a patch, the use of separate, double-armed, braided U stitches, buttressed with small Teflon pledgets, is generally recommended (■ Fig. 14.2). It is advantageous to fix the first sutures on the anteroinferior aspect of the muscular septum. Armed with small rubber-shod clamps and draped on a hole towel for clear view, they facilitate stepwise exposure if put under gentle traction—similar to the implantation technique for a mitral valve prosthesis. Advancement

is made in a clockwise direction first, caudally taking great care that the pledgets rest directly on the septum and that no chordae or papillary muscles are caught by the sutures. At the inferoposterior aspect the conduction system is approached (■ Fig. 14.3). Here the sutures are to be applied stringently on the right ventricular aspect, somewhat detached from the true rim of the VSD. Adjacent to the tricuspid valve, especially if there is only a small ridge of tissue, one may need to pass some sutures from the atrium and through the tricuspid valve anulus to the ventricular side. Thus, the pledgets will be placed atrially. As soon as the most posterior point is reached, it is advised to return to the anterior aspect. Slight traction on the sutures already in place will expose the superior rim. Advancement, now counterclockwise, is in identical fashion. In the area of the outflow tract, generous portions of muscle can be used for secure anchoring. Reaching the aortic valve the available ridge can be distressingly narrow, probably the reason for the frequency of patch dehiscences in this area. This can be overcome by

■ **Fig. 14.3** Right ventricular aspect of VSD closure. Opened right ventricle. The hatched area marks the part of the septum bearing the conduction system. Here, sutures must be placed stringently on the right ventricular aspect and away from the rim. Illustrated suture techniques are U-stitches and continuous suture. A combination is possible

placing several, usually only one to three, unbuttressed stitches in a longitudinal fashion along the rim. Under very delicate circumstances and in direct neighborhood of valve tissue, the use of fine monofilament material is expedient, enabling better guidance. It is helpful to fill the aortic root intermittently with cardioplegia. This problematic region is then overcome and one reaches the posterior aspect close to the tricuspid valve again, which is dealt with as described above. Usually, for closure of a nonrestrictive infant VSD, 10–15 sutures are needed to guarantee secure anchoring of the patch, at the same time avoiding compromising neighboring structures.

Woven Dacron is a well-proven patch material, being both tear-proof and flexible. PTFE is preferred by some. Autologous pericardium (usually impregnated with 0.6% glutaraldehyde for 10 min) and xenopericardium are controversial because of lower tear resistance. One should bear in mind that after closure an enormous pressure load is inflicted on the patch and that the muscular part of the circumference is contracting with every systole, putting the whole suture line in this area at risk. More recently, a tissue-engineered matrix of porcine intestine (CorMatrix[®]) came into use also.

All stitches are now placed through the patch in their original order. The patch is then carefully lowered onto the septal defect where it comes to rest on its right ventricular aspect like a lid. It should therefore be tailored a bit larger than the actual defect size. When lowering the patch, great care must be taken again that it does not obstruct any chordae or parts of the tricuspid valve. Retracting these delicate structures with fine nerve hooks can be helpful. The sutures should only be tied after secure placement of the whole circumference of the patch.

If a tricuspid valve leaflet was detached for exposure's sake, it is then reattached, ideally with a fine monofilament running suture. Tricuspid valve competence is tested in any case by instilling fluid into the right ventricle. If necessary, reconstructive measures to alleviate valve incompetence are needed (adaptation of commissures, anuloplasty, but also replacement of awkward VSD patch sutures).

The left atrial vent catheter is now removed and the interatrial septum closed. We use absorbable monofilament material for closure of the right atriotomy in children. Before removing the aortic cross clamp, the left heart is meticulously de-aired through the cardioplegia site. For immediate

quality control of the operative result and especially in the presence of any difficult anatomical circumstances, an intraoperative transesophageal echocardiography is strongly recommended. Moreover, pulmonary arterial oxygen saturations can be measured and compared to SVC saturations. A step-up of more than 5% in absolute saturation is suspicious for a residual VSD.

Direct closure of a VSD with separate buttressed U stitches is vehemently advised against because of the high risk of dehiscence and distortion of neighboring structures. This is also and particularly true for small defects. Very rare indications for direct closure (concomitant very small VSD with fibrous, scarred borders) may exist.

14.4.2 Muscular VSD

Isolated midmuscular, inferior, or posterior defects can commonly also be reached through a right atriotomy. The more they are located in the trabecular part of the right ventricle, the more overview is obscured by these trabeculae. This may evoke the impression of multiple defects. Partial separation of muscle bundles may facilitate secure anchoring of a patch. The whole border of such a VSD is muscular, including that toward the tricuspid valve. Direct closure is therefore inappropriate.

If a muscular VSD is in close relation to a separate conoventricular or inlet defect, the conduction bundle often runs through the separating muscular bridge. Closure should be achieved by placing one large common patch covering both communications and avoiding sutures in the bridging area.

VSDs located in the very anterior region or apical ones may only be approachable through a ventriculotomy, which in case of an anterior VSD may be limited to an oblique infundibulotomy. Even if a left ventriculotomy enables good visualization, this access is rarely ever used due to its negative long-term sequelae. This has become possible because of the development of new and alternative closure technologies (see below, ► Sect. 14.6.6). The apical incision of the right ventricle has come somewhat back into fashion, especially where these new methods are not available (Myhre et al. 2004).

In very rare large anterior defects, which can be reached through an infundibulotomy, utmost care must be taken not to injure the left anterior descending coronary artery when placing the anterior stitches.

14.4.3 Inlet VSD

These defects can be easily reached through the tricuspid valve orifice because of their immediate proximity to it. By definition, they reach the valve annulus without an additional ridge of tissue. All sutures in this area must therefore be placed from the right atrial aspect. In the presence of multiple atypical chordae, it may be advantageous to use a single running stitch for the circumference bordering the valve. This can be woven in between the chordae and the usually short and plump papillary muscles like a mattress suture. The risk of dehiscence is low because the border of the defect in this area consists of firm connective tissue.

If the conduction system lies to the inferoposterior border, several separate U stitches are put some millimeters away from the edge and strictly on the right ventricular aspect. Thus, usually a combined running and single stitch closure technique is the result. The debate where the conduction system is most likely located in VSDs of the inlet septum is ongoing, depending on the pathological classification (Spicer et al. 2013).

14.4.4 Conus VSD

This type of defect in a subpulmonary position is usually associated with more complex congenital heart disease such as common arterial trunk. If isolated, it can be reached through a limited infundibulotomy or through the pulmonary valve itself.

A limited longitudinal ventriculotomy sparing right coronary conal branches offers good exposure of the conus septum that forms the backwall of the funnel just opened. The superior aspect of these defects commonly reaches directly onto a narrow fibrous ridge between the pulmonary valve anteriorly and the aortic valve posteriorly. If this tissue appears too fragile for secure anchoring of the patch, as is often the case, the sutures must be placed from the respective sinus of the pulmonary valve. Again, separate buttressed U stitches are used. For better orientation and precise placement of the sutures, intermittent filling of the aortic root with small doses of cardioplegia is advised. At the caudad end, a continuous running suture is usually appropriate. As only the conus septum is involved, the conduction system is far away and generous portions of muscle can be used.

In smaller, semilunar defects or insufficient tissue between aorta and pulmonary artery, the latter is incised transversely above the commissures. Then the sutures for the superior aspect are placed from the sinus. The lower circumference can be sutured continuously through the valve orifice. Should the defect extend deep into the ventricle, exposure is compromised.

While oblique infundibulotomies can be closed directly, longitudinal infundibulotomies should be closed with a patch to avoid RVOT obstruction.

14.5 Complications

The anatomy of the *conoventricular/perimembranous* VSD bears three danger zones, the injury of which leads to a respective specific complication:

- The upper border of the defect reaches the aortic valve in many instances. The valve must be visualized through the VSD during closure. Any distortion in this area may lead to postoperative valve insufficiency (Chiu et al. 2007). For visual inspection of valve competence, cardioplegia can be repeatedly administered into the aortic root during surgery.
- The lower border of the defect in the posterior direction toward the tricuspid valve hides the conduction system. If hurt by stitches, a block of the atrioventricular conduction will result, which then is often permanent and complete (third degree heart block). If complete heart block is seen during reperfusion and depending upon the anatomy, one may consider replacing several stitches during a second time of ischemia. However, this will not guarantee complete remission (Andersen et al. 2006). If complete heart block persists early postoperatively, we wait for 10–14 days before we implant a permanent pacemaker system, as recovery of stable sinus rhythm is possible within this time frame. For additional safety throughout this time, we always suture a second set of temporary pacemaker wires on the right ventricle when a higher degree of heart block is present at the time of chest closure.
- If several stitches were placed from the right atrium through the tricuspid valve annulus or if a valve leaflet had to be detached for better exposure, significant tricuspid valve

insufficiency may result. Before closing the right atrium, the right ventricle must be filled with fluid for visual inspection, cross clamping the pulmonary artery if necessary.

Closure of *apically located muscular VSDs* via a left ventriculotomy will lead to an impairment of left ventricular function, especially in the long term. Late occurrence of life-threatening ventricular arrhythmias has also been observed (Hanna et al. 1991). For these reasons, usage of this approach should be made only very restrictively.

In «*Swiss-cheese-type*» VSD, smaller communications may remain or be overlooked, the hemodynamic relevance of which is hard to judge early postoperatively.

Defects located in the *inlet part of the septum*, directly adjacent to the tricuspid valve, often offer little space for safe anchoring of the sutures in the area of the conduction system. An increased risk of complete heart block has to be expected.

Closure of *conotruncal defects* through the pulmonary or aortic valve may lead to an insufficiency of the respective semilunar valve. Inappropriate exposure of the lower margin in larger defects leads to an increased incidence of residual defects in this area.

If a residual defect is known, regular follow-up is needed to judge its hemodynamic relevance (Dodge-Khatami et al. 2007). Intraoperative transesophageal echocardiography is able to detect most valve insufficiencies and residual defects and may thus decisively influence the further course of action, e.g., immediate revision. Significant septal defects can also be detected or excluded by measuring oxygen saturation in the pulmonary artery. A defect needing closure usually leads to saturations above 80% under ventilation with room air. As said above, when in doubt, a comparison with the SVC oxygen saturation is advisable.

14.6 Special Forms of Operative Treatment

14.6.1 Pulmonary Artery Banding

The first operative closure of a VSD was performed by Lillehei under «cross circulation» on March 26, 1954 (Lillehei et al. 1955). In the preceding years, there had been several attempts of palliation by lowering pulmonary blood flow, narrowing the

pulmonary artery with the aid of a circumferential textile band (Muller and Dammann 1952). This had been based on the observation that moderate pulmonary stenosis would positively influence the prognosis of patients with single ventricle. The banding procedure enabled postponing correction into an age beyond infancy and had become quite common practice. In the current era of surgical treatment of VSD, pulmonary artery banding has almost completely lost its former role, being only considered in the presence of absolute contraindications for extracorporeal circulation or in pronounced forms of a «Swiss-cheese-type» septum (see below, ► Sect. 14.6.4). The technique still has its merits in the stepwise palliation of univentricular circulations with pulmonary vascular congestion in the newborn and is therefore described here.

Contrary to the historical technique which was done through a left posterolateral thoracotomy, access today is via a median sternotomy. Besides offering the advantage of equal ventilation and perfusion of both lungs, this route offers far better exposure, the possibility to establish cardiopulmonary bypass in an emergency, as well as the cosmetic aspect of just one scar for all subsequent operations. In addition, in cyanotic univentricular circulations, the development of post-thoracotomy chest wall-to-pulmonary collaterals complicating later Fontan type surgery is avoided.

After displacement or partial resection of the thymus, the pericardium is incised over the great vessels. The connective tissue between the aorta and the often rather short main pulmonary artery is sparingly dissected over the width of the intended band. Instead of the conventional braided textile bands which may migrate through the vessel wall over time and lead to considerable adhesions in any case, the use of smooth, inert silicone, ideally reinforced with a Dacron mesh, or a PTFE band is recommended. Starting from the historical Trusler's formula (Trusler and Mustard 1972), the initial length of the circumference to be marked on the band should amount to $20 \text{ mm} + 1 \text{ mm/kg}$ body weight (e.g., 24 mm in a 4 kg baby). After marking, the band is pulled around the pulmonary artery and fixed according to the marked length. Depending upon the hemodynamic situation, it can then be loosened or tightened further. According to Poiseuille's law, the radius of a tube influences the flow through it in the fourth power. Thus, minimal

changes can lead to sometimes dramatic effects. Before the band is eventually permanently fixed, the circulation must be given some time to adapt to the new resistances (■ Fig. 14.4). Usually we see a minimum increase of 10–15 mmHg systolic arterial pressure and a reduction of the heart rate by 10%. Pulmonary artery pressure does not need to be measured routinely. In a univentricular circulation, an arterial saturation between 75 and 80% (under ventilation with room air and with an open chest!) and a decrease of pulmonary arterial pressure to about one third systemic is considered the benchmark. When palliating a biventricular system, the arterial saturation should not drop below 85%, but rather be 90%.

To prevent distal migration of the band with the danger of compromising the bifurcation and inducing asymmetrical pulmonary blood flow, fixation sutures should be applied to the pulmonary root. In biventricular circulations the pulmonary valve must not be jeopardized in any manner. If the pulmonary trunk is very short, the band can be excised concavely at the underside of the right-angled take-off of the right pulmonary artery to prevent stenosis to the right side.

As the principle of palliation means transfer from one pathological state to another, which is presumably better tolerated, the time span with a banded pulmonary artery should be kept to a minimum. This is especially true for eventually curable congenital heart disease such as VSD or atrioventricular septal defect. The persistence of right-sided systemic pressures causes hypertrophy of the right ventricular muscle—up to the level of a hemodynamically relevant infundibular stenosis persisting after debanding, causing additional problems. With the growth of the child, the banding becomes constantly more effective and may induce critical spells of arterial desaturation. This should be prevented by early de-banding not later than 6 months post banding.

14.6.2 VSD with Secondary Aortic Valve Insufficiency

The increasing prolapse of an aortic valve cusp adjacent to a VSD can lead to distortion of the valve with consecutive regurgitation. Small conoventricular defects high in the septum or juxta-arterial conus defects are at particular risk. Usually it is the right coronary cusp which is closely

■ **Fig. 14.4** a, b Pulmonary artery banding. a Provisional adjustment of the band at the pulmonary artery by clamping. Direct distal pressure measurement. b Permanent fixation of the band with single sutures

related to the VSD, sometimes the non-coronary one or both (Tomita et al. 2005). A lack of support of the afflicted area as well as the Venturi effect are considered mechanisms contributing to progressive valvular insufficiency (Tatsuno et al. 1973; Tweddell et al. 2006; see above ► Sect. 14.2). Closure of the defect before the development of valvular insufficiency or as long as it is only minor has the best prognosis (Jian-Jun et al. 2006; Kostolny et al. 2006; Saleeb et al. 2007; Tomita et al. 2004). In these cases closure of the VSD is often sufficient with the patch providing the necessary support. If the valve has already undergone morphological alterations, extension of the operation becomes necessary.

Reconstruction of the aortic valve according to the technique described by Trusler has very good long-term results (Trusler et al. 1973, 1992). After a transverse aortotomy above the sinotubular junction, the aortic valve is inspected. One usually finds an elongation of the cusp prolapsing into the defect. To correctly judge the extent of the asymmetry, it is recommended to pass a fine monofilament suture through the noduli Arantii to elevate the valve («Frater stitch»; Frater 1967). The afflicted cusp will crimp along its pathologically elongated part close to the commissure. A buttressed suture then fixes the resulting fold transmurally to the neighboring aortic wall, thus reestablishing the symmetry of the free cusp edges (■ Fig. 14.5). The central marking suture is then

removed. Instillation of cardioplegia into the aortic root gives a first impression of valve patency. An intraoperative transesophageal echocardiography will exactly define the success of the reconstruction. In the presence of additional congenital valve asymmetries, e.g., a bicuspid valve or advanced changes, prognosis is obviously limited.

14.6.3 VSD and Coarctation of the Aorta

A VSD can be a defined, fixed part of a complex malformation, e.g. in tetralogy of Fallot or common arterial trunk. Often it is only loosely associated with a second malformation without this constituting a direct syndromal relationship. The most common malformation encountered in the presence of a VSD is coarctation of the aorta (see ► chapter «Congenital Anomalies of the Great Vessels», Sect. 21.2.1.1).

Whereas concomitant correction during a single procedure is well accepted for complex heart disease (Heinemann et al. 1990), the strategy for optimal treatment of VSD with aortic coarctation is still subject of debate (Gaynor 2003). A two-staged approach is the historically established one, in which the coarctation is corrected first through a left lateral thoracotomy. Then the VSD is closed transsternally in a second operation. In the presence of large defects, this

Fig. 14.5 a–d Trusler's plasty in aortic valve insufficiency. Transverse incision of the aortic root. **a** «Frater stitch» through the noduli Arantii. The right coronary cusp is elongated. **b** Tension on the «Frater stitch» creates crimping of the elongated cusp into a fold close to the aortic wall. **c** Right and non-coronary cusp are attached to each other. Then the fold is fixed transmurally with pledgeted sutures to gather the elongation. **d** Safety suture between the two cusps, creating a cover

strategy can be complemented with pulmonary artery banding during coarctectomy to gain some time until the second procedure. Disadvantages are the necessity of two different incisions, two anesthetics, and a longer or repeated hospital stay in combination with a state of palliation.

Technical advances have led to the increased endeavor of concomitant correction of an isolated VSD and aortic coarctation through a sternotomy in analogy to the strategy in more complex heart disease. The aortic isthmus is then approached during a short phase of deep hypothermia and, when necessary, circulatory arrest. During the cooling phase the aortic arch with its branches as well as the descending aorta can be dissected free extensively.

A disadvantage is the use of hypothermia which would not be necessary for VSD closure alone and is therefore a considerable extension of the procedure with all associated risks. An increased rate of recoarctations, presumably because of worse exposure, has also been reported (Brouwer et al. 1996; Gaynor et al. 2000; Isomatsu et al. 2001). The successful combination of both strategies is also possible: First, a standard coarctation repair is done through a lateral thoracotomy, to be followed—after repositioning but during the same anesthesia—by VSD closure through a sternotomy, avoiding deep hypothermia (Kanter et al. 2007).

Our experience leads us to recommend the following approach: in a small VSD and aortic coarct-

tation, the aorta is repaired first and the VSD closely followed and closed at a later date as necessary. If size and extent of a VSD necessitate early closure, this is regarded an indication for single stage repair. If the aortic narrowing also extends into the aortic arch as a tubular hypoplasia, which is often observed in these cases, sternotomy and the use of hypothermic techniques for extended aortic reconstruction are appropriate anyway. If a VSD/coarctation patient presents in poor condition, even after compensation, we rather proceed with coarctation repair only, regardless of VSD size.

In adult patients an extra-anatomic bypass to circumvent the coarctation can be a very good alternative option (Myers et al. 2011; Reents et al. 2012).

14.6.4 «Swiss-Cheese-Type» VSD

The malformation somewhat colloquially called a «Swiss-cheese-type» VSD represents a profound disturbance of the development of the muscular ventricular septum, primarily in its trabeculated part. The multiple connections between right and left chamber existing during embryonic and fetal life do not close, resulting in several defects in the muscular septum. In the case of anteroapically located small communications, spontaneous closure within the first year of life is highly likely.

A combination of larger VSDs extending into the midmuscular portion with a considerable combined passage area can become hemodynamically very significant at the time of the physiological postnatal drop in pulmonary vascular resistance. Number and location of these communications make their surgical exposure very difficult. A decision must be made between pulmonary artery banding and a right ventriculotomy (Seddio et al. 1999), if pulmonary artery banding is not the institutional approach in these cases anyway. A left ventriculotomy should be avoided if at all possible.

14.6.5 VSD and Aneurysm of a Valsalva Sinus

Congenital aneurysm of a sinus of Valsalva represents a separation of the media of the afflicted sinus from that of the hinge point of the respective aortic cusp (Edwards and Burchell 1957). The structural weakness between the aortic root and the heart in combination with the aortic blood pressure leads

to bulging of the sinus into the cardiac structures below, up to the point of perforation. Usually only the right coronary sinus is afflicted, sometimes in combination with the adjacent half of the noncoronary one. Perforation ensues into the right atrium or ventricle. Coexistence of a VSD bordering the aortic valve can also be part of the malformation, leading to valvular insufficiency. An increased incidence of this combination has been observed in Asia, giving an indirect hint to genetic predisposition (Brizard 2006; Sakakibara and Konno 1962, 1968; Lee et al. 2013).

The operative strategy consists of resection of the «aneurysm,» VSD closure, and aortic valve reconstruction. After inspection of the anatomy through an aortotomy, an exposition from the ventricular side, e.g., through an infundibulotomy, is adequate in most cases. This allows for a definitive discrimination between a conoventricular and a pure conus defect and therefore the supposed course of the conduction system. The aneurysmatic tissue is resected, resulting in a larger defect in the right coronary sinus. The Dacron patch used for VSD closure is also utilized for reconstruction of the aortic root. First, complete VSD closure is performed with the anchoring of the middle part of the patch directly into the insertion zone of the right coronary cusp in the usual fashion. The excess patch length cranially can then be tailored into the aortic root defect with a continuous suture. In a classical conus defect, as is often seen in Asian patients, the whole procedure can be done transaortically. Asymmetry of a valve cusp may call for additional valve reconstruction or even replacement.

14.6.6 Catheter Interventional Techniques

The endeavor to avoid a ventriculotomy for closure of hemodynamically highly significant muscular defects led to the development of interventional techniques by catheter (Lock et al. 1988; Okubo et al. 2001; Waight et al. 2002; Bacha et al. 2005). Because of the limitations of vascular access in small children, these are often combined with open exposure of the heart through a thoracotomy as so-called hybrid procedures and have become well-established in several centers. Purely percutaneous closure of a muscular VSD can be regarded safe under certain conditions too.

Further refinement of the devices has meanwhile led to their use for closure of conoventricular/perimembranous defects as an alternative to surgery. This was evaluated in several studies (Michel-Behnke et al. 2005; Holzer et al. 2006; Butera et al. 2007a, b; Hirsch et al. 2007; Xunmin et al. 2007; Mo et al. 2011). Because secure placement of these devices in a defect needs appropriate protrusions at the borders of the right and left ventricular aspect, several modifications of the established models for atrial septal defects became necessary. The «Amplatzer membranous septal occluder» shows recesses of the Nitinol meshwork for the aortic valve (■ Fig. 14.6).

This proved to be successful in older children and adults with accordingly relatively small

defects. Direct contact of the device with the neighboring structures of the VSD did lead to some insufficiencies of the aortic and tricuspid valves, which was to be expected. Pressure upon the inferior border of the VSD also induced higher degree heart block up to the need of temporary transvenous stimulation over several weeks (Butera et al. 2006; Walsh et al. 2006; Zhou et al. 2008). Contrary to surgical therapy the possibilities to manage complications are limited, and even the theoretical benefit of a shorter hospital stay with low morbidity may then become obsolete. At present, elective interventional closure of a conoventricular VSD should be limited to a few centers and closely followed by rigid study protocols (Butera et al. 2007a, b; Carminati et al. 2007).

■ Fig. 14.6 «Amplatzer membranous septal occluder.» Lateral aspect. Device mounted on the catheter and expanded; left ventricular disk between 3 and 4; aortic excess length 4 with 0.5 mm being smaller than the septal one 3 with 5.5 mm. Right ventricular disk between 1 and 5, equal excess length of 2 mm. Waist fitting into the VSD (2) with a depth of 1.5 mm. **A** «delivery sheath»; **B** «pusher catheter»; **C** connector at catheter; **D** screw coupling at disk. The dacron-polyester patch material can be seen through the Nitinol mesh (Reproduced from Hijazi et al. (2002); with permission

The limited financial means of emerging countries have stimulated research to further modify occlusive devices for use in the setting of a hybrid approach through a (limited) thoracotomy but without cardiopulmonary bypass. Given the population density of China and the frequency of VSDs as isolated defects, impressive series were published over the recent years (Xing et al. 2010, 2011; Zheng et al. 2009; Chen et al. 2013). The remarkable early outcomes and the active participation in their development have now brought these new techniques to Europe (Schreiber et al. 2012). However, long-term results remain to be evaluated.

14.6.7 Pushing the Limits

Advancements in microtechnology have led to amazing developments like that of a telemetrically adjustable banding device (Bonnet et al. 2004). This plays no role for standard treatment of a VSD. Transcutaneous tunneling of fixation sutures of a pulmonary band also serves the same purpose of avoiding operative readjustments (Choudhary et al. 2006).

Such notions are primarily generated in emerging countries which in theory do offer modern cardiac surgery, but where many patients are presenting only late or in dismal condition due to infrastructural shortcomings. If primary closure of a VSD is attempted in the presence of markedly elevated but still responsive pulmonary vascular resistance, patches with a valve mechanism may be considered (Novick et al. 2005; Zhang et al. 2007). In the event of a critical increase in pulmonary artery pressure, these allow for an overflow of desaturated blood from the right into the left ventricle and thus maintenance of systemic blood pressure at the expense of arterial oxygen saturation. We still use a simple fenestration of the Dacron patch with a standardized punch. Such an opening, usually with a diameter of 3 mm, can be closed consecutively with a catheter intervention if necessary. We feel this to be the safer approach—no risk of «valve» failure—as the limited fenestration should reliably prevent a suprasystemic right ventricular pressure rather than prevent right-sided volume overload which rarely will occur in these patients during long-term follow-up. The

typical scenario is spontaneous closure once the pulmonary resistance drops.

14.7 Perioperative Aspects

For getting informed consent, besides the general risks of open heart surgery, the typical risks of VSD closure must be mentioned: complete heart block with pacemaker dependency, residual defect, and valvular insufficiencies (aortic, tricuspid). On a positive note, it should be emphasized that quality and expectancy of life as well as exercise capacity can be considered normal after a successful transatrial operation (Roos-Hesselink et al. 2004).

Recommendations for the prevention of infective endocarditis have evolved over the years. Antibiotic prophylaxis should be administered in unrepaired VSD as well as any residual defects. Depending on the material, endothelialization of a patch can be considered complete after 6 months, making aggressive antibiotic prophylaxis unnecessary thereafter (Backer et al. 1993; Dajani et al. 1997; Wilson et al. 2007).

During postoperative intensive care therapy, the principles for preventing so-called pulmonary hypertensive crises must be followed, especially in young infants with a markedly raised preoperative Qp:Qs ratio (relaxation, NO application, etc.; see ► chapter «Critical Care in Pediatric Cardiac Surgery», Sect. 10.7 and Sect. 10.11). An early complete heart block may be caused by swelling of the tissue, which will usually resolve within 10–14 days. During this time period, the indication for permanent pacemaker implantation should be handled very restrictively. It is a recommended safety measure to implant two sets of temporary ventricular stimulation leads in any patient who has a higher degree heart block at the end of the operation.

Even if closure of a VSD historically belongs to the first successful cardiac procedures ever, it is by no means a bagatelle or a beginner's operation. Nowadays, it is a requirement to limit this operation only to centers with the necessary expertise in the treatment of congenital heart disease, which is particularly important because the majority of VSD closures must be performed during the newborn period or in early infancy. This is the only way to achieve the necessary quality regarding morbidity and mortality and long-term outcome.

15.1 Tetralogy of Fallot (TOF) with Pulmonary Stenosis

15.1.1 Historical Remarks

The congenital heart defect with ventricular septal defect (VSD), infundibular pulmonary stenosis and/or pulmonary valve stenosis/hypoplasia, dextroposition of the aorta, the aorta overriding the VSD, and right ventricular hypertrophy was clinically and pathoanatomically described and published by Etienne Louis Fallot in 1888 (Fallot 1888), at that time professor for hygiene and forensic medicine in Marseille, France. Although the first pathoanatomic observation was already made by Stensen in 1671 (Stenonis 1671) and again reported by Sandifort in 1777 (Sandifort 1777), the clinical relevance with cyanosis being the leading symptom was first described by Fallot («maladie bleu»). In 1989 his original publication was translated by Richard Van Praagh (Van Praagh 1989). In his comments he emphasized as a key morphologic feature in the cases described, the underdevelopment or hypoplasia of the infundibulum and the right ventricular outflow tract.

It took more than 40 years after the first description by Fallot that the term tetralogy for the four pathoanatomic features was coined in the literature as mentioned by Maud Abbott (1936) and Helen Taussig (1948). At that time the therapeutic options for congenital heart diseases with cyanosis (aka «Morbus caeruleus,» Pfaundler and Schlossmann 1926) were extremely limited. Since November 9, 1944, the options for surgical management opened up with the first subclavian-to-pulmonary-artery-shunt procedure—the so-called Blalock-Taussig shunt (Blalock and Taussig 1945; see also ► Chapter «Surgery for Congenital Heart Defects: A Historical Perspective», Sect. 11.2).

During these years, other systemic-pulmonary artery shunt connections were generated as there were the Potts anastomosis (Potts et al. 1946), the Waterston shunt (1962), and its modification by Cooley and Hallman (1966). The first modified Blalock-Taussig shunt was introduced by using a homograft artery as an interposition graft between the subclavian artery and pulmonary artery (Vishnevsky and Donetsky 1960). A Dacron prosthesis was used by Klinner et al. (1962); DeLeval

et al. introduced small polytetrafluorethylene tubes as shunt material (1981).

The concept of intracardiac procedures developed in 1948 with the «blind» palliative dilatation of the pulmonary stenosis with or without tetralogy of Fallot (Sellors 1948; Brock 1948). The first intracardiac surgical correction of tetralogy was performed at the University of Minnesota in 1954 by Walt Lillehei and Richard Varco using «controlled cross-circulation» (Lillehei et al. 1955; see also ► Chapter «Surgery for Congenital Heart Defects: A Historical Perspective», Sect. 11.2). One year later (1955), the first tetralogy repair employing extracorporeal circulation provided by a heart-lung machine was performed by John Kirklin at the Mayo Clinic (Kirklin et al. 1955). In Germany, the first series of correction of tetralogy of Fallot was published 10 years later (Klinner and Zenker 1965).

Aldo Castaneda in Boston propagated since since the early 1970's primary intracardiac repair in symptomatic infants without prior shunt surgery (Castaneda et al. 1977). The concept of the early primary correction turned out to be advantageous with respect to the development of the pulmonary artery system and the protection of right ventricular function during long-term follow-up (Bacha et al. 2001; Kirsch et al. 2013). Extending the primary repair into the neonatal period mainly for symptomatic patients has been successfully described in the early 1990s by the groups from Boston, Melbourne, and Ann Arbor (Di Donato et al. 1991; Karl et al. 1992; Hennein et al. 1995).

15.1.2 Surgical Anatomy

15.1.2.1 Ventricular Septal Defect (VSD)

The usually large VSD lies posterior and inferior to the infundibular septum. The outlet septum is shifted to an anterolateral position resulting in the overriding position of the aorta and the typical malalignment VSD. The defect comprises a large portion of circumference of the aortic anulus. These morphological signs can easily be demonstrated by echocardiography and have to be considered during surgery to preserve the integrity of the aortic valve.

The VSD may reach the tricuspid valve annulus or is separated from it by a muscular border (posteroinferior limb of the septal band). As this protects the conduction system, suture lines can be placed directly at the inferior VSD rim. If the VSD reaches the tricuspid valve annulus, stitches should be placed at the right ventricular aspect of the septum in some distance to the defect rim and through the tricuspid valve annulus.

Most frequently the hypoplasia or underdevelopment of the right ventricular infundibulum/conus characterizes TOF. The infundibular or conal septum is the cranial margin of the VSD. The conal septum lies in a more horizontal position as a muscular bridge between the interventricular septum and right ventricular free wall, and it has septal and free wall insertions. The septal insertion of the conal septum is cranial to the anterior limb of the trabecula septomarginalis; its lateral portion lies anterior to the tricuspid valve annulus. The patch suture line in this area between the tricuspid valve annulus and conal septum has to run deeply through the trabeculations of the right ventricular free wall. These deep stitches should prevent an intertrabecular residual VSD which has an increased prevalence in this location (so-called intramural residual VSD; Preminger et al. 1994).

15.1.2.2 Right Ventricular Outflow Tract

The anterior deviation of the conal septum, hypoplasia of the right ventricular outflow tract with pulmonary stenosis, and hypoplasia of the pulmonary valve annulus and pulmonary artery trunk are the characteristic anatomic features in TOF. Van Praagh used the term «hypoplasia of the whole right ventricular infundibulum» (Van Praagh et al. 1970). The left and right pulmonary arteries themselves are not hypoplastic. Arborization abnormalities are rarely associated.

Conal septum and trabeculae septomarginalis as a muscular ring create the entrance to the infundibulum («os infundibuli») and contribute mainly to the right ventricular outflow tract obstruction when muscular hypertrophy of the right ventricle increases (■ Fig. 15.1). This hypertrophy leads to the hemodynamically relevant dynamic obstruction by the hypercontractile muscle bundles clinically presenting with hypoxic spells.

■ Fig. 15.1 Transverse axis through the right ventricular outflow tract and «os infundibuli.» The muscular ring is created by the moderator band (trabecula septomarginalis) with the anterior and posterior limb and the anterior and cranial deviation of the conal (infundibular) septum

During intracardiac repair, these muscle bundles are cut (myotomy rather than myectomy) opening the infundibular entrance; in addition secondary endocardial thickening («jet lesions») should be resected to avoid further right ventricular hypertrophy and to preserve right ventricular geometry.

15.1.2.3 Absent Infundibular Septum

Rarely the infundibular septum is extremely hypoplastic or even absent. Aortic and pulmonary valve annuli are separated only by a small fibrous band; the VSD is orientated to both the aorta and pulmonary artery, i.e., it lies subarterial («doubly committed»). In these cases, predominantly a pulmonary valve stenosis with valve dysplasia or associated pulmonary annulus or trunk hypoplasia determines the right ventricular outflow tract obstruction; if the dynamic obstructive component is missing, typical hypoxic spells cannot develop. However, sudden hypoxemia might occur as a result of an acute increase in pulmonary vascular resistance leading to intracardiac right-to-left shunt.

15.1.2.4 Pulmonary Valve and Pulmonary Arteries

The pulmonary valve is usually abnormal. It may display a wide spectrum of dysplasia. The anulus might be hypoplastic with a thickened, cartilaginous, and immobile valve without identifiable commissures; the valve might be bicuspid with less severe stenosis or has a nearly normally developed anulus with a mildly stenotic tricuspid valve.

The pulmonary trunk can be small or hypoplastic corresponding to a narrowed or hypoplastic right ventricular outflow tract. The pulmonary arteries most often are not hypoplastic and they are in continuity. The bifurcation shows a more superior-inferior relation of the arteries; angiography might demonstrate the «seagull sign.»

In many patients, especially in presence of hypoplastic pulmonary arteries, a coarctation of the pulmonary artery can develop at the site of the entrance of the ductus arteriosus (Luhmer and Ziemer 1993). Distal pulmonary artery stenosis is uncommon in TOF with pulmonary stenosis. Isolation of the pulmonary artery is a rare finding; the pulmonary artery has some connection to the aortic arch via arterial duct or its ligament. Aortopulmonary collateral arteries are rare also. This might indicate severe right ventricular outflow tract obstruction or even functional atresia.

15.1.2.5 Coronary Artery Anomalies

Abnormal origin and distribution of the coronary arteries can be expected in nearly 4% of the patients (Fyler 1992). They have surgical relevance mainly in two variants: anomalous origin of the left anterior descending coronary artery (LAD, or: ramus interventricularis anterior, RIVA) from the right coronary artery, which crosses the right ventricular outflow tract and interferes with the surgical transinfundibular correction and transanular patch insertion. A comparable situation is given if the right coronary artery originates from the RIVA. The coronary artery anatomy is almost always identifiable in infancy. Enlarged conal branches arising from the right coronary artery can cross the right ventricular outflow tract to reach the ventricular apex; these branches should also be preserved at surgery.

Coronary artery anomalies are well known in the setting of TOF and should be diagnosed preoperatively; detailed preoperative description is especially mandatory in the situation of reoperation when intraoperative identification might be difficult.

15.1.2.6 Associated Anomalies

The most relevant associated intracardiac anomaly is the atrioventricular septal defect (described in nearly 4% of TOF patients) (Fyler 1992; McElhinney et al. 1998b; Najm et al. 1998) with the pathoanatomy of Rastelli type C (Suzuki et al. 1998). The primum defect component is often small, the VSD huge, extending anteriorly into the infundibular septum. A right aortic arch is often found in patients with TOF; an additional muscular defect, straddling tricuspid valve, or atrial septal defect has to be detected preoperatively as well as partial anomalous pulmonary venous drainage or left-sided persistent superior caval vein (LSVC).

Associated syndromes as microdeletion 22q11, trisomy 21, or Goldenhar syndrome have to be considered.

15.1.3 Clinical Diagnosis

Clinical symptoms depend on the severity and progression of the right ventricular outflow tract obstruction. Neonates with severe right ventricular outflow tract narrowing may present with cyanosis immediately after birth. Cyanosis aggravates with physical activity. An arterial duct may significantly contribute to pulmonary blood flow and arterial oxygenation and has to be maintained patent by infusion of prostaglandin E. In most infants right ventricular outflow tract obstruction initially causes only mild or moderate cyanosis; first symptom could be a systolic murmur at routine examination. As the infundibular (dynamic) obstruction will increase over time, cyanosis can deepen, and hypoxic spells can occur. These hypercyanotic attacks are the indication for treatment either surgical (intracardiac repair; BT shunt) or by catheter intervention depending on patient's age, anatomy, or

associated anomalies. Medication with β -blockade can bridge to surgical or catheter intervention.

Clubbing of fingers, squatting, and complications of intracardiac right-to-left shunt such as brain abscesses are now rare observations since intracardiac repair is usually performed during infancy when first clinical symptoms appear; elective repair is preferentially performed beyond the age of 3 months (Kirsch et al. 2013).

15.1.4 Diagnostic Procedures

Comprehensive diagnosis with description of all anatomic details is provided by echocardiography. Features such as right ventricular hypertrophy, anterior deviation of infundibular septum, infundibular elongation or hypoplasia, central pulmonary artery system, and overriding of the aorta with a malalignment VSD are identified; associated anomalies including coronary artery anomalies can be ruled out.

Cardiac catheterization at primary diagnosis is now rarely indicated; in consultation with surgery, it can be combined with an interventional procedure as balloon valvuloplasty, stent implantation, or occlusion of aortopulmonary collateral vessels depending on the individual situation of the infant. Angiography allows judgment of the development of the pulmonary artery system or coexisting aortopulmonary collateral vessels (Mackie et al. 2003). It has to be considered that in low pulmonary flow situations, the potential diameters of the neonatal and infant central pulmonary arteries are underestimated.

15.1.5 Surgical Management

The diagnosis of tetralogy of Fallot implicates the need for an intracardiac repair in infancy. Symptomatic infants, especially those with hypoxic spells, have to be admitted to hospital for urgent surgery. Neonates on prostaglandin infusion require surgery between the second and fourth week, most often corrective, seldom palliative.

In symptomatic neonates or infants as an emergency measure or in patients with associated anomalies requiring attention, cardiac catheterization with intervention may be indicated: for balloon valvuloplasty of the pulmonary stenosis or stent implantation into the patent arterial ductus. In these special situations, the intracardiac repair can be postponed.

While our general practice is primary repair for TOF whenever surgery is indicated, we prefer palliative procedure with a modified BT shunt in situations after cardiac decompensation and metabolic acidosis or if during anesthesia induction for primary repair prolonged acidosis and resuscitation occurred.

Elective surgical repair in oligo- or asymptomatic infants should be performed at the age of 3–6 months (Kouchoukos et al. 2003; Kirsch et al. 2013). Although elective neonatal repair in all patients has been recommended (Hirsch et al. 2000; Parry et al. 2000), waiting beyond the neonatal period is advisable considering the aspect of maturation of organ system (i.e., pulmonary vascular system, kidney). The incidence of a transanular patch plasty is reported to be higher in this age group (Stellin et al. 1995).

With the high incidence of reoperation for pulmonary regurgitation after TOF repair, originally valve-sparing transatrial approach was favored whenever possible. More recently, valve-sparing and reconstructive procedures were suggested in any TOF patient. Their long-term benefit has not been shown, yet; however, the requirement of early reoperation for residual stenosis became more frequent (Stewart et al. 2005; Hirji et al. 2010; Robinson et al. 2011). If the pulmonary valve cannot be spared, there is no long-term benefit of a strict transatrial vs. a transinfundibular repair with transanular patch after 12 years (own unpublished data from Tuebingen, Germany, in 110 uncomplicated TOF patients repaired in infancy).

If the left anterior descending coronary artery (LAD) coming off the right coronary artery (RCA), or less often a RCA coming off the LAD, is crossing the RVOT and a transatrial approach for repair is not feasible, we prefer RV to PA conduit parallel to the native RVOT as part of a repair rather than a palliative shunt procedure.

15.1.6 Surgical Management in TOF with Pulmonary Stenosis

15.1.6.1 Palliative Procedures

The concept of aortopulmonary *shunt procedures* was developed to treat deep cyanosis in critically ill infants and/or to replace the prostaglandin-manipulated ductus arteriosus. Intracardiac repair can follow at the age of 2–3 months electively. In very small (<2 kg) or preterm infants or those with hypoplastic pulmonary arteries or associated extracardiac anomalies, palliation by transcatheter *balloon valvuloplasty* can postpone surgery if desired (Qureshi et al. 1988; Sluysmans et al. 1995); additional β -blocker medication can be useful to reduce the dynamic infundibular obstruction.

Surgery should be performed via a median sternotomy. Several technical variants have been suggested.

■ ■ Blalock-Taussig Shunt

The subclavian artery opposite to the side of aortic arch is divided and the proximal part is anastomosed to the same-sided pulmonary artery end to side, i.e., in patients with left aortic arch, the right subclavian artery and right pulmonary artery will be connected. Sufficient collateralization will develop via the vertebral artery if left patent but also via neck and shoulder vessels. Deficiencies of peripheral circulation are rarely found (Mearns et al. 1978), but growth retardation or «subclavian steal» syndrome has been described as late complications (Skovranek et al. 1976; Sokol et al. 1969). If this «classic» Blalock-Taussig shunt is created with the subclavian artery on the side of the aortic arch, stenosis at the takeoff of the subclavian artery frequently develops, and special precautions have to be taken (Laks and Castaneda 1975).

■ ■ Modified Blalock-Taussig Shunt

The procedure of choice for primary palliation in selected patients with TOF as well as in duct-dependent univentricular circulation is the modified Blalock-Taussig shunt (MBTS; deLeval et al. 1981; Vishnevsky and Donetsky 1960; Klinner et al. 1962). It is created via median sternotomy by interposing a polytetrafluorethylene prosthesis with a diameter of 3.5–4 mm between the brachiocephalic trunk/proximal subclavian artery and the right pulmonary artery with end-to-side anastomoses at both ends of the prosthesis. In patients

with left-sided aortic arch, the shunt runs interaortocaval to the right pulmonary artery. In right-sided aortic arch with «mirror-image branching,» the shunt runs around the aortic arch. Regardless of the sidedness of the aortic arch, we suggest to always use the right subclavian artery/brachiocephalic trunk and right pulmonary artery as first choice for a MBTS. Potential risks are pulmonary artery stenosis at the site of the shunt insertion and distortions, damage to the recurrent laryngeal or phrenic nerves, and increased pulmonary blood flow with systemic steal. Acute thrombosis is a rare complication in small infants; many centers use aspirin for prophylaxis of thrombosis. Newer antiplatelet agents may be more efficient. The best preventive measure to avoid shunt thrombosis is a nonrestrictive anastomosis at both shunt ends.

A theoretical *advantage* of the MBTS over a central aortopulmonary shunt is a kind of auto-regulation of blood flow due to the dampening action of the brachiocephalic trunk against the dynamic component of the aortic «Windkessel» function. This supposedly leads to less diastolic runoff (hearsay).

A *disadvantage* of the MBTS is secondary hypoplasia or iatrogenic stenosis of the pulmonary artery, both being repeatedly reported (Sachweh et al. 1998). These sequelae are less important in patients after emergency creation of a shunt, as in these instances further palliation or definitive repair should follow rather timely within weeks or a few months.

After mobilization of the innominate vein and the brachiocephalic trunk, the right pulmonary artery should be circumferentially dissected up to the branching sites. We prefer to use individual vessel loop maneuvers around the upper lobe and intermediate right pulmonary artery branch. Conventional vascular clamps tend to be too bulky. Alternatively a C-clamp (e.g., Cooley clamp) can be used which is placed from cranial and centrally. For the proximal (systemic) anastomosis, the polytetrafluorethylene prosthesis should be cut obliquely, while the pulmonary end is cut in a convex fashion to ensure a good adaptation of the T-shaped anastomosis to the circumference of the pulmonary artery. The length of the prosthesis is estimated in situ without any tension or distortion of the target vessels (■ Fig. 15.2).

Subadvential sutures delineating sites and size of the planned arteriotomies may facilitate

■ **Fig. 15.2** Trimming of the polytetrafluorethylene prosthesis to perform the modified Blalock-Taussig shunt. The systemic arterial end is cut obliquely to align with the brachiocephalic trunk. At the pulmonary end, a convex cut longitudinal with the RPA allows for best fit

and optimize the correct placement and course of the shunt. After administration of heparin (100 IU/kg), both the pulmonary artery and the brachiocephalic trunk are clamped. Peripheral and cerebral (NIRS) oxygen saturations and hemodynamics are monitored. Typically systemic saturations remain unchanged. If not, increase of FIO_2 by anesthesia may be helpful. In case of hemodynamic instability which cannot be treated with volume (erythrocyte concentrate) and ventilatory alteration, the procedure should be performed employing extracorporeal circulation with the heart beating. Circulatory impairment may have been caused also by mechanical interference from pulling at the pulmonary artery or compressing the aorta.

Our preferred method in both biventricular (very rare) and univentricular heart is the *central aortopulmonary shunt* employing a ring-reinforced polytetrafluorethylene prosthesis. Newborns with a patent arterial duct in general tolerate side bite clamping of the pulmonary

trunk very well. While the site for the pulmonary anastomosis is only slashed, at the aorta after a short incision a punch hole (diameter 4 mm) is created. This circular orifice allows a more harmonized anastomosis. If clamping of the pulmonary artery is not tolerated or in case of a pulmonary coarctation, normothermic cardiopulmonary bypass may be established as described for MBTS above. In infants the shunt should be about 4 mm in diameter (with a body weight of less than 3 kg 3.5 mm), beyond the first year of age no more than 5 mm. The use of oversized shunts doesn't enhance the systemic oxygenation, and it even leads to an increased left ventricular afterload, unrestricted pulmonary artery vasculature provided. For the course of central shunts in neonates and infants, see also ■ Fig. 15.13b.

Any other historical shunt procedures (Potts, Waterston, Cooley) are obsolete for many years due to frequent secondary complications. They may, however, be used as a rare bailout procedure in repetitive early, sometimes already intraoperative prosthetic shunt thrombosis unrelated to surgical technique.

15.1.6.2 Intracardiac Repair

■ ■ Management of extracorporeal circulation

Correction of a tetralogy of Fallot in neonates and infants can be performed in deep hypothermic circulatory and cardiac arrest (DHCA). Normothermic or mild hypothermic bypass and cardioplegia, however, are the most frequently used techniques. After pericardiotomy, the arterial duct if still patent is dissected. With acceptable levels of peripheral oxygenation, the dissection of the main pulmonary artery and its branches (if required) can be performed before installing cardiopulmonary bypass. If oxygenation is impaired, these maneuvers should be performed with the aid of cardiopulmonary bypass conveniently during the cooling period. The arterial cannulation may be selected distal at the ascending aorta slightly shifted to the right to facilitate better access to the potential area of surgery: RVOT and MPA. In presence of a right aortic arch (25% of TOF patients), the left-sided brachiocephalic trunk is dissected to install the aortic cannulation proximal to it avoiding an iatrogenic stenosis of the origin of

the trunk by tightening the purse-string suture. Depending on the bypass strategy, a solitary venous cannula is inserted via the right atrial auricle or two cannulae are used for both SVC and IVC individually. During the cooling period, the dissection of the pulmonary artery is completed. The clamping of the aorta is carried out in deep hypothermia or whenever cardioplegia is planned to be delivered. In circulatory arrest the venous cannula is removed routinely, and the right atrium is incised and inspected. In cases with an intact atrial septum, temporary atrioseptostomy in the area of the fossa ovalis is performed. This helps venting the left heart and finally de-airing also.

Immediately after closure of the VSD, in cases where DHCA was employed, systemic reperfusion may start with a reduced flow rate of 25% of the calculated flow returning the venous blood by the cardiotomy sucker. The temperature of the perfusate should be maintained at 20°, and rewarming should start only after release of the aortic cross clamp, allowing for coronary perfusion. This may happen immediately after the left heart is de-aired through the atrioseptostomy and the proximal ascending aorta, and the atrial septum is closed. The venous cannula is reinstalled after closing the atriotomy. For patients after DHCA, after release of the aortic clamp, the pressure of the perfusion may stay at <30 mmHg for 10 min. With flow rates of >50%, the rewarming can be continued at temperatures of 25°. During the rewarming period, the patch of the right ventricular/transannular outflow tract can be sewed if necessary. Usually the time of the circulatory arrest needed for a transinfundibular correction of a TOF lies between 20 and 30 min.

For patients operated upon in normothermia or mild hypothermia with bicaval cannulation, de-airing of the left heart is performed immediately after VSD and ASD closure, followed by release of the aortic cross clamp, allowing for myocardial reperfusion and rewarming as necessary. The remainder of the repair is performed on the beating heart.

■ ■ Transinfundibular Repair

The classical surgical technique of tetralogy of Fallot associated with a pulmonary stenosis is

carried out via transinfundibular access. The incision is performed in a longitudinal direction in continuation of the center line of the pulmonary artery. It is not necessary to extend the incision beyond the infundibulum into the right ventricular cavity. Former descriptions including their drawings show ample incisions in direction of the apex and beyond the infundibulum cause right ventricular dysfunction. If a transannular patch plasty is not necessary, the infundibulotomy should start strictly inferior to the anulus. Cutting the crista supraventricularis should be avoided also.

In neonates, the spatial relations are more critical than in older patients. As the sutures of the outflow tract patch consume relatively more of the ventricular wall, the course of the RIVA/LAD has to be considered at any time, with any stitch of the RVOT patch suture. A retrospective study attributed the strikingly increased mortality after performing surgery of the tetralogy of Fallot in neonates at that time to a possible ischemia of the area provided by the RIVA/LAD without showing pathological signs of a complete occlusion (DiDonato et al. 1991). Placing two superficial sutures at the collapsed right ventricle before infundibulotomy provides a guideline for the incision projected in the longitudinal axis of the pulmonary artery.

A retractor placed in the apical angle of the infundibulotomy helps in identifying the intracardial anatomy.

In today's approach of neonatal and infant tetralogy repair, transection rather than resection of abnormal and potentially obstructing muscle bundles is required. After sectioning some bundles of muscles in the area of the lateral insertion of the deviated conus septum, the so-called dynamic component of stenosis is usually eliminated. More incisions, or eventual resection of muscles, may be necessary in presence of «jet lesion,» especially in older kids, which can be found at spots of distinct flow acceleration. Although jet lesions are located very often at the conus septum, a resection of muscles is not recommended because of the aortic

valve closely behind the middle part of the septum. Only a sparing resection of the fibrotic component is required and suggested.

Regarding the long-term results, the actual Achilles' heel of tetralogy repair is the pulmonary valve. In symptomatic patients with TOF, there almost always is a valvular component of the obstruction, which requires surgery. In fact a complete resection is only considered in cases of an acommisural cartilaginous membrane. A stepwise separation using Hegar dilators should be performed even at tenuous tricuspidal designed valves. More recently intraoperative balloon dilation combined with pulmonary valve sparing and reconstructive techniques are suggested without having produced superior intermediate results, yet.

The diameter of the anular ring can be sufficiently determined preoperatively by echocardiography and may be taken as a measurement for the extent of dilation rather than the calculated diameter related to the surface of the body. The use of dilators larger than the diameter of the anulus minus the standard variance is not recommended. The use of bigger dilators can lead to paracommissural tears in the wall of the pulmonary artery and the anulus. It is absolute important to handle the valve tissue gently and to maintain/preserve the sufficient valve. But it has to be considered that the anulus of the pulmonary valve, in contrast to all other heart valves, is completely muscular. Therefore, regurgitation can develop caused by an aneurysmatic dilation of the infundibulum and anulus even in the case of an originally preserved tenuous tricuspidal designed valve (see also below, ► Sect. 15.2: «Long-term Complications After TOF Repair»).

For VSD closure, we prefer using a Dacron patch. The patch is sutured using a running polypropylene suture (5/0 or occasionally 6/0 in neonates, 5/0 in infants and young children, later 4/0).

Despite different techniques of sutures and patch materials, it is expedient to apply some principles of surgery to a VSD closure (■ Fig. 15.3). The suture should commence at the deepest and farthest point, at the area of the tricuspid anulus for the transinfundibular approach. In the case of a defect reaching the tricuspid valve (perimembranous malalignment VSD), the first U-stitch of any suture should be placed preferably through the orifice

of the valve to the anulus, entering now from the atrium and placed in the area of the antero-septal commissure (A in ■ Fig. 15.3b). Placing a rigid sucker through the VSD facilitates visualization and technical accessibility. Lowering the patch into the field, the next stitches should be placed close to the aortic valve (B in ■ Fig. 15.3b), followed by sutures postero-caudal on the side of the right ventricle, far apart from the defect (C in ■ Fig. 15.3b). It is imperative not to touch or enclose the medial papillary muscle by the suture (Lansici muscle), because a resulting insufficiency of the tricuspid valve will not be tolerated hemodynamically by the hypertrophic and hyperdynamic right ventricle in the early postoperative period. After four to five stitches, ensuring the critical area, the patch should be sewn in the posterior cranial angle using an additional suture (D in ■ Fig. 15.3b). This area has some irregular trabeculae and was usually incised during the former resection/incision of the infundibulum. To avoid intramural residual VSDs and to compensate the missing relative solid endocardium, the stitches should be applied very profoundly. Reaching the lower edge of the conus septum, the stitches should be applied also strong but more superficial to avoid any injury of the aortic valve situated directly behind the conal septum (E in ■ Fig. 15.3b).

Patch closure of the infundibulotomy (isolated at the infundibulum or extending transanular) may be performed during rewarming on bypass with the heart beating.

For patch closing the infundibulotomy, it is absolutely necessary to use two suckers to obtain a blood free and sufficiently clean situs. Any distortion has to be avoided in order to prevent any stenosis especially in the area of the critical distal angle in the MPA or at the anulus, respectively.

■ ■ Transanular right ventricular outflow tract patch

We almost exclusively use polytetrafluorethylene (0.4 mm thick) as reconstruction material for the right ventricular outflow tract. An alternative can

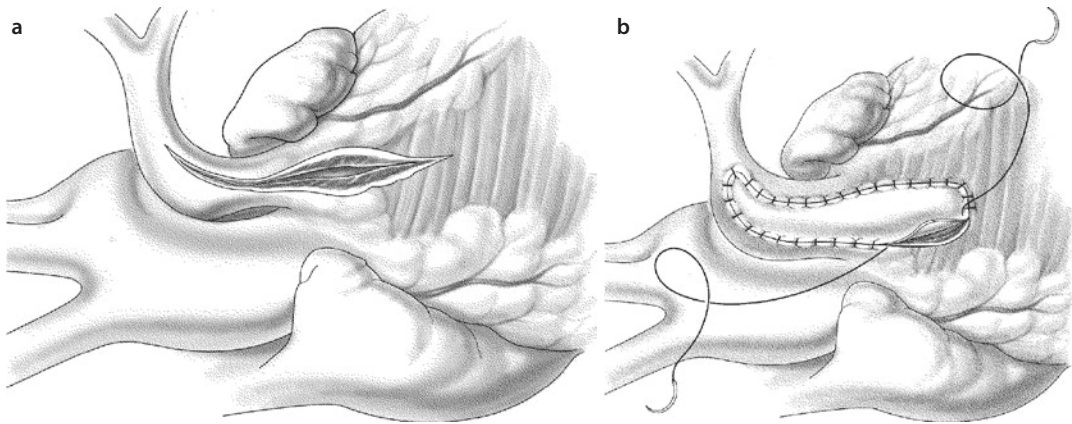

Fig. 15.3 a Transfundibular approach for tetralogy of Fallot repair. The septal and parietal branches, respectively, of the conus septum are already incised. In general the edges of the VSD cannot be visualized simultaneously at one glance. b Semi-schematic depiction of the circumference of the VSD. Segment A aortic tricuspidal angle; segment B inlet septum with the bundle of His running at the edge of the ventricular septum, sometimes place of insertion of isolated tricuspid valve chordae; segment C trabecular septum (smooth surface); segment D conus septum with the aortic valve directly behind it; segment E crista supra-ventricularis with irregular and sometimes very deep trabeculae. c Distance and depth of the stitches from the defect to the different parts of the circumference of the VSD

be autologous pericardium, homograft, xenograft, or Dacron. In case of a sufficiently wide pulmonary valve anulus (>2 standard variation compared to normal), the integrity of anulus and valve may be retained by using only a strict infundibular patch. But in the case of a severely hypoplastic or atretic anulus, a transanular patch has to be used. The incision is carried out into the pulmonary bifurcation, at least to the origin of the right pulmonary artery or in case of a pulmonary coarctation even further into the left pulmonary artery (■ Fig. 15.4). In order to avoid distortion of the bifurcation or its

branches by the patch and to achieve a sufficient dilatation at the same time, we occasionally use third- or half-pipe-shaped pieces produced by longitudinal incised appropriate-sized PTFE grafts (diameter 6–8 mm). The given convexity of the graft/vascular prosthesis prevents the distortion or occlusion of the vascular lumen even using a corresponding wide patch. These bulged reconstructions adapted itself to the growing vascular structure by time. A notable oversizing is not desirable; the diameter of the anulus may not exceed the calculated item related to the surface of the body.

■ **Fig. 15.4** a In case of a suspected pulmonary artery coarctation, the incision may reach into the left pulmonary artery. b The bulging patch may be cut almost rectangular at its ends. The maximum diameter is located at the level of the anulus

The suture line commences in the distal angle and runs proximal to both sides in increments using a running suture (polypropylene).

For the patch suture line, the stitches in the pulmonary artery wall should be congruent to those in the patch, whereas the stitches performed in the myocardium of the infundibulum are far wider and deeper than in the patch for reasons of hemostasis. At the apical end of the patch, more length of the patch than in the myocardium is used to retain the bulge of the patch. It is not necessary to aim for full-thickness bites, as the main mechanical hold for the suture is provided by the epicardium. The adjacent coronary arteries must not be compromised, especially the LAD. The covering epicardium overlying the coronary has to be incised occasionally, giving relief of tension which may have occurred.

There are different suggestions regarding technical innovation to replace the valvular function by some working groups, e.g., the so-called monocusp valve by the Loma Linda group (Gundry et al. 1994). This technique utilizes insertion of a semilunar cusp of the same material as the transannular patch (autologous pericardium or 0.1 mm thick PTFE membrane). Originally this idea came up in the early 1970s but did not show any ongoing effects on the pulmonary regurgitation except an early postoperative improved function of the valve (Ionescu et al. 1979). John Brown from Riley Children's reported midterm results on improved function of the monocusp valve without any major regurgitation in 48% of his patients after 10 years (Brown et al. 2007).

■ ■ Transatrial correction

This technique had been already described in the early 1960s (Hudspeth et al. 1963). But in the following three decades, the original transinfundibular correction (Lillehei et al. 1955) was established (Kirklin and Karp 1970) and became accepted as the almost exclusively used method (Castaneda et al. 1977). There were occasional reports in the literature using a transatrial correction, e.g., in case of coronary anomalies or as a secondary correction after primary palliation in older children (Brizard et al. 1998). The use of a «partial-transatrial» correction with a transatrial closure of the VSD and a limited distal infundibulotomy had been also established in some centers (Edmunds et al. 1976; Kawashima et al. 1985; Atallah-Yunes et al. 1996).

With a growing number of patients undergoing reoperation after transinfundibular repair, a renewed interest in transatrial approach came up, hoping to preserve right ventricular integrity and thereby long-term function. During the last 25 years, our strategy moved also toward this direction; beyond the early postnatal phase, it became our preferred access for repair of uncomplicated tetralogy of Fallot.

After performing a right atriotomy, the VSD can be seen through the tricuspid valve after retracting the septal leaflet and anterior anulus with the assistance of two small retractors, set asserted at 11 and 2 o'clock position in the surgeon's view. The VSD is located far more cranially compared to a perimembranous VSD. The overriding aortic valve is seen very clearly through the VSD (■ Fig. 15.5).

■ **Fig. 15.5** Transtricuspid exposure of the intraventricular anatomy after the conal septum had been already incised. In this view and exposure, the entrance of the right ventricular outflow tract is located somewhat apical and slightly cranial of the VSD

The more or less narrow entrance of the right ventricular outflow tract seems to be almost at the same level as the VSD, immediately distal to it. As first measure after exposure, it is recommended to identify the VSD as well as the right ventricular outflow tract («os infundibuli») before any further surgical maneuver. A cranially directed right angle clamp introduced into the distal right ventricular outflow tract or even farther into the pulmonary artery should be palpable.

The further enlargement of the right ventricular outflow tract follows the same principles and anatomic points of reference as described for the transinfundibular approach. First the septal and parietal extensions of the conus septum have been transected enlarging the entrance of the right ventricular outflow tract. A slightly opened right angle clamp placed around the muscle bundles prevents accidental perforation of the infundibular wall. To expose the immediate subpulmonary infundibulum more clearly, the conal septum can be retracted. The principles of resection on the basis of «jet lesions» present apply with the transatrial approach also. The goal of the transatrial resection is free access to the pulmonary valve, which is reached when the valve can be clearly seen. This at times may be burdensome but is easier with a short

infundibulum. Further distal infundibular stenosis has not been described in infants. The valvular stenosis is treated by a stepwise dilation with Hegar dilators through the tricuspid valve. Giovanni Stellin's group described intraoperative balloon valvuloplasty (Vida et al. 2012).

Patch closure of the VSD is performed with a running suture. Typically, neither septal chordae nor aneurysmatic tissue of the tricuspid valve is in the way. The first U-shaped suture should be placed at the apical angle/deepest point of the VSD. The further steps are corresponding to the transinfundibular approach.

We do not have any experience with the recently revisited technique by Rene Petre when he still was in Zurich (Till et al. 2011). Whenever possible, they employed a method of direct closure of the VSD or just with a tiny patch after mobilization of the conal septum.

■ ■ Atrial septal defect/patent Foramen ovale

Among others, several reference articles (Hirsch et al. 2000; Jonas 2004) favor to leave a small communication in the atrial septum in neonatal and infant TOF repair. The argument for this procedure is similar to a «fenestrated Fontan»: the gap acts as a relief when early postoperative right ventricular dysfunction leads to high venous pressures with low cardiac output, maintaining at the same time a better cardiac output at the expense of cyanosis. Though in most TOF patients the right atrial pressure is 10 mmHg or more during the first 24 h postoperatively, it seems to be exaggerated as a routinely performed preventive measure. The short-term advantage may be transformed later into a disadvantage as most of the patients do not require such a procedure—a technical perfect surgery presumed.

If, however, right ventricular dysfunction persists at the end of surgery, not explainable intraoperatively by measurements of hemodynamic parameters and echocardiography atrioseptostomy or an open foramen ovale may be helpful. During postoperative care, one has to be aware of the cause of lower oxygen saturation and act/not act appropriately.

■ ■ Termination of the extracorporeal circulation

Coming off bypass, two fundamental principles of TOF repair should be kept in mind:

- The hypertrophic right ventricle used to systemic pressure has to adjust to the lower afterload while still requiring elevated preload. This process of adaptation takes a few days during which a certain degree of diastolic dysfunction will persist.
- Although relatively common, a low systemic arterial pressure immediately after termination of the extracorporeal circulation is not ideal for the hypertrophied right ventricle. With a usually good systolic function of both ventricles, we limit pharmacological intervention in most instances to dopamine 5–10 µg/kg/min and nitroglycerin 5–10 µg/kg/min. Further enhancement of inotropy is usually not necessary; it may even be counterproductive. With a moderately elevated preload of the right ventricle of 11–12 mmHg (temporarily not exceeding 14–15 mmHg) to start with, spontaneous and lasting improvement of the arterial blood pressure occurs almost constantly accompanied by a simultaneous decrease of the atrial pressure by 1–3 mmHg within about 10 min after coming off bypass.

Left atrial monitoring catheters are rarely used, only when poor left ventricular function requires additional monitoring.

The early postoperative management on the ICU follows the principles already applied intraoperatively. Only a decrease of myocardial contractility of the left ventricle may mandate additional support with inotropic drugs. Due to the prevailing diastolic dysfunction of the right ventricle, an increased use of inotropic drugs is not sufficient and may produce or maintain a junctional tachyarrhythmia (see ► Chapter «Critical Care in Pediatric Cardiac Surgery», Sect. 10.3.2.3). Phosphodiesterase inhibitors may be indicated; however, their peripheral vasodilation may limit their effectiveness.

15.1.7 Restrictive Physiology of the Right Ventricle Early and Late Postoperatively

After corrective surgery for TOF, diastolic dysfunction with reduced right ventricular compliance can develop and is well documented by echocardiographic Doppler studies even in

presence of an ideal surgical result. Systolic right ventricular function may be preserved. The Doppler profile in restrictive RV physiology is characterized by antegrade diastolic flow at the time of atrial contraction, sometimes accompanied by retrograde flow in the superior caval vein (Gatzoulis et al. 1995a); the duration of pulmonary regurgitation may be shortened. During the early postoperative period, it is important to establish sinus rhythm and an adequate preload (12–15 mmHg). As systolic function is preserved, catecholamine support is less necessary and has potentially disadvantageous inotropic and chronotropic effects; the use of inodilators is preferred. Whether early postoperative restrictive physiology is associated with superior right ventricular performance and less right ventricular dilatation during long-term follow-up is still matter of discussion.

15.2 Long-Term Complications After TOF Repair

15.2.1 Recurrent Right Ventricular Outflow Tract Obstruction

The surgical concept of primary intracardiac repair in symptomatic infants and neonates includes patch closure of the ventricular septal defect and relief of the right ventricular outflow tract obstruction. Whenever possible, a functional pulmonary valve will be preserved, even if a mild to moderate transvalvular gradient will persist. This bears the potential advantage of less pulmonary insufficiency and right ventricular dilatation during midterm follow-up. If the postoperative right ventricular pressure exceeds 75% of systemic ventricular pressure, a second operation with muscle bundle resection or transannular patch plasty is indicated, depending on the site of residual obstruction. This is also true for the intraoperative residual RVOT at the time of primary repair. Restenosis at the annular level might develop in children with annular hypoplasia (also in patients with primary pulmonary atresia). Using a transannular patch in pulmonary atresia patients, growth can occur only at 20% of the annular circumference. Therefore trans «annular» repair of TOF/PA bears the rather calculated risk

of reoperation, while the alternative, namely using a conduit, will definitely lead to later reoperations in all patients.

15.2.2 Pulmonary Stenosis and Bifurcation/Left Pulmonary Artery Stenosis

The rare event of pulmonary arteries being primarily very small can result in a significant post-operative elevation of right ventricular pressure to start with.

Recurrent or residual stenosis at the origin of the left pulmonary artery, at the site of the former ductus entrance, is discussed as *Coarctatio pulmonalis* in ► Chapter 21, «Anomalies of the Great Intrathoracic Vessels». The insertion of the BT shunt can cause peripheral branch stenosis requiring patch plasty or catheter intervention (balloon angioplasty ± stent implantation). The same intervention might be necessary if the stenosis at the distal patch end of the RVOT patch plasty is compromising the vessel lumen or causing bifurcation stenosis to the right and or left pulmonary artery. Decision-making for interventional dilation ± stent placement versus surgery should take the state of the repaired RVOT into account: if no further surgery for the RVOT is planned, catheter intervention may be the treatment modality of choice. If in the near future, for example, a conduit replacement was planned anyways, it may be performed sooner and now would include bifurcation plasty also.

Reconstructive procedures at the pulmonary bifurcation can cause kinking by vessel remodeling even years after primary surgical correction. Elongation of the right ventricular outflow patch plasty into the pulmonary bifurcation can cause distortion of the pulmonary arteries resulting in relevant Doppler sonographic pressure gradients. As a catheter intervention approach, balloon angioplasty alone can rarely relieve the stenosis, stent implantation is required; surgical reintervention allows usually restoration of the geometry of the bifurcation (■ Fig. 15.6). Replacement of the patch by a new one and individual techniques to solve the distortion are recommended (Fraser et al. 1995), sometimes with reinsertion of the left pulmonary artery (McElhinney et al. 1998a). In

most patients with peripheral pulmonary artery stenosis after TOF repair, pulmonary insufficiency is the second leading symptom. Therefore, in these cases, pulmonary valve replacement should be combined with a patch plasty (see ► Sect. 15.2.3).

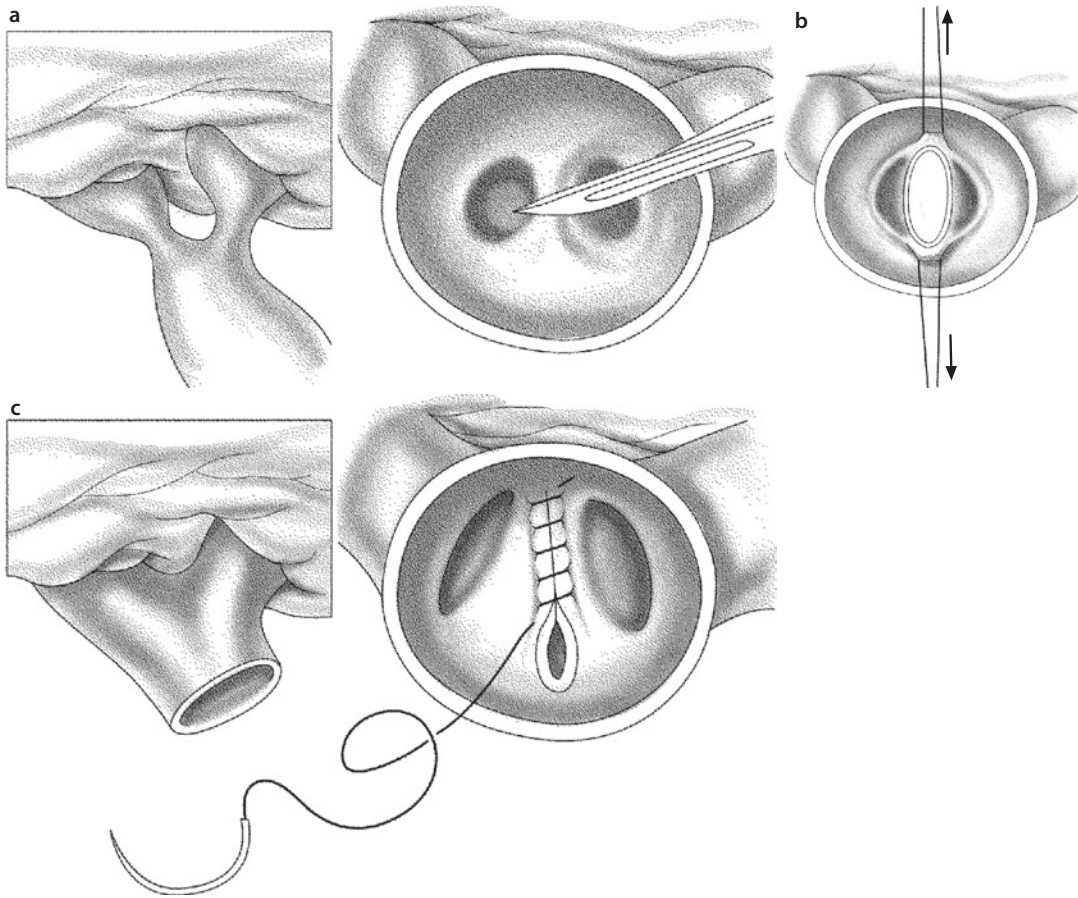

In patients less than 5 years of age, we rarely implant pulmonary valves unless severe right ventricular dilatation and dysfunction is present. These patients are rather candidates for adequate patch reconstruction of RVOT/MPA/pulmonary bifurcation.

15.2.3 Pulmonary Regurgitation

15.2.3.1 Consequences of Pulmonary Regurgitation

Pulmonary «valve» insufficiency is described in up to 90% of the patients after correction of tetralogy of Fallot. The right ventricular volume load and dilatation are clinically compensated for many years, but reduced exercise tolerance will develop in adolescent patients with an increased risk for exercise-induced arrhythmia. Because of the interventricular interaction also the left ventricular function might be impaired. The increase in right ventricular conduction delay aggravates the ventricular dyssynchrony. Relevant ventricular arrhythmia turned out to be associated with older age at operation, higher proportion of ventricular fibrosis, and extended infundibulotomy/ventriculotomy; ventricular dysrhythmia, right ventricular dilatation, and QRS prolongation are associated with the risk for sudden death (Gatzoulis et al. 1995a; b; Norgard et al. 1996). An overview of post tetralogy repair RV pathophysiology was published by Andrew Redington, whose group took the lead in these investigations (Redington 2006).

Increasing right ventricular dilatation in the context of pulmonary regurgitation is the main indication for reoperation. During recent years, criteria for intervention have been continuously discussed: currently right ventricular enddiastolic volume on MRI >140 ml/m² and a regurgitation fraction of >35%. A right ventricular volume index of less than 160 ml/m² is said to allow normalization of right ventricular volume and function after relief of volume load. Right ventricular

■ **Fig. 15.6** Internal plasty for pulmonary bifurcation stenosis. **a** Potential outer appearance of bifurcation with proximal branch stenosis (not to be externally dissected), may be anatomical or functional. **b** Excision of neighboring RPA/LPA wall, creating a whole thickness defect, extended by stay stitches. **c** By suturing the edges of the defect, a V-Y plasty is performed, enlarging both LPA and RPA ostia

dilatation ($<120 \text{ ml/m}^2$) is now often used as the cutoff value to preserve the right ventricular function; in addition to right ventricular end systolic volume index, development of tricuspid valve regurgitation or presence of branch pulmonary artery stenosis will influence the decision for surgery also (Lee et al. 2012). The optimal timing for surgical intervention remains often difficult to define.

Pulmonary insufficiency is probably not only determined by the integrity of the valve annulus per se but also by dilatation of the subvalvular infundibular region. Resection and incision of muscle bundles of the right ventricular outflow tract can cause dilatation of the infundibulum that promotes annulus dilatation with valve insufficiency regardless of the approach chosen (del Nido 2006).

Our own follow-up data in 101 patients after infant TOF repair could demonstrate that the transatrial approach will not reduce the incidence of pulmonary valve replacement at 12 years. An undefined subgroup of patients after transinfundibular repair employing transannular RVOT patch also required valve replacement somewhat earlier, but this did not influence the result at 12 years when compared to the exclusively transatrially repaired patients (unpublished data Ziemer and Nagy 2010).

15.2.3.2 Surgical Pulmonary Valve Replacement

In symptomatic patients with pulmonary regurgitation, valve replacement is necessary; to prevent right ventricular functional decline, indication is

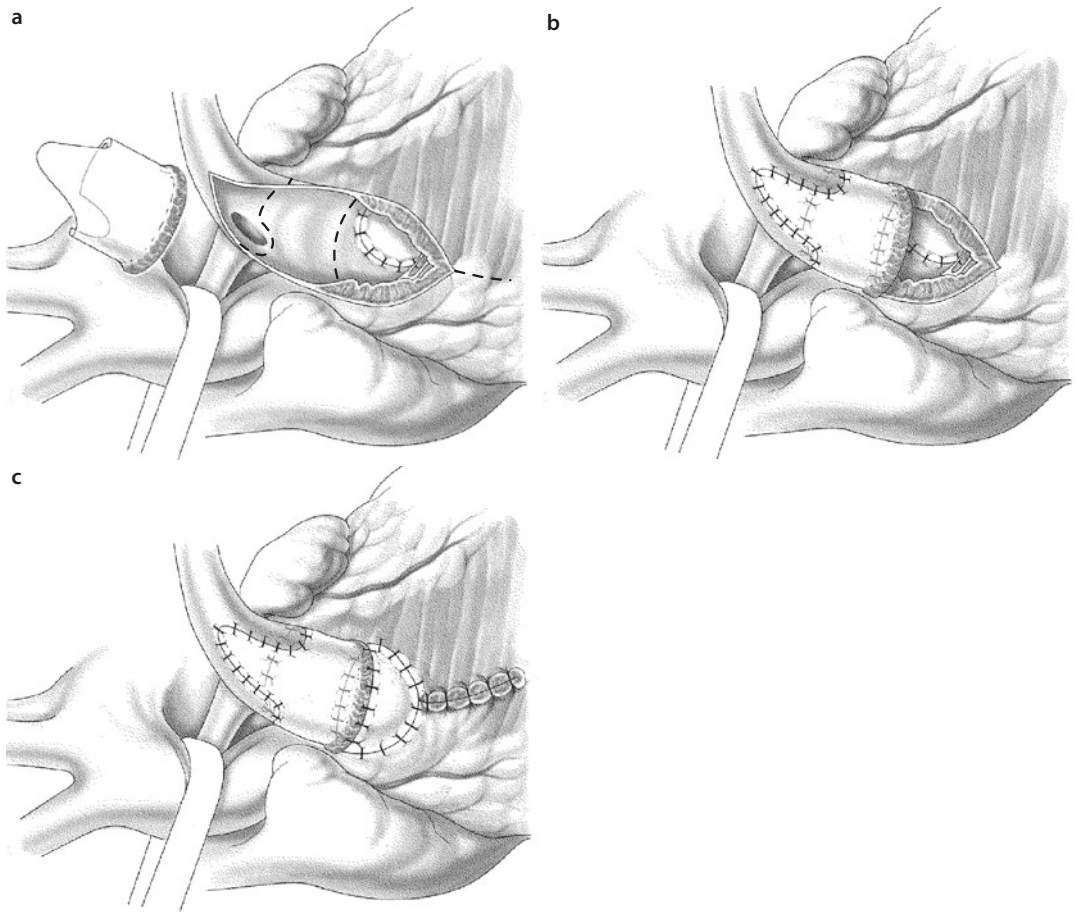

given even in asymptomatic patients (criteria see above). The operation is performed employing normothermic extracorporeal circulation with the heart beating. Bicaval cannulation is preferred. In cases with severe scarring, the right atrium may not be dissected and a large single atrial cannula used instead. As in these operations the heart is not displaced during the procedure, a two-stage cannula seems not to have an advantage over large solitary venous cannula.

Residual intracardiac shunts (PFO, residual ASD, residual VSD, PDA) have to be definitely excluded preoperatively. Otherwise they have to be corrected during cardiac arrest or induced ven-

tricular fibrillation at the beginning of surgery. The RVOT surgery will follow as described above and below.

The right ventricular outflow tract is opened; the patch material after a transannular patch procedure is removed. In presence of an aneurysm proximal/apical to the old RVOT patch, the incision is carried out farther into it until good RV muscle is reached; the distal incision can be shorter.

After transatrial correction, the incision is comparable to that for primary transfundibular repair (■ Fig. 15.7a). For valve replacement, a pulmonary homograft is preferred; an aortic homograft might be useful in patients with pulmonary

■ Fig. 15.7 Implantation of the homograft for pulmonary valve replacement in repaired TOF. **a** Prospective sutures for anastomosis are marked as dotted lines. The distal suture line goes around the RPA, indicating that the corresponding sinus of the valve to be implanted needs to be excised accordingly. The proximal anastomosis can posteriorly reach the VSD patch insertion. The infundibulotomy may be extended into the ventricle if an aneurysm is present. **b** After creation of the distal anastomosis, the posterior part of the proximal anastomosis was performed, assuring proper valve function by saline injection. **c** To further preserve valve geometry and function, the proximal anastomosis is enlarged anteriorly with a trapezoid patch. Plication of an aneurysmal infundibulum is performed at the same time («right ventricular reduction plasty»)

hypertension but bears the risk of earlier and more extensive calcification. Pulmonary homografts with small diameters (10–18 mm) have a limited availability.

Since 1966, the homograft develops to the gold standard of right ventricular outflow tract reconstruction. However, reintervention has to be expected because of shrinkage, calcification, and valve dysfunction, especially in young patients; accelerated degeneration was described in patients less than 1 year at implantation. Freedom from right ventricular outflow tract reintervention was calculated as 67% at 10 years and 47% at 15 years (Yuan et al. 2008). Multiple right ventricular-pulmonary artery conduit revisions may be required in patients now surviving to adulthood.

Different from conduit placement/replacement in patients with pulmonary atresia or for/after Rastelli surgery, in TOF/pulmonary stenosis patients requiring pulmonary valve replacement, the valve can be positioned in an almost orthotopic position. The technical details during implantation of the homograft valve include the placement of the proximal suture lines at the former valve annulus, at the transition from ventricle to pulmonary artery. The distal suture lines or anastomosis are placed first and then checked for proper orientation and function of the valve by injecting normal saline into the graft. The proximal sutures often need a patch insertion at the anterior hemi-circumference to avoid valve distortion (■ Fig. 15.7c).

Sometimes the somewhat oversized homografts have an excessive relative length due to the length requirements for the commissures to assure good valve function. In these patients the valve needs to be oriented in a way that after excision of one Valsalva sinus of the valve, the right pulmonary artery will originate out of it close to the valve level (■ Fig. 15.7b).

Bioprosthetic valves—although most widely used in the adult population in any valve location—provide limited durability in younger patients because calcification and valve dysfunction are accelerated.

TM*Bovine jugular vein conduits* (ContegraTM) are available in adequate sizes (12–22 mm) and can yield a functionally good result (Brown et al. 2006). Other reports showed them to be functionally worse when compared to homografts (Bautista-Hernandez et al. 2008; Meyns et al. 2004). Problems during midterm follow-up

are valve incompetence and more frequently distal conduit stenosis by fibrosis at the Contegra pulmonary anastomosis leading to reoperation. Leaving the conduit too long can result in angulation and conduit obstruction. In addition, proximal aneurysmal dilatation in presence of distal stenosis develops more often than in homografts or porcine xenografts (Holmes et al. 2012). The overall need for reintervention was calculated as 19% after 4 years. Postoperative administration of ASA is supposed to reduce neointimal proliferation and stenosis at distal anastomosis (Brown et al. 2006). For primary insertion in patients less than 2 years of age, bovine jugular vein conduit revealed superior long-term results when compared to both aortic and pulmonary homografts in a large multi-institutional study (Poynter et al. 2013).

15.2.3.3 Percutaneous Pulmonary Valve Implantation (PPVI)

The limited lifespan of right ventricular-pulmonary artery conduits is leading to multiple conduit revisions historically all requiring cardiopulmonary bypass. PPVI allows to extend conduit life span and postpones the next surgical revision. Thereby, it decreases the number of surgical procedures required during lifetime. This strategy limits right ventricular volume and/or pressure overload. Indications include right ventricular dilatation in presence of moderate pulmonary insufficiency, outflow tract obstruction with right ventricular pressure greater than two thirds systemic or compromised systolic right ventricular function. An important selection criteria is a positive coronary safety evaluation to avoid to compromise coronary artery perfusion by compression (McElhinney et al. 2010).

The procedure is usually performed as percutaneous valve implantation. Prestenting prepares the landing zone for the implant and reduces the risk of stent fractures and valve dysfunction; upper limit of the diameter is 21 mm (Bonhoeffer et al. 2000; Lurz and Bonhoeffer 2008). The hybrid implantation is described in patients with difficult catheter course or limited vessel access. The subxiphoid incision allows directly passage of the delivery system into the right ventricle (Simpson et al. 2011). The transinfundibular implantation requires a sternotomy; on the other hand, a valve with a larger diameter can be implanted (Schreiber et al. 2006; Berdat and

Carrel 2006). Once complete sternotomy is required for this «hybrid» approach in a re-sternotomy setting with an enlarged heart, the advantage over a plain surgical approach may become rather questionable and may have to be reserved for very special cases where extracorporeal circulation is clearly detrimental.

15.2.4 Right Ventricular Aneurysm

The concept of exclusion of the dyskinetic segment of the ventricular wall in patients with cardiomyopathy of various underlying causes was used as the basis for right ventricular outflow tract plasty with resection of the hypokinetic infundibular wall to reduce the right ventricular volume. Del Nido describes the technique performing an incision along the right ventricular anterior wall down to the apex if deemed necessary, plicating and resecting the thinned anterior wall («right ventricular remodeling,» del Nido 2006). In a randomized trial, this right ventricular remodeling in addition to pulmonary valve replacement did not provide any additional benefit with regard to right ventricular ejection fraction or midterm functional result (Geva et al. 2010).

15.2.5 Aortic Root Dilatation and Aortic Valve Insufficiency After Tetralogy Repair

In conotruncal malformations, the aortic root is primarily enlarged; after 10–12 years after surgical repair during infancy, the indexed aortic root diameter tends to normalize (Francois et al. 2010).

Structural abnormalities similar to those in patients with Marfan syndrome have been described in those patients operated during childhood (Tan et al. 2006). Nearly one third of adult patients are expected to have an aortic root diameter of more than 40 mm after TOF correction. Aortic root dilatation can reach a diameter up to 45–50 mm in adolescent or adult patients. In a multicenter study in adults with TOF correction, 29% revealed aortic root a diameter above 40 mm; the indexed observed to expected ratio was greater than 1.5 in nearly 7% (Mongeon et al. 2013). Aortic root complications as aortic dissection are an extremely rare complication (Kim et al. 2005; Rath et al. 2005). This explains that there is no

indication for prophylactic surgical intervention with replacement of the ascending aorta.

If the aortic root/ascending aorta diameter reaches more than 40 mm, MRI or CT should be performed annually.

Another aspect of postoperatively persistent aortopathy is the aortic valve regurgitation observed in 6–20%; this might accompany the aortic root dilatation (Mongeon et al. 2013; Niwa et al. 2002). An indication for surgical intervention can develop; this should be reconstructive at first line (see ► Chapter «Acquired Lesions of the Aortic Valve», Sect. 24.3.2.2 and Sect. 24.5.1).

15.3 Tetralogy of Fallot with Pulmonary Atresia (TOF/PA)

15.3.1 Nomenclature and Pathoanatomy

Morphologic characteristics of TOF/PA are:

- Large malalignment ventricular septal defect.
- Anterior deviation of the infundibular septum, hypoplasia of the infundibulum (as in classical TOF) and blind-ending outflow tract, or anteriorly deviated and overriding aorta, that is in contact with the anterior right ventricular wall, the infundibulum may be absent (as in truncus arteriosus).
- Right ventricular hypertrophy.

The intracardiac anatomy resembles that of tetralogy of Fallot. It is known from fetal echocardiography that in some of these patients, the right ventricular outflow tract was initially patent and became functionally and later anatomically atretic during fetal life. An alternative terminology names this malformation «pulmonary atresia/VSD.» While this term describes the main features of the malformation sufficiently, regarding the intracardiac anatomy, it is rather nonspecific. Therefore, in accordance with Van Praagh, we prefer the term tetralogy of Fallot with pulmonary atresia, being one end of the tetralogy spectrum of which the other end is marked by double outlet right ventricle/pulmonary stenosis (TOF type).

Tetralogy of Fallot with pulmonary atresia sometimes coexists with microdeletion 22q11.

15.3.1.1 Intracardiac Anatomy

The right ventricular outflow tract may be obstructed by an imperforate pulmonary valve (membranous atresia). More often a muscular obstruction is present either at the os infundibuli or immediately subvalvular. While there is no luminal connection from the right ventricular outflow tract to the pulmonary artery, most often the pulmonary trunk at its blind origin is in tissue continuation with the epi-myocardium.

The ventricular septal defect may be considered perimembranous; with anterior extension due to the malalignment of the septum in TOF type, it can create a doubly committed situation. In rare cases the septal defect might become restrictive if tricuspid valve tissue tags cover the defect; this situation would become comparable with pulmonary atresia with intact septum. The aorta is in overriding position, rarely connected only to the right ventricle, leading to a situation as in double outlet ventricle. There is no correlation between intracardiac anatomy and morphology of pulmonary artery branching or pulmonary arterial supply (Thiene et al. 1977; Anderson et al. 1991).

15.3.1.2 Morphology of the Pulmonary Arteries

In early pregnancy, around the 40th day, the vascular plexus of the lung buds connect to the systemic segmental arteries; these originate from the dorsal aorta. Additionally, there is antegrade blood flow from the right ventricle to the pulmonary arteries originating from the sixth branchial arches; during this period, there is obviously a dual blood supply for the pulmonary parenchyma. As the segmental arteries normally involute, the only pulmonary blood supply is provided by the pulmonary arteries.

In patients with TOF-pulmonary atresia, this development is disturbed as part of the cardiac malformation and characterized by collateral systemic arterial blood supply in presence of a wide spectrum of pulmonary artery morphology. In the presence of hypoplastic or even absent central pulmonary arteries, the segmental arteries persist providing a variable amount of pulmonary blood supply. The aortopulmonary collaterals can connect to central pulmonary artery, to lobar or segmental pulmonary arteries, or enter the lungs without connection to the pulmonary arteries; sometimes they perfuse parts of the contralateral lung also (Haworth and Macartney 1980).

There is a wide spectrum of the pulmonary artery morphology—from normal developed pulmonary arteries with an atretic connection to the right ventricle and ductal blood supply to absent intrapericardial pulmonary arteries and multiple pulmonary collateral arteries from the aorta (■ Fig. 15.8).

Rabinovitch et al. (1981) describe three sources of arterial blood supply with different connection to the pulmonary arteries: bronchial artery collaterals take their origin from bronchial arteries and are connected to pulmonary arteries inside the lung. Direct aortic collaterals arising from the descending aorta supply a lobe or a segment after entering the lung at the hilum. Indirect aortic collaterals arise from major branches of the aortic arch (e.g., subclavian artery or internal mammary artery) and connect to the central pulmonary arteries. The collateral vessels may become stenotic at the site of anastomosis with the pulmonary artery; this protects the vascular bed from high flow and pressure damage by otherwise unobstructed flow. Reduction of pulmonary blood flow in early infancy will decrease the number of alveoli of the corresponding part of the lung in almost all patients; lung function tests demonstrated a smaller lung volume only in a few patients.

In the presence of major aortopulmonary collateral arteries (MAPCA), the central and peripheral pulmonary arteries are hypoplastic (Haworth and Macartney 1980). Vessel stenosis might be found at the aortic origin or at the anastomosis with the pulmonary artery in nearly 60%. The vessel origin is mainly found at the descending thoracic aorta at the level of the left main bronchus (in left aortic arch) or carina (in right aortic arch). MAPCA may also arise from the branches of the aorta (e.g., subclavian artery) or rarely from the common aortic trunk. They connect to the central pulmonary arteries, to lobar or segmental pulmonary arteries within the lung, or any pulmonary artery supplying the lung independently. In this way MAPCA may supply nearly 45% of the bronchopulmonary segments directly and 50% via the central pulmonary arteries, while 5% of the lung parenchyma have a double blood supply (Haworth 1990).

Based on the pulmonary artery anatomy and blood supply (dominant via native pulmonary arteries or MAPCA, rarely dual), five subgroups of pulmonary atresia have been defined for classification of pulmonary artery morphology :

■ **Fig. 15.8** Morphology of pulmonary perfusion in tetralogy of Fallot/pulmonary atresia. **a, b** group I, ductal-dependent pulmonary blood supply, no MAPCA, with or without an identifiable pulmonary trunk (unifocal lung perfusion); **c** group II, hypoplastic intrapericardial pulmonary arteries, connected to all pulmonary segments; multiple segments will have dual blood supply; **d** group III, extremely hypoplastic intrapericardial pulmonary arteries with multiple MAPCA-dependent blood supply of the lung segments; **e** group IV **e**, absent intrapericardial pulmonary arteries; pulmonary blood supply exclusively by MAPCA; **f** group V, absence of any angiographically identifiable pulmonary arteries or MAPCA, pulmonary blood supply via diffuse small collateral vessels only. While group I may be considered a unifocal lung perfusion, groups II–V represent situations with multifocal lung perfusion (Modified after Castaneda et al. (1994) and completed after Griselli et al. (2004); both used with permission)

- Group I (■ Fig. 15.8a, b): ductal-dependent pulmonary blood supply, no MAPCA, with or without an identifiable pulmonary trunk (unifocal lung perfusion).
- Group II (■ Fig. 15.8c): hypoplastic intrapericardial pulmonary arteries, connected to all pulmonary segments; multiple segments will have dual blood supply.
- Group III (■ Fig. 15.8d): extremely hypoplastic intrapericardial pulmonary arteries with multiple MAPCA-dependent blood supply of the lung segments.
- Group IV (■ Fig. 15.8e): absent intrapericardial pulmonary arteries; pulmonary blood supply exclusively by MAPCA.
- Group V (■ Fig. 15.8f): absence of any angiographically identifiable pulmonary arteries or

MAPCA, pulmonary blood supply via diffuse small collateral vessels only (Griselli et al. 2004).

While group I may be considered a unifocal lung perfusion, groups II–V represent situations with multifocal lung perfusion.

15.3.2 Clinical Presentation and Diagnosis

Onset and severity of clinical symptoms will depend on the type of pulmonary blood supply; the interventricular communication is large with obligatory right-to-left shunt. If pulmonary blood flow is ductus dependent, closure of the ductus

after birth will rapidly cause cyanosis, hypoxemia, acidosis, and death if not treated; prenatal diagnosis of pulmonary atresia will allow starting prostaglandin infusion immediately after birth, preventing arterial desaturation. In presence of MAPCAs, the clinical presentation can vary between moderate and no cyanosis at all. The latter even with congestive heart failure, if the MAPCAs are unobstructed. Some of the MAPCAs may become stenotic or occlude leading to an increase in cyanosis during infancy or childhood. Large unrestrictive MAPCAs can cause pulmonary hypertension in the corresponding lung segment with secondary pulmonary vascular obstructive disease. Hyperperfused and underperfused segments can coexist adjacent to each other. As in other cyanotic cardiac anomalies, additional aortopulmonary collateral blood supply may develop. While the vessels of this additional pulmonary blood supply connect to the pulmonary arteries at precapillary level, MAPCAs connect at the hilum or farther upstream at segmental level.

Clinical findings are not so impressive; a continuous murmur might be audible in patients with relevant MAPCAs, more localized in patients with just patent ductus arteriosus.

Historically, it was said that Helen Taussig's detection of a murmur in her TOF patients who were doing well gave her the idea that an artificial ductus arteriosus, the later Blalock-Taussig shunt, would be beneficial for those patients without a murmur. The idea most probably originated in listening to MAPCAs rather than to the rare long-term patent ductus arteriosus in unifocal lung perfusion or a ductus in any other severe form of tetralogy (Richard Van Praagh, personal communication).

15.3.3 Diagnostic Procedures

Radiological findings represent the typical configuration of the heart («coeur-en-sabot», French for «Boot-shaped heart») with the lack of the pulmonary trunk and irregular pulmonary vascular markings.

Echocardiography allows the definition of the intracardiac anatomy; often it is possible to identify the central pulmonary arteries in continuity. Cardiac magnetic resonance imaging can pro-

vide information on origin and course of MAPCAs; this diagnostic information is also provided by computerized tomography (Lofland 2004). However, complete clarification of pulmonary blood supply can only be obtained by angiography. This includes selective catheterization of the ductus and MAPCAs at any level of origin from the aorta. Retrograde pulmonary venous wedge angiography allows the identification of central pulmonary arteries if they are present. Pressure measurement and test occlusion of the MAPCAs identify the perfusion pattern of the lung segments and the individual contribution to oxygenation. For surgical decisions, the perfusion pattern of all 20 lung segments has to be investigated.

15.3.4 Surgical Management of Tetralogy of Fallot with Pulmonary Atresia

15.3.4.1 Ductus-Dependent Pulmonary Blood Flow

Definitive primary repair is possible in ductus-dependent pulmonary lung perfusion with confluent, sufficiently developed pulmonary arteries. Closure of the ductus or stenosis at the pulmonary end might induce a critical situation with cardiac decompensation; in a critical situation, palliation with a BT shunt may be preferred. Dilatation and stenting of the stenotic ductus was suggested also (Gibbs et al. 1992, Gewillig et al. 2004). In patients with bilateral ductus and discontinuity of the pulmonary arteries, primary neonatal repair is recommended; the discontinuity can be bridged by a PTFE conduit with mobilization of both pulmonary arteries into the hilus. If in older infants a homograft is used, its intact pulmonary bifurcation should be preserved and may be used for reconstruction of the bifurcation; the risk of early homograft stenosis has to be considered (Shanley et al. 1993).

Primary repair is possible if 15–18 lung segments are in connection to the central pulmonary arteries. The postoperative right-to-left ventricular pressure ratio is of prognostic value. If only 11–14 segments could be connected, there is a high risk for right ventricular pressure overload after corrective surgery. Patient selection after

careful and extensive diagnosis is a quite important point. Less than 10 segments do not allow for a subsystemic right ventricular pressure (Reddy et al. 1995).

Primary repair should be electively performed in the second week of life. In patients with a membranous atresia or in those with a short muscular atresia but tissue continuity (the majority of patients), surgical correction is comparable with transinfundibular correction of uncomplicated tetralogy of Fallot avoiding primary conduit implantation. Restenosis might develop at «anular» level, which even after the best repair remains the most narrow and therefore most critical part of the RVOT reconstruction. A longitudinal infundibular incision will be extended into the pulmonary trunk through the atretic valve or muscular segment. In order to reduce the risk of early reoperation in patients with muscular atresia, we mobilize the hypoplastic pulmonary trunk a couple of millimeters, divide it at mid-length, and reanastomose it into the distal end of the infundibulotomy with absorbable sutures (e.g., PDS). A transanular patch completes the reconstruction, still leaving the «anulus» as the most narrow but sufficiently wide part for the time being. Sufficient growth of the autochthonous tissue has to be anticipated. Before RVOT reconstruction, closure of the VSD follows the procedure described in tetralogy of Fallot with pulmonary stenosis or truncus arteriosus.

In patients with complete atresia or severe hypoplasia of the pulmonary trunk, implantation of a conduit is necessary. For this, only limited mobilization of the pulmonary arteries will be performed; as the branch pulmonary arteries are often small, additional elongation/distortion by mobilization should be avoided. The conduit might be a homograft or xenograft or—for us preferable—a PTFE tube of 10–12 mm diameter; a functioning valve at the right ventricular outflow tract is not necessary during infancy. The main disadvantage for any neonatal or early infancy conduit implantation is the need for conduit replacement after 4–5 years because of outgrowth. Comparing long-term results after homograft and xenograft conduit implantation in patients less than 2 years of age, a multicentric Congenital Heart Surgeons' Society Study more recently showed advantages for the bovine jugular vein xenografts employed (Poynter et al. 2013).

Our preference for PTFE tubes in primary conduit placement in babies is the relative ease at reoperation for the unavoidable conduit chance in any case.

Reconstruction of the right ventricular outflow tract allows potentially a better growth of the pulmonary arteries compared to a shunt procedure but needs cardiopulmonary bypass and bears a higher risk. The risk of pulmonary artery distortion after BT shunt is avoided using a central shunt which we prefer in patients with small-sized pulmonary arteries anyways.

If there is coarctation of the pulmonary artery associated with closure of the ductus, extended incision into the pulmonary branch 3–4 mm distal to the insertion of the ductus is necessary (see ■ Fig. 15.4a)

15.3.4.2 Surgical Management in Multifocal Lung Perfusion

Depending on the individual anatomic situation, different surgical strategies are conceivable. The decision has to be made in early infancy as some MAPCAs might become stenotic or atretic leaving segments without perfusion, while other lung segments might develop pulmonary vascular obstructive disease with irreversible pulmonary hypertension already during childhood. The aim is to establish antegrade pulmonary perfusion from the central pulmonary arteries for as many lung segments as possible.

The *surgical options* for treatment of multifocal lung perfusion are:

- Palliation with peripheral shunt procedures
- Staged peripheral unifocalization followed by central unifocalization and conduit placement from the right ventricle with or without complete VSD closure (Puga et al. 1983, 1989; Sawatari et al. 1989; Sullivan et al. 1988)
- Primary central operation and later unifocalization with the option of catheter-based interventions as dilatation or coil occlusion: with aortopulmonary shunt insertion (Iyer and Mee 1991; Watterson et al. 1991) and with right ventricular to pulmonary artery conduit without VSD closure (Rome et al. 1993)
- Primary total correction (Lofland 2004; Reddy et al. 1995)

■ ■ Palliative shunt procedure

Peripheral shunt procedures have to be integrated in the further surgical strategy; their indication is mostly seen in patients with absent intrapericardial pulmonary arteries with severe or increasing cyanosis. This patient group has the less favorable prognosis (Griselli et al. 2004).

■ ■ Staged peripheral unifocalization

The concept of stepwise unifocalization was propagated by Francisco Puga (Puga et al. 1983, 1989), Jarda Stark and Marc de Leval (Sullivan et al. 1988), Yasuharu Imai (Sawatari et al. 1989), and Yasunaru Kawashima (Yahagira et al. 1996). Staged unifocalization tries to interconnect as many intrapulmonary arteries as possible in a stepwise procedure—directly or by using prosthetic material. The created confluence of this interconnection is anastomosed to an aortopulmonary shunt. Unifocalization on both sides of the lung is performed via lateral thoracotomies. In a later procedure, a right ventricular to pulmonary artery conduit is implanted as a T- or Y-shaped prosthesis/graft. The VSD might be closed completely or with a fenestrated patch.

Collateral vessels have to be occluded by coils as they can support relevant left-to-right shunt.

If VSD closure (even only fenestrated) is the positive endpoint in these staged unifocalization procedures, success varies in the studies cited from 12 to 60% only.

■ ■ Primary central procedures

In the presence of central pulmonary arteries, with or without continuity, a central procedure as a primary approach is the first step of choice. Thereby not only antegrade flow into the true pulmonary arteries is established but also access for potential catheter intervention made possible. It may consist of a central aortopulmonary shunt or of a RV to PA conduit. Both procedures may be extended with central PA patch plasties if an additional localized stenosis cannot be taken care of with the prosthetic anastomosis alone.

Royal Children's Hospital in Melbourne preferred a primary central aortopulmonary shunt (Iyer and Mee 1991). As in extremely hypoplastic central pulmonary arteries the shunt procedure might be technically difficult, they introduced what was called the «Melbourne shunt»: a direct end-to-side anastomosis of the hypoplastic main pulmonary artery with the ascending aorta

(Watterson et al. 1991). Bilateral thoracotomies are used for peripheral unifocalization as subsequent procedures. Later on right ventricle to pulmonary artery conduit with or without VSD closure may follow.

Boston Children's Hospital favored the approach of a primary conduit procedure during infancy (Rome et al. 1993) choosing valved or nonvalved conduits for right ventricle to pulmonary artery connection to encourage growth of the central pulmonary arteries. The usually larger size of this connection should allow for more pronounced pulsatility, eventually giving a better impulse for PA growth. A further benefit may be the advantage of a streaming effect, leading mainly desaturated venous blood into the pulmonary arteries.

■ ■ Primary unifocalization

Primary unifocalization as a corrective procedure in early infancy (age 3–4 months) was favored by Frank Hanley and Mohan Reddy (Reddy et al. 1995). Basic principle is complete mobilization of all MAPCAs (■ Fig. 15.9). They preferred one-stage repair via median sternotomy. Other groups (Moritz et al. 1996; Luciani et al. 1997) recommended bilateral thoracotomies in the fourth intercostal space («clamshell» incision) establishing a more radical approach for the extensive dissection of the lung hilus. Their patients, however, were older.

Before going on bypass, complete dissection of the hilum in both lungs is required. Dissection of pre- and retrobronchial MAPCA is facilitated by anterior luxation of the lungs, if hemodynamically tolerated. As the majority of the MAPCAs originate from the middle part of the descending aorta, sinus transversus incision of the posterior pericardium between the ascending aorta and the vena cava superior gives access to the infracarinal triangle. The collaterals are cut immediately at their aortic takeoff. These vessels own a fragile structure, similar to a mixture of vein and ductal tissue, and they require most delicate handling. After completion of the dissection and transection, they might be guided into the intrapericardial space by separate retrophrenic but prehilum pericardial incisions.

Hanley and Reddy recommend to dissect, disconnect, and unifocalize as many collaterals as possible before establishing cardiopulmonary bypass, only employing it earlier when desaturation and/or hemodynamic instability requires it (Reddy et al. 1995). Lofland

recommends to perform the complete dissection and unifocalization already during normothermic extracorporeal circulation with the heart beating (Lofland 2004). He claims superior and more extensive dissection on one hand with a safe environment on the other.

All authors emphasize the importance of a customized approach in any individual patient to unifocalize the collaterals and reconstruct the central pulmonary arteries at the same time.

The pattern of anastomosis favored by Reddy and Hanley shows a long segment side-to-side junction of the vessels (see ■ Fig. 15.9) to gain a larger circumference to accommodate the cardiac output. The anastomosis between right ventricle and pulmonary artery and any intracardiac procedure if necessary is performed during cardioplegic cardiac arrest.

■ **Fig. 15.9** Suggested patterns of unifocalization. Right: end-to-side anastomosis. This kind of anastomosis requires only minimal mobilization of the MAPCA («major aortopulmonary collateral arteries»). Left: a side-to-side anastomosis after extended complete mobilization of MAPCA, using the MAPCA itself as an augmentation of the central pulmonary artery

Richard Jonas prefers a minimal mobilization of the MAPCA and an end-to-side connection with the central, intrapericardial pulmonary arteries (Jonas 2004). Another approach avoids any manipulations of the MAPCA and preserves their native/original course to the lung by isolating the aortic segment with its MAPCA takeoffs. This aortic segment is then connected to the right ventricle using a conduit. The aorta is reconstructed by using an adequate aorto-aortic vascular graft (Abella et al. 2004).

■ ■ Separation of the circulation with complete or fenestrated VSD patch

The ultimate goal of surgery is to obtain a complete separation of systemic and pulmonary circulation with occlusion of any intracardiac connections. Limiting factor is the capacity/cross section of the pulmonary vascular bed available for the right ventricular output. The resistance of either or both the proximal unifocalized hypoplastic vessels or distally the arterioles may not accommodate a cardiac output at subsystemic pressures. The postoperative increased pressure ratios of the right and left ventricles become the predictors of the mid- and long-lasting outcome of the patients. Therefore, management of the VSD is the key to successfully attack this problem. In contrast to the tetralogy of Fallot with a stenosis of the pulmonary artery and a dynamic and regressive component of the intraoperative high right ventricular pressure, the intraoperative and early postoperative pressure of the unifocalized vessels is anatomically and functionally fixed. A prediction of the postoperative right ventricular pressure due to the connected lung segments (at least 10 of the 20 segments; Reddy et al. 1995) or other indices calculating the area or cross section of the lung vessels (e.g., Nakata index; Nakata et al. 1984) is vague and of limited value for the final decision.

An assessment based on a preoperative angiography is, in principle, suitable to estimate the option of a definitive closure preoperatively. The final decision has to be taken by the measurements of the intraoperative pressure conditions of the ventricles and/or great arteries.

In case of suprasystemic values of the right ventricle, the VSD patch should be fenestrated or—if necessary in very rare cases—be removed completely. Richard Jonas suggested fenestration of the VSD patch only if RV pressures exceed 110–120% of systemic values (Jonas 2004).

Mohan Reddy and Frank Hanley based their decision for VSD management on a complicated but in their hands useful intraoperative procedure: after completion of the unifocalization and the distal connection of the future conduit, they perform an isolated lung perfusion via the conduit. The flow of the lung perfusion pump should equal the theoretical cardiac output of the patient. If the pulmonary vascular bed can accept the calculated cardiac output with a pulmonary artery pressure of <25 mmHg, the VSD closure can be tolerated hemodynamically. In case of pressure values between 25 and 40 mmHg, a fenestration should be created. A VSD closure is contraindicated at values above 40 mmHg (Reddy et al. 1997).

A primary elective fenestration of a VSD patch is performed only in rare cases. Even with unfavorable results of the preoperative angiography, different and advantageous conditions at the end of the operation may occur. With suprasystemic pressure of the right ventricle, a secondary fenestration is created using an aortic puncher in normothermia and electrically induced ventricular fibrillation. The diameter of 2.8 mm in neonates and 4 mm in infants allows a sufficient decompression of the right ventricle without the risk of a lung flooding later on. In case of an angiographically frugal pulmonary vascular bed to start with, we do not perform a VSD patch closure at all.

15.3.4.3 Destiny of the Unifocalized MAPCAs

The original enthusiasm for unifocalization based on MAPCA/PA reconstruction was significantly dampened by reports of angiographic long-term results of the Royal Children's Hospital in Melbourne (d'Udekem et al. 2005; Nørgaard et al. 2006). Sixty-five patients were examined after a complete repair partially based on MAPCAs. Comparing former and current angiographic results, constantly unfavorable outcomes of the incorporated MAPCAs were shown. Either most of the vessels which were open early postoperatively were occluded now or did not show any growth neither relatively nor absolute over the time.

In default of any long-term studies to date, a competent judgment regarding the relevance of a perfusion of individual MAPCA or MAPCA in general is difficult. It is common sense to first connect the original pulmonary arteries independent of their size to develop as much diameter and peripheral distribution of original pulmonary

arteries as possible by enhancing antegrade flow. MAPCA are incorporated only if deemed absolutely necessary for a significant part of the pulmonary perfusion, in our hands rather reluctantly.

15.4 Tetralogy of Fallot with Absent Pulmonary Valve («Absent Pulmonary Valve Syndrome» APVS)

15.4.1 Definition

Absent pulmonary valve syndrome is a rare cardiac anomaly. The most common association (in >80%) is given with tetralogy of Fallot. Extremely rare is the isolated absent pulmonary valve syndrome or the association with tricuspid atresia. Two to 6% of patients with TOF present with absent pulmonary valve syndrome. It is characterized by rudimentary, hypoplastic pulmonary valve cusps resembling a wide-open fibrous ring at the level of an almost normal-sized anulus. It is associated with severe dilatation of the main pulmonary trunk and branch pulmonary arteries in presence of severe pulmonary regurgitation and mild to moderate pulmonary stenosis; tracheobronchial abnormalities result from bronchial compression by the pulmonary arteries which may lead to respiratory compromise already in the immediate postnatal period. On the other hand, patients with APVS may only have minor respiratory symptoms and moderate cyanosis for several years.

15.4.2 Anatomy

In patients with absent pulmonary valve syndrome and TOF, the intracardiac anatomy is characterized by the large subaortic malalignment VSD, anterior deviation of the conal septum, and moderate right ventricular outflow tract obstruction with a somewhat hypoplastic, fibrotic anulus and rudimentary cusps and moderate-to-severe pulmonary insufficiency. The aneurysmal dilatation of the pulmonary arteries might extend into its first- and second-order branches. Severe bronchial obstruction might result from the longstanding in utero compression by the tortuous dilated pulmonary arteries; this might extend from the main stem bronchi into the hilar regions

(Milanesi et al. 1984; Rabinovitch et al. 1982). At birth severe respiratory compromise might develop and is associated with significant perinatal morbidity and mortality. Urgent neonatal corrective surgery might be indicated including pulmonary artery arterioplasty.

Absence of ductus arteriosus is a rather typical finding in APVS (Emmanouilides et al. 1978). Ductal agenesis was thought to be protective in the setting of severe pulmonary regurgitation and large VSD as a patent duct would result in huge aortopulmonary shunting, the regurgitant absent pulmonary valve acting as in severe aortic insufficiency. Consequently, severe biventricular volume overload and heart failure would develop (Zach et al. 1979). It was assumed that the elevated right ventricular pressure in utero leads to underdevelopment of the pulmonary valve and the to-and-fro flow across the right ventricular outflow tract and consecutive dilatation of the pulmonary arteries that cause tracheobronchial compression and malacia. The most severe compromise of pulmonary vasculature and airway development during fetal life may result in airway occlusion and fluid retention in the distal lung segments.

In association with tetralogy of Fallot, microdeletion 22q.11.2 is the most common chromosomal abnormality.

15.4.3 Diagnostic Procedures

Intensity of diagnostic procedures depends on the clinical presentation: some infants present as «pink» Fallot without respiratory symptoms even if pulmonary artery dilatation is present; later they might become symptomatic with airway disease or bronchospasm. Others develop severe respiratory compromise and become ventilator dependent as early as in the immediate postnatal period. Chest radiograph will demonstrate cardiac enlargement, lobar atelectasis, and areas of obstructive emphysema. In neonates and infants, the intracardiac anatomy is comprehensively described by echocardiography; a cardiac catheterization is not indicated.

Older, less symptomatic patients from both the bronchial and the cardiac side may be candidates for elective bronchoscopy defining airway involvement, also.

MRI can be used to illustrate the cardiac anatomy and extension and pattern of airway disease

(Taragin et al. 2006). Thoracic CT can complete the preoperative airway assessment (Vincenti et al. 2012).

Prenatal diagnosis has become important. Fetal case series described prenatal and postnatal survival rates of less than 20%. Cause of death includes termination of pregnancy, fetal heart failure, respiratory decompensation, and chromosomal abnormalities (Wertaschnigg et al. 2013).

15.4.4 Therapy

15.4.4.1 Preoperative Management

Compression of the tracheobronchial tree can result in severe respiratory distress before surgery requiring intubation and high-pressure ventilation. The respiratory situation might become worse because of secondary barotrauma and the risk of atelectasis, obstructive emphysema, or pneumothoraces. Special ventilation modalities including belly or prone position management are used (Takabayashi et al. 2005). Emergency sternotomy and temporary chest wall plasty might widen the intrathoracic space and might improve the preoperative ventilatory status (Heinemann and Hanley 1993). Ultimate therapeutic option is the venovenous extracorporeal membrane oxygenation for preoperative stabilization (Kirshbom and Kogon 2004).

15.4.4.2 Surgical Strategies

Corrective surgery is planned as a one-stage repair to treat cardiac and bronchial disease. While TOF repair is a standardized procedure (► Sect. 15.1.6.2), extension of reduction pulmonary arterioplasty depends on the varying degree of vessel dilatation and actual airway obstruction. We prefer the extensive posterior and anterior reduction arterioplasty as suggested by Roger Mee's group (Stellin et al. 1983) (see ■ Fig. 15.10).

Corrective surgery is performed with cardiopulmonary bypass and moderate hypothermia and intermittent cold-blood cardioplegia or as in our preference for neonates and infants in limited deep hypothermic circulatory arrest and hypothermic cardiac arrest. Aortic cannulation for cardiopulmonary bypass should be performed far distal in the ascending aorta or better in the proximal aortic arch. This may allow to transect the ascending aorta in order to facilitate pulmonary artery reconstruction.

Surgical treatment of the pulmonary arteries depends on the varying degree and extension of pulmonary dilatation. Both right and left pulmonary arteries as well as the main pulmonary artery should be circumferentially dissected in part before going on bypass and completely before cross clamping the aorta. Pulmonary bifurcation should be opened by an anterior y-shaped incision; the anterior wall of main, left, and right pulmonary artery is partially resected and the posterior wall plicated, starting even farther distal in the pulmonary hilum than the anterior resection did reach (■ Fig. 15.10). While an anterior reduction plasty only reduces pulmonary artery diameter, the addition of the posterior inner plication not only further diminishes the diameter in a symmetric way, more importantly it separates and elevates the pulmonary artery from the affected bronchi. During vessel closure, the lumen of the pulmonary artery should be calibrated by Hegar dilators to prevent overdoing the diameter reduction. In neonates and infants, we use 8 mm Hegars. A reduction to the correctly age and weight matched diameters of 5–6 mm would increase the risk of iatrogenic obstruction. The distal pulmonary

trunk will also be plicated posteriorly. It may even be transected and somewhat shortened. The reconstruction of the right ventricular outflow tract can be managed in different ways, the individual surgeon's preference for tetralogy repair: transannular patch, monocusp valve, homograft valved conduit, Contegra jugular vein valved conduit, or Gore-Tex conduit. In infancy a valved conduit is not really necessary even in situation of respiratory distress; an oversized homograft or Contegra conduit might compromise tracheal bifurcation. Reduced infundibular resection is performed for relief of obstruction of the right ventricular outflow. In neonates and infants, we prefer transannular patch to ensure luminal reconstruction. Patients over 5 years receive valved homografts or bovine jugular veins. Decisions between 1 and 5 years, rarely to be made, may be again very individual.

Intraoperative bronchoscopy allows for assessment of the central respiratory tract and residual tracheobronchial obstruction; if indicated airway decompression can be achieved by retrosternal suspension of the pulmonary artery as long as not dissected circumferentially (Bove et al. 1972; Alsoufi et al. 2007).

■ **Fig. 15.10** Complete circumferential reduction plasty of pulmonary artery employing endoluminal posterior plication and anterior resection. **a** The planned excision of the anterior wall (*dotted line*) extends from hilum to hilum in right and left pulmonary artery and also in a T-shaped fashion into the pulmonary trunk/main pulmonary artery. Decision-making for how much to resect as well as for the actual reconstruction may be facilitated by transecting and re anastomosing the ascending aorta. **b** After generous endoluminal everting plication of the posterior wall and resection of the anterior wall, the reconstruction is completed by direct suture of the anterior wall, employing absorbable suture material. Introducing a somewhat oversized Hegar dilator into the arteries during reconstruction may secure proper sizing (not shown in figure) (Modified from Stellin et al. (1983); with permission by Elsevier)

15.4.4.3 Alternative Surgical Approaches

■ Complete resection of the mediastinal pulmonary arteries and reconstruction with a bifurcated homograft

In APVS patients with respiratory distress, Hew et al. (2002) recommended a total replacement of the aneurysmal central pulmonary arteries by implantation of a bifurcated valved homograft. The early experience demonstrated comparable results to the strategy with pulmonary artery plication and nonvalved reconstruction of the right ventricular outflow tract.

■ Lecompte maneuver for relief of airway compression («Hraska technique»)

Translocation of the pulmonary artery anterior to the aorta is a different approach to relief airway obstruction in APVS (Hraska 2000). Extensive mobilization of the SVC with division of the azygos vein as well as a right lateral wedge resection of the ascending aorta including mobilization of the aortic arch also aim at avoiding SVC distortion and obstruction by the Lecompte maneuver. The right lateral wedge resection and reanastomosis of the ascending aorta translocates it to the left and posteriorly. Viktor Hraska also emphasizes shortening of the almost always lengthy LPA. Favorable early and midterm results in infants with tracheobronchial compression have been described (Nölke et al. 2006). Translocation of the ascending aorta, however, might have the risk of bronchial compression.

15.4.4.4 Postoperative Management and Late Outcome

In neonates, it is beneficial to use temporary chest wall patch plasty for the first postoperative days and eventually perform chest closure in a staged fashion. A complicated postoperative course can result from persistent bronchomalacia after long-term tracheobronchial compression requiring prolonged postoperative ventilator support. Respiratory complications include severe pulmonary infection (Hu et al. 2013) or bronchospasm. For patients with persistent diffuse central airway compression, advantages of endotracheal or endobronchial stent implantation were seen (Dodge-Khatami et al. 1999). Rarely lung resection or lobectomy might be indicated if pulmonary infections persist in functionally or anatomically compromised lung segments (Alsoufi et al. 2007).

15.5 Double Outlet Right Ventricle (DORV)

15.5.1 Definition

Double outlet right ventricle is a rare congenital heart defect (less than 1 % of the defects) with both the aorta and the pulmonary artery originating from the right ventricle; the ventricular septal defect is the only outlet from the left ventricle. Associated abnormalities with discordant, univentricular, or atrioventricular canal connection, valve atresia, or malposition of the great arteries may create complex structural and functional situations.

Uncomplicated DORV patients present with atrioventricular concordance and subaortic ventricular septal defect, relatively balanced ventricle, no atrioventricular valve abnormality or straddling, and no major pulmonary artery anomaly. Patients with a subpulmonary ventricular septal defect and d-transposition of the great arteries represent the Taussig-Bing anomaly (Taussig and Bing 1949) with the aorta to the right or parallel to the pulmonary artery in a side-to-side relation. While these patients clinically resemble patients with d-TGA and VSD, the two great vessels are not both transposed: only the aorta is. The pulmonary artery still arises from the right ventricle. In this special DORV situation, we rather should speak from *d-malposition* of the great vessels. Complex anomalies can be associated with the double outlet right ventricle as straddling or common atrioventricular, various left atrioventricular valve anomalies, hypoplastic valve or ventricle, aortic arch or venous anomalies.

Double outlet right ventricle with intact ventricular septum is extremely rare; the left ventricle has no outlet and might be hypoplastic.

The constellation of double outlet left ventricle is described in some cases, often associated with functionally univentricular heart and showing an extreme morphologic heterogeneity.

15.5.2 Anatomy

Double outlet right ventricle (DORV) belongs to the group of conotruncal malformations as there are transposition of the great arteries, tetralogy of Fallot, and truncus arteriosus. These similarities were described as being either a spectrum or morphologic continuum from double outlet right

ventricle to tetralogy of Fallot on one side and from double outlet right ventricle with subpulmonary ventricular septal defect to transposition of the great arteries on the other (Lev et al. 1972). In their understanding, DORV is characterized by the origin of both great arteries from the right ventricle. Richard Van Praagh (1968) defined the absent fibrous continuity (namely, discontinuity) between aortic and mitral valve (pulmonary and mitral valve in d-malposition) with bilateral subarterial conus as the most important diagnostic feature. Bob Anderson and colleagues (Anderson et al. 1983) demanded for the diagnosis DORV only one complete and one more than 50% origin of the great vessels from the right ventricle.

15.5.2.1 Ventricular Septal Defect

The classification of the ventricular septal defect is given by its relation to the great arteries (■ Fig. 15.11).

■ ■ Subaortic VSD (■ Fig. 15.11a)

The most common subaortic interventricular communication is a membranous defect less frequent a muscular posteroinferior rim can be identified. Often fibrous continuity between aorta and atrioventricular valve can be described (if mitral valve,

then not necessarily a DORV by Richard Van Praagh's classification), but both great arteries can also be supported by subarterial infundibulum (bilateral conus); while these patients reveal a ventricular anatomy close to tetralogy of Fallot, in case of pulmonary or subpulmonary stenosis, they even act clinically like a tetralogy patient. Not infrequently, the great arteries are in a side-by-side position. The conal septum can fuse with the anterior septomarginal trabecular muscle. In some cases, the subaortic VSD may become restrictive which represents functionally subaortic stenosis after repair.

■ ■ Subpulmonary VSD (■ Fig. 15.11b)

In those patients, where the VSD has a subpulmonary location, the aorta lies to the right and most often parallel to the pulmonary artery (dextromalpositioned). Both the great arteries are supported by an infundibulum. While the pulmonary trunk is usually unobstructed, obstructive anomalies on the systemic side are more frequent, however, more distal including aortic coarctation and interrupted aortic arch (original description by Taussig and Bing 1949). The interventricular communication is between the anterior and posterior trabecular muscle; the muscular outlet septum can fuse with the posterior limb of the septomarginal trabeculation.

■ Fig. 15.11 Double outlet right ventricle with the interventricular communication between the anterior and posterior limb of the septomarginal trabeculation. The muscular outlet septum is a right ventricular structure and can fuse with the anterior limb of the septomarginal trabeculation in subaortic VSD **a** or the posterior limb in subpulmonary VSD **b**

■ ■ Subarterial («doubly committed») VSD

With absence of the muscular outlet septum, the aortic and pulmonary valves are in fibrous continuity. Therefore, the VSD cannot be related more to one or the other but rather to both semilunar valves. This does not mean, however, that tunneling of the VSD to either semilunar valve may have the same preference or ease/result of construction.

■ ■ Remote («noncommitted») VSD

In patients with a noncommitted ventricular septal defect, the interventricular communication is remote from the ventricular outflow tracts; as a membranous defect it extends into the right ventricular inlet, it may be situated in the inlet part of the muscular septum or a component of an atrioventricular defect. The tunnel to the outflow tract may be obstructed by straddling atrioventricular valve apparatus, especially tricuspid valve leaflets. The great arteries may arise in parallel or spiraling position. In most cases, a remote VSD in DORV prevents biventricular repair.

This classification of VSD location does not only reflect pathoanatomy and physiology, it is of major importance for surgical strategy and actual repair.

15.5.2.2 Infundibular Septum (Conus Septum)

This muscular structure, dividing the right from the left ventricular outflow tract in the normal heart, is rather a freestanding muscle bundle of the RV in patients with DORV. The great arteries in typical DORV are parallel to each other in a frontal plane. In echocardiography, both semilunar valves are next to each other in the same plane, also. The conal septum, being the muscle between the two semilunar valves, is a rectangular muscle mass, located between the interventricular septum and the subarterial conus. While in DORV with subaortic VSD, the conus septum gets in contact with the anterior bifurcation of the moderator band; in subpulmonic VSD it has contact to the posterior extension of the moderator band. These anatomic landmarks are important when it comes to intraventricular repair employing conal resection.

Subarterial obstruction, in most cases in the subpulmonary location, is related to the conal septum, also.

15.5.2.3 Associated Morphologic Variations

Less common variants of double outlet right ventricle are those with discordant atrioventricular connection or mirror-imaged atrial arrangement, usually in dextrocardia.

The combination of double outlet right ventricle with atrial isomerism (heterotaxy syndrome) increases the morphologic heterogeneity extremely often associated with unbalanced atrioventricular septal defect, hypoplasia of the mitral valve, and ventricular hypoplasia. These diagnoses are not suitable for biventricular repair.

Position of the great arteries and their relation to each other may vary. Most frequent are side-by-side arrangements with the aorta being to the right of the pulmonary artery. D-malpositions of the great arteries are not infrequent (see ► Sect. 15.5.1; also Sect. 15.5.2.1). L-malpositions are extremely rare. The extracardiac position and relation of the great arteries to each other is not predictive of intracardiac anatomy. In planning surgical strategy, knowing the exact anatomic relations of the great arteries is of major importance.

Coronary artery anomalies have to be suspected as in any other form of conotruncal malformation.

15.5.3 Pathophysiology

Corresponding to the morphologic heterogeneity, the clinical presentation is variable and depends mainly on the relation of the ventricular septal defect to the arterial outlets, association of obstruction of the pulmonary or aortic outlet, anomalies of the atrioventricular valves or aortic arch anomalies, and pulmonary vascular resistance.

In patients *with subaortic ventricular septal defect*, absence of obstruction to the pulmonary artery causes a hemodynamic situation as a simple but large VSD; with subvalvar or valvar pulmonary stenosis, the situation resembles that in tetralogy of Fallot. If the *interventricular connection is subpulmonary*, the aorta will obtain predominantly deoxygenated blood (d-TGA hemodynamics); without surgical intervention, the unobstructed pulmonary blood flow and pulmonary hypertension might induce pulmonary vascular obstructive disease already in early infancy. Associated aortic coarctation or interrupted aortic arch leads to

acute cardiac failure during ductal closure. The *subarterial VSD* can have both clinical pictures, in most cases, however, it will resemble a large VSD.

Clinical presentation in *doubly committed or remote ventricular septal defect* depends on intracardiac streaming and the potentially associated systemic or pulmonary arterial obstruction. A restrictive ventricular septal defect leads to left ventricular hypertrophy, sometimes left atrial hypertension.

15.5.4 Diagnostic Procedures

There is no clinical diagnosis leading to DORV. Auscultation, chest x-ray, and ECG are not helpful. Echocardiography is the most important diagnostic tool in primary diagnosis of double outlet right ventricle. It should also allow for a detailed description of associated anomalies. Nowadays in the majority of patients, diagnosis is made already prenatally because of the large interventricular communication and position of the arterial outlets being picked up rather easily (Kim et al. 2006).

Prenatal diagnosis of DORV should lead to term delivery close to a unit with extensive experience in management of neonates with congenital heart disease (Kim et al. 2006).

Because of surgical relevance, the echocardiography incl. Doppler sonography should give information on the following anatomical features:

- Type of interventricular communication (incl. location obstruction y/n)
- Outlet septum and position of the great arteries and subvalvular anatomy of the great arteries
- Morphology and function of semilunar valves
- Atrioventricular valve function and anatomy incl. chordae insertion for potential interference with the ventricular septal defect
- Coronary artery anatomy
- Aortic arch anatomy

Cardiac catheterization is necessary if echocardiography in neonates cannot offer complete preoperative diagnosis. Later in infancy, it is necessary to determine pulmonary vascular resistance.

Magnetic resonance imaging can support complete diagnosis of atrial arrangement and associated pulmonary or systemic venous anomalies.

15.5.5 Surgical Management

15.5.5.1 General Remarks

A variety of surgical techniques allow for intracardiac repair also in complex, but biventricular forms of double outlet right ventricle. Univentricular palliation following the Fontan principle or other palliative procedures should be preferred in patients with increased risk for repair and more complex forms with atrial isomerism, unbalanced ventricles, anomalies of the atrioventricular valves, or pulmonary atresia.

Palliative procedures preceding intracardiac repair include atrioseptostomy, pulmonary artery banding, or shunt procedures. An atrioseptostomy may be performed in patients with subpulmonary VSD or mitral stenosis, pulmonary banding, or shunt procedures in those patients with additional risk factors or unbalanced ventricles. In patients with accompanying aortic arch anomalies, separate arch surgery may precede definite repair (Brown et al. 2001).

Although Lev's classification is rather a continuous spectrum than a distinction of separated groups (Lev et al. 1972), we will discuss the surgical options along his classification and will mention atypical procedures as necessary. Technical details and controversies, like management of abnormal chorda insertion or VSD enlargement, will be dealt with in an own paragraph.

15.5.5.2 Repair of DORV with Subaortic VSD

Intraventricular correction is the typical form of repair for the most frequent variant of DORV: DORV with subaortic VSD. It is performed with a patch, which creates a tunnel from the left ventricle to the aorta employing muscular wall from the right ventricular outlet septum. Transatrial access is possible, but it might preclude sufficient visualization of the VSD to decide on a potentially necessary VSD enlargement. In these cases we suggest liberally employing an oblique infundibular incision across the outflow tract, which allows visualization of the semilunar valves,

enlargement of the VSD, and also correction of abnormal chordae insertion if present. A curved patch cutout of a PTFE tube graft is used to create the intraventricular tunnel, often a little bit oversized to prevent development of secondary subaortic stenosis. Patch insertion begins at the most distal point for the surgeon: next to the tricuspid valve for the transinfundibular approach and in the most apical corner working through the tricuspid valve. We always employ running polypropylene suture (5/0 for neonates and infants; 4/0 for older children). For relief of subpulmonary obstruction, resection of the conal septum may be necessary but might increase the risk of residual VSD (as lack of endocardium increases the risk of suture dehiscences). It also may lead to compromise of the aortic valve during patch insertion. The oblique infundibular incision may be closed directly but has to be checked for potential secondary obstruction. To avoid this, if in question, it is closed with implantation of a patch to enlarge the right ventricular outflow tract. In primary subvalvular obstruction, a longitudinal infundibular incision as in tetralogy of Fallot is used and if indicated later combined with transannular patch insertion. In infancy a myotomy is often sufficient; in older children muscle resection or resection of the conal septum might be required.

15.5.5.3 Repair of DORV with Subpulmonary VSD (Taussig-Bing Anomaly)

The term «Taussig-Bing anomaly» originally was coined for the famous heart described with the features of DORV, subpulmonary VSD, d-malposition of the great arteries, subaortic stenosis, as well as coarctation of the aorta (Taussig and Bing 1949; Van Praagh 1968). Thereafter, the term was generously applied for any DORV with subpulmonary VSD/d-malposition of the great arteries.

Two different surgical strategies are known: intraventricular conduit from the left ventricle to the aorta or tunnel patch closure of the VSD as in subaortic VSD now combined with arterial switch operation.

Intraventricular conduit repair has been described by Kawashima et al. (1971), Patrick and McGoon (1968) and Doty (1986). During recent years, the arterial switch operation is preferred (Belli et al. 1998) and offers good mid- and long-term functional results (Schwarz et al. 2013).

■ ■ Kawashima operation

In the Kawashima operation, intracardiac rerouting is performed posterior to the pulmonary valve (Kawashima et al. 1971) along the subarterial conus to the aorta (■ Fig. 15.12a). This operation is only possible with side-by-side relation of the great arteries. An anterior-posterior great vessel relation is a

■ Fig. 15.12 Schematic drawing of RVOT in coronal plane in DORV with subpulmonary VSD. Dotted lines show the course of suture lines of the future tunnel patch. **a** In Kawashima operation the intracardiac tunnel patch is running posterior to the pulmonary valve along the subarterial conus. **b** In Patrick-McGoon and Doty operation, the intraventricular tunnel lies anterior to the pulmonary artery

contraindication for this approach. Thus, the intracardiac conduit runs between tricuspid and pulmonary valve and needs sufficient space between them: at least half of the aortic diameter in order to prevent creation of subaortic obstruction. Surgical access for this operation is an infundibular incision that allows inspection of the intervalvar space and also the sub AV-valve apparatus to exclude straddling chordae (see ► Chapter «Anomalous Pulmonary Venous Connections and Congenital Defects of the Atria, the Atrioventricular Septum, and the Atrioventricular valves», Sect. 12.5). The tunnel patch should be redundant to prevent subaortic stenosis. Its suture line may be reinforced and/or comprised with deep suture bites where it passes resected conus septum or VSD enlargement areas.

■ ■ Rastelli operation

The intracardiac tunnel patch is implanted between the VSD and aorta passing the subpulmonary region. The connection from the right ventricle to the pulmonary artery is created via a valved or nonvalved conduit (Rastelli et al. 1969) or as a direct connection from the right ventricle to the pulmonary artery simultaneously with a Lecompte maneuver (Lecompte and Bex 1985); the pulmonary trunk has been transected and is closed at valvular level to avoid a residual pulmonary stump which may become a source for systemic thromboemboli. See also ► Chapter «Congenitally Corrected Transposition and D-Transposition of the Great Arteries», Sect. 19.2.6.4.

Rastelli surgery for DORV with normal pulmonary valve should only be considered in those patients who reveal very unusual coronary pattern or the awkward «double outlet both ventricles» (see below).

■ ■ Patrick-McGoon and Doty operation

Nowadays these techniques are seldom used. Intraventricular rerouting is yielded with a tunnel running anterior to the pulmonary valve (Patrick-McGoon operation) or with a tube graft (Doty operation) (■ Fig. 15.12b).

■ ■ Special features of arterial switch operation in DORV

The technique of the arterial switch operation is described in ► Chapter «Congenitally Corrected

Transposition and D-Transposition of the Great Arteries», Sect. 19.2.5.2. Coronary artery anomalies and the position of the great arteries in DORV can complicate the procedure further; as said above, patients with a side-by-side position of the great arteries may be more suitable for intracardiac rerouting repair. With side-by-side position of the great arteries, the Lecompte maneuver should be combined with a translocation of the pulmonary bifurcation to the right pulmonary artery; the original pulmonary bifurcation can be closed directly or with a patch. In the rare situation of posterior position of the aorta, a Lecompte maneuver might be unnecessary (Van Praagh et al. 1970; Wilkinson et al. 1975; Tanaka et al. 1993). Coronary artery anomalies have to be suspected more often than in transposition of the great arteries; most often is a common origin of the LAD and the right coronary artery from the anterior sinus. This relates to coronary pattern type AB1 according to the SAUER classification (Gittenberger-de Groot et al. 1983) or type 1L 2RCX of Quaegebeur's classification (Quaegebeur 1986). Even with normal origin of the coronary arteries, their course might be tortuous around the arterial root before the coronary arteries reach the atrioventricular groove in a «looping pattern» (Jonas 1998; Planche et al. 1998). This has to be considered during the early postoperative period when changes in pre- and afterload could cause aortic and pulmonary root dilatation and increased tension on the reimplanted coronary arteries compromising myocardial perfusion. This may result in an unstoppable vicious cycle of ischemic myocardial failure despite originally undisturbed coronary perfusion. These patients react very unfavorably to «fluid resuscitation» in face of a deteriorating arterial blood pressure.

Side-by-side relation of the great arteries is not infrequently associated with subaortic obstruction, aortic valve hypoplasia, or hypoplasia of the ascending aorta. Resection of the conal septum and patch enlargement of the infundibulum might be necessary. In presence of annular hypoplasia, a transannular patch (for the neopulmonary artery) is needed.

Patients with aortic arch obstruction including hypoplasia, interruption, or coarctation often undergo separate surgical arch repair as a stage one palliation, but also one-stage repair is recommended with even better survival as claimed (Kleinert et al. 1997; Schwarz et al. 2013).

15.5.5.4 Repair of DORV with Noncommitted VSD

The interventricular communication remote from the ventricular outflow tracts still allows interventricular tunnel repair in otherwise noncomplex forms of double outlet right ventricle (Barbero-Marcial et al. 1998; Brown et al. 2001). This type, however, often is complicated by straddling atrioventricular valves, ventricular imbalance, or atrial isomerism making enlargement of the VSD and/or adequate placement of the tunnel patch quite difficult. In these cases intracardiac repair bears a high risk and a conversion to univentricular circulation or bidirectional cavopulmonary anastomosis is frequently preferred as it overcomes the technical difficulties and risks still offering good long-term results (Kleinert et al. 1997; Delius et al. 1996; Jonas 2004).

In biventricular repair of DORV with remote VSD, enlargement of the VSD is mandatory in order to permanently provide unrestricted systemic blood flow.

Despite adequate enlargement at the original operation, midmuscular VSD have the tendency to shrink causing severe post repair SAS at times. The question may be raised whether a biventricular repair is ever indicated in DORV/remote VSD, despite primary feasibility and «success.»

An intermediate variant of surgical management may be a one-and-a-half ventricle repair, when intra right ventricular rerouting lead to critical RV volume reduction. A bidirectional Glenn anastomosis is added to the intraventricular «repair» (see also ► Sect. 15.6).

15.5.5.5 Repair of DORV with Doubly Committed VSD

This form is the least frequent of the four groups as defined by Lev. It accounts for only 4–7% of biventricular repairs in DORV (Aoki et al. 1994; Lacour-Gayet 2008). The VSD is of oval, sometimes slitlike shape located immediately underneath the semilunar valves. Both the semilunar valves are in fibrous continuity by absence of the muscular outlet septum sometimes overriding both ventricles. Due to the questionable 100% + 51% rule for DORV set up by Bob

Anderson (Anderson 1983), the rather grotesque definition of «double outlet both ventricles» came up (Brandt et al. 1976). Intraventricular repair is always feasible, however, and may be complex. Enlargement of the VSD may almost always be indicated, and depending on the intracardiac rerouting and tunnel patch insertion, an arterial switch operation or Rastelli procedure may become necessary.

15.5.5.6 Surgical Management Controversies

VSD size and/or chordal attachments close to the VSD or en route of the planned subaortic tunnel may complicate DORV repair further. This includes any type of atrioventricular valve abnormalities such as common atrioventricular valve or straddling or abnormal chordae insertion at the ventricular septum or conal septum. We try to separately look at both anatomic features, VSD, and chordae tendineae.

■ ■ Abnormal chordal attachments at the conus septum

While preoperative echocardiography allows exact diagnosis, defining any abnormal insertions of chordae, their functional importance can often only be judged intraoperatively. Insertions of *tricuspid valve* chordae at the VSD or conal septum can be detached to reliably close a VSD. Thereafter, these chordae may be reimplanted at the VSD patch or be replaced by PTFE neochordae, with patch attachment also or at any other suitable site providing a functionally satisfactory result. Abnormal chordae insertion of the *mitral valve* is much more difficult to handle and can cause severe postoperative valve dysfunction; often conversion to a univentricular palliation has to be recommended, preferably before any chordae are detached. The problems with the abnormal chordae are twofold: (1) reimplantation has to be carried out at the left side of the patch, which means it has to be done while the patch still needs to be sutured in place and (2) mitral valve function after biventricular repair is a critical factor for success, much more than the tricuspid valve.

Double outlet right ventricle with *atrioventricular septal defect* carries an increased mortality and reoperation rate for both biventricular repair and single-ventricle palliation; common atrioventricular valve regurgitation is an additional significant risk factor (Ong et al. 2012).

■ ■ Enlargement of the VSD

This is an often debated topic. Some suggest to routinely perform it during intracardiac repair and others only in presence of small or uncommon VSDs (noncommitted or doubly committed VSD). If the anteroapical enlargement is technically feasible, we recommend to do it always. The distal border of resection should be the septal papillary muscle and muscle of the outflow tract (M. Lancisi) to avoid a conduction/heart block. Closing the VSD with a patch after enlargement, one has to be reminded to take deep bites in the endocardial-free area of enlargement.

15.5.6 Follow-Up

Early postoperative mortality is low in patients with noncomplex forms of double outlet right ventricle undergoing biventricular repair. Late morbidity is determined by ventricular arrhythmia and reoperations for atrioventricular valve dysfunction, residual VSD, subarterial/conduit obstruction, or aortic valve insufficiency (Kleinert et al. 1997; Brown et al. 2001).

For patients with complex forms of double outlet right ventricle or those unsuitable for biventricular repair, the Fontan circulation is recommended although its own late morbidity and mortality during long-term follow-up has to be considered.

15.6 Pulmonary Atresia with Intact Ventricular Septum (PA/IVS)

15.6.1 Definition

Pulmonary atresia with intact ventricular septum (PA/IVS) is a rare defect accounting for 1–3% of congenital heart disease. It presents with great morphologic heterogeneity. Right ventricular cavity, tricuspid valve, pulmonary valve, and pulmonary annulus are affected; in addition, right ventricle to coronary artery connections are present. Sounding very much straight forward and simple by nomenclature, pulmonary atresia with intact ventricular septum reveals both complex pathoanatomic variations and surgical strategies.

Early fetal echocardiography may show a forward flow in right ventricle and a patent infundibulum in patients presenting later with pulmonary atresia. As it seems to develop later in fetal life, it may be even looked at as an «acquired» process (Sandor et al. 2002).

15.6.2 Pathoanatomy

15.6.2.1 Right Ventricle and Tricuspid Valve

The right ventricle in PA/IVS is always hypoplastic. The historical classification distinguishing between two forms, one with a hypoplastic and one with a dilated RV (Davignon et al. 1961), is not used anymore, as the form with the dilated «ventricle» is rather a variant of Epstein's disease of the tricuspid valve (see also ► chapter «Anomalous Pulmonary Venous Connections and Congenital Defects of the Atria, the Atrioventricular Septum, and the Atrioventricular Valves», Sect. 12.4).

Patients with pulmonary atresia and intact ventricular septum present with a broad morphologic spectrum characterized by membranous atresia or infundibular obstruction and muscular atresia; right ventricular hypoplasia with tri-, bi-, or unipartite morphology; and dysplastic or hypoplastic tricuspid valve. In addition, major or minor right ventricle-coronary arterial communications can coexist (in 30–60% of the infants), resulting in a potentially right ventricular-dependent coronary artery circulation and bearing the risk of future coronary artery stenosis or interruption. The initial tricuspid valve diameter (z-score) can be used as a surrogate parameter for the right ventricular hypoplasia (Hanley et al. 1993; Ashburn et al. 2004). This size and the association with the presence of major right ventricle-coronary artery connections determine surgical decision and are associated with survival and functional result. This was also thought to be influenced by the more descriptive classification of a tripartite (and mild hypoplastic right ventricle), bipartite, or unipartite right ventricle (with severe hypoplasia) (Bull et al. 1982), based on an original model from Goor and Lillehei (1975). Combining measurements of the tricuspid valve diameter and right ventricular volume will probably give the most sensitive parameters for surgical decision (Yoshimura et al. 2003).

- Mild right ventricular hypoplasia is often present in patients with membranous atresia and a well-developed infundibulum.
- Severe right ventricular hypoplasia with an obliterated infundibulum represents the other end of the morphological spectrum; the apex volume is often taken up by severe hypertrophy of papillary and trabecular muscles. This situation is complicated by right ventricle-dependent coronary artery circulation.
- The intermediate form can be characterized by a borderline right ventricular size with an infundibular portion; the trabecular portion might be reduced. Major or minor right ventricle-coronary arterial communications can be present (Alwi 2006).

Patients with dysplastic or severely insufficient tricuspid valve or Ebstein's anomaly (present in 5–10%) and concomitant right ventricular dilatation need separate judgment.

Hypertrophic myocardium, myocardial fiber disarray, and endocardial fibrosis are discussed for the restrictive right ventricular physiology during long-term follow-up; neonatal endocardial fibrosis is a rare finding and may be related to volume loading of the left ventricle or unstable coronary perfusion in right ventricular-derived perfusion of the left and right ventricle.

15.6.2.2 Coronary Arteries

Coronary artery abnormalities are found in 30–60% of patients with pulmonary atresia with intact ventricular septum; right ventricular hypertension promotes the persistence of embryonic right ventricle-coronary artery fistulas (Freedom et al. 2005). They are less frequent in the well-developed ventricle and can be diagnosed using fetal echocardiography allowing right ventricular decompression. Right ventricular-dependent coronary artery circulation is characterized by retrograde high-pressure hypoxic perfusion; turbulent flow may cause endothelial lesions predisposing to stenosis, occlusion, or secondary ostial atresia, an ongoing process even postnatally (Gittenberger-de Groot et al. 1988). The presence of right ventricular-dependent coronary circulation is only a contraindication for right ventricular decompression when stenosis is present in both the right and left coronary systems; this could result in myocardial steal and infarction. A palliative single-ventricle repair is recommended in

these patients (Giglia et al. 1992; 1993). With a non- or less stenotic coronary system in right ventricular-dependent circulation to start with, the RV to coronary connections diminish or may even disappear, as seen also in our own experience. Therefore, in most of the so-called right ventricular-dependent coronary circulation, dependency is rather a term used for coronary flow originating from the right ventricle, while definitive dependency is present in only a few cases with proximal stenosis of a solitary coronary artery or stenoses in both the right and left coronary artery.

15.6.2.3 Pulmonary Valve and Pulmonary Arteries

The atretic pulmonary valve may be well developed with fused commissures, but most often it is only rudimentary and appears as a fibrous membrane. The anulus frequently is hypoplastic. Typically the pulmonary trunk and branches distal to the atretic valve are normal; hypoplastic branch pulmonary arteries or arborization abnormalities are a rare finding (nearly 6%). Also significant aortopulmonary collaterals are usually absent. As in any right ventricular obstructive lesion, pulmonary artery coarctation/LPA stenosis may develop (Luhmer and Ziemer 1993).

15.6.2.4 Ductus Arteriosus

The morphology of the arterial duct is important regarding the option of ductal stenting (origin from the aorta, tortuosity, shape and length, diameter).

15.6.3 Symptoms and Diagnostic Procedures

Neonatal cyanosis with closure of the arterial duct is the leading symptom, so prostaglandin infusion immediately after birth is indicated. Usually fetal echocardiography has allowed for prenatal diagnosis.

Precise morphologic diagnosis as well as estimation of right ventricular size, tricuspid valve size, and calculation of the initial z-score can be obtained with transthoracic echocardiography. Right ventricular inlet length or area can be measured leading to an enddiastolic volume calculation. This, however, has some limitations in presence of severe myocardial hypertrophy resulting from complete right outflow tract

obstruction. For detailed evaluation of the right ventricle, nature of pulmonary atresia, morphology of the infundibulum, and arterial duct angiography may be necessary when echocardiography is incomplete. Angiography may be also necessary to reveal detailed coronary artery anatomy as coronary fistula and/or stenosis involving both the right and/or left coronary artery have to be considered especially in patients with hypoplastic right ventricle and suspicion of coronary abnormalities. This is especially advisable in major right ventricle-coronary arterial connections described in echocardiography in order to define number, size, and course of the vessels; right ventriculography documents retrograde filling of the aorta as well as significant stenosis. Additional antegrade selective coronarography can be performed also.

15.6.4 Surgical Management

15.6.4.1 Introduction

Historically rather poor results of surgical treatment for PA/IVS up to the 1980s may be attributed to neglect of coronary anatomy and aiming too often and too early at a biventricular repair. Now stratified management algorithms have been used for surgical decision-making and correspond to the morphologic classification (Hoashi et al. 2012; Alwi 2006). Surgical strategy depends on size and morphology of the right ventricle (tripartite right ventricle), nature of valvar atresia, size and function of the tricuspid valve, and presence of right ventricle-dependent coronary artery circulation. The goal of surgical repair is separation of systemic venous and pulmonary venous circulation using either univentricular or biventricular repair. The one-and-a-half ventricle repair is the surgical option in patients with borderline right ventricular size. One-and-a-half ventricle repairs for PA/IVS have been first performed by Hillel Laks and his group. At that time 4 of 15 patients were still presented in the biventricular repair group, although surgery also included a Glenn anastomosis and an adjustable ASD (Billingsley et al. 1989).

As it is rather unreliable to decide early on about the final strategy, primary palliation in neonates shall keep all therapeutic options open. This first stage surgery aims at improvement of oxygenation and to establish antegrade flow through

the right ventricle. Both measures promote growth of the right ventricle and tricuspid valve. They consist of pulmonary valvotomy, balloon valvuloplasty (if necessary repeatedly) or right ventricular outflow tract patch in combination with a systemic-to-pulmonary shunt if oxygenation is insufficient. The second step of surgery has to decide between biventricular repair and palliation following the Fontan principle and depends more on the initial right ventricular size and tricuspid valve z-score than on the growth capacity of the right ventricle as ventricular enlargement might result from volume load by tricuspid and right ventricular insufficiency more than real growth. The morphology of the coronary arteries with fistula and stenosis and right ventricle-dependent coronary artery circulation precludes a procedure with right ventricular decompression when more than one coronary artery or a single coronary artery reveals stenosis.

Most patients undergo surgery, and only in selected patients with membranous atresia a *catheter-based intervention* can be performed employing membrane perforation followed by balloon valvotomy; catheter-derived stenting of the ductus arteriosus is an alternative option to surgical shunt procedure in order to avoid prolonged treatment with prostaglandin (Udink ten Cate et al. 2013). Neointimal proliferation requires redilatation of the ductus or replacement by a shunt. The need for a systemic-to-pulmonary *shunt procedure* for sufficient pulmonary blood flow shows some association with the right ventricular size but does not preclude biventricular repair during later follow-up. In some patients this will initially cause a period of left ventricular volume overload and congestive heart failure.

The surgical approach will be dealt with separately for mild, moderate, and severe hypoplasia as well as for presence of right ventricular-dependent coronary circulation. Thereafter, surgical controversies are discussed. Any surgical procedure comprising more than an isolated shunt implantation requires support of extracorporeal circulation.

15.6.4.2 Mild Right Ventricular Hypoplasia

In patients with mild right ventricular hypoplasia as described with a tricuspid valve z-score > -2.5 , well-developed infundibulum, most often membranous atresia, and usually absence of major right ventricle to coronary artery connections, a

biventricular repair should be feasible. Preferably surgical valvotomy and transanular patch plasty or alternatively catheter-based valvotomy and balloon dilatation establish antegrade flow and allow increase in right ventricular volume. Severe muscle hypertrophy might require myectomy for relief of infundibular obstruction. Prolonged prostaglandin infusion might be necessary in persistent restrictive right ventricular physiology. Insufficient increase in oxygenation requires a shunt procedure either as a central aortopulmonary shunt or modified BT shunt procedure. Shunt flow will depend on shunt size and length. Shunt size is chosen in relation to body weight (<2.5 kg 3-mm shunt; up to 4 kg 3.5-mm shunt, >4 kg 4-mm shunt); the length of a central shunt and thereby its resistance can be modified by a course around the right ventricular infundibulum (■ Fig. 15.13b)

Closure of the ductus arteriosus might induce coarctation of the pulmonary artery (Luhmer and Ziemer 1993); in expecting this situation, the transanular patch plasty should be extended into the left pulmonary artery in these patients. A shunt prosthesis may already be ex situ anastomosed to the PTFE patch, before used as plasty material for the pulmonary artery («chimney patch»; Plunkett et al. 1998; ■ Fig. 15.13a).

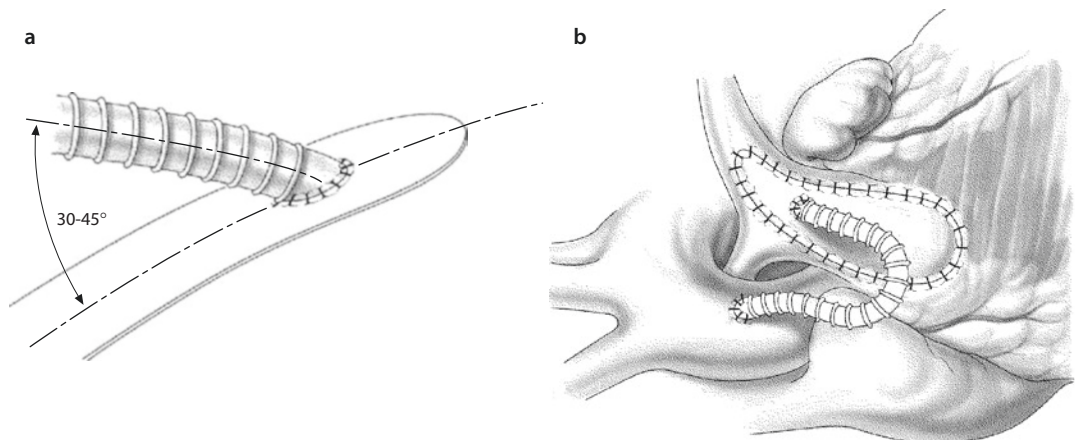

The foramen ovale or an atrial septal defect remains open to allow for right atrial decompression in presence of restrictive right ventricular myocardium. During later follow-up, partial or definitive closure can be performed after test occlusion during cardiac catheterization.

15.6.4.3 Moderate Right Ventricular Hypoplasia

With usually valvular and membranous atresia, the right ventricular trabecular component is often absent or attenuated. The infundibulum may be patent to its end at the atretic valve, the pulmonary valve anulus and infundibulum being small. Major and minor right ventricular coronary artery connections may be present. Borderline right ventricular size with a tricuspid valve z-score between -2.5 and -4.5 usually precludes biventricular repair although some reports describe successful biventricular repairs in initially small right ventricles (Foker et al. 2008; Shaddy et al. 1990). However, in this situation restrictive physiology might develop after biventricular repair if right ventricular enddiastolic volume is less than 60% of normal.

■ ■ Neonatal Palliation

In any case of moderate hypoplasia, the option should be kept to later incorporate the RV into the circulation. The initial right ventricular outflow tract plasty combined with a shunt procedure is the surgical procedure of choice (catheter-based intervention is described above). Cardiac catheterization with test occlusion of the shunt and atrial communication about 1 year later might allow the decision to go further with biventricular repair. If right atrial pressures increase prohibitively high after probatory shunt and atrial septal occlusion, one-and-a-half ventricle repair has to be considered.

■ Fig. 15.13 a Ex situ created PTFE shunt anastomosis with the patch plasty; b redundant shunt course around the right ventricular infundibulum

■ ■ One-and-a-half ventricle repair

Considering initial tricuspid valve z-score, the *one-and-a-half ventricle repair* is preferable in these patients. This stage II procedure consists of the bidirectional Glenn anastomosis with closure or restriction of the atrial septal defect. The central shunt from stage I neonatal palliation is explanted.

This procedure can be applied as early as 6 months of age, although adequate oxygenation and low pulmonary artery pressures may allow waiting into the second year of life.

The decision-making of whether the moderate hypoplastic right ventricle can pump the IVC blood with normal preload may be made by individual estimation of right ventricular volume and function; however, most important are the hemodynamics after probatory occlusion of the atrial septal defect during preoperative cardiac catheterization. Right atrial pressures should not exceed 15 mmHg with impaired cardiac output. Published data see reduced right ventricular function and a right atrial pressure of more than 12 mmHg or more than twice the left atrial pressure at probatory ASD occlusion as indication for univentricular approach (Alwi et al. 2000). Z-values of the tricuspid valve outside the neonatal period are rather unreliable predictors.

■ ■ Bidirectional Glenn anastomosis

The bidirectional Glenn anastomosis as the only stage two surgery is the procedure of choice in any borderline small right ventricle. It allows reduction of the ventricular volume load and balances systemic and pulmonary blood flow for a long time. This strategy has the advantage of encouraging right ventricular and pulmonary artery growth and provides some pulsatile pulmonary blood flow by conducting the inferior caval and hepatic venous blood through the right ventricle without increasing right atrial pressures; with the superior vena cava–pulmonary artery anastomosis, one third to one half of the systemic venous return diverts directly to the pulmonary circulation. The Glenn procedure can be performed at the age of 6 months or later if the arterial oxygenation remains adequate. We suggest to always leave the aortopulmonary shunt open for better postoperative oxygenation as tolerated by PA pressures. This may allow to postpone the decision for the Fontan procedure for a mean of 6 years as shown by Pascal Vouhe's group

(Gerelli et al. 2012). During that time, further evaluation for the preferential one-and-a-half ventricle option is possible.

■ ■ Modified Fontan Surgery

Details of Fontan Surgery are outlined in ► Chapter «Definite Palliation of Functionally Single Ventricle», Sect. 13.6 and Sect. 13.7. It may be mentioned for patients after central shunt and RVOT patch that the RVOT has to be occluded/divided from the pulmonary circulation if not done so at the time of Glenn procedure. Then the tricuspid valve should be excised or at least made completely insufficient in order to prevent suprasystemic pressures in the RV that could provoke rhythm problems, extremely unfavorable in a Fontan state.

15.6.4.4 Severe Right Ventricular Hypoplasia

Severe right ventricular hypoplasia is characterized by an initial neonatal tricuspid valve z-score < -4 ; the trabecular portion is often absent, the infundibulum diminutive or absent (muscular atresia), and the right ventricle unipartite, the only open part being a diminutive RV inlet portion. For long-term treatment, these patients are best served with a Fontan procedure (Hanley et al. 1993). In these diminutive right ventricles, major right ventricle to coronary artery connections are common and may show on angiography stenosis or interruptions. The association with suprasystemic right ventricular pressure leads to the term right ventricular-dependent coronary circulation. Often the significance of right ventricle to coronary artery connections, the actual RV dependency is unpredictable. The Boston Children's Hospital group found only two stenotic/interrupted coronary arteries or a stenotic/atretic single coronary artery defining actual dependency with immediate death after RV decompression (Giglia et al. 1992; 1993).

The duct-dependent pulmonary blood flow requires an aortopulmonary shunt procedure. As atrial septostomy is only rarely necessary in neonates, an alternative primary procedure could be interventional ductal stenting. This, however, leaves the RV under high pressure and therefore in our mind is only indicated when significance of coronary stenosis requires an undecompressed RV. Prior to any decision for or against decompression, coronary arterial anatomy has to be investigated angiographically in detail.

If the univentricular surgical pathway is chosen, decompression of the right ventricle by partial or complete tricuspid valvectomy only can be considered using cardiopulmonary bypass.

With going on bypass, the ductus arteriosus is closed, and the pulmonary shunt anastomosis is created; as pulmonary coarctation has to be supposed, the pulmonary shunt anastomosis should be extended into the left pulmonary artery (■ Fig. 15.14). For decompression of the right ventricle, the hypoplastic tricuspid valve will be resected. Then atrial septectomy is performed, complemented by coronary sinus incision for definite and reliable creation of permanent unrestrictive interatrial communication (Schraut et al. 1974).

At the age of 6–8 months, a bidirectional Glenn anastomosis is performed followed by completion of the Fontan circulation as outlined in ► Chapter «Definite Palliation of Functionally Single Ventricle», Sect. 13.5.5 and Sect. 13.7. The functional result can be expected to be the same as for other Fontan patients with the left ventricle as the systemic ventricle. Patients with persistent RV-dependent circulation, however, will do worse (Giglia et al. 1993).

15.6.4.5 Right Ventricular-Dependent Coronary Circulation

If proximal coronary stenoses are present, tricuspid valvectomy for *right ventricular decompression* can cause myocardial ischemia and ventricular arrhythmia and remains a high-risk procedure with high mortality. If left not decompressed, change in ventricular geometry can cause subaor-

■ Fig. 15.14 Anastomosis of the PTFE shunt with the hypoplastic pulmonary artery and enlargement of the left pulmonary artery by oblique shunt insertion in patients with presumed pulmonary coarctation

tic stenosis by bulging of the hypertensive right ventricle (Razzouk et al. 1992). Beyond the neonatal period, other surgical considerations like *patch closure of the tricuspid valve* or right ventricular thromboexclusion to prevent coronary steal have been reported (Waldman et al. 1984; Williams et al. 1991). To improve coronary perfusion during infancy, an aorta to right ventricle conduit was considered (Freeman et al. 1993; Laks et al. 1995). In addition, this conduit should cause right ventricular decompression during systole; clear indication and long-term results are missing (Laks and Plunket 2001). However, the Fontan procedure allows for coronary perfusion with oxygenated blood coming from the left atrium via tricuspid valve to perfuse the coronary arteries during right ventricular systole.

Heart transplantation was considered as an alternative strategy in these patients (Rychik et al. 1998), but is not a realistic concept for primary surgical intervention in the neonatal period. It may remain a secondary option once myocardial dysfunction leads to clinical deterioration.

15.6.4.6 Surgical Controversies and Therapeutic Alternatives

■ Closure of coronary fistulas during primary neonatal surgery

After preoperative diagnosis and intraoperative identification by epicardial echocardiography, this concept suggests ligation of right ventricle to coronary artery connections off bypass before right ventricular decompression. Probatory ligations of coronary connections with 7/0 sutures are immediately and individually checked for resulting wall motion abnormalities by transesophageal echocardiography. The idea is to induce antegrade coronary flow taking away the high-pressure hypoxic coronary flow, which might induce the observed secondary coronary lesions. In their experience ligation did not produce visual myocardial consequences or wall motion abnormalities during intraoperative echocardiographic surveillance (Foker et al. 2008). The authors claim, as others before (Hausdorf et al. 1987; Rychik et al. 1998), that these noncritical connections contribute to early postoperative myocardial dysfunction. The risk of this concept is, however, that instead of awaiting the spontaneous closure of these small vessels, actual autochthonous coronary arteries are damaged.

■ ■ Extensive right ventricular muscle resection (right ventricular «overhaul»)

Originally from Melbourne, Australia, and then in Cleveland, Ohio, Roger Mee's group suggested in hypoplastic RV with open infundibulum to perform an extensive transatrial and transinfundibular myectomy to enlarge the diastolic right ventricular cavity. The idea was to improve right ventricular growth for biventricular repair (Pawade et al. 1993). While some patients who may have been candidates for biventricular repair anyways may have become ready for repair earlier than without myectomy, the aim of the procedure to make more patients eligible for biventricular repair could not be reached (Bryant et al. 2008).

■ ■ Closed («off-pump») pulmonary valvotomy during primary surgery

These procedures stem from an era where morbidity from extracorporeal circulation in neonates overwhelmed the early postoperative management. The last who published on this track, going even further, were Laks and Plunket (2001): they suggested off-pump infundibulectomy and transanular outflow tract patch insertion. We think that with today's technology, a technically perfect procedure overcomes the disadvantages of extracorporeal circulation.

■ ■ Catheter-based interventions

In patients with membranous atresia, a catheter-based procedure can be considered with perforation of the atretic plate followed by repeated balloon dilatation. A high technical success rate of 80–90% can be expected in selected patients (Alwi et al. 2000), but only a relative small proportion of patients with pulmonary atresia and intact ventricular septum can be considered for this procedure (Parsons et al. 1991; Bichell 1999). In some patients this procedure has to be combined with a surgical shunt procedure or later a right ventricular outflow tract patch resulting in a hybrid biventricular repair (Hoashi et al. 2012). Stenting of the arterial duct is recommended in selected patients as an alternative to prolonged prostaglandin administration and perhaps shunt procedure (Alwi 2006).

15.6.5 Follow-Up

Long-term studies could demonstrate that functional capacity after PA-IVS repair is reduced

regardless of the surgical strategy with uni- or biventricular repair; oxygen consumption was positively correlated to initial tricuspid valve z-score (Karamlou et al. 2013). Patients after univentricular palliation present with similar results as other Fontan patients characterized by inadequate chronotropic response and limited cardiac reserve and unfavorable ventricular filling (Romeih et al. 2012). Only patients with mild right ventricular hypoplasia (tricuspid valve z-score < -2.5) and with two or more right ventricular segments bringing them to a favorable end of the spectrum of PA-IVS might show normal exercise capacity (Romeih et al. 2012; Karl 2012). Late clinical follow-up after biventricular repair describes complications due to tricuspid or pulmonary insufficiency with right ventricular dilatation or arrhythmia; a small or hypertrophied right ventricle predisposes to restrictive physiology with compromise of systemic cardiac output (Hoashi et al. 2012). Careful initial management and selection for those who undergo biventricular repair are indicated. And even in selected patients, biventricular repair may cause systemic venous congestion and low output because of increased pulmonary vascular resistance or decreased left ventricular filling; leaving the ASD open or fenestrated for right-to-left shunting can stabilize the hemodynamic situation.

For borderline right ventricular size, better outcome may be achieved with a one-and-half ventricle or univentricular repair (Karamlou et al. 2013).

15.7 Double-Chambered Right Ventricle (DCRV)

15.7.1 Definition

Double-chambered right ventricle is an uncommon congenital heart defect and potentially progressive disease although natural history is unknown. The underlying morphologic substrate is supposed to be congenital, while the course of the disease resembles an acquired disease (Hartman et al. 1964). The incidence varies from 0.5 to 2%.

15.7.2 Anatomy

Right ventricular cavity is divided in two chambers by abnormal muscle or fibromuscular bundles. The

proximal chamber becomes the high-pressure, hypertrophied chamber; the distal chamber has low pressure. The anomalous muscle bundle traverses the right ventricular cavity and shows a midventricular fibrous ridge, hypertrophied moderator band, or hypertrophied papillary muscles. Severity and location of the obstructing muscular is variable (Alva et al. 1999; Wong et al. 1991).

A VSD is associated in more than 80%, most often a perimembranous type of VSD.

Double-chambered right ventricle might develop postoperatively after VSD closure or after correction of TOF with the typical morphologic criteria (Moran et al. 1998).

15.7.3 Symptoms and Diagnostic Procedures

In childhood a systolic murmur is leading to diagnosis by echocardiography. In infancy dyspnea and failure to thrive or cyanosis might rarely develop. Diagnosis is made usually before the age of 10 years. Late diagnosis in adulthood might be accompanied by dyspnea and syncope or angina (McElhinney et al. 2000). The description of an anomalous right ventricular bundle needs regular follow-up because of well-known progression; sometimes β -blocker medication might be indicated in this situation (Arai et al. 2001).

Echocardiography usually allows the diagnosis and description of associated lesions in pediatric patients (Hoffman et al. 2004). In adults the echocardiographic diagnosis might be incomplete and needs confirmation by right heart catheterization or—predominantly—MRI (Kilner et al. 2002).

15.7.4 Surgical Approach

Indications for surgical intervention are clinical symptoms, increasing right ventricular gradient (exceeding 40 mmHg at rest) and associated anomalies as a VSD with relevant left-to-right shunt, or aortic regurgitation. For relief of intraventricular obstruction, usually a combined transatrial-transventricular or transatrial approach is chosen; in pediatric patients often the transventricular approach is indicated for accurate demonstration of the right ventricular obstruction. The surgical result is functionally

and morphologically excellent. Late ventricular dysfunction and arrhythmia are rarely described (Said et al. 2012).

16.1 Introduction

Congenital left ventricular outflow tract obstruction accounts for approximately 10% of congenital cardiac malformations (Samanek et al. 1989). For practical purposes, the site of obstruction is anatomically classified as valvular, subvalvular, or supravalvular aortic stenosis or as a combination of the three—multilevel stenosis.

The decision-making process and planning of operative care are complicated by the heterogeneous makeup of patients with left ventricular outflow tract obstruction. In neonates, the critical point is to decide whether biventricular repair is feasible. Patients with isolated stenosis and a well-developed left ventricle are optimal candidates for biventricular repair. At the other end of the spectrum, the left ventricular outflow tract obstruction may be part of complex congenital cardiac malformations with a morphologically or functionally (endocardial fibroelastosis) borderline left ventricle, with multiple sequential outflow obstructions (Shone syndrome, HLHS, etc.) where single-ventricle pathway may be the optimal approach (see ► Chapter «Surgery for Aortic Atresia, Hypoplastic Left Heart Syndrome, and Hypoplastic Left Heart Complex», Sect. 17.6.8).

Normal growth, desire for an active lifestyle with the appropriate activity level, and difficulty in medical compliance, especially in teenagers, represent another specific set of requirements posed by this subset of patients. In general, the prosthetic materials should not compromise cardiac growth and lifestyle. In particular, the development of pulmonary autograft procedure for replacement of the aortic valve and aortic root has dramatically changed the approach to children with congenital aortic valve disease and complex left ventricular outflow tract obstruction. On the other hand, in some children the best alternative is still to use a prosthetic valve or allograft, despite the well-known drawbacks of these procedures.

The indication criteria and the current techniques applied for left ventricular outflow tract obstruction will be discussed later on.

This chapter will not cover left ventricular outflow tract obstructions that are associated with other complex malformations such as conoventricular malalignment as seen in ventricular septal defects with an interrupted aortic arch (see ► Chapter «Congenital Anomalies of the Great Vessels», Sect. 21.2.1.2), double-outlet right ventri-

cles (see ► Chapter «Congenital Heart Disease with Anomalies of the Right Ventricular Outflow Tract», Sect. 15.5), atrioventricular canal defects (see ► Chapter «Anomalous Pulmonary Venous Connections and Congenital Defects of the Atria, the Atrioventricular Septum, and the Atrioventricular Valves», Sect. 12.1.5), complete transposition of the great arteries with a ventricular septal defect (see ► Chapter «Congenitally Corrected Transposition and D-Transposition of the Great Arteries», Sect. 19.2.6.3), restrictive bulboventricular foramen in single-ventricle hearts (see ► Chapter «Definite Palliation of Functional Single Ventricle», Sect. 13.3.2.1; 13.3.2.2; 13.4; 13.5.2; 13.7.1.1; 13.7.4.4; 13.8.1.1), or other complex structural defects.

16.1.1 The Normal Anatomy of the Left Ventricular Outflow Tract and Aortic Root

16.1.1.1 Aortic Valve

The normal aortic valve is composed of three cusps attached in a semilunar fashion beneath each of the three sinuses of Valsalva. The sinuses and the cusps are named according to the origin of the coronary arteries, namely the left, right, and noncoronary sinuses and cusps. The valve cusps are composed of fibrous tissue lined with endothelium. There is a small fibrous thickening in the middle of the free edge, the nodule of Arantius (Latin: nodulus Arantii). The cusps are attached to the aortic anulus at the hinge points. It is not a true anulus as it is not circular and all the points of attachment do not lie in the same vertical plane. The aortic valve rarely is symmetrical with regard to commissure distances and the size of the cusps. The noncoronary cusp is normally the largest, with the left, the deepest and the right, the shallowest cusp (Ralph 1998).

Above the valve, the aortic wall is expanded to form the sinuses of Valsalva. The dilatation of the sinuses ends at the level of the tip of the commissures. At that level there is a discrete ridge marking the sinotubular junction of the aorta. The diameter of the sinotubular junction is 10–15% smaller than the diameter of the aortic anulus (Kunzelman et al. 1994; Sands et al. 1969; Silver and Roberts 1985; Swanson and Clark 1974). The cusps are separated by the commissures. On the ventricular aspect, the insertion of the valve delineates three triangular areas between each cusp

where the aortic wall is thinner. These triangles separate the left ventricular outflow tract from the pericardial cavity. The height and width of the intercusp triangle govern the area of cusp apposition.

In a normal three-cusp aortic valve, the length of the free edge of each cusp equals the diameter of the aorta. This «extra length» of the cusps represents an important element of normal valvular function. During the ventricular systole, the extra length of each cusp allows the free edge of each cusp to approach the aortic wall, thereby allowing the aortic orifice to open freely. At the same time, the eddy currents in the sinuses of Valsalva prevent occlusion of the coronary ostia. During diastole, all three cusps meet at the central nodules of Arantius and overlap in their closed position.

The combined lengths of the free edge of the three cusps equal the circumference of the aorta at the sinotubular junction. In a bicuspid valve, the combined length of the free edges of cusps is at best, twice the diameter of the aorta. The orifice is therefore significantly smaller than the circumference of the aorta (Doty 1987; Tsang et al. 2006). The bicuspid valve is not necessarily stenotic. It is, however, more susceptible to hemodynamic damage, so that often during the second decade of life, the valve tissue wears out prematurely with fibroplastic thickening of the cusps and occasionally, with deposits of fat, hyaline, and calcium.

■ Fig. 16.2 Normal aortic valve from the surgeon's perspective

16.1.1.2 Aortic Root

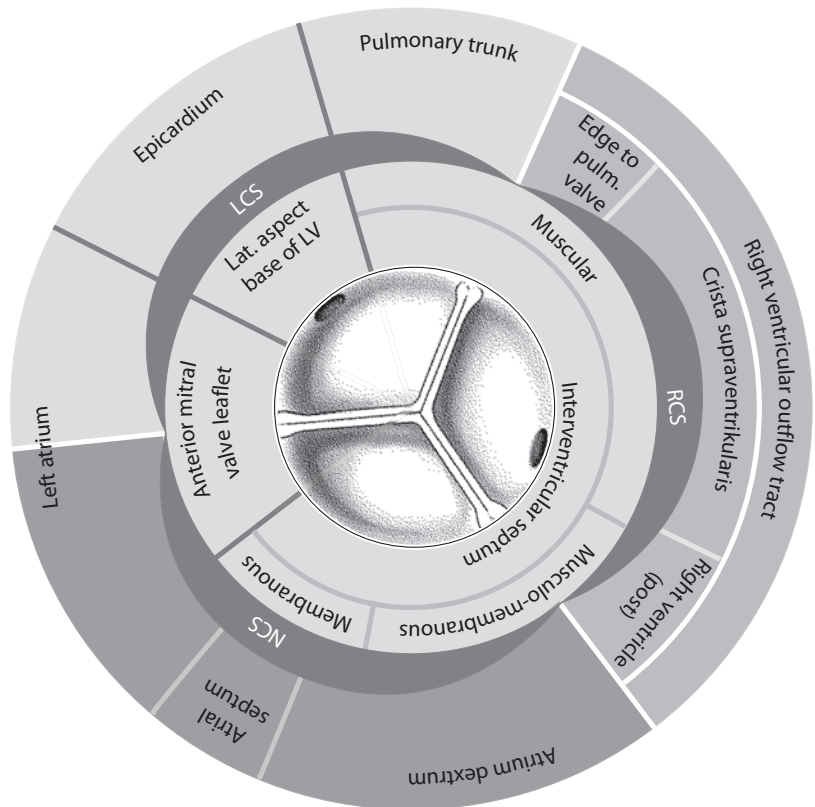

The surgeon must be familiar with the anatomic relationship of the aortic root to the surrounding structures (■ Figs. 16.1, 16.2, and 16.3). The term «aortic root» includes the aortic anulus, the sinuses of Valsalva, and both the right and left coronary ostia.

The aortic and mitral valves have a fibrous continuity. The right side of the aortic root is attached to fibrous tissue which makes up 55% of its circumference, and its left side is attached to

■ Fig. 16.1 Normal anatomy of the left ventricle outflow tract (longitudinal section, through the left ventricle)

Fig. 16.3 The anatomic relationship of the aortic root. *ANT* anterior, *LV* left ventricular, *PULM* pulmonary, *POST* posterior, *LCS* left coronary sinus, *NCS* noncoronary sinus, *ANT* anterior, *LV* left ventricle, *PULM* pulmonary, *POST* posterior, *LCS* left coronary sinus, *NCS* nonkoronarer sinus (Picture: Sud et al. 1984:77; used with permission)

the ventricular muscle which makes up 45% of the circumference.

The entire right coronary sinus lies adjacent to the right ventricular outflow tract. Inferiorly, it relates to the interventricular septum. The noncoronary sinus lies adjacent to the right and to the left atrial chambers and the interatrial septum. Inferiorly, the commissure between the right and the noncoronary cusps is related to the membranous septum and to the penetrating atrioventricular bundle. The bundle of His passes through the interventricular septum beneath the noncoronary cusps, near its junction with the right coronary leaflet. The left part of the noncoronary sinus inserts into the anterior mitral leaflet. The commissure between the noncoronary and the left coronary leaflets is positioned above the area of aortic-mitral valve continuity. The left coronary sinus lies adjacent to the left atrium on the right and to the lateral aspect of the base of the left ventricle on the left. Inferiorly, it relates to the anterior leaflet of the mitral valve. To the right, this is the only part of the aortic root that does not relate to a cardiac chamber but to

the free wall of the left ventricle. The commissure between the left and the right coronary cusps lies adjacent to the corresponding commissure of the pulmonary valve, and there is an area of dense fibrous tissue between these commissures (Tsang et al. 2006).

16.2 Valvular Aortic Valve Disease

16.2.1 Introduction

Congenital aortic valve stenosis accounts for 3–5% of all patients with congenital heart disease. The incidence in males is up to five times higher than in females. Valvular aortic stenosis has a wide spectrum of anatomical and clinical variations. Most patients, especially those with bicuspid aortic valves, will remain asymptomatic during childhood. Later in life, as the leaflets become thickened and fibrotic, they may need surgical treatment. Critical aortic stenosis in newborns and infants lies at the other end of the spectrum. These patients represent a distinct and challenging group

with severe obstruction at valvular level and ductus-dependent systemic circulation. They may become severely ill when the ductus closes, manifesting with low cardiac output, acute renal failure, and severe metabolic acidosis.

Many other cardiac anomalies are associated with valvular aortic stenosis, including interruption of the aortic arch with posterior malalignment of the ventricular septal defect (see ► Chapter «Congenital Anomalies of the Great Vessels», Sect. 21.2.1.2), multiple left-sided obstructions such as supramitral or mitral stenosis (see ► Chapter «Anomalous Pulmonary Venous Connections and Congenital Defects of the Atria, the Atrioventricular Septum, and the Atrioventricular Valves», Sect. 12.2.4; Sect. 12.3.5.2), underdevelopment of the left ventricular cavity (see ► Chapter «Surgery for Aortic Atresia, Hypoplastic Left Heart Syndrome, and Hypoplastic Left Heart Complex», Sect. 17.6.8), hypoplasia of the ascending aorta and aortic arch (see ► Sect. 21.2.1), and coarctation of the aorta (see ► Sect. 21.2.1.1). In critical aortic stenosis, important endocardial fibroelastosis may be presented.

16.2.2 Aortic Stenosis in Neonates and Infants

16.2.2.1 Anatomy

A reduced cross-section area in critical aortic stenosis is the result of (1) deficiency or absence of one or more commissures, leading to a unicuspid or bicuspid aortic valve; (2) immaturity with myxomatous change and thickening of the valve cusps, with or without commissural fusion/non-separation; and (3) hypoplasia of the valvular anulus (► Fig. 16.4).

The unicuspid valve usually has an eccentric, pinhole orifice with one defined commissure, or no commissural attachment laterally to the aortic wall at all (Roberts 1973). Even in the absence of commissural fusion, the valve is severely stenotic from birth. The dysplastic bicuspid or tricuspid aortic valves may have a myxomatous appearance and thick cusps with a variable degree of peripheral commissural fusion. This type of valve in systole produces a dome with a central opening. It is believed that swollen, thickened leaflets, rather than fusion of commissures, cause the obstruction (Ho et al. 1988). The aortic anulus and ascending aorta are usually hypoplastic. In general, immaturity (gelatinous, myxomatous primitive tissue) and incomplete development (poorly defined leaflets, bicuspid or unicuspid morphology, borderline aortic anulus) are typical features of critical neonatal aortic valve stenosis (McKay et al. 1992; Roberts and Ko 2006).

16.2.2.2 Pathophysiology

The postnatal course depends on the combination of the severity of outflow tract obstruction and the function and development of the left ventricle and shunts on the atrial and ductal level. There are two potential scenarios.

If stenosis at valvular level is mild and the left ventricle is well developed with no obvious dysfunction, systemic circulation remains stable despite closure of the arterial duct. Over time, the left ventricular hypertrophy develops without signs of endocardial fibroelastosis.

More severe forms of valvular aortic stenosis cause increased ventricular afterload, resulting in increased ventricular wall stress and workload. This provides the stimulus for concentric

► Fig. 16.4 a–c Types of congenital valvular aortic stenosis. a Tricuspid valve. b Bicuspid valve with anterior and posterior pocket. c Unicuspid valve

hypertrophy of the left ventricle in order to normalize left ventricular wall stress, keeping an appropriate left ventricular ejection fraction. The pressure gradient across the stenotic valve in addition to the increase in myocardial wall thickness may cause a mismatch between coronary and myocardial perfusion pressure, potentially leading to myocardial ischemia, arrhythmias, and infarction. Endocardial fibroelastosis, as focal or diffuse cartilage-like fibroelastic thickening of the mural endocardium, may develop as a consequence of chronic in utero or postnatal subendocardial ischemia.

This process could severely impair the systolic and diastolic function of the left ventricle. If left ventricular hypertrophy is incapable of normalizing wall stress, afterload mismatch develops. At that point there is no further preload recruitable stroke volume, and any increase of afterload results in a progressive decrease in stroke volume. As a result, there will be elevated left ventricular end-diastolic pressure and inadequate antegrade flow through the left ventricle outflow tract. The left ventricle starts to be more dilated than hypertrophied. Both systemic and coronary perfusions become dependent on the patent ductus arteriosus. As the ductus begins to close after birth, in these cases, signs of circulatory collapse develop with hypotension, oliguria, and metabolic acidosis (Jonas 2004).

16.2.2.3 Clinical Presentation and Diagnostics

Neonates and infants with critical aortic valve stenosis and ductus-dependent circulation present with varying degrees of cyanosis and reduced peripheral perfusion. Systolic ejection murmur may or may not be present, depending on the function of the left ventricle and the amount of blood flow across the aortic valve. Occasionally, a neonate will present with circulatory collapse following ductal closure.

Neonates and infants with severe, noncritical aortic stenosis, without ductal dependency, may present with a history of irritability, failure to thrive, and poor feeding within several weeks. The remaining cases with less severe aortic stenosis will be asymptomatic for the time being (Jonas 2004).

Echocardiography and Doppler flow studies are essential diagnostic tools. Apart from anatomic diagnosis, ventricular function should be assessed, and the severity of aortic valve stenosis

and degree of fibroelastosis should be estimated. All cardiac structures should be assessed in two planes, and the Z-score for each parameter should be calculated. The Doppler gradient across the stenotic aortic valve can be greatly underestimated in a situation of low cardiac output with depressed left ventricular contractility and right to left shunt at ductus level. Cardiac catheterization to gain additional anatomic information is rarely necessary.

16.2.2.4 Indications for Surgery

Critically ill neonates should be stabilized by aggressive treatment, including mechanical ventilation, inotropic support, and correction of metabolic acidosis, while patency of the ductus is maintained by prostaglandins. After stabilization, a trial discontinuation of prostaglandins can be undertaken if the structures on the left side are well developed, left ventricle function is adequate, and the degree of aortic valve stenosis is not severe. No intervention is needed if ductal closure is tolerated. On the other hand, dependency on the ductal circulation is a clear indication for urgent valve centered measures.

16.2.2.5 Decision-Making

The key issue is to decide whether structures on the left side of the heart are adequate to sustain the systemic circulation, or whether they may become adequate with available surgical approaches, leading to a biventricular type of repair. Neonates with a well-developed mitral valve, left ventricle, and aortic root will benefit from biventricular repair. At the other end of the spectrum, there are patients with severe hypoplasia of the mitral valve, left ventricle, and aortic root, who are suitable only for single-ventricle repair (Norwood procedure). The most challenging group consists of patients with a borderline left ventricle (Corno 2005). Correctly choosing the appropriate surgical pathway at the very beginning is critically important and contributes to an overall improvement in outcome for patients with critical aortic stenosis. Converting the failed biventricular repair to Norwood Stage I is associated with increased mortality (Rhodes et al. 1991). The decision-making process in critical aortic stenosis, when deciding between a uni- or biventricular type of repair, should include the following considerations with respect to morphometric and hemodynamic parameters:

1. Morphometric parameters

The adequacy of the left ventricle is based on assessment of inflow and outflow structures and on the size of the left ventricle. In neonates with isolated aortic stenosis, the assessment by way of Rhodes score may predict the suitability of a biventricular approach (Rhodes et al. 1991). The scoring system is based on the aortic root dimensions indexed to body surface area ($<3.5 \text{ cm}^2/\text{m}^2$), the ratio of the long-axis dimension of the left ventricle to the long-axis dimension of the heart (<0.8), the indexed mitral valve area ($<4.75 \text{ cm}^2/\text{m}^2$), and left ventricular mass ($<35 \text{ g}/\text{m}^2$). If one or more of these factors are present, a univentricular approach should be considered.

Reduced dimension of the mitral valve orifice ($<9 \text{ mm}$), a small diameter of the aortic anulus ($<5 \text{ mm}$) (Leung et al. 1991), and a cardiac apex not formed by the left ventricle (Karl et al. 1990) are recognized risk factors for mortality if a biventricular approach is undertaken. The degree of endocardial fibroelastosis and previously recognized risk predictors for hospital mortality in neonates with critical aortic stenosis (younger age, left ventricular length, lower Z-score of the aortic valve diameter, presence of moderate or more tricuspid regurgitation) were identified in a multi-institutional study conducted by the Congenital Heart Surgeons' Society (Lofland et al. 2001).

2. Hemodynamic parameters

Left ventricular end-diastolic pressure $>20 \text{ mmHg}$, left ventricular ejection fraction $<40\%$ (Pelech et al. 1987), and indexed left ventricular end-diastolic volume $<20 \text{ mL}/\text{m}^2$ of body surface area (Keane et al. 1983) were clearly associated with death if biventricular repair was undertaken. The presence of total or predominant antegrade blood flow in the ascending aorta and transverse aortic arch correlated with survival after a biventricular type of repair (Kovalchin et al. 1998).

16.2.2.6 German Pediatric Heart Center Protocol (Deutsches Kinderherzzentrum (DKHZ) Protokoll)

Proposed formulas have limited clinical value, and at this point there is no agreement on what combination of left-sided structures would be

adequate to perform biventricular correction (Eicken et al. 2010; Colan et al. 2006; Hickey et al. 2007; Alsoufi et al. 2007).

The main limit of all recommendations and studies was that in the comparison between the biventricular and univentricular type of repair, the only surgical approach taken into consideration for biventricular repair was the aortic valvotomy. All data shows that death after aortic valvotomy is increasingly likely in patients with smaller aortic valves and in the presence of endocardial fibroelastosis. Aortic valvotomy does not address either of these morphologic issues, so it is not surprising that attempting an aortic valvotomy in the face of an increasingly small aortic valve and increasing endocardial fibroelastosis will be completely ineffective. Other surgical options available in neonates with critical aortic stenosis such as the Ross or Ross-Konno procedures, including the resection of fibroelastosis, have not been taken in consideration. The Ross procedure normalizes the left ventricular outflow tract dimensions and hemodynamics and allows easy access to the left ventricular myocardium for resection of endocardial fibroelastosis. Thereby, it directly addresses the three most important morphologic risk factors for biventricular repair: the presence and degree of endocardial fibroelastosis, the left ventricular length, and the lower Z-score of the aortic valve diameter (Hanley et al. 2001).

The decision-making protocol for critical aortic stenosis in our institution emphasizes assessment of the inflow structures of the left ventricle, the length of the left ventricle, the flow characteristic in the ascending aorta, and the presence and degree of endocardial fibroelastosis (Hraska et al. 2007a, b).

Single-ventricle palliation can be contemplated if the mitral valve anulus is smaller than 7 mm (more than $-2z$); if the apex of the heart is not formed by the LV, with diminished left ventricular length and developed endocardial fibroelastosis; and if flow in the ascending aorta is predominantly reversed. Left ventricular outflow structures, such as hypoplasia of the aortic anulus and presence of endocardial fibroelastosis, are not contraindications for biventricular repair if a Ross operation is an option and the endocardial fibroelastosis can be resected (Aszyk et al. 2012).

Historically, our treatment protocol was surgically driven. Recently, we have preferred an interdisciplinary consensus-based approach. Critically ill neonates are stabilized by aggressive

■ **Fig. 16.5** Treatment protocol for critical aortic valve stenosis at the German Pediatric Heart Center, Sankt Augustin. AoS aortic stenosis, LV left ventricle, EFE endocardial fibroelastosis, Ao aorta, BV balloon valvotomy, OV open valvotomy

resuscitation, while patency of the ductus is maintained by prostaglandins. A trial discontinuation of prostaglandins should be undertaken. Intervention (balloon or open valvotomy) is indicated on a semi-elective basis if ductal closure is tolerated. Dependency on the ductal circulation is a clear indication for semi-urgent intervention. If the LV function is depressed, a ballooning with a balloon not larger than 70% of diameter of the aortic anulus is performed to slightly increase the effective orifice area of the aortic valve, creating a minimal risk of regurgitation. This so-called gentle ballooning is used as an intermittent step to stabilize the patient before open valvotomy. If the LV function is not severely depressed, surgery is the method of choice (Hraška et al. 2012).

In case of a hypoplastic aortic anulus and developed but resectable endocardial fibroelastosis, a Ross-Konno operation can be considered. A Ross option is considered also if balloon valvotomy or open valvotomy fails (■ Fig. 16.5).

16.2.3 Aortic Stenosis in Children

16.2.3.1 Anatomy

Although all anatomic variations are possible, the valve is bicuspid in about 70% of aortic valve stenosis cases in children, with the two remaining commissures arranged as anterior and posterior, or left and right. There may be a third raphe or false residual commissure. There are usually variable degrees of peripheral fusion of one or both commissures, creating a stenosis (Roberts 1973). Stenosis can occur without commissural fusion, simply as a result of thickened or myxomatous cusps and a bicuspid configuration. If the free

edges of both thickened bicuspid cusps are taut with no extra length and equal in length to the diameter of the aortic root, they cannot open completely and thereby produce obstruction (Tsang et al. 2006). The aortic anulus is usually of adequate size. Abnormal tricuspid aortic valves may not be obstructive during early infancy, but may become stenotic later in life due to leaflet thickening and calcification.

16.2.3.2 Pathophysiology

Pressure overload leads to the development of concentric hypertrophy of the left ventricle to compensate for increased left ventricular wall stress. Even though myocardial oxygen consumption and coronary blood flow normalize at rest, there are many alterations of coronary circulation in the hypertrophied left ventricle, with development of a noncompliant left ventricle susceptible to ischemia. Myocardial perfusion pressure is reduced because of reduced aortic pressure (both systolic and diastolic) on one side and elevated left ventricular end-diastolic pressure on the other side. During exercise there may be development of subendocardial ischemia, causing angina-like symptoms. Ineffective increase of cardiac output may lead to syncope (Jonas 2004).

16.2.3.3 Clinical Presentation and Diagnosis

Typically, children with aortic stenosis may remain asymptomatic, despite a significant gradient. With further progression of stenosis, symptoms of breathlessness, syncope, and angina will develop at some point. This is accompanied by a constant risk of bacterial endocarditis and sudden death.

The ECG demonstrates left ventricular hypertrophy, with T-wave inversion in V6, eventually with ST changes.

ECHO and Doppler flow studies are highly reliable to estimate aortic valve gradient, morphology of the valve, and functional and morphometric parameters of the left ventricle. In the presence of additional defects and multilevel stenosis, catheterization is indicated.

In patients with normal left ventricular function, the severity of aortic stenosis is graded according to well-established Doppler gradient measurements. The stenosis is considered to be mild if the peak Doppler gradient is <40 mmHg or the mean gradient is <25 mmHg. If peak Doppler gradient is up to 60 mmHg, or the mean gradient between 25 and 40 mmHg, the stenosis is considered to be moderate. If the maximum gradient is greater than 60 mmHg, or the mean gradient >40 mmHg, the stenosis is severe (Hossack et al. 1980; Baumgartner et al. 2010).

16.2.3.4 Indications for Surgery

Surgery for aortic valve stenosis is indicated in symptomatic patients when the peak Doppler gradient exceeds 40 mmHg, and LV hypertrophy and ECG changes are notable. In asymptomatic patients, a peak gradient more than 60 mmHg is an indication for procedure. Although each patient should be evaluated individually, evidence suggests that early intervention before myocardial changes develop is beneficial (Jonas 2004). Currently intervention/surgery is indicated even

in asymptomatic patients with a peak gradient between 40 and 60 mmHg, in order to promote aortic annulus growth (■ Fig. 16.6).

16.2.4 Aortic Insufficiency in Childhood

16.2.4.1 Anatomy

The morphology depends on the etiology. In children, aortic regurgitation may be associated with certain congenital heart diseases (ventricular septal defect, truncus arteriosus, tetralogy of Fallot, subaortic membrane, etc.) or with bicuspid aortic valves, with or without coarctation (Bonderman et al. 1999). Currently, postintervention aortic regurgitation with resting aortic stenosis is frequently seen. Predominant morphological factors contributing to aortic regurgitation after balloon dilatation of the aortic valve are a combination of several pathologies: anterior commissural avulsion, cusp dehiscence with retraction (presumably caused by long-standing balloon-induced tear), cusp tear or perforation, central incompetence due to calcified cusps and sinus of Valsalva dilation, deficient cusps, and free cuspal edge adhesion to the aortic wall (Solymar et al. 1992; Bacha et al. 2001; Jonas 2004).

■ **Fig. 16.6** Treatment protocol for aortic valve stenosis and insufficiency at the German Pediatric Heart Center, Sankt Augustin. *LVEDD* left ventricular end-diastolic diameter, *AVR* aortic valve replacement

Prolapse appears to be the most frequent cusp pathology in pure aortic regurgitation. This pathology may also coexist with root dilatation. Most importantly, prolapse may be induced by reduction of root diameters, particularly at the sinotubular level (de Kerchove et al. 2008; Jeanmart et al. 2007).

Anuloaortic ectasia may be the result of dilatation of the aortic root due to tissue disorder (Marfan syndrome, Ehlers-Danlos syndrome, Turner syndrome) (Dervanian et al. 1998). This process begins in the sinuses of Valsalva with pear-shaped aneurysmal enlargement of the aortic root, creating valvular incompetence by dilatation at the commissural level. Another cause of aortic regurgitation is rheumatic process with shortening of the cusps between their free edges and the annular attachments. This results in rolling of the free edges and central incompetence. Less common courses are bacterial endocarditis, myxomatous degeneration, spontaneous cusp rupture, etc. Pure congenital aortic insufficiency is very rare.

16.2.4.2 Pathophysiology of Aortic Regurgitation

Chronic aortic regurgitation represents a condition of combined volume overload and pressure overload. The balance between afterload excess, preload reserve, and hypertrophy cannot be maintained indefinitely in many patients, and afterload mismatch and/or depressed contractility ultimately result in a reduction in ejection fraction, first into the low normal range and then below normal. With time, during which the ventricle develops progressive chamber enlargement and a more spherical geometry, depressed myocardial contractility predominates over excessive loading as the cause of progressive systolic dysfunction. This can progress to the extent that the full benefit of surgical correction of the regurgitant lesion in terms of recovery of left ventricle function and improved survival can no longer be achieved (Bonow et al. 1998; Jonas 2004).

16.2.4.3 Clinical Presentation and Diagnosis

With the advent of balloon valvotomy, patients originally treated for aortic stenosis later present with predominant aortic regurgitation. The majority of children remain asymptomatic. With the progression of declining systolic function or elevated filling pressures of the left ventricle,

breathlessness, syncope, and angina may develop. There is constant risk of bacterial endocarditis.

The ECG demonstrates the left ventricular hypertrophy, with left ventricular strain or ischemia.

ECHO and Doppler flow studies are highly reliable in estimating aortic valve regurgitation, morphology of the valve, and functional and morphometric parameters of the LV. Aortic valve insufficiency is scored as 0–4 (none, trivial, mild, moderate, and severe). The proximal aortic regurgitation jet diameter to aortic anulus diameter ratio offers more precise quantification of aortic insufficiency, even in children. Catheterization is rarely indicated.

16.2.4.4 Indications for Surgery

The timing for surgery in patients with chronic aortic regurgitation is controversial. Accepted indications are the presence of symptoms, increasing significant LV dilation with or without dysfunction, or both in the setting of moderate or even worse AR.

In order to achieve complete recovery of the left ventricular function, surgery should be performed before the Z-score of the preoperative left ventricular end-diastolic dimension is no greater than 4 (■ Fig. 16.6) (Tsang et al. 2006). A further echocardiographic estimate of more than moderate aortic regurgitation is, for example, a jet length more than two-thirds back into the left ventricle, or if insufficiency induced reversed flow is detectable in the descending aorta.

16.2.5 Simple Reconstruction

16.2.5.1 Open Valvulotomie in Neonates and Infants

The operation is performed on cardiopulmonary bypass with mild hypothermia (32 °C) (Jeanmart et al. 2007; Hraska and Murin 2012).

The heart is approached through median sternotomy. The ductus arteriosus is dissected. After systemic heparinization, the patient is cannulated for cardiopulmonary bypass with two venous cannulas and with an arterial cannula in the distal ascending aorta. The bypass is commenced, and the patent ductus arteriosus is occluded with a snare. A left atrial vent is placed through right pulmonary veins. Alternatively, vent could be

placed through interatrial septum after opening of the right atrium. The aortic cross-clamp is applied and antegrade cold crystalloid cardioplegia is delivered. An oblique, inverted hockey stick type of incision is made from the anterior aspect of the aorta toward the noncoronary sinus of Valsalva. The aortic valve is carefully examined. A small cardiotomy sucker placed through the valve orifice can improve inspection of the valve. The fused/nondivided commissures are carefully divided with a knife, ensuring that the individual cusps created are well supported and not liable to prolapse. The incision is short, usually 1–2 mm in length. Even a short incision may result in an adequate opening of the outflow orifice, because the flow is a function of the fourth power of the radius. Obstructive myxomatous and fibrous nodules on the leaflets are removed. This implies careful and meticulous thinning/shaving of cusps with a knife. Frequently, a cleavage plane is identified between the fibrosis and what seems to be thin pliable aortic cusp tissue. Properly performed «shaving» greatly improves mobility of the cusps and increases the effective orifice area of the aortic valve. The false raphe, if present as the ultimate remnant of a nondeveloped commissure, does not provide any lateral support for the cusp and should not be incised. After performing the valvulotomy, the aortotomy is closed with a running suture, the left side of the heart is de-aired, and the aortic cross-clamp is removed. After rewarming, the patient is weaned off cardiopulmonary bypass. Transesophageal echocardiographic assessment of left ventricle function, aortic valve function, and flow characteristic in the left ventricle outflow tract should be carried out routinely. The ductus arteriosus should always be ligated, if the patient is stable. If cardiac output is not adequate, even on aggressive inotropic support, the arterial duct can be left open and maintained patent on prostaglandins or intraoperatively stented to provide additional systemic perfusion from the right ventricle. Under these circumstances, bilateral pulmonary artery banding should be considered as well (■ Fig. 16.7).

16.2.5.2 Open Valvulotomie in Childhood/Tricuspidalization of the Aortic Valve

The management of the operation is similar to that described for neonates and infants. Visualization of the aortic valve anatomy is much

easier. In order to maximize the effective orifice area, especially in a bicuspid scenario, the commissurotomy can be extended in circumferential fashion beyond the commissure into the aortic wall, splitting the aortic wall in two layers (Ilbawi et al. 1991). Incision into a false raphe should be avoided; however, debridement of the raphe usually improves mobility of the cusps with subsequent enlargement of the effective orifice area of the valve. In older patients, bicuspidalization even of an unicuspid valve can be considered (Schäfers et al. 2008). Nevertheless, the design of a bicuspid aortic valve has a limited prognosis with potential failure and the invariable development of stenosis (Robicsek et al. 2004).

If completion of the commissurotomy does not result in adequate opening, despite the normal anulus dimension, conversion to a three-cusp valve should be considered. Usually, there is a prominent, thickened, even calcified false raphe. The false raphe is incised. Thickened and immobile parts of the newly created cusps are completely removed, leaving as much native mobile tissue as possible. Autologous or bovine pericardial augmentation of these two cusps is performed. Augmentation of the third cusp depends on the effectiveness of coaptation with the already augmented cusps. Usually, the symmetric augmentation of all cusps involved provides sufficient overlapping of cusps and optimizes the height and width of the intercusp triangle, which governs the area of cusp apposition (Hraska and Murin 2012).

Alternatively, the raphe between the other unsupported cusp is incised, and a pericardial triangle patch is folded and sutured along both edges of the divided raphe and vertically to the aortic wall to provide support in the diastole, preventing cusp prolapse (Tolan et al. 1997, ■ Fig. 16.8).

Dysplastic bicuspid aortic valves are suitable for tricuspidalization using most of available native tissue for creation of two adjacent cusps while adding a third cusp from pericardium. One or both native cusps are detached from the anulus and reattached to anatomically ideal position, creating new commissures. Subsequently, cusp from pericardium is fashioned in between (Pretre et al. 2006).

If there is a risk of aortic narrowing at direct aortotomy closure, the supra-annular aortic segment should be augmented with a patch instead. Should there be post stenotic dilatation of the ascending

Fig. 16.7 **a** The fused/non-separated commissures are incised and the incision is extended in a circumferential fashion beyond and above the commissures into the ventriculoaortic junction. **b** The incision is deepened in the muscle underneath the commissure between the right and left leaflets. **c** Myxomatous nodules and areas of leaflet thickening are thinned out. **d** Releasing of the rudimentary commissure. **e** Enlargement of the supra-annular area with a patch

aorta, wedge resection of the anterior part of aorta is performed to restore optimal sinotubular dimension.

16.2.5.3 Discussion: Simple Reconstruction

The therapeutic goal is to relieve the aortic obstruction and provide lasting freedom from residual or recurrent stenosis, without causing significant aortic regurgitation. Satisfactory early outcomes have been reported in neonates and infants with critical aortic stenosis treated with both balloon valvotomy and open valvotomy

(Borghi et al. 1999; McCrindle et al. 2001). Both are palliative procedures: sooner or later, reintervention is likely. Whereas patients undergoing open valvotomy are more likely to have residual stenosis, those undergoing balloon valvotomy are more likely to develop severe insufficiency (Lofland et al. 2001). Predominant postvalvotomy pathology is an important predictor of the long-term outcome. Mild aortic stenosis is usually very well tolerated, and patients have normal exercise tolerance (Mitchell et al. 2003). The need for aortic valve replacement can be prolonged by

repeated operation/dilatation. In contrast, young patients with even trivial or mild initial regurgitation are at risk for progressive insufficiency and ventricular dysfunction and should be considered for earlier aortic valve replacement (Karamlou et al. 2005; Balmer et al. 2004).

Balloon valvotomy relieves aortic stenosis by causing rupture along the lines of least resistance, either along underdeveloped commissures or into cusp tissue (Solymar et al. 1992). A particular problem is the severely abnormal valve, usually bicuspid or unicuspid, in which there is a high risk of procedural failure and subsequent reintervention. Usually the transvalvular gradient is effectively reduced, but there is increased risk of progressing aortic regurgitation, predisposing to early or late reoperations. Reintervention is almost inevitable (Zeevi et al. 1989; Hawkins et al. 1996; Robinson et al. 2000). The incidence of immediate and late important aortic regurgitation is 13% and up to 40%, respectively (Ewert et al. 2011; Brown et al. 2010a, b; Han et al. 2007).

Reintervention rates are about 50% at 8 years after the initial balloon valvotomy (Moore et al. 1996). In the neonatal group, the results are worse, with less than 30% of patients surviving to 15 years without reintervention (Reich et al. 2004). The incidence of procedure-related mortality up to 2% is certainly not negligible, demonstrating that the «less-invasive» approach is not necessarily the safest (McCrinkle 1996; Brown et al. 2008).

There is high incidence of procedural femoral artery damage. Despite treatment, the majority of children show evidence of obstructive lesions of the iliofemoral vessels after balloon valvotomy (Balmer et al. 2004). Open valvotomy allows a more accurate fashioning of commissurotomies, attempting to construct the cusp as close to normal anatomy as possible. Shaving of thickened cusps, excision of obstructive myxomatous nodularities, and mobilization of cusps effectively increase the orifice area of the valve, with minimal risk of creating regurgitation. This is not achievable with «blind» balloon dilatation, where cusps are likely to get torn or perforated, while trying to relieve the obstruction.

Morphology of the valve determines the need for reintervention. Unicuspid and bicuspid valves by definition have fundamental morphological and functional abnormalities; the number of reinterventions and patients needing an aortic valve

replacement is therefore higher. If three cusps could be constructed without producing significant aortic regurgitation, the need for any reintervention for recurrent stenosis is less than in patients with bicuspid valves (Bhabra et al. 2003). Not surprisingly, the tricuspid valve morphology showed exceptional outcomes, with 100% freedom from aortic valve replacement at 20 years of follow-up. These figures provide evidence of superior long-term outcomes of open valvotomy in comparison with ballooning regarding preservation of the native aortic valve (Hraska et al. 2012).

Overall, early mortality after open valvotomy is less than 5%, with the mortality rate approaching zero among infants over 1 month and older children. Early mortality in critical neonates is associated with the adverse prognostic factors such as mitral stenosis, small-sized left ventricles, small aortic anulus, depressed fractional shortening, low aortic gradient, endocardial fibroelastosis, and other coexisting defects (Agnoletti et al. 2006; Alexiou et al. 2001a, b; Miyamoto et al. 2006; Chartrand et al. 1999). Overall, the 10-year survival rate is approximately 90%, with nearly 100% survival rate for isolated aortic stenosis. There is a late death hazard with a 60–70% survival rate for neonates and infants with associated other severe lesions. The 10-year freedom from recurrent aortic stenosis is approximately 80%. Mild aortic stenosis is stable and nonprogressing, and if so, it is amenable to repair (Keane et al. 1993). Development of severe aortic regurgitation after open valvotomy is unlikely, with 10-year freedom from severe aortic regurgitation more than 90%. Usually, postsurgical aortic regurgitation is related to monocuspid valves, or a technically inadequate commissurotomy with rather overenthusiastic incisions in the valve (Alexiou et al. 2001b). Overall, the 10-year reintervention-free survival rate is between 75 and 90%, reflecting the underlying age at repair, being less favorable for critical newborns (Alexiou et al. 2001a; Miyamoto et al. 2006; Detter et al. 2001).

The underlying anatomy of the left ventricular outflow tract and associated lesions determines the outcome of critical aortic stenosis more than the method of treatment. Superior longer-lasting results can be achieved by direct surgical intervention, where exact splitting of fused commissures and shaving off of obstructing nodules can produce a better valve with maximum valve orifice, without causing regurgitation. Ballooning is

relatively safe and simple but frequently converts the physiology of aortic stenosis to aortic regurgitation with a detrimental effect on ventricular performance. The reintervention rate is higher and the need for aortic valve replacement is sooner than after a direct surgical valvotomy (Tweddell et al. 2005b).

16.2.6 Complex Reconstruction

16.2.6.1 Aortic Valve Reconstruction

In normal hearts, the aortic root including the flexible sinotubular junction expands during systole, straightening the free cusp edges and maintaining a constant strain in order to minimize fatigue stress (Brewer et al. 1976). Apart from this mechanism, the proper coaptation depends on the aortic anulus, the sinotubular dimension, and the height and position of each commissure in relation to the other commissures (Bierbach et al. 2010).

Commissural attachments should be always higher than the plane of the valve, giving the cusps the necessary depth for coaptation. The crescent-shaped portion of the leaflet's free edge forms the area of coaptation. Abnormalities in the length or structure of the free edges result in poor mobility or insufficient coaptation. A deficient cusp usually results from the long-standing balloon-induced tear with retraction of the free cusp edge. Anatomic elements necessary for valve repair include a sufficient anulus diameter, mobile cusps or cusps that can be mobilized by resection or shaving off excess fibrous tissue, and an ability to achieve coaptation without inducing stenosis.

The goal of reconstruction is to restore the normal geometry of the valve, leaving as much as possible the native valve and tailoring the construction to individual cusps. Autologous pericardium, pretreated with 0.3% glutaraldehyde, has excellent mechanical and handling properties and shows only a minor rate of calcification, retraction, and fibrosis (Duran 1993, 1998). A fixation time of 5–30 min improves handling and increases the strength of the pericardial patch. An alternative is bovine pericardium (CardioFix bovine pericardium; CarboMedics). This material is highly resistant to calcification, supports the growth of host cells, has excellent handling characteristics, and does not require a preimplantation rinse, making it rapidly available (Moore 1997).

The access to the valve, the bypass strategy, and myocardial protection are the same as in other operations for aortic valve surgery. After opening the aorta, each cusp is inspected with respect to depth, length, thickness, mobility, commissural arrangement, and subvalvular area, including the diameter of the anulus.

The first step of the operation is to relieve commissural fusion and to perform an extensive thinning of the valve cusps. Then the appropriate technique of repair for aortic valve regurgitation is chosen based on the underlying pathology. There are several scenarios:

1. Perforations or tears in the aortic cusps are repaired either with a direct suture or with pericardial patches.
2. Redundant tissue is corrected by shortening the coaptation edge to match the adjacent cusps. For the assessment of cusp prolapse in a tricuspid anatomy, a fine suture («Frater stitch»; Frater 1967) is passed through the nodules of Arantius and placed under traction to estimate the relative length of all free cusp margins. In bicuspid aortic valves, radial tension is exercised on the opposite commissures to identify the extent and location of prolapse. A redundant, prolapsing cusp can be repaired by several similar methods:
 - Shortening is provided by triangular resection of redundant tissue. A small extra amount of tissue is left for incorporation into the suture line. The resected margins are approximated by means of interrupted or continuous polypropylene sutures (■ Fig. 16.9) (Mariani et al. 1997).
 - Plication of redundant tissue in the prolapsed cusp achieves the same effect. No resection of valve tissue is needed (Trusler et al. 1973).
 - Correction of the cusp's length does not automatically result in the correction of the cusp prolapse. To improve coaptation of the cusps, the free edge reinforcement of the leaflet can be applied, reducing the length of the free cusp margin. Free margin reinforcement is performed by an over and overrunning Gore-Tex CV-7 (Gore WL Gore and Associates, Flagstaff, AZ) suture. Both ends of the suture are suspended at the level of corresponding commissures, reinforcing and shortening the free edge.

■ Fig. 16.9 a, b The prolapse of the fused leaflet is corrected by a triangular resection only. LCO left coronary artery orifice, RCO right coronary artery orifice

3. More extensive cusp destruction, with deficient cusps, requires an extension procedure using a pericardial patch. The length of the half moon-shaped patch should be 15–20% greater than the diameter of the aorta. The 20% additional length accounts for a reduction in the pericardial free cusp edge width from a purse string effect with a running polypropylene suture. The height is governed by the extent of augmentation and anticipated height of the newly created commissure. The destroyed part of the cusp is removed, and the patch is tailored to achieve a «normal» morphology of the newly created cusp. A deliberate overcorrection in the cusp reconstruction is attempted to provide additional material to extend the line of coaptation of the cusps 3–5 mm above the line of original coaptation and 2–3 mm above

the sinotubular bar. The running 6–0 monofilament suture line is carried from the center of the native cusp to each commissure and then up onto the aortic wall 2–3 mm above the original commissural insertion, staying away from the coronary ostia. With each patch in place, the newly constructed pericardial cusp edges are trimmed to provide a uniform cusp depth. The commissures are suspended and reinforced with 5–0 monofilament sutures (Caspi et al. 1994; Polimenakos et al. 2010; Hraška and Murin 2012) (■ Fig. 16.10). A small ascending aorta should be enlarged with a patch, especially if a three-cusp extension is performed, to avoid stenosis at the sinotubular junction.

4. Mild dilatation of the anulus can be managed with a subcommissural anuloplasty.

■ **Fig. 16.10** a, b The deficient shallow cusp is augmented with a glutaraldehyde-treated pericardial patch suspended to the aortic wall, to achieve normal depth and length. At the commissures, an overlap is created, thereby ensuring optimal coaptation and thus addressing the commissural separation. *LCO* left coronary artery orifice, *RCO* right coronary artery orifice

This reduces the circumference of the annulus and increases cusp coaptation without interfering with the range of motion of the cusps. The amount of plication depends on the level at which the sutures are placed. The lower the sutures are placed at the commissures, the greater the anular plication and degree of cusp coaptation. Horizontal mattress sutures with pledgets are placed through the annulus on each side of the commissure and tied. Care is taken to avoid contact with the cusps and coronary ostium (Cosgrove et al. 1991).

5. Aortic regurgitation resulting from restricted cusp motion due to dilatation in the sinotubular junction with no aortic annulus dilatation

is suitable for a valve-sparing remodeling technique, the so-called Yacoub procedure (Sarsan and Yacoub 1993). The native valve is preserved; all three sinuses of Valsalva are excised. The scalloped Dacron graft is sewn proximally to the residual aortic sinus tissue around the aortic cusps and commissures. The coronary arteries are reimplemented to the newly created sinuses (see ► Chapter «Acquired Lesions of the Aortic Valve», Sect. 24.5.1.2). One putative advantage of the remodeling approach is that the graft billows, thereby mimicking the natural sinuses of Valsalva. This allows more natural cusp motion (Leyh et al. 1999) and should theoretically reduce cusp-closing stresses and thereby enhance

long-term valve durability (Grande-Allen et al. 2000). The main drawback is the absence of fixation of the aortic anulus, which can predispose to postoperative anular dilatation and recurrent aortic regurgitation.

6. For important root dilatation with progressing aortic valve insufficiency due to tissue disorder (Marfan syndrome, Ehlers-Danlos syndrome, Turner syndrome) or congenital heart diseases (bicuspid aortic valve) (Massih et al. 2002), a reimplantation valve-sparing procedure should be used (David et al. 1996, 2001; Vricella et al. 2005; Cameron and Vricella 2005).

The diseased root and all three sinuses of Valsalva are excised, thereby preserving the valve (see ► Chapter «Acquired Lesions of the Aortic Valve», Sect. 24.5.1.2). A tubular ascending aortic graft with prefabricated sinuses is firmly anchored proximally at the ventriculoaortic junction below the leaflets, with the commissures sewn inside the Dacron graft. The prefabricated sinus of Valsalva may limit the potential for leaflet damage. The reimplantation technique minimizes the risk of late aortic anulus dilatation, which is seen in patients after the remodeling procedure.

7. In the case of central cusp incompetence with dilatation of the noncoronary sinus of Valsalva, a reduction plasty is performed to reduce commissural splaying. A wedge of the noncoronary sinus wall is resected, followed by primary closure of the aortotomy (Bacha et al. 2001).
8. In isolated cusp prolapse associated with normal root anatomy, a sinotubular junction plasty is performed to improve coaptation of the leaflets. Pledged 4/0 prolene (Johnson and Johnson medical NV/SA®) sutures are placed in the middle part of the inter-commissural segment. The dilated sinotubular junction or the ascending aorta, or both, may require plication, aortic wrapping with prosthesis, or resection.
9. Aortic regurgitation that develops in association with a ventricular septal defect can be corrected through a transaortic approach. The series of pledged supported mattress sutures are inserted through the crest of the ventricular septal defect, staying on the right side of the septum, away from the conduction system. The sutures are then passed through the anulus of the aortic cusp into the sinus of

Valsalva, incorporating the thin portion of the aortic sinus as well. This results in closure of the ventricular septal defect, elevation of the right coronary cusp, and reduction of the size of the right coronary sinus (Yacoub et al. 1997).

Intraoperative assessment of the reconstruction of the valve is essential. The effective orifice area of the valve should always be checked by dilators. A dimension of 1–2 mm larger than that predicted by the tables is necessary to achieve a minimal gradient. The potential for insufficiency is assessed during the delivery of cardioplegia after the aortotomy is closed. If the root is pressurized appropriately, and vent return is minimal, aortic insufficiency is not severe (Tweddell et al. 2005a, b).

After weaning, a direct measurement of the pressure gradient between the LV and ascending aorta should be obtained. The TEE is an essential tool for assessment of the function of the LV and of gradients and insufficiency of the aortic valve. If a peak gradient is >40 mmHg and aortic insufficiency is moderate or more, attempts to reduce these residuals should be considered. In general, residual stenosis is better tolerated than insufficiency. Increased experience with three-dimensional echocardiography and better understanding of aortic valve anatomy and the mechanism of failure might play a promising role in the surgical treatment of these complex patients in the future.

16.2.6.2 Mechanical Aortic Valve Replacement

The technique of routine mechanical aortic valve replacement is described in see ► Chapter «Acquired Lesions of the Aortic Valve», Sect. 24.5.2. If the aortic valve anulus is hypoplastic and a modest degree of enlargement of the aortic anulus is necessary, we prefer posterior enlargement of the anulus. A standard cardiopulmonary bypass setup and perfusion technique is used. The Nicks procedure enlarges the aortic anulus between the left coronary and noncoronary commissure. The incision is carried into the fibrous continuity between the aortic and mitral valve, staying away from the anterior leaflet of the mitral valve. A Dacron patch is used to enlarge and support the anulus. After excision of the aortic valve, inverting horizontal mattress sutures are placed through anulus and through the patch. If the sutures are placed more distally on

Dacron patch, the valve can be slightly tilted to accommodate the larger size of the valve (Nicks et al. 1970; Jonas 2004). The Manouagian technique is similar to Nick's procedure, but the incision starts rather in the middle of the coronary sinus and is extended into the anterior leaflet of the mitral valve and the roof of the left atrium (see ► Chapter «Acquired Lesions of the Aortic Valve», Sect. 24.5.2.2; Fig. 24.19 a–c). A pericardial patch is used for enlargement of the aortic root and closure of the defect in the mitral valve.

16.2.6.3 Ross Operation

In small children, a standard technique of complete root replacement is used (Stelzer et al. 1998; Hraska and Murin 2012).

The approach and cardiopulmonary bypass are conducted in the usual way. Myocardial protection is preferentially provided by retrograde cardioplegia. A left ventricular vent is inserted through the right pulmonary vein entrance. Extensive dissection and mobilization of the ascending aorta, the pulmonary trunk, and both pulmonary arteries are carried out. The arterial ligament is ligated and transected to improve mobility of the pulmonary arteries. After aortic cross-clamping, the aorta is partially transected and the feasibility of valve repair is assessed. If the decision is made to proceed with the Ross operation, the main pulmonary artery is transected just proximal to the bifurcation of the PA. The pulmonary valve is inspected to ensure no abnormality exists. In the case of severe abnormalities or bicuspid anatomy of the pulmonary valve, one should consider abandoning the Ross operation and use a mechanical valve, or an aortic homograft if aortic root is too small for mechanical valve. After complete transection of the aorta, the coronary arteries are removed as buttons with maximum adjacent aortic wall tissue. Mobilization of both coronaries is performed. The aortic cusps and sinus wall are removed leaving an approximately 3–5 mm cuff of the aortic wall anulus in place. Then the pulmonary artery autograft is harvested. A right-angled clamp is used to identify the opening on the right ventricle anterior wall, staying away from the nadir of the anterior sinus of the pulmonary artery root. The infundibular incision is extended in both directions around the pulmonary valve leaving an approximately 3–5 mm muscular cuff of tissue in place. One should try to avoid the conus branch of the right coronary artery as the incision is carried toward

the aorta. Great care should be taken during the dissection of the posterior aspect of the valve, where the left main coronary artery, the left anterior descending artery, and the first septal branch lie. A shallower incision of the endocardial surface is made at the septum with fine scissors. Subsequently, the dissection plane is developed with the scissors angled to prevent deep dissection into the interventricular septum and injury to the first septal branch of the left anterior descending artery. After harvesting the pulmonary valve, cardioplegia is delivered, and any bleeding points from the area of the previous dissection are either controlled by diathermy or oversewn with a shallow suture. In adolescents, in the case of a geometric mismatch of at least 3 mm in favor of the aortic anulus, the commissures on either side of the non-coronary sinus are plicated down with pledget-supported sutures to ensure the proper autograft fit and function. The pulmonary autograft is then sutured to the left ventricular outflow tract opening using a continuous suture. The autograft is orientated in such a way that the right and left coronary arteries face the sinus. The suture line is subanular so that the autograft is plugged into the left ventricular outflow tract, thus having the fibromuscular support of the outflow tract. The second running adventitial suture over the remnant of the aortic wall reinforces the first one and decreases the risk of inaccessible bleeding, especially from the posterior aspect of the anastomosis. The left coronary artery button is implanted into the circular opening made in the pulmonary artery wall, avoiding rotation, tension, or kinking. The right anterior commissure is marked on the outside of the autograft to avoid inadvertent injury to the valve leaflet during the implantation of the right coronary artery button. The autograft is then anastomosed to the distal aorta using a continuous suture. A pericardial strip can be used in adult size aortic anulus to reinforce the neo-aortic root and avoid potential root dilatation (Charitos et al. 2009). After completing the distal anastomosis, the neo-aortic root is expanded with a dose of cardioplegia, and the appropriate position for implantation of the right coronary artery is determined. A circular opening is made in the pulmonary artery/neo-aortic wall, staying away from the valve commissure, and the coronary is implanted. For reconstruction of the right ventricular outflow tract, a cryopreserved pulmonary homograft is used. The distal anastomosis is carried out first,

■ **Fig. 16.11** a–c Ross operation: **a** The aorta is transected just above the sinotubular junction, and the pulmonary autograft is harvested taking care to avoid injury to the LCA, the PA valves, and septal perforator of the LAD. **b** The right and left coronary buttons are formed and dissected for maximal mobilization. The pulmonary autograft is implanted in the left ventricular outflow tract using a running suture technique. **c** The left and right coronary arteries are reimplanted into the neo-aortic trunk. The neo-aortic reconstruction is completed by proximal anastomosis with the ascending aorta. A pulmonary homograft is used for reconstruction of the right ventricular outflow tract

placing the sinuses of the homograft into the appropriate position. A mobile pulmonary artery bifurcation facilitates construction of this anastomosis. The posterior aspect of the proximal suture line between the right ventricular outflow tract and the homograft is performed by placing shallow bites avoid the coronaries. Anteriorly, the suture line takes the full thickness of the muscle of the right ventricular outflow tract. After de-airing, the aortic clamp is released. An ECHO may be routinely performed after weaning the patient off bypass (Mohan Reddy et al. 1998; Elkins et al. 1994) (■ Fig. 16.11).

16.2.6.4 Aortic Root Replacement with an Aortic Homograft

Homograft aortic root replacement is currently used for treatment of complicated bacterial endocarditis with aortic root abscesses and in the management of complex left ventricular outflow tract obstructions, when Ross-Konno is not an option. The operation is performed using a standard bypass cannulation technique. We provide myocardial preservation preferentially through the coronary sinus.

The proximal transverse aortotomy is performed. The coronary arteries are harvested on

large buttons with as much adjacent aortic wall tissue as possible. Full mobilization of the coronaries is achieved. The aortic valve cusps are excised and root enlargement (Konno incision) is performed if necessary. An aortic homograft of an appropriate size is chosen. It is always possible to use larger homograft than native aortic root. The homograft is then sutured to the left ventricular outflow tract opening using a continuous suture. Sewing muscle to muscle is avoided by anticlockwise rotating the homograft 120°, so that the right coronary artery ostium faces the recipient's left coronary artery. The second running adventitial suture over the remnant of the aortic wall reinforces the first one. The left coronary artery button is sewn into the enlarged ostium of the homograft's right coronary artery. The right anterior commissure is marked on the outside of the homograft to avoid inadvertent injury to the valve leaflet during the implantation of the right coronary artery button. The homograft is then anastomosed to the distal aorta using a continuous suture. The aortic root is pressurized by cardioplegia, and the right coronary artery is reimplanted to the appropriate site, avoiding rotation, tension, or kinking (Clarke 1991).

16.2.6.5 Discussion Complex Reconstruction

The ideal operation for aortic valve insufficiency would preserve the native aortic valve and as much of its functional unit (comprising the left ventricular outflow tract, the anulus, the sinus of Valsalva, and the sinotubular junction) as possible. Surgical options in children with aortic valve disease remain limited. There is no ideal valve substitute; therefore, valve repair should take preference over any type of valve replacement if a reduction of aortic regurgitation and/or stenosis can be accomplished to an acceptable level. A mild degree of postrepair residual hemodynamic lesions is well tolerated in the long run. The repaired valve has growth potential and no anticoagulation is needed. Not all valves are amenable to repair. Anatomic elements necessary for valve repair include a sufficient anulus, mobile cusps, and the ability to achieve coaptation without inducing stenosis. Repair of congenitally bicuspid aortic valves by tricuspid conversion confers better outcomes, probably due to reduction in leaflet stress load and improved flow patterns (Odum et al. 2005).

The best results are obtained when sufficient native aortic tissue, including the hinge point of the native leaflet, remains prior to leaflet exten-

sion. A variety of valvuloplasty techniques have demonstrated good early and intermediate results; these techniques range from commissurotomy, reattachment of a torn leaflet, resuspension of cusps, thinning of a dysplastic valve, removal of dysplastic nodules, and symmetrical pericardial augmentation of cusps to a reduction anuloplasty. Aortic valve repair is safe, with early mortality approaching zero and with 3-, 5-, and 18-year freedom from valve replacement of 90, 75, and 60% (McMullan et al. 2007; Alsoufi et al. 2006; Polimenakos et al. 2010).

With this time frame, aortic valve repair is considered to be a good temporary solution as it offers reduction of regurgitation and stenosis and stabilization of the ventricular dimensions until the patients grow older, at which time the full range of possible treatment options, including mechanical valve or the Ross procedure, might be used if necessary (Bacha et al. 2001; Tweddell et al. 2005a, b; Caspi et al. 1994; Alsoufi et al. 2006). The selection of the most appropriate substitute in children with irreparable aortic valve lesions remains controversial, with all the available options having certain drawbacks. The pulmonary autograft procedure is an alternative to a mechanical prosthesis, but disproportionate dilation of the neo-aortic root, autograft regurgitation, and the need for pulmonary homograft exchanges remain concerns (Elkins et al. 1996; Hörer et al. 2009).

The Ross procedure is not a cure for aortic valve disease. The Ross procedure should not be considered if the pulmonary valve is deformed, damaged by acquired disease, or compromised by previous surgical procedures. Furthermore, certain connective tissue disorders, such as the Marfan syndrome, probably affect the pulmonary valve and also disqualify it from consideration for autografting. Results achieved with the Ross operation in rheumatic aortic valve disease were disappointing. The great advantages of the Ross procedure are the superior hemodynamic performance, the growth potential, and the lack of need for anticoagulant therapy (Al-Halees et al. 2002). The Ross procedure even allows replacement of stenotic or regurgitant aortic valves earlier in life, thus avoiding repeated surgical reinterventions, which may provide only short-term palliation and potentially exacerbate ventricular function (Mohan Reddy et al. 1998; Marino et al. 1999; Ohye et al. 2001). Root replacement technique, exclusively used for small children, demonstrated excellent midterm

functional results with a mortality rate <5% in both simple and complex left heart lesions, even in neonates and infants (Stelzer et al. 1998; Marino et al. 1999; Ohye et al. 2001). Eighty-eight to 95% freedom from more than trivial neo-aortic regurgitation or valve replacement at a 5-year follow-up can be expected (Elkins 1996; Hraška 2004; Elkins et al. 1998; Takkenberg et al. 2009; Brown et al. 2009).

In adults, excellent midterm outcome can be expected, when aortic root was enforced or sub-coronary implantation technique was used (Charitos et al. 2009). The main concern is dilatation of the neo-aortic root leading to progression of aortic regurgitation, especially in the settings of geometric mismatch of the aortic and pulmonary roots and bicuspid, chronically regurgitant aortic valves (David et al. 1996; Laudito et al. 2001).

The adjustment of the diameter of the aortic anulus and/or the sinotubular junction of the aorta seems to be an important factor in preventing neo-aortic regurgitation after the Ross procedure. The sinotubular junction can easily be adjusted to the appropriate diameter by reducing the diameter of the ascending aorta before the autograft-ascending aorta anastomosis is finished. Adjustment of the diameter of the aortic anulus by plication or anular reinforcement should be considered only in older children (over 15 years old) (Brown et al. 2010b).

If the growth of the patient is not an issue, it was suggested encasing the autograft in a Dacron tube to prevent dilatation (Slater et al. 2005; David et al. 2000). Mechanical adaptation phenomena in the wall of the autograft associated with elastic fiber fragmentation are another potential risk factor for Ross failure (De Sa et al. 1999; Carr-White et al. 2000; Ishizaka et al. 2003), which call for decreasing wall stress by aggressive postoperative control of blood pressure (Hraška et al. 2004).

Patients with bicuspid valve, chronic aortic insufficiency, and a dilated aortic root are less suitable candidates for a Ross operation. It is possible that aortic insufficiency alters the geometry and tissue characteristic of the subvalvular left ventricle outflow tract, with propensity to postoperative dilatation of the neo-aortic root and progression of aortic insufficiency. Another possibility is that these patients have an inherent abnormality of the pulmonary anulus, or valves with mucocystic degeneration of the stroma (Laudito et al. 2001).

The risk of autograft failure in these specific subsets of patients remains to be determined, and mechanical valve replacement should be considered as a reasonable option. On the other hand, patients with mixed severe aortic stenosis and insufficiency might benefit more from a Ross operation than a repair (Bacha et al. 2001). Freedom from pulmonary homograft replacements after the Ross procedure is about 90% at 12-year follow-up (Elkins et al. 2001). These results are superior to other right-sided reconstructions, most probably because an orthotopically placed pulmonary homograft provides the ideal hemodynamics and flow pattern. Nevertheless, reoperation is likely to be necessary in very young children in whom more accelerated degeneration of the homograft can be expected. Remodeling of the left ventricle after the Ross procedure, with normalization of the left ventricle diastolic diameter index and left ventricle mass index, can be expected over a 3–12 months period in every patient without the associated lesion (Hraška et al. 2004). The long-term outcome of the Ross operation is better than other aortic valve replacement options for children, but the unknown long-term outlook of autograft replacement and degeneration of homograft placed to the RVOT remind us that the Ross procedure results in a two-valve pathology.

Mechanical valve replacement in children is complicated by the need for systemic anticoagulation, by lack of anular growth, and by patient-prosthesis mismatch (see also ► Chapter «Acquired Lesions of the Aortic Valve», Sect. 24.5.5.7). Operative mortality is low, ranging between 0 and 5% (Ibrahim et al. 1994; Mazzitelli et al. 1998), and is associated with poor preoperative status. Long-term survival rates ranging from 85 to 64% at 20-year follow-up reflect the complexity of the underlying congenital disease, being more favorable for isolated aortic stenosis (Alexiou et al. 2000; Champsaur et al. 1997). The anticoagulation management in infants and small children is particularly cumbersome. In the adolescent age group, noncompliance with activity restriction and medical regimens, and high-risk behavior, makes the use of a mechanical valve less attractive. Although 93% freedom from thromboembolism at 20-year follow-up was reported, the risks of thromboembolism, valve thrombosis, anticoagulation-related hemorrhage, and prosthetic valve endocarditis remain long term (Alexiou et al. 2000; Vongpatanasin et al. 1996). Placement of a

prosthetic valve in small children requires annular enlargement to accommodate an adequate prosthesis which may result in late ventricular dysfunction (Sharma et al. 2004). Repeated prosthetic valve replacement is unavoidable during childhood, because of somatic growth and left ventricular outflow obstruction. Earlier referral for redo is warranted before the onset of ventricular dysfunction. Freedom from surgical reintervention rates range from 70 to 91% at 10-year follow-up and 53 to 86% at 20-year follow-up (Mazzitelli et al. 1998; Alexiou 2000). On the other hand, mechanical aortic valve replacement might be a lifelong solution, mainly for patients where large sizes (≥ 21 mm) of the valve can be inserted. The majority of survivors are in the NYHA I class, leading normal or nearly normal lives. Mechanical aortic valve replacement, with optional enlargement of the aortic root and long-term anticoagulation, remains a good alternative to the Ross procedure.

Other alternatives for valve replacement are unappealing, including a tissue valve with rapid degeneration in children, or an allograft with no growth potential. Aortic homograft replacement of the aortic valve is a reasonable alternative in the case of endocarditis. Unfortunately, the durability of an aortic homograft is limited, with an 82% 5-year freedom from reintervention (Lupinetti et al. 2003). Furthermore, the risk at reoperation is not negligible and warrants that they be used with caution. The allograft may be densely calcified, sternal reentry may be perilous, the coronary ostia may need to be reimplemented again, and the aortic anulus may have scarred down excessively.

16.3 Subaortic Stenosis

16.3.1 Introduction

Subvalvular stenosis is an obstruction of the left ventricular outflow tract below the aortic valve. The most common form is a fixed obstruction due to a discrete membrane or a diffuse, tunnel-like obstruction. This condition occurs in patients with associated congenital heart disease, including ventricular septal defect, coarctation of the aorta, interrupted aortic arch, atrioventricular canal, and others. The lesion may develop in patients with these defects before operation, but also may appear and progress significantly after surgical correction of the associated defects (Gersony 2001).

Other rare causes of subvalvular obstruction are abnormal attachments of the mitral valve, accessory tissue, abnormal insertion of the mitral papillary muscle, abnormal muscular bands within the left ventricular outflow tract, and space-occupying lesions in the left ventricular outflow tract. Shone and associates described a complex of subvalvular aortic stenosis in association with supralvalvular mitral ring, parachute mitral valve, and coarctation of the aorta (see also ► Chapters «Anomalous Pulmonary Venous Connections and Congenital Defects of the Atria, the Atrioventricular Septum, and the Atrioventricular Valves», Sect. 12.3.5.4 and «Congenital Anomalies of the Great Vessels», Sect. 21.2.1.1) (Shone et al. 1963). Rarely seen hypertrophic obstructive cardiomyopathy usually creates dynamic subvalvular obstruction due to opposition of the anterior leaflet of mitral valve against the asymmetrically hypertrophied ventricular septum.

16.3.2 Anatomy

Fixed subaortic obstruction can be discrete or diffuse. The discrete form represents about 70% of cases and is characterized by a thin, fibromuscular shelf located at the area of aortomitral continuity with the extension toward the interventricular septum.

It is typically seen in patients with a more acute angle between the long axis of the left ventricle and the aorta. This angulation leads to imbalance in shear forces which causes the proliferation of tissue that forms the membrane (Kleinert and Geva 1993; Jonas 2004). There may be an abnormal anatomic relationship with the mitral valve, which is displaced anteriorly and rotates in a clockwise direction.

Diffuse subvalvular aortic stenosis is caused by a circumferential narrowing which commences at the annular level and extends downward for 1–3 cm into the left ventricle cavity.

It is often a secondary lesion seen after previous resection of a discrete subvalvular aortic membrane. Scarring from the initial resection in conjunction with an abnormal-shaped left ventricular outflow tract may result in progressive fibromuscular proliferation and creation of a left ventricular outflow tract tunnel.

Hypertrophic obstructive cardiomyopathy is characterized by primary asymmetric ventricular

septal hypertrophy and a dynamic obstruction associated with abnormal systolic anterior motion of the anterior leaflet of the mitral valve. The histological hallmark of this disease is the presence of disorganized and bizarrely shaped hypertrophied myocytes (Goodwin et al. 1960).

16.3.3 Pathophysiology

Pressure overload leads to concentric hypertrophy of the left ventricle and myocardial hypoperfusion with the same sequels as seen in valvular aortic stenosis.

Increased shear stress due to turbulence might cause endocardial injury and subsequent proliferation and fibrosis (Cape et al. 1997). The membrane which results creates more turbulence, further accelerating the process of proliferation and fibrosis. The turbulence can also cause injury to the aortic valve leaflets, with subsequent thickening and distortion resulting in aortic insufficiency. As compared to other congenital heart defects, discrete subvalvular aortic membrane is virtually never recognized in early infancy, but appears to be an «acquired» lesion secondary to flow disturbances in the left ventricular outflow tract (Gewillig et al. 1992).

16.3.4 Clinical Presentation and Diagnosis

Isolated discrete subvalvular aortic membrane is typically seen in older children with symptoms similar to those of the valvular variety. Trivial or mild aortic regurgitation is present in about two-

third of all cases. Contrary to the discrete form, the tunnel type of obstruction is often seen as a part of complex lesions, even in neonates and infants. Hypertrophic obstructive cardiomyopathy is rarely seen in the pediatric population; symptoms usually develop in the second or third decade of life.

An ECHO is the method of choice for visualizing the narrowed left ventricular outflow tract, to discriminate between discrete and diffuse forms, to measure gradient, and to evaluate the function of the aortic valve and the functional and morphometric parameters of the left ventricle. Catheterization, with direct gradient measurement, is useful in assessing complex, multiple levels of obstruction of the left ventricular outflow tract and the aorta.

16.3.5 Indications for Surgery

Symptoms associated with left ventricular outflow tract obstruction (syncope, angina, diminished exercise tolerance, etc.) are indications for surgery (■ Fig. 16.12). The surgical intervention is indicated when the peak Doppler gradient across the left ventricular outflow tract is 30 mmHg or more in discrete subvalvular aortic membrane and a more than 60 mmHg (mean gradient ≥ 40 mmHg) in tunnel-type obstruction. Patients with peak gradient < 30 mmHg and no significant left ventricle hypertrophy are followed closely for progression, especially in the first several years of life. Surgery is also advocated in infants and children in the presence of aortic regurgitation regardless of gradient (Jonas 2004).

■ Fig. 16.12 Treatment protocol for subvalvular aortic stenosis at the German Pediatric Heart Center, Sankt Augustin, according to peak gradients measured, symptoms, or noted aortic regurgitation (AR)

Indication for operation in hypertrophic obstructive cardiomyopathy is driven by the progression of symptoms despite the maximum medical therapy. In symptomatic patients, a peak Doppler gradient above 50 mmHg under resting conditions or with provocation, preferably using physiological stress, is an indication for surgery. In asymptomatic patients, a peak Doppler gradient >75–100 mmHg at rest is an indication for surgery (Maron et al. 2003; Dearani et al. 2005).

16.3.6 Surgical Correction

16.3.6.1 Resection of a Discrete Subaortic Membrane

The approach, the bypass strategy, and myocardial protection are the same as in other operations for aortic valve surgery. An oblique, inverted hockey stick type of incision is made from the anterior aspect of the aorta toward the noncoronary sinus of Valsalva. The right coronary cusp is retracted anteriorly, exposing the subvalvular area. Alternatively, a nasal speculum can be used to improve exposure. The extent and relationship of the membrane to the surrounding structures, especially to the aortic valve and to the anterior leaflet of the mitral valve, are carefully assessed. The membrane is either grasped with forceps or stabilized by a skin hook. Caution should be exercised not to damage the aortic valve by instruments. Under the right coronary cusp, close to the intercoronary commissure, a radial incision is made through the white fibrous tissue only to its junction with the muscle. Combination of sharp and blunt dissection is used to peel the membrane off the muscle all the way round the entire circumference of the subaortic region. If the membrane is attached to the aortic valve cusps, careful sharp dissection should be performed to remove any fibrous tissue which could obstruct the left ventricular outflow tract. The location of the conduction tissue near the membranous septum should be identified, and any deep, sharp dissection must be avoided.

A myectomy is routinely performed to enlarge the left ventricular outflow tract and to reduce the likelihood of recurrence. A wedge of muscle under the left half of the right coronary cusp is excised.

The technique is similar to that utilized for diffuse fibromuscular stenosis (Hraska et al. 2007b).

Complications of this procedure include the creation of an iatrogenic VSD, if resection is excessively deep, damage to the conduction system if the resection is made under the noncoronary leaflet, and damage to the aortic cusps due to carefree manipulation with instruments (■ Fig. 16.13).

16.3.6.2 Modified Konno Operation

The aorta is opened vertically with an extension toward the intercoronary commissure, staying away from the right coronary artery. An oblique incision is made into the infundibulum of the right ventricle. A right-angled instrument is passed through the aortic valve to guide an incision into the infundibular septum. Because of the extreme thickness of the septum, the incision is always challenging. The incision should remain above the muscle of Lancisi in order to avoid the conduction system. The incision is enlarged leftward below the pulmonary valve. Working back and forth between the aortic approach and the septal incision, the incision is extended toward the intercoronary commissural triangle without injuring the cusps of the aortic valve. Extra care is taken when resecting tissue from the inferior edge of the incision, to reduce the risk of injury to the His bundle. At this point, any fibrous subaortic tissue is resected. A patch of glutaraldehyde-treated pericardium or Gore-Tex is sutured with interrupted pledgeted sutures (or a running suture) to close the created ventricular septal defect, with all the sutures remaining on the right ventricular aspect of the septum. The incision in the aorta and the free wall of the right ventricular outflow tract is then closed with a patch of pericardium (Jahangiri et al. 2000). Alternatively, the right ventricular aspect of the right ventricular outflow tract can be exposed working through the right atrium and the tricuspid valve. After pulling away the septal leaflet of the tricuspid valve, the septal incision is made, starting above the insertion of the Lancisi muscle, with an extension toward the pulmonary valve. The risk of damaging the conduction system is thereby lessened. The rest of the operation is the same as described above (■ Figs. 16.14, 16.15, and 16.16).

■ Fig. 16.13 a, b Diagram of a the pathoanatomy and b the resection of a subvalvular diaphragm, extreme form of discrete membranous subvalvular aortic stenosis

16.3.6.3 Ross-Konno Operation

In patients with left ventricle outflow tract obstruction and/or a hypoplastic aortic annulus, a Ross-Konno procedure is the method of choice (■ Fig. 16.17). The management of the cardiopulmonary bypass, myocardial protection, and preparation and dissection of the great vessels and coronary arteries is the same as for the Ross operation. After aortic cross-clamping and cardioplegia administration, the aorta is transected at the level of the sinotubular junction. The coronary arteries are explanted with large coronary buttons comprising almost the entire wall of the sinus of Valsalva. The pulmonary autograft is harvested, along with an extension of the infundibular free wall muscle attached to it. This extra tissue is used for patching the ventriculoplasty incision. The interventricular septum is incised to the left of the right coronary artery. The length of the incision depends on the morphology of the obstruction. If only annular enlargement is necessary, the septal incision is limited, extending to about 5–10 mm into the septum. In patients with long-segment subaortic stenosis, the septal incision is extended beyond the obstruction (Mohan Reddy et al. 1996). Resection of fibroelastosis or ventricular

myectomy is performed if necessary. The pulmonary autograft is seated with the infundibular muscle extension fitting into the Konno incision in the interventricular septum. The autograft is then sutured to the base of the aortic annulus using a continuous suture. The infundibular muscle extension is reinforced with nonabsorbable, interrupted, pledgeted mattress sutures. After reattaching the coronary artery buttons to the neo-aortic root, the distal end is anastomosed to the transected aorta using a continuous suture. The right ventricular outflow tract is reconstructed with an allograft valved conduit. The allograft is sutured directly to the right ventricular infundibular muscle without the use of any additional patching material (Hraska et al. 2008).

16.3.6.4 The Konno-Rastan Operation

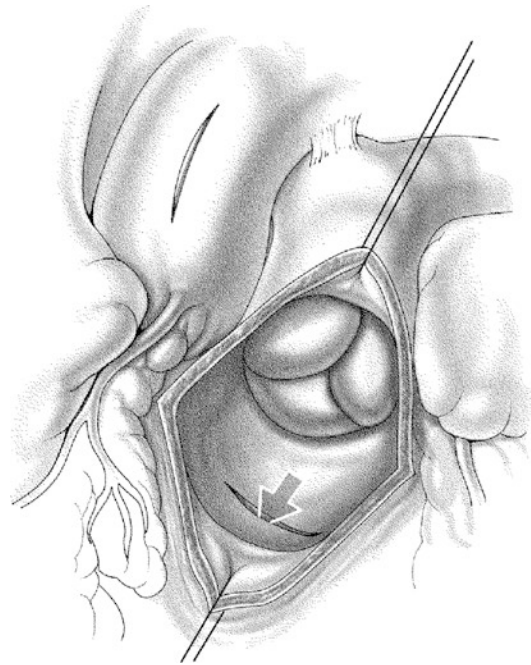

The approach, the bypass strategy, and myocardial protection are the same as in other operations for aortic valve surgery. The pulmonary artery is dissected away to reveal the base of the aorta. The aorta is opened vertically with an extension toward the intercoronary commissure, staying away from the right coronary artery. A transverse incision is made in the outflow tract of the right

■ **Fig. 16.14** Modified Konno operation I: The infundibular incision allows for access to the interventricular septum. In case a pulmonary autograft is needed, it can be harvested right away

ventricle, just proximal to the pulmonary anulus. After the opening of the right ventricle, the septum is visualized and the position of the pulmonary artery cusps is noted.

The aortotomy incision is extended down in the ventricular septum, staying above the muscle of Lancisi (away from conduction system) on the right side and away from the pulmonary cusps on the left side. This opening must be extended far enough below the tunnel stenosis. The aortic valve is completely removed, and the subvalvular fibrotic endocardial deposits are peeled away. An appropriate sizer is placed in the area of the divided anulus to estimate the amount of patch required to accommodate a predetermined valve size. Thereafter, a trigonal Dacron patch made to fit the desired enlargement is trimmed and sewn into the gap in the ventricle septum up to the aortic valve anulus by continuous suture technique, reinforced by several horizontal mattress sutures. At this point, sim-

■ **Fig. 16.15** Modified Konno operation II: Ventricular septal (broad arrow) incision starts below the left/right commissure of the aortic valve: an instrument can be passed from the aortotomy through the aortic valve to the appropriate location of the interventricular septum for orientation

■ **Fig. 16.16** Modified Konno operation III: The created septal defect is closed with an ellipsoidal patch on the right ventricular side

■ **Fig. 16.17** Ross-Konno procedure. **a** The aortic anulus is enlarged by incising the interventricular septum (*dashed line*) between the left and right commissures. The length of the incision is frequently limited to just beyond the anulus. A myectomy may also increase the orifice area, limiting the extent of the ventriculoplasty incision. **b** The autograft is sutured to the margins with interrupted pledgeted sutures. A short apron is left on the autograft to fill the ventriculoplasty site. **c** Coronary buttons are reimplemented into the autograft. **d** Completed reconstruction
