

Figure 3 Integrated mechanism for the target site-specific action of SERMs in breast or uterine cancer. The two extremes of anti-estrogenic or full estrogenic actions are shown. Estrogen-like actions could occur in cells expressing an excess of coactivators (CoAs) and/or a decrease in corepressors (CoRs). The charged surface of a tamoxifen-ER complex prevents CoR binding. The estrogenic action would be amplified by surface signaling from dimers of epidermal growth factor receptor (EGFR) and HER2/neu activating tyrosine kinases (tk). The phosphorylation cascade can activate AF-1 on ER- α directly or activate the excess of CoAs in a high-ER environment. Reduced levels of ER prevent the signal transduction pathway and promote anti-estrogenic actions in a surface silent cell. Reprinted from Jordan, V. C. (2002). The secrets of selective estrogen receptor modulation: Cell-specific coregulation. *Cancer Cell* 1(3), pp. 215–217. Copyright 2002, with permission from Elsevier Science.

in 1993, when Benz *et al.* showed that overexpression of HER2/neu, a member of the epidermal growth factor receptor family of receptor tyrosine kinases, in MCF-7 cells resulted in resistance to tamoxifen. Clinical evidence also strongly supports a correlation between overexpression of HER2/neu and the lack of efficacy of tamoxifen in ER- α -positive breast cancer. However, there are two models of tamoxifen resistance, observed in the laboratory and the clinic. Intrinsic resistance to tamoxifen occurs in ER- α -negative tumors or might result from the overexpression of HER2/neu in ER- α -positive tumors. Acquired resistance to tamoxifen can result from extended therapy of ER- α -positive breast tumors that initially regress with treatment but recur by tamoxifen-stimulated growth. Thus, the change in activity of the tamoxifen-ER- α complex from anti-estrogenic to estrogenic during breast cancer treatment might occur by crosstalk between surface receptors (HER2/neu) and the SERM-ER- α complex (Fig. 3).

NOVEL AGENTS

New drug discovery for SERMs is driven by the known side effects of tamoxifen, for example, the

increase in the incidence of endometrial cancer and the report of the negative effects of HRT on coronary heart disease. Several approaches are being pursued by altering the anti-estrogenic side chain or improving the pharmacokinetics of existing molecules. A novel SERM, GW5638, is a tamoxifen derivative containing a carboxylic acid side chain rather than a tertiary amino group (Fig. 1). As demonstrated in the rat, GW5638 is a nonsteroidal SERM with estrogen-like activity in bone without known uterotrophic activity. GW7604, the active metabolite of the prodrug GW5638, is less estrogenic than the active metabolite of tamoxifen (4-OHT) due to the carboxylate side chain of GW7604 causing a strong repulsion of the aspartate anion at residue D351 in the LBD of the ER- α . GW5638 might be a good candidate as a novel SERM for the prevention and treatment of osteoporosis and breast cancer with little risk of developing endometrial cancer because the drug has a longer biological half-life than raloxifene.

Arzoxifene is another novel SERM developed to improve the poor bioavailability of raloxifene (Fig. 1). Arzoxifene is being tested in clinical trials for the treatment of breast cancer. Preliminary clinical data show that arzoxifene is only a modest anti-estrogen for the treatment of breast cancer and is predominantly an

anti-estrogen in the rat uterus. Tamoxifen-stimulated endometrial tumors grown in athymic mice continue to grow with tamoxifen or arzoxifene, indicating that arzoxifene might be a poor candidate as a second-line treatment after tamoxifen failure.

EM-800 was developed in an effort to increase the bioavailability of SERMs for longer pharmacological effects. The active metabolite of EM-800, EM-652, is similar in structure to raloxifene (Fig. 1) and is a potent anti-estrogen in both *in vitro* and *in vivo* biological assays. EM-652 inhibits estrogen-responsive proliferation of a variety of human breast cancer cell lines and is observed to inhibit tumor growth and have little stimulatory effect on human endometrial cancer cells. EM-652 is a potent blocker of both estrogen-activated ER- α and ER- β , resulting in repression of estrogen-responsive gene transcription. The activation of both ERs by either H-Ras or SRC-1 is completely abrogated by EM-652. The pharmacology of EM-652 is similar to that of raloxifene due to the similar manner in which they both fit into the LBD and interact with residue D351. Based on the analogy of the prodrug EM-800 with raloxifene, the prediction would be that EM-800 should be effective as a bone-preserving SERM with little uterotrophic activity.

IDEAL MULTIFUNCTIONAL SERMS

Although the new SERMs, GW5638, arzoxifene, and EM-800, are improvements over tamoxifen and raloxifene with regard to bioavailability and the lack of uterotrophic activity, the need for the ideal multifunctional SERM still exists. The ideal SERM should have full estrogenic activity in the skeleton to maintain bone density, lower circulating levels of cholesterol to prevent coronary heart disease, and prevent hot flashes and should have anti-estrogenic activity in the breast and uterus to prevent breast and endometrial cancers. Most importantly, a SERM that prevents hot flashes will dramatically enhance compliance. Development of the ideal SERM with tissue-selective activity requires elucidating the exact mechanisms of SERM-ER complexes in diverse cellular and molecular contexts. The exploitation of both *in vivo* and *in vitro* SERM-ER models will assist in the identification of signal transduction pathways that interact with the SERM-ER- α or SERM-ER- β complex. Furthermore, understanding the role of coactivators and corepressors in modulating the activity of SERM-ER complexes in different tissues will further explain the selective nature of SERMs. Ultimately, this information will provide insight for development of

SERMs that will advance the prevention of breast cancer, endometrial cancer, coronary heart disease, osteoporosis, and postmenopausal symptoms.

Sertoli Cell Pathology

see Androgen Insensitivity Syndrome

due to the upregulation of nitric oxide synthesis. This concept is supported by a positive effect of administration of dopamine agonists such as apomorphine, bromocriptine, and pergolide on spontaneous penile erections, increased libido reported after dopamine precursor L-dopa is administered, and impaired libido associated with antidopaminergic agents. Epidemiological data include evidence that higher serum testosterone levels are associated with greater sexual activity in healthy, older but not younger men. Sexual studies suggest libido is restored in hypogonadal males when testosterone levels are increased from subnormal to the low normal range. Other studies showed that higher testosterone levels may shorten the latency of erection stimulated by the exposure to erotic material, and testosterone replacement in hypogonadal males restores sexual interest, shortens latency, and increases frequency and magnitude of nocturnal penile tumescence (NPT). Furthermore, withdrawal of androgen therapy in hypogonadal males leads to a decline in libido in 3 to 4 weeks and unreplace hypogonadal males have impairment in spontaneity of erections. These observations appear to have a threshold effect, as levels within the normal range seem to be adequate for normal libido and increasing the doses to superphysiologic levels does not further enhance sexual drive. It is also of note that testosterone is supportive of sexual drive and seems to be responsive to external stimuli. This is shown by the work of J. M. Davidson demonstrating that men with hypogonadism are able to achieve erections in response to viewing of erotic films.

Erectile Function

Penile erections occur when the paired corpora cavernosa and corpus spongiosum of the testes are filled with blood under pressure. Erection is the ultimate response to multiple psychogenic and sensory stimuli from imaginative, visual, auditory, olfactory, tactile, and genital reflexogenic sources that affect several neurologic and vascular cascades that lead to penile tumescence and rigidity sufficient for vaginal penetration. Coincident with penile engorgement sexual arousal is heightened, with testicular ascent and swelling and dilation of the urethral bulb. There is also an increase in the glands and coronal size and vasodilation of blood vessels in the skin of the chest and buttocks.

The mechanisms that increase penile blood flow have been studied extensively, with nitric oxide having been identified as the predominant endothelial-derived relaxation factor. Nitric oxide is synthesized from its precursor arginine under the enzymatic

regulation of nitric oxide synthase (NOS). While a constitutive NOS is produced by the endothelial cells and nerve terminals of the penile vascular tissue, the predominant effect leading to an erection is an increase in neuronal NOS. Nitric oxide is a major vasodilator with its effects mediated by the production of cyclic GMP. Cyclic GMP is in turn inactivated by a relatively penile specific enzyme phosphodiesterase type 5. It was the recognition that phosphodiesterase 5 is a regulator of the persistence of nitric oxide induced cyclic GMP effects on penile blood flow that led to the development of a class of drugs (phosphodiesterase 5 inhibitors; e.g., Sildenafil) that selectively enhance erectile function. While nitric oxide seems to be the predominant stimulus for local penile vasodilatation, other factors, including vasoactive intestinal polypeptide (VIP), bradykinin, peptide, histidine, nithiamide, pituitary adenal cyclase activating polypeptide, helospectin, gallamine, calcitonin-related peptide (CGRP) and prostaglandin E-1, may play a role. Thus, increased sexual drive produced by cognitive and other erotic signals from the brain, sleep-induced CNS signaling, and tactile stimulation of the sensory component of the penis all induce increased vascular dilatation.

Once increased penile blood flow occurs, there is compression of the penile veins, which course on an angle from the corpora cavernosa to the tunica albuginea to the deep dorsal vein. Engorged corpora cavernosa compress the venous outflow maintaining erection until the signals for enhanced blood flow disappear. It should be noted that the nonadrenergic perisymphatic pathway provides the neuronal pathway between the brain, spinal cord, and the penis. The sympathetic pathway probably plays a role in the ultimate detumescence, providing inhibitory signals to the NOS containing perisymphatic neuron and having direct vasocontractile effects on the smooth muscle. The latter appears to be mediated by norepinephrine and neuropeptide Y.

Ejaculation

The ejaculation phase is controlled by sympathetic innervation of the genital organs. It occurs as a result of a spinal cord reflex arc. There is considerable voluntary inhibitory control over this space of the sexual response, and this has been described as having two sequential components. The first component is called emission and is associated with deposition of seminal fluid into the posterior urethra. Contraction of the ampullae of the vas deferens, the seminal vesicles, and the smooth muscles of the prostate mediate emission.

The second process is the true ejaculation; it results when the seminal fluid is expelled from the posterior urethra through the penile meatus as a result of organized smooth muscle contraction.

Orgasm

Much less is understood about the regulation of male orgasm than about erectile function. It is generally believed that both physiological and psychogenic elements contribute to the genesis phase. The process seems to be associated with afferent stimuli that transmit via the pudendal nerve, inducing the following physiologic events: smooth muscle contraction of the accessory sex organs; build-up and release of pressure in the posterior urethral; sensation of the ejaculatory inevitability; contraction of the urethral bulb and perineum; rhythmic contractions of the pelvic floor muscles; semen emission and ejaculation; and finally the reversal of the generalized physiologic changes and sexual tension. These processes are sensed by the cortical neuron as pleasurable. Factors that influence the subjective sensation of orgasmic pleasure include the degree of sexual excitement, recency of sexual activity, and the psychosexual makeup of the individual. Although uncommon, it is possible for orgasm to occur without either erection or ejaculation. Conversely, contraction of the pelvic musculus and ejaculation may occur in the absence of the pleasurable component of orgasm.

Detumescence

The final phase of the erectile process is called detumescence. In this phase the penis returns to the flaccid state. This occurs when vasoconstriction occurs in the arterials, reducing the blood flow to the penis and allowing increase in venous drainage of the corpora cavernosal contents. Local penile α -adrenergic receptor activation is the most important neuro mediator effecting detumescence. Interference to this function through the α -1 adrenergic receptor blockade may lead to the development of priapism.

A list of the causes of sexual dysfunction by clinical manifestations is provided in [Table I](#).

ANDROGENS AND ERECTILE FUNCTION

Androgen Actions on Libido and Penile Erections

Testosterone has its primary effect on erectile function by enhancing libido with secondary effects on

penile NOS activity. Libido is highly sensitive to testosterone, thus explaining the preservation of erectile capacity in many men with partial androgen deficiency. Young men with marked hypogonadism are usually free of functional and anatomical impairment of the penile vasodilatory apparatus. Thus, severely hypogonadal young men with impaired libido and secondary decrease in erectile activity usually benefit from treatment with testosterone therapy. In contrast, middle-aged and, in particular, older males with androgen deficiency may have a secondary penile neurovascular disorder and may respond poorly to testosterone therapy alone.

Testosterone Deficiency and Impaired Sexual Function

There has been considerable debate about the usefulness and cost-effectiveness of hormonal evaluation and the extent to which testosterone deficiency should be investigated in men presenting with erectile dysfunction. Of all men with erectile dysfunction, only 8–10% have demonstrated low total testosterone levels. Because serum testosterone concentrations fall progressively with age and sex hormone binding globulin concentrations increase with age, the incidence of chemically low bioavailable or free testosterone is higher in the older age group. Using total testosterone as a chemical marker, studies have reported that only 6–8% of men with erectile dysfunction have an endocrine basis to the condition, particularly in the older age group. These data are contrasted with the high incidence of subnormal serum-free and non-SHBG bound testosterone in the overall elderly male population. These findings are confirmed in the MMAS study, where longitudinal data revealed a 1.6% per year and 2–3% per year decline in total and bioavailable testosterone, respectively, in men between the ages of 40 and 70 years.

Erectile dysfunction and androgen deficiency may be considered two common but often independently distributed disorders. Thus, while testosterone deficiency represents only a small component of the total population of men with erectile dysfunction, it is important to be able to identify testosterone deficiency in this patient population, in part because androgen deficiency is a correctable cause of sexual dysfunction, and some men with erectile dysfunction and low testosterone concentrations respond rapidly to testosterone replacement. In addition, testosterone deficiency is responsible for many other systemic complaints, including muscle wasting, osteoporosis, increased

Table 1 Causes of Sexual Dysfunction in the Male Classified by Clinical Manifestation

| Clinical manifestation | Most common causes |
|--|--|
| Disorders of desire | |
| Hypoactive sexual desire (HSD) | Psychogenic (e.g., depression, marital discord leading to desire deficiency, performance anxiety leading to excitement inhibition) CNS disease (partial epilepsy, Parkinson's, poststroke, adrenoleukodystrophy) Androgen deficiency (primary or secondary), androgen resistance Drugs (antihypertensives, psychotropics, alcohol, narcotics, dopamine blockers, antiandrogens) |
| Compulsive sexual behaviors | Psychogenic (obsessive-compulsive sexuality, excessive sex-seeking in association with affective disorders, addictive sexuality, sex impulsivity) |
| Erectile dysfunction | Psychogenic Drugs (antihypertensives, anticholinergics, psychotropics, cigarette smoking, substance abuse) Systemic diseases (cardiac, hepatic, renal, pulmonary, cancer, metabolic, postorgan transplant, pelvic irradiation) Androgen deficiency (primary or secondary), androgen resistance, other endocrinopathies Vascular insufficiency (atherosclerosis, pelvic steal, penile Raynaud's, venous leakage) Neurological disorder (Parkinson's, Alzheimer's, Shy-Drager, encephalopathy, spinal cord or nerve injury) Penile disease (Peyronie's, priapism, phimosis, smooth muscle dysfunction, trauma) |
| Disorders of ejaculation | Psychogenic (neurotic personality, anxiety/depression, partner discord or other situational factors) |
| Premature ejaculation (primary or secondary) | Organic (increased central dopaminergic activity, increased penile sensitivity) |
| Absent or retarded emission | Sympathetic denervation (diabetes, surgical injury, irradiation) Drugs (sympatholytics, CNS depressants) Androgen deficiency (primary or secondary), androgen resistance |
| Postejaculation | Psychogenic |
| Orgasmic dysfunction | Drugs (selective serotonin reuptake inhibitors, tricyclic antidepressants, monoamine oxidase inhibitors, substance abuse) CNS disease (multiple sclerosis, Parkinson's, Huntington's chorea, lumbar sympathectomy) Psychogenic (performance anxiety, conditioning factors, fear of impregnation, hypoactive sexual desire) |
| Failure of detumescence | |
| Structural penile disease | Penile structural abnormalities (Peyronie's, Phimosis) |
| Priapism (primary or secondary) | Primary priapism: Idiopathic Priapism secondary to disease: Hematologic (sickle cell anemia, leukemia, multiple myeloma), infiltrative (Faber's disease, amyloidosis), inflammatory (tularemia, mumps), and neurologic disease, solid tumors, trauma Priapism secondary to drugs: Phenothiazines, trazodone, cocaine, intrapenile vasoactive injections |

body fat, fatigue, and mood impairment. Androgen deficiency may be due to multiple causes, which can be generally divided into a central (hypothalamic, pituitary) and primary testicular disease. Only a small fraction of men with erectile dysfunction and low testosterone levels have been found to have space-occupying lesions of the hypothalamic-pituitary region. The vast majority of individuals with structural hypothalamic pituitary lesions have serum testosterone levels below 150 ng/dL and/or significantly elevated prolactin levels.

Testosterone Treatment for Erectile Dysfunction

There have been numerous studies characterizing the dose-response relationship of testosterone treatment to improve sexual desire, motivation, and sexual performance. A positive response may be seen within 30 days of initiation of testosterone treatment. Positive responses are seen in treatment with a wide range of testosterone delivery systems including injections, oral agents, transdermal patches, and testosterone

gels. As suggested previously, the majority of elderly men have impaired penile vasodilation as the cause of their erectile dysfunction. A majority of these men respond to various penile vasodilatory agents, the most popular of which are phosphodiesterase 5-inhibitors. Studies have demonstrated that individuals who have androgen deficiency and impaired erectile function may benefit by the combined treatment of a phosphodiesterase-5 inhibitor and testosterone.

Table I Stages of Sexual Maturation (P1 to P5) at Puberty in Girls

| Stage | Description |
|-------|--|
| P1 | Prepubertal stage |
| P2 | Early development of subareolar breast bud; widening of areolae; small amounts of labial, pubic, and/or axillary hair may be present |
| P3 | Increase in size of palpable breast tissue and areolae; increased amount of pubic hair and axillary hair; development of adult body odor |
| P4 | Further increase in breast tissue and areolae that protude above breast level; adult amounts of pubic hair; acne |
| P5 | Menarche; adult breast and areolar size; adult amount and distribution of pubic hair with extension to the upper thigh |

In most developed countries, 50% of girls show minimal breast development by the age of 10.5 years (Table II). Very few of them experience breast budding before the age of 9 years and nearly all have some breast development by the age of 14 years. Menarche is present in 50% of girls at 12.9 years of age and is considered early if it occurs before 10 years of age. Almost all girls experience menarche by the age of 15 years. In Europe, precocious puberty is therefore

usually defined by the appearance of pubertal signs before the age of 8 years. In the United States, it has been suggested that precocious puberty should be defined as sexual maturation that is observed before the age of 7 years. Delayed puberty is defined by the absence of breast budding by the age of 14 years. Primary amenorrhea is considered to occur if menarche has not occurred by the age of 15 years. The size of the uterus is another way to examine how pubertal

Figure 1 Stages of puberty and height increase and height velocity during sexual maturation. (P1) Absence of sexual maturation. (P2) First signs of sexual maturation, i.e., onset of puberty with the first breast budding (arrow). (P3, P4) Further development of the genitalia and development of secondary sexual characteristics, such as pubic and axillary hair. (P5) Menarche and adult status.

Table II Stages of Development of Breast and Peak Height Velocity in Girls in Relation to Chronological Age and Bone Age^a

| | Chronological age (years) | Bone age (years) |
|---|---------------------------|------------------|
| Development of the breast | | |
| B1 Prepubertal | | |
| B2 First budding enlargement of the areola | 10.9 (8.5–13.3) | 10.5 (8.5–13.2) |
| B3 Enlargement of the breast palpable mammary gland | 12.2 (9.8–14.6) | 12.0 (10.2–14.0) |
| B4 Additional enlargement of the breast and of the areola | 13.2 (11.4–15.0) | 13.5 (11.5–15.0) |
| B5 Adult breast | 14.0 (11.6–16.4) | 15.0 (12.5–16.0) |
| Menarche | 12.9 (9.9–14.9) | 12.8 (11.3–13.6) |
| Peak height velocity | 12.2 (10.2–14.2) | 12.4 (10.0–14.5) |

Adapted from Sempé *et al.* (1996). Croissance et développement. In "Précis de Pédiatrie" (P. C. Sizonenko and C. Griscelli, eds.), pp. 64–65. Editions Payot, Lausanne, Switzerland, with permission.

^aChronological age and bone age are expressed as means and confidence limits (given in parentheses).

development is progressing. It requires an ultrasonographic examination of the pelvis, which is costly and perhaps not as precise as the assessment of breast size and other signs of sexual maturity. However, it can contribute significantly as it allows one to measure the ovaries and to observe their morphology. Multifollicular or microscopic cystic morphology is observed in 50% of ovaries in normal adolescents after the age of 9 years. Such morphology can last for several years after menarche, before the ovary becomes homogenous with the typical appearance of the dominant follicle.

HORMONAL CHANGES

During pubertal development, the secretion of pituitary gonadotropins increases and, in response, the ovary will develop, with increasing secretion of estradiol (Fig. 2). The increase in plasma estradiol occurs between 10 and 12 years of age. A plasma concentration >25 pg/ml suggests pubertal ovarian secretion. However, marked variations in plasma estradiol levels are observed over 24h, even after menarche. Therefore, the measurement of plasma estradiol is not a reliable marker of the onset of puberty. The levels of plasma estrone, testosterone (Fig. 2), and adrenal androgens (Δ^4 -androstenedione and DHEA) increase during sexual maturation (Fig. 3). Plasma prolactin and inhibin concentrations also increase during pubertal development.

GROWTH HORMONE AND GROWTH FACTORS

As observed mainly in boys, plasma growth hormone levels as measured over 24h indicate a rise in

growth hormone (GH) secretion every 24h, mainly in relation to the increased secretion of sex steroids inducing an increase in GH pulse amplitude. Insulin-like growth factor-I (IGF-I) and insulin-like growth factor-binding protein (IGFBP-3) are secreted at an increased rate, in order to promote, together with GH, skeletal growth. Plasma levels of IGF-I and IGFBP-3 increase maximally at the time of the pubertal growth spurt (Figs. 4 and 5).

NUTRITION AND BODY COMPOSITION

Nutrition is considered to be an important factor in the onset of puberty and menarche. In 1972, Frisch and Revelle showed that in order to experience menarche, the adolescent girl should achieve an ideal critical weight, which is 47.8 ± 0.51 kg (mean \pm standard error of the mean). Although the concept still remains generally valid, there is a considerable variation within that critical weight. It depends on the adolescent height and should be adjusted for height. Fat, which secretes leptin, is considered to be one of the critical players in the onset of puberty and the occurrence of menarche.

PATTERNS OF GROWTH DURING PUBERTY

In a normal population of girls, peak height velocity in normal puberty is usually 8.6 ± 1.2 cm/year at a mean chronological age of 12.0 years and at a mean bone age of 12.2 years (Table II). Remaining growth is approximately 4 to 5 cm during the 2 years following the occurrence of menarche.

Figure 2 Changes in follicle-stimulating hormone (FSH), luteinizing hormone (LH), testosterone, and estradiol during female sexual maturation plotted at 6-month intervals before and after height velocity peak (HVP), which occurred at a mean age of 12 years and was 4.2 cm/6 months. Reprinted from Sizonenko and Aubert (1990), with permission.

SECULAR TREND

Data obtained since the midnineteenth century confirm that there has been a decrease in the age of onset of puberty, mainly in developed countries, as observed by the age at which menarche occurs, ranging from 16–17 years in 1880 in Norway, Finland, and Sweden to 12–13 years in the past decade (Fig. 6). The median age for the onset of puberty (i.e., changes in the genitalia) was 10.0–10.5 years in the United States in 1960, not different from the median age of 10 years found in surveys performed in the past decade. No significant secular trend is observed in developed countries. Such changes have not been observed at all in European countries, such as the Netherlands, or

Figure 3 Changes in plasma concentrations of estrone (E1), Δ^4 -androstenedione, testosterone, and DHEA during female sexual maturation, in girls with normal development [younger group (open circles) and older group (closed circles)]. Vertical interrupted line represents the onset of puberty (P2) for both normal groups. Both groups have menarche (M). The older group was followed until the end of puberty (stage P5). The younger group achieved midpubertal stage P3. Reprinted from Sizonenko and Aubert (1990), with permission.

else only small changes were observed, such as a shift of 0.6 years in Sweden between 1970 and 1980. The appearance of pubic hair was observed at a median age of 10.9 to 11.9 years between 1970 and 1980, decreasing to 11.3 years in the 1990s. Maturity and tempo of

Figure 4 Mean (± 1 SD) plasma IGF-I levels during female sexual maturation.

puberty appear to remain the same, suggesting that sexual maturation takes longer to be completed. This secular trend, which is so clearly shown in girls, has been attributed to the improvement in socioeconomic conditions (food, hygiene, better working conditions in lower social classes) in developed countries. As mentioned earlier, such a secular trend seems to disappear and, if present, remains very small and barely discernible.

BONE MASS DENSITY

During puberty, there is a marked increase in the bone mass and in particular an increase in the bone mineral density, as measured by several methods. Several endocrine and growth factors, in addition to genetic factors and nutrition, in particular calcium intake, are responsible for bone mineral accretion: sex steroids (particularly estradiol), IGF-I, GH, and two growth factors, IGFBP-4 and IGFBP-5, as well as the hormones involved in calcium and bone metabolism: parathyroid hormone and vitamin D and its metabolites. In a group of female adolescents, followed longitudinally, bone mineral density increases markedly at the time of puberty. In girls, the increase in the bone mineral density of the lumbar vertebrae, L2 to L4, already begins at 11–12 years of age and is at a

Figure 5 Mean (± 1 SD) plasma IGFBP-3 levels during female sexual maturation.

maximum between 12 and 14 years of age, at stage P3–P4. The increase in the bone mineral density of the femoral neck follows the same pattern. Bone mineral accretion decreases after the age of 15 years in girls and stops after the age of 18 years in girls. Therefore, during puberty, there is a considerable increase in the amount of minerals in the bone.

CONCLUSION

The evaluation of pubertal development is purely clinical, by staging the maturation of the sexual characteristics. The early stage of puberty is defined in girls by the onset of breast budding. Menarche appears 2.5 to 3 years after the onset of puberty. A considerable gain in height and bone mineral density is observed during the same period.

^aChronological age and bone age are expressed as means and 95% confidence limits (given in parentheses).

^bTesticular volume index (TVI) is expressed by the length \times width of the right side plus the length \times width of the left side, divided by 2.

appearance of the pubic and axillary hair. Stage P3 is also characterized by an increase in height and growth velocity—the pubertal growth spurt, which is crucial to achieving normal final height (Fig. 1).

Fifty percent of boys experience the first increase in the size of the testes, to a volume >4ml, at the age of 11.5 years. Almost none of them have a testicular volume >4ml before the age of 9 years and almost all of them have passed stage P2 at age 14 (Table II). Precocious puberty can be defined as puberty occurring before the age of 9 years in boys and delayed puberty can be defined as puberty occurring after the age of 14 years. It is evident from the range in ages observed for each stage of pubertal maturation that individual variability in pubertal development is important. In a few boys, sperm were found in the urine by the age of 12, and in 50% of boys, sperm were found by 14.5 years of age.

Figure 2 Changes in follicle-stimulating hormone (FSH), luteinizing hormone (LH), and testosterone during male sexual maturation and testicular volume index (TVI; in cm²) plotted at 6-month intervals before and after height velocity peak (HVP), which occurred at a mean age of 14 years and was 5.5 cm/6 months. Reprinted from Sizonenko and Aubert (1990), with permission.

Testicular volume was approximately 8–15 ml. Both adrenal androgens and testosterone are responsible for skeletal growth, growth of the penis, scrotum, prostate, and seminal vesicles, the development of axillary and pubic hair, the change in voice, and increase in muscle strength.

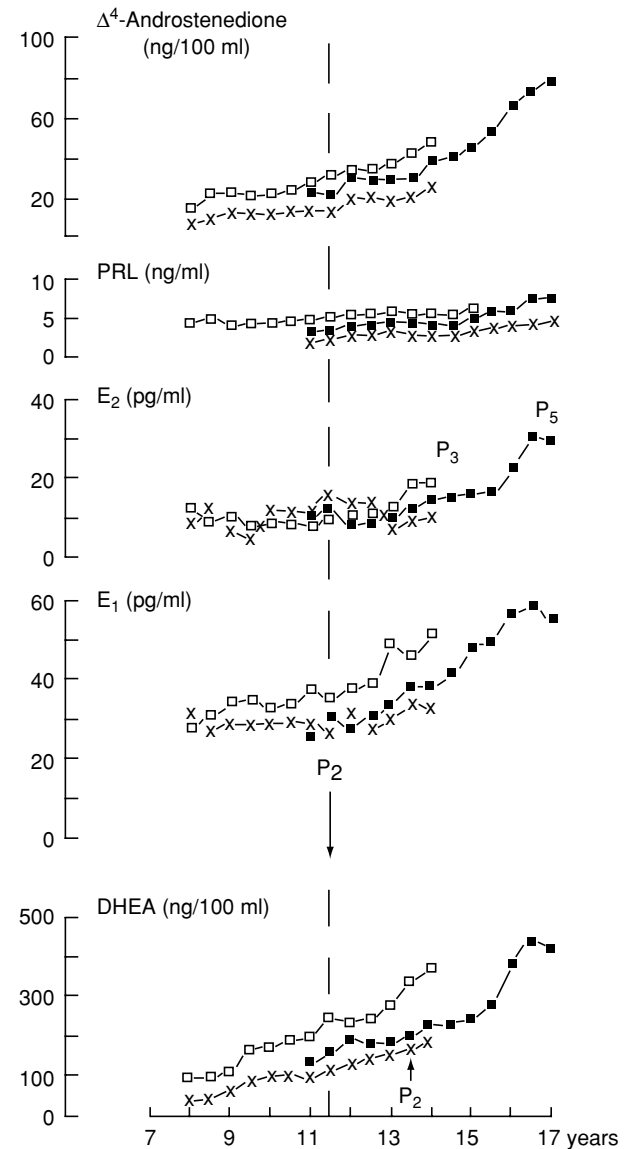

Figure 3 Changes in plasma concentrations of Δ⁴-androstenedione, prolactin (PRL), estradiol (E₂), estrone (E₁), and dehydroepiandrosterone (DHEA) during male sexual maturation, in boys with normal [younger group (open squares) and older group (closed squares)] and delayed sexual maturation (×symbols). Vertical dashed line represents the onset of puberty (P₂) for both normal groups. The older group was followed until the end of puberty (stage P₅). The younger group achieved midpubertal stage P₃. The onset of puberty of the delayed-maturation group was retarded by 2 years. Reprinted from Sizonenko and Aubert (1990), with permission.

HORMONAL CHANGES

The hormonal changes that occur at the onset of puberty are characterized by an increase in both of the gonadotropins, follicle-stimulating hormone and luteinizing hormone, as well as testosterone. Testosterone is an excellent parameter along with testicular size for the determination of the onset of puberty. Most boys who have started puberty have testosterone levels >0.25 ng/ml (Fig. 2). Plasma adrenal androgens, prolactin, and estrogens increase during sexual maturation (Fig. 3). Plasma inhibin concentrations also increase during pubertal development. In addition, plasma growth hormone (GH) levels as measured over 24 h indicate an increase in GH secretion, mainly in relation to increased secretion of sex steroids, inducing an increase in GH pulse amplitude (Fig. 4). Secretions of insulin-like growth factor-I (IGF-I) and insulin-like growth factor-binding protein (IGFBP-3) increase markedly, in order to promote, together with GH, skeletal growth. Plasma levels of IGF-I and IGFBP-3 increase maximally at the time of the pubertal growth spurt (Figs. 5 and 6).

Figure 5 Mean (± 1 SD) plasma IGF-I levels during male sexual maturation.

Nutrition is considered to be an important factor for the onset of puberty. However, this factor has not been as well studied in boys as it has been in girls.

Peak height velocity occurs at approximately 14 years of chronological age and at 14.5 years of bone age. Mean peak height velocity is 10 ± 1.2 cm (Table I).

SECULAR TREND

Data obtained since the midnineteenth century confirm that there has been a decrease in the age of onset of puberty, mainly in developed countries, as observed by the age at which the change in voice in choirboys occurs. The median age of onset of puberty (i.e., changes in genitalia) was 11.5–12 years in the United States in 1960, which is different from the median age of 10 years that was observed in surveys performed in the past decade. Such changes have not been observed at all in European countries, such as the Netherlands, or else only small changes were observed, such as a shift of 0.6 years in Sweden between 1970 and 1980. The appearance of pubic hair was observed at a median age of 12.5 years between 1970 and 1980, decreasing to 11.3 years in the 1990s. The maturity and tempo of puberty appear to remain the same, suggesting that sexual maturation takes longer to be completed.

BONE MASS DENSITY

During this period of rapid growth and sexual maturation, a marked increase in bone mass and in particular an increase in the bone mineral density, as measured by several methods, are observed. In addition to genetic factors and nutrition, in particular calcium intake, several endocrine and growth factors

Figure 6 Mean (± 1 SD) plasma IGFBP-3 levels during male sexual maturation.

are responsible for bone mineral accretion: sex steroids (testosterone and estradiol), IGF-I, GH, and two growth factors, IGFBP-4 and IGFBP-5, as well as the hormones involved in calcium and bone metabolism: parathyroid hormone and vitamin D and its metabolites. In boys, the increase in the bone mineral density of the lumbar vertebrae, L2 to L4, starts at 13–14 years of age and is at a maximum between 14 and 16 years of age, at stage P3–P4. The increase in the bone mineral density of the femoral neck follows the same pattern in both boys and girls. Bone mineral accretion decreases after the age of 16 years and stops after the age of 20 years. Therefore, during puberty, there is a considerable increase in the amount of minerals in the bone.

CONCLUSION

The evaluation of pubertal development is purely clinical, by staging the maturation of the sexual characteristics. The early stage of puberty is defined by the increase in the size of the testes and also by plasma testosterone levels. A considerable gain in height and bone mineral density is observed during the same period. Finally, data fail to show a clear secular trend for an earlier onset of puberty during the past decades in developed countries.

Table I Hemodynamic Patterns Determined by Pulmonary Artery Catheter Measurements in Specific Forms of Shock

| Type of shock | CVP and PCWP | CO | SVR | SvO ₂ |
|----------------|--------------|----|-----|------------------|
| Hypovolemic | ↓ | ↓ | ↑ | ↓ |
| Cardiogenic | ↑ | ↓ | ↑ | ↓ |
| Septic (early) | ↑ or ↓ | ↑ | ↓ | ↑ |
| Neurogenic | ↓ | ↓ | ↓ | ↓ |

Note. CO, cardiac output; CVP, central venous pressure; PCWP, pulmonary capillary wedge pressure; SvO₂, mixed venous saturation; SVR, systemic vascular resistance.

Inflammation plays an important role in the progression of shock. Shock and tissue injury lead to the activation of pro-inflammatory cells, such as neutrophils, macrophages, and platelets. Activation of these inflammatory cells leads to the release of inflammatory mediators, which govern virtually all manifestations of shock. These inflammatory mediators include chemokines/cytokines, eicosanoids, activated complement components, and coagulation cascades.

The primary pro-inflammatory cytokines include tumor necrosis factor α (TNF α) and interleukin-1 β (IL-1 β) (Table I). These molecules have potent biologic effects, inducing fever, anorexia, hypercortisolemia, neutrophilia, hypotension, and activation of the coagulation cascades and they greatly augment the entire immunoinflammatory process. Activation of complement components produces chemokines and activators of neutrophils and monocytes (C3a and C5a) and may also lead to the C5–C9 “attack complex,” causing further cytolysis. Activation of the coagulation cascade produces microvascular thrombosis, worsening cellular ischemia. Eicosanoids are vasoactive and immunomodulatory products of the arachidonic acid pathway released from the cell membrane. These include prostaglandins (PG) and thromboxane A₂. PGI₂ and PGE₂ cause vasodilation, enhance capillary leakage, and contribute to edema. Thromboxane A₂ causes vasoconstriction, contributing to pulmonary hypertension and renal acute tubular necrosis. Nitric oxide produced by inducible nitric oxide synthase in endothelial cells and macrophages is released in excess, leading to further vascular dilation and permeability and secondary oxidant-induced bystander tissue injury.

END-ORGAN EFFECTS

Shock has profound effects on every organ system in the body. However, this discussion is limited to

four specific areas that illustrate the interdependent physiology of shock.

Neuroendocrine

Decreased blood volume is sensed by carotid and aortic arch baroreceptors and mechanoreceptors in the right atrium. This directly stimulates the sympathetic nervous system (SNS), which increases the heart rate, causes peripheral vasoconstriction, and increases pituitary release of adrenocorticotropic hormone (ACTH) and antidiuretic hormone (ADH). ACTH stimulates cortisol release from the adrenal cortex and ADH cause the kidneys to retain water. The SNS stimulates catecholamine release from the adrenal medulla, which increases heart rate and causes peripheral and mesenteric vasoconstriction to maintain mean arterial pressure (MAP) and conserve blood flow to the heart and brain. Hypotension also causes activation of the renin–angiotensin arc, the net effect of which is to maintain blood pressure through vasoconstriction and retain sodium and water by the kidneys. Increased cortisol leads to decreased glucose uptake in the tissues and enhanced lipolysis, increasing serum osmolality. These hormonal effects all work synergistically to maintain blood pressure.

Cardiovascular

Cardiac function may be depressed in all forms of shock. Maintenance of blood pressure is dependent on three cardiac factors: preload, afterload, and contractility. Preload is the volume seen by the heart during ventricular filling, afterload is the resistance to ventricular ejection, and contractility is the ability of the myocardium to eject blood during systole. The combination of stroke volume and heart rate determines cardiac output, which is the major determinant of tissue perfusion. With decreased blood volume, preload and therefore stroke volume are decreased. The heart rate increases to maintain cardiac output but has a limited ability to compensate. Shock, through ischemia and reperfusion injury, often leads to increased myocardial interstitial fluid and decreased myocardial compliance, and a higher than normal filling pressure is required to attain an adequate end-diastolic volume to generate a normal stroke volume. In addition, the shock-related problems of acidemia, hypothermia, trauma, and sepsis may also depress myocardial contractility due to mitochondrial dysfunction and uncoupling of oxidative phosphorylation.

Pulmonary

The pulmonary vasculature, like the systemic vasculature, generally vasoconstricts in shock. This increased pulmonary vascular resistance creates a relative hypoxemia and the patient becomes tachypneic to compensate. However, the rapid, shallow breathing increases both dead space and work of breathing through the increased minute ventilation. In addition, shock is a major cause of the acute respiratory distress syndrome or noncardiogenic pulmonary edema, which is likely secondary to an ischemia–reperfusion-induced systemic inflammatory injury. Histologically, there is diffuse alveolar epithelial and capillary endothelial damage, influx of neutrophils, and loss of surfactant. This leads to alveolar flooding, decreased lung compliance, alveolar collapse, and resistant hypoxemia.

Renal

Oliguria is a frequent manifestation of shock. The decreased urine output is not simply due to hypoperfusion and dysfunction, but also a renal compensatory response to decreased blood flow (i.e., “renal success”). Increased afferent arteriolar vasoconstriction, stimulated by the renin–angiotensin arc, causes decreased glomerular filtration. Increased ADH and aldosterone increase urine concentration. The retention of sodium and distal tubular reabsorption of water produce concentrated urine with low sodium content and high osmolarity. However, if hypotension goes uncorrected, renal ischemic toxicity may occur. Necrosis of tubular epithelium, tubular obstruction

by debris, and depletion of renal ATP all lead to impaired renal function, manifesting as acute tubular necrosis (ATN). In addition, ATN can be seen with skeletal muscle trauma, with precipitation of muscle breakdown products, such as myoglobin, in the kidneys. Radiocontrast dye, aminoglycoside antibiotics, and other nephrotoxic agents may also lead to ATN in patients with shock.

SPECIFIC TYPES OF SHOCK

Shock has classically been arbitrarily divided into four basic subgroups with somewhat unique hemodynamic profiles, recognizing that there is frequent overlap. Although debate continues on the therapeutic utility of pulmonary arterial catheterization, most critical care physicians use the data generated from these catheters to help both diagnose and treat the various types of shock (Table II).

Hypovolemic

Hypovolemic shock occurs due to decreased intravascular volume. Most commonly, this is due to external or internal hemorrhage. Other sources of massive fluid loss include diarrhea, cholera, burns, or diffuse “capillary leakage” that occurs with pancreatitis or following severe trauma with ischemia–reperfusion-induced injury. Hypovolemia produces the classic hemodynamic picture of shock syndrome. It is characterized by decreased cardiac filling pressures and stroke volume with a compensatory increased heart rate and peripheral vascular resistance. Mild hypovolemia ($\leq 20\%$ of the circulating blood volume) may be

Table II Sources and Effects of Selected Cytokines

| Cytokine | Cellular source | Biologic effects |
|---------------------------------------|---|--|
| TNF α | Macrophages | Fever, anorexia, increased ACTH, hypotension, hypercoagulability, others |
| Interleukin-1 | Macrophages, others | Similar to TNF α |
| Interleukin-6 | Macrophages, others | Fever, promotes B cell maturation, stimulates adrenals |
| Interleukin-8 | Macrophages, endothelial/epithelial cells | Chemokine for neutrophils |
| Prostanoids (PG, TX) | Macrophages, platelets, endothelial cells, others | Vasoactive agent (dilators and constrictors), permeability, thrombosis |
| Nitric oxide | Endothelial cells, macrophages, others | Vasodilator, excessive production causes oxidant-induced damage |
| Interferon- γ | TH1 cells | Activates macrophages, promotes TH1 differentiation |
| Granulocyte colony-stimulating factor | Macrophages, fibroblasts | Enhances bone marrow production of granulocytes |

Note. ACTH, adrenocorticotropic hormone; PG, prostaglandin; TX, thromboxane; TH1 cells, T-helper 1 cells; TNF α , tumor necrosis factor α .

well compensated by cellular and interstitial fluid shifts and remain virtually asymptomatic, particularly in a young, supine patient. Moderate hypovolemia (20–40% decrease in blood volume) is accompanied by increased tachycardia, postural hypotension, and anxiety, as homeostatic mechanisms begin to fail to maintain perfusion. Classic severe shock, including hypotension and other signs of end-organ hypoperfusion, appears with loss of 40% or more of the blood volume. Treatment includes rapid replacement of intravascular volume with isotonic crystalloid solutions and/or blood with simultaneous treatment of the underlying disease process.

Cardiogenic

Patients in cardiogenic shock have a primary failure of myocardial contractility (i.e., “pump failure”). This most commonly is due to acute myocardial infarctions or chronic congestive heart failure and may manifest as right, left, or complete cardiac dysfunction. In these individuals, the filling pressures, as well as the systemic vascular resistance, will be high in an attempt to maintain cardiac output and MAP, which are both characteristically very low. The patient may show signs of intrinsic cardiac dysfunction, such as murmurs or arrhythmias, pulmonary edema (with left heart failure), and distended neck veins (with right heart failure). In contrast to all other forms of shock, neither absolute nor relative hypovolemia is present, but frequently, even in the presence of total body fluid overload, myocardial function will transiently improve with a small bolus of fluid until the diagnosis is confirmed. Treatment includes coronary revascularization, if possible, and cardiac support with inotropes, vasodilators, or intra-aortic balloon pump, as necessary.

Septic

Septic shock is caused by the systemic response to severe infections. Although gram-negative rods are typically responsible, gram-positive cocci or rods, fungi, viruses, and other microorganisms may all cause shock. Bacterial endo- or exotoxins lead to the release of cytokines, including IL-1 β and TNF α . Fibrin deposition increases, which, if unchecked, may lead to disseminated intravascular coagulation. Inducible nitric oxide synthase is stimulated, releasing nitric oxide, a powerful vasodilator and, in excess, a source of oxidant-induced injury. In addition, a massive capillary leak occurs with the progressive endothelial cell damage.

Sepsis classically creates a hyperdynamic picture. Even though there is splanchnic vasoconstriction and intestinal hypoperfusion, there is peripheral arterial vasodilation and cardiac output becomes supranormal. In contrast to other forms of shock, oxygen extraction by the tissues is reduced due to impairment of microcirculatory blood flow and mitochondrial oxidative metabolism. Diffuse microvascular injury and thrombosis lead to massive capillary leak and severe intravascular hypovolemia. In end-stage sepsis, however, patients become hypodynamic from organ failure, primarily cardiac. Abnormalities in myocardial contractility have been linked to endotoxins, which cause myocardial depression mediated by TNF and other potent inflammatory mediators. The treatment includes massive fluid repletion and hemodynamic support, along with prompt treatment of the underlying infection and adequate source control.

Neurogenic

After trauma to the spinal cord, hypotension occurs due to the interruption of sympathetic vasomotor input with profound loss of venous and arterial vascular tone and pooling of blood peripherally. Because of the vasodilation, the extremities are typically warm and well perfused. There is no reflex-induced tachycardia. Treatment is directed toward repletion of the relative hypovolemia due to dilation of venous capacitance vessels and augmentation of vascular tone with pressors, including norepinephrine, if necessary, once hemorrhage is ruled out.

Hypo-adrenal

Sudden loss of glucocorticoid production (which may be seen with adrenal hemorrhage associated with sepsis, malignancy, or anticoagulation) or a sudden, severe stress in individuals with chronic (due to pharmacologic corticosteroid therapy) or acute relative adrenal insufficiency may precipitate fulminant shock or hemodynamic instability. This is manifested by decreased systemic vascular resistance, refractory hypotension, and reduced cardiac output. Hypoadrenal shock often occurs concomitantly with other shock states, such as hypovolemia and sepsis, and diagnosis requires a high index of suspicion. The diagnosis is made with a short synthetic ACTH stimulation test. Treatment consists of fluid resuscitation, pressor support as needed, and intravenous steroids, 100 mg hydrocortisone every 6–8 h.

Several other types of shock have been described, including anaphylactic shock (similar to hyperdynamic sepsis with massive “capillary leak”) and extracardiac compressive shock (similar to cardiogenic shock and due primarily to pericardial tamponade, particularly acute, and tension pneumothorax from trauma). Each, however, has subtle, unique hemodynamic differences that require specific therapies. Interested readers should consult the reference materials at the end of this article.

PROMISING THERAPIES AND THE FUTURE

Shock represents the clinical syndrome due to loss of homeostasis. Until the advent of critical care medicine with ventilator support, recognition and emergent surgical interventions, modern antimicrobial therapy, and intravenous resuscitation, shock was not survivable. The mortality of shock from all causes has been gradually decreasing, although it still approaches 50%. Advances in shock research have uncovered promising new therapies that have demonstrated significant survival advantages. For patients in shock, early goal-directed resuscitation targeting specific oxygen delivery end-points has been shown to improve survival. In addition, treatment with activated protein C, a molecule with anticoagulant and anti-inflammatory properties, has been shown to reduce mortality among patients in septic shock, although its applicability to all patients is still being tested. Among patients with cardiogenic shock, early angioplasty with revascularization and anti-thrombotic agents has been shown to significantly reduce mortality. The careful use of insulin to tightly control glucose levels and the avoidance of unnecessary blood transfusions have both led to a decrease in infectious

complications, organ dysfunction, and mortality. These and many other advances in shock research are continuing to improve outcomes for this once unsurvivable “unhinging of the basic machinery of life.”

are frequent and can be of great diversity by nature; they can also involve both the number (loss, multiplication) and the structure of chromosomes (duplication, inversion, translocation, ring formation). Such aberrations either occur during the development of an individual or are inherited from a parent. If the chromosomal aberration occurs at the level of oocyte-sperm fusion (zygote), all cells of the body will subsequently be affected (constitutional aberrations). If such an aberration occurs at a later stage of development, the aberration is passed on only to the cells that derive from the affected cell. Thus, the patient will have cells containing normal as well as abnormal chromosomes, an occurrence that is referred to as “mosaicism”; this indicates that not all chromosomal abnormalities are detectable if chromosomes from blood leukocytes are investigated. It is important to establish whether an aberration of the chromosomal constitution of an individual is causally related to a disorder, since some deviations are functionally irrelevant (e.g., balanced translocations). On the other hand, there are specific chromosomal abnormalities that lead to typical structural and functional disorders in an individual, the most prominent of which is impaired growth. Traditionally, evidence of chromosomal abnormalities is sought in children whose physical features are indicative of a congenital disorder or in whom abnormal structures or abnormal functioning of internal organs has been established. Chromosomal abnormalities occur more frequently as parental age increases; thus, if the expectant parents are older, fetal cells are harvested during early pregnancy for chromosomal analysis by means of amniocentesis or chorionic villous sampling. Genetic counseling for an abnormality discovered at the prenatal stage necessitates detailed knowledge on the lifelong development of affected individuals. The aim of this article is to provide a brief discussion of a few chromosomal abnormalities that present with a characteristic clinical pattern and short stature.

Distinct Characteristics

Disorders caused by chromosomal abnormalities are commonly associated with four key features: (1) pre- and postnatal growth retardation, (2) mental retardation, (3) organ malformations, and (4) abnormal facial and body features. Chromosomal abnormalities occur when there is either an excess or a loss of a total chromosome or when a portion of a chromosome is absent (macrodeletions and microdeletions). Only a few of these chromosomal aberrations are compatible with pre- and postnatal life. For example, only the loss of a whole sex chromosome is compatible with life

(Turner’s syndrome), whereas the total loss of any other chromosome is not. Therefore, no information is available on long-term growth development in most disorders.

DISORDERS INVOLVING AN EXCESS OF ONE CHROMOSOME

There are only a few disorders involving a complete trisomy of an autosome compatible with postnatal life: Down’s syndrome (trisomy 21), Patau’s syndrome (trisomy 13), and Edwards’ syndrome (trisomy 18). Information on the long-term development of children with trisomy 13 and 18 (see [Table I](#)) is limited because of their reduced life expectancy. No disease-specific growth curves exist yet and the genetic foundation of the growth disorder is unknown. The development of long-term survivors tends to follow an individual path and thus requires special attention to individual needs. Children with the rare case of trisomy 8 [deep set eyes, thick lips, inability to stretch fingers and toes (camptodactyly)] survive only in the case of mosaicism of the chromosomal abnormality; they may vary in stature from short to small. The same holds true for children with trisomy 9 (hearing defect, joint contractures, mental retardation, malformed ears).

DOWN’S SYNDROME (TRISOMY 21)

The clinical appearance of Down’s syndrome was first described by the physician Langdon Down, for whom this chromosomal abnormality was named (see [Table II](#) and [Fig. 1](#)). After the technique of chromosomal analysis became available, it was observed that Down’s syndrome is caused by an additional chromosome 21 (three instead of the normal two). The extra chromosome is either in the cell in free form (95%) or is attached to another chromosome (translocation). Down’s syndrome is also the most familiar of chromosomal abnormalities, not least because of its relatively high frequency and the characteristic (mongoloid) appearance of the affected individual. Down’s syndrome is characterized mainly by a consistent clinical appearance, mental retardation, and short stature. The affected individuals are basically affectionate by nature and have a special sense for music: their life expectancy, however, is limited, particularly among those with a complex cardiac failure.

Chromosome 21 is a rather small chromosome, but the genetic basis of the disorder is not yet known in detail. Information is still being acquired on some critical regions of the chromosome that relate to

Table I Characteristics of Edwards' Syndrome and Patau's Syndrome

| | |
|--|---|
| Edwards' Syndrome | |
| Chromosomal aberration | Trisomy of chromosome 18 (47,XY + 18) |
| Incidence (cases per number of newborns) | 1 in 3000; male to female ratio 1:3 |
| Characteristic clinical features | Polihydramnios, severe mental deficiency (seizures), small oral opening, clenched hand, index finger overlapping third, hypoplasia of nails, small nipples, herniation of abdominal wall, redundancy of skin, heart failure (VSD) |
| | Death is common during first year (90%) |
| Growth pattern | Small placenta, birth weight \approx 2300 g at term, progressive short stature with an adult height of <150 cm |
| Patau's Syndrome | |
| Chromosomal aberration | Trisomy of chromosome 13 (47,XY + 13) Trisomy 13 mosaicism and partial trisomy (13pter to q14) are rare |
| Incidence (cases per number of newborns) | 1 in 5000 |
| Characteristic clinical features | Incomplete development of forebrain, severe mental retardation, seizures, microcephaly, hearing defect, cleft lip, polydactyly, cardiac failure (e.g., VSD [ventricular septal defect]), genital abnormalities in both sexes |
| | Death common before 6 months of age |
| Growth pattern | Small size at birth (\approx 2500 g), short stature in childhood, restricted information on adult height |

specific features. In particular, there is no information on the cause of the growth disorder. Thus far, there is circumstantial evidence indicating that the growth hormone system plays no major role in the development of short stature, which suggests that the

principal defect is connected to bone growth. The typical growth pattern in children and adolescents with Down's syndrome is, however, well-described. The birth size of newborns is normal. From infancy onward, there is a progressive decrease in height

Table II Characteristics of Down's Syndrome

| | |
|--|---|
| Chromosomal aberration | Trisomy of chromosome 21 (47,XY + 21); in rare cases (5%) translocations (partly inherited) or partial trisomy |
| Incidence (cases per number of newborns) | Depending on the age of mother (<35 years 1:1000; > 45 years 1:50) |
| Characteristic clinical features | "Mongoloid" position of the eyes Speckling of iris (Brushfield spots) Open mouth and protruding tongue Short hands with simian crease Wide gap between first and second toes Mental retardation (moderate to severe) Muscular hypotonia |
| Major associated abnormalities | Cardiac failure (AV canal, VSD, ASD) Hypogonadism Hypothyroidism |
| Growth pattern | Normal size at birth Progressive short stature; adult height \approx 153 cm in males and \approx 145 cm in females Microcephaly and obesity |
| Life expectancy | Reduced; with cardiac failure <30 years, without cardiac failure <50 years |
| Treatment (general) | Functional abnormalities (e.g., cardiac abnormalities and hypothyroidism are treated accordingly) -Patients need lifelong special care -Patients are sociable and musically inclined |
| Treatment (growth disorder) | None |

Note: AV, atrioventricular; VSD, ventricular septal defect; ASD, atrioventricular septal defect.

Figure 1 Girl with Down's syndrome as an infant (A) and at school age (B).

increment; the onset of puberty is delayed and a reduced pubertal growth spurt occurs. Female patients generally reach an adult height of approximately 140 cm and males attain an adult height of approximately 150 cm (Fig. 2). There is a tendency toward obesity. The discussion about improving height with growth hormone treatment—as for other chromosomally caused growth disorders—centers around the issues of the disease-specific efficacy, safety, and psychosocial implications. Since patients with Down's syndrome have a high risk of developing leukemia, there have been no conclusive long-term studies conducted on the efficacy and safety of growth hormone treatment for this diagnosis. In addition, the question needs to be asked whether a therapy-induced increase in height would improve the quality of life for the affected individuals.

DISORDERS INVOLVING A LOSS OF A PORTION OF THE CHROMOSOME

The loss of a total chromosome is not compatible with life. The loss of a sex chromosome (X or Y) is an exception. The most frequent and characteristic disorder is Turner's syndrome (TS), which involves the total or partial loss of an X chromosome (typically 45,X). This disorder occurs in approximately 1:2000 newborn females. The individuals are physically and emotionally female in gender and have a characteristic appearance; there is a malformation of internal organs (e.g., heart failure), absent ovaries (gonadal dysgenesis), and short stature. TS girls are characteristically short during childhood and their spontaneous final height is approximately 20 cm below the mean female height for a given population (equivalent to ≈ 145 cm). Spontaneous growth in Turner's syndrome has been well described in several populations. Effective treatment with growth hormone is possible. The growth disorder is caused by the loss of one SHOX gene (also known as "haploinsufficiency"), which is located at the tip of the short arm of the X (and Y) chromosome (Xp23) (the presence of two SHOX genes is required for normal growth). The SHOX genes are thought to play a major role in the prenatal development of bones. The selective loss of a SHOX gene can lead to disproportionate short stature (Léri-Weill syndrome). It is remarkable that Noonan's syndrome (incidence 1:1000), which greatly resembles Turner's syndrome (and can affect both sexes), is caused by a mutation of a gene on chromosome 12 (PTPN11 on 12q24) encoding a protein phosphatase. Growth in Noonan's

Table III Characteristics of Syndromes with a Partial Loss of Chromosomes

| Name | Chromosomal defect | Symptoms |
|---|---|--|
| Wolf-Hirschhorn syndrome | Deletion at 4p (~20 Mb) | Microcephaly with frontal hemangioma, prominent nose, cleft lip/palate, coloboma of eye, heart failure, kidney malformations, severe mental retardation, severe intrauterine growth retardation |
| Cri-du-chat syndrome | Deletion at 5p (~20 Mb); incidence 1:20,000 | Cat-like screaming during infancy, microcephaly, flat nasal bridge, downward slant of the palpebral fissures, short hands and feet, mental retardation, low birth weight, short stature |
| William's syndrome | Microdeletion 7q11 (~2 Mb); incidence 1:10,000 | Supravalvular stenosis of the aortic stenosis, peripheral pulmonary arterial stenoses, perinatal hypercalcemia, typical facies (elfin face), mild mental retardation, short stature ^a |
| Prader-Willi syndrome | Microdeletion 15q11-q13 (paternal chromosome) (~4 Mb) in ≈70% | Muscular hypotonia in infancy, hyperphagia and obesity in later life, hypogenitalism, mental retardation, short stature |
| CATCH22 (cardiac defect, abnormal facies, zymic hypoplasia, cleft palate, hypocalcemia, 22q11 deletion) | Microdeletion 22q11 (~2 Mb) | Extremely varied picture; most frequent is the di George syndrome—immune deficiency due to thymic aplasia, hypocalcemia, cardiac failure, facial dysmorphia, stature varies |

^aSee Fig. 3.

syndrome is also well described and females with this diagnosis are slightly taller than TS patients.

The partial loss or augmentation of chromosomal material may relate to a whole arm (p denotes “petite,” referring to the short arm; “q” is the next letter after “p” and refers to the long arm) or even smaller regions. The visibility of a microdeletion in chromosomal

material depends both on the size and on the methodology. It is possible to visualize a loss of chromosomal material equivalent to approximately 5 Mb. This is the magnitude available with FISH, a relatively new diagnostic tool. Using this method, the DNA that carries information on a specific chromosomal region is marked with a dye and is mixed with the patient's

Figure 2 Mean height development of children with Down's syndrome (thick boldface line) and Williams' syndrome (dotted line).

Figure 3 Infant with Williams' syndrome.

chromosomes on glass laboratory slides. If corresponding chromosomal material exists in the patient's DNA, a visible signal appears through the fluorescence microscope; if the signal does not appear, it can be assumed that the material is not present in the patient's DNA. Conversely, more than two signals from the normal two chromosomes are indicative of an excess of genetic material. The number of disorders in this category is extremely large, although the condition itself is rare. Some disorders are listed in Table III; see also Fig. 3.

Despite the fact that the human genome has been analyzed in totality, there is incomplete knowledge pertaining to the genetic code and its implications for the development and maintenance of structures and the functioning of the various parts of the human body. It is known that even in well-defined abnormalities of a single gene, the resulting functional deviation from normal may vary widely. This is particularly so in cases in which several genes are affected, such as in cases involving chromosomal abnormalities. Therefore, researchers need to refrain from regarding the affected individuals only from the perspective of chromosomes and, instead, study them as unique expressions of the variability of human creation.

chromosomes) play a key role in height determination. It is well established that complete or partial loss of the human X chromosome is directly implicated in the development of short stature together with a number of other skeletal abnormalities and somatic stigmata observed in Turner syndrome. Genotype–phenotype correlations suggested the major pseudo-autosomal region (PAR1), located at the tip of the short arm of the X and Y chromosomes, as a candidate region for the presence of a growth-determining genetic locus. Since genes residing within PAR1 escape X inactivation, two active copies of these loci are required for normal function. Consequently, the loss of a single copy of such genes leads to a lower dose of functional gene product, a condition known as haploinsufficiency.

In 1997, two independent research teams identified a candidate gene for short stature within PAR1 from patients with short stature who had rearrangements encompassing the Xp22 and Yq11 regions of the sex chromosomes. As a consequence of its location within the pseudo-autosomal region, this gene—designated short stature homeobox-containing gene or *SHOX*—was proposed to also be responsible for the short stature phenotype associated with Turner syndrome. According to its chromosomal localization, the *SHOX* gene has two active copies in normal individuals, and a defect in one copy caused by point mutations, deletions, or chromosomal rearrangements results in *SHOX* haploinsufficiency. A number of studies have shown that this *SHOX* haploinsufficiency not only leads to short stature, but is also involved in a number of skeletal abnormalities and other congenital problems that are seen in a variety of clinical conditions that include idiopathic short stature, Léri-Weill dyschondrosteosis [LWD, or Léri-Weill syndrome (LWS)], Langer mesomelic dwarfism, and Turner syndrome.

The underlying and consistent phenotypic feature of each of these disorders is impaired growth. However, the extent of short stature in these different entities is variable and may also vary between affected individuals within the same family. Léri-Weill dyschondrosteosis, Langer mesomelic dysplasia, and Turner syndrome are also characterized by a range of skeletal abnormalities, again of variable expression, which start to develop during embryogenesis and continue to progress during adolescence. From this correlation, and from the fact that the expression of *SHOX* is primarily found in the midportion of the limbs (i.e., the radius/ulna and the tibia/fibula) as well as the first and second pharyngeal arches, it has

been proposed that the *SHOX* gene acts as a key regulator of skeletal development within these regions.

Accurate identification of defects in the *SHOX* gene is possible thanks to the growing understanding of the molecular biology of this gene. It is possible to screen large numbers of patients for deletions and base pair mutations that result in clinical phenotypes. This will allow the physician to offer patients a more accurate diagnosis and will inform both the patient and physician about the likely abnormalities that may occur over time in these syndromes. As a consequence, appropriate therapeutic interventions that may enhance the quality of life of individuals with these disorders can be undertaken.

THE *SHOX* GENE

The existence of a critical gene involved in growth determination, which resides in the pseudo-autosomal region, was proposed after deletions of the short arm of the X chromosome and small terminal deletions of the short arm of the Y chromosome were shown to be consistently associated with short stature. Genes residing in the PAR escape X inactivation, and so, for normal function, both copies of the gene need to be expressed. Therefore, it was proposed that these short stature phenotypes arose as a consequence of haploinsufficiency of the critical short stature gene.

Significant efforts were made to identify and characterize the critical gene. Mapping studies narrowed the short stature critical interval to a 170 kb region residing 500 kb from the Xp telomere and allowed the molecular cloning of a single gene, designated *SHOX*. Shortly thereafter, another team independently reported the isolation of the identical gene from a YAC contig of this chromosomal region.

SHOX encodes a homeodomain protein that has been shown to act as a transcription factor. A variety of studies have indicated that the *SHOX* product is likely to be a key regulator of growth. The gene spans approximately 40 kb of the PAR and consists of seven exons that encode two alternatively spliced transcripts, *SHOXa* and *SHOXb*. These are translated to produce two isoforms of 292 and 225 amino acids residues, respectively. The gene was shown to be expressed from both the active and the inactive X chromosomes, as is expected based on its pseudo-autosomal location. Expression studies show that the two isoforms differ in their expression patterns.

SHOXa is widely expressed in different tissues, whereas the *SHOXb* isoform has a more restricted expression pattern and is found at its highest levels in bone marrow fibroblasts, providing additional evidence for its role in linear growth. Rao *et al.* have suggested that *SHOXb* may act as a transcriptional modulator of *SHOXa*.

Furthermore, *in situ* hybridization studies of *SHOX* gene expression during human embryogenesis have shown that expression occurs in the midlimb regions (i.e., the radius, ulna, elbow, wrist, tibia, fibula, knee, and ankle), which is in agreement with both the short stature phenotype and the typical skeletal dysmorphisms that are observed in patients with *SHOX* gene defects and disorders such as Turner syndrome.

SHOX GENE DEFICIENCY—CLINICAL CONSEQUENCES

The phenotypes associated with *SHOX* gene deficiency vary widely. Although short stature is the underlying phenotypic feature, *SHOX* haploinsufficiency is also associated with significant skeletal abnormalities as seen in Léri-Weill dyschondrosteosis and Turner syndrome. The complete absence of any *SHOX* gene product is the basis for the severe short stature and dysmorphic features that are seen in Langer mesomelic dysplasia. In contrast, females with an extra X chromosome (47,XXX) have three copies of the *SHOX* gene and are taller than normal 46,XX females. Thus, there exists a continuum of growth defects that relates directly to the dose of functional *SHOX* gene product.

Therefore, *SHOX* deficiencies are correlated with a variety of different skeletal phenotypes and clinical conditions with a significant degree of clinical and molecular overlap complicating the differential diagnosis.

Léri-Weill Dyschondrosteosis

LWD, or LWS, is characterized by disproportionate short stature with shortening of the middle segments of the long bones of the arm and leg, more usually referred to as mesomelic short stature, and was first recognized by Léri and Weill in 1929. Like the other *SHOX* disorders, short stature in LWS is variable, with affected individuals ranging in adult height from 135 cm to normal height for their age and gender. The primary skeletal abnormality, the sign that permits the clinical diagnosis of LWS, is Madelung deformity.

This is a characteristic deformity of the forearm, consisting of shortening and bowing of the radius and distal dislocation of the ulna, leading to limited mobility of the wrist and the elbow. Madelung wrist deformity likely originates with disorganized growth of part of the radial epiphysis, leading to radial bowing, premature fusion of that epiphysis, dorsal dislocation of the ulna, and wedged carpal bones.

Another feature of LWS is the striking preponderance of affected females, with four times as many females affected as males. However, this predominance may be the result of a bias of ascertainment, as females appear to be more severely affected than males and thus may come to a clinician's attention more readily. However, since the location of the *SHOX* gene has been unambiguously determined, the inheritance can be classified as pseudo-autosomal dominant.

Langer Mesomelic Dysplasia

Langer mesomelic dysplasia was described by Langer in 1967. This disorder is thought to be the homozygous form of Léri-Weill dyschondrosteosis. Evidence in favor of this proposal came from an observation of a male newborn diagnosed with Langer mesomelic dysplasia, whose parents and maternal family exhibited Madelung deformity and mesomelic dwarfism. Complete absence of the *SHOX* gene has been demonstrated in a fetus with Langer mesomelia.

The clinical features of this disorder are severe. Most patients exhibit a much more extreme reduction in stature than in LWS, with severe mesomelic shortening of the limbs. The limb malformation is severe hypoplasia of the ulna and/or fibula with a severely shortened radius and tibia. Other features include Madelung deformity and hypoplasia of the mandible, or micrognathia. The main radiologic findings observed in Langer patients include severely shortened long bones of the limbs, Madelung deformity, varus deformity of the humeral head, angulation of the radial shaft, distortion of the carpals, short femoral neck, early fusion of tibial epiphyses, hypoplastic or absent proximal half of fibula, and lumbar lordosis.

Turner Syndrome

Turner syndrome (monosomy of the X chromosome, 45,X/partial monosomy of the X) is the most common sex chromosome abnormality known in females. It is associated with a high degree of embryonic lethality and thus fewer cases than expected are observed clinically. In fact, approximately 3% of all female conceptions have X chromosomal abnormalities typical of

Turner syndrome but, as a consequence of this high rate of embryonic lethality, only 1:2500 of live female births are diagnosed with the disorder. All affected individuals are female and the most common, invariable physical features that are observed are short stature and ovarian failure. The syndrome is also characterized by a variety of major and minor skeletal malformations as well as heart and renal abnormalities.

In patients with Turner syndrome, the incidence of short stature and ovarian failure is nearly 100%. Skeletal anomalies appear at a lower frequency—approximately 35–60% for abnormalities such as short fourth metacarpals, cubitus valgus, genu valgum, high-arched palate, scoliosis, micrognathia, and short neck. Madelung deformity and mesomelic limb shortening, which characterize LWS, also occasionally occur in Turner syndrome.

Idiopathic Short Stature

The term “idiopathic short stature” represents a heterogeneous group of patients who have short stature for different unknown reasons, but not due to any of the syndromes described above. Patients are generally physically normal and routine laboratory tests also appear normal.

Diagnostic endocrinological tests do not normally reveal any abnormalities relating to short stature and there is, e.g., no evidence of growth hormone deficiency. However, patients’ heights are below the normal adult range. By definition, 3% of the general population fall below the third percentile and are therefore described as short. The majority of these patients are defined as having idiopathic short stature.

Careful review of a child’s history and physical exam may reveal clues to the presence of an unsuspected condition or disease, but the underlying basis for retarded growth remains unknown—hence the use of the term “idiopathic” to describe this condition. Rappold *et al.* have described *SHOX* gene mutations in 2.4% of children with idiopathic short stature.

CLINICAL BENEFITS OF IDENTIFYING *SHOX* DEFICIENCY

There are a number of benefits that can be realized from early identification of defects in the *SHOX* gene. With the advent of molecular techniques, screening for *SHOX* defects has become fairly routine and large numbers of samples can be tested to permit early identification of mutations. The main benefits are outlined below.

Identification of *SHOX* Defects

Identification of *SHOX* defects can be helpful, informative, and educational in helping patients understand the basis of their condition. This may resolve patients’ anxiety regarding the etiology of their condition and may provide a greater understanding of the development of their disease over time. In addition, genetic counseling can help individuals understand the probability of having affected children in the future.

Identification of Contiguous Gene Disorders

Large-scale *SHOX* deletions that extend beyond the boundary of the pseudo-autosomal region on the X chromosome may express themselves as contiguous gene deletion syndromes. Therefore, it is important for the physician to be aware of the extent of the deletion in order to assess the likelihood that such disorders will develop. Depending on the size of the deletion, the X recessive form of chondrodysplasia punctata, mental retardation, ichthyosis, and Kallmann syndrome can be expected in boys with a complete Xp22.3 deletion.

Genetic Counseling

Although Léri-Weill syndrome may be a debilitating condition, patients can, with appropriate therapy, live normal lives. Genetic counseling may provide useful advice in terms of the probability of a child having LWS. For example, if either parent has LWS, there is a 50% likelihood that any given male or female offspring will have LWS. Both the knowledge of the inheritance of *SHOX* mutations and the use of techniques to identify such defects are extremely important in cases in which both parents have *SHOX* defects. In these cases, offspring have a 25% chance of developing the more severe disorder, Langer mesomelic dysplasia. The ability to identify such defects prenatally together with ultrasound techniques to identify early skeletal abnormalities will allow parents the opportunity to make informed decisions.

Surgical/Clinical Implications

Identification of a *SHOX* defect should alert the physician to monitor the development of skeletal abnormalities such as Madelung deformity. In general, skeletal abnormalities tend to be more severe in females and increase in severity with increasing age, particularly during puberty. Therefore, a physician

may intervene at an early stage with appropriate surgery to minimize the effects of the expected skeletal abnormality. Disorders such as Turner syndrome are associated with a variety of somatic stigmata that also require effective monitoring and clinical management.

Differential Diagnosis

Molecular analysis of *SHOX* is a potentially important and effective tool in differentiating between dyschondrosteosis and other types of skeletal dysplasia associated with disproportionate short stature, including hypochondroplasia. This is of particular value when used in less severe cases and in early childhood, where clinical signs may not be readily apparent.

Opportunities for Therapy

Patients with Turner syndrome are indicated for growth hormone therapy. Anecdotal reports have demonstrated beneficial effects of treating *SHOX*-deficient patients with growth hormone.

Future Therapeutic Opportunities

In the future, identification of *SHOX* mutations and other defects, together with identification of target genes and proteins that *SHOX* acts on, may permit the development of novel therapeutic approaches that minimize the effects of such defects. For example, in haploinsufficiency of *SHOX*, a potential therapeutic objective would be to up-regulate the remaining copy of the gene at an early stage in development.

model in position and topography the shape of the bone. Depending on the location of these condensations, the cells differentiate into osteogenic cells to form bone directly (intramembranous, or membrane bones) or these mesenchymal condensations differentiate into chondrocytes to form bone indirectly (endochondral bone).

Mesenchymal condensations in the region of the future clavicle, most of the mandible, and most of the skull form bone directly. The other bones form indirectly via replacement of a cartilage model or anlage. Membrane bones enlarge only by appositional growth. Endochondral bones, however, can also grow interstitially by taking advantage of this property of cartilage in their growth plates. Synchondroses mediate growth in the skull base and are essentially double-ended growth plates. Connections between bones depend on their location and their functions. Those between two membrane bones occur at sutures, which permit little movement, but isolated membrane bones (clavicle and mandible) connect to other bones via other types of joints that allow considerable movement.

FORMING A SKELETON: MECHANISMS AND REGULATION

The skeleton is the result of a series of inductive interactions between cell populations that elaborate matrices that control their differentiation. The initiation and coordination of skeletal growth are accomplished by regulating the temporospatial expression of many genes. Among those known to participate are transcription factors, extracellular matrix molecules, growth factors, cell adhesion molecules, and membrane receptors. Many of these genes were first discovered in *Drosophila melanogaster* and their unusual names reflect this heritage. What is known about each stage of skeletal development, including the events themselves, the genes known to be involved, and their interactions, is discussed next.

Pattern Formation

The position of future skeletal elements is first indicated in the mesenchyme of the embryo by aggregates of cells at specific sites. This mesenchymal pattern thus establishes the location of the bone to be formed. Pattern formation proceeds differentially in a cranio-caudal direction and has a distinct dorso-ventral axis, but generally exhibits bilateral symmetry. The skeleton consists of axial and appendicular components. The axial components are derived from mesenchyme in the somites (sclerotome) postcranially and from

neural crest cells in the craniofacial skeleton. The appendicular skeleton is derived from mesenchyme in the lateral plates of the body wall.

Hox gene expression determines developmental events in the cranio-caudal axis. These transcription factors are found in four gene clusters, for a total of 39 genes in vertebrates, and they specify regional skeletal development by regulating the local expression of other genes. Similarly, members of the *Pax* gene family regulate development in the dorso-ventral (anterior-posterior) axis. Ventral signaling is derived from the notochord, especially cranially, and involves sonic hedgehog (*Shh*) and *Noggin*, an antagonist of bone morphogenetic protein (BMP). Dorsal signaling is derived from the dorsal neural tube and surface ectoderm and involves the *Wnt* (*Wingless*) family. The appendicular skeleton arises as limb buds from the lateral plate mesenchyme and develops in a complex pattern along three axes. The proximo-distal axis is established by orchestrating the participation of a variety of transcription factors, growth factors, and adhesion molecules. The initial outgrowth, the apical ectodermal ridge (AER), is dependent on the fibroblast growth factor (FGF) family and their receptors (FGFRs), whose expression patterns dictate the position and eventual size of the limb. The cranio-caudal limb axis is specified by *Shh* gene expression in a small patch of mesoderm at the caudal junction of the AER and the body wall. Dorso-ventral patterning is under the control of *Wnt* genes, specifically *Wnt7a*.

Developmental abnormalities in skeletal patterning result in a variety of skeletal aplasias and dysplasias.

Mesenchymal Condensations

Mesenchymal condensations establish the position and shape of the eventual skeletal component. They are initiated by epithelial-mesenchymal interactions that up-regulate the production of cell adhesion molecules, which, together with extracellular matrix proteins, cause cell aggregations. Proliferation, adherence, and differentiation in these mesenchymal condensations set them apart from adjacent cell populations. Cells in these condensations eventually differentiate into either bone cells (osteoblasts) or cartilage cells (chondrocytes). Where a series of bones will appear, such as in the limbs, less condensed areas demarcate the positions of joints. This pattern of mesenchymal condensations for the metatarsal bones can be seen in Fig. 2. These bones form by the endochondral pathway and the central cells have already advanced to the next stage, differentiating into chondrocytes and secreting cartilage matrix, which is visualized by its

Figure 2 Mesenchymal condensations as illustrated by the developing metatarsals of a rat fetus. Metatarsals (numbered) show the progressive development of mesenchymal condensations, including transformation into chondrocytes (darkly staining matrix-secreting cells) and hypertrophy (visible in the center of metatarsal 3).

metachromatic staining in this preparation. Note that the intervening areas between metatarsals are less differentiated and occupy the sites of the eventual attachments between these bones.

Genes regulating mesenchymal condensations include *Shh*, FGFs, BMP2–5 and 7, and other members of the transforming growth factor- β (TGF- β) superfamily. They program the site-specific expression of adhesion molecules and extracellular matrices and regulate the proliferation and differentiation in these condensations. Expression of *Sox9* and *Cbfa1* occurs in all mesenchymal condensations as a prelude to their differentiation along the endochondral or intramembranous pathways.

Developmental disturbances of mesenchymal condensations lead to a variety of skeletal dysplasias, including craniofacial defects, chondrodysplasias, and osteodystrophies.

Direct Bone—The Intramembranous Pathway

Once the cells in the initial condensation of mesenchymal cells differentiate into osteoblasts, they form bone as flat plates. Some of the osteoblasts become surrounded by matrix and become osteocytes. The osteocyte/osteoblast network is connected by canaliculi that maintain metabolic communications between all cells. When these metabolic units reach the limits of diffusion, vascularized Haversian systems (osteons) form to allow them to remain connected metabolically (this process also occurs in endochondral bones). All membrane bones eventually develop marrow spaces by resorption internally. In the flat bones of the

skull, the marrow spaces are small, discrete areas between the internal and external cortical plates. In the mandible and clavicle, these spaces are larger. Adjacent membrane bones form a specialized interface called a suture, a site where the periosteae of two membrane bones come in contact. This is shown in [Fig. 3](#). Note that cells in the center of sutures contain the progenitors of osteoblasts for adjacent bone surfaces and that proliferation and differentiation among these cells is the mechanism by which membrane bones grow at their edges. As bones grow in thickness, sutures become more complex with numerous, complex interdigitations. These are most obvious in the membrane bones of the skull that must grow rapidly to accommodate the early expansion of the brain.

Bone formation is dependent on expression of *Cbfa1* (*Aml3* or *Runx2*), a member of the Runt-domain family of transcription factors. *Cbfa1* is expressed by all osteoblasts and its expression is necessary for their

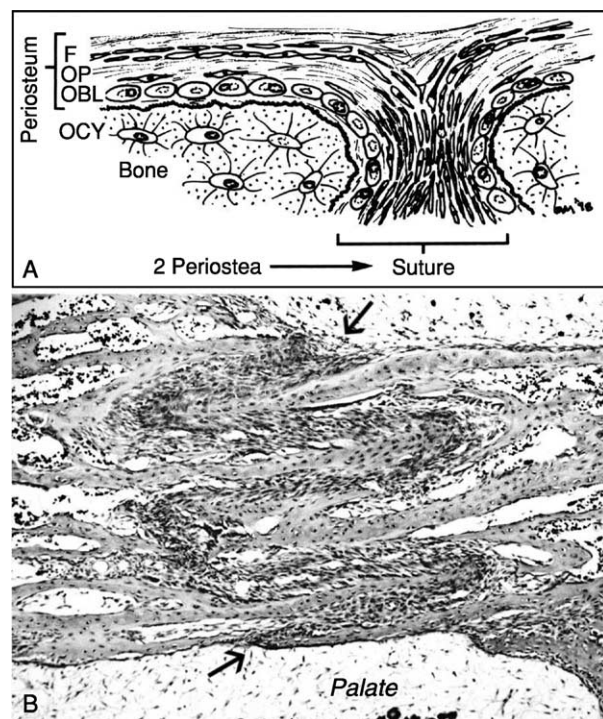

Figure 3 Cellular organization in sutures. (A) Cellular relationships illustrate that sutures are composed of the apposed periosteae of adjacent bones with a central proliferative region blending into the osteoprogenitors and osteoblasts on bone surfaces. F, fibroblast; OP, osteoprogenitor cell; OBL, osteoblast; OCY, osteocyte. Reprinted from Marks *et al.* (1999). *Dev. Dyn.* **215**, 117–125, with permission. (B) Histological section of the suture between the maxilla (left) and the premaxilla (right) in a 10-day-old rat. The densely cellular suture (arrows) oscillates between the two bone surfaces, which are highly interdigitated during this period of maximal growth.

differentiation. Its absence is lethal—no osteoblasts develop, no bone is formed, and the rib cage collapses. Haploinsufficiency of *Cbfa1* results in cleidocranial dysplasia.

Growth at sutures is regulated by growth factors and transcription factors. Signaling through fibroblast growth factor receptor 1 (FGFR1) induces osteogenesis by up-regulating *Cbfa1* and type I collagen formation, whereas signaling through FGFR2 promotes stem cell proliferation in the center of the suture. During growth, these are balanced. The cessation of sutural growth and closure of sutures is promoted by BMP4, BMP7, FGF9, TWIST (a basic helix-loop-helix transcription factor), MSX1 (a *Hox* family member), and MSX2, which upset this balance in favor of osteogenesis, leading to the obliteration of most sutures. Premature closure leads to a variety of congenital craniosynostoses.

Indirect Bone—The Endochondral Pathway

The differentiation of cells in mesenchymal condensations into chondrocytes marks the beginning of the endochondral (“inside cartilage”) pathway, which gives rise to the axial and appendicular skeletal elements, and can be seen in Fig. 2. Subsequent stages in the endochondral pathway are shown in Fig. 4. After formation of the miniature cartilage model, or “anlage,” of the future bone, endochondral bones can grow both externally, by appositional growth via the surrounding sheath of cells called the perichondrium, and—unique to endochondral bones—internally via proliferation and hypertrophy of the chondrocytes and the expansion of their secreted matrix, which consists mainly of type II collagen. Cells in the center of these chondrogenic islands enlarge (hypertrophy) and begin to mineralize the adjacent matrix (dark central areas of Fig. 4B). Soon thereafter, the cells surrounding this mineralized central region differentiate into osteoblasts, thus forming a periosteum, and they secrete type I collagen-containing bone matrix that becomes mineralized, forming a “bony collar” that surrounds the central portion of what will be the bone shaft. The periosteum becomes vascularized and its vessels invade the mineralized cartilage interior through an opening that eventually becomes the nutrient foramen of the bone (Fig. 4C). The oldest (central) hypertrophied chondrocytes begin to die as vessels invade, bringing with them osteoclast precursors that resorb approximately two-thirds of the mineralized matrix, producing the earliest marrow spaces. Marrow stromal

Figure 4 Stages of endochondral bone formation as illustrated by segments of the rat sternum at birth. Hypertrophy of chondrocytes in the center of the cartilage model (A) is followed by mineralization of cartilage matrix and transformation of the central perichondrium (pc in A) into a vascularized periosteum (po in B), which forms a collar of mineralized bone (B). Vessels in the periosteum invade (arrow in C) the mineralized cartilage model, bringing osteoclast precursors, which differentiate and resorb the mineral, and hematopoietic stem cells, which populate the newly formed marrow cavity (mc). Osteoblasts also invade and form bone on longitudinally oriented rods of mineralized cartilage. This produces a central marrow space surrounded by a mineralized cylinder (diaphysis) with mineralized cartilage and bone at each end (dark areas in C). This leaves cartilage islands, epiphyses (e), with regions of proliferation and hypertrophy, in their bony ends.

cells occupy this space and hematopoietic stem cells then migrate from the spleen. Osteoblasts begin to secrete bone matrix onto the mineralized cartilage septa that remain. Thus, a disc of bone is formed and divides the cartilage model in half between its proximal and distal ends. The transition point between cartilage and bone is called the chondroosseous junction.

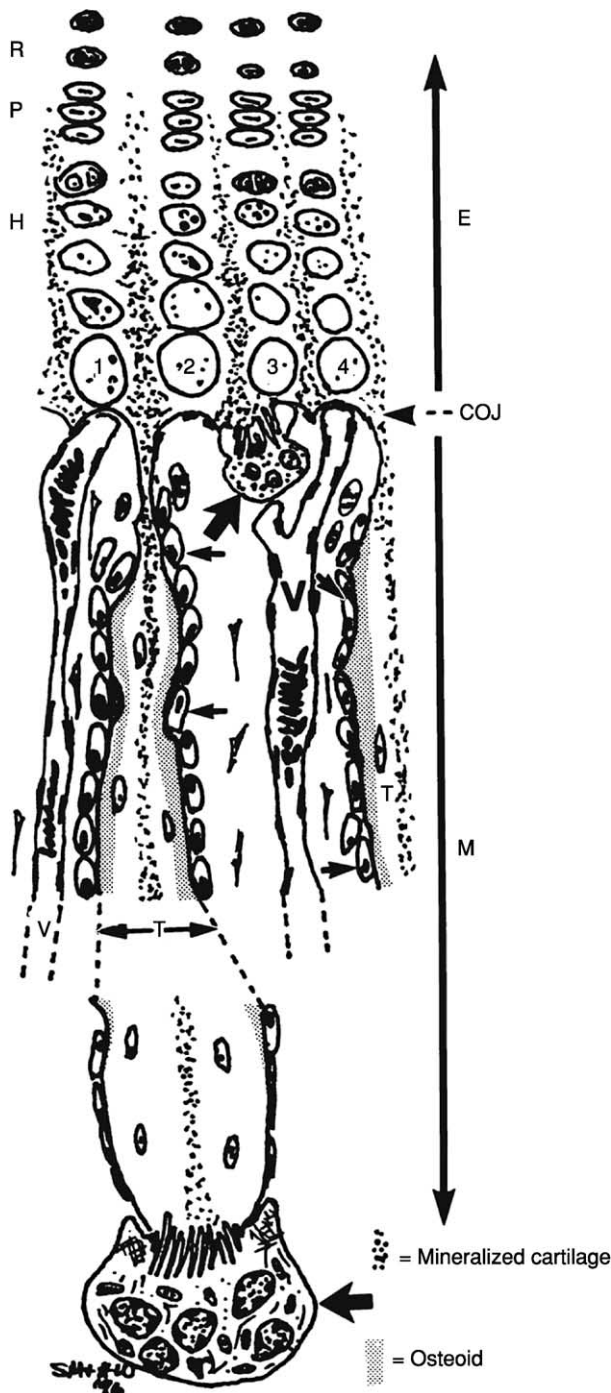

Figure 5 Schematic of cellular location and activities at the chondroosseous junction (COJ) of a growing bone. The epiphyseal growth plate (E) consists of resting (R), proliferating (P), and hypertrophied (H) chondrocytes. In the metaphysis (M), trabeculae (T) alternate longitudinally with vascular channels (V). Osteoblasts (small arrows) line trabecular surfaces beginning just below the COJ and osteoclasts (large arrows) are found in two locations: at the COJ and at the marrow cavity ends of trabeculae. Chondrocytes are aligned in columns (numbered) and their alignments are maintained by mineralization of the longitudinal matrix between columns

Growth in length in endochondral bones is accomplished by continuing proliferation and hypertrophy of the chondrocytes on either end of the central bony region. The process of hypertrophy results in a four- to sixfold increase in cell volume and drives the lengthening of the bone. The chondrocytes align themselves along the (weight-bearing) long axis of the bone and differentiate directionally to form columns of proliferating and hypertrophied cells. In the zone closest to the chondroosseous junction, the longitudinal septa of cartilage (i.e., between columns) become mineralized, whereas the transverse septa (i.e., between cells in the same column) do not. On reaching hypertrophy, chondrocytes' energy metabolism switches to glycolysis, and when their abundant stores of glycogen are exhausted, they undergo programmed cell death, the final metabolic state of the last cell in each column. The last transverse septum is resorbed by specialized perivascular cells, clearing the way for vascular invasion and transition to bone.

Approximately two-thirds of the longitudinal septa are resorbed by osteoclasts and the remainder are covered by bone matrix to form bony trabeculae. These trabeculae inhabit the region where the bone narrows, or flares, from the rounded ends to the shaft. The trabeculae are in turn resorbed from their ends as the bone grows, leaving an open marrow space surrounded by the dense bone of the shaft. The flared area containing the trabeculae is called the metaphysis and the central shaft is the diaphysis.

The rounded ends of the cartilage bone model, the epiphyses, enlarge for a time as cartilaginous structures, but eventually they too undergo a wave of vascular invasion and replacement by bone, forming a secondary ossification center at each end of the bone. Between the bony interior of the epiphysis and the metaphysis lies a discoid layer of growing cartilage called the physis, or the epiphyseal growth plate. The growth plate is the site at which the continued lengthening of the bone occurs, again via chondrocyte proliferation and hypertrophy. As the bone grows,

beginning in the zone of proliferation. Osteoclasts resorb two-thirds of these mineralized cartilage struts at the COJ to make room for vascular channels (V). The vascular channels and adjacent cells resorb the horizontal septum between the last hypertrophied chondrocyte and the metaphysis (illustrated for columns 1 and 4). Osteoblasts form bone on the remaining mineralized cartilage struts at the COJ and the bone content of trabeculae increases with time. At the marrow ends of trabeculae, osteoclasts resorb both cartilage and bone. Reprinted from Marks, S. C. (1998). *In* "Diagnostic Imaging in Child Abuse" (P. K. Kleinman, ed.), pp. 2-7, Mosby, St. Louis, MO, with permission.

chondrocytes at the chondroosseous junction die and are replaced by bone and the lengthening trabecula are resorbed at their ends in a closely regulated manner that is proportional to the length of the bone. The result is that the metaphysis occupies a nearly constant fraction of a bone's length. These events are shown diagrammatically in Fig. 5 and in a photomicrograph of a rat chondroosseous junction in Fig. 6.

The conversion of the epiphysis from cartilage to bone is initiated by the formation of canals from the surface, which are invasions by vascular structures that bring skeletal cells and/or their precursors with them. The beginning of this process is shown in Figs. 7 and 8.

It should be noted that the cartilaginous epiphysis consists of chondrocytes that have divided only once, producing lacunae occupied by two cells. The canals enter the epiphysis and expand and their interiors become ossified. The enzymes involved have been identified and are shown in Fig. 9, where they are compared and contrasted with similar resorptive events at the chondroosseous junction.

Long bones grow in width along the central shaft by formation on the periosteal surface and resorption on the endosteal surface. This is coordinated with each bone's growth in length to maintain its characteristic shape and may not be bilaterally symmetrical. Thus, the flared epiphyseal ends of long bones, largely cancellous bone (i.e., occupied by trabecula), are converted to the denser bone of the diaphysis by sequential waves of formation and resorption on endosteal and periosteal surfaces. These regions and their activities are summarized in Fig. 10.

When bone growth is complete, the mechanisms for growth in length and girth disappear. The cartilage of the growth plate disappears when chondrocyte proliferation ceases, hypertrophy is exhausted, and bones in the epiphysis and metaphysis are joined. Similarly, bone formation and resorption no longer occur on opposite surfaces in the shaft.

Each bone has a characteristic time at which the primary (diaphyseal) and secondary (epiphyseal) ossification centers appear. Similarly, for each bone there is a time at which its growth plates disappear by fusion of the primary and secondary centers. These events can be monitored radiographically and form the basis for determinations of skeletal or metabolic age, as opposed to the chronological age of an individual.

Regulating Chondrogenesis and Endochondral Growth

Chondrocytes clearly must integrate a complex variety of signals from both local and circulating sources

Figure 6 Photomicrograph of the chondroosseous junction (COJ) in a young rat. Hypertrophied chondrocytes (H) occupy most of the growth plate visible in this field. Vascular invasion of chondrocyte lacunae is occurring at several sites (vertical arrows) along the COJ, and vascular channels (V) are common between trabeculae (T). Osteoblasts (small arrows) can be identified on most metaphyseal surfaces and a large group (star) appears where trabeculae converge out of the plane of this section. Several osteoclasts (O) can be seen near the COJ. Toluidine blue stain. Reprinted from Marks, S. C. (1998). In "Diagnostic Imaging in Child Abuse" (P. K. Kleinman, ed.), pp. 2–7, Mosby, St. Louis, MO, with permission.

during their proliferation and differentiation in the growth plate. Gene expression in the endochondral pathway begins with the *Sox9* transcription factor

Figure 7 Parts of a growing long bone as illustrated in the proximal tibia of a newborn mouse. The knee joint cavity can be seen as a thin white space at the top of the figure. The epiphysis stretches from the knee joint to the chondroosseous junction (COJ). At the distal end of the epiphysis, the growth plate consists of regions of resting (r), proliferating (p), and hypertrophied (h) chondrocytes. In the proximal epiphysis, cartilage canals (cc) have invaded to establish the secondary (epiphyseal) ossification center.

and with type II collagen, aggrecan, and other characteristic proteoglycans. These can be found in the earliest cartilage condensations (Figs. 2 and 4). Chondrocyte hypertrophy is essential for endochondral bone formation and *Cbfa1* is required for this step. This may be related to the concurrent expression of this gene in the adjacent periosteum. Chondrocyte proliferation is promoted by *Sox9* and Indian hedgehog (*Ihh*) and inhibited by FGF signaling. Chondrocyte differentiation and hypertrophy are promoted by *Ihh* and *Cbfa1* and inhibited by parathyroid hormone-related peptide (PTHrP) and *Sox9*.

The dynamics of chondrocyte biology in the growth plate are produced by the integrated interactions of

Figure 8 Higher magnification of the proximal epiphysis in Fig. 7, showing the cartilage canals and their cellular composition, which is distinct from that of the surrounding cartilage. The tibial articular chondrocytes (arrow) are flatter and longer than the other chondrocytes in the epiphysis.

these local influences as modified by systemic influences. PTHrP is produced by periarticular chondrocytes and its receptor is expressed at high levels in prehypertrophic chondrocytes. *Ihh* is expressed at the prehypertrophic–hypertrophic chondrocyte boundary. Cells that escape the inhibitions of PTHrP signaling therefore express *Ihh*, which feeds back to increase PTHrP expression. Thus, PTHrP and *Ihh* are major players in a negative feedback loop that regulates the proliferation/differentiation balance in the growth plate. *Ihh* signaling promotes the proliferation and columnar orientation of chondrocytes, activates PTHrP to inhibit hypertrophy, and is necessary for osteoblast differentiation in endochondral bones. Furthermore, *Ihh* signals the conversion of the perichondrium to the periosteum, another overlapping function with *Cbfa1*. Developmental disturbances in chondrogenesis are the major causes of chondrodysplasias.

Adding to the complexities of endochondral growth are the events at the chondroosseous junction (and its precursor, the initial vascular invasion of the lacunae of hypertrophied chondrocytes and resorption of mineralized cartilage in the center of the developing bone). Matrix metalloproteinases (MMPs), particularly MMP-9, and vascular endothelial growth factor (VEGF) are required for osteoclast recruitment and differentiation and for vascular invasion. MMP-9 is produced by mesenchymal cells in the

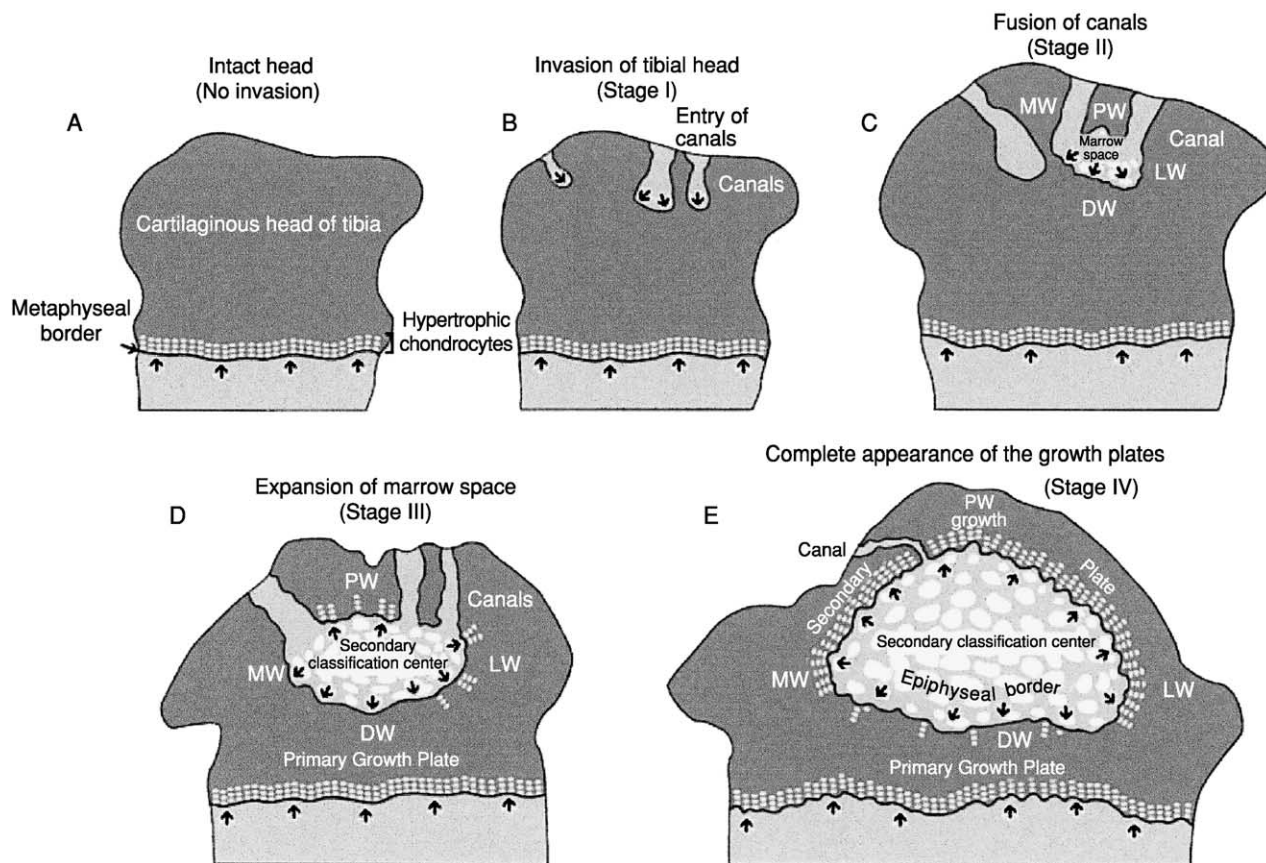

Figure 9 Epiphyseal transformation from cartilage into bone, illustrated diagrammatically. Secondary ossification centers are initiated by vascular penetration of epiphyses, producing canals. These erosions depend on the local production of a specific enzyme, MMP-14, eventually coalescing to form a central space where bone is formed on trabeculae. As this space expands laterally and proximally, a secondary growth plate is established to provide for epiphyseal growth. Modified from Lee *et al.* (2001). Enzymes active in the areas undergoing cartilage resorption during development of the secondary ossification center in the tibiae of rats ages 0–21 days. I. Two groups of proteinases cleave the core protein of aggrecan. *Dev. Dyn.* 222, 52–70, with permission.

periosteum and by osteoclasts. VEGF is made by hypertrophied chondrocytes, is stored in the adjacent matrix, and is released during hypertrophy. Resorption of the transverse septum between the last hypertrophied chondrocyte and the metaphysis releases additional VEGF, which promotes angiogenesis at this site. Thus, VEGF-mediated angiogenesis appears to be a key event at the chondroosseous junction, where chondrogenesis is coupled to osteogenesis.

MMPs are also involved in ossification of the epiphyses, in this case MMP-14. Elaboration of MMP-14 by the invading cartilage canals is essential for vascular penetration of epiphyses. In its absence, ossification and skeletal age are markedly delayed.

In addition to these local regulations of skeletal development, there are many systemic regulations that are likely mediated through local processes. Among them are growth hormone and insulin-like growth factor-I (IGF-I), which promote cell proliferation in growth plates. Thyroid hormones support metabolism generally and have an indirect effect on growth hormone release and IGF-I action. Estrogens are significant promoters of prepubertal growth and the general maintenance of bone mass. Vitamin D metabolites are important for mineralization. Glucocorticoids, on the other hand, stunt growth by shortening the life span of skeletal cells.

A variety of endochondral skeletal malformations ensue when these processes do not occur in the proper sequence, time, or place.

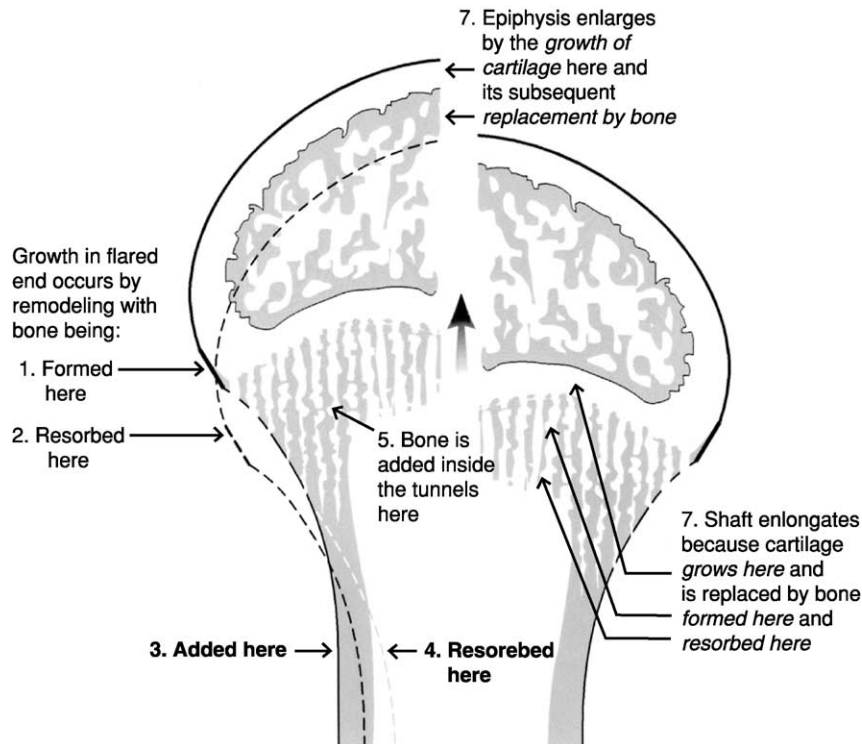

Figure 10 Diagram of regional changes in cartilage and bone that produce growth in the length (large arrow) and width of long bones. Reprinted from Marks, S. C. (1998). In "Diagnostic Imaging in Child Abuse" (P. K. Kleinman, ed.), pp. 2-7, Mosby, St. Louis, MO, with permission.

Joints

Connections between skeletal elements differ depending on whether there will be significant movement between the bones. Joints with little or no motion are fibrous or cartilaginous. Growth plates and synchondroses are temporary cartilaginous joints between the diaphysis and epiphyses or between the bones of the craniofacial base, respectively, and disappear when growth is complete. Symphyses are fibrocartilaginous articulations that permit movement that varies directly with the amount of intervening fibrocartilage. The pubic symphysis is a wide joint with considerable movement, whereas the mandibular symphysis is extremely narrow, has no movement, and is temporary. Sutures are fibrous joints with little or no movement. Synovial joints are designed to allow significant movement and mechanical load transfer between bones. The articulating surfaces of both bones throughout the range of movement are covered by a thin layer of cartilage overlying bone. A fibrous capsule encloses the joint and most of its internal surface consists of a synovial membrane that extends over all internal surfaces except those actually in

contact during movement. The synovial fluid, secreted by this membrane, is a highly viscous material that participates in joint lubrication and cellular maintenance. Depending on the shapes of the articulating surfaces, joints may be strengthened internally and/or externally by ligaments and tendons and the congruence of articulating surfaces enhanced by fibrocartilaginous discs. Various classifications of joints characterize mechanisms and/or movements.

Articular cartilage is derived from the original epiphyseal cartilage but does not undergo hypertrophy. Resisting differentiation, they produce abundant matrix, including tenascin-C, an extracellular matrix protein unique to articular chondrocytes. Endogenous TGF- β appears to maintain the appropriate undifferentiated state of articular chondrocytes.

SKELETAL TURNOVER AND MAINTENANCE

Once formed, the skeleton continues to renew itself throughout life. This is accomplished by a precise, localized resorption that is followed by formation,

| Development, maintenance, and pathology of the skeleton | | | |
|---|--------------------|--------------------|-------------------------|
| | <u>Development</u> | <u>Maintenance</u> | <u>The osteoporoses</u> |
| <u>Age</u> | 0–20 | 20–50 | 50+ |
| <u>Sequence</u> | BF → BR | BR → BF | BR → BF |
| <u>Activity</u> | Modeling | Remodelling | |
| | BF > BR | BF = BR | BF < BR |

Figure 11 Development, maintenance, and acquired pathology of the skeleton. Summary of the relative levels of bone formation (BF) and bone resorption (BR) during the human life cycle. Reprinted from Marks and Odgren (2002), with permission.

which restores the original volume of bone at that site. This is summarized in [Fig. 11](#).

Skeletal development takes place during the first 2 decades of life. During this period, formation of bone precedes and exceeds resorption. This phase is termed modeling. On skeletal maturation, skeletal mass is maintained and microdamage is repaired for the next 3 decades or longer by localized remodeling in which approximately 10% of the skeleton is replaced each year. This begins by resorption followed by an equal amount of formation. Remodeling leaves a trail in cortical bone by producing overlapping Haversian systems of different configurations. With increasing age, the osteoblastic progenitor pool is depleted sooner than the osteolytic pool, leaving the formative

phase of maintenance progressively reduced compared to the resorptive phase. This reduces skeletal mass, the hallmark of osteoporosis.

DEVELOPMENTAL PATHOLOGY OF THE SKELETON

In each phase of skeletal development, the appropriate, timely integration of the complex expression of many genes is responsible for normal development. Many skeletal disorders result from the inappropriate expression or nonexpression of genes and these gene sequences and genetic disorders are available at the Online Mendelian Inheritance in Man web site. This database includes the latest tabulation of more than 11,000 congenital human malformations, first published as 1487 entries in book form by Victor McCusick, in 1968. Many disorders affecting the skeleton are summarized in [Table I](#).

more descriptive term material BMD (BMD_{material}) may be preferable, because a variety of densities have been labeled “true.”

BMD_{material} reflects the degree of mineralization of organic bone matrix. The degree of matrix mineralization varies widely in any single piece of bone and therefore BMD_{material} is always the average of a continuum of density values. Bone matrix has a mineral density of zero when it is released from the osteoblast and mineralization starts only ≈ 2 weeks later at a typical remodeling site. Within a few days after the start of mineralization, inorganic material has filled 75% of the matrix volume originally occupied by water molecules (primary mineralization, not to be confused with primary bone). During the following 6 months, mineral continues to be slowly incorporated into the matrix (secondary mineralization). Because of this time-dependent increase, recently deposited bone matrix has a lower mineral density than “old” matrix. From this fact, it follows that BMD_{material} is inversely related to bone remodeling activity: when remodeling activity is high, there will be more unmineralized osteoid and there will be more “young” bone matrix, which has not yet completed secondary mineralization. These considerations refer to secondary (remodeled) bone. Primary (unremodeled) bone, which osteoblasts add to the periosteal surface during growth, is denser than secondary bone, even though it is younger. Therefore, when there is rapid periosteal expansion and little intracortical remodeling, cortical BMD_{material} will be high. The functional mechanisms influencing BMD_{material} and the structural components reflected by BMD_{material} are summarized in [Table I](#).

Table I Factors Determining BMD_{material}

| Factor | Effect on BMD_{material} when increased |
|--|---|
| Functional mechanisms | |
| Periosteal expansion (modeling) | ↑ |
| Remodeling | ↓ |
| Structural features | |
| Ratio between primary and secondary bone | ↑ |
| Relative volume of unmineralized osteoid | ↓ |
| Average age of bone matrix | ↑ |

Age Dependency

In adults, the relative ash weight of trabecular bone is a few percent lower than that of cortical bone. This probably reflects the fact that the turnover of trabecular bone is higher than that of cortical bone. As trabecular bone turnover decreases from childhood to adulthood, BMD_{material} should increase during bone development. In fact, BMD_{material} of trabecular iliac bone shows such a trend between the first and the fourth decades of life.

THE DEVELOPMENT OF TRABECULAR AND CORTICAL TISSUE—COMPARTMENT BONE MINERAL DENSITY

The trabecular compartment is defined as the space within the endocortical surface. The cortical compartment is delimited by the periosteal and endocortical surfaces. Both compartments contain not only bone matrix, but also nonbone tissue. In trabecular bone, this is mainly hematopoietic and fat marrow. In cortical bone, the nonbone composites are blood vessels and the connective tissue within osteonal (Haversian) and Volkmann’s canals. In this article, the term compartment BMD ($BMD_{\text{compartment}}$) is used to denote the mass of mineral per unit volume of the trabecular or cortical compartment. In the densitometric literature, trabecular $BMD_{\text{compartment}}$ has been called cancellous bone density or volumetric trabecular apparent BMD. The cortical $BMD_{\text{compartment}}$ has been referred to as true cortical bone density or material density of cortical bone. $BMD_{\text{compartment}}$ depends on BMD_{material} and relative bone volume, which is the relative amount of space occupied by bone matrix.

Structural features and functional mechanisms reflected by $BMD_{\text{compartment}}$ are listed in [Table II](#). In trabecular bone, $BMD_{\text{compartment}}$ depends on trabecular number (defined as the number of trabeculae that an imaginary line through the bone would hit per millimeter of its length) and mean trabecular thickness. The mechanisms determining trabecular number during growth have not been well characterized. Trabecular thickness depends on remodeling activity and on remodeling balance.

Age Dependency

$BMD_{\text{compartment}}$ of the femoral midshaft decreases in the first months after birth and then increases until adulthood. The increase in $BMD_{\text{compartment}}$ between

Table II Factors (Other than BMD_{material}) Determining $BMD_{\text{compartment}}$

| Factor | Effect on $BMD_{\text{compartment}}$ when increased |
|---------------------------|---|
| Functional mechanisms | |
| Remodeling | |
| Cortical bone | ↓ |
| Trabecular bone | ↓↑ |
| Structural features | |
| Trabecular bone | |
| Trabecular number | ↑ |
| Trabecular thickness | ↑ |
| Cortical bone | |
| Number of osteonal canals | ↓ |
| Size of osteonal canals | ↓ |

the age of 3 and 5 months and adulthood amounts to 36%, but most of this increase occurs in early childhood. The difference between the age group of 4–13 years and young adults is only $\approx 6\%$. These variations in cortical $BMD_{\text{compartment}}$ appear to be more pronounced than the corresponding changes in relative ash weight. The changes in cortical BMD_{material} probably are caused by variations in both BMD_{material} and relative bone volume.

THE DEVELOPMENT OF TOTAL BONE DENSITY

The volume to determine total BMD (BMD_{total}) is enclosed by the bone's periosteal envelope and articular surfaces. Terms used in the literature to denote BMD_{total} include bone mineral apparent density, volumetric bone density, and true bone density. BMD_{total} is determined by trabecular and cortical $BMD_{\text{compartment}}$ and by the relative volumes of the two compartments. Table III lists the functional mechanisms and structural features that influence BMD_{total} .

Age Dependency

The dry total density of long bones (i.e., mineral plus organic mass divided by external bone volume) decreases by approximately 30% in the first few months after birth. This is followed by a rapid increase until approximately 2 years of age and a slower increase thereafter. The postnatal drop in BMD_{total} is partly

Table III Factors (Other Than $BMD_{\text{compartment}}$) Determining BMD_{total}

| Factor | Effect on BMD_{total} when increased |
|---|---|
| Functional mechanisms | |
| Modeling | |
| Endocortical resorption | ↓ |
| Endocortical apposition | ↑ |
| Periosteal apposition | ↑ |
| Structural features | |
| Relative volume of the cortical compartment | ↑ |
| Relative volume of the trabecular compartment | ↓ |

caused by decreasing relative cortical area. The simultaneous decline in cortical BMD_{material} and $BMD_{\text{compartment}}$, as outlined previously, also will contribute to lower BMD_{total} in early infancy.

The decrease in cortical thickness during the first months of life was dubbed “physiological osteoporosis of infancy” a century ago. However, in growing children, a decrease in cortical thickness and BMD_{total} is not necessarily a sign of bone loss. This is exemplified in Fig. 1, which summarizes studies on femoral mid-shaft development during the first 6 months of post-natal life. In healthy babies, the decline in BMD_{total} reflects a redistribution of bone tissue from the endocortical surface to the periosteal surface rather than bone loss. Therefore, bone mineral mass increases considerably during the first months of life, despite the precipitous drop in BMD_{total} (Fig. 1).

THE REGULATION OF BONE DEVELOPMENT

Interpreting bone density in terms of the underlying biological organization not only provides a better understanding of bone development, but is helpful in reconciling seemingly contradictory results of densitometric studies in children with bone diseases.

A viable model of functionally controlled bone development must take into account a general principle of regulation, which applies to biology, engineering, and even human organizations: Control requires not only the ability to act, but also information on the current state of affairs. Thus, a controlled

Figure 1 A model of bone development at the femoral midshaft from birth to 6 months of age. At birth, the external bone diameter (d) is approximately 6.0 mm and cortical thickness is 2.15 mm. Thus, 92% of the cross section is cortical bone. At 6 months of age, BMD_{total} has dropped by 30% and cortical thickness has decreased. However, the external bone diameter has increased to 9.0 mm. Therefore, the mineral mass in a 2 mm thick slice of bone has increased by 58%. Reproduced from *J. Bone Miner. Res.* 2001; **16**: 597–604, with permission of the American Society for Bone and Mineral Research.

system needs to have both effector and sensor mechanisms. The former performs an action and the latter generates feedback signals, which indicate whether or not the desired effect has been achieved. This automatically indicates that there must be information within the system about what the “desired effect” is.

These requirements for a controlled system are met by Frost’s mechanostat model and related approaches (Fig. 2). It is proposed that the desired effect of bone homeostasis is to keep the mechanically induced deformation of bone (in biomechanical terminology this is called strain) close to a preset level, called the setpoint. The deformation of a bone is a surrogate measure of its strength, because a strong bone will deform less than a weak bone when a mechanical challenge is applied. Bone deformation generates canalicular fluid flow, which could be monitored by osteocytes. When bone deformation exceeds a certain acceptable limit, osteocytes might sense this and send out signals, which could lead to adaptations in bone mass and architecture. These adaptations increase bone strength and the mechanical strain returns to the acceptable level.

According to this model, changes in bone mass and architecture occur when bone stability is challenged and bone deformation exceeds an acceptable level. To put it differently, the required mechanical strength of

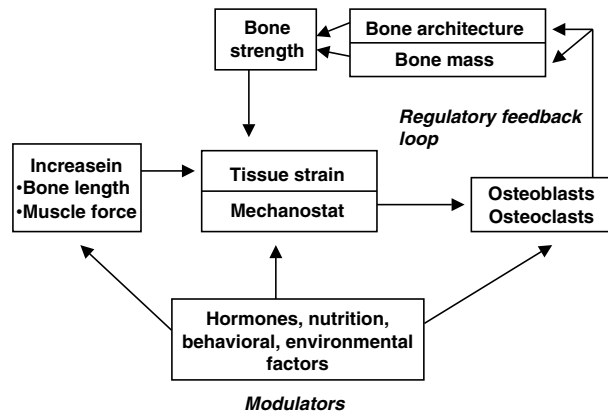

Figure 2 A functional model of bone development based on mechanostat theory. The central feature of bone regulation is the feedback loop between bone deformation (tissue strain) and bone strength. During growth, this homeostatic system is continually forced to adapt to external challenges. Factors shown at the bottom modulate various aspects of the central regulatory system.

a bone determines its mass and architecture, not vice versa. During growth, bone stability is continually threatened by two processes: the increase in bone length and the increase in muscle force. Longitudinal growth increases lever arms and bending moments and therefore leads to greater bone deformation. Greater muscle force will also increase bone deformation during muscle contraction. Body weight alone puts relatively small loads on bones, but the effect of weight is amplified by muscle action. These challenges create the need for adaptational changes in bone mass and architecture.

BONE DEVELOPMENT IN NEWBORNS AND PREMATURE INFANTS

The role of estrogen in the mechanostat system is to lower the setpoint on endosteal bone surfaces, thereby increasing the amount of endocortical bone. This could not only explain certain aspects of pubertal bone development in girls, but is also of relevance for early postnatal events. During intrauterine life, the fetus is exposed to high placental estrogen levels. Accordingly, endosteal surfaces are very sensitive to mechanical strain, leading to small marrow cavities and high organ-level bone density. Cutting off the placental estrogen supply at birth should increase the mechanostat setpoint on endosteal surfaces. Therefore, a substantial amount of bone next to the marrow should then be interpreted as mechanically unnecessary by

the mechanostat. This leads to endocortical resorption and expansion of the marrow cavity, which in densitometric terms corresponds to a decrease in volumetric bone mineral density. There is a postnatal increase in the size of the marrow cavity, which leads to a drop of approximately 30% in directly determined bone density within the first 6 months of life.

At the same time, bones rapidly grow in length. From the perspective of the mechanostat theory, the destabilizing effect of longitudinal growth leads to the addition of bone tissue on periosteal surfaces, where the effect on stability is largest. The combined effect of decreased estrogen levels and increasing mechanical strain during the first postnatal months is a redistribution of bone tissue from the endocortical surface to the periosteal surface. This is a useful mechanism, because it optimizes the distribution of bone mass with regard to mechanical stability and decreases the amount of calcium that must be added from nutritional sources.

When birth occurs prematurely, the placental estrogen supply is cut off earlier. According to mechanostat theory, decreasing estrogen levels should lead to marrow cavity expansion and a decrease in organ-level bone density, similar to mature newborns. Compared to mature newborns at birth, premature babies have larger marrow cavities and lower bone density when they have reached expected term, because they have already started to adapt their bones to postnatal conditions. The differences in bone density between term and preterm babies are only transient. Premature babies have a larger marrow cavity and lower densitometric results than term newborns have at birth. Although prematurity may have a deleterious effect on longitudinal bone growth, there is ample evidence from follow-up studies that the mass of the (shorter) bones is normal for size. From the perspective of mechanostat theory, the so-called “osteopenia of prematurity” (not to be confused with rickets of prematurity) is the expression of physiological postnatal adaptations.

BONE DEVELOPMENT DURING PUBERTY

When estrogen levels rise again in female puberty, endosteal bone surfaces are resensitized to mechanical strain, leading to endocortical apposition at many skeletal sites. Adding bone to endocortical surfaces has a smaller effect on bone stability than adding the same amount of bone to the periosteal surface.

Consequently, postpubertal, premenopausal girls and women have more bone relative to their mechanical needs than males. The purpose of this estrogen-dependent “excess bone” on endocortical surfaces could be to create a calcium reservoir that can be tapped during pregnancy and lactation.

THE FRAGILITY OF GROWING BONES

According to mechanostat theory, bone reacts to challenges to its stability. Since the response can only follow but not precede the challenge, bones are “overloaded” and thus fragile for as long as growth continues. The lag between growth in length and growth in strength should be exaggerated when longitudinal growth accelerates. In fact, the dissociation between bone’s growth in length and in mass is a well-documented phenomenon during the pubertal growth spurt in both genders and could explain the increased fracture rate during that period in life. Since the timing of the maximal increase in bone length and muscle mass differs between musculoskeletal regions, the increase in bone mass follows a region-specific pattern during puberty.

at the expense of rT3. Finally, to reconcile the finding of decreased thyroid hormone levels and normal/decreased TSH values reported by some authors, an impairment of TSH secretion at the hypothalamic and/or pituitary level might concomitantly occur. No evidence for this effect of smoking has been thus far provided and it must be mentioned that, at least under acute conditions (20 min of continuous smoking), cigarette smoking does not cause any significant variation in serum TSH levels.

In summary, cigarette smoking seems to be associated with minor and controversial changes in thyroid function tests, whose pathophysiological relevance seems to be marginal (Table I).

SMOKING AND GOITER

Several reports have documented that smoking is associated with an increased prevalence of goiter (Table I). In addition, it was shown that heavy smokers have an increased frequency of nodular goiter. These findings may be related to iodine intake, because many of these studies were performed in iodine-deficient areas. At variance, no differences in the prevalence of goiter among smokers and nonsmokers were found in iodine-sufficient areas. It is likely that cigarette smoking represents only a cofactor and its goitrogenic effect becomes more apparent when other goitrogenic factors, and particularly iodine deficiency, are also present.

It is not completely clear how cigarette smoking can contribute to the development of goiter, but a candidate goitrogen in smoke is thiocyanate, produced by detoxification of hydrogen cyanide. The role of thiocyanate in the etiology of endemic goiter has been clearly shown in the presence of iodine deficiency. Body fluids of smokers contain increased thiocyanate concentrations. The increase in the thyroid volume/birth weight ratio in newborns parallels the increase in cord serum thiocyanate levels, taken as an index of

maternal smoking habits, suggesting that smoking during pregnancy may be a relevant cause of thyroid gland enlargement in the newborn. The effects of thiocyanate and other cigarette smoking products (nicotine, cotinine) have also been studied *in vitro* using porcine thyroid follicles in culture; whereas nicotine and cotinine did not inhibit iodide transport or thyroid hormone synthesis, thiocyanate, at concentrations equivalent to those reached in the serum of smokers, inhibited iodide transport and iodine organification while increasing iodide efflux. In addition to underscoring the role of thiocyanate, these findings may explain the interaction of cigarette smoking and iodine deficiency in the development of goiter.

In summary, it appears that smoking plays a role in the development of goiter and most reports agree on a higher prevalence of goiter in smokers. Although it is conceivable that many (and yet unidentified) smoke products may contribute, thiocyanate appears to be the most likely culprit, in view of the high circulating levels found in smokers and in view of its complex effects on thyroid function. Smoking-related goitrogenesis appears to be frequent, particularly in iodine-deficient areas, where smoke may also represent a relevant cause of neonatal thyroid enlargement.

RELATIONSHIP BETWEEN SMOKING AND THYROID AUTOIMMUNE DISORDERS

Cigarette smoking has a number of immunological effects involving both humoral and cellular components of the immune system. These include a depression of natural killer cell activity, an increase in the total number of T lymphocytes, with a relative decrease in CD4⁺ (helper) and increase in CD8⁺ (suppressor) subpopulations in heavy smokers. Serum immunoglobulin (Ig) G, IgM, and IgA levels are decreased by 10–20% in the serum of smokers, whereas IgE levels are increased

Table I Effects of Smoking on the Thyroid

| | |
|---------------------------------------|--|
| Thyroid function tests | Minor and controversial changes in serum thyroid hormone and TSH concentrations |
| Goiter | Goitrogenic effect, more evident in iodine-deficient areas |
| Graves' disease | Increased prevalence of smokers among Graves' disease patients; increased risk of occurrence of Graves' disease in smokers, higher recurrence rate after anti-thyroid drug withdrawal |
| Graves' ophthalmopathy | Increased prevalence of smokers among Graves' patients with ophthalmopathy; relationship between smoking and severity of eye disease; lower effectiveness of treatment for ophthalmopathy in smokers |
| Hashimoto's thyroiditis | Association of smoking with thyroiditis, but not with subsequent progression to hypothyroidism |
| Postpartum thyroid dysfunction | Conflicting results on the role of smoking in the occurrence of postpartum thyroid disorders |

in light-to-moderate smokers and decreased in heavy smokers. A lower level of immunosuppression has been observed in mice as an effect of smoking. The numerous immunological effects of smoking may have some relevance in human pathophysiology. For example, it has been shown that, although smoking is associated with Crohn's disease, ulcerative colitis is strongly associated with not smoking. The underlying mechanism might not necessarily be related to immunological effects of smoking, but to substances contained in smoke that might be somehow beneficial to ulcerative colitis patients. An association between rheumatoid arthritis and cigarette smoking, as well as an increased prevalence of antinuclear antibodies in smokers, has been reported.

Graves' Disease

Graves' disease is an autoimmune disease to which both genetic and environmental factors contribute. The latter may include stressful life events and infections. Smoking represents an additional and important environmental factor. An increased prevalence of smokers has been observed in patients with Graves' disease and smoking increases the risk of developing this disease. In addition, smoking has been reported to be associated with an increased incidence of recurrence of Graves' hyperthyroidism following anti-thyroid drug treatment withdrawal.

Why should cigarette smoking be associated with an increased risk of developing Graves' disease? Smoking might simply be a coincidental, unrelated factor and Graves' patients might smoke more because they are nervous and stressed. Stress is indeed associated with an increased desire to smoke. It should be mentioned that, in most cases, Graves' patients smoked prior to the development of hyperthyroidism. Alternatively, smoking might enhance other activities (e.g., drinking alcohol or coffee) or other factors that bear the true responsibility for the occurrence of the disease. However, the possibility cannot be excluded that smoking may be effectively involved in the pathogenesis of the disease. This might occur through different smoke-related mechanisms, such as an alteration of the TSH receptor structure, an enhancement of responsiveness to a factor(s) responsible for the initiation of the disease, or an impairment of restoration of tolerance to thyroid autoantigens. Evidence that these hypothetical mechanisms participate in the development of Graves' disease is lacking.

Graves' Ophthalmopathy

Graves' ophthalmopathy is the most frequent extrathyroidal manifestation of Graves' disease and represents a complex therapeutic problem. A possible relationship between cigarette smoking and Graves' ophthalmopathy was initially suggested in a small series of patients and subsequently confirmed in a large number of patients in a different series (Table II). Another series reported a 64% prevalence of smokers among 307 patients with Graves' ophthalmopathy, a percentage much higher than that in Graves' patients without ophthalmopathy (48%) or controls (29%). Furthermore, there seems to be a relationship between smoking and disease severity. Interestingly, the current number of daily cigarettes smoked, but not lifetime tobacco consumption, appears to be an independent risk factor, and ex-smokers have a lower risk of developing severe Graves' ophthalmopathy than current smokers with a comparable lifetime tobacco consumption. In a survey by the European Thyroid Association, 43% of respondents indicated an apparent decrease in the incidence of clinically relevant Graves' ophthalmopathy in the past decades, whereas 12% reported an increasing incidence of the disease. Interestingly, most respondents of the former group belonged to countries (e.g., the United Kingdom, France, the Netherlands) where tobacco consumption has decreased; conversely, respondents in the second group belonged to countries (e.g., Hungary, Poland) where tobacco consumption has increased.

This association between cigarette smoking and Graves' ophthalmopathy is unexplained. In addition to direct irritative effects, cigarette smoking might influence ongoing immune reactions in the orbit. It is well accepted that cytokines play an important role in the pathogenesis of Graves' ophthalmopathy. Cigarette smoking may affect the process, because smoking-induced hypoxia in the retrobulbar tissue increases the release of cytokines from orbital fibroblasts *in vitro*. Furthermore, it has been reported, but not unequivocally confirmed, that smokers, compared to nonsmokers, have lower circulating levels of soluble interleukin-1 (IL-1) receptor antagonist levels, an anti-cytokine antagonizing the effects of IL-1.

Cigarette smoking may also affect treatment outcomes of Graves' ophthalmopathy (Table I). A more favorable response to orbital radiotherapy and high-dose systemic glucocorticoid treatment for severe Graves' ophthalmopathy is more frequent in smokers than in nonsmokers. In patients with nonsevere Graves' ophthalmopathy, radioiodine treatment may cause a progression of eye disease in approximately 15% of cases; postradioiodine progression is more likely to occur in smokers, whereas improvement of preradioiodine ophthalmopathy with the concomitant glucocorticoid treatment is more frequent in nonsmokers.

In summary, although the mechanisms whereby cigarette smoking operates remain to be elucidated, the relationship between smoking and eye disease is well established, in terms of the epidemiology of the disease and its influence on the severity of the disease and the efficacy of its management. Accordingly, Graves' ophthalmopathy patients should be vigorously encouraged to refrain from smoking, even though it remains to be proven that smoking withdrawal beneficially affects the course of the disease.

Hashimoto's Thyroiditis

Data on the relationship between smoking and the occurrence or exacerbation of Hashimoto's thyroiditis are not completely clear. Several studies failed to show a sound relationship. However, a meta-analysis of several published papers seems to indicate that a relationship exists between smoking and autoimmune thyroiditis, but not between smoking and the subsequent progression of thyroiditis to hypothyroidism (Table I). In this regard, it is worth mentioning that anthracene derivatives cause experimental autoimmune thyroiditis in susceptible rats.

Postpartum Thyroid Dysfunction

Conflicting results have been reported concerning a possible association between cigarette smoking and the development of postpartum thyroid dysfunction. However, in most studies, smoking apparently does not play a relevant role in the occurrence of postpartum thyroid disorders (Table I).

CONCLUDING REMARKS

The relationship between cigarette smoking and the thyroid is complex and not yet completely understood. Marginal changes in thyroid function have been described in smokers, but an overall evaluation of reported series shows that these effects are controversial and, therefore, unlikely to have a relevant pathophysiological significance. More clearly established is the goitrogenic effect of smoking, which is probably related to the action of thiocyanate (and possibly of other compounds liberated in smoke). This effect might be particularly important in iodine-deficient areas. An interesting observation is the high prevalence of smokers among patients with Graves' disease, but it is unclear whether this has a pathogenic importance or merely represents an epiphenomenon of behavioral changes related to thyroid hyperfunction. Even more striking is the association between smoking and Graves' ophthalmopathy. Although the underlying mechanisms need to be elucidated, smoking might play a role in the pathogenesis of Graves' ophthalmopathy and unfavorably affect its course.

cyclase–cAMP signal transduction pathway. Forskolin and $(\text{Bu})_2\text{cAMP}$ mimic this stimulatory effect on both iodide transport activity and NIS expression. Furthermore, adenosine, which acts as an autocrine factor in cultured thyroidal cells, has been shown to stimulate NIS mRNA and protein expression, as well as iodide transport *in vitro*. In addition to various agents that stimulate NIS expression and function, several inhibitors of NIS expression and/or iodide uptake activity have been identified *in vitro* and *in vivo*. Thyroglobulin, a suppressor of thyroid-specific gene expression, ceramide and sphingomyelinase, which play important roles in the nonthyroidal illness syndrome, in age-associated hypothyroidism, and in intrathyroidal apoptosis, and excessive iodide (Wolff-Chaikoff effect) all act to decrease NIS mRNA and protein expression in FRTL5 cells or *in vivo*. Whereas estradiol increases the proliferation of FRTL5 cells, it down-regulates NIS mRNA expression. Moreover, various cytokines, such as transforming growth factor- β 1, tumor necrosis factor α , interferon- γ , interleukin-1 α (IL-1 α), IL-1 β , and IL-6 act to down-regulate NIS expression and iodide uptake.

In the lactating mammary gland, iodide accumulates in breast milk by NIS-mediated transport in order to supply adequate amounts of iodide to the newborn. Several lines of evidence suggest that iodide transport activity and NIS expression in mammary gland are stimulated by prolactin, representing an important regulatory mechanism for iodide accumulation in breast milk. Further studies in rats showed that NIS protein expression in the lactating mammary

gland is up-regulated during nursing and is significantly decreased within 24 h following separation of pups from their mothers. These data indicate that NIS expression in the mammary gland is regulated in a reversible manner by suckling, suggesting a regulatory mechanism involving the hormone oxytocin.

EXPRESSION OF SODIUM IODIDE SYMPORTER IN BENIGN AND MALIGNANT THYROID TISSUE

Several studies have demonstrated that benign toxic multinodular goiters reveal a heterogeneous pattern of NIS protein expression, with overall expression being stronger than in normal thyroid gland. Furthermore, NIS mRNA levels have been shown to be low in nontoxic multinodular goiter and diffuse iodine deficiency goiter. Whereas NIS mRNA and protein expression levels are increased in autonomously functioning thyroid nodules with increased radioiodine uptake, they are decreased in cold thyroid nodules with low or absent radioiodine uptake.

In contrast to benign thyroid tissue, malignant thyroid tumors reveal decreased, unchanged, or even increased levels of NIS mRNA and decreased levels of cell membrane-associated NIS protein expression with less pronounced basolateral orientation, indicating a defect in intracellular processing and trafficking. Correct NIS protein expression at the cell membrane appears to correlate inversely with the state of cellular differentiation, with more advanced tumor stages

being associated with lower levels of NIS expression. A lack of cell membrane-associated NIS protein expression has been observed in anaplastic and Hurthle cell carcinomas. These data suggest that oncogene activation may be involved in the suppression of NIS expression in thyroid cancer. In a limited number of cases, comparison of radioiodine scans and NIS expression patterns in thyroid carcinomas and metastases revealed a positive correlation between iodide uptake activity and NIS expression levels, suggesting that NIS expression levels might predict radioiodine uptake behavior and therapeutic effectiveness of radioiodine therapy in thyroid cancer. However, NIS mRNA expression has been detected in lymph node metastases with negative iodine uptake, indicating that NIS mRNA expression is not an adequate predictor of NIS functional activity.

NIS IN THYROID AUTOIMMUNE DISEASES AND IN DISORDERS OF IODINE TRANSPORT

There is general agreement that NIS expression is markedly stimulated in active Graves' disease, whereas it is low or suppressed in Hashimoto's thyroiditis. In contrast, studies exploring the role of NIS autoantibodies in autoimmune thyroid diseases have generated inconclusive and often contradictory results, mainly due to methodological difficulties in identifying and differentiating linear and conformational NIS epitopes. Therefore, it has remained difficult to determine the existence, true prevalence, functional activities, and possible pathological implications of NIS-directed autoantibodies in autoimmune thyroid diseases. Using stringent cutoff criteria, NIS autoantibodies are detected in less than 6% of patients with Graves' disease and in less than 7% of patients with Hashimoto's thyroiditis. Thus, it appears that there is no clinical rationale for measuring NIS autoantibodies in patients with autoimmune thyroid diseases.

Congenital iodine transport defect (ITD) is a rare autosomal recessive condition caused by mutations in NIS. The clinical picture comprises hypothyroidism, the presence of a goiter, low thyroid iodine uptake, and a low saliva/plasma iodine ratio. Fifty-eight cases of ITD from 33 families have been reported. Among 27 cases from 13 families, nine NIS mutations have been identified. Only three mutations (T354P, Q267E, and G395R) have been characterized in greater detail, revealing some clues as to the molecular mechanisms that underlie the effects of these mutations. Continued study of naturally occurring NIS mutations is likely to

advance the understanding of functionally significant residues or segments of NIS.

EXPRESSION OF SODIUM IODIDE SYMPORTER IN EXTRATHYROIDAL TISSUES

The thyroid gland shares its capacity to actively accumulate iodide with several other tissues, such as salivary and lacrimal gland, gastric mucosa, lactating mammary gland, choroid plexus, ciliary body of the eye, skin, nasopharynx, thymus, and placenta. Iodide transport in these nonthyroidal tissues is TSH-independent, but reveals several functional similarities to that in the thyroid gland, such as inhibition by thiocyanate and perchlorate and generation of iodide concentration gradients of similar magnitude. In addition, numerous data suggest that iodide is organified by certain extrathyroidal tissues. Detection of NIS mRNA and protein expression in salivary and lacrimal glands, gastric mucosa, and mammary gland suggests that iodide transport in these tissues is conferred by the expression of functional NIS protein. Inorganic iodide secreted by exocrine glands, such as salivary and lacrimal glands, and gastric mucosa followed by oxidation to hypoiodite may act as an antimicrobial agent, offering mucosal protection against environmental microorganisms. Consequently, salivary and lacrimal gland dysfunction observed in thyroid cancer patients after treatment with radioiodine may result from radioiodine accumulation in glandular tissue by NIS. Moreover, lactating breast tissue is capable of concentrating iodide in milk via NIS, thereby providing an adequate supply of iodide to the newborn.

NIS-BASED THERAPEUTIC APPROACHES IN THYROIDAL AND NONTHYROIDAL CANCERS

As decreased NIS expression and iodide uptake in dedifferentiated thyroid carcinomas reduce the efficiency of radioiodine therapy, several novel therapeutic strategies to stimulate NIS expression levels in dedifferentiated thyroid cancer cells have been explored. A promising candidate seems to be retinoic acid, as it has been shown to suppress iodide uptake and NIS mRNA levels in normal, nontransformed FRTL-5 thyroid cells, whereas NIS mRNA expression levels were up-regulated in human follicular thyroid carcinoma cell lines *in vitro*. Treatment with retinoic acid

may therefore act to up-regulate iodide transport in thyroid cancer cells while down-regulating iodide accumulation in surrounding normal tissue, thereby reestablishing or enhancing the therapeutic effect of radioiodine therapy on malignant cells while sparing normal thyroid tissue. Furthermore, data suggest that DNA methylation may be involved in the loss of NIS expression in thyroid cancer, which might offer the possibility of restoring responsiveness to radioiodine treatment by chemical demethylation. A therapeutic effect was also achieved in mice xenotransplanted with transfected and NIS-expressing thyroid tumor cells following radioiodine treatment.

Tissue-specific expression of functionally active NIS in cancer cells without endogenous NIS may confer onto these cells the capacity to concentrate iodine from plasma and thereby establish the possibility of radioiodine therapy for nonthyroidal cancer cells. This therapeutic approach is theoretically feasible in all cancers that specifically express a particular gene, such as calcitonin (medullary thyroid cancer), prostate-specific antigen (prostate tumors), and carcinoembryonic antigen (colorectal cancer), by transferring an expression vector coding for the full-length human NIS under the control of this tissue-specific promoter. Several studies have demonstrated both radioiodine uptake and a selective cytotoxic effect of trapped radioiodine *in vitro* and *in vivo* in malignantly transformed cells without iodide transport activity, following transfection with a NIS-coding expression vector. Using retroviral or adenoviral vectors for NIS gene delivery, expression of functionally active NIS under the control of a nonspecific viral promoter was demonstrable in melanoma, liver, lung, breast, cervical, prostate, ovarian, and colon carcinoma cells, as well as in human follicular thyroidal, cervical, and breast cancer xenotransplants *in vitro* and *in vivo*. Although these data underscore the potential of NIS gene transfer to induce iodide accumulation activity in tumor cells, the therapeutic efficacy of accumulated radioiodine remains to be confirmed in an *in vivo* setting that resembles more closely the clinical situation.

Prostate cancer cells were shown to be selectively killed by accumulated ^{131}I following induction of tissue-specific iodide uptake activity by prostate-specific antigen promoter-directed NIS expression *in vitro*. The magnitude of iodide uptake observed *in vivo* suggested that a therapeutic effect of accumulated radioiodine is likely to be achieved *in vivo*, which has been confirmed. Thus, prostate cell-specific NIS gene transfer appears to be a promising approach to prostate cancer therapy using radioiodine, particularly once the disease has

reached the metastatic stage. Whether and how this approach can be applied to its main clinical target, metastatic cancer of the prostate, remains to be seen. Furthermore, strong evidence of NIS expression in breast cancer has been reported. From these studies, it appears that active iodide transport in mammary gland tissue is mediated by NIS in healthy lactating mammary gland as well as in mammary tumors, but not in non-lactating mammary gland. In contrast to thyroidal NIS, expression of NIS by mammary gland tissue is not regulated by transcription factors such as Pax-8, TTF-1, and TTF-2, but is induced by a combination of estrogen, oxytocin, and prolactin. Over 80% of human breast cancer samples examined by immunohistochemistry expressed NIS immunoreactivity, compared with none of the normal, nonlactating breast tissue samples obtained from reductive mammoplasties. In contrast to normal thyroid or lactating mammary cells, expression of NIS protein was not restricted to the cell membrane of tumor cells, but was also detected intracellularly. Demonstration of NIS expression in mammary tumors may explain why these tumors are sometimes visualized by radioiodine and $^{99\text{m}}\text{Tc}$ -pertechnetate scintigraphy. Knowing the level of functional NIS protein expression in breast cancer cells may be informative both therapeutically and prognostically. Furthermore, similar to expression of HER2/neu or the estrogen/progesterone receptor, NIS expression may play a role in the prognosis of patients. In NIS-positive breast cancer, additional radioiodine therapy might be considered, similar to anti-estrogen therapy in estrogen receptor-positive tumors, or chemotherapy combined with anti-HER2/neu antibody therapy in HER2/neu-positive breast cancers.

California, the presence of a factor with GH-release inhibiting activity (somatotropin-release inhibitory factor, SRIF) was confirmed. Only about 8.5 mg of a product with SRIF activity could be extracted from about 500,000 sheep hypothalamic fragments. The chemical structure of SRIF was determined and the tetradecapeptide was synthesized. The synthetic peptide had the biological activity of the native SRIF on pituitary GH release. The cyclic peptide was called somatostatin. P. Brazeau and colleagues reported the findings of this group in January 1973 in a *Science* article.

It took nearly another 10 years before two groups, those of R. Guillemin and of W. Vale, working independently at the Salk Institute, reported in 1982 the isolation and sequencing of GH-RF peptides, the target of research which led to the discovery of somatostatin.

The simple concept of somatostatin as a 14 amino acid-containing peptide whose main function is the inhibition of growth hormone secretion has been substantially widened through further research in the 1970s and 1980s. Somatostatin-related peptides constitute a family that includes the originally identified peptide (somatostatin-14), an amino-terminal extended somatostatin (somatostatin 28), several species-specific variants, and larger prohormone forms. Somatostatin is distributed widely in cells that have nothing to do with growth hormone regulation, including an extensive distribution within the nervous system, and is found in many tissues outside of the brain, including the gut and endocrine and exocrine glands, the retina, the immune system, and walls of blood vessels.

Biological Effects of Somatostatin

In addition to being a potent inhibitor of pituitary GH secretion, somatostatin also inhibits the secretion of other hormones such as thyrotropin (TSH), insulin, glucagon, pancreatic polypeptide (PP), and vasoactive intestinal polypeptide (VIP). Furthermore, a variety of physiological functions such as gastrointestinal motility, gastric acid production, pancreatic exocrine secretion, bile, and colonic fluid secretion are also inhibited. In the light of this additional knowledge acquired in the 10 years following its discovery, it is evident that the name somatostatin for this peptide does not take into account the multitude of its activities that reach far beyond GH inhibition. Somatostatin acts as a neurohormone, a neurotransmitter, or as a local factor acting via autocrine or paracrine mechanisms.

SOMATOSTATIN RECEPTORS

Actions of somatostatin are mediated through specific membrane receptors. They have been shown in the anterior pituitary, the endocrine and exocrine pancreas, the mucosa of the gastrointestinal tract, and in various regions of the brain, as well as in cells of the immune system. Five subtypes of the human somatostatin receptor (sst_1 to sst_5) have been cloned and characterized. These subtypes are identical in 42 to 60% of their amino acid sequences. They belong to the superfamily of G protein-coupled receptors with seven membrane-spanning domains. The genes for these subtypes are located on different chromosomes, suggesting different functions in different organs.

All five receptor subtypes are able to mediate the inhibition of adenylate cyclase activity. Signal transduction mechanisms not coupled with specific somatostatin receptor subtypes are the activation of potassium channels and inhibition of voltage-dependent calcium channels that are reversed by pertussis toxin. In the brain, somatostatin activates phospholipase C and A and mobilizes calcium. Stimulation of sst_1 and sst_2 results in the activation of tyrosine phosphatase, which is related to the antimetabolic effects of somatostatin in some types of cells. In addition, inhibition of cell proliferation is mediated through sst_5 , probably involving changes in intracellular calcium mobilization.

Table I shows a summary of the biological effects mediated through the different subtypes of somatostatin receptors.

SOMATOSTATIN ANALOGS

The ability of somatostatin to inhibit a variety of physiological processes created expectations that this peptide could be of therapeutic value in clinical conditions involving hyperfunction of several organ systems. However, native somatostatin has several properties that limit its therapeutic use. First, the elimination half-life is only about 3 min, making continuous intravenous infusions mandatory. Somatostatin exerts at pharmacological concentrations multiple simultaneous effects in different organs. This lack of selectivity could lead to adverse events. After stopping a somatostatin infusion, a rebound effect with post-infusion hypersecretion of hormones is observed. There was therefore a clear need to synthesize analogs that are more stable to enzymatic degradation and have a more selective activity than native somatostatin.

Several groups of peptide chemists were involved in the design of analogs with improved properties

Table I Summary of Selected Biological Effects Mediated through the Different Somatostatin Receptor Subtypes (sst)

| Biological effect | Sst ₁ | Sst ₂ | Sst ₃ | Sst ₄ | Sst ₅ |
|-----------------------------------|------------------|------------------|------------------|------------------|------------------|
| <i>Inhibition of secretion</i> | | | | | |
| GH | (+) | + | | | + |
| Insulin | | + | | | + |
| Glucagon | | + | | | |
| Prolactin | | (+) | | | + |
| Serotonin | | + | | | |
| Gastric acid | | + | | | |
| Amylase | | | | | + |
| <i>GI motility</i> | | | | | |
| Gastric and intestinal relaxation | | | + | | |
| Colonic contraction | | | | | + |
| <i>Cell proliferation</i> | | | | | |
| Cell cycle arrest | + | + | | + | + |
| Induction of apoptosis | | + | + | | |
| Inhibition of angiogenesis | + | + | | | |

compared to natural somatostatin. However, the first analogs tested in humans showed no significant advantages. It was an increased understanding of structure–activity relationships of the somatostatin molecule that allowed the synthesis of smaller, more stable, and more potent molecules.

The same methodology that was used for the discovery of somatostatin was also applied for the characterization of analogs. It was based on their ability to inhibit the release of GH in monolayer cultures of rat pituitary cells. This approach led to the selection of analogs with high potency for GH inhibition, or as it is now understood, a high affinity to somatostatin receptor subtype 2.

In 1982, W. Bauer *et al.*, working in the laboratories of the former Sandoz Company (now Novartis) in Basel, Switzerland, introduced octreotide to the scientific community. Octreotide represented the first

analog that obtained marketing authorization. Its duration of action after subcutaneous injection is between 6 and 12 hours for GH inhibition and the elimination half-life is 90 min. The potency of octreotide for GH, glucagon, and insulin inhibition in monkeys is 45 times, 11 times, and 1.3 times higher, respectively, than that of native somatostatin 14. No rebound hypersecretion of hormones occurs after cessation of octreotide administration.

Other cyclic analogs with similar activity profiles, lanreotide and vapreotide, were clinically tested and in the case of lanreotide also marketed in some countries outside the United States.

Figure 1 shows the amino acid structure of somatostatin and somatostatin analogs and Table II compares their affinity for the five somatostatin receptor subtypes. Somatostatin-14 and somatostatin-28 bind with high affinity to all five somatostatin receptor subtypes, whereas the analogs octreotide, lanreotide, and vapreotide bind predominantly to sst₂ and to a lesser degree also to sst₃ and sst₅. They have very low affinities for sst₁ and sst₄.

Long-Acting Depot Formulations

The first formulation of octreotide for clinical use was an immediate release aqueous solution for subcutaneous injection. It has to be administered two or three times daily in doses of 100 or 150 µg. Individual patients may need daily doses up to 1500 µg. The observation that a given dose of octreotide administered as a continuous subcutaneous infusion was more efficacious than three daily subcutaneous injections, along with the inconvenience of three-times daily injections, led to the development of depot formulations for intramuscular injection. The active molecules are embedded in microspheres of DL-lactide-co-glycolide polymer. The duration of action of octreotide LAR is 28–42 days and that of lanreotide SR 7–14 days. Octreotide LAR is supplied as 10 mg, 20 mg, and 30 mg and lanreotide SR as 30 mg. Recently, a

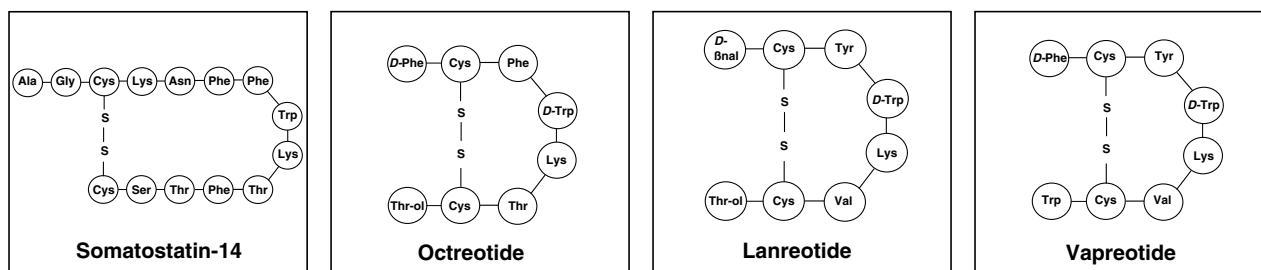

Figure 1 Amino acid structure of somatostatin-14 and somatostatin analogs.

Table II Binding Properties of Human Somatostatin Receptor Subtypes sst_1 – sst_5 Expressed in Chinese Hamster Ovary Cells (sst_1 – sst_4) or African Green-Monkey COS-1 Cells (sst_5)

| Peptide | pK _i [–log M] | | | | |
|-----------------|--------------------------|------------------|------------------|------------------|------------------|
| | Sst ₁ | Sst ₂ | Sst ₃ | Sst ₄ | Sst ₅ |
| Somatostatin-14 | 9.2 | 9.7 | 9.6 | 8.9 | 9.4 |
| Somatostatin-28 | 9.2 | 9.7 | 9.5 | 9.1 | 9.4 |
| Octreotide | 6.6 | 9.5 | 8.3 | < 6.0 | 8.3 |
| Lanreotide | 6.3 | 9.3 | 7.2 | < 6.0 | 8.4 |
| Vapreotide | 6.8 | 10.1 | 7.7 | 6.8 | 8.3 |

new once-monthly aqueous preparation of lanreotide, lanreotide autogel, has become available in some European countries. For chronic treatment with somatostatin analogs, long-acting depot preparations are the formulations of choice.

CLINICAL APPLICATIONS OF SOMATOSTATIN ANALOGS

Pituitary Adenomas

GH-Secreting Pituitary Adenomas

In more than 95% of patients, acromegaly is caused by a GH-secreting pituitary adenoma. Therapeutic options include surgery, radiotherapy and drug treatment. Transsphenoidal surgery can achieve biochemical disease control, defined as circulating concentration of GH ≤ 2.5 μ g/liter and insulin-like growth factor-1 (IGF-1) levels within the age- and sex-adjusted normal range, in up to 90% of patients harboring tumors with a diameter of ≤ 10 mm, a so-called microadenoma. However, larger tumors, especially those with extrasellar extension, reach postoperative biochemical disease control in less than 50%. Radiotherapy takes up to 10 years before being fully effective, and hypopituitarism is a frequent side effect. Dopamine agonists have been used for the treatment of acromegaly since the mid 1970-s. High doses of these drugs are needed, and the proportion of patients who can reach a satisfactory response is maximally 40%.

The addition of somatostatin analogs to the armamentarium of physicians in the late 1980s revolutionized the therapy of acromegalic patients. Chronic treatment with octreotide LAR can achieve biochemical control in 60–70% of patients. Symptoms of acromegaly improve significantly within days of the start of therapy. Several publications have reported a reduction in the size of the pituitary adenoma in the majority

of patients during treatment with somatostatin analogs. There are no reports of an increase in size of GH-secreting adenomas in patients who responded to somatostatin analogs with a decrease in the circulating GH concentration as long as therapy is continued. It has been suggested that somatostatin analogs may be used as primary medical therapy in acromegalic patients who have a small chance of surgical cure or who are unwilling to undergo an operation. Presurgical treatment for up to 3 months before surgery is also employed by some centers; the purpose is to improve the patient's condition and thereby reduce the perioperative morbidity as well as change the consistency of the adenoma to ease extirpation. The evidence of the usefulness of preoperative somatostatin analog treatment is not strong.

TSH-Secreting Pituitary Adenomas

TSH-secreting pituitary adenomas causing hyperthyroidism are very rare tumors. They respond to somatostatin analog treatment with a reduction in TSH levels and a normalization of serum thyroxin concentrations in about 75% of patients.

Functioning Endocrine Tumors of the Gastro-Entero-Pancreatic System

Endocrine tumors of the gastro-entero-pancreatic (GEP) system are rare. They are divided into functionally active and inactive tumors. The clinical symptoms of the functionally active tumors are mainly caused by the secretory products released into the circulation. They usually present with metastatic disease, not allowing curative surgical resection. Table III summarizes the leading clinical symptoms/syndromes, the main secretory tumor product, the main primary site of these tumors, and the percentage of malignancy of these tumors. Nearly all of the functionally active tumors express somatostatin receptors. Sst₂ are found in 80 to 90% of them. The therapeutic response to the available somatostatin analogs is correlated with the density of the sst₂ expression of these tumors. Symptoms of most patients are controlled with daily doses of 300 to 450 μ g of octreotide divided into three doses, 20 mg of octreotide LAR once monthly, or 30 mg of lanreotide SR every 10 or 14 days.

Types of GEP Endocrine Tumors

Carcinoid Tumors and Carcinoid Syndrome

Carcinoid tumors behave differently depending on the localization of the primary. For example, appendiceal carcinoids are practically never malignant,

Table III Main Characteristics and Leading Symptoms of GEP Endocrine Tumors

| Tumor | Leading clinical symptoms | Main tumor product | Location of primary tumor | Percentage malignant |
|---|---|--|---|--|
| Carcinoid tumor | Carcinoid syndrome (flushing, diarrhea); dependent on location of primary tumor | Serotonin, tachykinins, histamine, (ACTH, GH-RH, etc.) | Small intestine (20%), bronchial system (15%), appendix (40%), rectum (20%), other locations (5%) | 2–80% (dependent on location of primary tumor) |
| VIPoma (Verner–Morrison Syndrome) | Watery diarrhea, hypokalemia, achlorhydria | VIP | Pancreas | 80–90% |
| Glucagonoma | Necrolytic migratory erythema, diabetes, cachexia | Glucagon | Pancreas | 60% |
| Insulinoma | Hypoglycemia | Insulin | Pancreas | 5–10% |
| Gastrinoma (Zollinger–Ellison Syndrome) | Peptic ulcers, diarrhea | Gastrin | Pancreas (30–60%), duodenum (30–40%), other locations (10–20%) | 60–90% |

whereas midgut carcinoid tumors are more than 80% malignant, and secrete high amounts of serotonin, histamine, tachykinins, and peptides that can cause the carcinoid syndrome. The carcinoid syndrome is a systemic manifestation of the release of tumoral secretion into the systemic circulation, comprising flushing of the face and upper part of the body, diarrhea, cardiac valvular lesions, and wheezing. Somatostatin analogs are indicated only for the treatment of the carcinoid syndrome. Their usefulness in the therapy of functionally inactive carcinoid tumors has not been established. Flushing episodes and diarrhea are improved or resolved in up to 80% of patients during treatment with somatostatin analogs. A significant reduction of the main biochemical marker, urinary excretion of 5-hydroxy-indolic acetic acid (5-HIAA), is observed in up to 70%. The median duration of biochemical response is about 12 months.

Somatostatin analogs have been successfully used to prevent or treat the life-threatening carcinoid crisis, which can be triggered by laparotomy or embolization of liver metastases.

VIPoma (Verner-Morrison Syndrome)

Control of watery, high-volume diarrhea and decrease of elevated levels of circulating VIP can be achieved in 80 to 90% of patients with inoperable VIPoma. Somatostatin analogs are the treatment of choice for symptoms due to the VIP hypersecretion of this tumor type.

Glucagonoma

Necrolytic migratory erythema, diarrhea, mild diabetes mellitus, and protein hypercatabolism are the leading symptoms in patients with the glucagonoma syndrome. Treatment with somatostatin analogs can significantly improve these symptoms.

Insulinoma

Insulinomas express in only about 50% of sst₂. Somatostatin analog therapy will reduce tumoral insulin secretion only in the presence of sst₂. However, in their absence, somatostatin analogs suppress GH and glucagon more pronounced than tumoral insulin, resulting in a worsening of hypoglycemia. The presence or absence of sst₂ can be determined *in vivo* with OctreoScan.

Gastrinoma (Zollinger-Ellison Syndrome)

Somatostatin analogs inhibit gastrin release from tumor cells and suppress gastric acid secretion by a direct effect on the parietal cell. However, with the introduction of proton pump inhibitors, the importance of

somatostatin analog treatment has been reduced. There may be subgroups of malignant gastrinoma patients that could benefit from this treatment.

General Remarks on the Treatment of GEP Endocrine Tumors with Somatostatin Analogs

Tachyphylaxis

Loss of therapeutic effect to somatostatin analog treatment after initial response is a well-recognized phenomenon in patients harboring GEP endocrine tumors. The median duration of response to somatostatin analog therapy is about 12 months, but the beneficial effects can decrease, in a small number of patients, just a few days after initiation of therapy. The loss of response may be overcome by an increase of the dose or a drug-free interval. The mechanism for tachyphylaxis is largely unknown. Interestingly, this phenomenon does not exist in acromegalic patients.

Antiproliferative Effects of Somatostatin Analogs in GEP Endocrine Tumors

In vitro and *in vivo* studies have demonstrated antiproliferative effects of somatostatin analogs. The growth rate of endocrine tumors of the GEP system is in general slow but variable: in addition to long phases of spontaneous tumor standstill or even tumor regression without any treatment, rapid increase in tumor burden have been observed. Using the classical oncological criteria for tumor growth assessment can be misleading. During chronic somatostatin analog treatment, regression of the tumor size is observed in about 10% and stabilization was reported in up to 70%. There are, however, still many open questions such as whether somatostatin analog therapy prolongs survival in patients harboring GEP endocrine tumors, duration of antiproliferative effect, or optimal dose of somatostatin analogs.

Prevention of Complications Following Pancreatic Surgery

Patients undergoing major pancreatic surgery are at high risk of developing postoperative complications related to exocrine secretion such as fistula, fluid collection, and leakage of the anastomosis. Somatostatin analogs temporarily inhibit the exocrine pancreatic secretion. Several double-blind, randomized, placebo-controlled studies have shown that octreotide administered subcutaneously started at least 1 hour before laparotomy and continued for 5–7 days is able to reduce the postoperative complication rate significantly.

Esophageal Variceal Bleeding

More than 50% of patients with liver cirrhosis will develop esophageal varices. About one-third of them will experience variceal bleeding within 2 years of diagnosis. Thirty percent of those who bleed will eventually die as a consequence of the bleeding episode. Somatostatin and its analogs have been shown to decrease the hepatic venous pressure gradient and azygos blood flow in patients with liver cirrhosis. Intravenous infusion of somatostatin or octreotide has been helpful in the management of patients with bleeding varices. Administration shortly after admission to the hospital was able to stop bleeding and to facilitate the endoscopic intervention. Continuation of the infusion for 2–5 days reduced the number of rebleeding episodes and the need for blood transfusions. However, somatostatin or octreotide infusions did not influence the long-term mortality.

Diarrhea

Severe refractory diarrhea may constitute a serious and challenging clinical issue. Diarrhea occurring in conditions such as AIDS, after antitumor chemotherapy or radiotherapy applied to the abdomen or pelvis, or in diabetes mellitus or intestinal graft-versus-host disease may fail to respond to specific antimicrobial treatment. The rationale for the use of somatostatin analogs in diarrhea is based on their effects on the gastrointestinal tract: inhibition of gastrointestinal motility, inhibition of intestinal and exocrine pancreatic secretion, inhibition of gastrointestinal peptides, and induction of net water and electrolyte absorption. The quality of most of the clinical studies performed in these conditions is not optimal and the response rates are highly variable. Well-designed controlled trials with a sufficient sample size are needed to define the value of somatostatin analogs in the treatment of patients with refractory diarrhea.

Diabetic Complications

Endocrine and growth factors that may play a role in the pathogenesis of later stages of diabetic retinopathy and nephropathy include GH, IGF-1, and vascular endothelial growth factor (VEGF). The role of GH for the progression of diabetic retinopathy is especially supported by experimental data and clinical observations. A small controlled trial demonstrated that treatment with octreotide was able to stop or delay the progression of preproliferative diabetic retinopathy. Another study in patients who underwent pan-retinal

laser photocoagulation for proliferative diabetic retinopathy showed that octreotide could decrease neovascularization and prevent vitreous hemorrhages. However, larger controlled studies are needed to confirm these findings.

There were only short-term experimental studies performed for the investigation of the effects of somatostatin analogs in diabetic nephropathy. They demonstrated that octreotide treatment can reduce albuminuria.

Oncological Indications

The rationale for the use of somatostatin analogs for solid nonsecreting tumors is mainly based on three potential mechanisms of action: (1) Many malignant tumors originating from tissue that is free of somatostatin receptors under physiological condition start to express somatostatin receptors at advanced stages. The somatostatin receptor expression is not homogeneously distributed in the nonendocrine tumoral tissues. (2) Growth factors such as IGF-1, GH, or gastrin influence the proliferation rate of several tumors. Somatostatin analogs are potent inhibitors of some of these factors. (3) Octreotide has been shown to possess angiogenesis inhibitory properties.

Cell line experiments but also a series of experiments with transplanted tumors in animals supported the antiproliferative activity of somatostatin analogs. Clinical trials in different adenocarcinomas, including breast and pancreas, were not able to confirm the postulated antitumor effect of monotherapy with the presently available *sst*₂-predominant somatostatin analogs.

Other Clinical Applications

In the mid 1980s, it was hoped that somatostatin analogs would be beneficial for improving blood glucose control in type 1 diabetic patients. The hypothesis was that inhibition of nightly surges of GH secretion would decrease the early morning hyperglycemia known as the dawn phenomenon. Another potential application was the reduction of acute bleeding from gastric or duodenal ulcers, the rationale being the somatostatin-induced decrease of splanchnic blood flow. For both of these two indications, large clinical programs did not demonstrate a benefit of treatment with somatostatin analogs.

The effects of somatostatin analogs were studied in a multitude of other applications. Some of the pilot studies gave positive results, e.g., external pancreatic fistula, hyperinsulinemic hypoglycemia syndromes

of infancy, and hypoglycemia due to overdosage of sulfonylureas. For various reasons, none of them was proposed for a full clinical development.

SAFETY AND TOLERABILITY OF SOMATOSTATIN ANALOGS

Chronic therapy with somatostatin analogs is generally well tolerated. Transitory adverse events frequently seen after initiating somatostatin analog treatment include abdominal discomfort, diarrhea, steatorrhea, nausea, and bloating. They can be explained by the inhibition of the exocrine pancreatic secretion and effects on the motility of the gastrointestinal tract. These adverse drug reactions usually improve without treatment within 10 days, despite continued therapy with somatostatin analogs.

Somatostatin and its analogs inhibit the secretion of hormones involved in carbohydrate metabolism, such as insulin, glucagon, and growth hormone. Furthermore, the absorption of carbohydrates is delayed during somatostatin analog therapy. Long-term treatment with somatostatin analogs seldom leads to overt diabetes mellitus, and the occurrence of hypoglycemia is even rarer.

Formation of cholesterol-rich gallstones occurs in 20–30% of patients on chronic therapy with somatostatin analogs. Only about 1% of them cause symptoms. Their prevalence varies geographically and may be influenced by dietary or racial factors. Reduced gallbladder contractility through inhibition of cholecystokinin and decreased gastrointestinal motility resulting in increased intestinal and biliary production of deoxycholic acid are contributing to the increased prevalence of gallstones.

RADIOLABELED SOMATOSTATIN ANALOGS

In the late 1980s, E. Krenning and S. W. J. Lamberts, in Rotterdam, The Netherlands, together with researchers from the former Sandoz company (now Novartis) developed the concept of targeting ss_{t_2} -expressing tissues with an octreotide derivative coupled with a γ -rays-emitting isotope for diagnostic purposes. The product of their efforts is ^{111}In -linked with a chelating agent to D-Phe-octreotide, which has been marketed under the name OctreoScan since 1994. Somatostatin receptor scintigraphy has proved especially helpful for staging of GEP endocrine tumors. An extension of the use of radioactive isotopes bound to

somatostatin analogs for therapy of tumors with high expression of ss_{t_2} was proposed by the same group. One of the preferred radionuclides for therapeutic purposes is the β -particle emitter ^{90}Y . Compounds using this principle of targeted radiotherapy are being clinically studied.

FUTURE OF SOMATOSTATIN ANALOGS

Somatostatin analogs available for clinical use have been selected from a large number of analogs based on their ability to inhibit pituitary GH secretion, long before somatostatin receptor subtypes were cloned. The therapeutic potential of somatostatin analogs with high affinity for receptor subtypes other than ss_{t_2} is largely unknown. I. Shimon, from S. Melmed's group in Los Angeles, and A. Saveanu, from P. Jaquet's laboratories in Marseille, France, have shown that a combination of an analog with high affinity for ss_{t_2} and one for ss_{t_5} is able to inhibit GH secretion of cell cultures of GH-secreting pituitary adenomas stronger than octreotide or lanreotide alone. An ss_{t_5} agonist—in contrast to ss_{t_2} agonists—also decreased prolactin secretion of prolactinoma cells. These examples, together with the increase in knowledge on specific physiological regulatory roles of the individual somatostatin receptor subtypes and their expression in tumoral and nontumoral tissues, could significantly expand the potential for new applications of ss_{t} selective somatostatin analogs.

Y. C. Patel's group in Montreal, Canada, published data that generated new insights into somatostatin receptor physiology. They demonstrated ligand-induced somatostatin receptor homo- or heterodimerization of ss_{t_1} and ss_{t_5} . In another experiment, they showed that the dopamine receptor D2R and ss_{t_5} can also interact through hetero-oligomerisation. This creates a new receptor with enhanced functional activity.

The findings that there are interactions between somatostatin receptor subtypes and that there is a cross-talk with other G protein-coupled systems creates new opportunities for medicinal chemists. Somatostatin analogs that will be designed considering this knowledge could result in drugs with an increase in the responder rate in the classical somatostatin analog indications, but they could also represent new therapeutic approaches for autoimmune and endocrine diseases. Oncological applications may also become targets for the next generation of somatostatin analogs.

Figure 1 Phylogenetic tree based on the alignment of amino acid sequences of the known preprosomatostatins in vertebrates. The multiple sequence alignment and phylogenetic tree were derived using the public domain ClustalX program with default parameters. The phylogenetic tree in ClustalX uses the neighbor-joining method on a matrix of “distances” between all sequences. The branch lengths are proportional to the estimated divergence along each branch.

products. The PSS-II gene identified in a number of teleost has not been found in tetrapods.

In goldfish brain, three SRIF genes have been identified. Two of them code for PSS-I and PSS-II, whereas the third gene from goldfish brain encodes a precursor (PSS-III) with [Pro²]SRIF-14 at its C terminus. [Pro²]SRIF-14 peptide was first identified in Russian sturgeon and then its cDNA was cloned from African lungfish, pufferfish, zebrafish, and sturgeon. In frog, SRIF-14 and [Pro², Met¹³]SRIF-14 peptides have been isolated and their cDNAs

cloned from brain. In addition, a SRIF-related gene, termed cortistatin (CST), has been described in rat, mouse, and human. The cortistatin precursor contains a tetradecapeptide at its C terminus sharing an 11-amino-acid homologous sequence with SRIF-14. A second SRIF cDNA coding for [Pro²]SRIF-14 was isolated from chicken. These extend the existence of a multigene family for SRIF to tetrapods.

A 22-amino-acid peptide (SRIF-22), which differs from SRIF-14 at 7 of 14 residues, and the cDNA for SRIF-22 have been identified in catfish. The cDNA

sequence for SRIF-22 shows less than 30% similarity to those of the cDNAs for teleost PSS-I and PSS-II.

PHYLOGENETIC RELATIONSHIP OF SOMATOSTATIN GENES

According to phylogenetic analysis based on the amino acid sequence alignment of the known SRIF precursors deduced from the known cDNA or gene sequences (Fig. 1), the vertebrate SRIF genes can be grouped into three major clades. PSS-I genes, which code for the SRIF-14 precursor, are highly conserved from fish to mammals. Anglerfish SRIF-14 precursor and the second zebrafish SRIF-14 precursor show a relatively lower degree of homology to other SRIF-14 precursors in vertebrates. PSS-II from several teleost species are grouped together in a separate clade, except that the PSS-II from *G. petersii* and *C. chitala* share a high level of homology with fish PSS-Is. This suggests that the teleost PSS-II gene is phylogenetically close to the PSS-I gene and the PSS-II from *G. petersii* and *C. chitala* could serve as intermediate forms between the two genes. The precursors of [Pro²]SRIF-14 from several teleost species (goldfish, African lungfish, sturgeon, zebrafish, and pufferfish) are highly homologous to that from chicken (not shown in Fig. 1) and these [Pro²]SRIF-14 precursors also show homology to frog [Pro²,Met¹³]SRIF-14 precursor and mammalian CST precursors. Generally, the PSS-I gene product is widely distributed in brain and peripheral tissues including the gastrointestinal (GI) tract. However, the mammalian CST gene is expressed in a restricted fashion in the brain with functions in neuronal depression and sleep modulation. In frog, [Pro²,Met¹³] gene expression is restricted to the brain. Similarly, the [Pro²]SRIF-14 gene is expressed only in brain of African lungfish. In goldfish, the PSS-I and PSS-II genes are expressed in brain and peripheral tissues, such as the GI tract, whereas the PSS-III ([Pro²]SRIF-14) gene is expressed in brain, but not in the GI tract. The restricted expression of the third SRIF gene in brain supports a close phylogenetic relationship among the members of this gene group.

Multigene families for neuropeptides arise mainly by duplication of individual genes or duplication of the entire genome (e.g., tetraploidization) and subsequent accumulation of mutations. Extreme conservation of the primary structure of SRIF-14 in vertebrates suggests that the SRIF gene likely existed earlier than the appearance of cyclostomes. Notably, SRIF-14 immunoreactivity has been detected in invertebrate species, plant, and *Escherichia coli* extracts. Based on the phylogenetic relationship of SRIF

precursors and the phylogenetic distribution of SRIF forms, a scheme for SRIF evolution has been hypothesized. Duplication of an ancestral SRIF-14-like gene occurred at an early stage of vertebrate evolution. One SRIF-14 gene is conserved throughout vertebrate evolution from cyclostomes to mammals, whereas the other SRIF-14 gene gave rise to the [Ser¹²]SRIF14 gene in cyclostomes, the [Ser⁵]SRIF-14 gene in holocephalians, and the [Pro²]SRIF-14 gene in dipnoans and chondrosteans by accumulation of mutations. In some primitive fish species closely related to dipnoans, from which ancestral amphibians were derived, another duplication of the [Pro²]SRIF-14 gene may have taken place, giving rise to the amphibian [Pro²,Met¹³]SRIF-14 and mammalian CST genes. The [Pro²]SRIF-14 gene is maintained in some primitive fish species (e.g., lungfish, sturgeon), in some teleost species (e.g., goldfish), and in avian species (e.g., chicken). On the other hand, duplication of the SRIF-14 gene in fish gave rise to a gene coding for PSS-II containing [Tyr⁷,Gly¹⁰]SRIF-14 in teleosts.

Figure 1 Organization of spermatogenesis.

in an adluminal compartment containing all later germ cell types. The blood–testis barrier is very important since the milieu in the adluminal compartment differs considerably from serum or interstitial fluid and is stringently controlled by the Sertoli cells. Complex mechanisms allow the germ cells to enter the adluminal compartment without disrupting the blood–testis barrier.

Temporally, the successive changes in developing germ cells follow a very strict time schedule and, as a result, only particular associations of cells are observed in transverse sections of testicular tubules. Such associations are indicated as stages of spermatogenesis. In human, six stages are routinely described. A spermatogenic cycle is the time required to pass through these successive stages (16 days in human). The complete development from spermatogonium to spermatozoon requires approximately 74 days (more than four cycles). Successive stages of spermatogenesis are observed not only on transverse sections but also along the length of testicular tubules (a wave of spermatogenesis). In rats and mice, transverse sections reveal only one particular stage. In human, the situation is more complicated since stages are arranged in an intertwining helical pattern. As a result, single-tubule cross sections may display up to six different stages. Interestingly, studies in rats have revealed that Sertoli cells also undergo cyclic functional changes during progression of the spermatogenic cycle.

FACTORS CONTROLLING QUANTITY AND QUALITY OF SPERM OUTPUT

The final efficiency and quality of sperm production depend on at least three determinants: a genetic program inherent to the germ cells themselves, a number of variables defining maximal spermatogenic capacity, and a series of regulatory factors deciding whether the system is used at maximal capacity or not. This article focuses only on the second and third of these determinants in which hormones play a definite role. The role of factors inherent to the germ cells themselves is probably illustrated most clearly by germ cell transplantation experiments showing that essential characteristics, such as the duration of the spermatogenic cycle, are maintained when rat germ cells are transplanted into a mouse testis.

DETERMINANTS OF MAXIMAL SPERMATOGENIC CAPACITY

The capacity of the testis to produce sperm cells differs considerably from species to species. In human, for instance, total daily sperm production expressed per gram of testis is five times lower than that in rat, rabbit, or rhesus monkey. Maximal spermatogenic capacity depends on the number of germ cells that can be supported by an individual Sertoli cell, the number of Sertoli cells available, the number

of germ cells entering the spermatogenic cycle, and the number of germ cells that become lost during the entire process.

The number of germ cells that can be nurtured by an individual Sertoli cell varies considerably from species to species. It is three times lower in human than in rabbit or rat.

The number of Sertoli cells determines the ultimate ceiling of sperm output and the size of the testis. Sertoli cell proliferation is maximal in the perinatal period and ceases at the time of puberty, concordant with Sertoli cell maturation and the formation of tight inter-Sertoli cell junctions. This explains why, after unilateral orchidectomy or other testicular damage, compensatory hypertrophy is observed only prepubertally. In human, some proliferation may continue throughout the prepubertal period. The most important regulator of Sertoli cell replication is FSH and, accordingly, absent or reduced levels of FSH will limit Sertoli cell numbers, testis size, and sperm output. Research findings indicate that, apart from FSH, thyroid hormone may also affect testicular size. Hypothyroidism in the prepubertal period delays Sertoli cell maturation, prolongs the period of FSH-dependent proliferation, and increases testicular size as well as sperm output.

The number of germ cells entering the spermatogenic cycle depends on species-specific characteristics, such as the number of mitotic divisions at the level of type A spermatogonia and hormonal factors affecting spermatogonial proliferation.

Finally, it is important to know that large numbers of germ cells undergo apoptosis during germ cell development. In rat, cell losses are observed mainly during spermatogonial stages and may exceed 75%. In human, losses seem to be most pronounced during meiosis and may reach as high as 40%. This reduction in germ cells may serve to adapt the number of germ cells to the germ cell supportive capacity of Sertoli cells and may also prevent further progression of (chromosomally) aberrant germ cells through spermatogenesis. Disturbances in the endocrine and local control mechanisms affecting spermatogenesis, however, may markedly increase germ cell apoptosis.

ENDOCRINE CONTROL OF SPERMATOGENESIS

An overwhelming amount of data indicates that gonadotropins are the major hormones controlling spermatogenesis (Fig. 2). Partial or complete inhibition of germ cell production is observed after procedures that

suppress gonadotropins [e.g., hypophysectomy, gonadotropic hormone-releasing hormone (GnRH) agonists or antagonists, immunization against GnRH] or selectively reduce LH (e.g., supraphysiological doses of testosterone in the rat) or FSH (FSH antibodies). None of these procedures is both completely effective and selective, however. Moreover, the effects of a particular intervention may differ depending on the species studied and whether the selected endpoint is initiation, maintenance, or restoration of spermatogenesis. It is safe to say that quantitatively and qualitatively normal spermatogenesis requires both LH (androgens) and FSH, but that the individual actions and interactions of these hormones remain only partially understood. Reports of rare mutations as well as the development of knockout animals have offered additional clues to the relative role of FSH and androgens in spermatogenesis.

FSH and Spermatogenesis

FSH does not act on the germ cells directly but activates specific receptors on the Sertoli cells. The FSH receptor belongs to a large family of membrane receptors that are coupled to G proteins and that are characterized by seven hydrophobic helices forming the transmembrane domain. This family also comprises the receptors for LH and TSH. Ligand binding results in activation of the adenylate cyclase signaling pathway and other signaling pathways and induces a cascade of protein phosphorylations that ultimately mediates the intracellular effects.

As discussed above, FSH is the major factor responsible for the proliferation of Sertoli cells during prepubertal life and accordingly its presence during this critical window is of major importance in determining the ultimate size and spermatogenic capacity of the testis. However, FSH action may not be compulsory for pubertal onset of spermatogenesis and for adult fertility. The most convincing evidence for this contention comes from a report of five Finnish males who are homozygous for a mutation in the FSH receptor gene that severely impairs signal transduction. As expected, these men have reduced testicular volumes but two of them fathered two children each. Semen examination revealed a variable degree of oligozoospermia and teratozoospermia, but none of the five men displayed azoospermia. Very similar observations were made in FSH receptor knockout mice. In these animals also, a lack of FSH action resulted in small testis size and partial spermatogenic failure. Fertility was reduced in one study and normal in

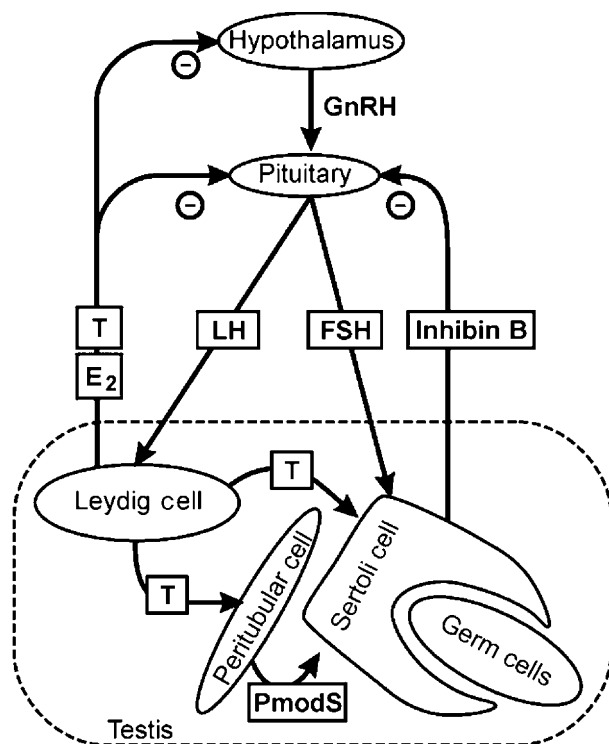

Figure 2 Endocrine control of testicular function.

another. Taken together, these observations suggest that FSH is required for quantitatively and qualitatively normal spermatogenesis, but that, in the presence of normal testicular androgen production, fertility is possible in the absence of FSH action.

Conversely and surprisingly, under some conditions, FSH may be able to maintain spermatogenesis in the presence of low concentrations of androgens. Relevant to this issue is the anecdotal description of a hypophysectomized patient undergoing treatment with testosterone who had normal spermatogenesis despite undetectable levels of gonadotropins and in which spermatogenesis appeared to be maintained by an activating mutation of the FSH receptor.

Stereological studies in rodents as well as in monkeys suggest a major and specific role for FSH in the proliferation of spermatogonia. In addition, FSH seems to favor spermatocyte and round spermatid development, most probably by supporting cell survival. Finally, and in cooperation with testosterone, FSH may promote the release of mature spermatozoa from Sertoli cells. The last two effects might be related to the actions of FSH on cytoskeletal elements and on the specialized Sertoli cell junctional apparatus.

Androgens and Spermatogenesis

Androgens play a key role in the control of spermatogenesis. This key role is probably best illustrated by the fact that androgens alone can restore spermatogenesis and fertility in a number of test systems where FSH is extremely low or absent, including severely hypogonadotropic mice deficient in GnRH (*hpg* mice). Many questions remain, however, regarding the ultimate target cells for androgen action, the concentration of androgens required to maintain spermatogenesis, the exact effects of androgens, and the role played by active androgen metabolites.

Similar to FSH, androgens do not act directly on the germ cells. The effects of androgens are thought to be mediated by the androgen receptor (AR), a member of the nuclear receptor superfamily, and most studies have failed to demonstrate this AR in germ cells. Moreover, transplantation experiments of AR-deficient germ cells ($T^{fm}X/Y$ mice) into the seminiferous tubules of azoospermic mice expressing a functional AR resulted in complete and qualitatively normal donor-derived spermatogenesis. Accordingly, the effects of androgens on spermatogenesis are probably indirect and mediated by somatic testicular cells. Sertoli cells are considered the prime candidates. These cells express the AR, they interact intimately with the developing germ cells, and they control the intratubular environment. Nonetheless, attempts to identify specific genes or molecular events controlled by androgens in Sertoli cells have been rather disappointing and the possibility that androgens have effects on other somatic components of the testis cannot be excluded. Peritubular myoid cells surrounding the seminiferous tubules, for instance, also express AR and some data suggest that under the influence of androgens these cells produce one or more local mediators referred to as "PmodS," modulating Sertoli cell function in an androgen-controlled way.

The maintenance of quantitatively and qualitatively normal sperm production apparently requires intratesticular levels of testosterone that are 20–50 times higher than those observed in the circulation. These high concentrations are normally present in the testis as a result of local production by LH-stimulated Leydig cells. Administration of physiological or slightly suprphysiological amounts of testosterone, however, suppresses LH, reduces these high intratesticular concentrations of testosterone, and suppresses spermatogenesis. It is unclear why spermatogenesis requires such high levels of androgens. Given the low level of 5α -reductase in testicular target cells, testosterone rather than its active metabolite

5 α -dihydrotestosterone (DHT) is considered to be the active androgen in the testis. The absence of DHT formation might explain the need for 3- to 10-fold higher concentrations of testosterone. It is unlikely that this is the only mechanism involved, however. The possibility of other mechanisms reducing androgen sensitivity or alternative pathways of androgen action cannot be excluded.

Stereological approaches to the study of spermatogenesis and particularly the so-called optical disector model have contributed considerably to a more quantitative evaluation of the effects of androgens on germ cell development. In rats, testosterone seems to be essential for the adhesion of round spermatids to Sertoli cells. In its absence, round spermatids are sloughed from the epithelium and spermatid elongation fails. Spermiation also is under the control of testosterone (and FSH) in rat as well as in monkey and human. Studies on the contraceptive effects of testosterone indicate that impairment of spermiation may be a key to achieving azoospermia. Rodent models provide little evidence that androgens promote spermatogonial proliferation. Rather, studies on the restoration of spermatogenesis in irradiated rats suggest that high concentrations of androgens are detrimental to spermatogonial development.

In many target organs, androgen action is mediated by so-called active metabolites. Testosterone can be 5 α -reduced to form DHT, a more potent androgen with a higher affinity for the AR. Alternatively, it can be aromatized to 17 β -estradiol, which can act via one of the estrogen receptors (ER- α or ER- β). As explained above, testosterone is considered to be directly responsible for the maintenance of spermatogenesis under normal conditions. However, under conditions in which intratesticular testosterone levels are reduced, for instance, by the administration of testosterone-based contraceptives, an up-regulation of 5 α -reductase activity has been observed. Similarly, in rats treated with suboptimal concentrations of testosterone, coadministration of a 5 α -reductase inhibitor further impairs the production of mature spermatids. These findings suggest that suppression of intratesticular testosterone may induce a compensatory reaction involving enhanced conversion to DHT. Differences in the ability to activate this reaction could contribute to the observed interracial and interindividual differences in the efficiency of testosterone-based contraceptives.

Along the same lines, there is increasing evidence that aromatization of testosterone to 17 β -estradiol is required for normal spermatogenesis. Aromatase activity and estrogen receptors are widely distributed in the somatic and germinal elements of the testis and in

the efferent ducts. Moreover, fertility defects have been described in mice with a knockout of the ER- α or the aromatase. Some of these defects may be related to defective fluid resorption at the level of the efferent tubules and retrograde accumulation of fluid, causing Sertoli cell dysfunction. Additional sites of action for estradiol, however, seem very likely. Only two men with mutations resulting in aromatase deficiency and one man with a mutated ER- α have been described. Data available are too limited to allow definitive conclusions, but there are indications that here too germ cell development may be impaired.

Interactions of Testosterone and FSH

The data discussed above indicate that both FSH and testosterone affect multiple steps in the spermatogenic process, though to a variable degree. Although under some conditions one of these hormones may maintain spermatogenesis in the absence of the other, qualitatively and quantitatively normal spermatogenesis requires both hormones. Multiple sites of interaction have been identified. Some parameters of Sertoli cell function require both androgens and FSH for maximal expression (e.g., secretion of androgen-binding protein [ABP], expression of N-cadherin) and others (e.g., aromatase activity) are regulated in an opposite fashion by FSH (stimulation) and testosterone (suppression). Different stages of the cycle may display a variable need for either androgens or FSH. In rat Sertoli cells, AR concentration and androgen sensitivity are maximal at stages VII and VIII, whereas FSH effects are more pronounced at stages XII to II. Finally, AR concentration in Sertoli cells is up-regulated by FSH, whereas maturation of Leydig cells and production of androgen are promoted by Sertoli cell-derived paracrine regulators produced under the influence of FSH.

The mechanisms by which androgen- and FSH-induced changes in Sertoli cell function ultimately affect germ cell development also remain far from understood. As already mentioned, both hormones contribute to the development of specific cell-cell contacts that may allow adhesion, migration, and release of germ cells as well as exchange of information and material between Sertoli and germ cells. Furthermore, Sertoli cells control the concentrations of ions, nutrients, and transport molecules responsible for the specific environmental conditions in the adluminal compartment. Finally, FSH and androgens undoubtedly affect the complex network of paracrine communications responsible for bilateral communications between germ cells and Sertoli cells.

CONCLUSIONS

Quantitatively and qualitatively normal spermatogenesis requires both FSH and high local concentrations of androgens. FSH plays a key role in determining the ultimate number of Sertoli cells and the spermatogenic capacity of the testis, but in rodents and in human some degree of sperm production and fertility may be maintained by high concentrations of androgens in the virtual absence of FSH. The reasons for the need for high local concentrations of androgens and the exact role played by active androgen metabolites remain unknown. Androgen-based contraceptives may act both by suppressing intratesticular androgen levels and by lowering FSH. The data available suggest that both FSH and androgens affect germ cell development indirectly by modulating the function of somatic testicular cells and particularly of Sertoli cells. The processes and genes involved are only partially understood but it may be anticipated that approaches such as DNA microarray technology will provide powerful tools to clarify these issues in the near future.

Note. BMI, body mass index; BP, blood pressure. HDL, high-density lipoprotein; WHR, waist/height ratio.

popularly dubbed the “pear” distribution. Once the metabolic syndrome was defined and its boundaries were ratified, it became the subject of intense investigation, particularly investigation of potential mechanisms that might explain the links between hitherto discrete disorders within the syndrome.

The metabolic syndrome is common, affecting up to 20% of Western populations and increasingly so. Each component is prevalent and the key effector processes, such as insulin resistance, are becoming much more frequent, driven by the rapidly rising prevalence of obesity. The changes in the incidence of obesity are too fast to be accounted for by genetic alterations. Instead, they are commonly attributed to the dietary excess and relative sedentary nature of modern urban life, acting on a basic genotype primed by natural selection over millennia of human evolution to avidly retain calories in times of plenty for the inevitable times of famine to come (the thrifty genotype hypothesis). It is estimated that more than 30% of Western populations will have abdominal obesity (waist circumference greater than 40 in. in men and greater than 37 in. in women) within the next 20 years. This is associated with very substantially increased morbidity (type 2 diabetes mellitus, dyslipidemia, hypertension, and heart disease) and mortality. The disorder is more common among men, but women after menopause have an increasing incidence of the metabolic syndrome, which has implicated sex steroid deficiency in its pathogenesis.

THE METABOLIC SYNDROME AND GLUCOCORTICOID

The metabolic syndrome strikingly resembles Cushing’s syndrome, which is caused by circulating

glucocorticoid excess (either due to elevated levels of endogenous cortisol or to exogenous pharmacotherapy). A series of studies suggests that plasma cortisol is subtly elevated in subjects with hypertension, glucose intolerance, and dyslipidemia. However, it has not been possible to reliably document plasma glucocorticoid excess in obesity. Plasma cortisol has a pronounced diurnal rhythm, with concentrations being highest on waking and lowest on retiring to bed. Although in obesity, plasma cortisol levels are sometimes slightly elevated at the diurnal nadir in the afternoon and evening, they are typically low at the morning peak. Thus, although elevated circulating cortisol has been invoked as a cause of the association between some aspects of the metabolic syndrome, it does not explain amplification of the features of the syndrome by obesity. A series of studies has taken an entirely different tack and examined tissue sensitivity to glucocorticoids in obesity and the metabolic syndrome.

TISSUE GLUCOCORTICOID SENSITIVITY

Tissue sensitivity to glucocorticoids is classically determined by the relative density and affinity of intracellular receptors for cortisol. There are two receptors: the lower affinity glucocorticoid receptor (GR) and the higher affinity mineralocorticoid receptor (MR). Both are members of the nuclear hormone receptor superfamily of ligand-activated transcription factors. As far as the metabolic syndrome is concerned, the primary target tissues (liver, adipose tissue, vascular tissue) typically express high levels of GR, although MRs are reported in the heart and vessels too.

The effects of alterations in GR or MR function depend on the tissue concerned. GR mediates the adverse effects of glucocorticoids on glucose and lipid metabolism in liver, adipose tissue, and skeletal muscle. MR may contribute to adverse effects in more selected sites including blood vessels, heart, and kidney. However, both receptors are also involved in glucocorticoid negative feedback control of the hypothalamic–pituitary–adrenal (HPA) axis, which suppresses endogenous glucocorticoid production in the presence of glucocorticoid excess.

“Global” changes in GR function, affecting both peripheral tissues and central HPA feedback sites, may not influence net GR activation because of a compensatory change in glucocorticoid circulating levels, although there may be other consequences. For example, a number of families (fewer than 10) have glucocorticoid resistance due to deleterious mutations of the GR gene. Affected individuals show HPA axis activation, which compensates for the glucocorticoid resistance, but the concomitant elevated adrenocorticotropic hormone levels drive adrenal androgen excess, producing masculinization in females, and elevated deoxycorticosterone levels, which are assumed to be responsible for the hypertension observed. The patients do not have obesity or the metabolic syndrome.

A key finding, however, is that control of glucocorticoid sensitivity is tissue-specific rather than generalized. Thus, there is no correlation between sensitivity to glucocorticoids in tests of vascular responses and HPA feedback. This is perhaps not surprising given the numerous alternative promoters/first exons of the GR gene that show some tissue-associated independence of expression.

A series of studies of patients with components of the metabolic syndrome have suggested increased glucocorticoid sensitivity in some peripheral tissues, notably the vasculature and skeletal muscle. At least in muscle, the change occurs at the level of mRNA expression. Such increased tissue sensitivity in the absence of compensatory decreased cortisol levels, since HPA feedback sensitivity is unaltered, might be anticipated to increase glucocorticoid signaling in the affected organs, producing disease. The overall importance of this change remains to be fully determined.

The possibility of selective changes in HPA feedback sensitivity has been researched in great depth in patients with obesity and the metabolic syndrome. In general, little conclusive evidence has emerged, although some data in obese rats and humans suggest a possible role for MR dysfunction in producing

feedback insensitivity in some such individuals. This is difficult biology to dissect in humans, because of the overriding effects of stress.

11 β -HYDROXYSTEROID DEHYDROGENASE TYPE 1

Recent studies have suggested that the actions of glucocorticoids are determined not only by the concentration of active steroids in the circulation and the tissue density of intracellular GR and MR, but also by prereceptor metabolism by enzymes (Fig. 1). The best understood are the 11 β -hydroxysteroid dehydrogenases (11 β -HSDs). 11 β -HSDs were first identified over 50 years ago. They are microsomal enzymes that catalyze the interconversion of active 11-hydroxy glucocorticoids (cortisol in most mammals including humans and corticosterone in rats and mice) and their inert 11-keto forms (cortisone and 11-dehydrocorticosterone), which do not bind to GR or MR. There are two isozymes of 11 β -HSD that are the products of distinct genes and differ considerably in tissue distribution and function. 11 β -HSD type 2 (11 β -HSD2) has a well-recognized function as a potent dehydrogenase that rapidly inactivates glucocorticoids, thus allowing aldosterone selective access to the otherwise nonselective MR in the distal nephron. Humans or mice homozygous for deleterious mutations of the 11 β -HSD2 gene exhibit the syndrome of apparent mineralocorticoid excess in which cortisol and (or) corticosterone illicitly occupy renal MR, causing sodium retention, severe hypertension, and hypokalemia.

The function of the original 11 β -HSD type 1 (11 β -HSD1) isozyme, though purified and characterized from rat liver almost two decades ago by Monder and his colleagues, has been much less readily discerned. 11 β -HSD1 is highly expressed in liver, adipose tissue, and the central nervous system, but until the 1990s, its function was entirely obscure. The key to understanding the role of 11 β -HSD1 came from studies of its reaction direction in intact cells cultured *in vitro*. Although 11 β -HSD1 shows bidirectional activity in tissue homogenates and purified microsomal preparations, it acts predominantly as a reductase in intact cells transfected with 11 β -HSD1 cDNA. Such cells convert 11-dehydrocorticosterone in the medium to corticosterone and not vice versa. This is not merely due to differential access of 11-hydroxy and 11-keto steroids through the cell membrane, since both steroids can activate reporter genes driven by GR or MR in cells transfected with 11 β -HSD1

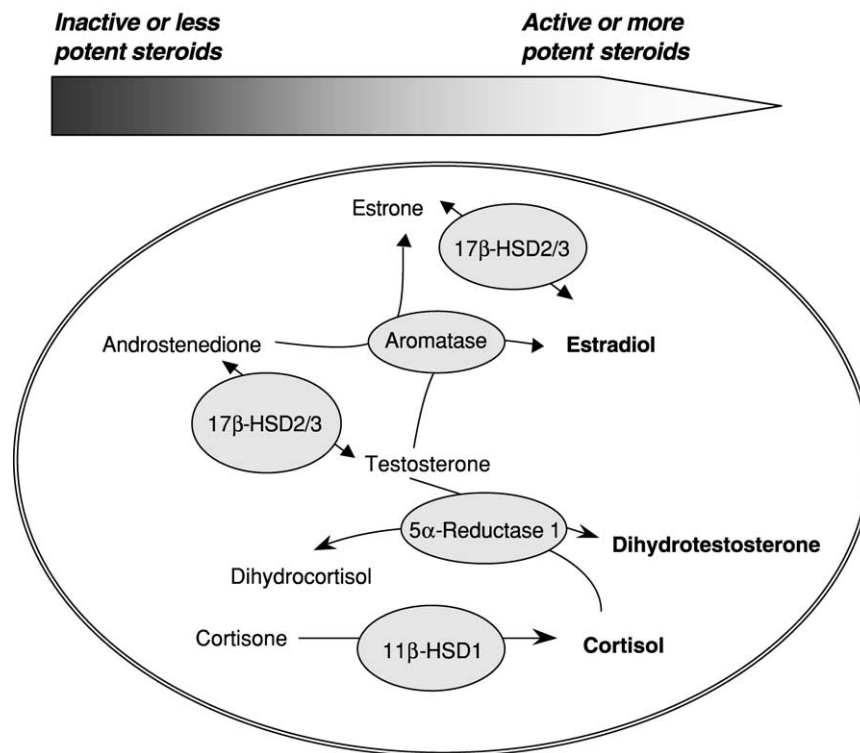

Figure 1 Intracrine conversions of relatively inactive steroids to potent steroids within the adipocyte.

cDNA but only corticosterone activates transcription in the same cell line lacking 11 β -HSD1. This is also not merely an effect confined to clonal cells, since intact primary cultures of hepatocytes, lung cells, neurons, and adipocytes also show predominant 11 β -reduction of inert 11-keto steroids to their active forms. This suggests that it is the subcellular context that is likely to determine 11 β -HSD1 reaction direction in intact cells; presumably the environment in the inner leaflet of the endoplasmic reticulum where the enzyme is thought to lie favors 11 β -reduction. This 11 β -reductase reaction direction, far from inactivating glucocorticoids, regenerates active glucocorticoids in target cells from the substantial levels of inert 11-keto steroids in the blood, themselves produced largely by the actions of renal 11 β -HSD2.

The 11 β -reductase activity of 11 β -HSD1 also predominates in intact organs and *in vivo*. Thus, the intact liver perfused *in situ* converts ~50% of 11-dehydrocorticosterone to active corticosterone on a single pass, whereas dehydrogenation of corticosterone is four- to fivefold lower. Moreover, the liver can activate large amounts of 11-dehydrocorticosterone, suggesting a large turnover of this reaction direction *in vivo*. In humans, reduction also predominates across the liver.

11 β -HSD1 AND THE METABOLIC SYNDROME

Of course, recognizing that key metabolic tissues such as liver and adipose tissue express a glucocorticoid-regenerating enzyme adds a novel dimension to hypotheses of the etiology of the metabolic syndrome–Cushing’s syndrome paradox. A series of studies in genetically obese rat and mouse strains has shown two- to threefold increased activity of 11 β -HSD1 selectively in adipose tissue, and particularly in abdominal adipose tissue, whereas the enzyme is down-regulated in the liver in the same animals. In humans, most but not all studies suggest the same pattern in obese subjects of two- to threefold increased 11 β -HSD1 expression in adipose tissue (in this case, using superficial adipose tissue biopsies, not intra-abdominal fat) and yet decreased enzyme activity in liver.

To examine the pathogenic potential of such increased 11 β -HSD1 in adipose tissue alone, mice that overexpress (two- to threefold) the enzyme in adipose tissue under the fat-specific aP-2 promoter have been generated. These mice are viable but have elevated intra-adipose corticosterone levels, whereas plasma levels of glucocorticoids are unaltered. The

consequences are striking. The mice develop selective abdominal obesity due to marked mesenteric fat hypertrophy and also exhibit glucose intolerance, insulin resistance, dyslipidemia, and hypertension. They also show hyperphagia, though expression of the transgene is confined to adipose tissues. Thus, modest overexpression of 11 β -HSD1 to levels mimicking those seen in obese rodents and humans can faithfully reproduce all key features of the metabolic syndrome.

11 β -HSD1 DEFICIENCY AND PROTECTION FROM METABOLIC DISORDERS

A series of studies with (nonselective) 11 β -HSD inhibitors has suggested that reduced 11 β -HSD1 activity increases insulin sensitivity and/or reduces plasma glucose and perhaps lipid levels in a variety of animal models and humans *in vivo*. Such studies, though interesting, are complicated by the lack of selectivity of the existing licorice-derived inhibitors, which act on both 11 β -HSD isozymes and related steroid dehydrogenases, albeit with much lower affinity. More convincing have been studies in mice homozygous for targeted disruption of the 11 β -HSD1 gene (11 β -HSD1 knockout mice). These animals have clearly shown that 11 β -HSD1 is the sole 11 β -reductase, at least in mice, since adrenalectomized 11 β -HSD1 knockout animals cannot regenerate active corticosterone from inert 11-dehydrocorticosterone. Moreover, the reaction appears to be important since the animals, despite normal or modestly elevated plasma corticosterone levels, resist hyperglycemia associated with stress or a high-fat diet. This appears to be due to attenuated responses of glucocorticoid-sensitive gluconeogenic enzymes in the liver, indicating a reduction in glucocorticoid levels within the hepatocyte. This contention is supported by lower levels of other glucocorticoid-sensitive enzymes in the liver, including those catalyzing the metabolism of lipids. This associates with reduced plasma triglycerides and increased HDL cholesterol levels, producing an apparently “cardioprotective” lipid profile. As predicted, 11 β -HSD1 knockout mice are insulin sensitized, both overall in plasma and in specific cells and tissues, notably liver and adipose tissue. Strikingly, when bred onto an obesity-prone background, 11 β -HSD1 knockout mice are modestly resistant to weight gain on high-fat feeding, an effect that does not appear to be due to altered calorie intake. Overall, the findings suggest that deficiency of this amplifier of intracellular glucocorticoids leads to a beneficial cardio-metabolic

risk factor profile, though whether it actually attenuates cardiovascular outcomes remains an unresolved question.

OTHER GLUCOCORTICOID-METABOLIZING ENZYMES AND THE METABOLIC SYNDROME

There are other glucocorticoid-metabolizing enzymes, the function of which is altered in obesity and metabolic syndrome (Fig. 1). These include the A-ring reductase, 5 α -reductase, and 5 β -reductase, which convert glucocorticoids to dihydro- and tetrahydro-metabolites, which are excreted mainly as conjugates in urine. Increased A-ring reductase activity in obesity may underlie the tendency to lower plasma cortisol levels and compensatory activation of the HPA axis in obesity. The consequences do not necessarily affect GR activation in peripheral tissues, but may include an increased drive to adrenal androgen production. In women, this may underlie the complaint of excessive hair growth in a male pattern (hirsutism), which, in polycystic ovary syndrome, coassociates with other features of the metabolic syndrome and is aggravated by obesity.

AROMATASE

Another key determinant of body fat distribution is the balance between estrogens and androgens in adipose tissues. Estrogen deficiency, for example, after menopause, is associated with a change in fat distribution from a gynecoid (pear-shaped) to an android (apple-shaped) pattern and with increased risk of cardiovascular disease.

Estrogens are produced from androgens by aromatase (Cyp19), which is expressed in the ovaries and also in target tissues including muscle and fat, but not liver. Estrogen action within adipose tissue, thought largely to be mediated via the α -subtype of the estrogen receptor (ER α) in the adipocyte nucleus, is therefore dependent not only on circulating estrogens but also on local production from circulating androgens (Fig. 1). Aromatase is expressed predominantly in subcutaneous adipose beds as opposed to visceral fat. In addition, aromatase influences androgen receptor activation by “consuming” androgen substrates.

The importance of aromatase in determining ER activation is illustrated in a series of clinical paradigms. Premenopausal women generate abundant circulating estrogens from their ovaries. By contrast, men throughout life rely on adipose production of

estrogen from circulating testosterone (from the testes) and androstenedione (from dehydroepiandrosterone produced by the adrenals). These steroids enter adipose tissue, yielding estradiol and estrone. In postmenopausal women, however, ovarian estrogen (and testosterone) production is negligible and androstenedione from the adrenal gland is the major substrate, yielding estrone, which relies on further transformation by 17 β -HSD to estradiol for activation. Paradoxically then, postmenopausal women are more estrogen-deficient than men of a similar age, which is thought to explain the relative protection of men from disorders such as osteoporosis and may explain the “masculinization” of body fat distribution after menopause. A role for aromatase in determining body fat distribution has been further highlighted by the generation of aromatase knockout mice, which have striking abdominal obesity in both genders. There are rare cases of humans with mutations in the aromatase gene and these subjects too are viscerally obese and insulin-resistant. In contrast, a male patient reported with overactivity of aromatase exhibited a feminized (pear-shaped) distribution of body fat. Early studies showed that conversion rates of androstenedione to estrone are increased with increasing body weight but did not characterize subjects according to the distribution of adipose tissue. The use of aromatase inhibitors for breast cancer has been associated with weight gain, although again the specific sites of adipose accumulation have not been defined. Overall, the observations support a role for the generation of active estrogens within adipose tissue in obesity and adipose distribution, but the fine details, notably in human pathology, still remain to be ironed out.

CONCLUSIONS

The metabolic syndrome, its component cardiovascular risk factors, and visceral obesity are all common and highly complex disorders that are undoubtedly caused by the interplay of multiple genetic and environmental influences. Nevertheless, the notion that steroid hormones play central pathogenic roles is attractive and reflects the striking parallels between the phenotype of the metabolic syndrome and Cushing’s syndrome or, less clearly, estrogen/aromatase deficiency. Moreover,

excess steroid production within adipose tissue and perhaps other tissues (liver, muscle) is anticipated to generate a host of downstream effects that contribute to the phenotype. These range from alterations to other local nuclear receptors/transcription factors, such as PPAR α and PPAR γ (the target receptors for fibrates and thiazolidinediones, respectively), insulin sensitivity, and more novel adipose gene products including “adipokines” (leptin, adiponectin, tumor necrosis factor α , and resistin). All are altered in mice with transgenic manipulations of 11 β -HSD1. Exactly how these various effectors interact and the relative role of aromatase and other steroid enzymes remain intriguing future topics for study. The possibility of exploiting drugs that manipulate such intracrine systems is an attractive prospect, heralding more tissue-selective targeting of steroid manipulations than the available generalized treatments with their legion of benefits and detriments.

Figure 1 Structures of the adrenal and sex steroids. The major circulating steroids in humans that bind to receptors are estradiol, cortisol, aldosterone, progesterone, and testosterone. In many androgen-responsive tissues, the metabolism of testosterone by 5 α -reductase yields 5 α -dihydrotestosterone, a more potent androgen.

phylogenetic trees are listed, with the hope that the reader will be tempted to use them in the future.

Central in the evolution of a family of related proteins that bind steroids is duplication of an ancestral steroid receptor gene followed by mutations in each gene, leading to two divergent proteins that can have different steroid-binding properties. One needs to be aware that not all mutations result in noticeable functional changes in a protein. Some mutations are “neutral”; that is, they do not change properties of the protein, as far as can be determined. Deciphering which sequence changes are functionally important is one of the applications of bioinformatics.

Two proteins with a common ancestor are homologues. Genes are either homologous to each other or not; there is no in-between state. Sometimes, mistakenly, percentage homology is used instead of percentage identity in a comparison of two proteins, for example, when two proteins are characterized as being 42% homologous, when they really are 42% identical and 100% homologous. Homologues can be either orthologues or paralogues. Analysis of orthologues and paralogues yields important information on the evolution of structure and function in steroid receptors and other proteins. Orthologues are the same gene in different organisms, for example, the estrogen receptor in humans, rats, and frogs. Analysis of orthologues illuminates how a protein evolved in response to different environmental conditions in the host organism. Thus, in fish, which are cold-blooded animals, the estrogen receptor is optimized to bind estradiol at a lower temperature than the estrogen receptor in mammals. This difference is reflected in the sequence in the estrogen-binding domain. Paralogues are genes that arise from

gene duplication and divergence. The paralogous androgen and progesterone receptors arose by a duplication of an ancestral gene. It is after this duplication that more complex regulation of androgen and progestin action evolved.

How can one determine whether two proteins are homologous? This is accomplished with computer programs that align the two protein's amino acid sequences and determine the percentage of identical amino acids and of conservative replacements. The latter are amino acids with similar properties, such as arginine/lysine or aspartic acid/glutamic acid. A variety of statistical algorithms are available to convert these data into a quantitative measure of similarity. Although either amino acid or nucleic acid sequences can be used, amino acid sequences, which have a 20-letter alphabet, are more sensitive to distant relationships than nucleic acid alignments, which have only a 4-letter alphabet. Various alignment programs are available on the Internet. One of the most popular is BLAST, which takes the sequences of two proteins (either the amino acid sequence or the DNA sequence), aligns them, and then calculates the probability of finding two proteins with such similarity by chance based on the number of proteins in the database (GenBank contains sequence data for approximately 900,000 proteins).

To analyze the evolution of steroid receptors, one needs a phylogenetic tree that depicts the relationships between the different steroid receptors from different animals. Just as in constructing a family tree, where one tries to obtain records of births and marriages that cover many generations, the most useful phylogenetic tree is one that contains steroid receptors from animals

that arose from the earliest times to the most recent. In this regard, it is fortunate that in the past few years, the sequences of steroid receptors from fish, amphibians, reptiles, birds, and mammals have been determined. This allows steroid receptor evolution close to the origins of vertebrates approximately 530 million years ago to be examined. Such a phylogenetic tree will be used to investigate the diversification of the steroid response in vertebrates.

The Internet contains a variety of computer programs, such as ClustalW and PHYLIP, that can construct a phylogenetic tree from a collection of sequences. However, analysis of steroid receptor evolution is not that simple. Steroid receptors are mosaics of functional domains, each of which is changing at a different rate, as was discovered in 1985 and 1986, when the glucocorticoid receptor (GR) and human estrogen receptor (ER) were cloned and sequenced. In the middle of each sequence is an ~65-amino-acid segment containing two sets of four cysteine residues complexed with zinc in a characteristic zinc finger motif. These two "zinc-fingers" bind DNA in the GR, ER, and other steroid receptors. At the C terminus is an ~250-amino-acid segment that binds the steroid. The DNA-binding domains on the GR and ER are well conserved; their amino acid sequences are approximately 60% identical. As expected, there is much less amino acid sequence identity—approximately 25%—in the steroid-binding domain on the ER and GR because estrogens and glucocorticoids have important structural differences. Subsequent sequencing of the progesterone receptor (PR), androgen receptor (AR), and mineralocorticoid receptor (MR) revealed that all adrenal and sex steroid receptors have a similar overall structure and there is much more sequence variation in the steroid-binding domain than in the DNA-binding domain. The domains at the amino terminus and the sequence between the DNA- and steroid-binding domains are changing even more rapidly than is the steroid-binding domain. An analysis of the entire steroid receptor sequence will be an average of the evolutionary rates of the various domains. This can obscure the evolution of the steroid-binding domain and the understanding of how the response to different steroids evolved. Another reason for using the steroid-binding domain is that it provides better resolution of the branches compared to the DNA-binding domain, which has a shorter sequence and is changing very slowly.

NUCLEAR RECEPTORS

To obtain a more complete understanding of steroid receptor evolution, steroid receptor homologues that

bind ligands with structures that differ from that of adrenal and sex steroids are included in the analysis. The idea that steroid receptors are a subset of a larger family of ligand-regulated transcription factors arose in 1986 with the surprising discovery that the thyroid hormone receptor is homologous to steroid receptors. Soon other receptors were found with a DNA-binding domain containing a zinc-finger motif and a ligand-binding domain at the C terminus. This includes receptors for retinoids, 15-deoxy- $\Delta^{12,14}$ -prostaglandin J₂, ecdysone, and 1,25-dihydroxyvitamin D₃. Since all of these receptors act in the cell nucleus, the term nuclear receptors was used to describe this protein superfamily, which contains hundreds of different proteins. Nuclear receptors are an ancient family that is found in invertebrates and vertebrates. However, sequence searches of the complete genomes of *S. cerevisiae* and *A. thaliana* show that neither genome has a protein with the zinc-finger motif characteristic of nuclear receptors. Thus, nuclear receptors arose in multicellular animals, in which they regulate a diverse set of physiological processes. Indeed, the nuclear receptor family is an excellent example of how gene duplication and divergence can lead to a family of proteins that respond to ligands with very different structures, providing flexibility in the regulation of gene transcription (see Fig. 2). In this article, some ligand-binding nuclear receptors are included in the phylogenetic analysis of adrenal and sex steroid evolution to explore their position in the nuclear receptor family.

WHEN DID STEROID RECEPTORS EVOLVE?

In 1997, Escriva *et al.* used polymerase chain reaction (PCR) to investigate the presence in vertebrates and invertebrates of genes with sequences that are homologous to DNA-binding domains of steroid receptors as well as other nuclear receptors. They used the DNA-binding domain on steroid receptors because it is changing very slowly, which makes it a good probe for finding homologues in organisms that diverged from a common ancestor over 600 million years ago. PCR with the zinc-finger domain clearly showed that nuclear receptors are present in invertebrates, including jellyfish, which are very simple invertebrates. However, genes with similarity to the DNA-binding domain of steroid receptors were restricted to vertebrates. In particular, Escriva *et al.* found evidence for the AR, ER, and GR in sharks, a cartilaginous fish, and the PR in hagfish, which diverged from the vertebrate line earlier than lamprey, the other jawless fish. The presence of the PR in hagfish

Figure 2 Other ligands for nuclear receptors. Thyroid hormone, 1,25-hydroxyvitamin D₃, all-*trans*-retinoic acid, 9-*cis*-retinoic acid, 15-deoxy- $\Delta^{12,14}$ -prostaglandin J2, and ecdysone bind with high affinity to nuclear receptors that are distantly related to the adrenal and sex steroid receptors.

places the origin of adrenal and sex steroid receptors in the Early Cambrian, approximately 540 million years ago, when ~35 phyla of multicellular animals appear in the fossil record. Steroid receptors are a “recent” evolutionary innovation, when one considers that unicellular eukaryotes arose at least 2 billion year ago and that plants and animals diverged from a common ancestor approximately 1.2 billion years ago. This means that the steroid response was integrated into what already was a sophisticated and robust signaling network for regulating differentiation, development, homeostasis, and reproduction. Steroid receptors assumed some activities that were regulated by other transcription factors, for example, the regulation by androgen and estrogen of spermatogenesis and oogenesis in vertebrates.

PHYLOGENETIC ANALYSIS OF ADRENAL AND SEX STEROID RECEPTORS

Figure 3 shows the phylogeny of the ligand-binding domain of adrenal and sex steroid receptors and that of some other nuclear receptors. Sites of gene

duplications are labeled. The lengths of the branches after each duplication are proportional to the changes in the receptor sequence. By adding the numbers between two branches, one can determine how fast a given receptor type is changing over time or how close two receptors are to each other. For example, the AR in frog and the AR in human are 9.2 units distant from each other. In contrast, the GR in frog and the GR in human are 18.2 units from each other, indicating that the GR is changing more rapidly in land animals than is the AR, as was shown by Thornton and Kelley in 1998.

A overview of the steroid receptor tree reveals that the adrenal and sex steroid receptors are a distinct clade in the nuclear receptor family, well separated from receptors for 1,25-dihydroxyvitamin D₃, ecdysone, thyroid hormone, and retinoids. The adrenal and sex steroid receptors appear to have evolved in jawless fish or a protochordate, which is consistent with the PCR data of Escriva *et al.*

Steroid receptors can be further subdivided. The ER is on one branch that subdivides at node I into ER- α and ER- β . In a separate group are the AR, PR, GR, and MR. The PR and AR cluster on one branch and the GR and

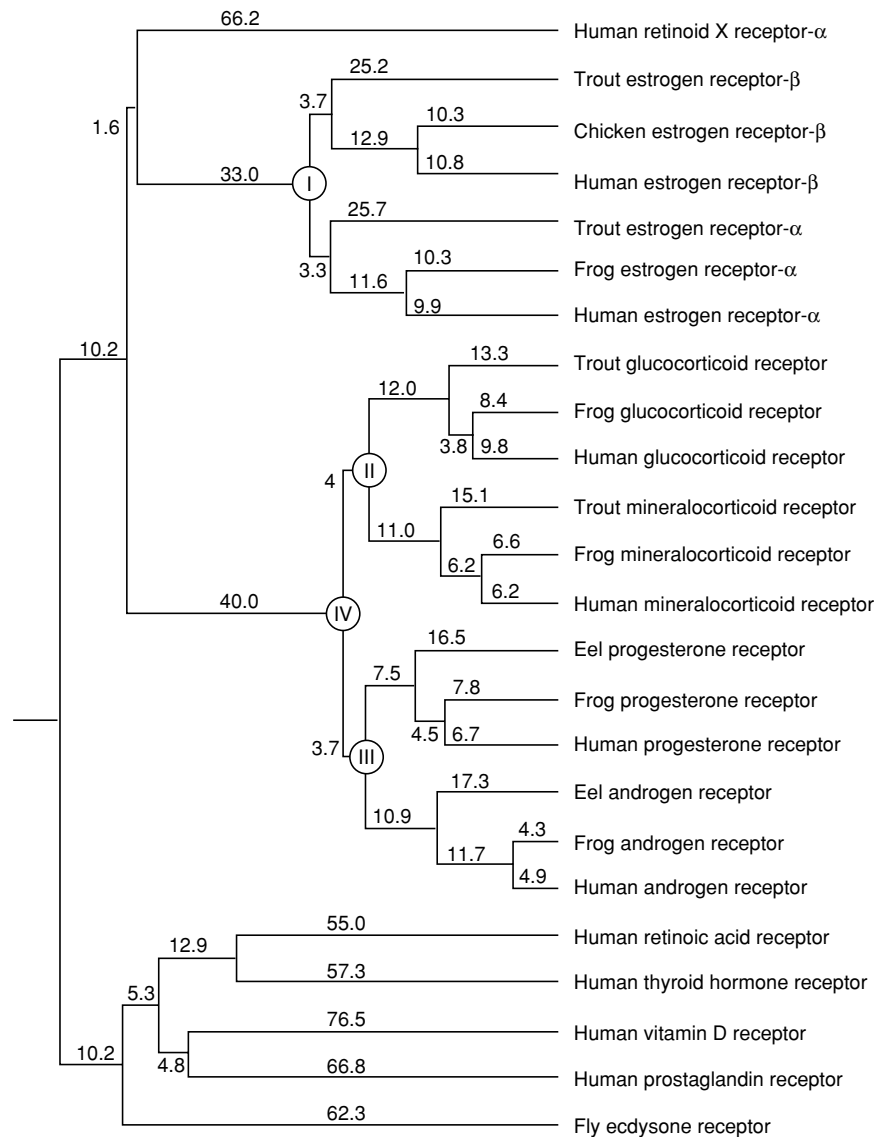

Figure 3 Evolution of the adrenal and sex steroid receptors and other nuclear receptors. The adrenal and sex steroid receptors form a separate clade in the nuclear receptor family. The estrogen receptor is closest to the duplication that led to the separation of estrogen from the Δ^4 steroids. This suggests that the estrogen receptor is most ancient of the adrenal and sex steroid receptors. Further duplications and sequence divergence led to ER- α and ER- β and the formation of the GR, MR, PR, and AR.

MR cluster on another branch. The phylogenetic grouping of the AR, PR, GR, and MR and their subdivision correlates nicely with their transcriptional and steroid-binding properties. The AR, PR, GR, and MR can bind to the same DNA sequence in the nucleus to regulate gene transcription. The AR and PR have similar recognition for some steroids; that is, some progestins have androgenic activity. Similarly, the MR binds glucocorticoids, such as cortisol and corticosterone, with an affinity similar to that of aldosterone, the main mineralocorticoid in humans.

STEROID RECEPTORS AND THE ORIGINS OF VERTEBRATES

The distances between the branches at the duplications in the ER, AR, PR, GR, and MR are short, which indicates diversification by a series of closely spaced (on a geological timescale) gene duplications. It is thought that two genome-size duplications occurred early in the evolution of vertebrates, before the evolution of fishes with jaws. Each genome-size duplication substantially increased the raw material

for diversification of protein function and complex regulatory networks that are characteristic of vertebrates. Analysis of the chromosomal location of steroid receptors indicates that it is likely that they formed during these genome-size duplications. Indeed, the diversification of steroid responses mediated by the ER, AR, PR, GR, and MR probably contributed a selective advantage to ancestral vertebrates during and after the Cambrian explosion.

WHAT WAS THE ANCESTRAL STEROID RECEPTOR?

The tree shows that the branch leading to the ER from the ancestral steroid receptor is shorter than the branch leading to the AR, PR, GR, and MR, indicating a slower change in the ER sequence since their separation. This suggests that the ER was under functional constraints during this time, which is consistent with the estrogen response being the most ancient of the adrenal and sex steroid responses. Thornton cloned the ER, PR, and GR from lamprey, a jawless fish, which has ancestors in the Cambrian period from 550 to 535 million years ago. Thornton clearly showed that the ER is the most ancient of the adrenal and sex steroid receptors. However, the identity of the steroid(s) that regulated the action of the primitive ER is not known. It could have been estradiol or a Δ^5 androgen, both of which bind with high affinity to human ER, or it could have been another steroid or a ligand with a nonsteroidal structure. This question of the identity of ancestral steroids will be explored further in the analysis of other steroid receptors.

STEROID RECEPTOR EVOLUTION IN FISH AND LAND VERTEBRATES

Figure 3 shows that the rate of change in the sequence, or “molecular clock,” of the hormone-binding domain is not uniform among the various vertebrate steroid receptors. Considering that humans and amphibians diverged from a common ancestor approximately 350 million years ago and that teleosts, fishes with jaws, arose approximately 425 million years ago, the branch lengths between the sequences of the hormone-binding domain in steroid receptors among various land animals are much shorter than said branch lengths between fish and amphibians. This indicates that there was a reduction in the rate of change in the steroid-binding domain in land animals compared to fish. This sequence divergence correlates with differences in ligand specificity between fish and land

vertebrate steroid receptors. Among the adrenal and sex steroid receptors, the hormone-binding domain of the AR has been most conserved and the hormone-binding domain of the GR has been least conserved since the separation of amphibians and humans from a common ancestor.

RECEPTOR DIVERSIFICATION AND PHYSIOLOGICAL RESPONSES

Glucocorticoid and Mineralocorticoid Receptors

The length of the branches in the GR/MR clade indicates that the duplication at node II leading to the MR and GR arose in jawless fish or earlier. In land vertebrates, the MR regulates electrolyte balance under the influence of aldosterone. Aldosterone is not found in most fish. It is in amphibians that aldosterone assumes the role of a mineralocorticoid, regulating electrolyte transport. In fish, cortisol regulates electrolyte transport. It is not known whether cortisol acts exclusively in fish through the MR to regulate electrolyte transport or whether this is accomplished by binding of cortisol to either the GR or the MR.

The evolution of the MR from a GR ancestor is consistent with the steroid specificity of mammalian MR. When recombinant human MR became available for analysis of steroid specificity, it was unexpectedly found to bind cortisol, corticosterone, and aldosterone with similar affinity, clearly showing the similarity of the MR to the GR. The high affinity of the MR for glucocorticoids has led to an alternative name, GR type 1, which also reflects the role of this receptor in mediating responses to glucocorticoids in some tissues, where aldosterone is not likely to regulate electrolyte balance, such as the brain. GR type 2 is the classical glucocorticoid receptor.

Evolutionary analysis of the GR type 1/type 2 can explain the presence of the MR in tissues that are not involved in electrolyte balance; it predicts that in a primitive vertebrate, GR type 1 regulated responses in the brain and these remain under its regulation. Later, in land animals, GR type 1 assumed exclusive regulation of the mineralocorticoid response. It also predicts that the GR type 1 sequence will change more slowly in land animals than the GR type 2 sequence. This is clearly seen in the shorter branches for GR type 1 (MR) in amphibians and mammals compared to GR type 2 in these animals as shown in Fig. 3. The requirement that the MR respond to aldosterone in kidney and gut, and to corticosterone and cortisol in brain and other tissues with GR type I/type II

physiology, puts constraints on changes in the MR sequence.

Androgen and Progestin Receptors

The AR/PR clade also has an origin in a jawless fish or earlier, such as a cephalochordate (modern example: amphioxus) or urochordate (modern example: tunicate). The lengths of the branches indicate a substantial sequence change in the fish AR, in contrast to the slow change of the AR in land animals. Similarly, the fish PR has mutated more than the PR in land animals. The identity of the steroid(s) that regulated the action of the ancestor at node III is unknown. It may have been an androgen or a progestin or both. It is likely that the proto-AR/PR had lower binding affinity and less specificity for its ligand(s) than is found in current AR and PR. Over time, after the gene duplication, these receptors evolved toward higher affinity and greater specificity for their cognate steroids, leading to a division of function between androgens and progestins. A similar division of function occurred in the MR/GR clade. Evolution leading to a division of function provides increased flexibility for specific regulation of gene expression.

It is likely that the ancestral receptor recognized steroids that differ from the active androgens or progestins in mammals because fish and mammals have different circulating androgens and progestins. In most fish, the major circulating androgen is

11-ketotestosterone (see Fig. 4). In land animals, the main circulating androgen is testosterone, which is biologically active. In addition, in some tissues, testosterone is metabolized to 5 α -dihydrotestosterone, a more potent androgen. In fish, progestins with 17 α -hydroxyl substituents have high affinity for the PR. In contrast, in birds and mammals, steroids with 17 α -hydroxyl substituents (e.g., 17 α -hydroxyprogesterone, cortisol) have an affinity for the PR that is less than 1% of that of progesterone. Thus, in the evolution from fish to land animals, there was a change in steroid specificity for androgens and progestins.

Estrogen Receptors α and β

The ER- α and ER- β branches appear to converge in a jawless fish. The duplication of ER- α and ER- β is interesting because it is ancient, yet the two genes have been conserved in an active form despite the fact that there are no major differences in steroid binding. In mammals, there are differences in the tissue-specific expression of these receptors. For example, ER- β is found in prostate. Clearly this function and certain other estrogen-dependent activities in tissues such as the placenta were not the function of either ER- α or ER- β in fish. Indeed, the ancestral GR, MR, and AR also are likely to lack functions that their orthologues have in land animals. This illustrates an important practical insight from evolutionary analyses. Modern

Figure 4 Steroids that are active in fish. Testosterone, 11-ketotestosterone, and 5 α -dihydrotestosterone have high affinity for the fish androgen receptor. However, the main androgen in fish is 11-ketotestosterone. In mammals, the biologically active androgens are testosterone and 5 α -dihydrotestosterone. In fish, 17 α -hydroxyprogesterone, 17 α ,20 β -hydroxyprogesterone, and progesterone bind to the progesterone receptor. However, it is 17 α ,20 β -hydroxyprogesterone that induces the final stages of spermatogenesis in fish. In contrast to fish, in mammals, 17 α -hydroxyprogesterone and other steroids with 17 α -hydroxy substituents have less than 1% of the affinity for the progesterone receptor than that of progesterone.

proteins could not have had some of their modern-day functions early in their evolution. Are some of these ancient functions still important in humans? That is, the reproductive functions of estrogens, androgens, and progestins may be only part of their actions in mammals. In the past decade, it has become clear that the “canonical” functions of steroids are not their only activities. Just as the MR or GR type 1 is important in the hippocampus, so the ER has important actions in the brain. Indeed, estrogens have been implicated in maintaining cognitive function and prevention of Alzheimer’s disease. The ER may have been important in the brain in a primitive vertebrate with a simple body plan, lacking the organs found in sharks, bony fish, and land animals.

Indeed, the cloning of receptors for adrenal and sex steroids in animals such as lamprey, hagfish, and amphioxus and the study of where these receptors are expressed and how expression is regulated will provide clues to their ancient functions. This information is likely to be relevant to less-well-studied functions and even unknown functions of adrenal and sex steroids in humans and other modern organisms.

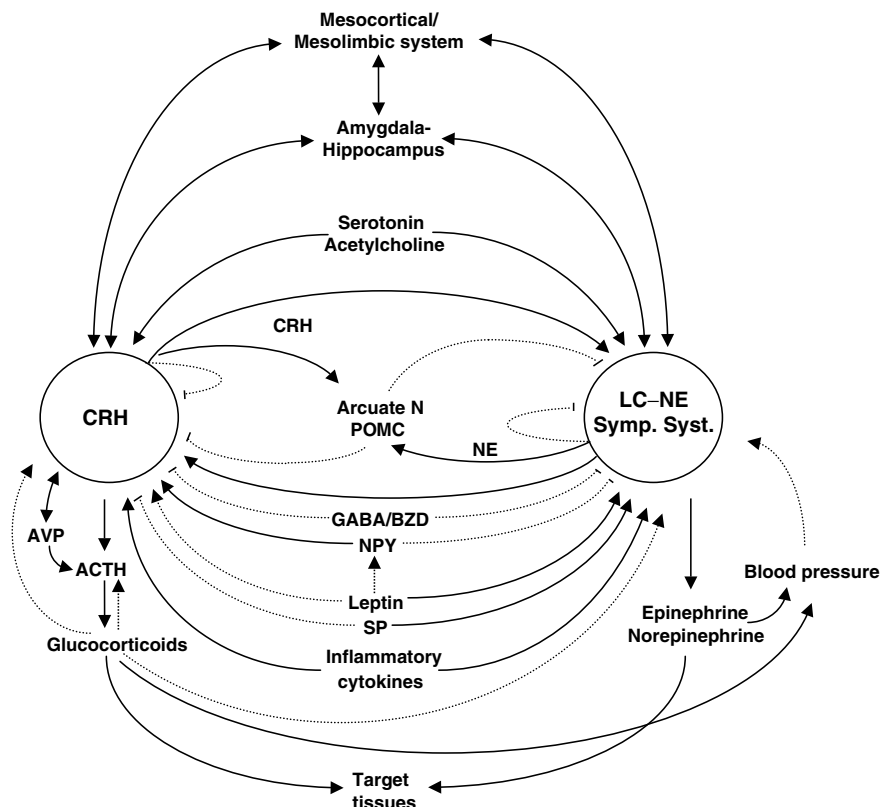

Figure 1 A simplified schematic representation of the central and peripheral components of the stress system, their functional interrelations, and their relationships to other central systems involved in the stress response. The CRH–AVP neurons and central catecholaminergic neurons of the LC–NE system reciprocally innervate and activate one another. The HPA axis is controlled by several feedback loops that tend to normalize the time-integrated secretion of cortisol, yet glucocorticoids stimulate the fear centers in the amygdala. Activation of the HPA axis leads to suppression of the GH/insulin-like growth factor-I, luteinizing hormone/testosterone/estradiol, and TSH/triiodothyronine axes; activation of the sympathetic system increases interleukin-6 secretion. Solid lines indicate stimulation; dashed lines indicate inhibition. BZD, benzodiazepine; GABA, γ -aminobutyric acid; NPY, neuropeptide Y; SP, substance P. Modified from Chrousos (1992).

The Hypothalamic–Pituitary–Adrenal Axis

The hypothalamus controls the secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary, which, in turn, stimulates the secretion by the adrenal cortex of glucocorticoid hormones, mainly cortisol in humans. The principal hypothalamic stimulus to the pituitary–adrenal axis is CRH, a 41-amino-acid peptide first isolated in 1981 by Wylie Vale. AVP is a potent synergistic factor with CRH in stimulating ACTH secretion; however, AVP has little ACTH secretagogue activity by itself. Furthermore, it appears that there is a reciprocal positive interaction between CRH and AVP at the level of the hypothalamus, with each neuropeptide stimulating the secretion of the other.

In nonstressful situations, both CRH and AVP are secreted in the portal system in a circadian, pulsatile

fashion, with a frequency of approximately two to three secretory episodes per hour. Under resting conditions, the amplitude of the CRH and AVP pulses increases in the early morning hours, resulting finally in ACTH and cortisol secretory bursts in the general circulation. These diurnal variations are perturbed by changes in lighting, feeding schedules, and activity and are disrupted by stress.

During acute stress, the amplitude and synchronization of the CRH and AVP pulsations in the hypothyseal portal system markedly increase, resulting in increases in ACTH and cortisol secretory episodes. Depending on the type of stress, other factors such as AVP of magnocellular neuron origin, angiotensin II, and various cytokines and lipid mediators of inflammation are secreted and act on hypothalamic, pituitary, or adrenal components of the HPA axis, potentiating its activity.

Circulating ACTH is the key regulator of glucocorticoid secretion by the adrenal cortex. Other hormones or cytokines, either originating from the adrenal medulla or coming from the systemic circulation, as well as neuronal information from the autonomic innervation of the adrenal cortex may also participate in the regulation of cortisol secretion.

Glucocorticoids are the final effectors of the HPA axis and participate in the control of whole-body homeostasis and the organism's response to stress. They play a key regulatory role on the basal activity of the HPA axis and on the termination of the stress response by acting at extrahypothalamic centers, the hypothalamus, and the pituitary gland. The inhibitory glucocorticoid feedback on the ACTH secretory response acts to limit the duration of the total tissue exposure to glucocorticoids, thus minimizing the catabolic, anti-reproductive, and immunosuppressive effects of these hormones.

Glucocorticoids exert their effects through their ubiquitous cytoplasmic receptors. On ligand binding, the glucocorticoid receptors translocate into the nucleus, where they interact as homodimers with specific glucocorticoid-responsive elements within the DNA to activate appropriate hormone-responsive genes. The activated receptors also inhibit, through protein-protein interactions, other transcription factors, such as c-jun/c-fos, and nuclear factor κ B, which are positive regulators of the transcription of several genes involved in the activation and growth of immune and other cells. Furthermore, glucocorticoids change the stability of mRNAs and hence the translation of several glucocorticoid-responsive proteins, as well as the electrical potential of neuronal cells.

The Autonomic Axes

The autonomic nervous system provides a rapidly responding mechanism to control a wide range of functions. Cardiovascular, respiratory, gastrointestinal, renal, endocrine, and other systems are regulated by the sympathetic nervous system or the parasympathetic system or both. Interestingly, the parasympathetic system may assist sympathetic functions by withdrawing and can antagonize them by increasing its activity.

Sympathetic innervation of peripheral organs is derived from the efferent preganglionic fibers, whose cell bodies lie in the intermediolateral column of the spinal cord. These nerves synapse in the bilateral chains of sympathetic ganglia with postganglionic sympathetic neurons that richly innervate the smooth

muscle of the vasculature, the heart, the skeletal muscles, the kidney, the gut, fat, and many other organs. The preganglionic neurons are cholinergic, whereas the postganglionic neurons are mostly noradrenergic. The sympathetic system also has a humoral contribution, providing most of the circulating epinephrine and some of the norepinephrine from the adrenal medulla. In addition to the classic neurotransmitters acetylcholine and norepinephrine, both sympathetic and parasympathetic subdivisions of the autonomic nervous system contain several subpopulations of target-selective and neurochemically coded neurons that express a variety of neuropeptides and, in some cases, ATP, nitric oxide, or lipid mediators of inflammation. Interestingly, CRH, neuropeptide Y, and somatostatin are colocalized in noradrenergic vasoconstrictive neurons. Transmission in sympathetic ganglia is also modulated by neuropeptides released from preganglionic fibers and short interneurons (e.g., enkephalin, neurotensin), as well as from primary afferent collaterals (e.g., substance P).

REGULATION OF THE STRESS RESPONSE

The orchestrated interplay of several neurotransmitter systems in the brain underlies the characteristic phenomenology of behavioral, endocrine, autonomic, and immune responses to stress. These transmitters include CRH, AVP, opioid peptides, dopamine, and norepinephrine.

CRH-AVP

Shortly after its isolation, it became apparent that CRH was implicated in other components of the stress response, such as arousal and autonomic activity. Supportive evidence was derived from intracerebroventricular or selective brain administration of CRH in rodents and nonhuman primates, which precipitated several coordinated responses characteristic of stress. Moreover, administration of CRH peptide antagonists into selected areas of the brain suppresses many aspects of the stress response. Finally, CRH type 1 receptor knockout mice were shown to have a markedly deficient ability to mount an effective stress response.

CRH and CRH receptors were found in many sites in the brain outside of the hypothalamus, including parts of the limbic system and the central arousal sympathetic systems (LC-sympathetic systems) in the brainstem and spinal cord. Stress is a potent general

activator of CRH release from the hypothalamus and extrahypothalamic sites. The mechanisms via which stress stimulates CRH neurons are unclear. Whether CRH or another transmitter (e.g., NE) is upstream in eliciting the neurocircuitry of stress remains to be determined.

CRH-binding sites are also found in various peripheral tissues, such as the adrenal medulla, heart, prostate, gut, liver, kidney, and testes. CRH receptors belong to the G protein-coupled receptor superfamily and CRH binding stimulates the intracellular accumulation of cyclic AMP. Two distinct CRH receptor subtypes, designated CRH-R1 and CRH-R2, have been characterized, encoded by distinct genes that are differentially expressed. CRH-R1 is the most abundant subtype found in the anterior pituitary and is also widely distributed in the brain. CRH-R2 receptors are expressed mainly in the peripheral vasculature and the heart, as well as in subcortical structures in the brain.

Locus Ceruleus–NE System

The locus ceruleus and other noradrenergic cell groups of the medulla and pons are collectively known as the LC–NE system. Brain epinephrine serves globally as an alarm system that decreases neurovegetative functions, such as eating and sleeping, and that contributes to accompanying increases in autonomic and neuroendocrine responses to stress, including HPA axis activation. NE also activates the amygdala, the principal brain locus for fear-related behaviors, and enhances the long-term storage of aversively charged emotional memories in sites such as the hippocampus and striatum.

Reciprocal neural connections exist between the CRH and catecholaminergic neurons (LC–NE neurons) of the central stress system, with CRH and norepinephrine stimulating each other, the latter primarily through β_1 -noradrenergic receptors. There is an ultrashort autoregulatory negative feedback loop on the CRH neurons exerted by CRH itself, just as there is a similar loop in the LC–NE neurons, by way of presynaptic CRH and α_2 -noradrenergic receptors, respectively. There is also parallel regulation of both central components of the stress system by other stimulatory and inhibitory neuronal pathways. Several neurotransmitters, including serotonin and acetylcholine, excite CRH and the LC–NE neurons. The negative feedback controls include glucocorticoids, γ -aminobutyric acid, corticotropin, and several opioid peptides, which inhibit both CRH and LC–NE neurons.

BODY SYSTEMS' RESPONSES TO STRESS

HPA Axis–Immune System Interactions

It has been known for several decades that stress, whether inflammatory, traumatic, or psychological, is associated with concurrent activation of the HPA axis. In the early 1990s, it also became apparent that cytokines and other humoral mediators of inflammation are potent activators of the central stress response, constituting the afferent limb of a feedback loop through which the immune–inflammatory system and the CNS communicate.

All three inflammatory cytokines, tumor necrosis factor α , interleukin-1 β (IL- β), and interleukin-6, can cause stimulation of the HPA axis alone or in synergy with one another. There is evidence to suggest that IL-6, the main endocrine cytokine, plays the major role in the immune stimulation of the axis, especially in chronic inflammatory stress.

Some of the activating effects of cytokines on the HPA axis may be exerted indirectly by stimulation of the central catecholaminergic pathways. Also, activation of peripheral nociceptive, somatosensory, and visceral afferent fibers would lead to stimulation of both the catecholaminergic and CRH neuronal systems via ascending spinal pathways. Other inflammatory mediators, such as eicosanoids, platelet-activating factor, and serotonin, may also participate in the activation of the HPA axis, via autocrine/paracrine and/or endocrine effects.

Conversely, activation of the HPA axis has profound inhibitory effects on the inflammatory immune response because virtually all the components of the immune response are inhibited by cortisol. Alterations of leukocyte traffic and function, decreases in production of cytokines and mediators of inflammation, and inhibition of the latter's effects on target tissues are among the main immunosuppressive effects of glucocorticoids.

The efferent sympathetic/adrenomedullary system apparently participates in a major fashion in the interactions of the HPA axis and the immune/inflammatory reaction by being reciprocally connected with the CRH system, by receiving and transmitting humoral and nervous immune signals from the periphery, by densely innervating both primary and secondary lymphoid organs, and by reaching all sites of inflammation via the postganglionic sympathetic neurons. When activated during stress, the autonomic system exerts its own direct effects on immune organs, which can be immunosuppressive or both immunopotentiating and

anti-inflammatory. CRH secreted by postganglionic sympathetic neurons at inflammatory sites has pro-inflammatory properties (immune CRH); one of its key actions is to degranulate mast cells.

HPA Axis–Other Endocrine Axes Interactions

Gonadal and Growth Axes

The systems responsible for reproduction and growth are directly linked to the stress system and both are profoundly inhibited by various components of the HPA axis, the effector of the stress response. Either directly or through arcuate proopiomelanocortin (POMC) neuron β -endorphin, CRH suppresses the gonadotropin-releasing hormone (GnRH) neurons of the arcuate nucleus of the hypothalamus. Glucocorticoids exert inhibitory effects at the levels of the GnRH neuron, the pituitary gonadotroph, and the gonads themselves and render target tissues of sex steroids resistant to these hormones. Suppression of gonadal function caused by chronic HPA axis activation has been demonstrated in highly trained athletes of both sexes, in ballet dancers, and in individuals sustaining anorexia nervosa or starvation.

During inflammatory stress, cytokines suppress reproductive function directly and indirectly by activating hypothalamic secretion of CRH- and POMC-derived peptides, as well as by peripheral elevations of glucocorticoids and inhibition of steroidogenesis at both the ovaries and the testes.

The interaction between CRH and the gonadal axis appears to be bidirectional. Thus, the presence of estrogen-responsive elements has been demonstrated in the promoter area of the CRH gene, as well as direct stimulatory estrogen effects on CRH gene expression. This finding indicates that the CRH gene is a potentially important target of ovarian steroids and a potential mediator of gender-related differences in the stress response and HPA axis activity.

The growth axis is also inhibited at many levels during stress. Prolonged activation of the HPA axis with elevations in glucocorticoids leads to suppression of growth hormone (GH) secretion, inhibition of somatomedin C, and other growth hormone effects on their target tissues. However, acute elevations of growth hormone concentration in plasma may occur at the onset of the stress response or after acute administration of glucocorticoids, presumably through stimulation of the GH gene by glucocorticoids through glucocorticoid-responsive elements in its promoter region. In addition to the direct effects of

glucocorticoids, CRH-induced stimulation in hypothalamic somatostatin secretion may also result in GH suppression, providing another potential mechanism for stress-related suppression of GH secretion.

Similarly, activation of the HPA axis is associated with decreased production of thyroid-stimulating hormone (TSH) and inhibition of the conversion of the relatively inactive thyroxine to the more biologically active triiodothyronine in peripheral tissues (the “euthyroid sick” syndrome). Both phenomena may be caused by the increased levels of glucocorticoids and may serve to conserve energy during stress. In the case of inflammatory stress, inhibition of TSH secretion may occur in part through the action of cytokines on both the hypothalamus and the pituitary.

Metabolism

Glucocorticoids directly inhibit pituitary growth hormone, gonadotropin, and thyrotropin secretion and make the target tissues of sex steroids and growth factors resistant to these hormones. Thus, glucocorticoids antagonize the beneficial actions of GH and sex steroids on fat tissue (lipolysis) and on muscle and bone anabolism. Chronic activation of the stress system would be expected to increase visceral adiposity, decrease lean body (muscle and bone) mass, and suppress osteoblastic activity (Fig. 2). Interestingly, the phenotype of central obesity and decreased lean body mass is shared by patients with Cushing’s

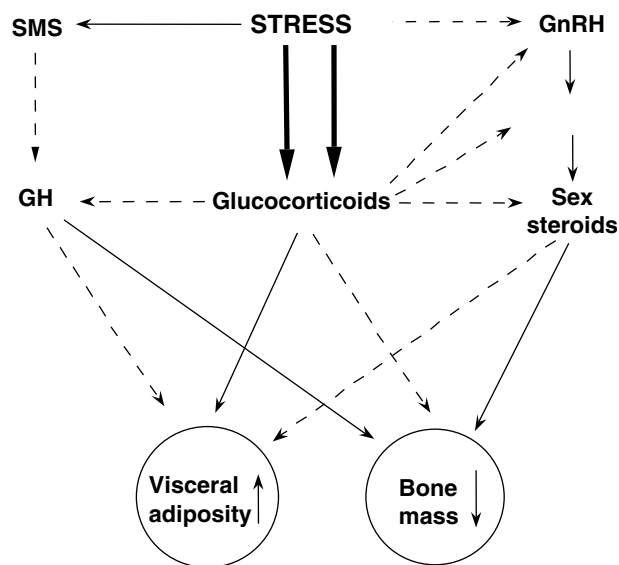

Figure 2 Detrimental effects of chronic stress on adipose tissue metabolism and bone mass. Solid lines indicate stimulation; dashed lines indicate inhibition. Modified from Chrousos (1992).

syndrome and some patients with the combined diagnosis of melancholic depression or chronic anxiety disorder and the metabolic syndrome (visceral adiposity, insulin resistance, dyslipidemia, hypertension) or “pseudo-Cushing’s syndrome.”

Because increased hepatic gluconeogenesis is a characteristic feature of the stress response and because glucocorticoids induce insulin resistance, activation of the HPA axis may contribute to the poor control of diabetic patients during periods of emotional stress or concurrently with inflammatory and other diseases.

Obese subjects with psychiatric manifestations ranging from those of melancholic depression to anxiety with perception of “uncontrollable” stress frequently have mild hypercortisolism, whereas carefully screened obese subjects without such manifestations are eucortisolemic. The former may have stress-induced glucocorticoid-mediated visceral obesity and metabolic syndrome manifestations, which in the extreme may be called a pseudo-Cushing’s syndrome state that needs to be differentiated from frank Cushing’s syndrome. Stress-induced hypercortisolism and visceral obesity and their cardiovascular and other sequelae increase the all-cause mortality risk of affected subjects two- to threefold and curtail their life expectancy by several years.

HPA AXIS: PATHOPHYSIOLOGY

Generally, the stress response with the resultant activation of the HPA axis is meant to be acute or at least of a limited duration. The time-limited nature of this process renders its accompanying anti-reproductive, anti-growth, catabolic, and immunosuppressive effects temporarily beneficial rather than damaging. In contrast, the chronicity of stress system activation would lead to the syndromal state that Selye described in 1936. Because CRH coordinates behavioral, neuroendocrine and autonomic adaptation during stressful situations, increased and prolonged production of CRH could explain the pathogenesis of the syndrome.

The prototypical example of chronic hyperactivation of the stress system (both the HPA axis and the LC-NE system) is manifested in melancholic depression, with dysphoric hyperarousal and relative immunosuppression. Indeed, cortisol excretion is increased and the plasma ACTH response to exogenous CRH is decreased. Hypersecretion of CRH has been observed in depression and suggests that CRH may participate in the initiation or perpetuation of a vicious cycle. Owing to chronically hyperactive stress,

patients with melancholic depression may sustain several severe somatic sequelae, such as osteoporosis, features of the metabolic syndrome, varying degrees of atherosclerosis, innate and T helper 1-directed immunosuppression, and certain infectious and neoplastic diseases. When not treated, these patients have a compromised life expectancy curtailed by 15–20 years after suicides are excluded.

In addition to melancholic depression, a spectrum of other conditions may be associated with increased and prolonged activation of the HPA axis (Table I), including anorexia nervosa with or without malnutrition, obsessive-compulsive disorder, panic anxiety, chronic active alcoholism, alcohol and narcotic withdrawal, excessive exercising, poorly controlled diabetes mellitus, childhood sexual abuse, and hyperthyroidism.

Another group of states is characterized by hypoactivation of the stress system, rather than sustained activation, in which chronically reduced secretion of CRH may result in pathological hypoarousal (Table I). Patients with atypical, seasonal depression and chronic fatigue syndrome fall into this category. Similarly, patients with fibromyalgia have decreased urinary free-cortisol excretion and frequently complain of fatigue. Hypothyroid patients also have clear evidence of CRH hyposecretion.

Withdrawal from smoking has been associated with decreased cortisol and catecholamine secretion. Decreased CRH secretion in the early period of nicotine abstinence could explain the increased appetite and weight gain frequently observed in these patients. In Cushing’s syndrome, the clinical picture of atypical depression, hyperphagia, weight gain, fatigue, and anergia is consistent with suppression of the CRH neuron by the associated hypercortisolism. The periods after cure of hypercortisolism or following cessation of chronic stress and the postpartum period are also associated with atypical depression, suppressed CRH secretion, and decreased HPA axis activity.

It is believed that an excessive HPA axis response to inflammatory stimuli would mimic the stress or hypercortisolemic state and would lead to increased susceptibility of the individual to a host of infectious agents or tumors as a result of T helper-1 suppression, but enhanced resistance to autoimmune/inflammatory disease. In contrast, a defective HPA axis response to such stimuli would reproduce the glucocorticoid-deficient state and would lead to relative resistance to infections and neoplastic disease, but increased susceptibility to autoimmune/inflammatory disease, such as Hashimoto’s thyroiditis or rheumatoid arthritis.

Table 1 States Associated with Hyperactivation or Hypoactivation of the HPA Axis

| Increased HPA axis activity | Decreased HPA axis activity | Disrupted HPA axis activity |
|-------------------------------|-----------------------------|-----------------------------|
| Severe chronic disease | | |
| Melancholic depression | Atypical depression | Cushing's syndrome |
| Anorexia nervosa | Seasonal depression | Glucocorticoid deficiency |
| Obsessive-compulsive disorder | Chronic fatigue syndrome | Glucocorticoid resistance |
| | Fibromyalgia | |
| Panic disorder | Hypothyroidism | |
| Chronic excessive exercise | Adrenal suppression | |
| Malnutrition | Post-glucocorticoid therapy | |
| Diabetes mellitus | Poststress | |
| | Nicotine withdrawal | |
| | Postpartum | |
| Hyperthyroidism | Menopause | |
| Central obesity | Rheumatoid arthritis | |
| Childhood sexual abuse | | |
| Pregnancy | | |

Modified from Chrousos (1992).

Thus, an increasing body of evidence suggests that patients with rheumatoid arthritis have a mild form of central hypocortisolism. Dysfunction of the HPA axis may actually play a role in the development or perpetuation of autoimmune disease, rather than being an epiphenomenon. The same rationale may explain the high incidence of autoimmune disease in the period after cure of hypercortisolism, as well as in glucocorticoid underreplaced adrenal insufficiency.

CONCLUDING REMARKS

Antalarmin, a novel CRH receptor type 1 antagonist, decreases the activity of the HPA axis and LC-NE system, suppresses neurogenic inflammation, and blocks CRH-induced skin mast cell degranulation, in addition to blocking the development and expression of conditioned fear and stress-induced colonic hyperfunction. Chronic administration of antalarmin is not associated with glucocorticoid deficiency and permits HPA axis and LC-NE responses to severe stress. These data suggest that such CRH antagonists may be useful in human pathologic states, such as melancholic depression and chronic anxiety, associated with chronic hyperactivity of the stress system, along with predictable behavioral, neuroendocrine, metabolic, and immune changes, based on the interrelations outlined above. Conversely, potentiators of CRH secretion and action are needed to treat atypical depression, postpartum depression, and the fibromyalgia/

chronic fatigue syndromes, all characterized by low hypothalamic-pituitary-adrenal axis and LC-NE system activity, fatigue, depressive symptomatology, hyperalgesia, and increased immune/inflammatory responses to stimuli.

hormones, corticotropin-releasing hormone (CRH) and vasopressin. CRH is the main stimulator of both the synthesis and secretion of adrenocorticotropic hormone (ACTH) from the pituitary gland; such secretion is augmented in the presence of vasopressin, which acts as a synergistic factor. ACTH, in turn, stimulates glucocorticoid synthesis and, if secreted in an excessive amount, may induce adrenal cortical hypertrophy and hyperplasia. HPA axis activity follows a diurnal rhythm, characterized in humans by an early morning peak (acrophase), declining over the daytime, a minimal secretory activity at approximately midnight (quiescent period), and an abrupt elevation during late sleep, resulting in an early morning maximum.

In the periphery, glucocorticoids are involved in many important functions including electrolyte homeostasis, glucose utilization, fat and protein metabolism, bone and cartilage formation and resorption, immune and inflammatory reaction regulation, and cardiovascular reactivity. Centrally, glucocorticoids affect the behavior, mood, excitability, and electrical activity of the neurons in a general manner. In addition, glucocorticoids have a regulatory feedback effect on the HPA axis, which might be overrun during stressful conditions. Glucocorticoids inhibit ACTH secretion directly by suppressing proopiomelanocortin expression in pituitary corticotrophs and indirectly by inhibiting the secretion of CRH and vasopressin at the hypothalamic level. A higher nervous system structure, the hippocampus, mediates part of the negative feedback effect of glucocorticoids on the HPA axis. The hippocampus is involved in the regulation of ACTH and glucocorticoid secretion under basal conditions, as well as in limiting the stress-induced activation of the HPA axis.

There are two types of receptors for glucocorticoids; the mineralocorticoid receptors (MRs, also called type I receptors) have approximately 10-fold higher affinity than the glucocorticoid receptors (GRs, also called type II receptors). GRs are widely expressed in the brain, including the hippocampus, and are also highly expressed in the paraventricular nucleus of the hypothalamus, whereas MRs are present mainly in the hippocampus and lateral septum. Since aldosterone, the natural ligand for MRs, is not present in brain, glucocorticoid is the preferential ligand for both receptors. In rats, inhibition of basal secretion of ACTH by corticosterone at the low point of diurnal HPA axis activity appears to be mediated through the MR and inhibition at peak activity occurs through the GR potentiated by the MR. Studies in humans have shown that spironolactone, a mineralocorticoid receptor antagonist, increases HPA axis activity.

SNS

The autonomic nervous system innervates vascular and visceral smooth muscles, exocrine and endocrine glands, and parenchymal tissues throughout the body. The CNS modulates autonomic nervous system activity. Neurons of the CNS receive diverse afferent inputs. After central integration of afferent information, autonomic outflow is adjusted to permit the functioning of the major organ systems in concordance with the needs of the organism as a whole. Sympathetic flow is initiated from the reticular formation of the medulla oblongata, from the pons, and from centers in the hypothalamus. The adrenal medullary chromaffin tissue is also involved in the synthesis and secretion of catecholamine, 85% of which is epinephrine. Catecholamine secretion is stimulated by acetylcholine from the preganglionic sympathetic nerves. All three of the naturally occurring catecholamines, norepinephrine, epinephrine, and dopamine, also function as neurotransmitters within the CNS. Catecholamines influence effector cells by interacting with specific surface receptors coupled to G protein α - and β -adrenergic receptors.

AGING

HPA Axis

Studies on the effects of normal aging on the HPA axis have revealed conflicting results. For the most part, these conflicting results could be explained; small sample size, lack of attention to diurnal variability of cortisol and ACTH concentrations or to sex differences in cortisol concentrations, and the variable of comorbid conditions are among the most important reasons for the differences in the results obtained.

Studies that have given careful attention to diurnal variation and sex differences have, however, consistently shown a clinically significant increase in mean 24h cortisol concentration with aging. However, random serum cortisol determinations and the 24h urinary cortisol concentration remain well within the reference range. The increase in mean cortisol concentration seems to be due to the net effect of two main changes associated with aging. First, there is an increased nocturnal nadir concentration. Second, the nocturnal quiescent period is shortened; that is, the quiescent period starts later and ends sooner. Although the circadian rhythmicity seems to be maintained with aging, the relative amplitude diminishes.

The effectiveness of the negative feedback is also diminished in aging as indicated by studies of the

ACTH response to glucocorticoid suppression and CRH stimulation testing. When exogenous cortisol is used for suppression of ACTH, there is a consistent delayed ACTH suppression in older subjects. However, studies using the synthetic glucocorticoid dexamethasone for HPA axis suppression have revealed conflicting results. CRH stimulation studies have also consistently shown greater pituitary–adrenal secretory responses in older subjects. In addition, there are also sex-related differences in aging; for instance, in one study cortisol response to ACTH was higher in postmenopausal women than in premenopausal women. As mentioned, in humans, spironolactone treatment increases HPA axis activity. This effect is more pronounced in the elderly. Overall, studies consistently show an increased HPA axis secretory activity with aging (see Fig. 1).

Studies in rats have been pivotal in shedding light on the underlying mechanism of aging-associated

changes in HPA axis activity. Under basal conditions, there is a progressive age-related decline in CRH mRNA levels in the paraventricular nucleus of the hypothalamus, hypothalamic CRH content, and hypothalamic *in vitro* CRH secretion. Prolonged treatment with stress doses of corticosterone in middle-aged rats is associated with learning impairment. Also, prolonged exposure to high social stress has been shown to be associated with learning impairment, whereas adrenalectomized rats that receive low-dose corticosterone replacement do not develop learning impairments. Chronic administration of corticosterone has been associated with down-regulation of both GRs and MRs in the hippocampus. An age-related decline in both the synthesis of GRs and MRs and the uptake of their ligands has been reported. Young rats exposed to corticosterone for a prolonged period of time have shown hippocampal neuronal loss similar to that in aged hippocampus. Middle-aged rats

Figure 1 The hypothalamus secretes corticotropin-releasing hormone (CRH) and vasopressin (AVP), which stimulate adrenocorticotrophic hormone (ACTH) synthesis and secretion from the pituitary gland. ACTH stimulates cortisol synthesis and secretion from the adrenal gland. Cortisol, in turn, inhibits hypothalamic CRH and AVP secretion and pituitary ACTH secretion. The hippocampus (HC) mediates part of the negative feedback effect of glucocorticoids on the hypothalamic–pituitary–adrenal (HPA) axis. Sympathetic flow is initiated from the reticular formation of the medulla oblongata, from the pons, and from centers in the hypothalamus. Aging is associated with hippocampal hypotrophy, a decreased number of hippocampal glucocorticoid receptors (GRs)/mineralocorticoid receptors (MRs), and increased axis activity. Overall, sympathetic nervous system (SNS) activity is decreased with aging, due to decreased β -adrenergic receptor density.

that were adrenalectomized have shown an improvement in hippocampal morphologic correlates of brain aging and reduced neuronal loss. Overall, these studies have led to the notion of central glucocorticoid toxicity; that is, prolonged exposure to glucocorticoid is associated with down-regulation of hippocampal GRs and MRs, leading to increased HPA axis activity and further elevation of glucocorticoid levels. Increased glucocorticoid concentration is also associated with hippocampal neuronal loss, leading to cognitive and memory impairment similar to that observed with aging.

SNS

Plasma norepinephrine concentration is increased in older adults compared with young adults. This is due to increased secretion and decreased clearance of norepinephrine with aging. On the other hand, plasma epinephrine concentration is slightly decreased with aging. This is due to a significant decline in epinephrine secretion from the adrenal medulla, whereas plasma epinephrine clearance decreases slightly (see Fig. 1). In addition, the adrenergic receptor density, especially the β -adrenergic receptor density, and adenylylase activity are reduced in aging. These changes have been observed in myocytes, detrusor muscles, and adipocytes.

MAJOR DEPRESSION

Major depression is associated with disturbances of the HPA axis and the SNS. Specifically, melancholic depression, a subtype of major clinical depression characterized by insomnia, loss of appetite, and weight loss, is associated with significantly higher cerebrospinal fluid norepinephrine levels around the clock.

Similar to the changes that are observed with aging, a higher mean 24 h plasma concentration cortisol has been observed in patients suffering from major depression, mainly due to a shortened quiescent period and an increase in the magnitude of the secretory episodes. Thus, patients suffering from major depression are exposed to higher glucocorticoid and catecholamine concentrations over time, which could theoretically accelerate the aging process.

ALZHEIMER'S DISEASE

There is some evidence that prolonged exposure to higher glucocorticoid concentrations might be associ-

ated with cognitive impairment and Alzheimer's disease. A group of healthy elderly subjects with different cortisol concentrations were followed over a period of 4 years. The subjects with a significant increase in cortisol concentrations over the years and with high current basal cortisol concentrations were impaired on tasks measuring explicit memory and selective attention compared to subjects who did not show increased cortisol concentrations. In another study, the mean plasma cortisol concentrations after dexamethasone administration were significantly higher in aged subjects suffering from dementia than in clinically healthy aged subjects.

SUMMARY

Aging is associated with changes in the CNS stress system, a reduced coping response to stressors, and, in some cases, memory and cognitive impairment. Chronic stress by itself induces changes in the HPA axis and SNS, leading to an accelerated aging process. Glucocorticoids are considered to be the main culprit; high concentrations of glucocorticoids are associated with synaptic loss in the hippocampus and hippocampal atrophy and thus cognitive dysfunction. Consequently, conditions that are associated with elevated glucocorticoid concentration, such as major depression, chronic stress, and Cushing's syndrome, could theoretically accelerate the aging process. Furthermore, a subset of the population with an exaggerated HPA axis response might be more prone to these changes. Likewise, interventions, whether pharmacologic or nonpharmacologic, that might decrease glucocorticoid concentrations or its actions might be proven beneficial in delaying the aging process.

fibrinolytic activity, and increased release of B thromboglobulin. Unfortunately, tight glycemic control in diabetic patients has not been shown to reduce the risk of stroke (as either a primary or a secondary preventive measure), although it does reduce the risk of many other mostly microvascular complications. In patients with myocardial infarction, treatment of hyperglycemia (blood sugar levels >11 mmol/L) was shown to decrease mortality. Recently, in a study by Gaede and colleagues published in the *New England Journal of Medicine*, the intensive concurrent treatment of various risk factors for cardiovascular disease, including diabetes, was shown to decrease the risk of stroke. Although nonfatal stroke was not the primary end point, and intensive treatment was simultaneously targeted at a number of risk factors such as diabetes, there were only 3 nonfatal strokes in the intensive treatment group and 11 in the control group. However, the specific contribution of glycemic control to this overall risk reduction is not clear.

Diabetes mellitus and acute hyperglycemia are associated with a poor outcome of stroke. Although it appears increasingly likely that hyperglycemia causes this poorer outcome, this has not been definitely established

in humans. Animal studies have shown convincingly that hyperglycemia, as compared with euglycemia, increases the extent of ischemic damage in rats and monkeys. However, in focal ischemia models, this effect was shown only for reperfused brain tissue, albeit less consistently. The negative effects of hyperglycemia on outcome of brain ischemia are probably mediated through increased lactic acidosis and increased release of excitatory amino acids (glutamate in particular) that may contribute to neuronal cell death (excitotoxicity), exaggeration of edema formation, blood-brain barrier disruption, and hemorrhagic transformations. In humans, the data underlining a causal relation between hyperglycemia and stroke are still only circumstantial. This is explained partly by the intricate relations between the pathogenesis of hyperglycemia and the evolution and type of the stroke.

First, reperfused brain tissue may be especially vulnerable to hyperglycemia, whereas anoxic tissue may even benefit from hyperglycemia. Recently, it was shown that the ischemic penumbra in stroke patients, represented as a mismatch between perfusion and diffusion on magnetic resonance imaging (MRI) (Fig. 1), is more likely to progress to infarction when

Figure 1 Diffusion weighted imaging (DWI) sequence 6 h after the onset of a stroke showing a circumscribed area of high signal indicating disturbed diffusion. This represents infarction of the brain. The magnetic resonance (MR) angiography after 6 h shows absent flow in the right middle cerebral and carotid artery. The mean transit time (MTT) MR shows hypoperfusion of the total right middle cerebral artery territory. The area of hypoperfusion on the MMT MR minus the area of disturbed diffusion on the DWI MR is generally considered to be the penumbra. The DWI MR after 3 days shows that the hypoperfused area has not progressed to infarction. The MR angiography shows reperfusion of the right middle cerebral artery through the circle of Willis. Courtesy of Geoffrey Donnan, National Stroke Research Institute.

the patient had hyperglycemia at presentation. Also, hyperglycemia levels were related to lactate levels, which in turn were independently related to salvage of mismatch tissue. In a previous study, a poorer outcome of strokes had been reported when hyperglycemia occurred in nonlacunar strokes that may show reperfusion but not in lacunar strokes with little or no reperfusion. A special vulnerability of reperfused brain tissue to hyperglycemia is also suggested by the experiences with thrombolysis in stroke patients. In the first trial showing the benefit of thrombolysis in acute stroke patients, the negative effects of hyperglycemia on outcome of thrombolysis were also reported. Further studies have shown that it was specifically in patients with reperfusion after tissue plasminogen activator (TPA) that hyperglycemia was associated with poor outcome. In these patients, there is a relation with hemorrhagic transformation of the infarct. Interestingly, diabetes mellitus has actually been reported to carry a decreased risk of primary intracerebral haemorrhage, so it seems less likely that diabetic vasculopathy explains the increased incidence of hemorrhagic transformation in thrombolized strokes. The fact that stroke type determines the association between hyperglycemia and stroke outcome is also underlined by the fact that, in hemorrhagic strokes, hyperglycemia is not related to a poorer outcome in both nondiabetic and diabetic patients.

Second, it seems that acute hyperglycemia may be more strongly related to poor outcome than is hyperglycemia due to diabetes mellitus. In a large meta-analysis, hyperglycemia was found to have a relative risk of mortality after ischemic stroke of 3.1 in nondiabetic patients and only 1.3 in diabetic patients. In conclusion, the literature suggests a causal relation between hyperglycemia and stroke outcome rather than hyperglycemia as a parphenomenon of strokes with more severe outcome. It seems sensible to withhold intravenous fluids containing glucose during the acute phase of a stroke, and hyperglycemia should be controlled with the usual measures, especially when blood sugar levels higher than 16 mmol/L are measured. However, whether tight control of hyperglycemia should be the goal in patients with stroke cannot be determined with certainty until currently conducted trials of treatment of hyperglycemia in acute stroke patients are concluded.

Hyperglycemia occurs in 20 to 50% of stroke patients. One-third of these hyperglycemic patients were known to have diabetes mellitus. In another third, the hyperglycemia is the initial presentation of *de novo* diabetes, demonstrated by an elevation of glycosylated hemoglobin (HbA1c) levels. In the remainder (with

a normal HbA1c at the time of hyperglycemia), the hyperglycemia is considered to be a result of the stroke, but the mechanism for this is unclear. Although a general stress response may lead to hyperglycemia, this is probably not the predominant cause in patients with a stroke. Other parameters of the stress response, such as levels of catecholamines, have been shown not to be related to blood sugar levels after stroke. Because the effects of focal ischemic events on neurotransmitter release at a distance from the focal ischemia can operate in the entire ipsilateral hemisphere of the stroke, the neuroendocrine axis may well be influenced by these alterations in neuronal excitation. Alternatively, the focal ischemic brain may mediate hyperglycemia directly through as yet unclarified mechanisms. If this were to occur preferentially in inadequately reperfused brain, the association of hyperglycemia and poor outcome of stroke would represent a parphenomenon and not a causal relationship.

Although hyperglycemia will rarely be confused with stroke, the differential diagnosis between stroke and hypoglycemia can be problematic. The blood sugar level in the patient presenting with coma or focal neurological deficit is obviously of crucial importance. If it is normal, hypoglycemia is unlikely. However, in the case of focal neurological deficit, the hypoglycemia may have been corrected by the patient's oral glucose intake before the neurological signs and symptoms resolve. When the patient is comatose, established hypoglycemia will be the likely cause. More difficulties arise when the patient presents with hypoglycemia and focal neurological deficits. Hypoglycemia can occasionally present with focal neurological deficit without any accompanying symptoms of hypoglycemia. Correction of blood glucose levels will generally lead to a rapid recovery of the deficit, but excluding a transient ischemic event might be impossible in these cases. In patients with previous strokes, hypoglycemia reproduces or worsens the previous deficit. When there are accompanying signs and symptoms of hypoglycemia, the balance will definitely shift toward hypoglycemia as a cause of the neurological deficit.

THYROID DISEASE

Both hyperthyroidism and hypothyroidism can contribute to a cardioembolic source for stroke. The most frequent event is hyperthyroidism leading to atrial fibrillation, a factor that generally leads to a fivefold increase in risk of subsequent stroke and

also a factor that, if it cannot be cured, leads to anticoagulation. Hypothyroidism can affect cardiac function and, thereby, the risk of intracardiac thrombus formation. Graves–Basedow disease is rarely associated with cerebral vasculitis, an entity also referred to as Hashimoto’s encephalopathy.

Thyroid disease has not been firmly established as affecting the outcome of strokes. However, in general, a range of systemic diseases affect the outcome of stroke, and it seems appropriate to diagnose and treat thyroid disease promptly in patients in these circumstances.

Strokes have not been shown to lead to thyroid disease.

Thyrotoxicosis may feature in the differential diagnosis of stroke. Delirium and coma may be a feature of both, but the fever, tachycardia, hypotension, vomiting, and diarrhea should point toward thyrotoxicosis. Hyperthyroidism has been reported to lead to isolated corticospinal tract dysfunction, the mechanism of which is not known. Hypothyroidism may present with limb and gait ataxia as signs of cerebellar dysfunction. The onset is often more gradual than in strokes.

PARATHYROID DISEASE

Hyperparathyroidism is known to contribute to hypertension. Patients with osteoporosis and compensatory hyperparathyroidism may have an increased risk of stroke due to this contribution. Hypoparathyroidism has not been identified as a risk factor for stroke, but it is related to MELAS syndrome. MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, stroke) is a mitochondrial disorder related to a point mutation in the transfer RNA^{Leu}(UUR) gene. It is typified by mitochondrial (ragged red fiber) myopathy, epilepsy, lactate acidosis, and stroke-like episodes. Frequently, this syndrome is associated with hypothalamo–pituitary axis dysfunction, diabetes mellitus, and/or hyperthyroidism.

Parathyroid dysfunction has not been shown to affect the outcome of stroke or to be the result of stroke.

Hypercalcemia, whether as a result of hyperparathyroidism or secondary to malignancy, may be confused with a stroke when a patient presents with confusion, nausea, and vomiting. In hypercalcemia, there is fatigue, anorexia, constipation, increased urination, a short QT interval, and generally a serum calcium level higher than 2.9 mmol/L (11.5 mg/dl).

HYPOTHALAMO–PITUITARY AXIS DISEASE

Hypopituitarism is associated with an increased risk of stroke, reflected in an excess mortality rate for cerebrovascular disease of 2.4. Because of the complexity of hormonal and metabolic disturbances in hypopituitarism, the causes of this excess mortality are poorly defined. A prothrombotic tendency due to growth hormone deficiency (which tends to persist even when hormones are adequately substituted), Cushing’s syndrome, and secondary hyperthyroidism are among the factors that may be implied in the pathogenesis of strokes.

Pituitary disease has not been shown to affect the outcome of stroke, although it may affect the chances of recurrence of stroke.

Pituitary apoplexy is the term that refers to a stroke in the pituitary gland. Such strokes can be either ischemic or hemorrhagic and are often complications of pituitary adenomas or the surgery or radiotherapy thereof. The condition is probably underdiagnosed given that the pathological correlate of apoplexy has a prevalence of 1 to 3% in autopsy studies. The clinical presentation is highly variable but should be suspected in any patient with severe headache, visual field defects, ophthalmoplegia, and/or altered mental status. In some cases, there is only headache at first. This headache is accompanied by nausea, vomiting, nuchal rigidity, fever, stupor, and coma (when blood and necrotic tissue leak and cause the features of subarachnoid hemorrhage or aseptic meningitis). In tumorous apoplexy, the destruction of the pituitary in most cases leads to hypopituitarism because most underlying adenomas are endocrinologically silent. In cases of endocrinologically active adenomas, there can be spontaneous resolution of preexisting endocrinopathy after apoplexy. The slowly evolving expansion of adenomas rarely leads to cranial nerve deficit because the nerves slowly lengthen in response to this expansion. In apoplexy (Fig. 2), there is sudden compression of cranial nerves due to hemorrhage or infarction and swelling. Compression of the optic nerve leads to visual field defects and decreased visual acuity, whereas compression of nerves III, IV, and VI leads to oculomotor disturbances. Compression of the trigeminal nerve may result in facial paresthesias and absent corneal reflex. Compression of the cavernous sinus may result in proptosis and eyelid edema. Finally, there can be Horner’s syndrome due to compression of the sympathetic chain and hyperpyrexia, and there can be diabetes insipidus or SIADH

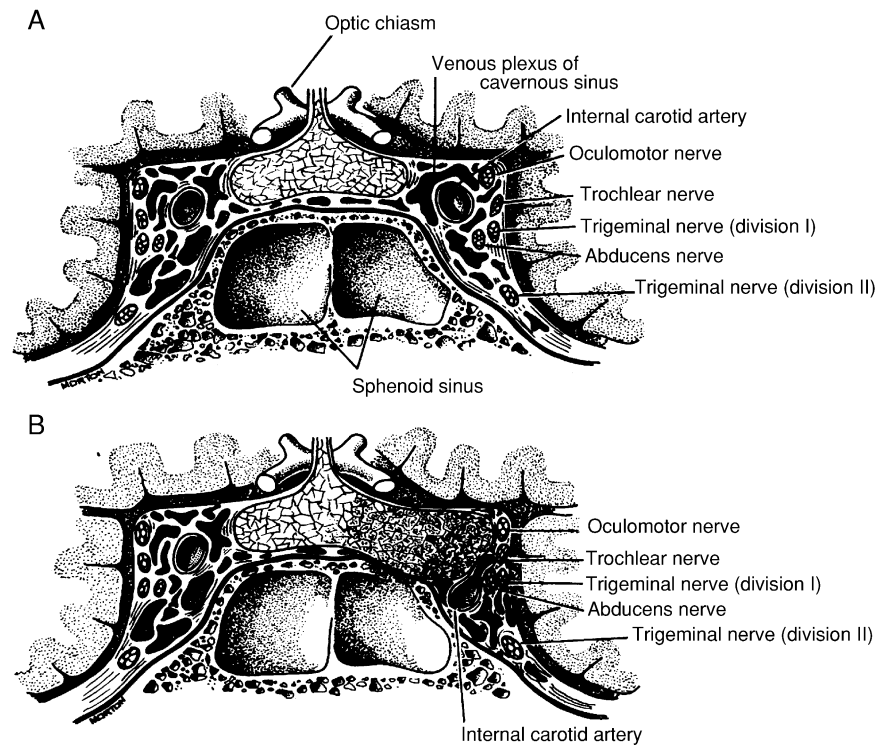

Figure 2 (A) Posterior coronal view showing anatomical relationship of pituitary gland to optic chiasm superiorly, sphenoid sinus inferiorly, and cavernous sinus laterally. (B) Mechanism of acute compression of structures within cavernous sinus from sudden expansion of pituitary adenoma due to hemorrhage or infarction and edema. Note that the further the tumor has eroded the floor of sella turcica prior to apoplectic episode, the more likely it is that multiple structures within the cavernous sinus will be involved. Reproduced from Reid, R., Quigley, M., and Yen, S. (1985). Pituitary apoplexy. *Arch. Neurol.* **42**, 712–719.

(syndrome of inappropriate antidiuretic hormone) when the hypothalamus is compressed.

The radiological diagnosis can be made on computed tomography (CT) if the stroke is hemorrhagic or if the adenoma is sufficiently large. The investigation of choice is MRI, which shows hemorrhage and underlying adenomas in great detail (Fig. 3). Infarction can be difficult to diagnose on routine magnetic resonance sequences. Diffusion-weighted images greatly increase the accuracy of the diagnosis of pituitary infarction. Peripheral enhancement of intrasellar masses can be another less specific sign. The hypothalamic–pituitary unit can be tested as outlined elsewhere. Pregnant women have a special predisposition to apoplexy due to the prothrombotic state related to pregnancy (and the resulting 12-fold increase in risk of stroke) and the dramatic enlargement of the pituitary gland due to the proliferation of prolactin-secreting cells. The classical features of postpartum pituitary apoplexy are absence of lactation, persistent amenorrhea, and lethargy. Other predisposing factors to pituitary apoplexy include bleeding disorders, anticoagulation, upper

respiratory tract infections, trauma, carotid angiography, Cushing’s disease, diabetes mellitus, adrenalectomy, atherosclerosis, sickle cell trait, and acromegaly. Surgical intervention is advocated in the majority of patients, with radiotherapy a less likely option.

Less catastrophic is the effect of nonpituitary stroke on the hypothalamic–pituitary–adrenal (HPA) axis. Stroke is associated with increased activity of the HPA, manifested particularly by hypercortisolism. The normal regulation of cortisol secretion by adrenocorticotropic hormone (ACTH) is disturbed after stroke, a process in which cytokines seem to be implicated. Such a pathological HPA axis may exhibit an overriding function on established risk factors for cardiovascular disease, diabetes mellitus, and stroke such as abdominal obesity, hypertension, cholesterol, and triglycerides. Whether there is a causal relation between stroke and increased HPA axis activity needs to be further elucidated given that depression, anxiety, alcohol consumption, and smoking all have been shown to have similar effects. Also, changes in growth hormone, prolactin, and thyrotropin response to

Figure 3 Axial and sagittal T1-weighted and transverse T2-weighted MRIs showing a large hemorrhage into the pituitary gland. Courtesy of G. Fitt.

thyrotropin-releasing hormone have been reported, and some of these changes may be a consequence of the hypersensitive HPA axis. They may explain some of the insulin resistance after stroke. It has been postulated that stroke in the caudate nucleus interrupts neurotransmitter pathways involved in the control of secretion of gonadotropins. Although hypercortisolism and some of the other disturbances have been related to disorientation and levels of motor impairment, the clinical relevance of many of the changes remains uncertain. In general, stroke leads to an increase in antidiuretic hormone (ADH) levels. However, this usually does not lead to hyponatremia. Patients with subarachnoid hemorrhage are especially likely to develop a syndrome of inappropriate ADH secretion (SIADH). However, it is important to distinguish SIADH from cerebral salt wasting, which is the more likely explanation for hyponatremia in patients with subarachnoid hemorrhage.

ADRENAL GLAND DISEASE

The intermittent hypertension in pheochromocytoma increases the risk of stroke. In some cases, the pheochromocytoma is actually not identified until the patients present with a stroke. Also, Cushing's disease

has been postulated to have an increased risk of stroke due to hypercortisolism or to the effects of treatment of Cushing's disease such as external pituitary irradiation and posttreatment hypopituitarism.

shortly after birth with the sensory neurotoxin capsaicin lack this extrinsic innervation to the alimentary tract, with the result that there is a marked depletion of SP fibers in the gastric mucosa and around gastric submucosal blood vessels. A scattered population of SP-immunoreactive endocrine-like cells is present in the mucosa of the human small intestine and colon.

In the pancreas, a sparse distribution of SP fibers, which are probably of extrinsic origin, innervate blood vessels and acini and such fibers are also found surrounding acini and along blood vessels in the salivary glands. In the hepatobiliary system, immunoreactive fibers are found in the parenchyma of the liver and hepatic vasculature and are localized to the ganglionated and mucosal plexi of the gallbladder. In the trachea and bronchi, extrinsic SP-containing nerve fibers are found within the smooth muscle layer and around local ganglion cells and, in the nasal mucosa, within and under the epithelium and around arterioles, venules, and exocrine glands. In the human heart, SP fibers are found in close proximity to arterioles and are localized to the adventitia and to the border between the adventitia and media in a wide range of blood vessels. Within the urogenital system, immunoreactive nerve fibers of extrinsic origin are present in the urinary bladder throughout the ureter close to smooth muscle cells and around blood vessels in the kidney cortex often close to renal tubules and glomeruli. The female (uterus, oviduct, and vagina) and male (seminal vesicle, testis, epididymis, and vas deferens) genital organs are also innervated by extrinsic SP fibers.

Consistent with predominantly neuronal localization of the peptide and its rapid rate of clearance from the circulation (half-life <1 min), the plasma concentration of SP in healthy subjects is very low (<10 fmol/ml). Elevated concentrations of circulating SP (and other tachykinins) are often seen in patients with carcinoid tumors, particularly metastatic tumors of the midgut region. The synthesis and release of SP by cells of the immune system (monocytes, lymphocytes, eosinophils and macrophages) have been reported and SP fibers innervate thymus, spleen, lymph nodes, and bone marrow, supporting the concept that the tachykinins constitute a link between the central nervous system (CNS) and the immune system.

NK₁ Receptor

Of the three structurally related cell surface receptors that recognize SP, the NK₁ receptor binds the peptide with the highest affinity, so this receptor is often termed the SP receptor. The NK₁ receptor is widely

but discretely distributed in different regions of the brains of mammals, although species differences are apparent. In peripheral tissues, NK₁ receptors are present on human pulmonary arterial blood vessels but not on bronchial smooth muscle, on circular and longitudinal smooth muscle throughout the human gastrointestinal tract, and over ganglia of the myenteric plexus. The potent sialagogic effect of SP is consistent with the high concentration of NK₁ receptors on rat submaxillary gland. The potent vasodilator action of SP is mediated primarily by binding to NK₁ receptors on the endothelium of peripheral arterial blood vessels. In the urogenital system, NK₁ sites are expressed on blood vessels in the urinary bladder, uterus, and ureter; in the skin, NK₁ sites are present at high density in postcapillary venules in the dermis. The occurrence of NK₁ receptors in spleen, in thymus, on arterioles and venules of the lymph nodes, and on T lymphocytes provides further evidence for an involvement of SP in immunoregulation.

PHYSIOLOGICAL ROLES

The principal biological actions of SP are summarized in [Table I](#). It is well established that SP acts as a neurotransmitter in primary afferent sensory neurons and is involved in the perception of pain. The release of SP from small-diameter sensory "pain" fibers into the dorsal horn of the spinal cord following intense peripheral stimulation promotes central hyperexcitability and increased sensitivity to pain. Intrathecal injection of SP in mice elicits behaviors suggestive of pain sensation. However, in rats, intracerebroventricularly administered SP displays a clear-cut antinociceptive activity in the hot plate test, which is abolished by treatment with the opioid antagonist, naloxone. It has been suggested that proteolytic conversion of SP to its (1–7) fragment is a prerequisite for development of the analgesic action. Knockout mice lacking expression of the preprotachykinin A gene exhibit a surprisingly healthy phenotype and a normal response to mildly painful stimuli, e.g., the tail flick assay, but the response to moderate to intense pain was significantly reduced. Similarly, mice with a targeted deletion of the NK₁ receptor for SP were healthy and fertile and responded normally to acute painful stimuli but were unable to develop fully the stress-induced analgesia of control animals.

Intracerebroventricular injections of SP in rats and mice induce a wide range of behavioral responses, including increased grooming and scratching, increased hindlimb rearing, decreased aggressive behavior, and an enhancement of inhibitory avoidance

Table I A Summary of the Principal Biological Actions of Substance P with Correlations to Human Diseases

| Organ system | Biological activity | Disease correlation |
|------------------------|--|--|
| Central nervous system | Neurotransmitter/neuromodulator function | Migraine |
| | Nociception | Riley-Day syndrome Parkinson's disease Huntington's disease Alzheimer's disease Depression/anxiety |
| Cardiovascular system | Vasodilation | Carcinoid flush |
| | Plasma extravasation | |
| | Tachycardia | |
| | Cardiac output ↑ | |
| Respiratory system | Bronchoconstriction | Asthma |
| | Vasodilation | |
| | Vascular permeability ↑ | |
| | Mucus secretion ↑ | |
| Salivary glands | Salivation ↑ | |
| Gastrointestinal tract | Peristalsis ↑ | Hirschprung's disease |
| | Water and electrolyte secretion ↑ | Ulcerative colitis |
| | Blood flow ↑ | Crohn's disease |
| Pancreas | Exocrine secretion ↑ | |
| Hepatobiliary system | Bile secretion ↓ | Inflammation |
| | Gallbladder motility ↑ | |
| Urogenital system | Motility of ureter and bladder ↑ | Urinary incontinence |
| | Blood flow and motility of uterus ↑ | |
| | Renal vasodilation | |
| Musculoskeletal system | Neurogenic inflammation ↑ | Arthritis |
| | Blood flow to skeletal muscle ↑ | |

learning. Studies in guinea pigs have suggested that blockade of central SP receptors may inhibit behavioral responses to psychological stress. A role for the SP metabolite SP-(1-7), presumably generated from SP within the CNS, in effecting these responses has been proposed.

Intra-arterial infusions of SP in humans result in a fall in diastolic blood pressure, an increase in heart rate, and an increase in cardiac output, due mostly to a greater stroke volume. The peptide is a powerful vasodilator in humans with high-dose (70 pmol/kg/min) infusions, producing a bright red flushing of the skin, particularly in the neck and face, with a subjective feeling of warmth. Intradermal injections of SP in humans produce flare, wheal, and itching that are related to the release of histamine and an increase in capillary permeability. The potent action of SP in causing plasma extravasation is mediated through the NK₁ receptor.

The precise actions of SP on the motility of the gastrointestinal tract are species-dependent, but

in vitro the peptide generally evokes a contractile response on tissues from all regions and *in vivo* is a strong stimulator of peristalsis by a mechanism that involves both a direct action on smooth muscle and a release of acetylcholine from cholinergic neurons. SP stimulates the secretion of water and electrolytes from the mucosa of the small intestine and colon of various mammals and produces an increase in short-circuit current in the guinea pig colon that is indicative of net ion transport across the tissue. The release of SP from afferent fibers innervating the stomach and gut and from intrinsic fibers of the submucous ganglia supplying submucosal arteries produces vasodilation, leading to an increase in blood flow in the mesenteric artery. A cytoprotective role for the gastric mucosa has been proposed for the SP released from primary afferent terminals.

Intra-arterial infusions of SP in dogs weakly stimulate basal output of pancreatic juice, amylase, and bicarbonate, whereas in the isolated rat pancreas, the peptide inhibits cholecystokinin-induced amylase

release and secretin-induced flow and, at high concentrations, weakly stimulates the release of insulin, glucagon, and somatostatin. However, a major physiological role for SP in the regulation of pancreatic function seems improbable. Similarly, although SP is a potent stimulator of salivary secretion in rodents, it has only weak sialagogic activity in humans.

PATHOPHYSIOLOGY AND DISEASE

The involvement of SP in human disease is summarized in [Table I](#). A link between SP and nociception has been clearly established. Cerebral and pial arteries are richly innervated by SP fibers and it has been suggested that neurogenic inflammation within the cerebral tissues leading to the release of SP may be involved in the pathogenesis of migraine and cluster headaches. Similarly, the inflammatory response to trauma in the eye may be due to a release of SP. Patients with reduced sensitivity to pain and temperature, as in Riley-Day syndrome, are associated with a marked depletion in the SP content of the medulla oblongata and substantia gelatinosa of the spinal cord. An involvement of SP in the pathophysiology of neurodegenerative diseases is indicated by the significant decrease in the concentration of the peptide in the substantia nigra and globus pallidus of patients with Huntington's disease and Parkinson's disease. A similar decrease in the SP content in the cerebral cortex and hippocampus has been found in patients with Alzheimer's disease.

In the periphery, a role for SP in the pathogenesis of rheumatoid arthritis is suggested by the observations that joints that develop severe arthritis are densely innervated by SP-containing fibers and concentrations of the peptide in synovial fluid are increased. NK₁ receptors are also found on synovial endothelial cells in patients with rheumatoid arthritis. Thus, tachykinins derived from hyperactive afferent nerve endings in the arthritic joints may promote the chronic inflammatory processes. In the gastrointestinal tract, SP-containing fibers are almost absent from the aganglionic colons of patients with Hirschprung's disease. In conditions of chronic inflammatory bowel disease, such as ulcerative colitis and Crohn's disease, there is an increase in the concentration of SP in the inflamed mucosa together with a marked increase in the expression of SP-selective NK₁ receptor sites in

the arterioles and lymphatic tissue. SP is a potent stimulator of histamine release from mast cells in the intestines of nematode-infected rats. Conversely, chronic constipation is associated with a decrease in colonic SP levels.

The synthesis of SP in neoplastic tissue has been described for a range of neuroendocrine tumors. The peptide has been detected at relatively low concentrations in pheochromocytomas, medullary carcinomas of the thyroid, and small-cell lung carcinomas. Much higher concentrations are found in carcinoid tumors, particularly those arising in the midgut region and their metastases. It is generally accepted that the etiology of the marked cutaneous vasodilation and tachycardia seen in the carcinoid flush is multifactorial but SP (and other tachykinins) released by tumor tissue into the circulation has been implicated in some, but not all, patients.

A wide range of antagonists, both peptide and non-peptide, for the NK₁ receptor have become available for potential use as therapeutic agents. Initial efforts at drug development were directed toward analgesics and anti-inflammatory agents but clinical trials are under way to assess the value of NK₁ receptor antagonists in the treatment of depression and anxiety disorders and irritable bowel syndrome and for use as anti-emetics, particularly in patients with chemotherapy-induced nausea and vomiting.

Figure 1 Sample superovulation cycle using human menopausal gonadotropin (hMG) for ovarian stimulation, human chorionic gonadotropin (hCG) to trigger ovulation, and intrauterine insemination (IUI). Follicular size (mm), as determined by ultrasound, and serial serum estradiol, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) levels are followed serially. Progesterone supplementation is started 2 days after the insemination.

are predictive of a poor ovarian response. A baseline ultrasound should also be performed to ensure that the endometrial lining is thin (menstrual) and that the ovary is free of functional cysts or any pathology that may potentially impact on follicular development. Initial doses are based on the patient's diagnosis, age, weight, and previous responses to ovarian stimulation, but typically range between 75 and 450 IU/day. Sequential serum estradiol levels and ultrasound assessment of follicle growth determine the patient's response and daily dosage requirements. Once the lead follicle reaches a preovulatory size (≥ 17 –18 mm), ovulation is triggered with an intramuscular injection of hCG. Intrauterine insemination (IUI) or intercourse follows over the subsequent 24–36 h, as ovulation can be expected approximately 36 h after the administration of hCG (Fig. 1). Pregnancy rates with gonadotropins and IUI range from 10 to 20% per cycle, compared to approximately 5% for clomiphene citrate and IUI. Adjuvant medical therapies are occasionally used to augment the ovarian response during superovulation. Insulin sensitizers, such as glucophage, have been successfully employed in women with polycystic ovary disease to yield higher spontaneous and clomiphene-induced ovulation rates.

COMPLICATIONS OF SUPEROVULATION

Use of exogenous gonadotropins presents the risk of ovarian hyperstimulation syndrome (OHSS), a multi-organ condition caused by increased capillary permeability within the peritoneal cavity with accumulation of ascites, which in severe cases can result in pulmonary edema, renal failure, thromboembolism, and, potentially, death. The incidence of OHSS can be minimized with close monitoring of the patient's serum estradiol and follicle numbers, by moderating gonadotropin dosages, and by having a low threshold for withholding the administration of hCG, which is required for the condition to manifest. Spontaneous abortion rates appear to be higher with superovulation; however, common causes of infertility, such as polycystic ovary disease, are independent risk factors for early pregnancy loss. Multiple gestation is a well-recognized complication of ovarian stimulation. The incidence of twin gestation is approximately 20% and the risk of higher order multiple pregnancies is approximately 5%. Superovulation also increases the risk of tubal pregnancy several-fold, as well as the risk of heterotopic pregnancy, where gestational sacs are

simultaneously present inside and outside the uterine cavity. Infertile patients, in general, are at increased risk for ectopic pregnancy because of their incidence of tubal disease, although increased embryo numbers and negative effects of gonadotropins on tubal motility have been implicated. The link between ovarian cancer and controlled ovarian stimulation is controversial; however, evidence seems to indicate that the increased risk of epithelial carcinomas can be attributed to independent risk factors common to this population of women, namely, that they have lower parity and reduced exposure to oral contraception.

TECHNIQUES OF INTRAUTERINE INSEMINATION

Intrauterine insemination is the process of introducing a prepared solution of sperm into the uterine cavity, with the objective of providing a concentration of sperm in the oviduct that is adequate for fertilization. Seminal specimens are collected by masturbation into a sterile container and then allowed to liquefy at room temperature. Sperm-washing procedures and separation techniques serve to remove antigenic proteins, prostaglandins, and infectious agents, as well as nonmotile spermatozoa, leukocytes, and immature germ cells. The end result is a small volume of highly concentrated motile sperm that is safe to introduce into the sterile environment of the uterine cavity. In the past, semen was injected in or around the cervix; however, intrauterine insemination provides the highest concentration of sperm in the tube and peritoneal cavity and yields higher pregnancy rates. Fecundity rates with superovulation appear to be higher when intrauterine insemination is used than when timed intercourse is carried out. Several small studies have demonstrated an increased fecundity with the use of IUI compared to timed intercourse, in both CC and gonadotropin cycles. Controversy exists regarding whether one or two inseminations should be performed. Ideally, an insemination should be performed as close to the time of ovulation as possible. This can be accomplished by detecting the preovulatory LH surge with urine or serum testing or by triggering ovulation pharmacologically with hCG. Ultrasound assessment of follicle size is also used to determine the proximity to spontaneous ovulation and for the timing of hCG administration.

COMPLICATIONS OF INTRAUTERINE INSEMINATION

Since the uterine cavity is normally a sterile environment, introduction of a catheter through the cervix

carries the potential for infection. Salpingitis has been described after IUI and appears to be linked to bacteria present within the sperm sample. Development of anti-sperm antibodies in the recipient is a theoretical concern, but occurs in less than 5% of women following IUI.

INDICATIONS FOR SUPEROVULATION AND INTRAUTERINE INSEMINATION

Superovulation and IUI are used for a wide variety of both male and female reproductive disorders. They are most commonly used to treat central and peripheral ovulatory disorders, as well as unexplained infertility. When infertility is the result of a male anatomic or ejaculatory problem, IUI is an effective treatment. It also has a theoretical benefit of overcoming subtle abnormalities in sperm concentration and motility and by circumventing a potentially hostile cervical environment. In vitro fertilization (IVF) is the only option for couples with significant male factor infertility. If the sperm impairment is profound, a single healthy sperm can be selected and placed within the cytoplasm of the egg to achieve fertilization—a process called intracytoplasmic sperm injection (ICSI). Alternatively, IUI with donor sperm is a simple and inexpensive option for couples who do not wish to pursue IVF. Despite the advent of assisted reproductive techniques such as IVF and ICSI, superovulation with IUI remains the most widely used and accessible fertility treatment worldwide.

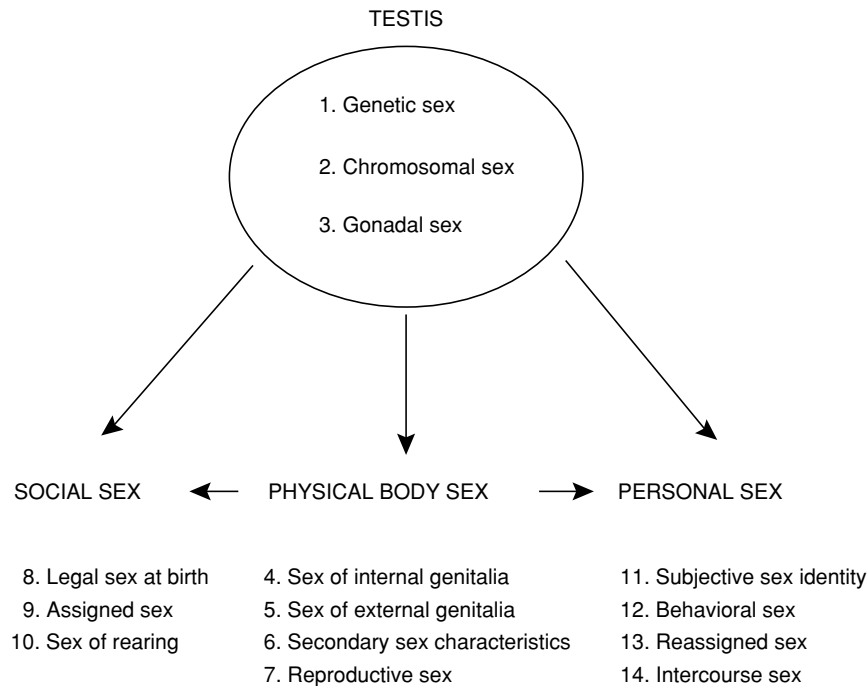

Figure 1 Central role of the testis in the regulation of sex differentiation of organs and functions in humans and other mammals. The modalities of sex at various developmental and organizational levels are numbered from 1 to 14 roughly according to the developmental sequences. The genetic sex (1) refers to the genes that regulate the cell differentiation and development of the gonads into the female or male direction. The measurement of their activity requires a small sample of the developing tissue. The chromosomal sex (2) refers to the presence of sex chromosomes that can be studied from a blood sample. Usually, at least one Y chromosome is needed for male development. The gonadal sex (3) refers to the presence of the testis or ovary. The testes can usually be identified in a newborn baby if they have normally descended into the scrotal sacs. The sex of the internal genitalia (4) refers to the presence of epididymis and ductus deferens, whereas the sex of external genitalia (5) refers to the presence of scrotal sacs with testes. The internal and external genitalia normally develop according to regulatory factors secreted by the testis. The secondary sex characteristics (6) include shaping of the body and breasts, as well as growth pattern of the body hair, that takes place at puberty under the control of the testis and ovary together with the pituitary hormones. The reproductive sex (7) in this context refers to the ability to produce spermatozoa or egg cells for reproduction. Partially parallel with the development of body sex, the social and personal aspects of sex develop under the direct or indirect control of the testis and its hormonal products. The legal sex (8) is determined at birth in normal cases according to the anatomy of the external genitalia. In the case of ambiguity, more detailed analysis of the chromosomal and genetic status of the individual is required before the sex can be decided legally (9) in the birth certificate. In normal cases, all of the various modalities of sex develop and can be easily identified without special examinations. The sex of rearing (10) includes the behavior of parents and other related adults in relation with the growing child. The person himself or herself develops a subjective sex identity (11) according to internal physical and functional development as well as the behavior of relatives. This is soon reflected in manifestation of the behavior (12) of the child according to the established role in each society. In some cases, the sex is reassigned into the opposite sex (13) due to a misinterpretation of the sex at birth or, for example, due to a change of subjective sex identity later in life. After maturation, the sex can also be identified according to anatomical and functional roles in sexual intercourse (14). From biological, medical, and practical experience and knowledge, it is evident that any of the modalities constitutes a spectrum from normal female through different intersect states into normal male and that successive developmental phases can be independent of, and different from, the previous phases.

on the surface of the mesonephros. In terms of cellular and molecular composition, it is similar in both sexes until the seventh week of embryonic age (from fertilization) in humans and by 12.5 days in mice. The cellular differentiation proceeds by organization of irregular epithelial cords inside the growing ridge into cylindrical looped cords.

THE TESTIS

The testicular cords consist of somatic Sertoli cells and the germ cells, which develop into spermatogonia (Fig. 4). The interstitium contains the testosterone-producing Leydig cells, undifferentiated mesenchymal cells, macrophages, developing peritubular myoid

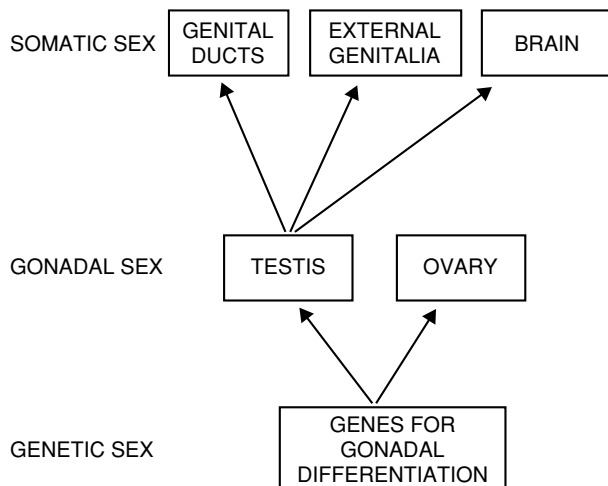

Figure 2 Regulatory pathways of testicular differentiation in comparison with the ovary. Specific genes direct the differentiation of the gonads, but only the testis regulates the next wave of development of the internal genital ducts, external genitalia, and brain into male structures and functions. In terms of sexual differentiation, the genetic, gonadal, and somatic phases are completed by or immediately after birth.

cells, and blood vessels. The most important regulatory hormones and their functions are illustrated in Fig. 4.

REGULATORY MECHANISMS

Several gene products are required for normal testicular differentiation. They are collectively referred to as testis differentiation factors (Figs. 3 and 5). Best known are Sry and Sox9, which regulate the early phase of testicular differentiation of cords, and Wt1, Gata4, and Sf1, which guide the functional differentiation of Sertoli and Leydig cells for hormone production.

After cellular differentiation, the Sertoli cells produce anti-Müllerian hormone, which causes regression of the paramesonephric (Müllerian) ducts. Otherwise, they would develop into female oviduct, uterus, and vagina (Fig. 3). Testosterone from the Leydig cells masculinizes the primordia of the male genitals and brain (Fig. 3).

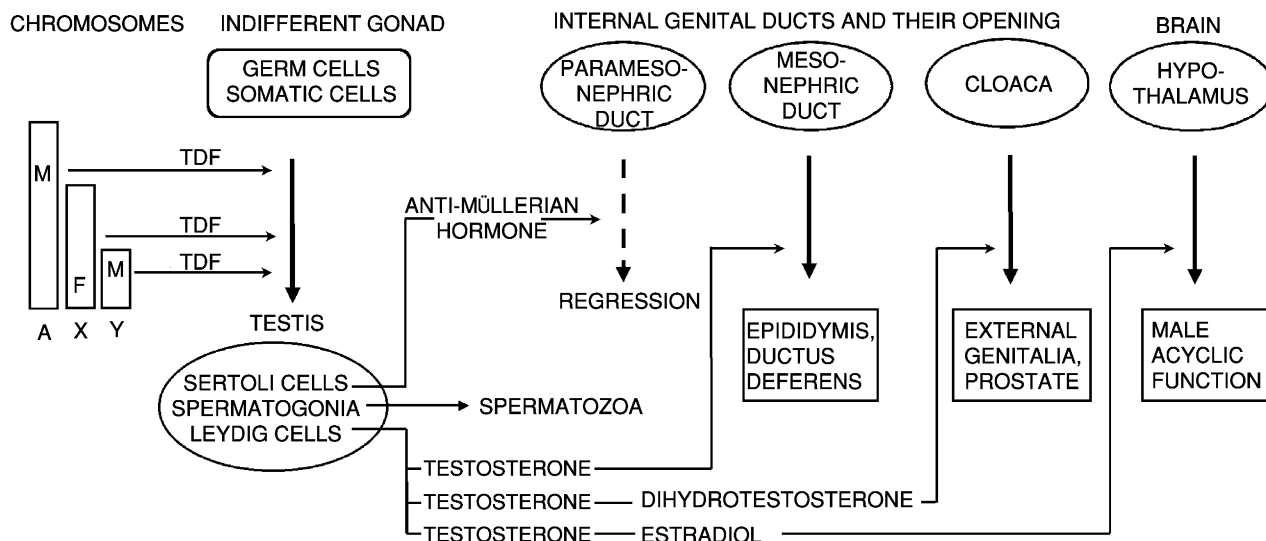

Figure 3 Schematic drawing of the differentiation of the testis and its subsequent activities in the regulation of the development of genital organs and brain into the male direction. The regulatory genes of the testis differentiation factors (TDF) are located in autosomes (A), X chromosomes (X), and Y chromosome (Y). The genes have male (M) or female (F) directing functions. Under the influence of these gene products, the indifferent gonads, consisting of germ cells and undifferentiated somatic cells, develop into a microscopically identifiable testis with cylindrical cords, consisting of Sertoli cells and spermatogonia and the interstitial tissue containing the Leydig cells. The Sertoli cells secrete anti-Müllerian hormone, which causes the female paramesonephric duct to regress and in this way prevents the development of the oviduct, uterus, and vagina. The Leydig cells secrete testosterone, which via the circulation reaches the embryonic mesonephric duct and stimulates its differentiation into epididymis and ductus deferens. In a similar fashion after conversion into dihydrotestosterone, the prostate and external genitalia develop from the cloacal region of the embryo. Another conversion of testosterone into estradiol takes place in the brain, where the regulatory neurons in the hypothalamus will develop male acyclic function and in this way prevent the later start of a menstrual cycle, which develops in the female brain without perinatal exposure to testosterone action. As indicated in Fig. 2, the internal and external genitalia, together with the brain, have an autonomous development program in the female direction and in this way do not require any known effect from the ovary.

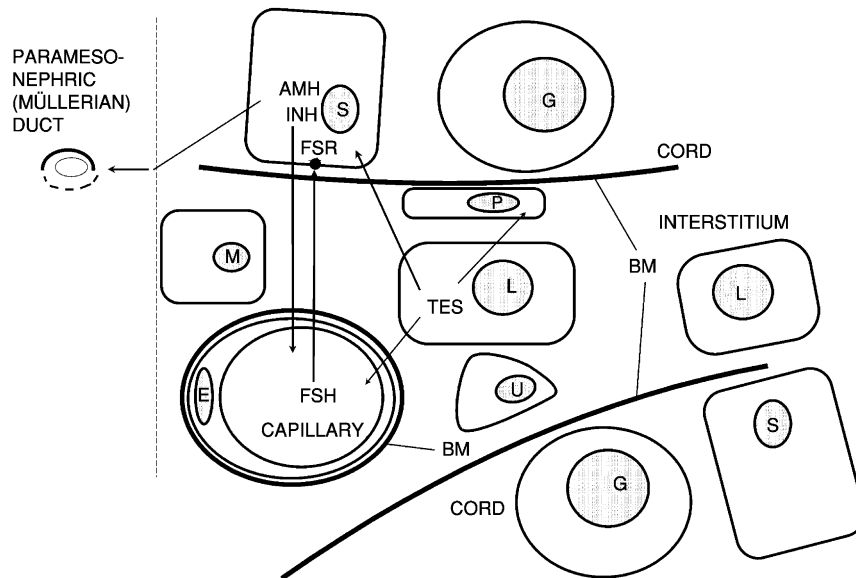

Figure 4 Schematic drawing of the cells and their histological organization in an embryonic testis. The testicular cords consist of Sertoli cells (S) and spermatogonia (G). The identification letter for each cell type is located in the shaded nucleus of the cell. The nucleus is surrounded by white cytoplasm of the cell outlined with a solid line drawn roughly to indicate the shape of the cell. A short arch of the circular outline of the cord is shown with a thick line labeled as basement membrane (BM). The cord itself is an elongated and curved cylinder that can be outlined by completing the arches of basement membrane into full circles with imagination. Between the cylindrical cords, the interstitial tissue consists of Leydig cells (L), peritubular developing myoid cells (P), undifferentiated mesenchymal cells (U), blood capillaries formed by endothelial cells (E) surrounded with their basement membrane (BM), and (toward the end of the embryonic period) phagocytosing macrophages (M). The embryonic Sertoli cells produce anti-Müllerian hormone (AMH), which diffuses into the adjacent paramesonephric duct and causes its regression (see Fig. 3). During the late embryonic period, the Sertoli cells have a receptor (FSR) for the follicle-stimulating hormone (FSH) produced by the pituitary gland. The Sertoli cells also secrete inhibin (INH), which via the circulation is carried into the pituitary gland, where it inhibits the secretion of FSH. The interstitial Leydig cells secrete testosterone, which is locally transported into peritubular cells and Sertoli cells and which via the blood circulation is transported through the capillaries and reaches the other more distant target organs. The mature fetal Leydig cells are regulated by luteinizing hormone (LH) via the LH receptor (LHR) in their plasma membrane.

DISEASES

The defects in regulatory genes cause a developmental disorder that reflects the function of the gene. In fact, many genes have been identified through analysis of these defects found in human patients. The ultimate disorder, a total lack of the testis, is the most severe defect and leads to subsequent structural and functional anomalies that can be deduced from the regulatory relationships illustrated in Figs. 1, 2, and 3.

The most common (and usually mild) disorder is cryptorchidism, where the testes of the newborn are still undescended in the abdominal cavity or in the inguinal canal. For subsequent personal health and fertility, it is important to bring the testes down to the scrotal sacs because the undescended testes are prone to cancers and remain infertile at adult age.

Testicular neoplasms are rare. The most common are germ cell tumors (95%), of which the seminomas

apparently originate from the early embryonic primordial germ cells. The Leydig cell tumors can cause strange symptoms that result from the effects of their abnormal hormones on target organs such as the genital organs, hair, and pituitary gland.

In comparison with the embryonic ovary (Fig. 2), the testis has a cardinal role in the regulation of sexual differentiation of the individual both before and after birth (Fig. 1). The endocrine activity enters a quiescent phase after birth and recovers at puberty together with the other major role of the testis, that is, the production of spermatozoa by spermatogenesis. This includes removal of active inhibition of meiotic divisions during the embryonic and prepubertal phases. Meiosis is a reductive type of cell division that is required for haploid germ cell production in both sexes; thus, it allows reorganization of genes and maintenance of constant chromosome number in the offspring.

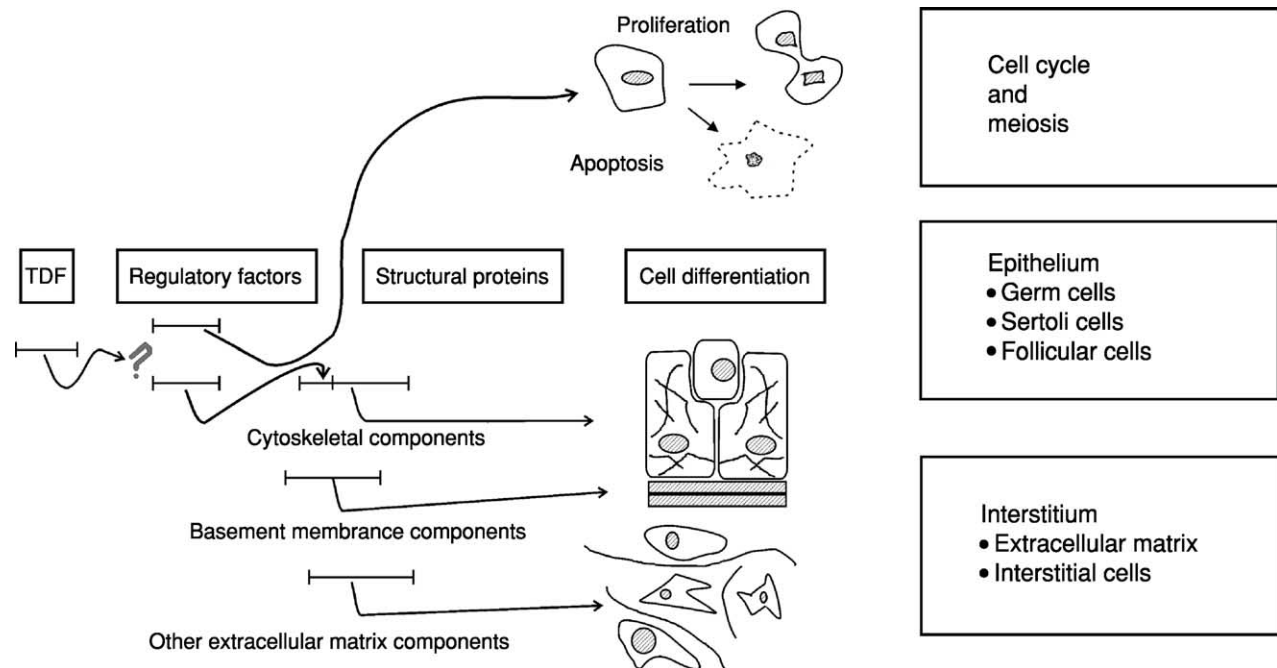

Figure 5 Regulatory pathways through which the testis differentiation factors (TDF) produced by the testis differentiation genes guide and regulate, via a cascade of successive regulatory steps, the numerical growth of the cells by proliferation through mitosis and after postnatal maturation by meiotic divisions in the spermatogenesis. In contrast to further cell divisions, some cells are directed to death by apoptosis. The primary targets of the testis differentiation factors are not known (?). The segment lines depict genes, and the arrows show the route and fate of the gene products. Some of the regulatory factors are apparently transcription factors of the next gene in the regulatory chain, and some are signal molecules that activate regulatory pathways in their target cells. At the end of the pathway, the final proteins are structural, secretory, and other proteins for the cells and the extracellular matrix, for example, cytoskeletal components for the regulation of the cell shape and motility, basement membrane components to separate and support the epithelial tissues (e.g., testicular cords in the testis), and extracellular matrix components (e.g., collagens and fibronectin in the interstitium of the testis). The interstitial cells have protein components different from those in epithelial cells. The rate of cell cycle, apoptosis, and later meiotic divisions determine the rate of growth of the testis. The internal organization of the originally undifferentiated epithelial tissue into the testicular cords, which comprise the germ cells and Sertoli cells, is a diagnostic feature of testicular differentiation at the light microscopic level. The follicular cells in the ovary correspond to the Sertoli cells in the testis and so constitute the epithelial component of the ovarian follicles around the oocytes. The line of the cytoskeletal component gene is divided into the segments where the left represents the promoter region and the right represents the actual coding sequence of the gene. These details are present in all genes, even though they are not shown in the figure.

Table 1 Histologic Classification of Testicular Germ Cell Tumors

| |
|--|
| Seminoma |
| Nonseminoma |
| Embryonal carcinoma |
| Teratoma |
| Mature |
| Immature |
| Mature or immature with malignant transformation |
| Choriocarcinoma |
| Yolk sac tumor (endodermal sinus tumor) |
| Mixed germ cell tumor (may include seminomatous component) |

carcinoma, teratoma, choriocarcinoma, or yolk sac tumor (endodermal sinus tumor). Seminoma may also be a component of a mixed GCT. If a tumor has both seminomatous and nonseminomatous components, it is classified as a nonseminomatous GCT and managed accordingly.

Nonseminomatous GCTs containing embryonal carcinoma with or without elements of choriocarcinoma may produce human chorionic gonadotropin (hCG), an important serum tumor marker. Elevations in alpha-fetoprotein (AFP), another important serum marker, are seen only in nonseminomatous GCTs and may be observed in tumors with embryonal and/or yolk sac components. Thus, a tumor is diagnosed as a seminoma only if there is no nonseminomatous component present (i.e., only pure seminoma) and if the AFP level is normal.

Pure seminomatous GCTs occur most frequently during the fourth decade of life. They are composed of uniform, large polyhedral cells surrounded by connective tissue stroma. Seminomas may contain syncytiotrophoblasts that are the source of increased serum concentrations of hCG; however, seminomas with syncytiotrophoblasts are not classified as nonseminomatous.

GENETICS

Cytogenetic and molecular genetic analyses have shown that an isochromosome of the short arm of chromosome 12, *i*(12p), is a specific marker of GCTs. It is detectable in approximately 80% of cases. *i*(12p)-negative tumors show excess 12p genetic material by fluorescent *in situ* hybridization (FISH) or other appropriate genetic techniques. Thus, excess 12p genetic material is present in all GCTs, including

ITGCN, and represents one of the earliest genetic changes associated with malignant transformation of germ cells. In some circumstances where tumor histogenesis is uncertain, identification of excess 12p copy number is an important diagnostic marker indicating germ cell origin.

DIAGNOSIS

The majority of patients with testicular GCTs present with scrotal discomfort, painless swelling, or testicular hardness. The pathognomonic finding of a painless testicular mass is present in only a minority of patients. Less commonly, patients present with back pain and/or nipple tenderness. In addition to a thorough bilateral testicular examination, the physical exam should focus on palpation for abdominal or cervical lymphadenopathy and gynecomastia (due to production of hCG).

Scrotal ultrasonography is necessary in the evaluation of a testicular mass with a high sensitivity for detection of a testicular tumor. Once a testicular tumor is suspected, all patients must undergo a radical inguinal orchiectomy with ligation of the spermatic cord at the internal ring. Embryologically, the testes originate in the genital ridge and descend during fetal life through the abdomen and inguinal canal into the scrotum; thus, the vascular and lymphatic drainage of the testes is to the renal or great vessels and retroperitoneal lymph nodes, respectively.

Because regional metastases usually first appear in the retroperitoneal lymph nodes below the renal vessels, computed tomographic (CT) imaging of the abdomen and pelvis is required. Right testicular tumors metastasize initially to interaortocaval lymph nodes, whereas left testicular tumors metastasize to para-aortic nodes. CT chest radiography is also required to evaluate for pulmonary nodules or supra-diaphragmatic adenopathy that may occur in the presence or absence of retroperitoneal disease.

Serum tumor markers, including AFP, hCG, and lactate dehydrogenase (LDH), have independent prognostic value and must be determined before, during, and after treatment. AFP concentrations may be elevated in other conditions, including hepatocellular carcinoma, liver disease, and gastrointestinal malignancies. hCG consists of α - and β -subunits, with the α -subunit sharing homology with several pituitary hormones, including luteinizing hormone (LH). False-positive elevations in hCG may result from cross-reactivity of the radioimmunoassay antibody with LH. An increasing AFP and/or hCG level in

a patient with a diagnosis of a GCT nearly always indicates active disease.

STAGING

Because of the prognostic significance of AFP, hCG, and LDH, the American Joint Committee on Cancer incorporated serum tumor markers into the standard "TNM" staging system (now TNMS). Stage I includes patients with tumors with or without vascular or lymphatic invasion as well as patients with persistently elevated tumor markers in the absence of clinical or radiographic evidence of metastases. Stage II includes patients with retroperitoneal nodal involvement with or without increased tumor marker levels. Stage III includes patients with distant metastases or high serum tumor marker levels.

MANAGEMENT

After radical inguinal orchiectomy, patients with early-stage seminoma (retroperitoneal disease less than 5 cm in diameter) are treated with radiation therapy to the retroperitoneal and ipsilateral pelvic lymph nodes. Approximately 4 to 10% of patients with stage I and II seminoma will relapse after radiation therapy. Chemotherapy will cure more than 90% of patients who relapse. Overall, approximately 99% of patients with early-stage seminomas are cured. Patients with bulky retroperitoneal lymph node involvement (>5 cm in diameter) initially receive chemotherapy.

Clinical stage I nonseminomatous GCTs can be cured in more than 95% of cases. Standard treatment options for clinical stage I disease without lymphatic or vascular invasion (stage 1A) include surveillance or retroperitoneal lymph node dissection (RPLND). The rationale for a rigorous surveillance program is based on a high cure rate with chemotherapy in the event of relapse. The likelihood of relapse is significantly higher ($\geq 50\%$) in patients with lymphatic, vascular, scrotal, or spermatic cord invasion (stage IB), and RPLND is preferable to surveillance. The presence of pure embryonal carcinoma may also be an adverse prognostic factor. Depending on the extent of disease, tumor marker levels, and tumor-related symptoms, patients with stage II nonseminomatous GCTs are treated initially with RPLND, chemotherapy, or both.

Patients with advanced nonseminomatous GCTs are initially treated with chemotherapy. Patients are staged according to the likelihood of cure with chemotherapy. Good, intermediate, and poor risk groups have been identified based on primary site, presence or absence of nonpulmonary visceral metastases, histology, and serum tumor marker concentration (Table II). Prior to the mid-1970s, chemotherapy for GCTs was only minimally effective. In 1977, Einhorn and Donohue reported impressive results with a chemotherapy regimen composed of cisplatin, vinblastine, and bleomycin (PVB) in patients with disseminated disease. In a series of subsequent clinical trials that investigated cisplatin-containing chemotherapy regimens over the ensuing 20 years, etoposide and cisplatin (EP) and EP with bleomycin (BEP) have been established as the standard treatment regimens

Table II International Germ Cell Cancer Collaborative Group Risk Classification

| | Nonseminoma | Seminoma |
|--------------------------|--|--|
| Good risk | Testicular or retroperitoneal primary AFP < 1000 ng/ml HCG < 5000 U/L LDH < 1.5 × upper limit of normal No nonpulmonary visceral metastases | Any primary site Nonpulmonary visceral metastases absent Normal AFP Any hCG Any LDH |
| Intermediate risk | Testicular or retroperitoneal primary AFP 1000–10,000 ng/ml HCG 5000–50,000 U/L LDH 1.5–10 × upper limit of normal No nonpulmonary visceral metastases | Any primary site Nonpulmonary visceral metastases present Normal AFP Any hCG Any LDH |
| Poor risk | Mediastinal primary tumor Any nonpulmonary visceral metastases AFP > 10,000 ng/ml HCG > 50,000 U/L LDH > 10 × upper limit of normal | None |

for previously untreated patients with advanced disease. Good risk patients may be treated with either four cycles of EP or three cycles of BEP. This strategy avoids the potential pulmonary, neurological, vascular, and myelosuppressive toxicity associated with bleomycin in patients who are most likely to be cured. Intermediate and poor risk patients should receive four cycles of BEP.

In advanced nonseminomatous GCTs treated with cisplatin-containing chemotherapy, surgical resection of all sites of residual disease, including RPLND and a resection of any additional disease sites, is necessary. If viable residual GCT is present in any resected specimen, two additional cycles of chemotherapy are administered to maximize the cure rate. A persistently elevated tumor marker (AFP or hCG) after chemotherapy is associated with viable GCT. These patients are usually treated with additional chemotherapy rather than immediate surgical resection.

FUTURE DIRECTIONS

In spite of the remarkable improvement in disease outcome over the past 25 years or so, 20 to 30% of patients with advanced GCTs do not achieve a durable remission with firstline therapy. Patients who do not have a complete remission (CR) or who relapse after a CR are treated with salvage chemotherapy or high-dose chemotherapy with stem cell rescue. In the United States, a prospective, randomized, cooperative group clinical trial is evaluating the role of high-dose chemotherapy with peripheral stem cell rescue as firstline therapy in patients with poor or intermediate risk disease. In addition, ongoing clinical trials of chemotherapy combinations, such as paclitaxel, ifosfamide, and cisplatin (TIP) and paclitaxel plus gemcitabine, have shown promise in the treatment of patients with refractory GCT.

60–80 mg/kg/day) of deferoxamine are used. These bone lesions include metaphyseal lesions, usually in younger patients, and spinal lesions (lordosis or kyphosis), generally in adolescents. However, after 10 years of age, despite the fact that adequate levels of hemoglobin are maintained, many of the β -thalassemia major children start having decelerated growth. In the pubertal children, there may be a reduced growth spurt with marked deceleration for which iron overload may be responsible. In this age group, truncal shortening, most likely due to hypogonadism secondary to iron deposition, may also be found.

The hormonal causes of growth retardation in β -thalassemia major children is complex, with the main causes being hypogonadism and hypothyroidism. However, it has become apparent that growth hormone (GH) also plays a role in their abnormal growth. It still remains unclear how the GH and insulin-like growth factor-1 (IGF-1) axis may play a role. Several authors reported reduced serum concentrations of IGF-1 in the presence of a normal GH response to provocative studies, and this led to the speculation that GH insensitivity is most likely the cause of the abnormal growth.

Our group reported that the IGF-1 and IGF-binding protein-3 (IGFBP-3) generation tests in children with β -thalassemia major help to distinguish the causes of their growth retardation. By using these generation tests, we noted that most of the β -thalassemia major patients had growth retardation secondary to disturbances in GH secretion rather than GH insensitivity. Classic GH deficiency and GH neurosecretory dysfunction are the causes of low IGF-1 and short stature in many β -thalassemia major children. Growth hormone treatment (hGH) in short β -thalassemia major has shown that these children can benefit from this therapy. This seems to be true in the β -thalassemia major children who have GH deficiency, both classic GH deficiency (Fig. 1) and GH neurosecretory dysfunction (Fig. 2). However, the growth of these children after hGH therapy is not as good as that of their nonthalassemic peers, possibly because a higher dose of hGH is required to achieve an optimal growth result. But because growth hormone is a natural antagonist of insulin, glucose metabolism parameters must be monitored closely in all β -thalassemia major children receiving hGH therapy.

Histological examination at autopsy of the endocrine glands of β -thalassemia patients has shown mild to moderate siderosis and a reduced number of cells in the pituitary gland as well as fibrosis and siderosis of the thyroid gland and gonads. This is consistent with the view that many β -thalassemia major patients

may have primary or secondary endocrine gland dysfunction secondary to iron overload. Undernutrition is also an important cause of low IGF-1 and associated growth disturbances in this group. This may be compounded by zinc deficiency in certain cases of undernutrition. Good nutrition with adequate vitamins and trace elements, along with calcium and vitamin D supplementation, can increase bone density and also enhance the growth of β -thalassemia major patients.

HYPOTHYROIDISM

The reported incidence of thyroid disorders in β -thalassemia major varies greatly in different countries, probably due mostly to the difference in iron chelation therapy and to the different genetic varieties of the defect of the β -chain. The frequency of primary hypothyroidism, which is usually compensated, can vary from 10 to 50%, also depending on the age of the patients selected, the criteria used to diagnose hypothyroidism, and the availability of deferoxamine (which is used as an iron chelating agent). The incidence of incipient hypothyroidism, as judged by an exaggerated thyrotropin (TSH) in response to thyrotropin-releasing hormone (TRH) in β -thalassemia major patients of all ages in Greece, was found to be 35%. These patients can also have an underlying defect present in the thyroid without an apparent thyroid abnormality. This can be detected by a substantial increase in serum TSH when these patients are exposed to pharmacological doses of iodide. The vast majority of β -thalassemia patients (64%) who developed subclinical hypothyroidism during iodide administration developed permanent hypothyroidism during a 5-year follow-up. This can be of major importance to the thalassemic patients who commonly present with heart failure and cardiac arrhythmias. The antiarrhythmic drug amiodarone, which contains iron, can cause subclinical hypothyroidism. This can be extremely detrimental to β -thalassemia major patients with cardiac problems, and these patients need to be treated with thyroxine while taking amiodarone.

The cause of thyroid dysfunction in β -thalassemia major seems to be iron overload, chronic anemia, or tissue damage by hypoxia that is detrimental to the thyroid tissue. Therefore, frequent screening for thyroid dysfunction in β -thalassemic major patients is mandatory to help these individuals maintain optimal health.

HYPAGONADISM

Hypogonadism is common in β -thalassemia major and seems to be the most frequent endocrine

Figure 1 Growth curve of a β -thalassemia major female with classic growth hormone deficiency before and after therapy with hGH (arrow).

Figure 2 Growth curve of a β -thalassemia male with GH neurosecretory dysfunction before and after therapy with hGH (arrow).

abnormality found in this group. Most β -thalassemia major patients have hypogonadotropic hypogonadism due to hypothalamic and pituitary dysfunction resulting from iron deposition in these areas. This can be compounded by gonadal insufficiency due to iron deposition in the ovaries and testes. These abnormalities can cause severe psychological problems in young developing β -thalassemia major patients.

The pituitary–gonadal axis dysfunction can present in different ways with delayed puberty, arrested puberty at various Tanner stages, or complete lack of sexual development. The incidence of these abnormalities can be quite high. Up to 47% of girls and 51% of boys present with hypogonadism, 23% of girls present with secondary amenorrhea, and 13% of patients of both sexes present with sexual maturation arrest. Because sex steroids play a major role in truncal growth, any impairment in sexual maturation can cause severe truncal growth problems and a loss of the pubertal growth spurt. Studies have shown that up to 80% of short β -thalassemia major children and 40% of normal-statured β -thalassemia patients present with a short trunk. The etiology of the short trunk is not only hypogonadism but also iron overload and deferoxamine-induced bone dysplasia. Consensus guidelines for the treatment of hypogonadism have been compiled to promote near-normal sexual development and optimal growth. They are as follows:

A. Puberty is pharmacologically induced with ethinylestradiol (2.5–5.0 μg orally for 4–6 months) in girls over 13 years of age who have a bone age of 10 to 11 years. If there is no evidence of further spontaneous pubertal progression, the sex steroid dose is progressively increased every 6 months, followed by hormonal replacement therapy with estrogens and progesterone.

B. Pubertal induction in boys is induced pharmacologically (25–50 mg/month of depot testosterone intramuscularly for 3–6 months) when they are over 14 years of age and have a bone age of 11 to 12 years. If puberty does not progress, the sex steroid doses are increased. In young adults, 100 mg depot testosterone twice monthly achieves the desired virilizing effect.

C. If GH insufficiency is also present, hGH treatment should be started at a dose of 0.6 to 0.8 IU/kg/week (0.20–0.26 mg/kg/week). With sex steroid treatment, sexual maturation and growth can be achieved and optimal height can be attained.

Alternative treatment to induce puberty in males has also been successful with human chorionic gonadotropin (hCG). Good results in testicular development and

fertility have been reported with doses of hCG (500–2000 IU twice weekly) plus human urinary follicle-stimulating hormone (75 IU two or three times/week).

CALCIUM AND BONE METABOLISM ABNORMALITIES

In β -thalassemia, major hypoparathyroidism often can be completely asymptomatic, with hypocalcemia detected only in routine laboratory examinations. However, in certain cases, the symptoms of hypocalcemia in β -thalassemia major can be extremely severe, with signs of tetany, seizures, and even cardiac failure.

Magnetic resonance imaging (MRI) of the brain can sometimes show calcium deposits at the thalamus, basal ganglia, and cerebral hemispheres. The treatment of choice is oral administration of oral calcium and calcitriol.

DIABETES MELLITUS

Diabetes mellitus (DM) is an endocrine complication in β -thalassemia major that is not infrequent. Its frequency progresses with age and can vary from 2 to 24% in various studies.

Both insulin-dependent diabetes mellitus (IDDM) due to insulin deficiency and non-insulin-dependent diabetes mellitus (NIDDM) due to liver function impairment or insulin resistance are found in β -thalassemia major patients.

Our group showed that before the onset of DM in β -thalassemia major, there is an impairment of glucose sensing of the islet beta cells of the pancreas, with the loss of the first-phase response of insulin to intravenous glucose similar to what occurs during the prediabetic state in IDDM and NIDDM in patients without β -thalassemia major. Oral glucose tolerance tests (OGTT) in β -thalassemia major patients also seem to exhibit significantly higher plasma glucose levels and more sustained glycemic responses. Evaluation by the homeostasis model assessment (HOMA) also showed a clear reduction in both beta cell function and insulin resistance indexes. What is of interest is that the impaired glucose tolerance (IGT) found in β -thalassemia major seems to be reversible since a significant decrease in IGT has been reported to follow bone marrow transplantation.

Risk factors that are associated with DM are lack of compliance to chelation therapy, iron overload, and the presence of cirrhosis and severe fibrosis. A decreased incidence of DM has been observed with ferritin levels of less than 2500 ng/ml.

Guidelines for the treatment of DM in β -thalassemia major are as follows. First, for patients with normal or impaired OGTT but increased or delayed insulin secretion, diet and exercise are recommended. Second, for patients with impaired or diabetic OGTT with an adequate but delayed insulin response, an oral hypoglycemic agent is indicated. Third, for patients with insulin deficiency and a diabetic OGTT, insulin is recommended.

CONCLUSION

The improved life expectancy of β -thalassemia major patients has brought to light a variety of endocrine problems for which early detection and treatment, together with an aggressive iron chelation program, are imperative so that β -thalassemia major patients can live longer and higher quality lives.

axis that may exert a central modulatory effect on thirst and vasopressin release.

Of interest is an additional thirst regulatory mechanism described as oropharyngeal metering. Evidence indicates that the act of swallowing may be the afferent limb of a conceptual pathway that ultimately determines the volume of fluid ingested in response to dipsogenic stimuli. Although the exact pathophysiology is unclear, these reflexes are thought to account for the rapid assuaging of thirst following drinking, even prior to the restoration of euolemia and normal tonicity. Additionally, these reflexes may also be involved in the dampening of vasopressin secretion that occurs during drinking. It is likely that the teleological role of this reflex is to bar the excessive ingestion of water.

Ultimately, drinking is a voluntary and highly coordinated function indicating involvement of multiple complex neural pathways. However, the cortical pathways responsible for the cortical control of drinking and dipsogenesis remain poorly defined. This is likely due to the confounding effect of multiple psychosocial and behavioral influences on drinking habits.

THIRST AND AGING: HOMEOSTATIC REGULATION

Older adults are more likely to develop hyperosmolar dehydration following water deprivation. Reasons for the increased risk of dehydration in older adults include a reduction in total body water with aging and

age-related impairment in renal tubular concentrating ability. Dipsogenic influences therefore assume increased significance in fluid homeostasis with aging.

Age-related hypodipsia is well recognized. Additionally, compensatory dipsogenic fluid repletion, following a period of water deprivation, proceeds at a much slower rate in older adults. However, available evidence indicates that fluid deficits are eventually fully replaced. Experimental data obtained from human studies of hypertonic saline infusion reveal comparatively lower levels of thirst and less water intake in older adults than in younger adults. These findings support the theory of age-related blunting of osmoreceptor sensitivity. Hypertonic saline infusion in older adults results in increased vasopressin release, suggesting an age-related increase in the sensitivity of central vasopressin neuroreceptors. Thus, it is plausible that age-related attenuation of the thirst response is more likely due to altered circulating vasopressin levels. Indeed, there is a loss of circadian rhythm resulting in nocturnal peaking of vasopressin secretion in older adults. However, studies have yielded conflicting results regarding age-related changes in circulating baseline and diurnal vasopressin levels.

Several other hormones have been implicated in the etiology of age-related hypodipsia. Intravenous infusion of pharmacological levels of atrial natriuretic peptide has been shown to inhibit osmotically induced dipsogenesis and vasopressin secretion. Similarly, data relating the relatively higher levels of circulating norepinephrine (NE) levels to the known anti-dipsogenic effect of NE suggest a possible role for NE in the genesis of age-related hypodipsia.

Altered opioid sensitivity may also play a causal role in age-related physiological hypodipsia. Administration of naloxone has been shown to suppress fluid intake after overnight water deprivation in younger subjects. However, the anti-dipsogenic effect of naloxone is far less pronounced in older adults, raising the possibility of reduced opioid receptor sensitivity with aging.

The effect of aging on oropharyngeal metering is unknown. Pharyngeal dysphagia, resulting from esophageal dysmotility, is a recognized complication of presbyesophagus. However, the effect of this condition on oropharyngeal metering as a fluid homeostatic mechanism requires exploration. Similarly, other age-related oropharyngeal responses are ill-defined. Traditionally, taste and tactile sensations are considered the primary sensory modalities perceived by the oral and lingual surfaces. However, degrees of moistness are perceived within the oral cavity. It is plausible that persons with age-related dysgeusia

might also exhibit an attenuated response to dryness of the oral mucosa. Further research is needed in this area.

THIRST AND AGING: NONHOMEOSTATIC REGULATION

Much of the research on thirst centers on homeostatic responses to fluid deprivation and altered plasma tonicity, possibly because fluid balance in the younger, healthy adult is notably threatened only under conditions that overtly disrupt homeostatic regulation. In contrast, older adults not only are subject to the effects of physiological attenuation of fluid homeostasis, but also face the threat of compromised nonhomeostatic dipsogenic influences.

The significance of nonhomeostatic factors is highlighted by studies of *ad libitum* fluid intake, indicating that physiological regulation of fluid intake rarely comes into play in free-living healthy individuals, regardless of age. Data indicate that, when fluid is available, in both young and old adults, thirst results in fluid intake well before hypovolemic or hypertonic deficits occur. Dipsogenic triggering events are undoubtedly complex and intricate. Multiple nonhomeostatic dipsogenic factors include hedonic influences such as appearance, ambience, fluid preferences, and palatability. Thus, age-related sensory impairments, such as dysgeusia, anosmia, and impaired vision, might detract notably from the hedonic qualities of fluids. Psychological influences, sociocultural expectations, health awareness, and lifestyle habits also affect the type and quantity of fluid consumed. Most importantly, data indicate a direct correlation between food intake and fluid intake, introducing age-related and pathological anorexia as additional factors in threatening fluid balance in older adults. Increased isolation and impaired functional status may further restrict access to fluid. Acute illness and chronic disease have a notable, albeit variable, effect on fluid balance in older adults. An added threatening variable to fluid balance is the effect of medication and polypharmacy on fluid balance.

DEHYDRATION IN THE ELDERLY: CLINICAL OVERVIEW

Dehydration is highly prevalent among older adults, occurring in approximately 1 million elders each year admitted to acute care facilities in the United States. Annually, health care expenditure on dehydration among persons older than 65 years exceeds 1.2 billion

Table II Complications of Dehydration in the Elderly

| Dysuria |
| Renal failure |
| Increased risk of uro-epithelial malignancies |

dollars. Complications of dehydration are myriad, including delirium, falls, and incontinence (Table II). Associated mortality rates approach 50%. Multiple clinical factors predispose the older adult to dehydration. Although an exhaustive review of the clinical causes, diagnosis, and treatment of dehydration is beyond the scope of this article, it is pertinent to note that most of the causes of dehydration are avoidable and easily reversible. Prompt clinical detection is, however, dependent on increased awareness of the risk of dehydration in geriatric patients. Reliance on clinical diagnosis of dehydration is confounded by the poor predictive value of traditional clinical indices of dehydration. Poor skin turgor and lack of axillary sweating correlate poorly with dehydration in older persons. Similarly, although dry oral mucous membranes are the most sensitive signs of dehydration in older patients, adverse effects of medication and mouth breathing may produce identical changes. Furthermore, available data show that orthostatic hypotension in older patients does not reflect dehydration severity as medications, age-related changes, and prolonged bed rest may also result in orthostasis via autonomic dysfunction. Thus far, selected laboratory indices of dehydration, namely, serum osmolality >300, blood urea nitrogen (BUN) >20, or BUN:creatinine ratio >20, are the most reliable indices of dehydration.

Ultimately, prevention of dehydration is the most cost-effective method to thwart this potentially fatal, yet easily treatable, condition. New dietary guidelines for older Americans recommend consumption of at least 2 liters of fluid daily. However, there is limited evidence to support this arbitrary figure. Available evidence-based data support the benefits of ingestion

of at least 1.5 liters of fluid daily. It is unclear whether regular consumption of fluids in excess of this amount may result in dilutional hyponatremia and other consequences of water overload. Treatment of dehydration mandates due attention to restoration of normal plasma tonicity and correction of the fluid deficit. Older persons who are unable to ingest fluids orally may require parenteral fluid administration. Intravenous administration is the traditional method. However, health professionals should be aware of the utility of alternative routes, such as percutaneous gastrostomy, that may be preferred in older adults with coexisting anorexia or dysphagia. Subcutaneous fluid infusion (hypodermoclysis) is a convenient, simple, relatively safe, and cost-effective method that may be particularly effective in frail, institutionalized persons at increased risk of dehydration.

Effective management of dehydration in the older adult mandates meticulous attention to pathophysiological stressors in the context of preexisting hypodipsia. Ultimately, the ideal therapeutic goal is the development of an individualized fluid maintenance and hydration intervention strategy for all older adults, healthy or otherwise.

Glycosylation is a key event in Tg maturation. Approximately three-quarters of the potential glycosylation sites in Tg are occupied. Human Tg contains different types of carbohydrate units. Common are the "polymannose" units consisting of mannose and N-acetylglucosamine and the "complex" unit that has a core of three mannose residues with several chains of N-acetylglucosamine, galactose, and fucose or sialic acid extending from it. Both types of carbohydrate complexes are linked to peptide through an asparagine-N-acetylglucosamine bond. Moreover, human thyroglobulin (hTg) contains two additional carbohydrate units linked to the peptide chain through the hydroxyl group of serine or threonine.

Tg contains several tyrosine residues that are preferentially iodinated. By coupling of two iodotyrosine residues, one functioning as a donor residue and the other as acceptor residue, thyroxine is generated at the acceptor site. The selectivity of tyrosine residues that become iodinated appears to be strongly dependent on the stereo-specific structure of the molecule. The main product is thyroxine and in much lesser quantities, 3,5,3'-triiodothyronine (I3) and 3,3',5' triiodothyronine (reverse I3) are formed.

The function of the 11 type 1 cysteine-rich repeats in the molecule, which is described in bovine and human Tg, is not clear. It has been shown that these repeats are protein modules that can act as pH-dependent binders and reversible inhibitors of the proteases implicated in Tg degradation and thyroxine release. Acetylcholine esterase is known to interact with the cell membrane in the nervous system, and a similar role for the homologous domain at the

carboxy-terminal end of the Tg molecule has been proposed for apical membrane interaction. Unfortunately, the mutation in the cog/cog mouse model, which is located in this domain, leads to ER storage of an apparently misfolded Tg molecule and, therefore, does not directly contribute to the elucidation of the function of this domain.

Recently, three conserved thioredoxin boxes have been identified in mammalian Tg, and studies on a bovine Tg fragment revealed a role for these boxes in self-assisted disulfide-bond formation leading to the intramolecular cross-linking of luminal Tg.

In rat Tg, the heparin-binding domain is proposed to bind to megalin that participates in the endocytosis of Tg-T4 complexes from the follicular lumen.

THYROGLOBULIN SYNTHESIS DEFECTS

The Tg synthesis defect has been studied extensively in three animal species. In Afrikaner cattle, a homozygous nonsense mutation in exon 9 results in truncated Tg protein of 75 kDa due to the conversion of arginine 697 to a premature stop codon. In this case, an alternatively spliced mRNA lacking exon 9 sequence also is present, encoding a Tg protein of 250 kDa. In Dutch goats, a homozygous nonsense mutation in exon 8 changes tyrosine 296 to a stop and results in a truncated Tg protein of 40 kDa, causing hypothyroidism with goiter. Administration of extra iodine to homozygous mutant Dutch goats restores euthyroidism, but goiter persists. Furthermore,

in a mouse model (*cog/cog* mouse), congenital goiter is linked to the Tg locus and is caused by the transition of leucine 2366 in the Tg protein to proline. This defect results in an ER storage disease.

Patients who are suspected of having disorders in the synthesis of Tg are moderately to severely hypothyroid. The plasma Tg concentration is usually low, especially in relation to the thyroid-stimulating hormone (TSH) concentration, and intravenous injection of TSH does not increase the plasma Tg concentration. Patients classified in the category “Tg synthesis defects” often have abnormal circulating iodoproteins, mainly iodinated albumin, and excrete iodopeptides of low molecular weight in the urine.

Mutations in the Tg gene have been elucidated only in four human families. A homozygous mutation at the acceptor splice site of intron 3 gives an “in-frame” deletion of exon 4 from the Tg mRNA, resulting in an aberrant Tg protein lacking the hormonogenic site tyrosine 130 and a characteristic Cys–Trp–Cys repeat. Another patient with a homozygous in-frame mRNA deletion of 138 nucleotides has been described. The preferential accumulation of a Tg mRNA alternative splice product with an in-frame deletion of exon 22, linked to a homozygous nonsense mutation at position 1510 and resulting in an ER storage disease similar to the *cog/cog* mice, has also been reported. Furthermore, a homozygous nonsense mutation in the Tg mRNA of moderately hypothyroid patients with goiter has been described. A homozygous nonsense mutation in exon 7 results in the conversion of arginine 277 to a premature stop codon and subsequently results in the synthesis of a truncated Tg protein of 30 kDa. As has been seen in Dutch goats, the truncated Tg glycoprotein can still be iodinated and is able to synthesize thyroid hormone.

In a study with six patients with the clinical classification “Tg synthesis defects”, no mutations are

present in the Tg mRNA. Therefore, the clinical entity “Tg synthesis defects” cannot be restricted to the Tg molecule itself, indicating that under this clinical entity other proteins involved in Tg synthesis and processing can be affected.

Table 1 Types of Thyroid Autoimmunity^a

| Type | Thyroid antibodies | Thyroid function | Other features |
|---|--|--|--|
| Focal thyroiditis | TG or TPO Abs in most cases at low titer | Normal or subclinical hypothyroidism | May progress to overt hypothyroidism |
| Silent thyroiditis | TPO Ab in most cases, TGAb variable | Transient thyrotoxicosis and/or hypothyroidism | Most commonly occurs 1 year after delivery as postpartum thyroiditis; may progress to overt hypothyroidism |
| Hashimoto's (goitrous) thyroiditis | TG and TPO Ab, usually high titer; occasional TBAb | Euthyroid or hypothyroidism | Associated rarely with thyroid lymphoma |
| Atrophic thyroiditis (primary myxedema) | TG and TPO Ab at variable titer; TBAb in up to 20% of cases | Hypothyroidism | May evolve from Hashimoto's thyroiditis |
| Graves' disease | TSAb in all cases; TPO Ab in 80% and lower frequency of TGAb | Hyperthyroidism | Strongly associated with TAO |

^aAbbreviations used: Ab, antibody; TG, thyroglobulin; TPO, thyroid peroxidase; TBAb, TSH receptor-blocking antibodies; TSAb, TSH receptor-stimulating antibodies; TAO, thyroid-associated ophthalmopathy.

variety of soft tissue changes, including periorbital edema, proptosis, diplopia, and, in severe cases, optic nerve compression. Approximately 90% of patients with TAO have Graves' disease, 5% have autoimmune hypothyroidism, and almost all of the remainder have subtle evidence of thyroid autoimmunity.

EPIDEMIOLOGY

Approximately 5% of pregnancies are followed by postpartum thyroiditis, although clinically significant features occur in only a small percentage of these cases. The prevalence of autoimmune hypothyroidism in women is 1 or 2% and in men it is 5–10 times less frequent. Approximately 2% of individuals with thyroid autoantibodies and presumed focal thyroiditis progress to overt autoimmune hypothyroidism annually; the rate is more than double if there are thyroid autoantibodies and subclinical hypothyroidism. The peak incidence of autoimmune hypothyroidism occurs in individuals between 50 and 60 years of age.

Graves' disease accounts for 60–80% of all cases of thyrotoxicosis, with a prevalence of approximately 1% in women, peaking in those aged 30–60 years. In men, the frequency is 5- to 10-fold lower than that in women. Approximately 50% of patients with Graves' disease have clinically obvious TAO, but subclinical evidence of this complication can be found in more than 90% of cases by using imaging techniques.

PATHOLOGICAL FEATURES

In Hashimoto's thyroiditis, the thyroid is enlarged, usually symmetrically, due to a diffuse infiltration by lymphocytes, plasma cells, and macrophages, together

with the formation of lymphoid germinal centers. Thyroid cells undergo hyperplasia and oxyphil metaplasia, with the latter leading to the formation of Hürthle or Askanazy cells. Progressively, however, thyroid cell destruction occurs, together with variable amounts of fibrosis. In primary myxedema (atrophic thyroiditis), there is more extensive fibrosis and follicular destruction and minimal or moderate lymphoid infiltration.

In Graves' disease, there is hypertrophy and hyperplasia of the thyroid follicles, which have columnar, folded epithelium and less colloid than usual. There is a variable degree of lymphoid infiltration, sometimes with germinal center formation. All these changes are largely reversed by antithyroid drug treatment. The changes seen in TAO consist of variable lymphocytic infiltration of the extraocular muscles and orbital connective tissue, edema, and, in the later stages, fibrosis and possibly muscle atrophy. Fat content may increase, especially late in the disease process, and mast cells may be prominent. The levator palpebrae muscle fibers are enlarged. Lymphocytic infiltration of the eyelids is uncommon, whereas this can often be seen in the lacrimal glands.

DETERMINANTS OF THYROID AUTOIMMUNITY

Like almost all autoimmune disorders, those associated with thyroid autoimmunity are the result of a complex interaction between a large number of genetic, environmental, and endogenous factors, with the same disease resulting from different combinations of factors in different patients. The contribution of genetic factors to disease susceptibility is unknown, but

Table II Diseases Associated with Thyroid Autoimmunity

| |

| Depression or bipolar affective disorder |
| Recurrent miscarriage |

concordance rates in monozygotic twins are approximately 20–30%, considerably higher than in dizygotic twins. Different autoimmune thyroid diseases may occur in the relatives of a proband in a single family, and there is a well-known set of associations with other autoimmune diseases (Table II), suggesting that these share common susceptibility factors, most likely genetic.

Genetic Factors

In common with the majority of autoimmune diseases, the highly polymorphic alleles of the major histocompatibility complex (MHC), called HLA (human leukocyte antigen) in man, have been the most intensively studied and are the most frequently associated genetic factors in thyroid autoimmunity (Table III). There are several reasons why HLA alleles might confer susceptibility to autoimmune thyroiditis. The MHC class II genes are crucial for antigen presentation (Fig. 1), and it is possible that only certain class II molecules can bind particular autoantigenic epitopes and thus initiate an autoimmune response (determinant selection). Particular class II alleles may also be critical for the thymic selection of T cells during early life, either permitting the evolution of autoreactive T cells (positive selection) or preventing their development (negative selection); in the latter case, the allele would have a protective effect. Alternatively, some MHC class II alleles may determine selection of an increasingly better defined subpopulation of regulatory T cells, previously called suppressor cells. Finally, the effects of the HLA-DR3 specificity are nonspecific and seem to be related to a general enhancement of immune responsiveness, which in turn may be related to the effects of polymorphisms in other genes in linkage disequilibrium, such as complement components or the cytokine tumor necrosis factor.

However, it is clear that many individuals possess HLA-DR alleles that confer susceptibility but never develop autoimmune thyroid disease. Conversely, approximately half of individuals with autoimmune thyroid disease do not have any known HLA allele associated with susceptibility. The inevitable conclusion is that other genes must be involved, and these may act independently or interact with MHC-encoded susceptibility, making the determination of their effect more difficult. This genetic diversity is

Table III Major HLA Associations in Thyroid Autoimmunity

| Condition | Ethnic group | Association |
|-----------------------------------|------------------------|---|
| Autoimmune hypothyroidism | Caucasian | HLA-DR3, DR4 |
| | Chinese | HLA-B46, DR9 |
| | Japanese | HLA-DR53, DR9 |
| Postpartum thyroiditis | Caucasian | HLA-DR5, possibly DR3 |
| Graves' disease | Caucasian | HLA-DR3 (DR17 and DR18 subtypes) |
| | Japanese, Korean | HLA-DR5, DR8, DPB1*0501 (DQB1*0501 protective) |
| | U.S. Black | None |
| | South African Black | HLA-DR1, DR3 |
| Thyroid-associated ophthalmopathy | Caucasian and Japanese | As for Graves' disease; HLA-DPB1*0201 may be protective |

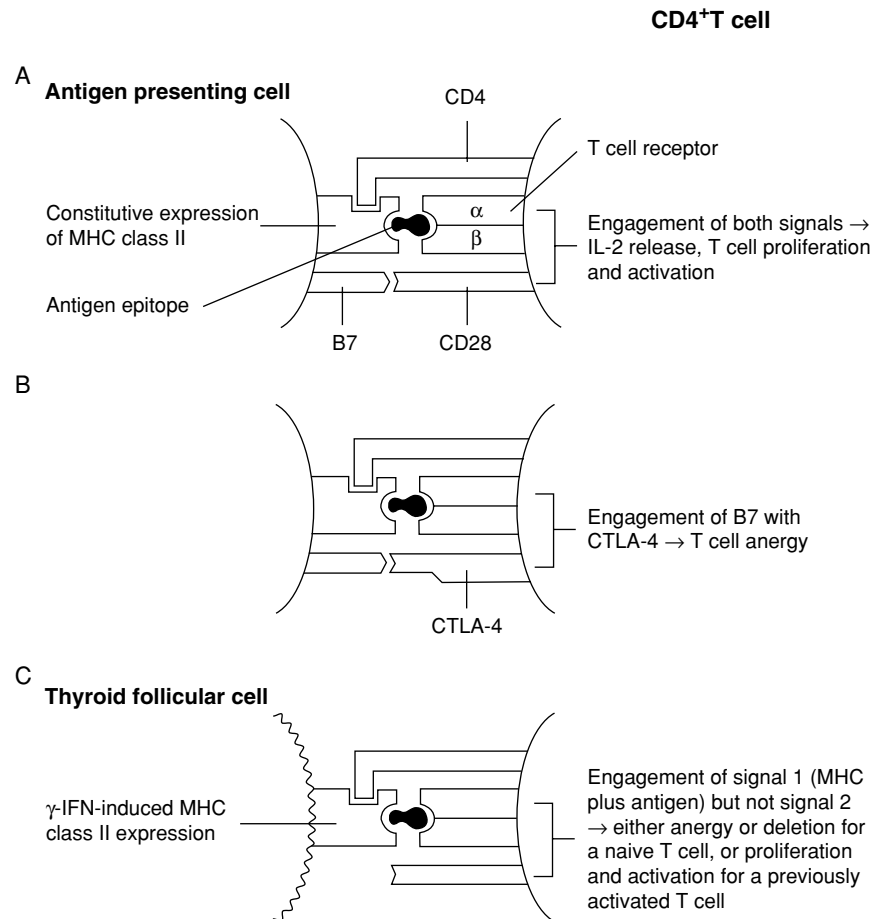

Figure 1 Pathways of antigen presentation leading to CD4⁺ T-cell stimulation (A, acute antigen presentation) or anergy (B, chronic antigen presentation; C, antigen presentation by endocrine cell). Reproduced from Weetman, A. P. (2003). Autoimmune thyroid disease: propagation and progression. *Eur. J. Endocrinol.* **148**, 1–9.

also demonstrated by the three to four times higher concordance rate for Graves' disease in monozygotic twins than in HLA-identical siblings.

The only other unequivocal genetic factor known to be associated with susceptibility is polymorphism in the *CTLA-4* gene, although it is unclear whether this is related to effects from the gene or closely related genes in linkage disequilibrium. Certainly, *CTLA-4* is an attractive candidate autoimmunity gene because the CTLA-4 molecule is critical to the termination of immune responses (Fig. 1) and CTLA-4 knockout mice develop a lymphoproliferative syndrome associated with widespread lymphocytic infiltration of tissues. The susceptibility conferred by *CTLA-4* polymorphisms is modest and similar in both Graves' disease and autoimmune hypothyroidism; despite initial observations, these polymorphisms do not confer any heightened risk of complications such as TAO. Moreover, the same polymorphisms are shared with

other disorders, such as type 1 diabetes mellitus, vitiligo, and Addison's disease, and therefore seem to confer a general propensity to develop organ-specific autoimmunity, which in turn may partially explain the frequent occurrence of the disorders.

Further progress in understanding the genetic basis of thyroid autoimmunity will only be achieved by performing large-scale family studies, either by testing candidate genes as these are discovered in other immunological disorders or by performing genomewide scanning in a search for previously unsuspected loci. Some progress has been made in this area, with certain candidate loci such as TSH-R being excluded from having a major role, whereas several potential loci have been identified, particularly on chromosomes 14q31, 18q21, 20q13, and Xp11. However, the power of these studies is insufficient to provide conclusive evidence for linkage, and several hundred families will need to be tested to obtain adequate power for

confidence. Even then, localizing the relevant susceptibility gene within a large locus will take much time and effort.

Environmental Factors

The importance of environmental factors in causing autoimmune thyroiditis is illustrated by the incomplete concordance in monozygotic twins and the lack of any family history of autoimmunity in many patients. Genetic factors are more likely to exert their effects in early onset cases, and environmental factors, which require exposure of the individual, likely operate at later stages in life, but matters are even more complex because there are certainly interactions between genetic and environmental factors. Our inadequate knowledge stems largely from the difficulty of analyzing such heterogeneous interactions.

Infections are frequently suggested to play a role in producing autoimmunity by causing release of autoantigens from damaged tissue, by molecular mimicry in which epitope sequences of the organisms provoke an immune response against matching host protein sequences, or by altering target cell surface molecules that render the cell susceptible to autoimmune attack. However, there is no good evidence that thyroid autoimmunity is precipitated by infection and, indeed, subacute thyroiditis caused by viral infection of the thyroid is characterized by recovery of normal thyroid function. *Yersinia* infection has been examined as a potential trigger because there is evidence that the organism contains TSH-R-like sequences, but any role is likely to be small at best because few patients with Graves' disease have evidence of infection. There is even less reliable support for the involvement of retroviruses.

Iodide intake may determine the frequency of thyroid autoimmunity because there is epidemiological evidence that increases in dietary iodide are associated with an increase in the incidence of thyroid autoantibodies, autoimmune hypothyroidism, and Graves' disease. Animal models of autoimmune thyroiditis have provided support for such an enhancing role; conversely, iodide depletion appears to be protective. Excess iodide may be toxic to thyroid cells or may have immunological effects, including enhanced immunogenicity of thyroid autoantigens.

Major stress may precipitate Graves' disease, at least based on evidence from retrospective surveys, and such an effect could be produced by the neuroendocrine consequences of stress, especially on glucocorticoids. Smoking is weakly associated with Graves' disease and is the strongest known determinant of TAO. The

Figure 2 Reciprocal regulation of T helper (Th) cell subsets. The dotted lines represent an inhibitory pathway.

reasons for these associations are not known, but it is possible that smoking may either modulate the immune response in some way (e.g., by affecting cytokine production) or enhance orbital fibroblast responses secondary to partial hypoxia.

At low doses, radiation may initiate thyroid autoimmunity because both Graves' disease and autoimmune hypothyroidism have been reported after mantle irradiation for lymphoma, and there is an increase in thyroid autoantibodies in the survivors of irradiation from nuclear weapon or reactor fallout. Some drugs may also precipitate thyroid autoimmunity, particularly in those who are genetically predisposed; examples include lithium, α -interferon, and other cytokines. For example, Graves' disease occurs in one-third of multiple sclerosis patients treated with monoclonal antibodies to deplete T cells; it is likely that during T-cell recovery from this treatment, the cytokine profile of the emerging T cells shifts from a T helper cell 1 (Th1) to a Th2 pattern, with the latter provoking autoantibody production (Fig. 2). However, it is unclear why the TSH-R specifically is targeted.

Endogenous Factors

Pregnancy is associated with amelioration of autoimmune thyroiditis, and patients with Graves' disease can usually stop drug treatment during the last trimester. However, a rebound in the autoimmune process occurs during the year after delivery. This is

when postpartum thyroiditis emerges and Graves' disease appears with an increased incidence. These changes are largely unexplained but presumably relate in part to massive fluctuations in various hormones during and after pregnancy. Sex hormones are likely the major determinants of the increased risk of thyroid autoimmunity in women, but the causes of the increased risk in Turner's and Down's syndromes are unknown.

THYROID AUTOANTIGENS

Understanding any autoimmune disease is contingent on a thorough knowledge of the nature of the autoantigens involved and their B- and T-cell epitopes. In addition to aiding in the determination of the etiology and pathogenesis of an autoimmune disease, autoantigen identification is central to assays for autoantibodies that may be markers or predictors of disease or for the delineation of particular subsets of patients, and it may lead to novel treatments, such as that based on modified T-cell peptide epitopes. Indeed, our poor understanding of the pathogenesis of TAO is due directly to an inadequate understanding of the autoantigens involved. A summary of the main thyroid autoantigens is shown in [Table IV](#).

Thyroglobulin

This was the first tissue autoantigen to be identified, based on the pioneering work by Witebsky and Rose, who immunized rabbits with thyroid extract in adjuvant, eliciting thyroglobulin antibodies and thyroiditis, and work by Doniach and Roitt, who first showed the presence of thyroglobulin antibodies in patients with Hashimoto's thyroiditis. Thyroglobulin is the thyroid hormone storage system; tyrosine molecules at hormonogenic sites are iodized to form T3 and T4. The protein is secreted into the follicular lumen, in which it is endocytosed and hydrolyzed to release

T3 and T4. Iodination of the molecule is important for its immunogenicity in animal models of autoimmune thyroiditis: there is no clear evidence that this is important in humans.

Two major epitopes and one minor conformational epitope exist on each thyroglobulin subunit for human autoantibodies, but the B-cell immune response becomes even more diverse with chronicity and increasing antibody titer, and some Hashimoto autoantibodies bind to linear determinants of thyroglobulin. The majority of thyroglobulin antibodies belong to the IgG-1 and IgG-4 subclasses but do not fix complement because the spacing of the autoantigenic epitopes prevents cross-linking. In the past, thyroglobulin autoantibodies were detected by immunofluorescence or hemagglutination assays, but these have generally been superseded by enzyme-linked immunosorbent assays (ELISAs) and radioimmunoassays, which express levels in units related to standard antibody preparation. The most sensitive assays indicate that low levels of thyroglobulin antibodies can be detected in up to 20% of the healthy female population.

Thyroid Peroxidase

There are two forms of thyroid peroxidase, TPO-1 and -2, but only the first has enzymatic activity and is expressed on the cell surface, where it catalyzes the iodination and coupling of tyrosine molecules to form T3 and T4. Originally, autoantibodies against TPO were called microsomal antibodies because they bound to an antigen in this subcellular fraction, although they were also recognized from immunofluorescence to bind to the apical microvillar surface of the thyroid cells. It was subsequently shown that binding of these complement-fixing microsomal antibodies could be inhibited by TPO-specific monoclonal antibodies, and studies of recombinant TPO confirmed that essentially all the binding to thyroid microsomes is directed against TPO.

Table IV Key Properties of Thyroid Autoantigens

| | Chromosomal location | Size (kDa) | Protein type | Function | Homology |
|---|----------------------|------------|----------------------------|-------------------------------------|---|
| Thyroglobulin | 8 | 660 | Iodinated glycoprotein | T3 and T4 prohormone and storage | Acetylcholinesterase |
| Thyroid peroxidase | 2 | 105–110 | Hemoprotein enzyme | Iodination and coupling of tyrosine | Myeloperoxidase |
| TSH receptor | 14 | 85 | G protein-coupled receptor | Thyroid stimulation by TSH | Related receptors (e.g., luteinizing hormone) |
| Na ⁺ /I ⁻ symporter | 19 | 65–77 | Transmembrane transporter | Iodide uptake | Na ⁺ /glucose transporter |

Further work localized two linear B-cell epitopes, C-2 (amino acids 590–622) and C-21 (amino acids 710–722), but these are only recognized by autoantibodies arising late in the disease process. In the early phase of any autoimmune response involving TPO, autoantibodies are directed against confirmational epitopes in two overlapping domains, A and B, and relative antibody binding to each of these domains is fairly constant over time. This narrow response seems to be related to the marked restriction of the immunoglobulin variable (V) region gene usage in TPO autoantibody formation, with each domain being recognized by antibodies encoded by different V gene sequences, indicating a genetic component to the control of autoantibody production. In contrast, T-cell epitopes are heterogeneous, with several different epitopes typically recognized by T cells from patients and only partially shared between patients. Such diversity is typical of a chronic immune response in which only one dominant T-cell epitope may initiate the process, but this is followed by “spreading” of the response to involve other epitopes over time, including so-called cryptic epitopes that only become exposed during the phase of tissue destruction.

TPO antibodies are measured using the same techniques as those used to measure thyroglobulin antibodies and are also found in healthy subjects in the absence of overt thyroid disease. They are predominantly of the IgG-1 and IgG-4 subclasses. Approximately one-fourth of patients with thyroid autoimmunity have TPO antibodies that can also bind thyroglobulin, so-called TGPO antibodies. Their pathological significance is unknown.

TSH-R

This receptor is similar to other G-coupled receptors and comprises two subunits, corresponding to the extracellular and transmembrane domains, joined by disulfide bonds. The fundamental importance of the TSH-R to Graves' disease was first established by the identification of a long-acting thyroid stimulator (LATS) in the serum of Graves' patients that matched the thyroid stimulatory action of TSH but had a much longer time course and, hence, could not be TSH. LATS was soon identified as an IgG antibody and assays were developed for these thyroid-stimulating antibodies that relied on the ability of IgG to simulate cyclic AMP production—that is, the second messenger produced from TSH-R interaction with its ligand. Other intracellular signaling pathways may be activated by certain TSH-R antibodies, which may lead to goiter formation.

Considerable effort has been directed at identifying the B-cell epitopes on TSH-R recognized by autoantibodies, but the results are not conclusive. However, multiple species of TSH-R autoantibodies exist and some actually prevent TSH from stimulating the receptor without causing any stimulation themselves. The effect of these blocking antibodies is hypothyroidism. Other “neutral” TSH-R antibodies bind but have no functional effects. Although the detection of TSH-R-stimulating and-blocking autoantibodies depends on bioassays, most commonly measuring the cyclic AMP responses of the FRTL-5 rat thyroid cell line or Chinese hamster ovary cells transfected with TSH-R, these are cumbersome and not suited to rapid diagnostic testing. Antibodies that bind to TSH-R can be measured simply in solid-phase assays that estimate competition between antibody and radiolabeled TSH for binding to the receptor. Results from assays of these so-called TSH-binding inhibiting immunoglobulins (TBIs) correlate well with the results of thyroid-stimulating antibodies in thyrotoxic patients, but TBII is also positive when blocking antibodies are present. Therefore, a positive TBII cannot be equated with the presence of the TSH-R-stimulating antibodies that cause Graves' disease.

There are multiple B-cell epitopes in the TSH-R that are generally conformational, comprising discontinuous segments that overlap the TSH binding site. Antibodies that bind to the carboxyl terminus of the extracellular domain have blocking activity, and those against the amino terminus have stimulating activity. Further dissection of these epitopes may allow the development of solid-phase assays for TSH-R-stimulating and -blocking antibodies that would render bioassays obsolete. In some Graves' patients, the TSH-R-stimulating antibody response is restricted in terms of light and heavy-chain use, implying genetic control of these strongly pathogenic antibodies. Another noteworthy feature is the very low concentration of these antibodies in sera, which makes their study difficult.

T-cell epitopes are heterogeneous and no clear dominant epitope has been identified. Nonetheless, the production of TSH-R antibodies is T-cell dependent, and presumably there are such dominant epitopes in the earliest phase of disease.

Other Autoantigens

The Na⁺/I⁻ symporter is recognized by antibodies in 5–30% of patients with Graves' disease or autoimmune hypothyroidism. Some of these antibodies have weak blocking effects on symporter activity *in vitro*, but *in vivo* iodide uptake is not a rate-limiting step in

thyroid hormone synthesis and it is unknown whether there is any pathogenic role for these antibodies. A poorly characterized second colloid antigen (i.e., in addition to thyroglobulin) has been recognized for decades based on immunofluorescence studies with patient sera, but its nature is obscure. It has been suggested that a set of thyroid growth-stimulating and growth-inhibiting antibodies, separate from TSH-R antibodies, cause goitrous and atrophic thyroiditis, but this hypothesis is controversial and these antibodies are poorly characterized.

The biggest enigma is the nature of the orbital autoantigen(s) in TAO. To explain the close association between this condition and thyroid autoimmunity, especially Graves' disease, the existence of an orbital autoantigen that cross-reacts with one in the thyroid has been proposed. The most attractive candidate is the TSH-R, which is expressed by the preadipocyte subset of fibroblasts; however, whether this is sufficient to explain pathogenesis is debated. A wide variety of extraocular muscle and fibroblast antigens have been suggested during the past 20 years based on ELISA and immunoblotting studies, and it seems likely that several autoantigens are targets of the autoimmune response, at least in the later stages of disease, akin to the situation in autoimmune thyroiditis and type 1 diabetes mellitus.

PATHOGENESIS

Animal Models

A wide variety of animal models have yielded invaluable insights into the pathogenesis of autoimmune

thyroid disease (Table V). Immunization of mice with thyroglobulin in Freund's adjuvant allowed the demonstration of the crucial role of MHC class II in controlling responsiveness as measured by the production of lymphocytic thyroiditis. It also showed that the production of thyroglobulin antibodies is under additional genetic control. Certain strains of mice (H-2^{k,s}) are so susceptible to autoimmune thyroiditis that immunization with thyroglobulin alone will induce disease, indicating that normal, healthy animals have thyroid autoreactive T cells that have failed to undergo thymic deletion or tolerance. From this it can be inferred that such T cells are kept under control, either through the actions of regulatory T cells or through the mechanism of clonal ignorance, so that there is no response because autoantigen is normally sequestered or because appropriate costimulatory signals, including cytokines, are not normally present. T cells, but not antibodies, from animals with immunization-induced thyroiditis can transfer the disease to recipients, and the critical effector cells appear to be CD4-dependent CD8⁺ cells.

One mechanism whereby T-cell-mediated regulation might occur is through the reciprocal inhibition of T helper cell subsets (Fig. 2). This has been shown in experiments in which Th1 responses, which are normally associated with autoimmune thyroiditis, were suppressed and Th2 responses enhanced by γ -interferon deficiency. Immunization with thyroglobulin under these conditions led to an eosinophilic granulomatous thyroiditis rather than lymphocytic thyroiditis, and high levels of thyroglobulin antibodies were induced.

Table V Animal Models of Thyroiditis^a

| Model | Species | Features |
|---|---|---|
| Immunization with TG or TSH-R and adjuvant | Mouse, rat, rabbit, guinea pig, monkey | TGAb or TBII, thyroiditis, euthyroid |
| T-cell depletion (thymectomy, with or without irradiation, cyclosporin A, depletion and reconstitution) | Mouse, rat | TGAb, thyroiditis, euthyroid; reversed by T _R cells from healthy animals |
| TSH-R cDNA immunization | Mouse | TBII, rare TSAb, thyroiditis, euthyroid in BALBc; TSAb and hyperthyroidism plus thyroiditis in outbred mice |
| Immunization with fibroblasts transfected with MHC class II and TSH-R or TPO | Mouse | TBII including TSAb or TPO Ab, no thyroiditis; animals with TSAb thyrotoxic |
| Spontaneous thyroiditis | Obese strain (OS) chickens, BB and Buffalo strain rats, NOD and MRL <i>Ipr/Ipr</i> mice | TGAb, thyroiditis, and in OS chickens hypothyroidism; incidence of thyroiditis in Buffalo strain rats increased by 3-methylcholanthrene |

^aAbbreviations used: TG, thyroglobulin; TPO, thyroid peroxidase; TSH-R, TSH receptor; TSAb, TSH-R-stimulating antibodies; TBII, TSH-binding inhibiting immunoglobulins; Ab, antibodies; T_R, regulatory T cells.

Another type of T-cell-mediated regulation has been shown in mice or rats subjected to T-cell depletion by thymectomy and other methods. The best characterized example is genetically susceptible rats, which develop autoimmune thyroiditis and thyroglobulin antibodies when subjected to neonatal thymectomy and sublethal irradiation. Disease can be prevented by the transfer of T cells from healthy donors, clearly indicating the presence of suppressor T cells in these animals. The concept of suppressor cells suffered from criticism and a decade of neglect after it proved impossible to characterize the mechanisms responsible for their antigen recognition and function. However, rebranded as regulatory T cells (T_R), it has become clear that such cells do exist in the $CD4^+$ population, are generated in the thymus, and express high levels of the interleukin-2 (IL-2) receptor (CD25).

The antigen specificity of these T_R cells is unclear but unlikely to be identical to the epitopes recognized by the effector T cells that they regulate. It is possible that T_R cells respond to epitopes on a separate autoantigen from the one generating the effector response, but this nonetheless allows their localization within a target organ, and their possible activation by the same antigen presenting cell that activates the effector T cell could allow "linked suppression." The exact mechanism whereby suppression is mediated is also unknown, but it probably involves cell contact as well as the release of inhibitory cytokines, such as IL-10, IL-13, and transforming growth factor- β . Other types of regulatory T cells may exist, especially in the $CD8^+$ population, and the relative importance of these various pathways, especially in the intact animal, will be the subject of intense research in the future since the potential for enhancing T_R function has been recognized to provide a novel way of controlling autoimmune responses.

Another valuable finding from the thymectomy/irradiation model of thyroiditis is that although disease is induced only in genetically susceptible animals, there is an important interaction with environmental factors. In particular, animals raised under germ-free conditions do not develop thyroiditis, whereas those that were germ free but were then given normal gut microflora developed thyroiditis with the expected incidence. In addition, disease in these animals, and in those with immunization-induced thyroiditis, can be modulated by sex steroids: The frequency and severity of thyroiditis are increased in castrated males or those given estrogens and decreased in female animals given testosterone.

The closest models to that of Hashimoto's thyroiditis are those that develop spontaneously in

genetically susceptible animals (Table V). Dietary iodide and other environmental factors have important permissive roles in these highly inbred strains. However, progress has been much slower in producing animal versions of Graves' disease, and only recently have closely corresponding models been developed. Perhaps the most interesting is the creation of pathological features suggestive of TAO in a specific strain of mouse (BALB/c) given TSH-R-activated T cells from donor animals immunized with TSH-R. Another mouse strain (NOD) developed a destructive thyroiditis under the same conditions, and this difference may be explained by the relative bias toward a Th2 response in BALB/c mice and a Th1 response in NOD mice.

Autoimmune Hypothyroidism

Cell-Mediated Effects

As previously discussed, T cells play a critical role in the pathogenesis of autoimmune thyroiditis in animals, and considerable evidence supports a similar role in humans. $CD4^+$ and $CD8^+$ T cells accumulate in the thyroid and the majority of these cells express markers of activation. Although some studies have suggested that these T cells are clonally restricted, others have found diverse uses of T-cell receptor $V\alpha$ and $V\beta$ genes, and this type of polyclonal response is in agreement with the known multiplicity of autoantigens and their epitopes and the likely spreading of antigenic determinants over time. Circulating T cells have an increased percentage of HLA-DR $^+$ T cells, marking a state of activation, and the proportion of $CD8^+$ T cells is probably decreased, but these are features of many autoimmune disorders and may have no autoantigen-specific cause or effect.

Circulating and intrathyroidal T cells from patients with autoimmune hypothyroidism can be activated by and proliferate in response to thyroglobulin or thyroid peroxidase, and many ingenious attempts have been made to use such assays to demonstrate a defect in suppressor cell function as an underlying feature in pathogenesis. However, firm evidence of any such defect remains elusive, and no studies have examined the potential role of $CD4^+/CD25^+$ T_R cells in human thyroid autoimmunity. Although a predominantly Th1-type response would be predicted in autoimmune hypothyroidism, a complex and heterogeneous cytokine profile has been found when the intrathyroidal lymphocyte population has been examined. Of course, thyroid autoantibody synthesis, which is likely Th2 dependent, is a prominent feature of this condition.

The mechanism by which thyroid-specific T cells are activated has been a major focus of attention for the past two decades. Conventional antigen presentation in the initiation of an immune response is primarily a function of dendritic cells, which can process antigen and present it with appropriate costimulatory molecules (Fig. 1). B cells and macrophages can also present antigen under appropriate conditions, and for B cells there is the additional feature that specific antigens can be processed because these are taken up by binding to antigen-specific antibody on the B-cell surface. The nature of the cell presenting antigen, and particularly the cytokines it secretes, plays a key role in determining whether a Th1 or Th2 response is mounted.

When it was discovered that thyroid follicular cells express MHC class II molecules in autoimmune hypothyroidism and Graves' disease, there was considerable interest in the idea that this could be the precipitant of the autoimmune process because the thyroid cell would be capable of presenting thyroid autoantigens to any specific T cells in the vicinity. It is now clear that such class II expression is a secondary rather than primary event, depending on the production of γ -interferon by locally infiltrating T cells, which clearly must have been activated by other antigen presenting cells. Moreover, the initiation of an immune response depends on the delivery of a second costimulatory signal to T cells at the same time as the first signal, namely MHC class II molecule complexed with antigenic epitope (Fig. 1). Failure to provide this second signal leads to anergy or even deletion—that is, the opposite outcome to activation. In general, thyroid cells do not appear to express B7, the most

important costimulatory molecule, although there is a single report suggesting its expression in Hashimoto's thyroiditis. However, it seems that MHC class II expression by thyroid cells, from a teleological standpoint, is a protective mechanism to provide peripheral tolerance, for instance, in the event of viral thyroiditis.

Once activated, T cells can be restimulated by cells presenting antigen in the absence of B7 and thus, in the setting of autoimmune thyroiditis, MHC class II expression of thyroid cells may have an important role in expanding the intrathyroidal pool of T cells and thus exacerbating the autoimmune process (Fig. 1). It is also possible that differences in the regulation of T cells at this critical stage of disease (e.g., through genetically determined variability in class II expression or cytokine availability) may determine whether a focal thyroiditis progresses to full-blown disease.

Following these observations, it has become clear that thyroid follicular cells express a vast array of immunologically active molecules, including adhesion molecules and cytokines (Table VI). Many of these are induced by the cytokines known to be present in the intrathyroidal milieu in autoimmune thyroid disease, especially IL-1, tumor necrosis factor, and γ -interferon. Their expression tends to exacerbate the autoimmune response, although in some cases, such as the up-regulation of complement regulatory proteins, the cell is protected from immune attack.

How thyroid cells are destroyed is unresolved. Data from animal models indicate that CD8⁺ cytotoxic T cells kill thyroid follicular cells, and perforin-containing cells exist in the thyroid infiltrate in human autoimmune thyroid disease. Recently, attention has focused on apoptosis as a major mechanism for

Table VI Immunological Active Molecules Expressed by Thyroid Cells in Autoimmune Thyroiditis^a

| Molecule | Function | Upregulatory factors |
|---|--|--|
| MHC class I | Recognition by CD8 ⁺ cytotoxic T cells | γ -IFN, TNF increase basal expression |
| MHC class II | Recognition by CD4 ⁺ helper T cells | γ -IFN induces expression; enhanced by TNF |
| Adhesion and homing molecules (ICAM-1, LFA-3, Hermes-1, CD44, NCAM) | Binding of T and NK cells | γ -IFN, IL-1, TNF |
| Cytokines (IL-1, IL-6, IL-8, IL-13, IL-15) | Multiple effects on bystander lymphocytes | γ -IFN, IL-1, TNF |
| Complement regulatory proteins (CD46, CD55, CD59) | Prevention of lethal complement attack | γ -IFN, IL-1, TNF |
| CD40 | Binds CD40 ligand on T cells, acting as a costimulator | γ -IFN, IL-1 |
| Nitric oxide | Tissue injury | γ -IFN, IL-1, TNF (decreased by IL-4, α -IFN, TGF- β) |
| Fas/Fas ligand | Apoptosis | IL-1 |

^aAbbreviations used: IFN, interferon; TNF, tumor necrosis factor; IL, interleukin; TGF, transforming growth factor; ICAM-1, intercellular adhesion molecule-1; NCAM, neural cell adhesion molecule.

thyroid cell loss. Thyroid follicular cells in Hashimoto's thyroiditis overexpress Fas (CD95), likely the result of locally released cytokines, especially IL-1. This could lead to an increased chance of thyroid cell destruction through interaction with CD8⁺ T cells that bind to Fas and thereby trigger apoptosis. Several groups have described expression of Fas ligand (FasL) on thyroid follicular cells in autoimmune thyroid disease, although normally this molecule is restricted to CD8⁺ T cells and sites of immunological privilege (e.g., trophoblast and testis), where it prevents T lymphocyte recognition of antigen by deleting these T cells through Fas engagement. In some studies, IL-1 up-regulated FasL expression by Hashimoto's thyroid cells *in vitro*, leading to the suggestion that exposure to this cytokine *in vivo* may cause suicide or fratricide within the Fas-positive thyroid cell population. However, questions have been raised over technical aspects of these experiments and, even if correct, the proportion of FasL⁺ thyroid cells is often low. Up-regulation of Bcl-2 and other anti-apoptotic intracellular proteins, especially in Graves' disease, may limit thyroid cell death. Finally, the opposite view of FasL expression could be taken; namely, that such expression may protect thyroid cells from immune attack by creating the conditions of immunological privilege. Much work remains to be done before the roles of Fas/FasL and other cytotoxic pathways in the thyroid can be determined.

Humoral Effects

Overwhelming evidence indicates that thyroid antibodies alone cannot cause thyroid cell destruction. Thyroglobulin antibodies do not fix complement. These antibodies and those against TPO and the Na⁺/I⁻ symporter can cross the placenta and yet neonates born to mothers with high levels of such antibodies have normal thyroid function, as do many adults who have detectable thyroid antibodies. Experimental data indicate that these antibodies cannot access their antigens within an intact thyroid follicle. Nonetheless, there may be a secondary role for TPO antibodies: they cause tissue injury once the follicular architecture is disrupted by cytokines or T-cell-mediated cytotoxicity. Also, there is *in vitro* evidence that thyroglobulin and TPO antibodies can effect antibody-dependent, cell-mediated cytotoxicity by engaging Fc receptors on natural killer cells. There is certainly widespread complement activation within the thyroid in both Hashimoto's thyroiditis and Graves' disease. Although heightened expression of complement regulatory proteins (Table VI) may protect the thyroid cells

Figure 3 Pathogenetic mechanisms in autoimmune hypothyroidism. Ab, antibody; TPO, thyroid peroxidase; TG, thyroglobulin.

from overt lysis, sublethal complement attack impairs the metabolic response of thyroid cells to TSH and induces cytokine production, which may exacerbate the autoimmune process.

TSH-R-blocking antibodies, in contrast, have pathogenic effects, causing hypothyroidism. This is most clearly demonstrated in the transient neonatal hypothyroidism that follows placental transfer. This effect lasts only as long as the antibodies persist and is therefore a functional rather than cytotoxic effect. As many as 20% of patients with hypothyroidism may have TSH-R-blocking antibodies, and these appear particularly common in patients with atrophic rather than goitrous thyroiditis in Asia, whereas in other regions TSH-R-blocking antibodies show no such dichotomy. Unexplained fluctuations in these antibodies (and sometimes in coincident TSH-R-stimulating antibodies) account for most, if not all, cases of hypothyroidism that show spontaneous recovery. The role of other potentially cytotoxic molecules, such as lymphotoxin- α , nitrous oxide, and reactive oxygen metabolites, in causing thyroid injury is unclear (Fig. 3).

Graves' Disease

Cell-Mediated Effects

Similar findings as those for autoimmune thyroiditis are found for Graves' disease. Circulating T cells show an increase in HLA-DR⁺ and a decrease in CD8⁺ subsets, and the thyroid infiltrate comprises CD4⁺ and CD8⁺ cells with little evidence of clonal restriction. Thyroglobulin-, TPO-, and TSH-R-specific T cells can be demonstrated in the circulation and thyroid infiltrate, but there is no evidence of a specific defect in their regulation. The same issues have been raised regarding antigen presentation as those for autoimmune hypothyroidism, and there is a mixed

in thyrotoxic cytokine profile with evidence of both a Th1 and a Th2 response. These observations help explain the transition of Graves' disease to autoimmune hypothyroidism seen in some patients spontaneously and in others years after treatment with antithyroid drugs. There is also indirect evidence that hypothyroidism is more likely to occur after radioiodine or surgery in Graves' patients with the most marked autoimmune responses against thyroglobulin and TPO.

Humoral Effects

Graves' disease is the prime exemplar of type V hypersensitivity, a disease caused by antibodies with a stimulatory action. The role of TSH-R-stimulating antibodies was discussed previously. Virtually all patients have detectable TSH-R-stimulating antibodies, providing the most sensitive assays are used. The few who do not most likely have antibodies but in an amount that is below the current limit of detection. The level of TSH-R-stimulating antibodies correlates loosely with the severity of hyperthyroidism due to the ongoing intrathyroidal T-cell-mediated events, the secondary effects of TPO antibody causing thyroid injury, and the simultaneous presence of TSH-R-blocking antibodies in some patients. There is a much clearer relation between the maternal level of TSH-R antibodies in women with Graves' disease in the last trimester of pregnancy and the occurrence of neonatal thyrotoxicosis, suggesting that the first two processes, which do not affect fetal or neonatal thyroid, are most important.

Effects of Treatment

Spontaneous remission of Graves' disease appears to be unusual, unless autoimmune hypothyroidism intervenes. Accurate data are not available, but clinical remission was seen in only 10–20% of patients treated decades ago with beta-blockers, and these patients had the mildest degree of thyrotoxicosis. Remission of other receptor antibody-mediated diseases, such as myasthenia gravis, is also rare. Therefore, the 40–50% remission rate of Graves' disease after treatment with the antithyroid drugs carbimazole, methimazole, or propylthiouracil indicates an immunomodulatory effect of these agents. TSH-R antibody levels decline during treatment and remain low in those who do not relapse. However, levels of nonthyroid antibodies do not decline. This apparent paradox is most likely explained by the actions of antithyroid drugs on the thyroid cells, including suppression of cytokine, reactive oxygen metabolite, and prostaglandin production. As a result, the thyroid lymphocytic infiltrate declines

and the production of thyroid autoantibodies is curtailed. Remission is not expected in patients in whom the autoimmune process has spread beyond the thyroid gland because antithyroid drugs do not easily influence any extrathyroidal autoreactivity; this is in accord with the observation that patients with the most severe disease do poorly on antithyroid drugs.

Subtotal thyroidectomy usually leads to cessation of thyroid antibody production, although this may continue in some patients due to the persistence of specific B cells in the bone marrow and lymph nodes. Thyroid antibodies show a characteristic rise and then fall during the year after ^{131}I therapy: this may be due to release of autoantigen from the damaged thyroid, followed by death of the intrathyroidal lymphocyte population. Activated T cells increase in the circulation in the first few months after ^{131}I and these cells, by homing to the orbit, may be responsible for the exacerbation of TAO seen in up to 15% of patients after such treatment. This worsening can be prevented by glucocorticoids.

Thyroid-Associated Ophthalmopathy

The pathogenesis of ophthalmopathy is complex and unclear. The extraocular muscles are the main focus of the autoimmune process, but occasional patients appear to have a primary expansion of the retro-ocular connective tissue, including fat. A separate process is likely involved in the clinical sign of lid retraction (which is more extreme than that in any type of thyrotoxicosis), at least based on the histological findings. There is no evidence that tissue destruction plays a role in initiating these changes, although extraocular muscle cell damage may occur late in severe disease; thus, attempts to find cytotoxic autoantibodies or lymphocytes seem ill founded. Apart from lid retraction, which could be mediated by the sympathetic overactivity secondary to thyrotoxicosis, no convincing signs of TAO have been reported in neonates born to women with TAO, arguing against a primary role for orbital autoantibodies. Attempts to find such autoantibodies are justifiable, however, because they may provide information on the nature of orbital autoantigens, and these autoantibodies may contribute to secondary events in TAO.

The most likely explanation for TAO is that fibroblasts in the extraocular muscles and orbital connective tissue are activated by cytokines from the infiltrating T cells and macrophages. IL-1, tumor necrosis factor, and γ -interferon all affect fibroblast function and may cause the increase in expression of HLA-DR and other immunologically active molecules

found in TAO. More important, they enhance glycosaminoglycan production, leading to water trapping and edema. An identical or related pathway of cytokine-induced activation may lead to fibrosis later in disease, the so-called burnt-out stage of TAO. Smoking may exacerbate this pathogenetic process by affecting cytokine secretion or action or by inducing partial hypoxia, which increases glycosaminoglycan production. Indeed, as the orbital contents increase, the pressure effects within the confines of the bony orbit may lead to partially hypoxic and congested conditions with impaired venous drainage, which in turn may cause further edema in addition to being a proinflammatory environment. In such a scenario, relatively modest initial increases in orbital tissue volume may quickly increase as in congestive ophthalmopathy. Anatomical differences between the capacity of the two orbits in an individual may accommodate different degrees of swelling, leading to the asymmetric form of TAO seen in 5–10% of cases. Another factor accounting for TAO is the likely heightened sensitivity of the orbital fibroblast population to cytokine activation compared to that of fibroblasts from other sites. Together with the presumed intraorbital location of a thyroid cross-reactive autoantigen, this susceptibility may explain the localization of disease.

Approximately 1% of patients with Graves' disease develop thyroid dermopathy, often situated over the shins, where it is called pretibial myxedema. These patients almost always have marked TAO, and dermopathy seems to be a more flagrant form of the same process, in which immunologically mediated fibroblast activation occurs within the dermis, presumably via the action of cytokines. Dermopathy is usually localized to sites where fluid retention and injury occur,

suggesting that a cascade of events similar to those of TAO may cause worsening of disease.

carcinomas in patients with no history of radiation and in 60 to 85% of papillary carcinomas in patients following irradiation, diagnosed either in children in Belarus exposed to radiation after the Chernobyl accident or in patients who were exposed to external radiation in childhood. The frequency of TRK rearrangements is at least twofold lower. In papillary carcinomas, RAS mutations are found in 15% of cases and B-RAF mutations in 40–60% of cases; thus, abnormalities in the RET/RAS/B-RAF/mitogen-activated protein kinase pathway are found in 80% of cases, suggesting an important role.

Activating point mutations of the RAS genes are found with a similarly high frequency in both thyroid adenomas and follicular carcinomas, suggesting that RAS mutations represent an early event in thyroid tumorigenesis. PPAR γ -PAX8 rearrangements were found in 26–63% of follicular carcinomas, mostly of the widely invasive subtype and more rarely in follicular adenomas.

Activating mutations of the genes encoding the thyrotropin receptor and the α -subunit of the G_s protein have been reported in some follicular carcinomas. Inactivating point mutations of the p53 tumor suppressor gene are rare in differentiated thyroid carcinomas, but are common in undifferentiated (anaplastic) thyroid carcinomas.

Thyroid Irradiation

External irradiation to the neck during childhood increases the risk of papillary carcinoma. The latency period between exposure and diagnosis of thyroid carcinoma is at least 5 years. The risk is maximal at approximately 20 years, remains high for approximately 20 years, and then decreases gradually. The risk is increased after a mean dose to the thyroid of as little as 10 cGy. Above this dose, there is a linear relationship between the dose (up to 1500 cGy) and the risk of carcinoma. Beyond this point, the risk per Gray decreases, probably due to cell killing. A major risk factor is a young age at irradiation; over the age of 15 or 20 years, the risk is not increased. In children exposed to 1 Gy to the thyroid, the excess risk of thyroid carcinoma is 7.7.

The risk of thyroid carcinoma is not increased in patients given ¹³¹I for diagnosis or therapy. However, the number of patients exposed to ¹³¹I for medical reasons during childhood is too small to exclude a carcinogenic effect of ¹³¹I at a young age. Conversely, a direct tumorigenic effect on the thyroid of radioactive isotopes of iodine, both ¹³¹I and short-lived isotopes, has been strongly suggested by the

increased incidence of papillary carcinomas in children in the Marshall Islands after atomic bomb testing and in Belarus and the Ukraine after the Chernobyl accident. In Belarus and the Ukraine, approximately 1500 cases have been reported in children and adolescents who were younger than the age of 10 years at the time of the accident, which corresponds in some regions to a 100-fold increase in incidence compared with nonirradiated children.

Other Factors

In countries where iodine intake is adequate, papillary and follicular cancers represent more than 80% of all thyroid carcinomas, with the papillary histologic type being the more frequent (60 to 80% of cases). There is no increase in the incidence of thyroid carcinomas in countries where iodine intake is low, but there is a relative increase in follicular and anaplastic carcinomas.

A high incidence of papillary carcinomas has been reported in patients with adenomatous polyposis coli and Cowden's disease (multiple hamartoma syndrome). Approximately 5% of cases of papillary carcinoma are familial and several loci for predisposing genes have been identified in these families.

PATHOLOGY

Papillary Carcinoma

Papillary carcinoma is an unencapsulated tumor with papillary and follicular structures that is characterized by changes in cell nuclei, such as overlap of the nuclei, large nuclei, a ground glass appearance, longitudinal nuclear grooves, and invaginations of the cytoplasm into the nuclei. Recognized histologic variants are the encapsulated cell, the follicular cell, the tall cell, the columnar cell, the clear cell, and the diffuse sclerosing variants; they are classified as papillary carcinomas due to their typical nuclear features. The tumor is multicentric in 20 to 80% of cases, depending on the care used to examine the thyroid, and is bilateral in approximately one-third of cases. It spreads through the lymphatics within the thyroid, to the regional lymph nodes, and less frequently to the lungs.

Follicular Carcinoma

Follicular carcinoma is characterized by follicular differentiation but is devoid of the nuclear changes characteristic of papillary carcinoma. These carcinomas are encapsulated and invasion of the capsule and

vessels are the key features distinguishing follicular carcinomas from follicular adenomas. Two forms are recognized according to the pattern of invasion: a minimally invasive form and a widely invasive form. The growth pattern may also vary, from a well-differentiated pattern with macrofollicular structures to a poorly differentiated pattern with areas of solid growth and a high degree of atypia (trabecular or insular carcinoma). Hürthle cell (oxyphilic or oncocytic) carcinoma is a cytologic variant of follicular carcinoma. Multicentricity and lymph node involvement are less frequent than in papillary carcinoma and distant metastases to the lungs and bones stem from hematologic spread.

DIAGNOSIS

Most differentiated thyroid carcinomas present as asymptomatic thyroid nodules, but occasionally the first signs of the disease are lymph node metastases and rarely lung or bone metastases. Hoarseness, dysphagia, cough, and dyspnea are suggestive of advanced stages of the disease.

At physical examination, the carcinoma, usually single, is firm, freely moveable during swallowing, and not distinguishable from a benign nodule. A thyroid nodule should be suspected of being a carcinoma when it is found in children or adolescents or in patients over the age of 60 years; in men, when it is hard and irregular; when ipsilateral lymph nodes are enlarged or compressive symptoms are present; and when there is a history of a progressive increase in size. Virtually all patients are clinically euthyroid and have normal serum thyrotropin concentrations.

Whatever the presentation, fine-needle aspiration cytology is the best test for distinguishing between benign and malignant thyroid nodules (Table I). Provided an adequate specimen is obtained, three cytologic results are possible: benign, malignant, and indeterminate (or suspicious). False-negative results, usually from sampling errors or interpretive errors, and false-positive results are rare. Among indeterminate results,

Table I Probability of Malignancy Based on FNA Cytology

| Cytology | Percentage of results (%) [mean (range)] | Probability of malignancy (range) |
|------------|--|-----------------------------------|
| Inadequate | 17 (15–20) | 10–20 |
| Benign | 70 (53–90) | 1–2 |
| Suspicious | 10 (5–23) | 10–20 |
| Malignant | 4 (1–10) | >95 |

only 10–20% are from malignant nodules, reflecting the difficulty of differentiating benign follicular adenomas from their malignant counterparts. Thyroid ultrasonography is useful for assessing the size of the nodule and detecting other nodules and to guide the fine-needle biopsy of small or poorly palpable nodules.

PROGNOSTIC FACTORS

The overall 10-year survival rates for middle-aged adults with thyroid carcinomas are approximately 80 to 95%. Five to 20% of patients have local or regional recurrences and 10 to 15% have distant metastases. Prognostic indicators of recurrence and of death are age at diagnosis, histologic type, and extent of the tumor.

There are many scoring systems for thyroid carcinoma, among which the pathological tumor node metastases (pTNM) staging system is the most widely accepted (Table II). Based on this system, 80 to 85% of patients are classified as being at low risk for cancer-specific mortality. Some patients have a higher risk of recurrence, even if their risk of cancer-specific mortality is low. They include young (<16 years) and older (>45 years) patients, those with certain histologic subtypes (among papillary carcinomas, the tall cell, the columnar cell, and diffuse sclerosing variants, and among follicular carcinomas, the widely invasive and poorly differentiated histologic types and the Hürthle cell carcinomas), and those with large tumors, extension of the tumor beyond the thyroid capsule, or lymph node metastases. Therefore, the extent of initial treatment and follow-up should be adapted according to these prognostic indicators.

INITIAL TREATMENT

Surgery

The goal of surgery is to remove all neoplastic tissue in the neck. Therefore, the thyroid gland and affected cervical lymph nodes should be resected.

Although some controversy still exists regarding the extent of thyroid surgery, there are strong arguments in favor of a total or near-total (leaving no more than 2 to 3 g of thyroid tissue) thyroidectomy for all patients. Total or near-total thyroidectomy reduces the recurrence rate compared with more limited surgery because many papillary carcinomas are multifocal and bilateral. Removal of most if not all of the thyroid gland facilitates total ablation with ¹³¹I. The argument against total thyroidectomy is that it increases the risk of surgical complications, such as recurrent

Table II TNM Staging System for Papillary and Follicular Carcinoma of the Thyroid

| | Definition of TNM | |
|---|--|--|
| | 1992 | 2002 |
| Primary tumor (T) | | |
| T0 | No evidence of primary tumor | No evidence of primary tumor |
| T1 | Tumor ≤ 1 cm limited to the thyroid | Tumor ≤ 2 cm limited to the thyroid |
| T2 | Tumor >1 to ≤ 4 cm limited to the thyroid | Tumor >2 to ≤ 4 cm limited to the thyroid |
| T3 | Tumor >4 cm limited to the thyroid | Tumor >4 cm limited to the thyroid or any tumor with minimal extrathyroid extension (e.g., extension to sternothyroid muscle or perithyroid soft tissues) |
| T4 | Any size extending beyond the thyroid capsule | |
| T4a | | Tumor of any size with extension beyond the thyroid capsule and invades any of the following: subcutaneous soft tissues, larynx, trachea, esophagus, recurrent laryngeal nerve |
| T4b | | Tumor invades prevertebral fascia or mediastinal vessels or encases carotid artery |
| Regional lymph node (N) (In the 2002 system, to classify a tumor as N0 or N1, at least six lymph nodes should be examined at histology; otherwise, the tumor is classified as Nx) | | |
| N0 | No regional lymph node metastasis | No regional lymph node metastasis |
| N1 | Regional lymph node metastasis | Regional lymph node metastasis |
| N1a | | Metastases in pretracheal and paratracheal region, including prelaryngeal and delphian lymph nodes |
| N1b | | Metastases in other unilateral, bilateral, or contralateral cervical or upper mediastinal lymph nodes |
| Distant metastases (M) | | |
| M0 | No distant metastasis | No distant metastasis |
| M1 | Distant metastasis | Distant metastasis |
| TNM Staging | | |
| | | Age <45 years |
| Stage I | Any T, any N, M0 | Any T, any N, M0 |
| Stage II | Any T, any N, M1 | Any T, any N, M1 |
| Stage III | None | None |
| Stage IV | None | None |
| | | Age ≥ 45 years |
| Stage I | T1, N0, M0 | T1, N0, M0 |
| Stage II | T2-T3, N0, M0 | T2, N0, M0 |
| Stage III | T4, N0, M0, or any T, N1, M0 | T3, N0, M0 or any T1-3, N1a, M0 |

| Stage IVB | | T4b, any N, M0 |
| Stage IVC | | Any T, any N, M1 |

laryngeal nerve injuries and hypoparathyroidism, and yet often some thyroid tissue remains, as detected by postoperative scanning with ^{131}I .

In low-risk patients (those with papillary carcinomas less than 1 cm in diameter, if unifocal and intralobar, and those with a small minimally invasive follicular carcinoma), a lobectomy may be appropriate.

Surgery of the lymph nodes is routinely performed in patients with papillary carcinomas. It includes dissection of the central compartment (paratracheal and tracheoesophageal areas) and may also include dissection of the supraclavicular area and the lower third of the jugulocarotid chain. A modified neck dissection is performed if there are palpable lymph node metastases in the jugulocarotid chain. Dissection

is preferable to lymph node picking. This type of lymph node dissection was proven to improve the recurrence and survival rates in several series and several arguments support its routine use in patients with papillary carcinomas: approximately two-thirds have lymph node metastases, more than 80% of whom have involvement of the central compartment; metastases are difficult to detect in lymph nodes located behind the vessels or in the paratracheal groove. In the case of follicular carcinomas, lymph node metastases are less frequent, being found in approximately 35% of cases. A lymph node dissection is performed only if follicular carcinoma is already diagnosed or if palpable lymph nodes are present.

¹³¹I Therapy

¹³¹I therapy is given postoperatively for three reasons: it destroys normal thyroid remnants, thereby increasing the sensitivity of subsequent ¹³¹I total body scans and the specificity of measurements of serum thyroglobulin for the detection of persistent or recurrent disease; it may destroy occult microscopic carcinoma, thereby decreasing the long-term recurrence rate, and it permits a postablative ¹³¹I total body scan, a sensitive tool for persistent carcinoma.

Postoperative ¹³¹I therapy should be used selectively (Table III). In low-risk patients, the long-term prognosis after surgery alone is so favorable that ¹³¹I ablation is not usually recommended. However, patients who are at high risk of recurrence are routinely

Table III Indications for ¹³¹I Ablative Treatment in Patients with Thyroid Carcinoma after Initial Surgery

| |
|---|
| No indication: |
| Low risk of cancer-specific mortality and low risk of relapse: pTNM stage I |
| Indication: |
| Definite |
| Distant metastases |
| Incomplete tumor resection |
| Complete excision of tumor but high risk of mortality/recurrence: pTNM stages II and III |
| Probable |
| Age <18 years |
| Histologic subtype: papillary tall cell, columnar cell, or diffuse sclerosing; follicular widely invasive or poorly differentiated follicular |
| Elevated serum Tg concentrations >3 months after surgery on L-thyroxine treatment |

treated with ¹³¹I, because it decreases both the rate of recurrence and the rate of death.

Postoperatively, ¹³¹I therapy is administered 4 to 6 weeks after surgery, during which no thyroid hormone treatment is given. A diagnostic total body scan with 2 mCi (74 MBq) ¹³¹I is performed only when thyroidectomy has been partial. Another total body scan is performed 4 to 7 days later and thyroxine therapy is initiated. Total ablation may be verified by a ¹³¹I total body scan 6 to 12 months later with 2 mCi (74 MBq).

Total ablation (no visible uptake) is achieved after administration of both 100 mCi (3700 MBq) and 30 mCi (1000 MBq) in more than 80% of patients who had a near-total thyroidectomy. After less extensive surgery, ablation is achieved in only two-thirds of patients with 30 mCi (1000 MBq). Therefore, near-total thyroidectomy should be performed in all patients who are to be treated with ¹³¹I. Total ablation requires that a dose of at least 300 Gy be delivered to thyroid remnants and a dosimetric study allows the ¹³¹I dose to be administered to be estimated more precisely.

External Radiotherapy

External radiotherapy to the neck and mediastinum is indicated only in patients older than 45 years in whom surgical excision is incomplete or impossible and in whom the tumor tissue does not take up ¹³¹I.

FOLLOW-UP

The goals of follow-up after initial therapy are to maintain adequate thyroxine therapy and to detect persistent or recurrent thyroid carcinoma. Most recurrences occur during the first years of follow-up, but some occur late. Therefore, follow-up is necessary throughout the patient's life.

Thyroxine Treatment

The growth of thyroid tumor cells is controlled by thyrotropin [or thyroid-stimulating hormone (TSH)] and inhibition of thyrotropin secretion with thyroxine improves the recurrence and survival rates. Therefore, thyroxine should be given to all patients with thyroid carcinoma, whatever the extent of thyroid surgery and other treatment. The initial effective dose is between 2.0 and 2.4 μg/kg body weight in young adults; children require higher doses. The adequacy of therapy is monitored by measuring serum TSH 3 months after

therapy is begun, with the initial goal being a serum TSH concentration of $\leq 0.1 \mu\text{U/ml}$ and a serum free-triiodothyronine concentration within the normal range, to avoid overdosing.

Early Detection of Recurrent Disease

Clinical and Ultrasonographic Examinations

Palpation of the thyroid bed and lymph node areas should be routinely performed but is poorly sensitive. Ultrasonography is performed in patients at high risk of recurrence and in any patient with suspicious findings. Palpable lymph nodes that are small, thin, or oval, that are found in the posterior neck chains, and that decrease in size after an interval of 3 months are considered benign. Serum thyroglobulin is undetectable in 20% of patients receiving thyroxine treatment who have isolated lymph node metastases and undetectable values do not exclude metastatic lymph node disease. These false-negative results can be found with neck ultrasonography, with an ultrasound-guided node biopsy performed in suspicious cases for cytology and thyroglobulin measurement in the fluid aspirate.

X Rays

Chest X rays are no longer routinely performed in patients with an undetectable serum thyroglobulin concentration. The reason is that virtually all patients with abnormal X rays have detectable serum thyroglobulin concentrations.

Serum Thyroglobulin Determinations

Thyroglobulin (Tg) is a glycoprotein that is produced only by normal or neoplastic thyroid follicular cells. It should not be detectable in patients who have had total thyroid ablation and its detection in such patients signifies the presence of persistent or recurrent disease.

The sensitivity of good Tg assays is 1 ng/ml or even less. The results can be artifactually altered by serum anti-Tg antibodies, which are found in approximately 15% of patients with thyroid carcinoma, and these antibodies should always be sought by radioimmunoassay or by a recovery test. In immunoradiometric assay (IRMA) methods, interference induces falsely reduced or false-negative serum Tg measurements.

The production of Tg by both normal and neoplastic thyroid tissue is in part TSH-dependent. Thus, when interpreting the serum Tg value, the serum TSH value should be taken into account, as well as the presence or absence of thyroid remnants (Table IV). When serum Tg is detectable during thyroxine

Table IV Percentages of Patients with Detectable ($>1 \text{ ng/ml}$) Serum Thyroglobulin Concentrations during Thyroxine Treatment and after Discontinuation of Thyroxine According to the Presence or Absence of Normal Thyroid Tissue^a

| | Total ablation | | Total thyroidectomy | |
|---------------------------------------|----------------|------|---------------------|-----|
| | On | Off | On | Off |
| L-T4 treatment | On | Off | On | Off |
| Complete remission ^b | <2 | 10 | 7 | 20 |
| Lymph node metastases | 80 | ~90 | — | — |
| Distant metastases with normal X rays | 95 | ~100 | — | — |
| Large distant metastases ^c | ~100 | ~100 | — | — |

^aDetectable serum thyroglobulin concentrations are $>1 \text{ ng/ml}$. Serum thyroglobulin values are highly dependent on the assay. In this study, an immunoradiometric method with a sensitivity of 1 ng/ml was used.

^bMost detectable serum thyroglobulin concentrations were $<5 \text{ ng/ml}$.

^cMost serum thyroglobulin concentrations were $>10 \text{ ng/ml}$.

treatment, it will increase after the treatment is discontinued.

The serum Tg concentration is an excellent prognostic indicator. Less than 1% patients not receiving thyroxine with undetectable serum Tg and normal neck ultrasonography relapsed after more than 10 years of follow-up. Conversely, 20–80% of patients with serum Tg concentrations above 40 ng/ml after thyroxine withdrawal and with no other evidence of disease have detectable foci of ^{131}I uptake in the neck or at distant sites after administration of therapeutic doses of ^{131}I .

^{131}I Total Body Scan

The results of ^{131}I total body scan (TBS) depend on the ability of neoplastic thyroid tissue to take up ^{131}I in the presence of high serum TSH concentrations, which are achieved by withdrawing thyroxine for 4 to 6 weeks. However, the resulting hypothyroidism is poorly tolerated by some patients. This can be attenuated by substituting the more rapidly metabolized triiodothyronine for thyroxine for 3 weeks and withdrawing it for 2 weeks. The serum TSH concentration should be above some arbitrary value ($30 \mu\text{U/ml}$) in patients managed in this way; if it is not, ^{131}I administration should be delayed until it is. Intramuscular injection of recombinant human thyrotropin (rhTSH) is an alternative [0.9 mg administered intramuscularly for 2 consecutive days with ^{131}I administration (4 mCi) on the day following the second injection and TBS and serum Tg determination 2 days later], because thyroxine treatment needs not be discontinued and side

effects are minimal. Its efficiency for the detection of persistent and recurrent disease is comparable to that of thyroxine withdrawal in most patients.

When ^{131}I scanning is planned, patients should be instructed to avoid iodine-containing medications and iodine-rich foods and urinary iodine should be measured in doubtful cases. Pregnancy must be excluded in women of childbearing age. For routine diagnostic scans, from 2 to 5 mCi (74 to 185 MBq) ^{131}I is given; higher doses may reduce the uptake of a subsequent therapeutic dose of ^{131}I . The scan is performed and uptake, if any, is measured 72 h after the dose using a double-head gamma camera equipped with high-energy collimators. False-positive results are rare.

Post ^{131}I Therapy Total Body Scans

Assuming equivalent fractional uptake after administration of a diagnostic and a therapeutic dose of ^{131}I , uptake too low to be detected with 2 to 5 mCi (74–185 MBq) may be detectable after the administration of 100 mCi (3700 MBq). Thus, a total body scan should be routinely performed 4 to 7 days after a high dose. This is also the rationale for administering a therapeutic dose of ^{131}I in patients with elevated Tg levels (>10 ng/ml off thyroxine treatment), even if the diagnostic scan is negative.

Follow-up Strategy

If the total body scan performed after the administration of ^{131}I to destroy the thyroid remnant does not show any uptake outside the thyroid bed, physical examination is performed and serum TSH and Tg are measured during thyroxine treatment 3 months later. A diagnostic ^{131}I total body scan was performed after thyroxine withdrawal, 6 to 12 months later. Reports have clearly demonstrated that ^{131}I TBS does not provide any useful information in these patients. Thus, the current protocol includes a determination of serum Tg following rhTSH stimulation and neck ultrasonography (Fig. 1).

If serum thyroglobulin following TSH stimulation is undetectable and neck ultrasonography is normal, low-risk patients are considered cured, and the dose of thyroxine is decreased to maintain a low but detectable serum TSH concentration (0.1 to 0.5 $\mu\text{U}/\text{ml}$). In higher-risk patients, higher doses of thyroxine are given, the goal being a serum TSH concentration of ≤ 0.1 $\mu\text{U}/\text{ml}$. Clinical, ultrasonographic, and biochemical evaluation is performed annually; any other testing is unnecessary as long as the patient's serum Tg concentration is undetectable.

If serum Tg is detectable following TSH stimulation, two attitudes can be considered: in those patients with a relatively low Tg level, another determination is obtained 6 to 36 months later, because with longer follow-up serum Tg became undetectable in two-thirds of these patients; in those with high serum Tg levels and in those with increasing serum Tg at consecutive determinations, a high dose, 100 mCi (3700 MBq), of ^{131}I is administered with a TBS 3–5 days later. If no uptake is detected, an ^{18}F -fluorodesoxyglucose (FDG) positron emission tomography scan may be performed.

In patients receiving thyroxine in whom serum Tg becomes detectable, serum Tg should be measured after TSH stimulation. If the serum Tg concentration increases above 10 ng/ml, 100 mCi ^{131}I should be given.

In low-risk patients who have had a near-total or a total thyroidectomy but who were not given ^{131}I postoperatively, the follow-up protocol is based on Tg determinations and neck ultrasonography.

In low-risk patients who underwent a lobectomy, yearly follow-up consists of a neck examination and of serum Tg determination during thyroxine treatment. Ultrasonography will show abnormalities in the remaining lobe in most patients with detectable Tg concentrations. If the abnormality is small, fine-needle biopsy may be impossible and surgery is frequently the only option.

LOCAL AND REGIONAL RECURRENCES

Local or regional recurrences occur in 5 to 20% of patients with differentiated thyroid carcinomas. Some are related to incomplete initial treatment (in a thyroid remnant or in lymph nodes) and others indicate tumor aggressiveness (in the thyroid bed after total thyroidectomy or in soft tissues).

A local or regional recurrence that is palpable or easily visualized with ultrasonography or computerized tomography (CT) scan should be excised. Total excision may be facilitated by total body scanning 4 days after administration of 100 mCi (3700 MBq) ^{131}I , because additional tissue that should be excised may be identified. Surgery is performed 1 day later, preferably using an intraoperative probe. The completeness of resection is verified 1 to 2 days after surgery by another total body scan.

External radiotherapy is indicated in patients with soft tissue recurrences that cannot be completely excised and that do not take up ^{131}I .

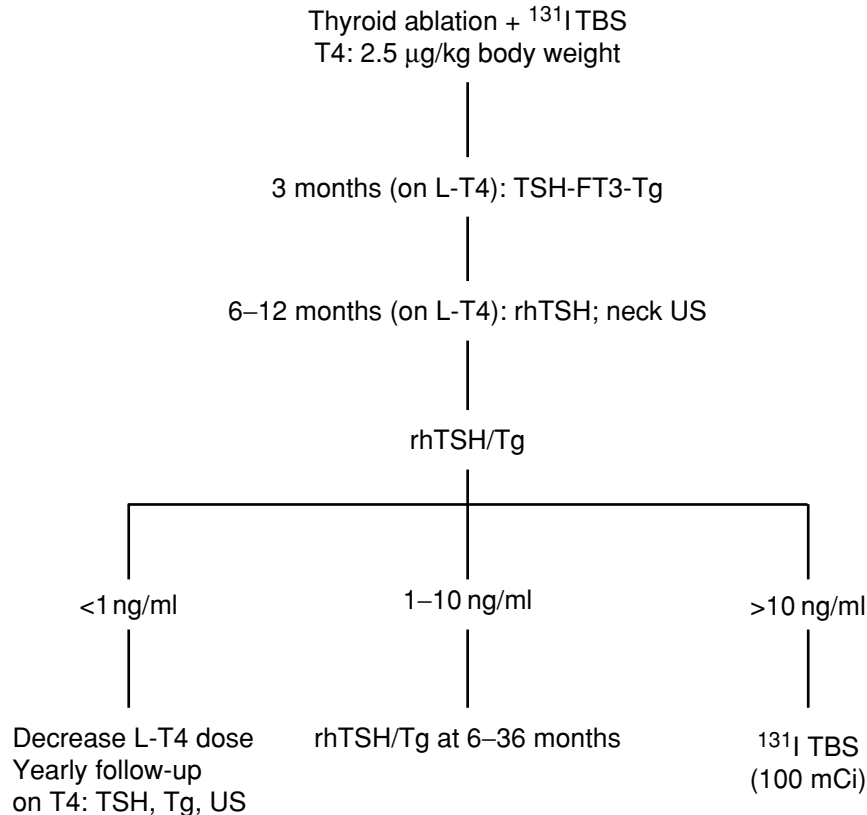

Figure 1 Follow-up of patients after total thyroid ablation, based on serum thyroglobulin determinations and neck ultrasonography. The point at which a decision is made depends on the assay used to measure serum Tg. TBS, total body scan; TSH, thyrotropin; T4, thyroxine; Tg, thyroglobulin; US, neck ultrasonography; L-T4, L-thyroxine treatment.

DISTANT METASTASES

Distant metastases, mostly in the lungs and bones, occur in 10 to 15% of patients with differentiated thyroid carcinomas. Lung metastases are most frequent in young patients with papillary carcinoma and are almost the only site of distant spread in children. Bone metastases are more common in older patients and in those with follicular carcinoma. Other less common sites are the brain, liver, and skin.

Diagnosis

Clinical symptoms of lung involvement are uncommon. In contrast, pain, swelling, or fractures occur in more than 80% of patients with bone metastases. The pattern of lung involvement may vary from macronodular to diffuse infiltrates. The latter, when not detected by chest X ray, are usually diagnosed with ¹³¹I total body scan and may be confirmed by CT; enlarged mediastinal lymph nodes are often present in

patients with papillary carcinomas, especially children. Bone metastases are osteolytic and are often difficult to visualize on X rays; bone scintigraphy may show decreased or moderately increased uptake, and bone involvement is better visualized by CT or magnetic resonance imaging. Nearly all patients with distant metastases have a high serum Tg concentration, unless the metastases are not visible on X rays, and two-thirds of patients have ¹³¹I uptake in the metastases.

Treatment

Palliative surgery is required for bone metastases when there are neurological or orthopedic complications or a high risk of such complications. Surgery may also be useful to debulk large tumor masses.

Patients with metastases that take up ¹³¹I should be treated with 100 to 150 mCi (3700 to 5550 MBq) every 4 to 6 months. The effective radiation dose, which depends on the ratio between total uptake and

the mass of thyroid tissue, and outcome of ^{131}I therapy are correlated. For this reason, higher doses [200 mCi (7400 MBq) or more] have been advocated in patients with bone metastases, but their effectiveness remains to be demonstrated. Lower doses [1 mCi/kg (37 MBq) body weight] are given to children. There is no limit to the cumulative dose of ^{131}I that can be given to patients with distant metastases, although above a cumulative dose of 500 mCi (18,500 MBq), further ^{131}I therapy has little benefit but the risk of leukemia increases significantly. External radiotherapy is given to patients with bone metastases visible on X rays. Chemotherapy is poorly effective and should be reserved for patients with progressive and nonfunctioning metastases.

Treatment Results

Complete responses have been obtained in 45% of patients with distant metastases with ^{131}I uptake, more frequently in younger patients and in those with small pulmonary metastases.

Overall survival after the discovery of distant metastases is approximately 40% at 10 years. Young patients with well-differentiated tumors that take up ^{131}I and have metastases that are small when discovered have a more favorable outcome. When the tumor mass is considered, the location of the metastases, be it the lungs or bone, has no independent prognostic influence. The poor prognosis of patients with bone metastases is linked to the bulkiness of their lesions. The prognostic importance of the small metastases at their discovery has led to the administration of 100 mCi (3700 MBq) doses of ^{131}I to patients with elevated serum Tg concentrations and no other evidence of disease.

Complications of Treatment with ^{131}I

Acute Side Effects

Acute side effects (nausea, sialadenitis) after treatment with ^{131}I are common but usually mild and they resolve rapidly. Radiation thyroiditis is usually trivial, but if the thyroid remnant is large, the patient may have enough pain to warrant corticosteroid therapy for a few days. Tumors in certain locations—brain, spinal cord, and paratracheal region—may swell in response to TSH stimulation or after ^{131}I therapy, causing compressive symptoms. Radiation fibrosis may develop in patients with diffuse lung metastases and eventually prove fatal if high doses [>150 mCi (5550 MBq)] are administered at short intervals (<3 months).

Genetic Defects and Infertility

Particular attention must be paid to avoid administration of ^{131}I to pregnant women.

After ^{131}I treatment, spermatogenesis may be transiently depressed and women may have transient ovarian failure. Genetic damage induced by exposure to ^{131}I before conception has been a major subject of concern. However, the only anomaly that has been reported is an increased frequency of miscarriages in women treated with ^{131}I during the year preceding the conception. Therefore, it is recommended that conception be postponed for 1 year after treatment with ^{131}I . There is no evidence that pregnancy affects tumor growth in women receiving adequate thyroxine therapy, who should be monitored carefully (at least every 2 months) during pregnancy.

Carcinogenesis and Leukemogenesis

Mild pancytopenia may occur after repeated ^{131}I therapy, especially in patients with bone metastases also treated with external radiotherapy. The overall relative risk of secondary carcinoma and of leukemia was found to be increased in patients treated with a high cumulative dose of ^{131}I [>500 mCi (18,500 MBq)] or in association with external radiotherapy. Because the dose–effect relationship is linear, any therapeutic dose of (30–100 mCi) ^{131}I may increase this risk.

CONCLUSION

Most patients with papillary or follicular carcinomas can be cured. However, both initial treatment and follow-up should be individualized according to prognostic indicators and thereafter to any evidence of disease in order to improve the patient's quality of life.

ANAPLASTIC CARCINOMA

Anaplastic carcinomas represent less than 5% of thyroid carcinomas. They occur in elderly patients with a long-standing goiter. They are one of the most aggressive carcinomas in humans and prognosis can be improved by the use of combined treatment modalities.

Usually, anaplastic carcinoma manifests by a rapid increase in the size of a thyroid nodule, frequently with enlarged neck lymph nodes. Compressive symptoms are frequent. The tumor does not concentrate radioiodine and does not produce thyroglobulin. Treatment should be initiated as soon as possible and includes surgery with gross resection of all tumor masses present in the neck and followed by a

combination of chemotherapy and radiation therapy. The authors' protocol combines chemotherapy with adriamycin (60 mg/m^2) and cisplatin (120 mg/m^2) every 4 weeks for six cycles with radiation therapy (1.25 Gy twice a day for 5 days per week for a total dose of 40 Gy to the neck and upper mediastinum) between the second and third cycles of chemotherapy.

When surgery is feasible, local control is obtained in the majority of patients and long-term survival of up to 40% of patients with no evidence of distant metastases has been reported. This protocol prevents death from local invasion and suffocation and most deaths are due to distant metastases.

Table 1 Physiological Changes in Pregnancy and the Influence on Thyroid Function Tests^a

| Physiologic change | Thyroid function test change |
|--|---|
| Increased thyroid gland size (women in areas of insufficient iodine intake) | Increased serum thyroglobulin |
| Estrogen-mediated increase in serum levels of TBG | Elevated serum total T ₄ and T ₃ concentrations |
| Increased plasma volume | Increased T ₄ and T ₃ pool |
| First-trimester elevation in serum hCG | Transient reduction in serum TSH concentration and possible increase in free T ₄ |
| Increased expression of type 3 5-deiodinase (D ₃) in placenta and uterus | Accelerated degradation of T ₄ and T ₃ |

^aAbbreviations used: T₄, thyroxine; T₃, triiodothyronine; hCG, human chorionic gonadotropin; TBG, thyroxine-binding globulin.

TSH that corresponds to the peak of serum hCG in the first trimester. Generally, serum TSH remains in the normal range, although subnormal values were reported in approximately 15% of women from an area of relative iodine insufficiency. The reduction of serum TSH is likely the result of an increase in circulating free thyroid hormones at this time. The increase in free T₄ level is most likely mediated by direct stimulation of the thyroidal TSH receptor by hCG.

HYPOTHYROIDISM DURING PREGNANCY

The previously described physiological factors that influence thyroid function during pregnancy—increased iodine clearance, increased serum TBG concentration, and increased D₃ activity in the placenta and uterus—are a “stress” on the thyroid gland. Women with normal thyroid glands in iodine-sufficient areas can compensate for these changes, but women in iodine-insufficient areas or those with underlying hypothyroidism may not be able to maintain euthyroxinemia. Although the fetal thyroid gland begins to function at 10–12 weeks of development, maternal thyroid status may influence fetal development throughout pregnancy.

Iodine Deficiency

Iodine deficiency remains an important cause of maternal hypothyroidism in a number of areas throughout the world, including parts of central Africa and Asia. It is estimated that as many as 500 million people live in areas of iodine deficiency, despite a worldwide program to eradicate iodine deficiency. The World Health Organization recommends that pregnant women receive 200 µg of iodine per day. Since iodine clearance increases during pregnancy, pregnant women in areas of relative iodine insufficiency are at

an increased risk of iodine deficiency. In the United States, a survey conducted from 1988 to 1994 indicated that, compared to a similar study conducted from 1971 to 1974, the percentage of women of child-bearing age with low urinary iodine (<5 µg/dl) increased from 4 to 15% and that of pregnant women increased from 1 to 7%.

Hashimoto's Disease

The most common cause of hypothyroidism during pregnancy is chronic lymphocytic thyroiditis, also referred to as Hashimoto's thyroiditis. There is a marked female predominance of Hashimoto's thyroiditis, with a female to male ratio of approximately 7:1. Hypothyroidism can also be seen as a consequence of radioiodine or surgical treatment of Graves' disease, thyroid cancer, or goiter. Transient hypothyroidism in the postpartum period is most often due to postpartum lymphocytic thyroiditis. Hypothyroidism can also occur after external radiation for cervical neoplasms and may also be caused by the medications lithium, amiodarone, or interferon.

Women may first be diagnosed with hypothyroidism during pregnancy. A survey of thyroid function studies of a sample of healthy individuals without known thyroid disease showed a high incidence of undiagnosed hypothyroidism. Thyroid tests were performed from 1988 to 1994 and showed that 4.3% of the group had undiagnosed subclinical hypothyroidism and 0.3% had undiagnosed overt hypothyroidism. Positive anti-thyroid peroxidase antibodies were found in 11.3% of the population without known thyroid disease. The incidence of abnormalities was significantly higher in women than in men. Approximately one-fourth of hypothyroid women have menstrual irregularity, with oligomenorrhea more common than hypomenorrhea and menorrhagia.

Complications

A variety of maternal and fetal complications of pregnancy have been associated with hypothyroidism. Although severe hypothyroidism can interfere with conception, women have become pregnant even when profoundly hypothyroid. Correction of subclinical hypothyroidism with thyroxine replacement has been associated with conception in women with ovulatory defects. Although complications of pregnancy are not uniformly seen in hypothyroidism, a number of complications are observed with a higher frequency in women who are hypothyroid during pregnancy. Among women who experience a miscarriage, a high percentage have positive anti-thyroid antibodies, and some have mild or overt hypothyroidism. Although it is possible that reduced thyroid hormone levels and thyroid autoantibodies play a pathogenic role in miscarriage, it is more likely that thyroid autoantibodies are a marker for antibodies to other fetal or placental components that result in miscarriage. Other complications of pregnancy associated with hypothyroidism include pregnancy-induced hypertension and preterm delivery. In a study of 150 pregnancies complicated by overt or subclinical hypothyroidism, the incidence of miscarriage and preterm delivery was much higher in patients with incompletely treated hypothyroidism than in those receiving adequate thyroxine replacement. Term deliveries were seen in approximately 20% of women with inadequately treated hypothyroidism and approximately 95% of women receiving adequate thyroxine replacement at the time of delivery. [Table II](#) summarizes the effects of hypothyroidism on pregnancy and fertility.

Increased Thyroxine Dose

In women known to be hypothyroid, the thyroxine dose should be titrated to a low-normal TSH prior to

conception, if possible. A number of studies suggest that maternal euthyroxinemia is important in early gestation, prior to fetal thyroid gland functioning at 10–12 weeks. Approximately 50–70% of hypothyroid women require an increase in thyroxine dose during pregnancy. Women who are completely athyreotic (as a consequence of radioiodine therapy or surgical thyroidectomy) have the least thyroid reserve and are likely to need the greatest increase in thyroxine dose. Women with some thyroid reserve will need only a small increment or no change in thyroxine dose. The average required increase in thyroxine dose is approximately 50 µg. It is also important to caution women about taking calcium and iron supplements simultaneously with thyroxine since this may interfere with thyroxine absorption. Many women may take such supplements for the first time during pregnancy. Thyroid function should be evaluated in the first trimester with subsequent monitoring every 4–6 weeks, with dose adjustments as necessary to keep the serum TSH normal. The dose can be returned to the prepregnancy dose immediately after delivery.

Fetal Development

The influence of hypothyroidism on fetal development is controversial. When identified and started on thyroxine replacement soon after birth, infants with congenital hypothyroidism have generally been found to have normal intellectual and neurological development. Some investigators have identified subtle defects of cognitive function in treated hypothyroid children. The placenta does not usually allow thyroxine to cross between mother and fetus. In congenital hypothyroidism, however, there is evidence that in the presence of a large maternal-to-fetal gradient, thyroxine will cross. This permits sufficient thyroxine for the fetus for development. The intellectual development of the offspring of hypothyroid mothers

Table II Hypothyroidism and Fertility/Pregnancy

| Maternal complications | Fetal complications |
|---|--|
| Ovulatory dysfunction | Low birth weight |
| Miscarriage (highly associated with positive anti-TPO ^a antibodies regardless of thyroid status) | Perinatal mortality (some studies show a small increase; others show no difference) |
| Pregnancy-induced hypertension | Increase in congenital anomalies (studies vary, with some showing a small increase and others no difference) |
| Placental abruption | Intellectual development (some studies show a small reduction in IQ at 8 years of age) |
| Preterm delivery | |

^aTPO, thyroid peroxidase.

is thought by some to be modestly reduced. One study showed a small but significant reduction in the IQ of 8-year-old children born to mothers with untreated hypothyroidism.

HYPERTHYROIDISM DURING PREGNANCY

Graves' Disease

Graves' disease is the most common clinically recognized cause of hyperthyroidism in pregnant women. The majority of patients have previously identified Graves' disease, although it can also develop for the first time during pregnancy. Most women with hyperthyroidism have oligomenorrhea or amenorrhea.

Complications

Graves' disease is associated with a variety of complications during pregnancy (Table III). There can also be significant fetal complications as a consequence of antithyroid drug treatment. Preterm labor and infants small for gestational age are associated with Graves' disease. Approximately 1 in 100 infants from mothers with Graves' disease will have neonatal Graves' disease. Since this results from maternal thyroid-stimulating immunoglobulin (TSI) crossing the placenta, the fetus is at risk even if the mother has been definitively treated with radioiodine or surgery. Some advocate measuring maternal TSI levels in the serum to determine the risk of neonatal Graves' disease, although the predictive value of this measurement is not known.

Treatment

There is controversy regarding the appropriate treatment for Graves' disease in anticipation of pregnancy,

and the recommendations vary with the severity of disease and the region of the world. Some advocate definitive treatment of Graves' disease with radioiodine prior to pregnancy. This eliminates the possibility of Graves' disease complicating pregnancy, although thyroxine dose during pregnancy must be carefully monitored and adjusted. Some endocrinologists recommend against radioiodine treatment in women of reproductive age because of fear of radiation dose to the ovaries. Although limited data are available, in follow-up of a small group of women treated as children with high-dose radioiodine for thyroid cancer, there was no increase in the incidence of congenital anomalies. In most cases of mild to moderate Graves' disease in women of reproductive age, treatment with antithyroid drugs is used.

The primary treatment for Graves' disease during pregnancy is antithyroid drugs. Most authorities recommend a treatment goal of keeping the free T₄ level at the upper normal to slightly elevated level and not attempting to normalize the serum TSH level. Studies that have correlated fetal thyroid hormone levels with maternal levels indicate that when the mother is treated to euthyroidism, there is a much greater risk of fetal hypothyroxinemia. The total dose of antithyroid drug should be limited to restrict transplacental passage. The choice of drug is controversial. A limited number of studies suggest that propylthiouracil (PTU) has less transplacental passage and is found in the breast milk to a lesser extent than methimazole. Methimazole therapy has also been associated with aplasia cutis, a rare congenital defect manifest as loss of cutaneous structures in the crown of the head. In Europe, the most popular drug is carbimazole, which is metabolized to methimazole and has not been associated with aplasia cutis. There is no compelling evidence to designate any single drug as superior in pregnancy, but most endocrinologists in the United States use PTU.

In general, Graves' disease becomes less active during pregnancy as general immunosuppression occurs in the later stages. The dose of medication required for treatment is often considerably less in the second and third trimesters. Postpartum, however, there can be a flare of Graves' disease, as seen with many other autoimmune diseases. Some women may have their first manifestation of Graves' disease in the postpartum period. This must be differentiated from postpartum thyroiditis. Although radioiodine uptake distinguishes between these conditions, it cannot be easily measured in women while they are nursing. TSH receptor antibodies can be tested to support a diagnosis of Graves' disease. Sequential thyroid studies show spontaneous improvement or transition to a hypothyroid state

Table III Hyperthyroidism and Pregnancy

| Maternal complications | Fetal complications |
|------------------------|---|
| Preeclampsia | Low birth weight |
| Preterm labor | Increased perinatal mortality |
| | Neonatal hypothyroidism (due to excessive treatment of mother with antithyroid drugs) |
| | Neonatal hyperthyroidism (due to transplacental passage of maternal thyroid-stimulating immunoglobulin) |

in those with thyroiditis, whereas those with Graves' disease have persistent hyperthyroidism.

HUMAN CHORIONIC GONADOTROPIN-ASSOCIATED HYPERTHYROIDISM

There is an exponential increase in serum hCG during the first trimester of pregnancy, with peak levels at 10–12 weeks of pregnancy. *In vitro* studies using cells transfected with the human TSH receptor demonstrate that hCG binds the TSH receptor and activates adenylate cyclase. This is likely responsible for the reduction in serum TSH seen in most women in the first trimester of pregnancy. There are also a number of clinical manifestations of excess hCG (Table IV).

Hyperemesis Gravidarum

Hyperemesis gravidarum is characterized by prolonged and severe nausea and vomiting in early pregnancy and is associated with a loss of 5% body weight, dehydration, and ketosis. It occurs in approximately 1–1.5% of pregnancies, is more prevalent in Asian women than in Caucasians, and is more common with multiple gestations. Abnormalities of serum chemistries include hyponatremia, hypokalemia, hypochloremic alkalosis, and abnormalities of liver function. There is a positive correlation between the severity of vomiting and serum hCG level.

The majority of hyperemesis patients have a suppressed serum TSH level and increased free thyroxine concentration. Free thyroxine and TSH levels normalize when the hyperemesis resolves in the second trimester. In general, these patients do not have clinical features of hyperthyroidism or goiter. The hyperthyroidism is most likely due to a less sialylated hCG, which stimulates the TSH receptor to a greater extent, although it has a reduced serum half-life.

In most patients, the increased thyroid function of hyperemesis gravidarum is self-limited and subsides with the disappearance of vomiting. In a small percentage of patients, however, there is clear clinical evidence of hyperthyroidism; this has been termed transient hyperthyroidism of hyperemesis gravidarum or gestational thyrotoxicosis. In these situations, the diagnosis of Graves' disease should be excluded. Treatment with antithyroid drugs does not influence the course of hyperemesis gravidarum, even when associated with elevated thyroid function tests. If they are used, these drugs should be discontinued as soon as thyroid function tests return to normal and the vomiting subsides.

Trophoblastic Tumors

Clinical thyrotoxicosis has been associated with excessive hCG produced by trophoblastic tumors, hydatidiform mole, and choriocarcinoma. The hCG produced by these tumors is used as a marker for the diagnosis and management of these patients. The serum concentration of hCG in affected patients may be severalfold higher than the peak levels of normal pregnancy. Molar pregnancies are estimated to occur in approximately 1 in 1500 pregnancies in the United States and 1 in 1000 pregnancies in the United Kingdom, and they are significantly more common in Asian and Latin America populations.

Molar pregnancies are usually diagnosed before 20 weeks of gestation because of abnormal vaginal bleeding. Toxemia and hyperemesis gravidarum may also occur in molar pregnancy with greater frequency than in normal pregnancy. Thyroid function abnormality ranges from subclinical hyperthyroidism to increased free thyroxine levels with minimal clinical features of hyperthyroidism and even to severe thyrotoxicosis causing atrial fibrillation and congestive heart failure. In general, the manifestations of hyperthyroidism probably depend on the severity and duration of

Table IV Spectrum of hCG Action in Pregnancy^a

| Nature of hCG elevation | Clinical consequences and changes in thyroid function |
|--|---|
| Physiologic elevation in first trimester | Mild elevation of serum free T ₄ , mild reduction in serum TSH concentration |
| Exaggerated first-trimester hCG elevation (commonly seen with multiple gestations) | Greater increase in serum free T ₄ and greater reduction in serum TSH concentration; associated with hyperemesis gravidarum |
| Pathologic elevation from hydatidiform mole or choriocarcinoma | Marked elevation in serum free T ₄ and free T ₃ concentrations; suppression in serum TSH; clinical thyrotoxicosis observed in some patients |
| Increased "sensitivity" to hCG due to a TSH receptor mutation | Gestational thyrotoxicosis |

^aAbbreviations used: hCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone.

the increased thyroid hormone levels, which are in turn proportional to the hCG level, and the hCG level is proportional to the mass of the tumor.

TSH Receptor Mutation Sensitive to hCG

A very rare but informative cause of gestational thyrotoxicosis was recently reported. A woman and her mother both had a similar history of hyperemesis and hyperthyroidism during pregnancy. The TSH receptor had an A-to-G heterozygous mutation at codon 183 in exon 7, resulting in substitution of arginine for lysine in the middle portion of the extracellular domain of the TSH receptor. *In vitro* studies indicated that cells transfected with the mutant TSH receptor were much more sensitive to hCG than those expressing the wild-type TSH receptor. The hyperthyroidism during pregnancy in this family is most likely due to activation of this mutant TSH receptor by hCG.

treatable cause of mental retardation. There is an inverse relationship between age at diagnosis and IQ in later life. In iodine-replete areas, 85% of the cases are due to sporadic developmental defects of the thyroid gland (thyroid dysgenesis), such as the arrested migration of the embryonic thyroid (ectopic thyroid) or a complete absence of thyroid tissue (athyreosis). The remaining 15% have thyroid dysmorphogenesis defects transmitted by an autosomal recessive mode of inheritance. Iodine deficiency ($<25\mu\text{g}/\text{day}$), particularly in preterm infants, accounts for many cases in Europe, Asia, and Africa. Clinical diagnosis occurs in less than 5% of newborns with hypothyroidism because symptoms and signs are often minimal. As a result, it is not possible to predict which infants are likely to be affected. Without prompt diagnosis and treatment, most affected children gradually develop growth failure, irreversible mental retardation, and a variety of neuropsychological deficits.

Spontaneous Hypothyroidism

A cross-sectional study of 2779 subjects of the community of Whickham, a mixed urban and rural area in northeast England, in the 1970s documented the prevalence of thyroid disorders. Other cross-sectional studies from Europe, the United States, and Japan have corroborated the findings of this survey. Therefore, its findings have a broad application to iodine-replete communities. The prevalence of spontaneous hypothyroidism is between 1 and 2%, it is more common in older women, and it is 10 times more common in women than in men. In an iodine-deficient community of Pescopagno, Italy, the prevalence of newly diagnosed overt hypothyroidism was 0.3% of 573 women (autoimmune thyroiditis confirmed as etiology) and 0% of 419 men. The testing of hospital inpatients, predominantly elderly women, might reveal a higher proportion of unsuspected hypothyroidism, but this is not supported by the available studies, which confirm a prevalence of 2%.

Subclinical Hypothyroidism

Subclinical hypothyroidism represents a compensated state in which increased thyrotropin (TSH) output is required to maintain normal circulating thyroid hormone levels. An elevated serum TSH is a sensitive indicator of some degree of thyroid failure and there is a clear inverse relationship with free thyroxine (FT_4) levels.

A substantial proportion of the population, particularly elderly women who live in iodine-replete areas, have circulating thyroid antibodies [antithyroid peroxidase (microsomal) and anti-thyroglobulin antibodies] and normal thyroid function. The presence of these antibodies correlates with the presence of focal thyroiditis in biopsy and in postmortem material of patients with no evidence of hypothyroidism during life. Patients with hypothyroidism caused by either atrophic or goitrous autoimmune thyroiditis usually have high serum titers of the same antibodies. Serum TSH concentrations do not change as a function of age among adult men, but in women older than age 40 the concentrations increase markedly (Fig. 1). If women with anti-thyroid antibodies are excluded, there is no age-related increase. Nearly all older women with elevated serum TSH values have subclinical hypothyroidism. With respect to epidemiological studies, the definition of subclinical hypothyroidism varies from any increase in serum TSH to values $>10\text{mU}/\text{liter}$ or, more stringently, a serum TSH value $>10\text{mU}/\text{liter}$ and a positive test for circulating thyroid antibodies in serum.

In the Whickham survey, 8% of women (10% of women older than age 55) and 3% of men had subclinical hypothyroidism. A cross-sectional screening survey of 25,682 subjects older than age 18 attending a health fair in Colorado found that 9% of the population, excluding 1525 on thyroxine therapy, had an elevated serum TSH level; of these, $<1\%$ had overt hypothyroidism. Community studies of elderly persons have confirmed the high prevalence in this age group, with approximately 10% of subjects older than age 60 having serum TSH values higher than the normal range. In iodine-deficient Pescopagno, the prevalence of subclinical hypothyroidism was slightly lower, 4% of women and 3% of men, but anti-thyroid antibodies were as prevalent, although at lower titers, as in iodine-replete communities. Subclinical hypothyroidism is found at higher frequency (18% in Iceland and 24% in Hungary) in areas where iodine intake is high, but most cases are not of autoimmune origin.

Incidence of Hypothyroidism

In the 20-year follow-up of the Whickham cohort, the mean annual incidence of spontaneous hypothyroidism in surviving women was 3.5 per 1000, increasing to 4.1 per 1000 if all cases are included, including those who had received destructive treatment for hyperthyroidism. The probability of a

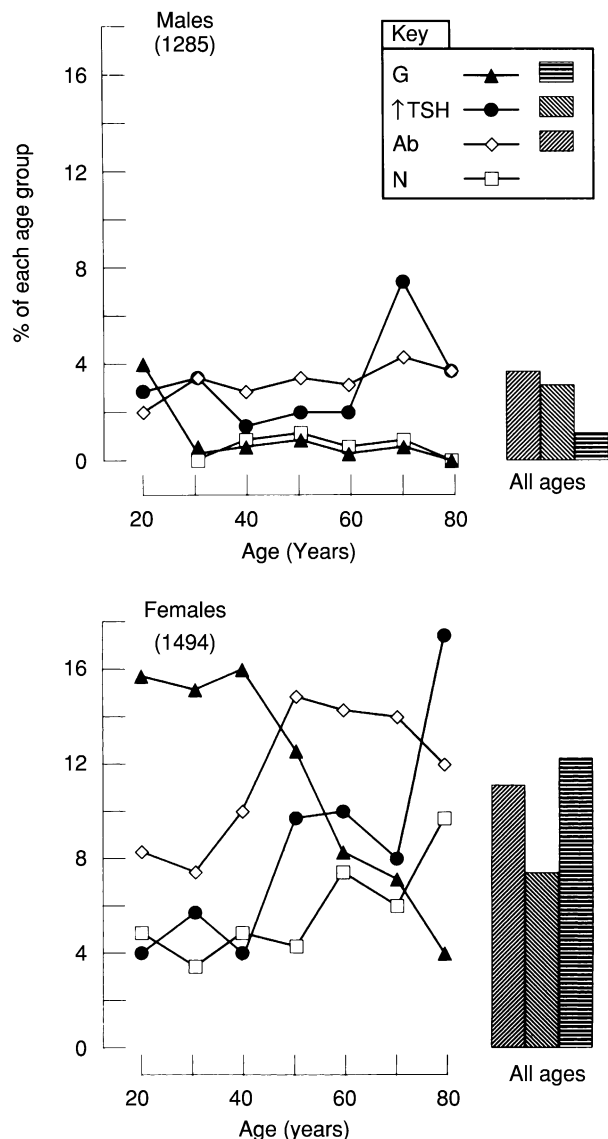

Figure 1 Age and sex distribution of thyroid cytoplasmic antibodies (Ab), raised serum TSH greater than 6 mU/liter (\uparrow TSH), visible goiter (G), and nodules (N) in the Whickham survey. From Tunbridge *et al.* (1977). The spectrum of thyroid disease in the community: The Whickham Survey. *Clin. Endocrinol.* 7, 485. Reproduced with permission from Blackwell Science Ltd.

woman developing hypothyroidism at a particular time (i.e., the hazard rate) increased with age to 14 per 1000 in women aged 75–80 (Fig. 2). The mean annual incidence in men (all spontaneous except for one case of lithium-induced hypothyroidism) was 0.6 per 1000. Either raised serum TSH or positive thyroid antibodies alone or in combination were associated with a significantly increased risk of hypothyroidism in women and men. The odds were greatly increased

Figure 2 Age-specific hazard rates for the development of overt hyperthyroidism and hypothyroidism in women at 20-year follow-up of the Whickham Survey. From Vanderpump *et al.* (1995). The incidence of thyroid disorders in the community: A twenty-year follow-up of the Whickham Survey. *Clin. Endocrinol.* 43, 60. Reproduced with permission from Blackwell Science Ltd.

when both risk factors were present and each had a similar effect. In the surviving women, the annual risk of developing spontaneous hypothyroidism was 4% in those who had both raised serum TSH levels and were thyroid-antibody positive, 3% if only serum TSH was raised, and 2% if only thyroid antibodies were positive. The cumulative incidence of hypothyroidism over 20 years was 55, 33, and 27%, respectively. The probability of developing hypothyroidism in women increases linearly when serum TSH is higher than 2 mU/liter; this is further increased if women are anti-thyroid antibody positive or decreased if anti-thyroid antibody negative (Fig. 3). The development of hypothyroidism also correlated with the strength of titer of anti-thyroid microsomal antibodies at first survey. A positive family history of any form of thyroid disease, the presence of a goiter at either the first or the follow-up survey, or parity at first survey were not associated with an increased risk of hypothyroidism. The prognostic importance of positive thyroid antibody tests and increasing serum TSH levels has been confirmed in other cohort studies.

Iatrogenic Hypothyroidism

After destructive treatment for hyperthyroidism (either radioiodine therapy or surgery), the incidence of overt hypothyroidism is greatest in the first year. Hypothyroidism occurs 2–4 weeks after total thyroidectomy, but the time course after subtotal thyroidectomy in Graves' hyperthyroidism is more

Figure 3 Probability for development within 20 years of hypothyroidism with increasing values of serum TSH at first Whickham Survey in 912 surviving women. From Vanderpump *et al.* (1995). The incidence of thyroid disorders in the community: A twenty-year follow-up of the Whickham Survey. *Clin. Endocrinol.* **43**, 63. Reproduced with permission from Blackwell Science Ltd.

variable. Factors that influence outcome are age, gland size (small glands are more likely to lead to hypothyroidism postoperatively), remnant size, and iodine intake (high intake is associated with recurrence). Radioiodine therapy for Graves' hyperthyroidism, toxic or nontoxic nodular goiter, or autonomously functioning thyroid adenomas can cause hypothyroidism months or years later. A fixed high dose of radioiodine (550 MBq), administered with the intent of ablating the thyroid and inducing early hypothyroidism, results in permanent hypothyroidism in at least 50% of patients by 1 year. Subclinical hypothyroidism is commonly found either postradioiodine therapy or postsurgery in up to 50% of apparently euthyroid patients. It may be evident for only a few months, but more often it represents a stage in the progression toward overt thyroid failure. If serum TSH remains raised, then the rate of progression toward overt hypothyroidism is 2–6% per year after either treatment. Treatment of Graves' disease with antithyroid drugs alone is also associated with the eventual development of hypothyroidism from either autoimmune thyroiditis or the presence of TSH-blocking antibodies in 5–20% of cases.

Other iatrogenic causes of hypothyroidism are surgery and external irradiation for head and neck cancer and drugs used to treat nonthyroid conditions, including amiodarone, lithium carbonate, interferon- α , and interleukin-2. In addition, patients with hypothyroidism who are taking thyroxine may become hypothyroid if given drugs that decrease thyroxine absorption (e.g., cholestyramine and iron salts) or drugs that

increase its clearance (e.g., phenytoin and carbamazepine or an estrogen-induced increase in the serum concentration of thyroxine-binding globulin). Poor compliance with thyroxine therapy or suboptimal treatment may also result in hypothyroidism.

HYPERTHYROIDISM

Prevalence

The prevalence of hyperthyroidism in women is between 0.5 and 2% and is 10 times more common in women than in men in iodine-replete communities. The prevalence data on elderly persons indicate a range from 0.4 to 0.9%. The prevalence of past and present hyperthyroidism in iodine-deficient Pescopagno was high at 3% (approximately one-third of these patients had a diffuse goiter), and the frequency in men and women was similar.

Hospital inpatients and even outpatients are selected populations. Isolated alterations in serum TSH concentrations [either slightly low (0.1–0.5 mU/liter) or high (5–20 mU/liter)] occur in approximately 15% of such patients due to the lability of TSH secretion in response to nonthyroidal illness or drugs. Approximately 2 or 3% of hospitalized patients have serum TSH concentrations that are suppressed (<0.1 mU/liter) or elevated (>20 mU/liter), but less than half have an underlying thyroid disorder. The reported prevalence rates for previously undiagnosed hyperthyroidism, between 0.3 and 1%, are consistent with community surveys. An accurate diagnosis can be achieved if clinical indications for measuring thyroid function exist, an accurate drug history is taken, the abnormal serum TSH is subsequently confirmed, and there is a reciprocal change in serum FT₄.

Subclinical Hyperthyroidism

More than 10 years ago, the introduction of assays for serum TSH that were sensitive enough to distinguish between normal and low concentrations allowed subjects with subclinical hyperthyroidism to be identified. This is defined as a low serum TSH concentration in the presence of normal serum T₄ concentrations and the absence of hypothalamic or pituitary disease, nonthyroidal illness, or ingestion of drugs that inhibit TSH secretion, such as glucocorticoids or dopamine.

In cross-sectional studies, 2–4% of subjects have below normal serum TSH (detection limit, 0.05 mU/liter), of whom half are on thyroxine therapy. Those with low but detectable levels may recover spontaneously when retested. In studies using more sensitive

serum TSH assays (detection limit, 0.01 mU/liter), approximately 2% of subjects have subnormal serum TSH and 1% have an undetectable serum TSH. The Colorado study, which screened more than 25,000 healthy volunteers with a similarly sensitive serum TSH assay, also found 2% of the population to have a subnormal serum TSH, with more than half on thyroxine therapy. In short follow-up studies, the incidence of hyperthyroidism has been calculated at 5% per year.

The prevalence of subnormal serum TSH (detection limit, 0.01 mU/liter and excluding those on thyroxine therapy) in Pescopagano was significantly higher (6%) due to functional autonomy from nodular goiters. In iodine-deficient Jutland, 10% of a random sample of 423 subjects aged 68 had a below normal serum TSH compared to 1% of a similar sample of 100 subjects in iodine-rich Iceland. Subclinical hyperthyroidism was not detected in a sample of elderly nursing home residents in an iodine-rich region of Hungary.

Incidence of Thyrotoxicosis

In the 20-year follow-up of the Whickham cohort, the mean annual incidence of hyperthyroidism in women was 0.8 per 1000. No new cases were detected in men. The estimated probability of developing hyperthyroidism in women at a particular time (the hazard rate) averaged 1.4 per 1000 between the ages of 35 and 60 (Fig. 2). Other cohort studies provide comparable incidence data. The incidence data for overt hyperthyroidism in men and women from large population studies are comparable at 0.4 per 1000 women and 0.1 per 1000 men per year, although the age-specific incidence varies considerably. The peak age-specific incidence of Graves' disease was between 20 and 49 years in two studies but increased with age in Iceland and peaked at 60–69 years in Malmö, Sweden. The only available data for a black population from Johannesburg suggest a 10-fold lower annual incidence of hyperthyroidism in black Africans than in European whites: 0.09 per 1000 women and 0.007 per 1000 men.

POSTPARTUM THYROIDITIS

Approximately 10% of women entering antenatal clinics at 16 weeks of gestation are anti-thyroid peroxidase antibody (anti-thyroid microsomal antibody) positive, which is comparable to the prevalence of thyroid antibodies in community surveys. Postpartum thyroiditis (PPT) is a transient, destructive autoimmune thyroiditis that occurs between weeks 12 and 16

postpartum in 40–50% of women. The presence of anti-thyroid microsomal antibodies early in pregnancy increases the risk of developing PPT. It presents as a temporary, usually painless, episode of hypothyroidism, occasionally preceded by a short episode of hyperthyroidism.

A proportion of women progress to permanent hypothyroidism following an episode of PPT, particularly those with high antibody titers. In one study, 17% of Japanese patients developed hypothyroidism during a 5- to 16-year follow-up period (mean, 9 years), whereas in Wales, approximately one-fourth of women with PPT became hypothyroid within 5 years after delivery. It is not clear whether pregnancy alters the final incidence of autoimmune thyroid disease or merely quickens the development of thyroid disease.

DIFFUSE AND NODULAR GOITER

The most common thyroid disease is simple (diffuse) goiter. The clinical grading of thyroid size is subjective and imprecise. The World Health Organization (WHO) grading system recognizes that an enlarged thyroid gland may be palpably but not visibly enlarged. Examiner variation is greatest in deciding whether a thyroid that is palpable but not visible is normal (WHO stage O-A) or enlarged (WHO stage O-B). Interexaminer variation may also lead to differences in classifying goiter as diffuse or multinodular. There is also considerable overlap between the five WHO grades based on clinical criteria and thyroid volume estimated by ultrasonography. Ultrasonography has been used in epidemiological studies to assess thyroid size, resulting in much higher estimates of goiter prevalence than in studies in which goiter size was assessed by physical examination.

Most studies define a thyroid that is visible and palpable as a goiter (WHO grade 1 or higher). Considerable regional variations exist, even in nonendemic goiter areas. In cross-sectional surveys, the prevalence of diffuse goiter declines with age, the greatest prevalence is in premenopausal women, and the ratio of women to men is at least 4:1. In the Whickham survey, 16% of the cohort had small but easily palpable diffuse or multinodular goiters. In men, the prevalence of goiter declined with age from 7% in those younger than age 25 to 4% in those age 65–74. No goiters were detected in men older than age 75. Among the women, 26% had a goiter; the frequency ranged from 31% in those younger than age 45 (mostly diffuse) to 12% in those older than age 75 (who had a higher proportion of nodular

goiter) (Fig. 1). Longitudinal studies confirm the decreasing frequency of diffuse goiter with age.

This decline in frequency of diffuse goiters with age is in contrast to the increase in frequency of thyroid nodules and anti-thyroid antibodies with age (Fig. 1). A nodular goiter may be solitary or part of a multinodular goiter. In the Whickham survey, fewer than 1% of the men but 5% of the women had thyroid nodules detected clinically, and the frequency increased to 9% in women older than age 75. In 5234 subjects older than age 60 who were studied for a 5-year period in Framingham, Massachusetts, the prevalence of single thyroid nodules was 3% and that of multinodular goiter nodules was 1%. A higher prevalence of nodular goiter is found in areas of iodine deficiency in Europe, such as Italy, Germany, and Denmark. The only available longitudinal data suggest an annual incidence for nodules of 1 per 1000 and that, once formed, they tend to remain present and benign for a long period of time. Ultrasonography can detect thyroid nodules in up to one-third of subjects screened and is thus too sensitive as a screening tool.

THYROID CANCER

The clinical presentation of thyroid cancer is usually as a solitary thyroid nodule or increasing goiter size. Although thyroid nodules are common, thyroid cancers are rare. The four major histological types are papillary, follicular, medullary, and anaplastic, and each displays a different epidemiology. The annual incidence of all thyroid cancers ranges between 1 and 10 per 100,000 population in most countries and is two to four times more frequent in women than men.

Papillary and follicular tumors, which comprise 60–90% of the total, are rare in children and adolescents, but their incidence increases with age in adults. Papillary thyroid carcinoma (PTC) is the most common thyroid malignancy and worldwide constitutes 50–90% of differentiated follicular cell-derived thyroid cancers. Papillary thyroid microcarcinomas (diameter, ≤ 1 cm) are found in 4–36% of adults post-mortem in population-based studies. The reported increase in the incidence of these carcinomas in recent years may be attributed to an improvement in pathological techniques. Most diagnoses of PTC occur in patients 30–50 years old (median age, 44 years), and the majority (60–80%) occur in women. Follicular thyroid cancer occurs relatively infrequently compared to papillary cancer and accounts for approximately 15% of all thyroid cancers. In contrast, there is an increased frequency of follicular to

papillary carcinoma (5:1) in iodine-deficient endemic goiter areas. It tends to be a malignancy of older persons, with a mean age of 50 years in most studies. External radiation exposure, particularly in childhood, is a major risk factor for papillary cancer. Four years after the nuclear accident at Chernobyl, a dramatic increase in the incidence of childhood thyroid cancer (almost exclusively papillary tumors) was recorded in the regions most exposed. There is no documented association between radioiodine therapy for thyrotoxicosis and subsequent development of thyroid cancer in adults.

Medullary thyroid cancer (MTC) occurs in both sporadic and hereditary forms. The highest incidence of sporadic disease occurs in the fifth decade. Hereditary MTC can be inherited as an autosomal dominant trait with a high degree of penetrance associated with multiple endocrine neoplasia type 2 syndrome or as familial MTC without any other endocrinopathies. It can be diagnosed before clinical presentation by genetic and biochemical screening. Anaplastic thyroid cancer is very rare and is more frequent in populations with endemic goiter. Thyroid lymphoma is also uncommon, constituting approximately 2% of extranodal lymphomas and occurring predominantly in older women. Up to one-third of patients have a history of goiter, whereas some have established autoimmune thyroiditis and may be taking thyroxine therapy.

SCREENING FOR THYROID DISEASE

In the 1970s, screening programs for congenital hypothyroidism were developed in which TSH was measured in heel-prick blood specimens to detect this condition as early as possible. Individuals with atrial fibrillation or hyperlipidemia should have an assessment of thyroid function at least once to detect hypothyroidism. There is a high frequency of asymptomatic thyroid dysfunction in unselected patients with diabetes, and it has been calculated that performing a test of thyroid function in the annual review of diabetic complications is cost-effective. The threefold increase in the prevalence of thyroid antibodies in patients with breast cancer suggests that it may be worth screening this group for thyroid dysfunction. There is no consensus on whether healthy women should be screened for PPT. However, because women with type 1 diabetes are three times more likely to develop postpartum thyroid dysfunction, it is recommended that all such diabetic women should be tested in the first trimester for thyroid antibodies.

Any woman with a history of PPT should be offered annual surveillance of thyroid function due to the possible long-term risk of permanent hypothyroidism. Because of the high prevalence of hypothyroidism in people with Down's syndrome and Turner's syndrome, an annual check of thyroid function is recommended. Thyroid function tests are indicated every 6 months for those receiving amiodarone and lithium and every 12 months following head and neck irradiation. Following destructive treatment for thyrotoxicosis by either radioiodine or surgery, indefinite surveillance for the development of hypothyroidism is required. Thyroid function should be assessed approximately 4–8 weeks post-treatment and then every 3 months up to 1 year and annually thereafter.

After hypothyroidism has been diagnosed and the appropriate dose of thyroxine has been established, the dose remains constant for most patients. During pregnancy, there may be a need to increase the dose by at least 50 μg daily to maintain a normal serum TSH, which should be measured each trimester. In order to improve compliance and account for possible variations in dosage caused by concomitant drug treatment, serum TSH should be measured annually. Access to a computerized thyroid disease register improves the surveillance of patients treated for thyroid dysfunction.

Controversy exists regarding whether healthy adults would benefit from screening for autoimmune thyroid disease. The prevalence of unsuspected overt thyroid disease is low, but a significant number of subjects tested have evidence of mild thyroid failure or excess. Is subclinical thyroid disease of sufficient clinical importance to warrant screening, and, once detected and confirmed, can therapy be justified?

In the absence of the confounding effects of non-thyroidal illness or drugs, a normal serum TSH concentration has a high predictive value in ruling out thyroid disease in the healthy ambulant subject. In unselected populations, serum TSH has a sensitivity of 89–95% and specificity of 90–96% for overt thyroid dysfunction compared to cases confirmed by history, examination, and additional testing. Normal concentrations of serum TSH may be recorded in hypothyroidism secondary to pituitary or hypothalamic disease, but both these situations are rare. In nearly all populations screened, a serum TSH higher than 5 mU/liter is accepted as being unequivocally increased. The standard follow-up investigation for subjects with a serum TSH higher than 5 mU/liter is the measurement of serum FT₄. However, the measurement of thyroid peroxidase antibodies in subjects with a borderline raised serum TSH may be

justified, and they should be offered long-term follow-up evaluation as part of the screening program with repeat serum TSH measurements. The ideal follow-up interval has not been established, but epidemiological studies suggest that retesting every 3 years is probably adequate, providing a mechanism for recall is established. The potential risks of lifelong thyroxine therapy are precipitating symptoms of ischemic heart disease or the development of osteoporosis, but the actual risks of properly monitored thyroxine therapy to maintain a normal serum TSH are almost certainly negligible.

Treatment of overt hypothyroidism with thyroxine is cheap and effective. There is evidence that in subjects with subclinical hypothyroidism, nonspecific symptoms and psychometric scores can be improved by thyroxine with a retrospective awareness of disability and that thyroxine may have beneficial effects on cardiovascular function and lipoprotein metabolism. No high-quality randomized, controlled trials of a complete screening program for subclinical hypothyroidism exist. A cost-utility analysis using a computer decision model assessed the consequences and costs of including serum TSH screening with cholesterol screening. It concluded that testing women age 35 or older with repeat serum TSH every 5 years for 50 years would be beneficial. More than half of the presumed benefit in quality-adjusted life-years was accounted for by preventing progression to overt hypothyroidism, 30% by improving associated mild symptoms, and 2% by preventing cardiovascular disease. This may be an overestimate because the 20-year follow-up of the Wickham cohort found no association with cardiovascular outcomes. Another assumption of the model was that only subjects with increased serum TSH levels and positive thyroid antibodies are at risk of progression to overt hypothyroidism. In the computer model, the cost of detecting subclinical hypothyroidism was \$9223 for women and \$22,595 for men per quality-adjusted life-year, but this cost was heavily dependent on the cost of the TSH assay kit (\$10–50). The cost-effectiveness of screening for mild thyroid failure was comparable with that of other commonly performed preventive and therapeutic health practices, such as hypertension, exercise, breast cancer screening, and estrogen replacement therapy, in women of the same age group, providing a similar increase in quality-adjusted years. The cost-benefit analysis did not justify the additional cost of measuring FT₄ with a serum TSH in the screening process or allow for the extra costs of detecting, investigating, and potentially treating subclinical hyperthyroidism. Few subjects screened will have overt

hyperthyroidism, but the consequences of finding a suppressed serum TSH have to be addressed even if it is not worth screening for hyperthyroidism. In addition to the possible risk of subsequent development of overt hyperthyroidism, other possible long-term complications include atrial fibrillation and osteoporosis. There is no consensus regarding the treatment of subclinical hyperthyroidism, even though it has been strongly argued that therapy with antithyroid drugs or radioiodine may be indicated. Any potential benefits of therapy in subclinical hyperthyroidism must be weighed against the significant morbidity associated with the treatment of hyperthyroidism.

From the available evidence, the following recommendations may be justified for an iodine-replete community:

Screening for thyroid dysfunction in women younger than age 50 and in men is not warranted in view of the relatively low point prevalence of unsuspected overt thyroid dysfunction.

Case-finding in women during menopause or during visits to a primary care physician with nonspecific symptoms is justified due to the high prevalence of subclinical hypothyroidism.

If increased serum TSH is found at screening, then measurement should be repeated 2 months later together with FT₄ measurement after excluding non-thyroidal illness, drugs, etc.

Treatment with thyroxine is recommended if the serum TSH is ≥ 10 mU/liter, irrespective of whether FT₄ is low.

Subjects with a serum TSH between 5 and 10 mU/liter and normal FT₄ are at increased risk of developing hypothyroidism, and repeat measurement of serum TSH is warranted at least every 3 years if not annually.

If a suppressed serum TSH is found at screening, it should be remeasured 2 months later, and if it is still suppressed, FT₃ should be measured.

After thyroxine replacement is initiated, for whatever indication, long-term follow-up with at least an annual measurement of serum TSH is required.

INTRODUCTION

When ancient vertebrates migrated from the iodine-rich oceanic environment to the iodine-poor terrestrial environment, evolution provided the new organisms' thyroid with an extremely complex and specialized machinery, completely devoted to the avid collection and storage of iodine, for the sole purpose of continuously providing enough substrate for the synthesis of thyroid hormone. As a very specialized organ, the thyroid therefore expresses, along with common housekeeping genes, a unique subset of genes, whose products are mostly enzymes involved in iodine metabolism and/or thyroid hormone synthesis. On one hand, some of these enzymes serve as unique and possibly confined targets (antigens) for the immune aggression characteristic of autoimmune thyroid diseases (AITD), which are very common conditions in humans, whose etiology is still incompletely understood. The susceptibility to these diseases has long been recognized to be largely hereditary in nature. Because of the high prevalence in the general population and because of the large amount of available data on genetic factors, AITD are given special emphasis in this article.

On the other hand, a wide range of thyroid disorders have been described in which a single inherited point mutation in one thyroid-specific gene causes clinically significant derangements in thyroid physiology and function, with or without hereditary goiter. Given their strong negative effect on survival, the latter conditions are distinctly rare but are usually inherited in a Mendelian fashion and therefore represent an important part of the genetics of thyroid disease. Thyroid cancer and goiter are also quite prevalent. Although epidemiological studies indicate that environmental factors are by far predominant in causing these disorders, emerging evidence shows significant inherited susceptibility to these disorders as well.

THE MONOGENIC DISEASES OF THE THYROID GLAND

Inherited Diseases of the Thyrotropin Receptor

The human thyrotropin receptor (TSHR) was cloned in 1989. The TSHR is a protein receptor, one of the G protein-coupled, seven-transmembrane domain receptors. The TSHR gene is located on chromosome 14q31. The primary structure of the TSHR is closely related to that of the follicle-stimulating hormone and luteinizing hormone receptors. Activation of the

TSHR is the key event leading to both increased thyroid hormone secretion and growth. Because of its central role in the regulation of thyroid physiology, the TSHR has been the focus of constant research in the history of endocrinology. In newer studies, however, inherited defects of the TSHR have been described as a cause of clinically relevant thyroid disease.

Activating Mutations of the TSHR

Site-directed mutagenesis initially showed that single point mutations in critical regions of the TSHR were capable of constitutively activating the TSHR, in the absence of its natural ligand, thyrotropin (or thyroid-stimulating hormone (TSH)). Such mutations, if found *in vivo*, would be expected to cause thyroid growth and hyperthyroidism. Indeed, naturally occurring, activating mutations of the TSHR have been described in a significant fraction of human toxic adenomas and toxic multinodular goiters. Mutations of the TSHR causing distinct hyperfunctioning nodules are always somatic, i.e., are found only within the nodular tissue. The nodules containing the mutation therefore represent monoclonal expansions of an initially mutated single thyroid cell and the condition is not hereditary. Since activation of the TSHR induces thyroid growth but also differentiation, these neoplasms are only very rarely malignant. More rarely, however, germ-line activating mutations of the TSHR have been described. The phenotype caused by these mutations is termed autosomal-dominant nonautoimmune hyperthyroidism [Online Mendelian Inheritance in Man (OMIM) 603372]. Although in many cases, this disease is inherited in a dominant fashion, at least half of the cases described thus far (>20) in the literature are sporadic; i.e., the mutation is found only in the index case and not in the parents (*de novo* mutation). The classical phenotype is characterized by severe congenital or neonatal hyperthyroidism and goiter. TSHR antibodies are usually negative and this helps differentiate the disorder from the other relevant cause of neonatal hyperthyroidism, the transplacental passage of maternal TSHR-stimulating antibodies. Treatment with anti-thyroid drugs can usually control the hyperthyroidism, but relapses are the rule. Thyroid growth is not contrasted by anti-thyroid drugs and the goiter evolves from initially diffuse to multinodular early during childhood, requiring surgery. Milder cases have been described, with later onset of hyperthyroidism and goiter. Several mutations of the TSHR have been identified as being responsible for the syndrome. The relationship of genotype to phenotype has been found to be somewhat inconsistent in large families with multiple

members carrying the same mutation. This indicates that other factors (genetic or environmental) play a role in determining the phenotype, at least with some of the known mutations.

More rarely, inherited mutations of the TSHR cause an inordinately responsiveness of the receptor to the placental hormone β human chorionic gonadotropin (β -HCG), which is closely related to TSH. In these cases, the effect of the mutation becomes evident only when high levels of β -HCG are present, i.e., during pregnancy, hence the appellation of familial gestational hyperthyroidism for this peculiar disease (OMIM 603373). Other than in pregnancy, the carriers of this rare mutation have a completely normal thyroid function.

Inactivating Mutations of the TSHR

Inactivating mutations of the TSHR manifest themselves with the clinical phenotype of resistance to TSH (OMIM 275200). Patients have often been detected at birth with severe primary congenital hypothyroidism (elevated TSH and low thyroxine) and a normally located but hypoplastic thyroid. In other cases, only mild, subclinical hypothyroidism has been found. Some of these patients have been noted to have an increased thyroglobulin level, an unexplained finding. Mutations leading to this disease have a variable effect on the receptor function, when studied *in vitro*. As expected with such a variable phenotype, several different mutations have been found; some completely abolish the expression of the receptor, whereas others only incompletely impair its responsiveness to TSH. The disease was initially described as autosomal-recessive, as predicted in many "loss-of-function" mutations. Initially reported cases have most often been compound heterozygotes, i.e., carrying two different mutations on each copy of the gene, but true homozygotes have also been found, usually in offspring of consanguineous marriages. However, since the first recognition of the syndrome, more and more heterozygous cases are being reported, with mild subclinical hypothyroidism, no goiter, and no evidence of thyroid autoimmunity. In one report of 10 such cases, 4 of the patients did indeed harbor mutations of the TSHR, 3 of which were heterozygous.

Inherited Defects of Thyroid Hormone Biosynthesis and Processing

Defective synthesis of thyroid hormone from the thyroid results in overt or compensated primary hypothyroidism. Since thyroid growth is largely independent

of the enzymatic pathways involved in the biosynthesis of thyroid hormone, ongoing TSH elevation as a consequence of low circulating thyroid hormone results in goiter. Therefore, the clinical phenotype of this group of diseases is characterized by hereditary goiter, usually early in onset, and various degrees of impairment of thyroid function, ranging from euthyroidism to overt primary hypothyroidism. Additional clinical features may be observed when the defect has consequences on other organs, as in Pendred's syndrome. The phenotype may be further characterized by the application of sophisticated thyroid function tests, such as the perchlorate challenge test or the measurement of thyroid hormone by-products. Because of their great impact on the overall health and survival of affected individuals, some of these diseases are quite rare and mostly recessive. However, their recognition has greatly enhanced the understanding of thyroid gland metabolism.

Pendred's Syndrome

Pendred's syndrome (OMIM 274600) is an autosomal-recessive disease characterized by congenital deafness, early-onset goiter, and euthyroidism (occasionally subclinical hypothyroidism). The prevalence of Pendred's syndrome is estimated at 1/1000. The sensory deafness is often due to a malformation of the inner ear in which the cochlea is replaced by a single cavity (Mondini's defect). However, an enlarged vestibular aqueduct, endolymphatic sac, and endolymphatic duct on magnetic resonance imaging (MRI) of the ear have been shown to be more specific signs. Except for its unusually early onset, the goiter is clinically not distinguishable from the more common endemic multinodular goiter. The pathology of the thyroid, however, displays marked hyperplasia and nodularity, sometimes suggestive of cancer. The incidence of true thyroid cancer, however, does not seem to be increased in these patients. The diagnosis of the disease relies on the classical perchlorate discharge test, which is highly sensitive but relatively nonspecific as other defects of thyroidal iodine organification result in a positive test. However, the combination of a positive perchlorate discharge test with typical malformations on MRI imaging of the inner ear establishes the diagnosis. The disease has been mapped by linkage analysis to chromosome 7q31. The cloned gene (termed PDS) encodes a protein (pendrin) that has features consistent with a transmembrane protein and is largely expressed in the adult human thyroid and (to a lesser extent) in the human cochlea and kidney. Although its function has not been fully clarified, pendrin seems to be an iodine-chloride transporter.

Sodium–Iodide Symporter Defect (OMIM 601843)

This extremely rare disease is characterized by an autosomal-dominant mode of inheritance, severe congenital hypothyroidism, and multinodular goiter. The diagnosis is clinically established on the basis of a very low thyroidal uptake of radioiodine in the presence of goiter. An additional feature is a partial response in terms of thyroid hormone production to high oral doses of potassium iodide. The disease is caused by homozygous inactivating mutations of the sodium–iodide symporter gene, located on chromosome 19p33.2–p12.

Thyroglobulin Defects (OMIM 274900)

Patients with this autosomal-recessive condition display a wide range of thyroid dysfunction, ranging from severe hypothyroidism to euthyroidism. Goiter is invariably present and the thyroidal radioiodine uptake is elevated. Thyroglobulin is a very large protein whose gene is located on chromosome 8q24.2–q24.3. Several structural (qualitative) and quantitative defects of thyroglobulin have been detected in patients with the disease. Usually, patients with qualitative defects have elevated circulating thyroglobulin levels, whereas patients with quantitative defects have low thyroglobulin levels.

Thyroperoxidase Defects (OMIM 274500)

Patients with thyroperoxidase defects have severe congenital hypothyroidism and various degrees of goiter. The disease is autosomal-recessive and is diagnosed by a positive perchlorate discharge test, in the absence of clinical features of Pendred's syndrome. The gene for thyroperoxidase has been mapped to chromosome 2p25 and has been found to be mutated in many but not all patients with this clinical presentation, suggesting some degree of heterogeneity in the syndrome.

Thyroid Hormone Coupling Defect (OMIM 247700)

This is a poorly defined group of disorders, also characterized by goiter and various degrees of hypothyroidism in which metabolic studies seem to suggest an altered coupling of iodotyrosil residues on thyroglobulin. Because part of this reaction is probably mediated by thyroperoxidase, there is a partial overlap with deficits of that enzyme and the phenotype could also be explained by alterations in thyroglobulin structure.

Dehalogenase Defects (OMIM 274800)

Deiodinases (or dehalogenases) are a group of enzymes capable of deiodinating metabolites of thyroid hormone degradation, such as diiodotyrosine (DIT)

and monoiodotyrosine (MIT). As such, they greatly contribute to the intrathyroidal pool of iodine by deorganifying “used” organic iodine and making it available for new hormone synthesis. Patients with a dehalogenase defect are incapable of reusing MIT or DIT and develop hypothyroidism and goiter secondary to urinary loss of iodine. The defect is inherited in an autosomal-dominant fashion and is diagnosed by an elevated urinary excretion of administered labeled diiodotyrosine and monoiodotyrosine. Also characteristic is a prompt resolution of hypothyroidism when dietary supplementation with high doses of iodine is given.

Developmental Defects of the Thyroid and Congenital Hypothyroidism

Congenital hypothyroidism (CH) has an incidence of approximately 1 in 3000–4000 newborns. Universal screening for the disease is available in most countries and allows early detection and treatment. Although CH can be observed in any severe form of the defects of thyroid synthesis described above, it is most often due to an abnormal *in utero* development of the thyroid gland, varying from its complete absence (thyroid agenesis) to various degrees of ectopy and hypoplasia (thyroid dysgenesis). Hereditary forms of the latter are very rare, most likely due to the severity of the consequences of CH, which include infertility. A number of genes involved in thyroid organogenesis have been identified and their role in the pathogenesis of CH has been partially clarified. The thyroid transcription factor 1 (TTF-1; OMIM 600635), mapped to chromosome 14q21, has been shown in animal models to be necessary for normal early thyroid organogenesis. Despite its central role, mutations in TTF-1 have been identified in only a few patients with congenital hypothyroidism due to thyroid dysgenesis. TTF-2 (on chromosome 9q22; OMIM 241850) is also highly expressed during thyroid ontogenesis. A familial case of thyroid agenesis associated with cleft palate and spiky hair has been shown to be due to heterozygous missense mutations of TTF-2 and was named Banforth-Lazarus syndrome. Paired-box gene 8 (PAX-8; OMIM 167415) is another transcription factor involved in thyroid organogenesis and regulation of the transcription of thyroid-specific genes, such as thyroglobulin and thyroid peroxidase. Nonsense and missense mutations of PAX-8 have been observed in two sporadic cases and one familial case of thyroid dysgenesis. Despite these encouraging findings, the etiology of the large majority of cases

of CH and thyroid dysgenesis remains unknown. It is likely that, in addition to other genetic factors, environmental factors play an important role.

GENETIC FACTORS IN THYROID AUTOIMMUNE DISEASES

The Clinical Phenotype

It is important to recognize that these diseases represent a group of diseases rather than a homogenous entity and that several clinical features may occur independently of one another, defining a variety of possible phenotypes. In general, the AITD are defined by the presence of a thyroid lymphocytic infiltrate, associated with serological evidence of thyroid autoimmunity in the form of circulating antibodies reactive to thyroid antigens and various degrees of thyroid dysfunction, ranging from profound hypothyroidism, as in the case of atrophic Hashimoto's thyroiditis (HT; OMIM 140300), to severe hyperthyroidism, as in the typical Graves' disease (GD; OMIM 275000). A number of other features may or may not be associated, such as the presence of Graves' ophthalmopathy, an autoimmune disease of the orbital tissues, typically observed in a relevant number of patients with hyperthyroid GD but occasionally also found in patients with HT. Pretibial myxedema is a puzzling inflammatory process of the dermis, localized to the pretibial regions, that is also associated (more rarely than ophthalmopathy) with GD. Finally, depending on various factors that are not completely understood, the thyroid gland may be enlarged as a consequence of either massive lymphocytic infiltration or of ongoing stimulation, it may be normal in size, or it may be strikingly reduced in size, as in the case of primary myxedema.

Evidence for a Role of Genetic Factors in the Pathogenesis of Autoimmune Thyroid Disease

It is a common experience in the practice of endocrinology to observe familial clustering of HT and GD. These diseases are quite prevalent in the general population (prevalence of approximately 1%). Therefore, given this high prevalence, random occurrence of the disease in more than one family member could account for the clinical observation, without necessarily indicating the presence of a genetic predisposition. However, a number of lines of evidence strongly

indicate an important influence of genetic factors in the etiology of these diseases. One indication of the presence of a genetic influence in the predisposition to AITD comes from family studies. In general, when there is such an influence, the prevalence of the disease in first-degree relatives of patients with the disease (probands) is significantly higher than in the general population.

In early studies conducted in the late 1950s and 1960s, a high incidence of thyroid autoantibodies was observed in first-degree relatives of patients with HT or GD. The prevalence of positive anti-thyroglobulin or anti-microsomal antibody tests in relatives ranged from 45 to 55%, compared to a general population prevalence of approximately 15%. Although those studies were exposed to a number of potential selection biases, they provided the first indication that at least one component of the disease phenotype (e.g., the formation of thyroid autoantibodies) had a possible inherited cause. Indeed, more stringent classical segregation analysis in families with autoimmune thyroid disease confirmed these earlier results, indicating a Mendelian dominant mode of inheritance for thyroid autoantibodies, at least in some families. It is interesting that such a model of inheritance would in fact result in a prevalence of the phenotype in first-degree relatives of patients of approximately 50%, as in the initial studies. In a further refinement of these findings, some investigators have indicated that in some families not only the predisposition to form thyroid autoantibodies is strongly hereditary, but also that even the fine molecular specificity of such antibodies can be inherited.

In summary, there seems to be a clear role for genetic factors in the formation of thyroid antibodies, at least in families in which the clinical disease exists in one member. In these families, the thyroid autoantibody trait seems to be inherited in a classical Mendelian fashion as an autosomal-dominant trait, with high penetrance. The situation was different when normal subjects with thyroid autoantibodies but without clinical HT were selected as probands. In one such study, only 30% of relatives had a positive result, compared to approximately 16% expected from population data, indicating at best a polygenic inheritance with low penetrance. Thus, the relatively common anti-thyroid autoantibody phenotype may represent the consequence of a strong genetic influence only in families with overt AITD.

The presence of circulating thyroid autoantibodies represents only one aspect of the AITD phenotype. Less clear data are available when one looks at the inheritance of the full AITD phenotype. Only

approximately 18% of relatives of patients with HT were found to be affected in one study, although the percentage also includes second-degree relatives. Another study observed that 33% of siblings of patients with HT were affected. Even lower percentages have been reported in GD, where a prevalence of 5 to 10% has been reported in siblings of patients. By dividing the prevalence of a disease in first-degree relatives of probands with the disease by the prevalence of the same disease in the population of origin, one can obtain the relative risk for the disease in sibs, also termed $\lambda(s)$. This measure provides an estimate of the importance of genetic factors in a disease. In nongenetic diseases, $\lambda(s)$ equals 1, whereas in highly inheritable and penetrant, monogenic disorders, it can rank as high as several hundred. The $\lambda(s)$ for HT can be estimated from available data to range from 20 to 45, quite a high number, indicating that indeed a significant genetic component in the etiology of HT exists. A somewhat lower value of 7.5 to 10 has been estimated for GD. It should be noted, however, that these numbers are somewhat artificial in that they are extrapolated from different studies, whereas no large population-based studies directly aimed at obtaining unbiased data are available.

Another way of estimating the role of the genetic contribution to the etiology of a disease is studying twins. In theory, although both dizygotic and identical twins share as much of the environmental influences as possible, including the intrauterine milieu, only dizygotic twins share approximately 100% of the genome, whereas dizygotic twins share on the average only 50% of the genome. For example, an autosomal-dominant, fully penetrant disease should be 100% concordant (i.e., present in both twins) in identical twins and only 50% concordant in dizygotic twins. By measuring the concordance rate of a disease in identical twins and comparing it to the rate observed in dizygotic twins, investigators can obtain very precise data on the relevance of genetic factors, the penetrance, and the mode of inheritance of disease. In both GD and HT, studies in twins have shown concordance rates well below 100% in identical twins (approximately 30% in GD and 55% in HT). However, much lower concordance rates (close to 0) have been observed in dizygotic twins. Thus, whereas a lower concordance rate in dizygotic twins indicates the presence of genetic factors, the less-than-100% concordance rate observed in identical twins indicates a role for environmental factors as well (incomplete penetrance). Interestingly, 80% of identical twins and 40% of dizygotic twins of HT patients had circulating thyroid autoantibodies. Again, these data suggest a dominant mode of

inheritance with high (80%) penetrance for the thyroid autoantibody trait, when part of a general predisposition to thyroid autoimmune disease.

Family and twin studies confirm the clinical impression of a genetic predisposition to AITD. However, the mode of inheritance of the full clinical phenotype seems to be complex rather than simple Mendelian inheritance. Admittedly, knowledge of the mode of inheritance of AITD is still very limited. In the search for the susceptibility genes, it is reasonable to consider two hypotheses. According to one hypothesis, the overall genetic susceptibility is provided by a relatively (>10) large number of disease-associated gene variations at many genetic loci (risk factors). When a sufficient number of these variants, in any combination, are inherited by an individual and appropriate environmental events take place, a threshold is reached and the disease develops. Given the small contribution to the overall susceptibility provided by these putative genes, they are more easily detected by sensitive association studies. If, in contrast, only a few (<10) major "necessary" genes exist, the disease will develop only in those subjects who will inherit the complete set of susceptibility genes. These genes are best detected by linkage analysis. Indeed, if many risk factors exist, it will be very difficult to develop efficient prediction tools to be used in clinical practice.

Predisposing Genes in AITD

The evidence summarized above has stimulated in the past few decades quite a large number of studies aimed at the identification of the genes involved in the genetic predisposition to AITD. Earlier studies mostly employed the method of genetic association analysis, using known genetic loci. Several candidate loci have been investigated, mostly genes of thyroid autoantigens and genes involved in the immune response. Since the development of large-scale genome sequencing data obtained through the Human Genome Project, powerful linkage analyses have been applied to the search for AITD genes. Data obtained with this tool are therefore as yet largely unconfirmed but quite promising. Given the relative simplicity of association studies, these have been most often used in order to detect putative inherited risk factors for AITD. Several genetic variations in different loci have been found to be positively associated with AITD. However, only two of those loci have been thus far convincingly confirmed in several studies, the human leukocyte antigen (HLA) gene complex and cytotoxic

T lymphocyte antigen 4 (CTLA-4). The HLA has been extensively studied given its complexity and its relevance to the regulation of the immune system.

The HLA Genes and AITD

The HLA gene complex is located on the short arm of the sixth chromosome (6p21) and encodes a large number of genes mostly (but not only) involved in the regulation of the immune response. A detailed description of the HLA complex is beyond the scope of this article and has been previously published elsewhere. In general, genes within the HLA complex have been subdivided into three classes. Class I includes the HLA class A, B, and C antigens, which are widely expressed on several tissues. Class I genes are mostly involved in direct cytotoxic reactions leading to the killing by the immune system of epithelial cells carrying exogenous antigens, mostly viral in nature. Class II includes the HLA DR, DP, and DQ antigens, mostly expressed on immune cells. These antigens are mostly involved in the presentation of antigen within the immune system. This process is central to the development of the normal immune response and, depending on several factors, it will lead to either the selection and amplification of antigen-specific T and B cells or to the silencing of these cells (tolerance). Class III includes genes coding for complement factors, heat shock proteins, tumor necrosis factor α , and several other proteins not directly involved in the immune response. As such, they truly represent genes that happen to be located within the HLA system. The HLA genes (especially class I and class II) are highly polymorphic and some alleles show striking linkage disequilibrium. Because of its function, the HLA complex has been widely studied in relation to autoimmune diseases. The AITD are no exception. GD was initially shown to be associated with the HLA-B8 allele in several studies involving Caucasian patients with relative risks from 1.5 to 3. However, the HLA-B8 antigen has been subsequently recognized to be in linkage disequilibrium with the class II allele HLA-DR3. Indeed, additional association studies have shown a slightly higher relative risk (2.5–4) when this allele was studied in Caucasian GD patients. It was concluded that the HLA-DR3 allele was more relevant than HLA-B8 in determining the inherited susceptibility to GD. GD has also been found to be associated with (relative risk 3.8) the allele HLA-DQA1*0501, also in linkage disequilibrium with DR3, as well as with the allele DRB1*0301, in linkage disequilibrium with DR3. HT has been occasionally found to be associated with HLA-DR3, HLA-DR4, and HLA-DR5, with similarly low relative risks,

ranging from 2 to 7. It is interesting that different haplotypes of the HLA have been involved, as GD and HT are often found in different members of the same family, portending a common genetic background. In summary, association studies have demonstrated (because of their consistency) a significant role for the HLA system in the genetic susceptibility to the AITD. The HLA gene complex has also been studied in linkage studies, although much less often. In keeping with the low relative risks obtained in association studies, most studies, including a whole genome screen analysis, have shown no evidence in favor of linkage with the HLA. Since one possible explanation for low relative risks in association studies with negative multi-family linkage studies is the presence of genetic heterogeneity, linkage to the HLA was sought in families in which the proband was DR3 positive. Even in this extremely selected subgroup of families, there was no evidence of cosegregation of the disease phenotype with the HLA gene complex. The only positive linkage analysis involved patients with GD and IDDM, a patient population that does not really reflect the common phenotype of AITD. In summary, genes within the HLA complex have been consistently shown to be involved in the genetic predisposition to AITD. However, as exemplified by low relative risks and negative linkage, the HLA complex failed to explain the large hereditary predisposition to the diseases shown by family studies. Indeed, the haplotypes found to be associated with AITD are quite prevalent in the studied control populations, indicating that most of the people who carry those haplotypes do not develop the disease. Conversely, only a fraction of the affected subjects carry the associated alleles. This shows that mutations within the HLA system are not absolutely required or sufficient to cause AITD, representing risk factors with a small overall effect.

CTLA-4 and AITD

The human CTLA-4 gene is located on chromosome 2q33 and its product is a protein belonging to the immunoglobulin gene superfamily. The CTLA-4 protein is expressed on T cells only after antigen or mitogen stimulation. It subsequently interacts with nearby activated T cells carrying a CTLA-4 receptor (B-7) and causes their silencing or death. Therefore, CTLA-4 acts as a key down-regulator of the immune response and represents an excellent candidate for an autoimmunity gene. As a proof of its importance, mice defective in CTLA-4 function (CTLA-4 $^{-/-}$) develop rapidly fatal multiorgan lymphocytic infiltrates, a condition that resembles human autoimmune diseases. CTLA-4 therefore represents an excellent

candidate for a gene predisposing to autoimmunity. Although there are no known variations or polymorphisms within the coding sequence of human CTLA-4, three polymorphic markers within or close to the CTLA-4 gene have been well characterized and used in association studies to test the CTLA-4 gene as a candidate predisposing gene in AITD. The first described allelic system is a typical microsatellite marker, located in the 3'-untranslated region of exon 3 of the gene. One of the alleles of the system (106 bp long) was found more often in GD chromosomes (27%) than in control chromosomes (14%), yielding a relative risk of 2.8. Subsequent studies using this marker have confirmed an association of this particular allele with AITD. Subsequent studies have employed single nucleotide polymorphisms (SNPs), which are less polymorphic and therefore more useful in association studies. Two SNPs within the CTLA-4 gene are known. The first polymorphism is an A-to-G transition at position 49 of the coding sequence, causing a threonine/alanine substitution at codon 17 of the protein. The G allele shows strong linkage disequilibrium with the 106 bp allele of the CTLA-4 microsatellite marker. This means that the two alleles are found associated together on chromosomes at a higher frequency than expected. Indeed, the G allele has been shown to be associated with GD, HT, and even postpartum thyroiditis in a number of studies, with only a few exceptions. Like the microsatellite marker, the G allele yields small relative risks in AITD, in the range of 2 to 4. It is thus far unclear whether the homozygous state confers additional risk, but the available data seem to indicate that the effect is dominant. The G allele is quite prevalent in the general population (in fact, it is the most prevalent allele, with a prevalence of up to 85% among the Japanese), much more frequent than the AITD themselves. It is therefore intuitive to conclude that this polymorphism plays a small, although probably significant role in the genetic predisposition to AITD. Two studies have reported a significant increase in the prevalence of the G allele in GD patients with ophthalmopathy as compared to GD patients without clinically relevant eye disease. However, the only available family-based study indicates that there is no genetic predisposition to Graves' ophthalmopathy existing independently of the general predisposition to GD.

Interestingly, the G allele has been associated with a variety of other autoimmune disorders, raising some questions about the specificity of these findings. The third known polymorphism of the CTLA-4 gene is a C-to-T (C/T) (SNP) transition at position -318 with respect to the start codon of the gene. This

polymorphism does not appear to confer additional risk over that derived from the 49 A/G SNP. The CTLA-4 locus has also been extensively analyzed by linkage analysis. Initial studies employing the CTLA-4 3' microsatellite marker in multiplex families with AITD excluded linkage of the CTLA-4 gene to the full AITD phenotype, i.e., with the clinical diseases. However, when the same data set was analyzed for linkage to the CTLA-4 locus but extending the definition of affected subjects to family members with positive thyroid antibody tests, even in the absence of relevant goiter or thyroid dysfunction, a high likelihood of linkage was observed and the model was consistent with an autosomal-dominant, highly penetrant trait. These results are in keeping with previous results obtained with a different type of linkage analysis, which showed positive linkage of CTLA-4 to GD but did not allow for the distinction between subjects with positive antibody tests and patients with the full-blown disease.

In summary, polymorphisms near the CTLA-4 gene represent a weak but significant risk factor for the development of AITD as shown by association studies. Moreover, evidence from linkage studies suggests that the CTLA-4 region (2q33) contains a major determinant of the genetic susceptibility to the development of thyroid autoantibodies, as a distinct part of the AITD phenotype, and that this major determinant is CTLA-4. However, CTLA-4 alone is not sufficient to explain the whole genetic predisposition to the development of overt AITD. Moreover, it is still unclear how these polymorphisms affect the function of CTLA-4, especially since they are located outside the coding region of the gene and are therefore not expected to cause major changes in its function. Promising but preliminary data from functional studies have shown that lymphocytes from CTLA-4 49 G/G carriers show a lower degree of CTLA-4-dependent T cell inhibition, regardless of the presence of AITD, a finding that provides some indication that this polymorphism may indeed underlie an altered immune system. It is also interesting to note that both of the genes (HLA and CTLA-4) that have been identified as risk factors for AITD participate in the same process, i.e., antigen presentation.

Gene Loci Identified by Whole Genome Screens

The availability of extensive mapping data from the Human Genome Project and of automated sequencing systems has allowed the performance of relatively fast analyses of the whole genome to search for susceptibility genes for common diseases. Some laboratories

Table I Putative Susceptibility Loci and Maximum LOD Scores for the AITD Detected in Linkage Studies and Their Chromosomal Location

| Linked phenotype | Chromosomal location | Name of locus | LOD score | Comments |
|---------------------|----------------------|---------------|-----------|--|
| AITD | 6p | AITD-1 | 2.9 | |
| AITD | 5q31-q33 | — | 3.1 | |
| AITD | 18q21 | IDDM6 | 3.46 | |
| AITD-HT | 8q24 | — | 3.7 | Confirmed in independent studies, contains thyroglobulin |
| GD | 14q31 | GD-1 | 2.5 | |
| GD | 20q11.2 | GD-2 | 3.5 | Confirmed in independent studies |
| GD | Xq21 | GD-3 | 2.5 | |
| GD | Xp11 | — | 2.21 | |
| HT | 13q32 | HT-1 | 2.1 | |
| HT | 12q22 | HT-3 | 1.7 | Statistical evidence of heterogeneity |
| Thyroid antibody GD | 2q33 | TAb-1 | 3.6 | Confirmed in independent studies, contains CTLA-4 |

have addressed the identification of susceptibility genes for the AITD with this powerful tool. Because of the inherent complexity of these studies, results obtained thus far should be considered largely preliminary, at least until mutated genes are isolated from the linked regions and firmly demonstrated to cause the diseases. However, a critical mass of data is rapidly accumulating from different groups of patients and populations and has begun to indicate regions in the genome highly likely to contain susceptibility genes. Table I summarizes putative loci identified thus far.

An initial genome scan performed in a large set of Caucasian families with AITD has shown three putative gene loci for GD, two putative loci for HT, and one common locus for GD and HT. Interestingly, the same genome screen identified the region containing CTLA-4 as being significantly linked to the presence of circulating antibodies, as summarized above. In general, LOD (logarithm of differences) scores of these initially reported loci were relatively low, although statistically significant. Moreover, given the relatively small (56 families) size of the sample, large areas of the genome gave indeterminate results; i.e., linkage could not be proved or disproved, leaving room for more loci to be identified. A subsequent whole genome screen performed in Japanese patients with AITD using sib-pair analysis (which involves some relevant statistical differences from classical linkage analysis as exemplified above by the case of CTLA-4) has shown linkage of AITD to 5q31-q33 and 8q23-q24. The locus on 8q23-q24 has subsequently been confirmed by an extension to 104 families of the first whole genome screen. This

chromosomal location is particularly interesting, since it contains the thyroglobulin gene. Indeed, association studies have shown that at least one allele of a polymorphic marker very close to the thyroglobulin gene is not only linked but also associated with AITD, strongly suggesting that thyroglobulin may represent a susceptibility gene for the AITD.

The susceptibility to AITD is largely genetically determined, although the inheritance pattern is complex, as is the case with most genetically determined, frequent disorders. Researchers have started to unravel the gene variations responsible for the AITD, and in the future, accurate prediction in at-risk individuals will likely be available.

GENETIC FACTORS IN SIMPLE AND MULTINODULAR GOITER

The main etiologic factor in goiter is indisputably iodine deficiency, a worldwide problem that affects almost 1 billion people around the world. In areas with iodine deficiency, the prevalence of goiter in the general population is >10%. Epidemiologists have traditionally distinguished “endemic” goiter, observed in geographic areas of iodine deficiency, from “sporadic” goiter, observed in areas of iodine sufficiency. The accuracy of the distinction is, however, questionable, as the clinical phenotype of the two forms of the disease is indistinguishable, except for areas of extreme iodine deficiency, where large goiters are associated with cretinism and hypothyroidism. In addition to iodine deficiency, other factors are likely involved in the pathogenesis of this common disease. This hypothesis stems from several circumstantial observations. In

areas with iodine deficiency, not all exposed subjects develop goiter. Universal iodine supplementation strikingly reduces but does not abolish the disease and goiter is observed in the absence of iodine deficiency, as mentioned above. Additional environmental factors, such as tobacco smoking, naturally occurring goitrogens, and pharmacologic goitrogens, have been demonstrated. Sex hormones are also likely to be involved as goiter is more prevalent in women living in areas with mild iodine deficiency. The observation of familial clustering of the disease is a daily experience of all endocrinologists, especially in areas with mild or no iodine deficiency, and this has led to the hypothesis that inherited factors coincide in the predisposition to the development of goiter. The familial clustering of the disease has also been reported in several epidemiological surveys, mostly from areas of endemic iodine deficiency. As in the case of the AITD, a number of twin studies have been performed. These have shown that the environmental factors are largely predominant when cases are drawn from endemic regions, as shown by similar concordance rates between dizygotic and monozygotic twins. However, a large, population-based study in twins has shown significantly different and overall higher concordance rates between monozygotic and dizygotic twins (Table II). Interestingly, the intrinsic population prevalence of goiter in this latest study is much lower than in the two older studies, performed in the 1960s in areas of iodine deficiency. One possible explanation for these apparently discrepant data is that once the effect of the major environmental factor (iodine deficiency) is removed from the population, cases with a stronger genetic effect emerge. In this view, the distinction between endemic and sporadic goiter seems to be justified. Despite evidence in favor of relevant genetic influences, these have not been clarified yet. As in many common diseases, there is no identifiable mode of inheritance and multiple, relatively frequent gene variants are likely to play a role. Thus far, only a few studies have addressed this problem on a large scale. Studies in single large kindreds

with highly prevalent and apparently dominant transmission of multinodular goiter have indicated linkage of the phenotype to a locus (termed MNG-1) located on chromosome 14q31. The same studies have ruled out the TSHR (which resides in the same chromosomal region) from the linked region. MNG-1 has been confirmed as a susceptibility locus in at least another large family. Interestingly, MNG-1 overlaps with GD-2, a susceptibility locus for GD. It is therefore possible that the region contains a novel thyroid-specific growth factor and/or antigen. Similarly, a point mutation in exon 10 of the thyroglobulin gene causing a substitution of histidine for glutamine at codon 870 has been described and linked to goiter in three families, in the absence of hypothyroidism. Finally, an Italian family with suggestions of X-linked transmission has been described. Indeed, linkage analysis has shown evidence of linkage of goiter to chromosome Xp22. These findings are encouraging but were obtained in a small subset of families with a seemingly large genetic effect and their epidemiological relevance to goiter found in the general population is unknown. Monogenic disorders of thyroid hormone metabolism represent a rare cause of hereditary goiter, with or without hypothyroidism. These conditions, described in some detail above, are distinct from the commonly encountered sporadic or endemic goiter in that there is usually an earlier appearance of goiter, a more distinct familial pattern (usually autosomal-recessive), and several degrees of thyroid dysfunction. Although it is conceivable that more subtle defects in any of these genes might be involved in the pathogenesis of goiter, extensive screening of the general population for association and/or linkage to known genes is lacking.

In summary, genetic predisposition is probably important in the etiology of simple goiter, both sporadic and endemic. In endemic areas, though, the effect of environmental factors (iodine deficiency) is predominant and widespread, making goiter very prevalent. In contrast, in areas with normal iodine intake, genetic factors are more relevant, but with a smaller

Table II Available Studies in Twins in Populations with Different Prevalences of Goiter

| Year of the study | Geographic location | Concordance rate in monozygotic twins | Concordance rate in dizygotic twins | Population prevalence of goiter |
|-------------------|---------------------|---------------------------------------|-------------------------------------|---------------------------------|
| 1967 | United Kingdom | 24% | 12% | 25.3% |
| 1967 | Greece | 89% | 73% | 53.0% |
| 1999 | Denmark | 42% | 13% | 1.5% |

Note. In populations with a lower prevalence, a higher concordance rate is observed in monozygotic twins when compared with dizygotic twins, suggesting a stronger genetic predisposition.

prevalence. As a consequence, the prevalence of goiter is strikingly reduced and the phenotype more clearly clustered in families. It is likely that multiple different genes are involved in the predisposition to simple goiter, but thus far only a few of these have been identified.

GENETIC FACTORS IN NONMEDULLARY THYROID CANCER

The etiology of thyroid cancer of follicular origin (OMIM 188550) is poorly understood, although several somatic mutations consistently associated with the neoplasm have been described. Exposure to ionizing radiation, especially during childhood, is a well-recognized environmental risk factor, accounting for only a minority of cases. Most other cases appear to be sporadic. In some instances, familial clustering has been observed. Although in many such cases, random occurrence of this relatively common disease in members of the same family can explain the observation, in some extended families, a clear pattern of inheritance has been observed, suggesting the existence of genetic factors. Clinically, familial nonmedullary thyroid cancer (NMTC) has been reported to be more aggressive and more often multifocal than its sporadic counterpart. A few population-based studies have shown an increased risk of NMTC in relatives of probands. For example, the Connecticut Tumor Registry study has demonstrated a fivefold increased risk in relatives of index cases with thyroid cancer. Such studies, however, are subject to several selection biases and may also reflect environmental influences shared by families. It is the opinion of many experts that a genetic predisposition to isolated nonmedullary thyroid cancer exists in only a few families. In two members of the family in which MNG-1 was identified, thyroid cancer was found. It is tempting to speculate that the same gene driving follicular cell hyperplasia in that family may also increase the risk for thyroid malignancy. Moreover, distinct loci have been identified in a few families. In a large multigeneration family with familial NMTC, linkage to a 20 cM segment on chromosome 1q21 was established. In two affected members, papillary renal neoplasms were also observed, suggesting a syndromic effect of the identified locus. In another large kindred with several cases of papillary thyroid cancer only, linkage was suggested with chromosome 2q21. The authors were able to confirm their results in a data set of 80 smaller families with more than one case of NMTC, obtaining significant evidence for linkage at the same locus, although the presence

of benign thyroid disease was included in the analysis. Even stronger evidence was found when the analysis was limited to families with the follicular variant of papillary thyroid cancer. A rare form of thyroid neoplasm, thyroid tumors with oxyphilia, has also been linked to chromosome 19p31. The phenotype in this case is represented by benign or malignant thyroid nodules, with prominent oxyphilia. The same locus (termed TCO1) was found to be linked to papillary thyroid carcinoma in a subsequent study in several families. Several genes are known to reside within that chromosomal location, but none has been found to be mutated in patients with NMTC thus far.

An increased risk of thyroid cancer has also been observed as a component of known hereditary syndromes. Cowden's disease (OMIM 158350) is an autosomal-dominant disease, characterized by multiple hamartomas of the skin, breast, thyroid, brain, and endometrium. Facial trichilemmomas are a distinctive feature of the syndrome. Other findings include craniomegaly, scrotal tongue, and cerebellar neoplasias. There is some overlap with related syndromes such as Lermite-Duclos syndrome and Ruvalcaba's syndrome, so that some investigators believe they are in fact synonyms. A significant increase in the incidence of breast cancer is seen in Cowden's syndrome families. Thyroid cancer, of both the papillary and follicular types, is also highly prevalent, as is benign thyroid nodular disease, although the magnitude of the relative risk is not known. Cowden's syndrome has been mapped to chromosome 10q23.31 and the mutated gene, termed PTEN for phosphatase and TENsin homologue (OMIM 601728), has been isolated. Several mutations of PTEN have been found in families with Cowden's syndrome, without a clear-cut genotype-phenotype relationship. Moreover, in several families with many features of the syndrome, no mutation of the gene has been found, indicating that some degree of heterogeneity exists. Several *in vitro* studies suggest that PTEN acts as a tumor suppressor gene. This observation is in keeping with an autosomal-dominant mode of inheritance and with the observation that most of the mutations identified thus far cause a loss of function. The PTEN protein is expressed in several tissues and is believed to function as a tyrosine phosphatase. As such, the protein is believed to be able to dephosphorylate activated regulator proteins, thus down-regulating proliferation pathways.

An increased risk of NMTC has also been observed in familial adenomatous polyposis (FAP; OMIM 175100), also termed Gardner's syndrome. FAP is inherited in an autosomal-dominant fashion. The most

prominent feature of the syndrome is early-onset colonic cancer and multiple widespread, preneoplastic polyps of the colon. Extracolonic manifestations include congenital hypertrophy of the retinal pigment epithelium in up to 90% of affected persons and has been used as a marker of the disease before genetic testing became available. Other features of the syndrome include benign bone tumors and hepatoblastomas. In women with the syndrome, the risk of papillary thyroid cancer has been estimated to be 160-fold higher than in the general population. Papillary thyroid cancer in the setting of FAP is often detected before age 30, is multifocal, and displays unusual pathological features. The gene responsible for FAP has been mapped to chromosome 5q21 and was designated adenomatous polyposis of the colon (APC). As expected by the autosomal mode of inheritance, APC functions as a tumor suppressor gene and detected mutations associated with the phenotype cause a loss of function of the gene product. The adenomatous polyposis of the colon (APC) gene product (β -catenin) is expressed on the membrane of several epithelial cell types. It has been hypothesized that loss of β -catenin function causes a loss of contact inhibition or a loss of cell adhesion mechanisms, leading to uncontrolled cell growth.

In summary, although the vast majority of cases of NMTC are sporadic, a few cases present in the setting of recognized hereditary syndromes. Knowledge of these clinical conditions is important to the clinician, in order to perform appropriate screening for associated conditions and to provide sound genetic counseling to individuals at risk.

FAMILIAL MEDULLARY THYROID CANCER

Approximately 7% of thyroid cancers originate from the parafollicular cell lineage. These cancers are termed medullary thyroid cancer (MTC) and account for approximately 15% of all thyroid cancer-related deaths. In contrast to NMTC, MTC is quite often familial (in approximately one-fourth of the cases). Familial medullary thyroid cancer (FMTC) arises in the setting of multiple endocrine neoplasia (MEN) type II syndromes or as an isolated disease. In MEN IIA (OMIM 171400), FMTC is associated with pheochromocytomas and parathyroid adenomas, and in MEN IIB (OMIM 162300), patients present a marfanoid habitus, mucosal neuromas, and ganglioneuromatosis, in addition to the above-described features (see Fig. 1). In isolated FMTC (OMIM 155240), there are no

Figure 1 Typical lingual neuromas in a patient with MEN IIB.

extrathyroidal manifestations. The inheritance of these closely related conditions is autosomal-dominant, with high penetrance. In MEN IIA and MEN IIB, MTC is found in almost 100% of carriers by the end of third decade of life if sought by biochemical screening, whereas pheochromocytomas occur in 50% of carriers and parathyroid tumors in 25% of carriers. Despite these clearly distinct phenotypes, all three conditions are due to germ-line mutations in the RET proto-oncogene sequence. The RET proto-oncogene maps to chromosome 10q11.2 and encodes a membrane-bound tyrosine kinase receptor. Causative mutations detected thus far are almost entirely limited to a few cysteine residues located in the putative extracellular domain. It is hypothesized that these mutations induce critical conformational changes in the gene product, causing constitutive activation of the receptor with ongoing production of intracellular proliferative signals. Interestingly, there is quite a strict genotype-phenotype relationship. Mutations involving codons 609, 611, 618, 620, and 634 are found exclusively in families with MEN IIA or with FMTC and mutations involving codons 768, 804, and 891 have been found only in families with FMTC, although even in these families occasional cases of pheochromocytoma and hyperparathyroidism are found. Since the molecular genetics of the two conditions partially overlap, other genes must be involved in determining the phenotype. In contrast, mutations at codon 918 are found in almost all families with MEN IIB. Somatic missense mutations at codon 918 are also found in one-half of cases of sporadic MTC. The RET gene is also mutated in many cases of Hirschsprung's disease, although most mutations detected in this disorder induce the loss of function of the mutant allele. Surprisingly,

Hirschsprung's disease has been found in some families with MEN IIA.

Detailed knowledge of the molecular genetics of these aggressive diseases has greatly enhanced the ability of clinicians to detect persons at high risk for multiple endocrine neoplasias. Genetic testing for RET mutations has become widely available for family members of patients and allows early, preventive treatment, which is expected to greatly increase the life expectancy of patients.

the elderly. Hypercholesterolemia is present in the majority of overt hypothyroid patients. Cardiovascular system abnormalities include cardiomegaly secondary to pericardial effusion, bradycardia, diastolic hypertension, and atherosclerosis. The myopathy of hypothyroidism causes proximal muscle pain and stiffness and weakness. Hypothyroidism also causes sleep apnea. Anemia—microcytic, normocytic, or macrocytic—is a well-characterized hematologic feature of hypothyroidism.

Thyroxine requirements are decreased in the elderly because of a decline in the metabolism of thyroid hormone. In elderly patients with coexisting cardiovascular disease, starting treatment with full replacement doses can result in exacerbation of angina and worsening of underlying heart disease. The starting dose of thyroxine should be small, 12.5–25 µg/day. The dose should be adjusted at 6- to 8-week intervals by an increment of 12.5–25 µg until the patient is euthyroid and the serum TSH is in the mid-normal range. Patients with central hypothyroidism should be monitored by FT₄ measurement and not serum TSH.

Drugs that block thyroxine absorption and increase thyroxine requirements are calcium carbonate, ferrous sulfate, cholestyramine, colestipol, sucralfate, and aluminum hydroxide. Rifampin, carbamazepine, phenytoin, and sertraline (Zoloft) accelerate T₄ clearance and increase the serum TSH level in patients on previously ideal replacement doses. Estrogen may also increase thyroxine requirements.

Subclinical Hypothyroidism

In an English survey, the prevalence of subclinical hypothyroidism was 17.4% in women older than age 75. In a survey in the United States, the prevalence of serum TSH elevation was 8.5% in women and 4.4% in men older than age 55. The causes of subclinical hypothyroidism are the same as those of overt hypothyroidism. Subclinical hypothyroidism increases the risk for myocardial infarction two- or threefold and increases low-density lipoprotein cholesterol significantly when serum TSH is increased threefold above normal. The potential benefits of treating mild thyroid failure include prevention of progression to overt hypothyroidism, reduction of elevated serum cholesterol, and improvement in the quality of life. Replacement therapy is recommended for all patients with serum TSH concentrations greater than twice the upper limit of normal. It is also recommended if there are any clinical features of depression, fatigue, hyperlipidemia, or goiter. The goal of therapy is to normalize the serum TSH concentration. In older

people, 12.5–25 µg of levothyroxine is recommended as the initial dose. With minimal TSH elevation and the absence of clinical features, patients should be followed at intervals of 6 months for worsening of the condition, indicating a need for treatment.

HYPERTHYROIDISM

The prevalence of hyperthyroidism varies from 0.5 to 2.3% in the elderly. Approximately one-sixth of all hyperthyroid patients are older than age 60. Graves' disease is the most common cause of hyperthyroidism in the elderly. TSH receptor antibodies are detectable in approximately 80% of untreated Graves' patients. Toxic multinodular goiter is more common in the elderly and has been reported in almost half of older patients with hyperthyroidism, especially in regions of relative iodine deficiency. Thyrotoxicosis can be precipitated in patients with nontoxic multinodular goiter by administration of a large iodine load such as radiocontrast agent. Some autonomously functioning thyroid adenomas have a mutation in the TSH receptor that results in chronic activation of the follicular cell. Amiodarone may cause destructive thyroiditis and thyrotoxicosis. Hyperthyroidism resulting from a TSH-secreting pituitary adenoma or pituitary resistance to thyroid hormone is very rare.

Elderly patients often lack typical features of hyperthyroidism, including goiter. The absence of the typical hypermetabolic manifestations of hyperthyroidism is termed apathetic hyperthyroidism. The dominant clinical findings may be weight loss, atrial fibrillation, or heart failure.

Serum TSH level is suppressed and FT₄ and FT₃ are elevated in hyperthyroidism. However, the serum T₃ level was found to be increased in only half of hyperthyroid patients between 75 and 95 years of age because of reduced conversion of T₄ to T₃ in peripheral tissues. A thyroid radioiodine uptake is useful to detect the conditions causing thyrotoxicosis with low thyroid uptake: thyroiditis, exogenous intake of thyroid hormone, or iodine-containing drugs.

Radioactive iodine-131 is the most common therapy of Graves' hyperthyroidism and toxic multinodular goiter. The usual doses are 5–15 mCi of ¹³¹I for Graves' disease and 15–50 mCi for large multinodular glands. Beta-adrenergic blockers are used to control symptomatic tachycardia, tremor, anxiety, and muscle weakness, and they are discontinued when the patient is euthyroid. Hypothyroidism is a common consequence after radioiodine treatment, with an eventual incidence of more than 50%.

Definitive therapy with an antithyroid drug, propylthiouracil or methimazole, is appropriate for otherwise healthy elderly patients. The recurrence rate is significantly less with advanced age than in younger patients. Surgical thyroidectomy is only advised if there are obstructive symptoms from a large goiter or the presence of a nodule that is suspicious for malignancy. Although the mortality from subtotal thyroidectomy is very low, the complications of recurrent laryngeal nerve damage and hypoparathyroidism can result in lifelong disability.

Subclinical Hyperthyroidism

Subclinical hyperthyroidism is defined as a state of suppression of serum TSH with normal free thyroxine and triiodothyronine levels in a patient who lacks clinical features of thyrotoxicosis. The causes of subclinical thyrotoxicosis are the same as those of overt thyrotoxicosis. In a study of patients older than 55 years of age, 0.7% had endogenous subclinical hyperthyroidism. Two meta-analyses found a significant loss of bone density in postmenopausal women with suppressed serum TSH. Subclinical hyperthyroidism has been associated with an increased frequency of nervous symptoms and an increased risk of dementia and Alzheimer's disease.

Therapy should be considered for any patient with subclinical hyperthyroidism who has mental symptoms, osteoporosis, atrial fibrillation, or cardiac disease. A trial of antithyroid drugs to normalize the serum TSH level is warranted. In patients with more severe features, such as atrial fibrillation, ablation of the hyperfunctioning thyroid with radioactive iodine is preferable.

Thyroid Nodules

Thyroid nodules, either solitary or multiple, increase in frequency with advancing age. Ninety percent of women older than age 60 and 60% of men older than age 80 have a nodular thyroid gland. Thyroid nodules in asymptomatic individuals (incidentalomas) are identified more frequently by ultrasonography rather than by examination of the gland by palpation.

Most thyroid nodules do not cause symptoms. Pain may occur with a hemorrhage into a preexisting colloid nodule or a benign adenoma. Rapid growth over a period of weeks is suspicious of malignancy, and persistent hoarseness may indicate recurrent laryngeal nerve invasion by tumor. A hard and fixed nodule is more likely to be malignant, but many papillary carcinomas or

follicular tumors are soft or cystic. Lymphadenopathy is strongly suggestive of malignancy.

Low serum TSH concentration in the setting of a nodular goiter suggests the presence of either an autonomously functioning adenoma or a toxic multinodular goiter. Positive anti-peroxidase antibody indicates lymphocytic thyroiditis that may present as a nodule. Thyroid ultrasound is capable of identifying impalpable nodules as small as 2 mm. The clinical significance of small nodules detected by ultrasonography is uncertain. Solitary incidentalomas larger than 1.5 cm should probably be biopsied under ultrasound guidance. Fine-needle aspiration (FNA) biopsy is the most important diagnostic test, with accuracy, sensitivity, and specificity of 98 or 99%. In a large series of FNA biopsy of thyroid nodules, benign cytology was found in 69% (mainly colloid goiter), malignant cytology in 3.5%, and suspicious cytology in 10%. The suspicious category consists of variants of follicular neoplasm, but follicular adenomas are approximately 10-fold more common than follicular carcinomas. In a patient with a follicular nodule, a radioiodine scan may be helpful. "Hot" or functional nodules are rarely malignant. The presence of nuclear atypia in a follicular lesion has a 44% prevalence of malignancy, and the absence of nuclear atypia denotes a benign lesion. Positive immunostaining for galectin-3 correlates with malignancy; immunostaining for galectin-3 and other proteins may improve the differential diagnosis of suspicious lesions.

Treatment of the thyroid nodule depends on the functional state of the nodule and cytologic diagnosis. If the cytology indicates malignancy or is strongly suspicious for malignancy, the nodule should be removed surgically. In the 10% of suspicious cytologic findings, approximately one-fourth of patients who go to surgery are found to have a malignant lesion. Altogether, only 6% of thyroid nodules are malignant. The hyperfunctioning hot nodule is treated with radioiodine ablation or surgery. The vast majority of thyroid nodules are benign and should be managed medically. Medical management with thyroxine suppression therapy is based on the assumption that growth of the nodule depends on TSH. Spontaneous regression of thyroid nodules may occur. Use of suppressive therapy of benign thyroid nodules has been challenged in the past few years due to the failure of some studies to show a significant decrease in nodule size and concern about reducing mineral bone density. However, several studies have shown >50% reduction in nodule size in 40% of patients with a single nodule. Generally, patients are followed by palpation at intervals of 3 months. Ultrasound examination

provides more objective assessment of growth or shrinkage of a nodule.

THYROID CANCER

Thyroid cancer accounts for 1.6% of all new cancers in the United States and causes 0.4% of all cancer deaths. It is classified into five major types: papillary, follicular, medullary, anaplastic, and thyroid lymphoma. Most thyroid cancers are indolent and grow slowly over years, whereas a few grow aggressively and cause death within 1 year. Thyroid carcinomas tend to be more aggressive and poorly differentiated in the elderly compared to younger patients.

Papillary carcinoma accounts for 80% of all thyroid cancers, and follicular carcinoma accounts for 10%. These differentiated cancers are more aggressive in older patients. Hurthle cell carcinoma is considered a variant of follicular thyroid carcinoma and carries an even worse prognosis. Extension of the tumor through the thyroid capsule and into the surrounding structures is associated with poorer prognosis. Cervical lymph node metastases occur in approximately 50% of patients with papillary carcinoma and are associated with only a slightly higher rate of recurrence and mortality.

Surgery, either near total or total thyroidectomy, is the initial treatment of choice for patients with differentiated carcinoma. Near total thyroidectomy is performed for extensive unilateral tumors with local metastases. Total thyroidectomy is performed for patients with extensive multifocal disease with metastases to the cervical lymph nodes, contiguous neck structures, or distant sites. The main disadvantage of total thyroidectomy is the higher incidence of hypoparathyroidism.

Radioiodine therapy is used as an adjunct to surgery to treat patients with residual or recurrent papillary cancer in the neck. Thyroid hormone in a suppressive dose is given after thyroidectomy to reduce the recurrence rate. TSH stimulates growth of thyroid tumors that contain TSH receptors. The dose of thyroxine should be adjusted to keep TSH suppressed without causing clinical thyrotoxicosis. The degree of suppression is based on the staging of the patient. In patients with a good prognosis, TSH should be suppressed to the slightly subnormal range. In patients with worse prognosis, which includes many of the elderly, TSH should be suppressed to <0.05 mU/liter without causing clinical thyrotoxicosis.

Medullary carcinoma accounts for 2–4% of thyroid cancers and is derived from the calcitonin-secreting

parafollicular cells. Elevated serum calcitonin levels establish the diagnosis and correlate with tumor mass. Approximately 80% of medullary carcinomas are sporadic and usually occur after age 50.

Anaplastic carcinoma of the thyroid, the most aggressive and lethal cancer, comprises 2% of all thyroid carcinomas and may be derived from a well-differentiated thyroid carcinoma. Its peak occurrence is in the seventh decade. Treatment includes surgery followed by external radiation and chemotherapy; the survival rate is only 20% at 12 months.

Thyroid lymphoma accounts for approximately 1% of thyroid malignancies and is always accompanied by chronic lymphocytic thyroiditis. The usual clinical presentation is a rapidly enlarging thyroid mass in an older woman with a long history of Hashimoto's thyroiditis. Definitive diagnosis usually requires an open biopsy. Treatment with external radiation and four to six courses of chemotherapy almost always produces a permanent remission.

strongly to the better selection of suspicious thyroid nodules that really need to be assessed by FNA cytology. When FNA is performed, aspirated material is placed onto a glass slide, fixed using standard techniques (95% alcohol, spray fixed or air-dried), and stained using Papanicolaou, hematoxylin and eosin, or May–Grünwald–Giemsa (MGG) staining methods. Cytological preparations fixed in cold acetone for 10 min can be used for a wide variety of immunocytochemical studies.

FNA IN NORMAL THYROID IN METABOLIC DISORDERS AND THYROIDITIS

Normal Thyroid

The thyroid gland is a bilobate structure located in the midportion of the neck, in front to the larynx and trachea. The lobes are connected medially by an isthmus, which lies across the trachea anteriorly below the level of the cricoid cartilage. In approximately 40% of cases, a narrow projection of thyroid tissue, the pyramidal lobe, may be present. This lobe, extending upward from the isthmus and lying on the surface of the thyroid cartilage, represents the vestige of the thyroglossal duct. The normal weight of the thyroid gland in a middle-aged adult is 15–25 g.

Microscopically, the thyroid gland is characterized by a follicular structure. The functional unit of the thyroid gland is the follicle, which is a ring-like structure lined by cubical follicular cells. The lumen of the follicles contains an eosinophilic viscous material known as colloid, in which concentrated thyroglobulin is present. Each follicle is surrounded by a richly vascularized stroma. The diameter of thyroid follicles is approximately 200 μm , but there is considerable variation in size, depending on the functional activity of the gland and age of the patient. Consequently, the height of the follicular epithelium varies from 3 to

20 μm . Flattened follicular cells and larger follicles are visible when the gland is relatively inactive, whereas cubical follicular cells and smaller follicles are generally observed in the functionally active gland. Follicular cubical cells are involved in secretion of colloid into the follicular lumen and may contain apical secretory vacuoles. Follicular columnar cells resorb thyroglobulin-rich colloid and excrete active thyroid hormones into blood vessels. In this case, basal vacuoles can be observed. The parafollicular cells (also called C cells) differ from thyrocytes in their morphology, function, and location. They are larger, triangle-shaped cells with clear cytoplasm and secrete calcitonin.

Parafollicular C cells are located along the central axes of the upper two-thirds of each lateral lobe and comprise less than 0.1% of the total thyroid cellular mass. The cytologic appearance of normal thyroid is variable, depending on the functional state of the gland and the age of the patient. Aspirated material typically consists of follicular cells generally associated with scant colloid. Sometimes, thyrocytes are dispersed or arranged in small clusters. Well-constituted follicular structures are rarely observed. Normal thyrocytes show a pale cytoplasm, a centrally located oval or round nucleus containing fine granular chromatin, and one or two small nucleoli. Colloid appears as proteinaceous material, which can be stained from gray-green to pink using the Papanicolaou method, red-violet using the MGG method, and pink using conventional hematoxylin and eosin staining.

Metabolic Disorders

Amyloidosis

Extracellular amyloid deposit in the thyroid gland can be detected in the majority of cases of secondary amyloidosis as a localized form of disease or as part of a systemic disease. Cytological material obtained by FNA may contain scattered normal thyrocytes and fragments of cyanophilic amyloid, which can be stained with Congo red and visualized by using a polarized-light microscope.

Hemochromatosis

In this pathological condition, thyroid can be involved by massive iron overload, which confers a brown color to the gland. The cytoplasm of follicular cells, as well as macrophages and fibroblasts, show intense deposit of hemosiderin. This yellowish-brown pigment can be stained blue by the Perls staining method. Focal iron deposits, which should not be confused with hemochromatosis, can be detected in areas of

hemorrhage that are commonly present in large adenomas, carcinomas, and nodular goiters, particularly after a previous thyroid FNA evaluation.

Thyroiditis

This inflammatory condition of the thyroid is common in clinical practice. Three different types of thyroiditis may be distinguished: acute, subacute, and chronic. However, the nosological spectrum of thyroiditis is much more complex if autoimmune thyroid disorders are included. For the latter, there is no internationally accepted classification. The cytological features of the most common thyroiditis are described here.

Acute Thyroiditis

Acute (suppurative) thyroiditis is rare. The pathogenesis is infectious; bacteria (gram-positive cocci) are the most common agents involved, but fungus- (*Candida*, *Aspergillus*, and *Cryptococcus*), virus- (*Cytomegalovirus*), and protozoa (*Pneumocystis carinii*)-induced acute thyroiditis have been also observed in immunosuppressed hosts.

In acute suppurative thyroiditis, cytological material obtained by FNA contains normal follicular cells, sometimes with degenerative changes, abundant neutrophils, and macrophages. In the background, cellular debris and fibrin are observed.

Subacute Thyroiditis

Subacute granulomatous or de Quervain's thyroiditis is a nonspecific, self-limited inflammatory condition of the thyroid that is thought to be of viral origin. It may account for 5% of thyroid abnormalities. This form of thyroiditis occurs mostly in middle-aged woman, who present with painful swelling of the gland and fever, generally associated with hyperthyroidism-related symptoms. Subacute thyroiditis commonly resolves spontaneously in 2 or 3 months. A typical cytological feature at the onset of de Quervain's thyroiditis is the presence of multinucleated giant cells, grouped in granuloma-like arrangement. Degenerated thyrocytes, epithelioid cells, lymphocytes, and granulocytes on a background containing cellular debris and colloid complete the cytological picture.

Chronic Thyroiditis

This term includes a heterogeneous group of lesions showing histological as well as pathophysiological differences: tuberculosis (TBC)-related granulomatous thyroiditis and other chronic granulomatous thyroiditis; Riedel's thyroiditis; focal lymphocytic thyroiditis; and chronic autoimmune thyroiditis, including Hashimoto's thyroiditis and its related entities,

Figure 2 Chronic granulomatous thyroiditis after thyroid surgery. A multinucleated giant cell (foreign body giant cell) in granuloma-like arrangement, scattered normal follicular cells, mature lymphocytes, epithelioid histiocytes, and blood cells are visible (Papanicolaou staining; $\times 250$). Kindly provided by M. R. Giovagnoli, Sant' Andrea Hospital, Rome, Italy.

Graves' disease, and other autoimmune thyroid disorders.

TBC-related chronic granulomatous thyroiditis is caused by mycobacterium tuberculosis and can be diagnosed during the course of secondary tuberculosis. On FNA, specific epithelioid granulomas with caseification are present. Different types of granulomas can be observed in other chronic thyroid diseases as well as in de Quervain's thyroiditis, sarcoidosis, mycosis, vasculitis, syphilis, and after thyroid surgery. In the latter, foreign body giant cells are commonly observed (Fig. 2).

Riedel's thyroiditis is a chronic fibrosing multifocal inflammation involving thyroid as well as extrathyroid structures. The thyroid shows a diffuse fibrosis with petrous consistence. Follicular structures are replaced by sclerosis; consequently, FNA material is very poor in follicular cells, whereas inflammatory cells and fibroblasts are prevalent. This condition needs to be distinguished from other fibrosing thyroid lesions (i.e., the late stage of Hashimoto's disease, malignant fibrous tumors, scleroderma, postradiation thyroid fibrosis, and posttraumatic fibrosis).

Focal lymphocytic thyroiditis may be associated with several thyroid (i.e., nodular goiter and papillary carcinomas) and not thyroid diseases. Histologically, thyroid gland shows focal areas of inflammatory cells, represented mostly by mature lymphocytes. FNA is usually not diagnostic; scattered lymphocytes and typical follicular cells may be observed.

Manifestations of autoimmune thyroiditis encompass a wide spectrum of functional abnormalities and morphological changes of the gland. Although some

clinical and histological features may be considered specific for certain autoimmune thyroid diseases, at least three anatomoclinical entities probably represent different stages of the same disease. Patients with chronic autoimmune thyroiditis present with hypothyroidism, goiter, or both. The hallmark of autoimmune thyroid diseases is the presence of anti-thyroid peroxidase antibodies and anti-thyroglobulin antibodies. In most cases, the presence of such autoantibodies precedes the clinical onset of the disease. General diagnostic criteria for autoimmune thyroiditis include a positive test for circulating thyroid autoantibodies, elevated serum concentration of thyrotropin (TSH), and the presence of lymphocytic infiltration of the thyroid gland.

In patients affected by autoimmune thyroiditis, FNA should be carefully evaluated and mostly directed at analyzing clinically suspicious nodules or rapidly enlarging goiters. In fact, during autoimmune thyroiditis, follicular cells may show oxyphilic changes and cytological atypia, which may be easily misinterpreted as malignancy, leading to unnecessary surgery. Cytological features of the various manifestations of autoimmune thyroid diseases are described in detail next.

Hashimoto's thyroiditis was first described by Hashimoto in 1912, who reported four patients with goiter histologically characterized by diffuse lymphocytic infiltration, atrophy of follicles, fibrosis, and eosinophilic changes (oxyphilic-metaplasia) in groups of follicular cells, also called Hürthle cells or oncocytes. This disease affects women more frequently than man, and it may be associated with hypothyroidism, euthyroidism, or, occasionally, hyperthyroidism. Hashimoto's thyroiditis is considered the most common form of noniatrogenic hypothyroidism.

In its classical presentation, hypertrophic lymphocytic thyroiditis, the thyroid gland may show a hypofunctional goiter. Histologically, thyroid follicles are small and atrophic and contain scant colloid. Frequently, oxyphilic cells are present. These cells have abundant eosinophilic and granular cytoplasm, due to the presence of a large number of mitochondria, and pleomorphic nuclei (Fig. 3A). Hyperplastic solid areas of oncocyte cells may be present. An intense infiltration of lymphoplasmocytic cells, sometimes organized in germinal centers, regenerative follicles, and interstitial fibrosis, complete the histological picture.

Cytological smears obtained by FNA commonly consist of a large number of mature lymphocytes and plasma cells but also centrofollicular lymphoid cells. Of course, this lymphoid infiltrate is not specific for Hashimoto's thyroiditis, but when it surrounds small

Figure 3 Hashimoto's thyroiditis. (A) Groups of oncocytes showing fine granular cytoplasm and mild pleomorphic nuclei. (B) Incipient Hashimoto's thyroiditis, in which mature lymphocytes and plasmacytes surround a small cluster of normal follicular cells, showing slight pleomorphic nuclei. (Papanicolaou staining; A, $\times 1000$; B, $\times 250$). Kindly provided by M. R. Giovagnoli, Sant' Andrea Hospital, Rome, Italy.

clusters of follicular and oncocyte cells, showing pleomorphic nuclei, it is quite suggestive for this disease. Fibrosis and the destruction of follicular cells are of variable intensity and evolution. Some Hashimoto's goiters become atrophic over years.

The so-called juvenile lymphocytic thyroiditis (adolescents' goiter) is viewed as the incipient stage of Hashimoto's thyroiditis. This diffuse goiter is difficult to distinguish from euthyroid sporadic goiter. Lymphoid cell infiltration is mild, oncocyte changes are focal or absent, and thyroid autoantibodies are not constant. Consequently, FNA will show normal lymphoid cells and a variable amount of thyrocytes. Scattered Hürthle cells may be observed sporadically (Fig. 3B).

Fibrous lymphocytic thyroiditis generally represents the final stage of Hashimoto's thyroiditis and is observed at an older age. The goiter is mild and associated with severe hypothyroidism. Histologically, the thyroid shows severe fibrosis, marked follicular

atrophy, oncocytic and squamous metaplasia, and lymphocytic infiltration. FNA yields little material consisting of fibroblasts, follicular cells, oncocytic cells, and lymphocytes.

Although the aforementioned cytological features may be variably observed in all different forms of Hashimoto's thyroiditis, clinical and laboratory evaluations will support the cytological diagnosis.

Sometimes, Hashimoto's thyroiditis may present as a palpable thyroid nodule, which can result from hyperplasia of follicular and/or oncocytic cells, heavy focal lymphoid infiltrate, the presence of fibrosis, or the development of cancer. It is noteworthy that association with a true thyroid carcinoma or lymphoma has been reported in approximately 20% of cases of Hashimoto's thyroiditis. This possibility should be always considered during the evaluation of FNA. An accurate evaluation of thyroid FNA cytology is very important to avoid unnecessary surgical procedures. In fact, because nuclear pleomorphism is easily observed in thyrocytes and/or oncocytic cells derived from this inflammatory condition, a misdiagnosis of thyroid cancer is not rare. Moreover, in the course of hypertrophic lymphocytic thyroiditis, in which lymphoid infiltrate is the main feature and follicular cells are scantily represented, FNA cytology may simulate a malignant lymphoma.

Graves' disease should not be considered an autoimmune thyroiditis. Diffuse symmetrical goiter, hyperthyroidism, and exophthalmos characterize this disorder. Graves's disease is not an all-thyroid disease since it also involves the musculoconjunctival retrobulbar orbital content and the subcutaneous tissue in the anteroexternal part of the legs, foot dorsum, and first metacarpal area (pretibial myxedema and hand acropachy). Thyroid hyperfunction is mediated by stimulating anti-TSH receptor antibodies. Histologically, follicles are lined by columnar or cubical thyrocytes showing numerous resorption vacuoles. Lymphoid infiltrate is occasionally seen.

For this pathological condition, FNA does not represent a useful diagnostic procedure because diagnosis is generally obtained on clinical bases. Cytological smears by FNA show typical follicular cells and scant colloid. The cytoplasm is pale and finely granular, and marginal vacuoles are frequently observed. When MGG staining is used, these vacuoles show pink, granular material (flame cells). These cytological features should be not considered specific for Graves' disease; they are common findings in all hyperfunctional thyroid conditions.

The spectrum of autoimmune thyroid diseases also includes radiation-induced thyroiditis, postpartum

thyroiditis, autoimmune polyendocrine syndromes involving the thyroid gland, and iatrogenic autoimmune thyroiditis. For all these conditions, thyroid FNA cytology is not useful for the clinical diagnosis.

FNA IN BENIGN AND MALIGNANT FOLLICULAR LESIONS

Hyperplasia is the most common thyroid disease, and it can be considered a compensatory response of the thyroid gland to thyroxin deficit. Different types of hyperplastic lesions can be distinguished. One type is diffuse colloid hyperplasia, in which proliferating follicular cells surround small or medium-sized follicles filled with little colloid. When thyrocytes cease to proliferate, an increased amount of colloid may be detected within follicles, which become larger. The thyroid gland is uniformly enlarged, and cytological smears obtained by FNA show typical follicular cells and abundant colloid.

Nodular hyperplasia is a common condition in which poorly delimited nodules of different sizes enlarge the thyroid gland asymmetrically. Hyperplastic nodule can be solitary, but the most frequent clinical picture is the so-called multinodular goiter. This condition is very common in iodine-deficient areas. Histologically, different types of hyperplastic nodules can be considered: colloid or hypocellular nodules, adenomatoid or hypercellular nodules, and papillary nodules. In hypocellular nodules, follicles are large and thyrocytes cubical or flat. FNA will provide abundant colloid, sparse follicular cells sometime arranged into follicles or monolayers (Fig. 4), scattered lymphocytes, and blood cells. When colloid is dense, typical cracked aspects can be appreciated after conventional staining. (Fig. 4C). Follicular cells show pale cytoplasm, homogeneous nuclei, uniformly distributed fine chromatin, and inconspicuous nucleoli. Isolated cells may look like lymphocytes due to their cytoplasm fragility.

In adenomatoid nodules, a large number of small follicles lined with cylindrical cells are present. In this case, FNA-cytology shows scanty colloid and a large number of follicular cells often arranged in monolayers and small follicles. Thyrocytes show abundant cytoplasm and small variation in nuclear size. Nuclear pleomorphism and prominent nucleoli may be observed in older patients and in patients treated with antithyroid drugs. In adenomatoid nodules associated with hyperthyroidism, cytoplasmic vacuoles may be observed.

Adenomatoid nodular hyperplasia, follicular adenoma, and well-differentiated follicular carcinoma represent the "gray lesions" of thyroid FNA cytology.

Figure 4 Nodular hyperplasia. (A) Colloid nodular hyperplasia showing a monolayer of normal and uniform follicular cells in a background of thin colloid. Scattered lymphocyte-like nuclei of isolate thyrocytes are visible. (B) Nodular hyperplasia showing numerous typical follicular cells, both isolate or forming small follicles. Nuclei are small and chromatin is finely distributed. Colloid is not present. (C) In nodular colloid goiter, abundant and dense colloid shows a cracked effect in conventional cytological preparations (Papanicolaou staining; A and C, $\times 100$; B, $\times 250$). Kindly provided by A. Vecchione, University La Sapienza, Rome, Italy.

In fact, no definitive and reliable cytomorphological criteria exist for discriminating among these entities.

In nodules with papillary hyperplasia, papillary structures (tufts) are observed histologically and normal thyrocytes arranged in papillary pattern may

be visible in cytological smears. This condition must be differentiated from papillary carcinomas. Occasionally, nuclear grooving and intranuclear cytoplasmic inclusions, which are considered cytological features of papillary carcinomas, may be observed in cellular smears from nodular goiters.

Dysormonogenic nodular hyperplasia is a congenital condition caused by a defect in the biosynthesis of thyroid hormones. A thyroid goiter develops in the first months of life. FNA shows scant colloid, a large number of follicular cells arranged in groups, and marked anisokaryosis. Preoperative cytological diagnosis of this condition is impossible without clinical information. This cytological picture can be easily misinterpreted as follicular neoplasm or as a poorly differentiated carcinoma.

In general, all the aforementioned hyperplastic conditions may be associated with regressive phenomena, ischemic necrosis, giant multinucleated cells, foamy macrophages, inflammatory cells, fibrosis, calcification, and even ossification. Hyperplastic nodules associated with single or multiple cystic spaces (colloid cysts) are a common finding.

Aspirates from colloid cysts yield a variable amount of liquid, which may be dark brown and dense (chocolate cyst), hemorrhagic, or yellow. Cytological smears may contain sparse follicular cells showing degenerative changes and a large number of foamy macrophages (Fig. 5).

The preoperative diagnosis of follicular neoplasms represents the “gray zone” in thyroid FNA cytology. In fact, distinction between hyperplastic/adenomatous nodules, well-differentiated follicular carcinomas, and follicular variants of papillary carcinoma is difficult

Figure 5 Cystic nodule. FNA material shows scattered follicular cells with degenerative changes (vacuolated cytoplasm) and foamy macrophages. Numerous red blood cells are present in the background (Papanicolaou staining; $\times 400$).

using this method, even in the hands of cytologists with extensive experience. Because of the specific criteria required for the diagnosis of follicular carcinoma, particularly the unequivocal demonstration of capsular penetration and vascular invasion, well-differentiated follicular malignancies are also sometimes difficult to distinguish from adenomas histologically. For this reason, when thyroid FNA is performed on follicular lesions, the diagnostic report is never definitive and is commonly worded "follicular nodule not otherwise specified." As a consequence, the majority of these lesions are referred to surgery more for diagnosis rather than for therapeutic necessity. The social cost of this clinical approach to the preoperative characterization of thyroid nodules is quite high for patients as well as for the health care system, considering that less than 10% of the resected lesions will be definitively classified as carcinomas. Attempts to improve the diagnostic accuracy of FNA cytology for follicular thyroid nodules, following strict instructions for obtaining adequate specimens or including clinical parameters (i.e., gender, dimension of the nodule, and character of the gland by palpation), have been made, but no clinical, radiological, or laboratory tests have been demonstrated to be sensitive and specific enough to reliably distinguish whether a follicular lesion identified by FNA is benign or malignant. The possibility of improving the diagnostic accuracy of thyroid FNA cytology using immunocytochemical detection of tumor-associated antigens is discussed later.

Among follicular adenomas, different histological types are recognized: normofollicular, macrofollicular (or colloid), microfollicular (or fetal), solid-trabecular (or embryonic), hyalinizing trabecular, atypical, oncocyctic (or Hürthle cell adenoma), and other rare variants. Histologically, these lesions are clearly encapsulated, and the adjacent thyroid parenchyma is compressed.

Follicular carcinoma represents 12–15% of thyroid carcinomas in the general population; however, in areas of endemic goiter and iodine deficiency, this type of thyroid cancer is much more frequent. Two histological types of follicular carcinoma are recognized: a microinvasive form, in which a minimal capsular invasion can be observed on histological bases, and a widely invasive form, showing prominent capsular and/or vascular invasion. These tumors may have normo-, micro-, or macrofollicular or trabecular morphology.

As discussed previously, there are no distinctive cytological features that can be used for a reliable distinction between benign and malignant follicular lesions. FNA cytology from normo- and macrofollicular

adenomas is also undistinguishable from that of the aforementioned hyperplastic nodule. When normo- and microfollicular adenomas are evaluated by FNA, overlapping cytological characteristics as those for well-differentiated follicular carcinomas are the rule.

In general, the presence of large pools of colloid in cytological smears may be suggestive of benign follicular proliferation; in fact, follicular carcinomas are generally associated with the presence of scanty colloid. However, normo- and macrofollicular carcinomas in which follicular cells are arranged in large follicles filled with abundant colloid have been reported. In thyroid follicular malignancies, both cellular characteristics and nuclear features are not diagnostic.

In fact, bizarre follicular cells with marked cytological atypia and anisokaryotic nuclei may be observed in FNA from the so-called atypical adenomas. Although the presence of prominent nucleoli is strongly suggestive of carcinoma, their absence does not rule out a thyroid malignancy. Therefore, distinction between benign follicular lesions and well-differentiated follicular carcinoma cannot be supported by specific and exclusive cytomorphological criteria (Fig. 6).

Thus, for the reasons mentioned previously, FNA cytology of follicular thyroid nodules cannot be considered a reliable diagnostic procedure. The use of monoclonal antibodies specific for tumor-associated molecules has consistently improved FNA performance.

Oncocyctic cells (also called Hürthle cells, oxyphil cells, or Askanazy cells) derive from metaplastic changes of follicular cells. These cells can be observed in association with several types of thyroid disease, including Hashimoto's thyroiditis, hyperplastic goiters, adenomas, and carcinomas. However, adenomas and carcinomas may arise from oncocyctic cells, showing histological features of follicular (Fig. 6B) or papillary neoplasms (Fig. 7C). Cytological smears obtained by FNA usually show a rich population of oncocyctic cells with little or no colloid. These cells show little cohesiveness; they can be dispersed or form small clusters. Oncocyctic cells show a fine granular eosinophilic cytoplasm with well-defined contour and large, eccentric, and slightly pleomorphic nuclei. As mentioned for the other follicular neoplasms, also for the oncocyctic follicular lesions FNA cytology has a limited ability to distinguish between adenoma and follicular carcinoma.

A high percentage of oncocyctic cells, a monomorphic aspect of the smear with small nuclear

Figure 6 (A) In this not otherwise specified follicular lesion, thyrocytes are both dispersed and organized in small follicular structures. Their cytoplasm is pale with poorly defined limits. Nuclei are round and uniform, and chromatin appears fine granular and uniformly dispersed. Some inconspicuous nucleoli are visible. (B) In this oncocyctic follicular lesion, oxyphilic cells with granular eosinophilic cytoplasm, hyperchromatic, and eccentric nuclei are arrayed in microfollicular structures. No reliable cytological criteria of malignancy can be defined (Papanicolaou staining; $\times 250$). Kindly provided by M. R. Giovagnoli, Sant' Andrea Hospital, Rome, Italy.

pleomorphism, and the absence of lymphocytic infiltrate with stromal and cellular debris help to differentiate oncocyctic neoplasms from thyroid lesions containing nonneoplastic oncocyctic cells (i.e., in Hashimoto's thyroiditis). Ischemic necrosis is a common finding in oncocyctic tumors after FNA biopsy.

FNA IN OTHER THYROID MALIGNANCIES

Papillary Carcinoma

Papillary carcinoma is the most common type of thyroid cancer, accounting for 65–80% of thyroid cancers in the United States. This malignancy is generally diagnosed in young females, and in most cases a clear association with radiation exposure can be

Figure 7 Papillary carcinoma. (A) Numerous neoplastic cells arranged in micropapillary structures. Cells show irregular nuclei and enlarged cytoplasm. Cytoplasmic nuclear inclusions and grooves are visible in some cells. (B) In this papillary carcinoma, nuclear inclusions are easily identified. (C) Papillary Hürthle cell carcinoma composed by large polygonal cells with granular cytoplasm and well-defined contours. Nuclei are slightly eccentric and polymorphic and show fine granular chromatin. Nucleoli are visible in some cells (Papanicolaou staining; $\times 400$). Kindly provided by M. R. Giovagnoli, Sant' Andrea Hospital, Rome, Italy.

demonstrated. Histologically, the two morphological hallmarks of papillary carcinomas are the presence of papillae and nuclear changes. Papillae consist of a central fibrovascular stalk lined by neoplastic epithelium formed by cubical, columnar, or tall follicular cells. These structures may show a complex branching

configuration. Psammoma bodies are frequently associated with thyroid papillary carcinomas. These round, calcific concretions exhibit concentric laminations and probably derive from necrotic tumor cells on which successive layers of calcium salt have been deposited. Abundant fibrous stroma and inflammatory infiltration are also common features of papillary carcinoma. The nuclei of the papillary carcinoma cells exhibit characteristic changes, which represent very useful diagnostic markers. These nuclear changes are ground glass appearance, presence of pseudoinclusions, and presence of irregular outlines and grooves. Both papillae and nuclear changes are easily visible on histology in the classical forms of papillary carcinomas.

FNA from papillary carcinomas yield highly cellular smears. Colloid is generally scant or absent, but if present it is very dense and shows the so-called "bubble gum" appearance.

Papillary structures or small clusters of neoplastic cells arranged in micropapillae may be observed together with monolayers and dispersed thyrocytes. Follicular structures are occasionally seen, and they are frequently observed in the follicular variant of papillary carcinoma. Papillary carcinoma cells can be cubical, columnar, or pleomorphic. They have abundant cytoplasm and occasionally may show oncocyctic changes. The nuclei are round, oval, and polymorphic and contain finely granular chromatin and inconspicuous nucleoli. The aforementioned nuclear changes are generally visible on the majority of cytological preparations, with the exception of nuclear clearing with ground glass appearance (called orphan Annie's eyes). This effect, which represents an artifact of fixation and embedding, is only visible in fixed and paraffin-embedded tissues. Although these features can be considered diagnostic when observed in the presence of well-defined papillary structures (Fig. 7), they are neither constant nor specific. In fact, nuclear changes can be observed in other primary thyroid malignancies, in metastatic tumors, and, unfortunately, also in nonneoplastic thyroid lesions (i.e., in Hashimoto's thyroiditis).

Several histological variants of papillary carcinoma have been described. Papillary microcarcinoma is an occasional finding during postsurgical examination of the thyroid as well as during autopsy. This malignancy is less than 1 cm, but it can be discovered as a cervical lymph node metastasis. FNA evaluation of the primary tumor is generally uncommon.

The follicular variant of papillary carcinoma shows an exclusively or almost exclusively follicular pattern of growth. As discussed before, for follicular thyroid lesions, FNA interpretation is very difficult. In fact, the follicular variant may be easily confused

with nodular hyperplasia, follicular adenoma, and well-differentiated follicular carcinoma.

Cystic papillary carcinoma is a cystic neoplasm that should always be considered when FNA from large cystic lesions identifies a fluid unusually rich in follicular cells or when the lesion is still palpable after FNA drainage of the thyroid cyst.

Diffuse sclerosing papillary carcinoma represents a papillary malignancy in which a strong desmoplastic reaction of the stroma is present. In this lesion, marked inflammatory infiltration and squamous metaplasia are common findings.

The tall-cell variant of papillary carcinoma is characterized by cylindrical cells with cyanophilic and eosinophilic cytoplasm and a high nucleus:cytoplasm ratio. Papillary structures are visible and are lined by pseudostratified columnar cells. Nuclear incisions are rare and pseudoinclusions are not present. As previously discussed, papillary carcinoma may show oncocyctic changes. When this aspect is prevalent, the occurrence of a papillary oncocyctic tumor should be considered. In this case, papillary structures are lined with neoplastic oncocyctic cells, granular eosinophilic cytoplasm, and pleomorphic and eccentric nuclei (Fig. 7C).

Poorly Differentiated (Insular) Carcinomas

This histological type of thyroid carcinoma arises from follicular cells, but some authors consider it to be the undifferentiated solid form of both papillary and follicular carcinoma. In fact, insular carcinomas with aspects of transition toward a papillary or follicular cancer are sometimes observed on histology, suggesting the possibility that these malignancies may represent a continuous spectrum of the same disease. Interestingly, insular carcinoma, although common in central Europe, is very rare in the United States.

Histologically, poorly differentiated thyroid carcinomas are characterized by solid nests of neoplastic cells of variable size, which are surrounded by thin stromal septa. FNA from these lesions shows a large number of malignant cells organized in large, medium, and small clusters or trabeculae. Dispersed elements are also present, and loss of cellular cohesion is evident. Neoplastic cells contain enlarged round nuclei with granular chromatin and prominent nucleoli. Sometimes, microfollicular structures may be observed. The cytological background presents cellular debris, necrosis, and no colloid. Nuclear changes similar to those observed in papillary carcinomas may occasionally be seen.

Anaplastic Carcinoma

This tumor represents less than 10% of all thyroid cancers. It is a very aggressive malignancy composed by undifferentiated cells. Anaplastic carcinoma is generally observed in older patients and can be considered exceptional in patients younger than age 50.

This tumor grows fast and produces a rapid thyroid enlargement with compression of adjacent anatomic structures. Histologically, squamous-epithelioid, fusiform, and giant neoplastic cells can predominate or be observed in different proportions. Extensive necrotic areas are frequently seen. The hallmarks of this tumor are nuclear pleomorphism, frequent atypical mitoses, necrosis, and vascular invasion. Differential diagnosis with the rare primitive thyroid sarcoma may be necessary in some instances. FNA cytology is variable, depending in the predominant cell type. However, pleomorphic and polymetric neoplastic cells are easily recognized in a dirty background in which cellular debris, necrotic material, and blood cells are present. Irregular nuclei and prominent nucleoli are common findings (Fig. 8).

Medullary Carcinoma

This malignancy, which constitutes approximately 12% of all thyroid cancers, does not derive from follicular epithelium but from calcitonin-producing cells (parafollicular C cells). It can occur sporadically or as a familial disease, often in association with other endocrine neoplasms (MEN syndrome). The presence of medullary carcinoma is almost invariably associated with a high serum level of calcitonin. This

Figure 8 Anaplastic carcinoma. Neoplastic cells show enlarged polymorphic and polymetric nuclei. An inflammatory component rich in neutrophils and neutrophilic cannibalism are visible (Papanicolaou staining; $\times 1000$).

serological parameter is a useful indicator of disease. Histologically, medullary carcinoma shows polymorphic and polymetric cells with uniform round or oval nuclei and granular amphophilic or eosinophilic cytoplasm, which are arranged in nests and cords. Connective tissue that surrounds the neoplastic cell nests is generally rich in amyloid. These neoplasms are not capsulated and may be multifocal. Cellular smears obtained by FNA contain isolated and loosely cohesive neoplastic cells, which are highly variable in size and shape. They include round, plasmacytoid (with eccentric nucleus), fusiform, epithelioid, and sometimes multinucleated and binucleated cells. In some cases, nuclear inclusions may be observed. If present, amyloid appears as amorphous material, which specifically stains with Congo red and can be visualized under a polarized light microscope. Differential diagnosis with anaplastic carcinomas and oncocytic neoplasms can be difficult. However, the presence of isolated polymorphic cells, plasmacytic-like cells, and a high calcitonin serum level are diagnostic for medullary carcinoma.

Calcitonin-producing neoplastic cells can be visualized by using immunocytochemical techniques and specific monoclonal antibodies to calcitonin.

Lymphoma

Primary lymphoma of the thyroid gland is rare, but approximately 15% of patients with systemic lymphoma present secondary thyroid involvement. When lymphoma is present, a monomorphic population of lymphoid cells with sparse typical follicular cells can be obtained by FNA. Differential diagnosis with thyroiditis (particularly Hashimoto's thyroiditis) should always be considered. Immunocytochemical demonstration of a monoclonal lymphocyte population using specific monoclonal antibodies to differentiate clusters of lymphocyte antigens will confirm the diagnosis.

Metastasis to the Thyroid Gland

Several malignancies can produce thyroid metastasis by contiguous invasion of primary tumors (e.g., larynx and pharynx) or after hematogenous dissemination of other malignant tumors (e.g., melanoma, lymphoma, and carcinomas from lung, breast, kidney, colon, etc.). In all these cases, FNA cytology will show variable populations of neoplastic cells mixed with normal thyrocytes. The clinical history is helpful for formulating a correct diagnosis.

ANCILLARY TECHNIQUES FOR IMPROVING THE DIAGNOSTIC ACCURACY OF THYROID FNA CYTOLOGY

Ultrasound evaluation of the thyroid gland is an important diagnostic tool with which FNA cytology should always be integrated. The ability to predict malignancy of nonfollicular neoplasms has been demonstrated by using a multiple logistic regression analysis based on five echographic features: margin, shape, echo structure, echogenicity, and the presence of calcification. Interestingly, in a preliminary study in which an ultrasonographic contrast agent called Levovist was used, it was possible to distinguish carcinomas from benign nodules by comparing the times of appearance of the contrast.

The use of specific monoclonal antibodies (mAbs) directed to tumor-associated antigens has contributed greatly to the improvement in diagnostic accuracy of conventional cytology for several neoplastic diseases. Interestingly, Galectin-3, a β -galactosyl-binding protein normally expressed in macrophages, is detectable in follicular thyroid cells only after malignant transformation. Using a specific mAb to galectin-3, it is possible to distinguish between benign (galectin-3-negative) and malignant (galectin-3-positive) thyroid nodules. This immunocytochemical approach to the preoperative evaluation of thyroid nodules has been recently validated in a large international, multicenter study. Sensitivity and specificity of immunodetection of galectin-3 in discriminating between benign and malignant thyroid lesions are 99 and 98%, respectively, and the positive predictive value and diagnostic accuracy are 92 and 99%, respectively. The integration of galectin-3 immunostaining with conventional cytomorphological and clinical diagnostic procedures represents a sensitive and reliable diagnostic approach for the preoperative identification of thyroid carcinomas. This method improves the diagnostic accuracy of conventional cytology, particularly for distinguishing between benign and malignant follicular lesions.

HBME-1 identifies a monoclonal antibody (mAb) directed to a biochemically unknown epitope expressed in mesothelioma and in several adenocarcinomas. Although this reagent seems to be focally reactive with some hyperplastic thyroid lesions also, it is commonly used in clinical practice as a diagnostic tool for thyroid cancer detection.

Molecular and immunochemical approaches directed to identify specific gene profiles and related

proteins in thyroid malignancies have been extensively reported in the recent literature. Several experimental data, mostly arising from molecular analysis of papillary thyroid carcinomas, show a clear pattern of over-expressed genes associated with this malignancy. Among these genes, GALS3L (galectin-3), FN1 (fibronectin-1), KRT19 (keratin 19), and MET gene (c-met related protein) have been found consistently over-expressed in papillary thyroid carcinoma.

Forty to 80% of papillary carcinomas are associated with rearrangements of two genes, which are not usually expressed in normal thyrocytes: *RET*, a neurotrophic factor with tyrosine kinase activity, and *NTKR1*, a nerve growth factor receptor with tyrosine kinase activity. Rearrangement of these genes with parts of other genes, or abnormally spliced promoters, leads to a constitutive activation of tyrosine kinase, which may activate uncontrolled cell growth and probably neoplastic transformation. It is noteworthy that these gene rearrangements are very common after exposure to radiation.

Specific translocation [t(2;3) (q13;p25)] involving the thyroid transcription factor PAX8 and the peroxisome proliferator-activated receptor PPAR γ 1 results in an aberrant fusion transcript, the expression of which seems to be restricted to follicular carcinomas. If these findings are validated in large multicenter studies, the availability of specific oligonucleotide primers to be used in polymerase chain reactions, as well as of mAbs directed to these aberrant and/or overexpressed proteins, could improve the diagnostic accuracy of conventional thyroid FNA cytology.

CONCLUSION

The application of thyroid FNA for the preoperative characterization of thyroid nodules has greatly enhanced the ability of the clinician to select appropriate patients for surgery. With this technique, most papillary carcinomas, undifferentiated carcinomas, most forms of thyroiditis, and cystic indolent lesions can be easily characterized. However, even cytologists with extensive experience with thyroid FNA find malignant follicular lesions difficult to distinguish from benign ones because capsular and/or vascular invasion, which are the distinctive hallmarks of follicular cancer, cannot be appreciated on cytological bases. In these cases, additional diagnostic techniques should integrate conventional FNA cytology (i.e., galectin-3 immunostaining).

Although FNA cytology is a useful diagnostic tool for the assessment of thyroid nodules, it has some technical and conceptual limitations. For example, diagnosis of micropapillary carcinoma by FNA is almost impossible because of the small size of the lesion. On the other hand, other interpretative problems due in part to the quality of cytological preparation (e.g., inadequate sampling) but also to the skill of the cytopathologist result in a certain number of false-negative and false-positive results.

As a general consideration, it should be kept in mind that FNA cytology of thyroid lesions has an important diagnostic potential in a specific setting. For this reason, and in order to optimize the clinical management of thyroid nodules, a careful clinical and endocrinological evaluation that includes thyroid ultrasound scanning should always be performed before considering a thyroid FNA. When these guidelines are followed, a significant number of patients will not have any suspicious nodules to be considered for cytological analysis. These patients should be reassured and followed by the referring physician.

the free fraction can enter the peripheral cell. If the free concentration falls, the pituitary will be stimulated to secrete thyroid-stimulating hormone (TSH) so as to restore adequate free T4 and T3 concentrations. This will occur when free T4 concentrations change due to altered TBG levels. The kinetics of the protein changes is slow (half-life = 6 h for transthyretin and 4 days for TBG).

For a long time, it was believed that the changes in serum concentrations of TBG would not affect thyroid hormone economy. Recently, it has been shown that in treated but severely hypothyroid patients, pregnancy or estrogen treatment increases the demands of T4 treatment and serum TSH values increase significantly. This is the first evidence that the increased total T4 pool under estrogen treatment cannot be achieved solely by decreasing the metabolic rate and metabolism of T4. Therefore, under physiological circumstances, there is a discrete adaptation of thyroidal secretion to ensure an unchanged thyroid function. The therapeutic adaptations are necessary in severely hypothyroid patients, whereas it is rarely necessary to increase T4 treatment in partially hypothyroid patients.

TBG binds T3 with a lower affinity than it does T4, with the affinity constant for T3 being 5×10^{-8} M, and its serum levels are less affected by changes in serum proteins. Despite this, and despite the fact that T3 is the active thyroid hormone, other factors markedly reduce the diagnostic value of T3:

1. T3 is mainly an intracellular hormone, and the circulating pool represents no more than 15 to 20% of its whole body pool.
2. T3's production is mainly nonthyroidal and is markedly influenced by the metabolic state of the organism.
3. T3's production is controlled by monodeiodination, and its degradation also by conjugation.

Monodeiodination plays a crucial role in the control of serum T3 levels. Three enzymes—deiodinase types I, II, and III—have been characterized. They are selenoproteins and, hence, very rare mammalian proteins. However, they differ markedly concerning their functional characteristics. Quantitatively, the most important enzyme is deiodinase type I, which is found mainly in the liver and kidney but in small amounts is ubiquitously present. It is localized at the inner plasma membrane. Under physiological conditions, approximately 30% of T4 is converted by this enzyme to T3. The expression and activity of this enzyme are stimulated by T3; for example, in hyperthyroidism the activity is very high, whereas in hypothyroidism it is very low. However, many other nonthyroidal factors

affect its activity. In any catabolic state—malnutrition, starvation, severe infections, or metabolic or malignant diseases—its activity is decreased and this is reflected in decreased serum T3 levels. Another example is drug interferences such as glucocorticoids and amiodarone, which are potent inhibitors of deiodinases. Stimulation of deiodinase type I can be observed with overfeeding and/or a high-carbohydrate intake.

The activity profile of deiodinase type II is very different. It has a very low affinity constant (K_m). The enzyme that is found in the pituitary and brain is most active when T4 is absent. It is inhibited with increasing T4 concentrations. It is directly implicated in the control of serum TSH. Both enzymes attack the outer ring of T4. The third enzyme, deiodinase type III, deiodinates only at the inner ring, a function that can be shared under particular conditions with deiodinase type I. Interestingly, deiodinase type III is localized at the outer cell membrane, and by degrading T4, it refuses its entry into the cell.

Thyroidal production of T3 is minimal compared with that of T4. Without iodine deficiency, T3 represents less than 5% of the secreted T4. There are at least two conditions where this percentage can increase: in iodine deficiency and in hyperthyroidism. In hyperthyroidism, the thyroidal deiodinase is strongly stimulated so that some of the T4 is converted during the process of secretion to T3. In iodine deficiency, this mechanism is also operating, but the poorly iodinated thyroglobulin (Tg) also has a high percentage of T3 that can go up to 50% that of T4. This contributes to a higher proportion of T3 in serum, and the T3-to-T4 ratio can increase from the physiological ratio of approximately 2% to 4% in hyperthyroidism and to much higher values in severe iodine deficiency. If selenium deficiency is associated with iodine deficiency, the increased ratio of T3 to T4 is not seen because the lack of selenium affects the activity of the deiodinases. Clinically, the increased T3-to-T4 ratio was of diagnostic significance for T3 toxicosis that is now diagnosed more adequately by a suppressed serum TSH in the presence of a still normal free T4. For practical purposes, one can conclude that the serum levels of T3 are influenced by many factors other than thyroidal secretion and, therefore, are of lower diagnostic value than free T4 values.

rT3 is the inactive counterpart of T3 and has been advocated as a diagnostic tool, but today none of them remains valid. Nevertheless, it is an interesting parameter that gives a good mirror image of T4-to-T3 conversion. If deiodinase type I is inhibited, serum rT3 levels increase. There are two reasons for this. First, rT3 needs deiodinase type I to be degraded and

accumulates if the enzyme is low. Second, there may be some shift of T4-to-T3 conversion to rT3.

For practical purposes, one can conclude that the serum levels of T3 are influenced by many factors other than thyroidal secretion and, therefore, are of lower diagnostic value than free T4 values.

Methods of Serum Free T4 and T3 Measures

As mentioned previously, free T4 represents an extremely small fraction of the total T4. Today, for routine purposes, no fully satisfactory free T4 measure is available.

The best but cumbersome methods use ultrafiltration or equilibrium dialysis. The latter method was the first reliable one; however, it can yield falsely elevated values if FFAs are artificially increased by the presence of *in vitro* heparin or by repeated freezing and thawing. Both methods cannot be used in routine work.

Two different approaches for measuring the free T4 indirectly are available. One is still widely used in the United States: the free T4 or T3 index test, which is based on the fact that the product of total serum T4 times the result of the T3 resin uptake gives an arbitrary index that roughly correlates with free T4 values. The T3 resin uptake methods are based on the following principle: because the serum protein binding of T4 is mainly dependent on TBG, an increase of it will shift the equilibrium between TBG and free T4 in favor of TBG. If ^{125}I T3 or T4 is added, a higher percentage will be bound to TBG, yet in any case the binding to TBG would be so strong and the free fraction of T3 or T4 would be so small that one could not measure it. Therefore, one adds a competitor, such as resins or antibodies, which binds in normal serum 15 to 30% of the ^{125}I T3. Artifactual results with T3 resin uptake methods are frequent and similar to the ones found using commercial free T4 methods.

The so-called direct measures of free T4 and T3 methods are based on radioimmunoassays (RIAs) or chemiluminescent assays. Yet the free T4 concentrations are far too low to be measured directly. Therefore, commercial companies have developed T4 analogues that do not bind to TBG and are distributed only within the free hormone fraction. In addition, this fraction is artificially increased by competitors of T4 for TBG. These methods have the advantage over the free T4 index in that they yield absolute concentrations of free T4 and their interpretation is easy. However, because of technical limitations, they are also prone to artifactual values, particularly in systemic

illness where unknown competitors for T4 binding to TBG have been described. It follows that some commercial methods will have a tendency of too low values in severe illnesses and with decreased serum protein concentrations. Some of these problems can be overcome by more cumbersome techniques (two-step methods), but even these methods are not free of artifactual results. The latter tend to give too high values in severe illness. Nevertheless, in ambulatory medicine, these commercial methods are satisfactory and render total T4 and T3 methods unnecessary. In addition, the clinician should rely first on serum TSH, with serum free T4 and T3 levels being useful adjuncts for the refinement of diagnosis and treatment and for excluding some extremely rare thyroidal conditions.

These are TSHomas (pituitary tumors secreting TSH) and thyroid hormone resistance. In TSHomas, serum TSH values are normal or slightly increased, yet both serum free T4 and T3 are increased and are associated with clinical signs of hyperthyroidism. In thyroid hormone resistance, serum TSH can be normal, low, or slightly increased in the presence of increased free T4 and T3. However, the clinical picture is composite, with the heart often being the sole organ with signs of hyperthyroidism.

In most instances, serum free T4 and T3 levels are confirmatory. Yet relying only on serum TSH for diagnosis might lead to misleading conclusions because there are rare diseases where serum TSH will not help or may be misleading. In the presence of a high clinical suspicion of thyroid dysfunction or abnormal serum TSH, free T4 and T3 are necessary. Total T4 and total or free T3 are indicated only when the results of serum TSH and free T4 values are discordant. Among thyroid function tests, serum TSH is the first choice.

Serum TSH

Measurement of serum TSH values is the firstline diagnostic test. Its sensitivity is very high, whereas its specificity is slightly lower (90%) because drugs and severe illness can decrease serum TSH levels in euthyroid patients. The predominant role of serum TSH as a diagnostic parameter is due to its being the most sensitive parameter of peripheral thyroid hormone action. It increases exponentially when serum free T4 decreases. It differs from the clinically more relevant effects of T3 on heart, liver, brain, and other tissues for the following reasons:

1. The intracellular regulation of thyroid hormone metabolism in the pituitary and brain is not encountered in peripheral tissues.

2. The action of thyroid hormones in the pituitary is inhibitory. In the periphery, it was thought that the action of T₃ was mainly stimulatory, yet recent studies (including gene screening) indicate that gene expression is more often down-regulated than stimulated by T₃.

3. The role of the hypothalamus for TSH secretion by thyrotropin-releasing hormone (TRH), somatostatin, dopamine, and others adds complexity of coordination between T₃ and these other factors.

Clinical Use of Serum TSH Measures

Serum TSH is measured with immunometric assays using chemiluminescent probes. Progress has been constant in this field, and the lower detection limit of the newest assays is 0.002 mU/L or less (fourth-generation immunometric assays). At 0.02 mU/L, most immunometric assays have a coefficient of variation of 20%, whereas at higher TSH values, this decreases to 5% or less. A coefficient of variation of 20% is the upper limit of what is clinically acceptable.

The clinician should be aware that these assays measure only the immunological, and not the biological, properties of TSH. This is no problem when diagnosing hyperthyroidism, but there is good evidence of discordance between these two parameters in primary and hypothalamic hypothyroidism in the fetus and (possibly) in severely ill patients.

It also appears that antibodies recognize variable degrees of TSH glycosylation that occur in several thyroid pathologies. Different results in the range of serum TSH from 3 to 7 mU/L have been reported and are possibly related to such differences in antibodies.

TSH is secreted in a pulsatile manner and has a circadian rhythm. TSH spikes do not exceed 0.5 mU/ml. Serum TSH levels are highest during the evening (at 23:00 h), that is, during the first hours of sleep. The peak is displaced in night workers. In young individuals, the mean serum TSH levels are in the morning (0.9 ± 0.3 mU/L) and at 23:00 h (1.9 ± 0.6 mU/L). In the elderly, serum TSH levels tend to be slightly lower (0.7 ± 0.6 and 1.3 ± 0.9 mU/L, respectively). These fluctuations are rarely critical for the clinical evaluation of thyroid function. The normal range extends from 0.4 to 4.0 mU/L. Recent studies tend to narrow the normal range to 0.4 to 2.5 mU/L, with a median of 1.0 to 1.5 mU/L and with the African American population having a slightly higher mean serum TSH than the Caucasian population (Fig. 1). This rigorous definition is based on 120 individuals who were tested for absence of goiter, antithyroid antibodies, and family history of thyroid disease. From the clinical point of view, a serum TSH of 0.4 mU/L or less

needs investigation. One study suggested that serum TSH values of 2.5 to 4 mU/L already represent an increased risk of developing overt thyroid disease, with the annual incidence of clinically manifest disease being approximately 5%. The concomitant presence of thyroid autoantibodies probably increases this risk. The significance of low serum TSH depends on the degree of serum TSH suppression that can be classified into three different degrees:

1. *Serum TSH 0.1 to 0.4 mU/L (for some authors, to 0.6 mU/L).* This is frequently seen in subclinical hyperthyroidism. Serum free T₄ values are normal and serum free T₃ values are only rarely increased. Such serum TSH values are not fully specific for subclinical hypothyroidism because they can also be found in severe nonthyroidal illness with or without glucocorticoid or dopaminergic treatment. In these latter situations, serum free T₄ and T₃ levels tend to be decreased or in the lower normal range. The differential diagnosis can be established by clinical observation and repetitive measures. If found repeatedly, this slight decrease of serum TSH is compatible with partial thyroid autonomy, with the cause being a hot nodule, a multinodular goiter, or euthyroid Graves' disease. Thyroid scintigraphy can be helpful in these situations. Recent iodine contamination may play an important role here and can be the origin of transient subclinical hyperthyroidism. Rarely, such serum TSH levels can be found in pituitary or hypothalamic insufficiency, but in these conditions the changes in thyroid function are mostly of secondary importance, with other pituitary insufficiencies being more pronounced.

2. *Serum TSH 0.05 to 0.1 mU/L (for some authors, 0.02 to 0.1 or 0.2 mU/L).* The differential diagnosis is similar to the previous one. In addition, serum free T₄ and/or T₃ levels tend to be at the upper limit or slightly increased. Some authors consider that even a small increase in free T₃ stands for overt and not subclinical hyperthyroidism, whereas others (including this author) prefer that the definition remain mainly clinical. Such serum TSH levels are the goal of T₄ treatment in patients with differentiated thyroid cancer. These patients present with serum free T₄ levels at the upper limit of normal, and in one-third of these patients free T₄ levels will be slightly increased. Serum T₃ levels are in the normal range. This can be explained by the absent thyroidal component of T₃ secretion. Low serum TSH levels are frequent in panhypopituitarism but not in hypothalamic disease. It is rather rare to find such low serum TSH levels in systemically ill patients unless they are treated with large doses of dopamine and/or glucocorticoids.

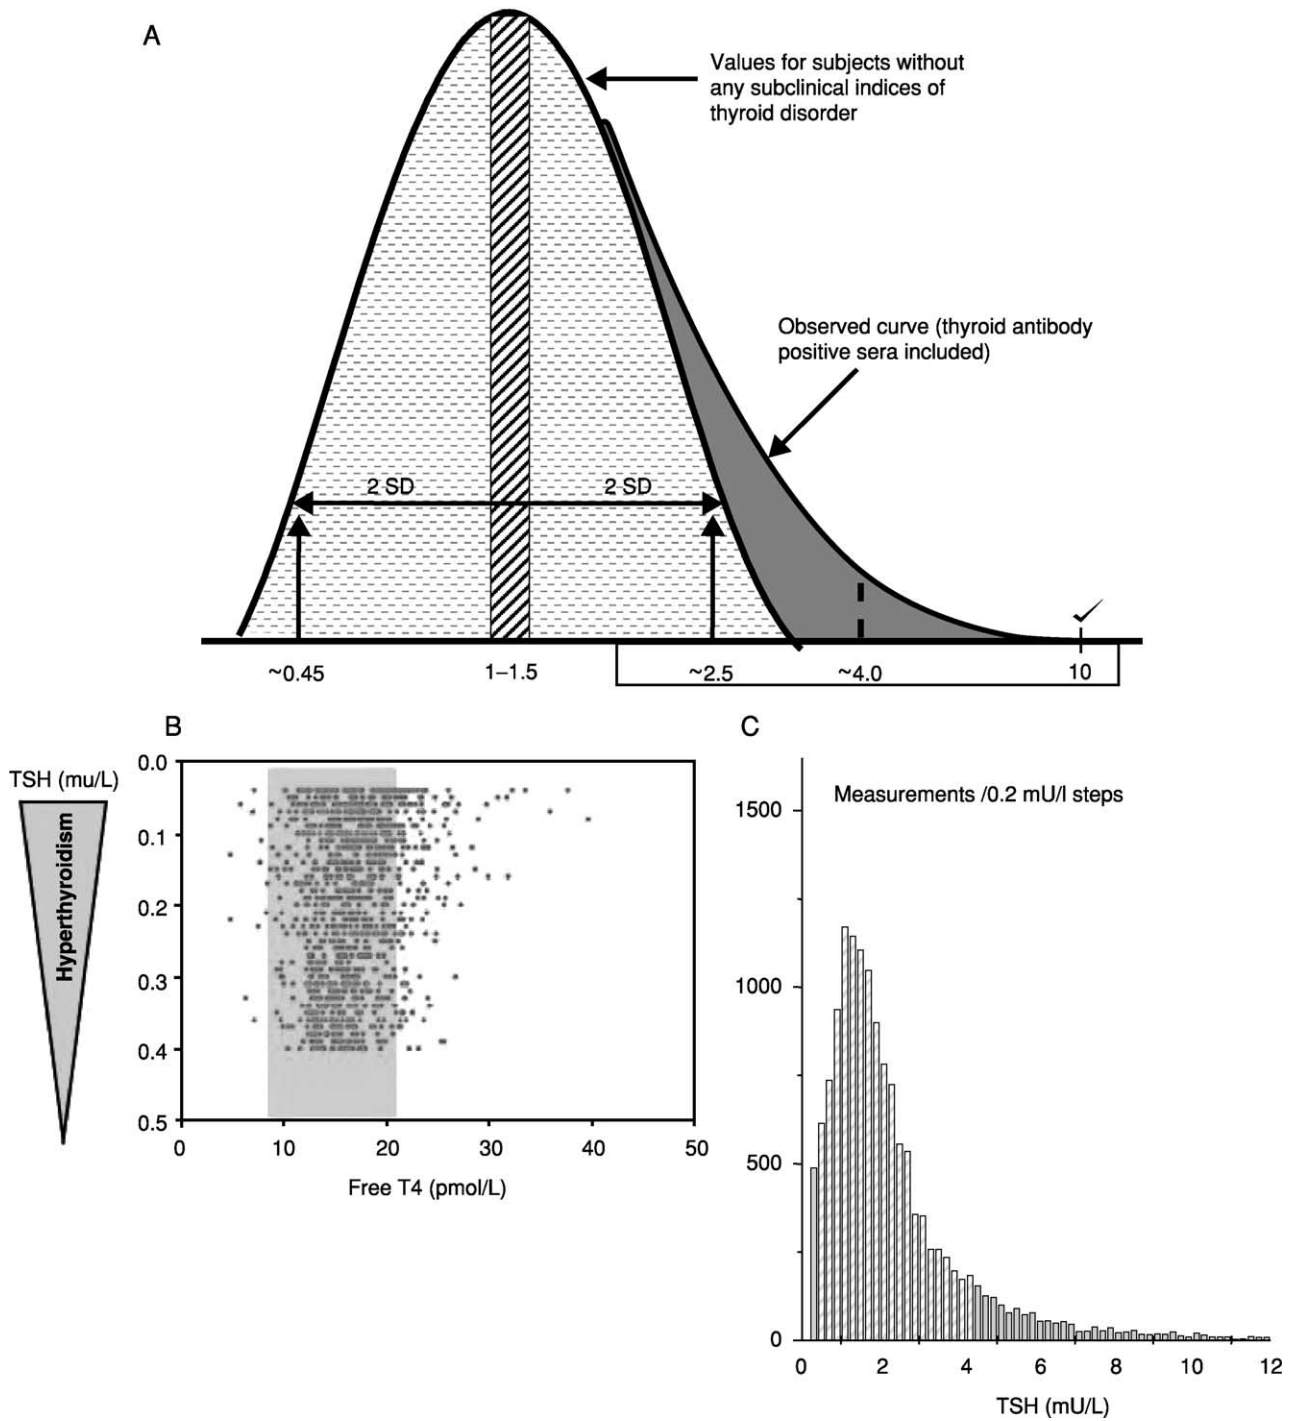

Figure 1 Current TSH immunometric assays. (A) The area between 0.45 and 2.5 mU/l represents the values for a population (mean \pm 2 SD) with documented absence of thyroid diseases. The bordering tails indicate that this population is not separated from the borderline pathological cases that represent for TSH levels above 2.5 mU/l in a majority of cases still euthyroid autoimmune thyroiditis (figure courtesy of Professor Carole Spencer). (B) Free T4 values in the subclinical hyperthyroid range as a function of decreasing serum TSH values are shown. Even though some free T4 values are above the normal range, the majority falls within the normal limits. Below TSH values of 0.1 mU/l, free T4 values tend to increase. Increased free T3 values are even less frequent despite partly suppressed serum TSH values (data not shown). (C) Consecutive serum TSH determinations (16,000) over 10 months in a diagnostic laboratory are shown. It includes known and unknown pathologies, the limits being arbitrarily set at 12 mU/l and 0.2 mU/l. It documents what is shown in panel A: one cannot separate three different populations (euthyroidism, subclinical hyper- or hypothyroidism). The free T4 values shown in panel B are extracted from the lower end of TSH values in panel C. The data in B and C were obtained by courtesy of UNILABS, SA, Geneva.

3. *Serum TSH less than 0.02 mU/L.* Such values are encountered only in endogenous hyperthyroidism and possibly in severe panhypopituitarism. Some assays will allow measuring levels as low as 0.002 mU/L. Therefore, even in frankly hyperthyroid patients, in the future, one might evaluate the severity of hyperthyroidism by serum TSH only. There are no data correlating the very low serum TSH levels with the clinical severity of hyperthyroidism. It is now well established that reactivation of TSH secretion during treatment for hyperthyroidism may lag behind the normalization of peripheral thyroid hormones and clinical manifestations by several weeks or even months. There is no clear explanation for this, but it is important to realize that in this situation serum TSH is not a valid parameter of euthyroidism.

Use of TSH Measurements in the Case of Artifacts Free T4 Values

Two diagnostic pitfalls can occur when serum TSH measurements are the only thyroid hormone parameter measured. Serum levels of thyroid hormones may be normal, slightly decreased, or increased in the case of thyroid hormone resistance with frankly increased serum free T4 and T3 levels.

In the case of a pituitary TSH-secreting adenoma, called a TSHoma, serum TSH levels are normal or moderately increased (up to 20 mU/L) despite clinical hyperthyroidism with increased serum free T4 and T3 levels.

Serum TSH measurements are essential for excluding thyroid dysfunction in two situations with apparently increased free T4 levels. One abnormality involves T4 binding to serum transport proteins. There can be a congenital high affinity and capacity binding of albumin or transthyretin for T4. T3 is much less affected. In addition, some neuroendocrine tumors secrete very large amounts of normal transthyretin (familial dysalbuminemic hyperthyroxinemia [FDH] and familial or acquired hyperthyroxinemia due to transthyretin excess). The affected patients are absolutely euthyroid because their free T4 values, measured by ultrafiltration or equilibrium dialysis, and T4 production rates are normal. Some commercial kits of free T4 measurements can yield artifactually increased very high free T4 values, even though newer versions of these kits avoid such errors. Few laboratories are equipped to identify these proteins. If this methodology is not available, differential diagnosis with pituitary tumors or thyroid hormone resistance should include serum T3, serum TSH α -subunit, a TRH test, and possibly magnetic resonance imaging

(MRI) of the pituitary. Serum T3 and the α -subunit are increased in TSHomas and in thyroid hormone resistance, but only exceptionally in dysalbuminemic hyperthyroxinemia. Basal serum TSH and the TRH test are normal in the case of abnormalities in serum transport proteins, whereas the response to TRH tends to be exaggerated in thyroid hormone resistance. In most but not all cases of TSHomas, there will be no response to TRH stimulation. Therefore, the value of this test is only indicative.

Another artifactual increase of free T4 values is encountered in the presence of autoantibodies to T4 or T3, even though most modern kits are no longer affected by such antibodies. Euthyroidism can be confirmed with a TRH test, yet in most countries TRH for clinical testing is no longer available.

Artifacts of TSH Measures

There is only one condition where serum TSH values can be artifactually increased, namely in the presence of antibodies against mouse immunoglobulin (IgG) in the patient's serum. Monoclonal mouse IgGs are part of all immunometric assays and, therefore, will be trapped by these antibodies. Recently, immunometric assays have overcome this problem. If necessary, the artifactual increase in serum TSH can be diagnosed by omitting anti-TSH antibodies in the assay and/or by a TRH test. It will show a complete nonresponse to TRH that may hint at this artifact or at a TSHoma.

The well-established overwhelming diagnostic power of serum TSH measurements can raise two questions. First, should one restrict the firstline diagnostic parameters of thyroid dysfunction to TSH only, thereby omitting free T4 measures? This might be justified for systematic screening, yet free T4 measurements are inexpensive and will be ordered mostly during further workup of the patient's thyroid disease. Second, should serum TSH be used systematically as a screening test of the adult female population over 50 or even over 35 years of age and be repeated at regular intervals (e.g., every 5 years)? There is already a precedent. The neonatal screening with TSH and the price of serum TSH measurements have decreased markedly and will probably decrease even further, making such a proposal a realistic issue.

Special Techniques

The main indications for the TRH test (200 μ g intravenously, blood sampling at 0, 15, 30, 60, and 120 min) are pituitary diseases. For primary thyroid dysfunction, it has lost all of its indications except those mentioned previously. In most countries, intravenous TRH is no longer available, with the nasal spray being

used instead. This way of testing represents a stronger and more prolonged TSH stimulation. Blood should be sampled before and 30 and 60 min after the TRH for measuring TSH or 3 h later for measuring an increase in serum T₃.

Measuring the α -subunit of TSH, the common subunit of all pituitary glycoproteins, is important in the case of TSHomas and obviously in gonadotropinomas as well.

Thyroglobulin

Physiologically, Tg is released in small amounts from the thyroid. It is estimated that 1 g of tissue corresponds to 1 μ g/L serum Tg if serum TSH is in the normal range. Disruption of the normal thyroid structure results in leakage of Tg, and high serum levels are found in goitrous patients. In multinodular goiter, Tg levels can reach very high levels that overlap with those found in metastatic thyroid cancer patients. Marked and transient increases can be seen after ¹³¹I treatment and after thyroid surgery. High levels are also found in Graves' disease and in functioning (and occasionally even nonfunctioning) thyroid adenomas.

The measurement of serum Tg levels has benefited from the advances in immunometric assays. Today, an assay should have a functional sensitivity (with a coefficient of variance of 20%) of less than 1.0 to 0.5 μ g/L, and interference of Tg antibodies should be kept to a minimum. In practice, there are considerable differences among the commercial kits, and each laboratory should determine the sensitivity of its assay. Therefore, two additional controls are recommended:

- Tg antibodies should be measured, and some authors recommend not using serum concentrations of Tg if anti-Tg antibodies are present.
- Another control consists in adding pure Tg to a separate sample of the patient's serum. A recovery of 80 to 120% of the added Tg excludes major interference. Adding small amounts of external Tg (1 μ g/L rather than 50 μ g/L) is recommended. Some authors consider that the recovery test does not guarantee absence of interference and so reject this approach. It is hoped that technical improvements of immunometric assays will allow most of these problems to be minimized.

Indications

Tg measurements are useful in neonatology where low levels are found in thyroid agenesis or dysgenesis and where high levels are found in thyroid hormone

resistance and in some rare inborn errors of thyroid hormone synthesis. They are a valuable adjunct to scintigraphy and thyroid ultrasound.

Low Tg values are an excellent means to differentiate between thyrotoxicosis factitia and endogenous hyperthyroidism. In the presence of a normal-sized or even moderately increased thyroid, the ingested L-thyroxine will suppress Tg levels to values of less than 10 μ g/L. Yet in the presence of very large goiters, Tg levels will often not be suppressible.

Tg values can be of value for following the evolution of hyperthyroidism and during remission. In addition, in subacute thyroiditis, an increase in Tg levels has been documented. The measurement of Tg values in these clinical situations is not frequently used.

Tg measures are not useful in the differential diagnosis between benign nodular goiter and thyroid carcinoma because Tg levels tend to be increased and overlap in both conditions. In an occasional patient with an unidentified pulmonary or bone metastasis, a very high Tg level may help to establish the origin of the tumor.

The greatest merit of Tg measurements comes from the surveillance of differentiated follicular or papillary thyroid cancer because it allows easy detection of recurrences (Table I). Tg levels are a function of the tumor mass and tumor differentiation. Tg levels tend to be lower in tumors that are more aggressive and are absent in undifferentiated cancers.

The surveillance of well-differentiated thyroid cancers with Tg values has become the first choice of approach. It is crucial not to rely only on basal Tg values and to consider values after TSH stimulation as well. The use of recombinant TSH has greatly facilitated the surveillance because its use is equally valuable than inducing severe hypothyroidism.

If Tg values are more than 2 μ g/L, the presence of thyroid tissue is certain, indicating the presence of neoplastic tissue in the case of complete surgical or ¹³¹I ablation. The changes in its concentration over time parallel the evolution of the tumor. Tg levels are particularly important for diagnosing absence of disease. For this purpose, one cannot rely on nonmeasurable Tg levels (<0.5 μ g/L) under T₄ treatment. If the patient is rendered hypothyroid, or if the patient receives recombinant TSH and serum Tg values do not exceed the critical limit of 2 μ g/L, the patient can be considered cured. In these situations, thyroid scintigraphy becomes obsolete.

Recently, a complementary method for determining the presence of tumor tissue has been advocated in cases of interference in serum measurements of Tg by anti-Tg antibodies. The presence of circulating

Table 1 Diagnostic Use of Serum Thyroglobulin Levels in Well-Differentiated Thyroid Cancer

| Thyroglobulin value | | Thyroglobulin antibodies | ¹³¹ I scintigraphy | Loco-regional tumor | Distant metastasis | "Cure" |
|---------------------|--------------|--------------------------|-------------------------------|---------------------|-----------------------|-------------|
| TSH <0.1 mU/L | TSH >30 mU/L | | | | | |
| <2 µg/L | <2 µg/L | Negative | Negative | Excluded | Excluded | Most likely |
| | | Negative | — | Not excluded | Unlikely | Not proven |
| 2 to 10 µg/L | 2 to 10 µg/L | Negative | Positive or negative | Certain | Unlikely but possible | No |
| | | Negative | Positive or negative | Certain | Unlikely | No |
| >10 µg/L | | Negative or positive | Mostly positive | Certain | Not excluded | No |

thyroid follicular cells is obtained by using real-time quantitative reverse transcription-polymerase chain reaction (RT-PCR) based on the amplification of Tg mRNA. If normal thyroid tissue has been destroyed, the presence of Tg mRNA strongly supports recurrence of disease. The method is sensitive and independent of circulating anti-Tg antibodies, but it currently is limited to specialized research laboratories.

Autoantibodies

For clinical use, three types of antibodies are of interest: the antithyroperoxidase (anti-TPO), the antithyroglobulin antibodies (anti-Tg), and the anti-TSH receptor antibodies (anti-TRAb). Among the anti-TRAb, one can distinguish blocking and stimulating antibodies. The recently discovered anti-sodium-iodide symporter antibodies do not seem to play a diagnostic role.

The thyroid antibodies belong to the IgG class, and only for anti-TPO antibodies have some complement fixing and cytotoxic activity been described in rare cases. The antigenic sites of the TPO have been well characterized; there are six of them. For anti-Tg and anti-TRAb, this is less well known because the antigenic sites are mainly conformational and not linear. Recently, it has been possible to produce functioning anti-TRAb in mice.

Indications to measure thyroid antibodies can serve diagnostic, follow-up, and screening purposes. TPO antibodies are the most sensitive antibodies for the diagnosis of any thyroid autoimmune process, and they are widely used in combination with the TSH for diagnosing the etiology of a thyroid disease. Unfortunately, the absolute values are not standardized and there are differences among the many commercial products. Their presence confers an increased risk of developing hypothyroidism and is an indication

for clinical follow-up. They are also useful in the follow-up of Graves' disease because their titer may reflect the activity of the disease. In Hashimoto's thyroiditis, the follow-up of these patients with measurements of antibodies may be confusing and is not generally recommended. There is no specific indication for Tg antibodies because they are identical with the ones enumerated previously. However, on rare occasions, the TPO antibodies may be negative, whereas Tg antibodies will reveal thyroid disease.

The TRAb are mostly not useful for the diagnosis of Graves' disease. Similarly to TPO antibodies, their titer may follow the activity of the disease. They can also be present in primary hypothyroidism and in postpartum thyroiditis; therefore, they are not diagnostic of Graves' disease.

There is one seldom but clear indication for measuring these antibodies, namely in pregnant patients with Graves' disease in whom the thyroid has been removed. In these cases, one has no clinical indication about the severity of the autoimmune process and, on rare occasions, placental transfer of a high titer of TRAb may cause neonatal hyperthyroidism.

Screening with anti-TPO antibodies is advocated during pregnancy because their presence indicates increased risk of postpartum thyroiditis.

IN VIVO ISOTOPE IMAGING

Diagnostic *in vivo* isotopic imaging will yield information on thyroidal uptake of the isotope and functional morphology of the thyroid. Two isotopes, 123-iodine (¹²³I) and Tc99m pertechnetate (Tc^{99m}), are used nearly exclusively. There is still some indication for ¹²³I for whole body scintigraphy of patients with thyroid cancers. The place for other isotopes, such as thallium and gallium, has not been established. Thallium has been used for identifying thyroid

Table II Isotopes for Thyroid Imaging

| | ^{123}I | ^{131}I | $\text{Tc}^{99\text{m}}$ | F18 thioglucose |
|------------------------------------|------------------|---------------------|--------------------------|--------------------------------------|
| Half-life | 13 h | 8 days | 6 h | 110 min |
| Emission | Gamma | Beta, gamma | Gamma | Gamma |
| Radiation exposure (rad)/mCi | 13 | 1300 | 0.13 | |
| Diagnostic dose (μCi) | 300 | 50 (or 5 to 10,000) | 2000 | |
| Route | Oral | Oral | Intravenous | Intravenous |
| Absorption | Gastric | Gastric | | |
| Particularities | | | | Uptake by metabolically active cells |
| Maximal uptake | 4 to 8 h | 4 to 8 h | 20 to 40 min | |

metastases, and gallium 67 is taken up by inflammatory cells, particularly mast cells, and therefore can be used in some cases of destructive thyroiditis such as subacute thyroiditis (Table II).

123-Iodine

The physical characteristics of ^{123}I are given in Table II. It is close to an ideal isotope in that the irradiation of the thyroid is minimal. Fasting, and with intact gastric acidity the iodide, is taken up specifically by the gastric mucosa. Thyroidal uptake occurs very rapidly. In the case of concomitant food intake, the uptake is delayed and occurs by intestinal absorption.

Its uptake is dependent on the activity of the sodium-iodide symporter, formally called iodide trapping of the thyroid. Once transported into the cell, the free intrathyroidal iodide is immediately incorporated into Tg. Only under pathological conditions is the free iodide pool of the thyroid increased. This can be tested by the perchlorate discharge test. Once stored in the colloid as Tg, the labeled T4 will remain in the thyroid for a long time, depending on the total amount of stored colloid. In most conditions, the reserve in Tg is huge; therefore, the turnover of this iodide is slow, even though the most recently formed colloid is preferentially resorbed and secreted. As a rule of thumb, only 1 to 2% of the accumulated dose will be secreted per day. Therefore, the disappearance of the isotope will be mainly a function of its physical half-life (13 h for ^{123}I). During secretion, most of the ^{123}I is secreted as T4 and to a lesser extent as T3, and only a minor part of iodide is lost.

Iodine contamination is one of the major technical problems resulting in invalid thyroid imaging. In individuals with a normal thyroid and a daily iodide intake of 200 μg or more, a single dose of 30 mg iodide together with the tracer will reduce the uptake

to background levels. A similar effect can be obtained with half the dose of iodide given over several days. However, it should be noted that this applies for a completely normal thyroid. In areas of moderate iodine deficiency where small multinodular goiters are frequent, the suppression of ^{123}I uptake by iodine needs higher and longer treatment with similar or higher doses. Accidental iodine contamination is a frequent event because large amounts of iodine containing contrast media are injected during axial tomography. These substances are highly water soluble and are eliminated within 4 to 6 weeks. Iodide is rapidly eliminated by the renal route (clearance of 50 ml/min), and in renal insufficiency they are correspondingly decreased.

Today, the major culprit of long-term iodine contamination is amiodarone. This substance and its biologically active metabolite, desethylamiodarone, have an approximate half-life of 4 to 6 weeks. However, iodine contamination from its degradation products can last for months or up to 1 to 2 years. Historically, other organic iodine compounds can be responsible for even longer lasting contaminations. For instance, dyes used for myelography give rise to lifelong contamination and can even pass the placenta with consequent low thyroid uptake in children.

Among the noniodinated substances interfering in thyroidal uptake, methimazole, propylthiouracil, and perchlorate should be mentioned, with the latter being a specific inhibitor of the iodide symporter. In severe nonthyroidal illness, thyroid function and thyroid uptake may be depressed. Drugs such as glucocorticoids (30–60 mg of prednisone) and dopamine and its analogues have multiple impacts, but the most significant one is a reduction of TSH secretion with a subsequent reduction in thyroid function. Older literature also mentions sulfonamides, but the more modern drugs in this class have not been reported to interfere.

Tc^{99m} Pertechnetate

Tc^{99m} is close to ideal for studying the trapping of iodide by the thyroid. It is easily available and of low cost. Because it can only give information on anion trapping, the measurements are performed within 1 h after intravenous injection. The thyroidal uptake of Tc^{99m} is approximately 10 times lower than that for ¹²³I (0.4–4.0%). The precise normal range is also dependent on iodine intake; therefore, it must be validated for each laboratory. As compared with ¹²³I, Tc^{99m} may occasionally show uptake of cold nodules that may erroneously be taken for functioning nodules.

It should be noted that on many occasions thyroid imaging with isotopes has been replaced by ultrasonography. The indications for scintigraphy could be summarized as follows. In hyperthyroidism, Tc^{99m} is as valid as ¹²³I for the differential diagnosis of nodular or diffuse goiter. If the thyroid is diffusely enlarged without concomitant exophthalmos or pretibial myxedema, the positive uptake will allow excluding silent and/or subacute thyroiditis and will help in establishing a diagnosis of thyrotoxicosis factitia and/or iodine contamination. In the case of multinodular goiter with a moderate decrease of serum TSH (<0.6 mU/L), the scintigraphy may confirm autonomous regions. In the case of very painful thyroid and inflammatory symptoms, an absent thyroid uptake may confirm the diagnosis of subacute thyroiditis. In the case of an isolated euthyroid thyroid nodule, the uptake will identify a cold nodule, even though Tc^{99m} may give erroneous results and the predominant position of this investigation has been superseded by cytology.

In most cases, ultrasound evaluation of the thyroid gland is as useful as or better than scintigraphy. Nevertheless, the two examinations can be complementary. Scintigraphy will allow identifying an inactive nodule of the thyroid that the ultrasound may reveal to be cystic, mixed, or solid. In multinodular goiter, the scintigraphy will clearly give the patchy appearance of the functioning and (possibly) autonomous tissue. However, its value in describing inactive or cold nodules in this situation is limited.

The Role of ¹³¹I-iodine

The disadvantage of the ¹³¹I isotope is its rather large delivered dose of irradiation to the patient. In thyroid cancer patients, ¹³¹I has kept its place for diagnostic procedures, even though the use of Tg is reducing its indications. During the follow-up of these patients, whole body scintigraphies are obtained with ¹³¹I

during intense TSH stimulation that is classically obtained by stopping T4 or T3 substitution or, more recently, by injecting recombinant human TSH.

Hypothyroidism is obtained by switching 7 weeks before ¹³¹I treatment to T3 substitution that has to be stopped 12 to 14 days before giving the dose. Serum TSH levels should increase to more than 30 mU/L, and the efficiency of the whole body scan or treatment can be increased by concomitant regimen recommendations such as avoidance of iodized salt and iodide-rich bread, eggs, and fish. A small dose of diuretics (thiazides) can also be recommended to decrease the circulating iodide pool. Large diagnostic doses of ¹³¹I are used (5–10 mCi) because the uptake of the cancerous cell is much lower than normal and is mostly markedly below 0.5% of the administered dose. The whole body scintigraphy is performed 3 to 4 days after administration of the radioactive iodide. A ¹³¹I scintigraphy or therapy should not be repeated before 8 to 12 weeks because it induces a stunting effect (transiently abolished uptake).

This technique is very sensitive for detecting small metastases and in most cases correlates very well with the presence of serum Tg levels. However, it has been reported that there can be some dissociation and that serum Tg levels can be increased even in the absence of residual ¹³¹I iodide uptake. It is thought that these patients have metastasis and should benefit from a more complete workup with subsequent surgery and/or ¹³¹I treatment.

Rare and/or Experimental Methods for Thyroid Imaging

The perchlorate discharge test can be performed only with ¹²³I or ¹³¹I. It is a rarely used test that was described initially for detecting inherited defects of intrathyroidal iodine metabolism (absence of sodium-iodide symporter, absence of Tg, and dehalogenase defect). Its diagnostic value was for acquired small iodine organification defects that can be seen in autoimmune thyroiditis and Graves' disease treated with ¹³¹I. Today, this test has no place in routine diagnostic procedures.

The methodology is as follows. One should measure the uptake and give 1 g of perchlorate 2 h after giving ¹²³I. One should measure the uptake again 1 h later. A decrease of more than 30% is significant. The test can be made more sensitive by giving 500 µg of potassium iodide (KI) together with the ¹²³I.

Positron emission tomography with fluoro-deoxyglucose is a very promising technique for detecting metabolically active tissue. The active principle,

deoxyglucose, can be taken up by cells but cannot be metabolized. Malignant cancer cells have a high glucose metabolism. Initially, it was thought that this test would yield the best results in poorly differentiated, and hence metabolically very active, tumors. However, experience has shown that even differentiated thyroid cancers can occasionally be identified with this technique.

midline of the floor of the primitive pharynx, in the presumptive sublingual region. At E 9.5, the thyroid primordium buds from the primitive pharynx and begins to migrate caudally, forming an endodermal-lined diverticulum that descends in the tissue in front of the neck. At this stage, the migrating thyroid primordium is still connected to the pharyngeal floor by a narrow channel, the thyroglossal duct. At E 11.5, the thyroglossal duct disappears and the thyroid primordium loses all connections with the floor of the pharynx and reaches its final destination, in front of the trachea, by E 13.5. Then, the thyroid expands and follicular organization appears. By E 14.0, the differentiation process of TFCs begins and thyroid-specific genes are expressed. Finally, 2 days later, thyroxine is detected in the fetal thyroid.

MOLECULAR ASPECTS OF THYROID GLAND DEVELOPMENT

During the past few years, it has become possible to identify a number of genes expressed in various stages of thyroid development and their role(s), as deduced by the phenotypes obtained in mouse models where such genes have been mutated (inactivated) by gene targeting.

The discovery that the transcription factors TTF-1 (thyroid transcription factor-1), Foxe1 (forkhead box e1, formerly called TTF-2), Pax8 (paired box gene 8), and Hhex (hematopoietically expressed homeobox) are expressed not only in mature thyroid cells but also in their precursors offered a useful tool for the exploration of the genetic basis of the developmental process of the thyroid gland.

At E 8.5, in the primitive pharynx, the endodermal cells fated to become TFCs are univocally specified by the expression of TTF-1, Foxe1, Pax8, and Hhex. These factors are also present in other embryonic tissues, but all four are coexpressed only in the presumptive thyroid bud from the moment a thickening composed by proliferating cells appears in the midline of the floor of the primitive pharynx. When the thyroid diverticulum forms and begins its migration, the thyroid primordium still expresses TTF-1, Foxe1, Pax8, and Hhex, and the simultaneous presence of these four factors will remain for the rest of the life as a hallmark of differentiated TFCs.

The expression of TTF-1, Foxe1, Pax8, and Hhex is necessary but not sufficient to guarantee the morphogenesis of the thyroid. Other genes also are required for the correct development of the gland. Among these, Tshr (thyroid-stimulating hormone receptor) seems to be involved in the final steps of differentiation of TFCs (Table I).

TTF-1

TTF-1 was first identified as a nuclear factor able to bind to specific sequences that are present in both *Tg* and *TPO* genes. TTF-1 is a transcription factor that recognizes and binds to specific DNA sequences via a 60-amino acid DNA-binding domain called homeo-domain. The protein is encoded by a single gene, *Titf1* in mice and *TTF1* in humans, located on chromosomes 12 and 14q13, respectively.

During embryonic life, TTF-1 is expressed in the developing thyroid, lungs, diencephalon, and posterior pituitary. Studies in *Titf1* knockout mice have demonstrated that this factor is absolutely necessary for the

Table I Timing and Molecular Phenotype of Thyroid Development in Humans and Mice

| Embryonic stage | | Histological feature | Gene expression ^a | | | | | |
|-----------------|---------------|--|------------------------------|---------------|-----------|------|-----|----------------|
| Mice (day) | Humans (week) | | TTF-1 Pax8 | Foxe1 Hhex | Tg TPO | Tshr | NIS | Hormonogenesis |
| 8.5 | 3.0 | Thyroid anlage | + | | – | | – | – |
| 9.5 | 3.5 | Thyroid primordium migration initiates | + | | – | | – | – |
| 11.5 | 4.0–5.5 | Thyroglossal duct disappears | + | | – | | – | – |

| 14.5 | 8.5 | Expansion and functional differentiation | + | | + | | – | – |
| 16.5 | 10.0 | Onset folliculogenesis | + | | + | | + | + |

^aThe expression of the indicated genes has only been studied in the mouse embryo.

correct development of the thyroid. *Titf1* null mice display a perinatal lethal phenotype characterized by severe defects in both lung and forebrain development as well as a lack of thyroid and posterior pituitary. At an early stage of development, in the absence of TTF-1, the thyroid primordium forms in its correct position, but already by E 10.0 the thyroid primordium appears to be smaller than that in wild-type embryos and soon undergoes degeneration, probably due to an apoptotic process. Hence, TTF-1 is dispensable for the initial commitment of thyroid cells but is required for the survival and subsequent differentiation of these cells. Because in the absence of TTF-1 thyroid cells disappear before the gland accomplishes its final differentiation, it is not possible to assess the role of TTF-1 *in vivo* in the adult thyroid. However, experiments performed in cultured differentiated thyroid cells have demonstrated that TTF-1 is relevant for the expression of thyroid-specific genes. The role of TTF-1 in embryonic life is being investigated. TTF-1 is present in organs derived from the ventral wall of the anterior foregut (thyroid and lungs) but is absent in the esophagus, which derives from the dorsal wall of the gut. Furthermore, in the absence of TTF-1, there is no septation between the trachea and esophagus. Hence, a possible role of TTF-1 could be to contribute to the specification of the anterior part of the gut. However, we do not know which genes TTF-1 controls during thyroid morphogenesis. Studies on the phenotype of *Titf1* null embryos indicate that this transcription factor regulates the expression of some signaling molecules. *Fgf8* and TGF-related peptide growth factor BMP4 are down-regulated in the diencephalon and lungs, respectively, in the absence of TTF-1. It is possible that in the developing thyroid as well, TTF-1 could control the expression of signaling molecules required for the survival of thyroid cells.

Pax8

Pax8 is a transcription factor characterized by the presence of a 128-amino acid DNA-binding domain (paired domain) that recognizes and binds to a single site present in *Tg* and *TPO* promoters. The gene encoding Pax8 (called *Pax8* in mice and *PAX8* in humans) is located on chromosome 2 in both species. During embryonic life, Pax8 is expressed since E 8.5 in the kidneys, brain, and thyroid primordium. In *Pax8* knockout mice, the thyroid is severely affected, follicular cells cannot be detected, and the mice die within a few weeks. In the absence of Pax8, at an early stage of embryogenesis, the thyroid primordium

forms, buds from the gut, and begins its migration. However the thyroid primordium is nearly undetectable by E 12.0. Hence, like TTF-1, Pax8 is required for the survival of thyroid precursor cells.

Experiments in cultured cells have demonstrated that Pax8 can activate transcription of thyroid-specific genes at their chromosomal locus. The coexpression of Pax8 and TTF-1 in thyroid cells only has suggested that these factors can cooperate in the stimulation of thyroid genes. Indeed, studies have provided us with the demonstration that Pax8 and TTF-1 directly interact *in vivo* in differentiated thyroid cells. Our knowledge of the function of Pax8 in the developing thyroid is still scarce. It has been demonstrated that in the absence of Pax8, the expression of both *Foxe1* and *Hhex* is strongly reduced in the precursors of follicular cells. Pax8 could then have a specific upper role in the regulatory pathway controlling the development of the thyroid.

Foxe1

Foxe1 is a transcription factor characterized by the presence of a forkhead domain as a DNA-binding domain. It is encoded by the *Foxe1* gene in mice and the *FOXE1* gene in humans, located on chromosomes 4 and 9q22, respectively. Early during development, at E 8.5, *Foxe1* is expressed along the whole foregut, at variance with TTF-1 and Pax8, whose presence in the gut is restricted to the thyroid anlage. *Foxe1* knockout mice display a perinatal lethal phenotype characterized by a severe cleft palate and athyreosis or ectopia of the thyroid. Analysis of thyroid development shows that in the absence of *Foxe1* at E 8.5, the thyroid anlage is specified, but at E 9.5, thyroid precursor cells are still on the floor of the pharynx, showing a clear defect of migration. At E 15.0, the *Foxe1* knockout embryos exhibit either a small sublingual thyroid remnant or no thyroid gland at all. Hence, *Foxe1* is absolutely necessary to promote migration of TFC precursors. Furthermore, *Foxe1* also could be implicated in the control of the survival of thyroid cells, as shown by the absence of thyroid in many *Foxe1* knockout mice.

Hhex

Hhex is a homeodomain containing the transcription factor encoded by the *Hhex* gene in mice and the *HHEX* gene in humans, located on chromosomes 19 and 10q23, respectively. During embryonic life, *Hhex* is present in the developing thyroid and in several organs derived from the foregut endoderm. In *Hhex* null embryos at E 8.5, the thyroid anlage is visible, but

already at E 9.5 the thyroid primordium is absent or hypoplastic and the expression of TTF-1, Foxe1, and Pax8 is down-regulated.

It is possible that Hhex is implicated in the regulation of the expression of TTF-1, Foxe1, and Pax8 in the thyroid primordium. Hhex could then be required to maintain the expression of these transcription factors in the thyroid.

Tshr

Tshr is a protein that belongs to the superfamily of G protein-coupled receptors encoded by the *Tshr* gene in mice and the *TSHR* gene in humans, located on chromosomes 12 and 14q31, respectively. Tshr is detected in the developing thyroid after the completion of the migration of the primordium, during the same stage at which Tg appears and before the first evidence of follicular organization in the gland.

In adults, thyroid-stimulating hormone (TSH) is the main physiological agent implicated in the regulation of the main functions of the thyroid and exerts its cellular effects by binding to Tshr. Inactivating mutations in this receptor cause severe hypothyroidism during postnatal life. During the early stages of thyroid development, a functional Tshr is not required but is necessary for the final step of follicular cell differentiation. Indeed, in the absence of a correct TSH/Tshr signaling, the expression of both TPO and NIS in TFCs is strongly down-regulated.

MOLECULAR GENETICS OF THYROID DYSGENESIS

In 85% of cases, permanent congenital hypothyroidism detected in newborns is due to impaired development of the thyroid. Defects in the mechanisms that allow the growth, survival, migration, or differentiation of the thyroid primordium can result in thyroid dysgenesis (TD). This term indicates an ectopic or hypoplastic thyroid (or both) as well as the absence of the gland.

It has been demonstrated that in some patients, TD is due to mutations in genes involved in thyroid development and already identified in mouse models such as *TITF1*, *PAX8*, *FOXE1*, and *TSHR*. These results confirm that the products of these genes are required for a correct thyroid morphogenesis (Table II).

TITF1

Some patients affected by a syndrome characterized by severe neurological disturbances, respiratory distress, and thyroid alterations have been found to carry heterozygous mutations within the *TITF1* gene. When tested *in vitro*, the various mutations described encode for proteins that do not display either functional activity or a dominant negative effect on the wild-type form. These data indicate that a reduced expression of TTF-1 is not compatible with the normal development of lungs, brain, and thyroid in humans. On the contrary, mice carrying only a

Table II Mouse and Human Phenotypes Following Inactivation of Some Genes Normally Expressed during Thyroid Development

| Protein | Gene | | Tissue expression | Phenotype | | Inheritance in humans |
|---------|--------------|--------------|--|---|---|-----------------------|
| | Mouse | Human | | Null mice | Patients carrying inactivating mutations | |
| TTF-1 | <i>Titf1</i> | <i>TITF1</i> | Thyroid Lung Brain Posterior pituitary | Thyroid and pituitary absent; severe defects in lung and diencephalon | Mild thyroid hypoplasia; respiratory distress; ataxia | Dominant |
| Pax8 | <i>Pax8</i> | <i>PAX8</i> | Thyroid Kidney | Thyroid absent | Thyroid hypoplasia | Dominant |
| Foxe1 | <i>Foxe1</i> | <i>FOXE1</i> | Thyroid Esophagus Palate Hair follicles Anterior pituitary | Thyroid absent or ectopic; cleft palate | Athyreosis; cleft palate; spike hair; choane atresia | Recessive |
| Tshr | <i>Tshr</i> | <i>TSHR</i> | Thyroid | Thyroid hypoplasia | Thyroid hypoplasia | Recessive |

functional allele of *Titf1* show a very mild, possible strain-dependent phenotype.

PAX8

Mutations in *PAX8* have been described in sporadic and familial cases of congenital hypothyroidism with TD. The phenotype of the patients ranges from mild hypothyroidism to severe hypoplasia of the thyroid. As in the case of TTF-1, all affected individuals are heterozygous from the mutated allele, and in the familial cases transmission is autosomal dominant. This dominant effect of *PAX8* mutations could be due to a gene dose requirement (haploinsufficiency). In these patients, the single functioning allele is not able to produce a sufficient amount of Pax8 to support the normal development of the gland.

FOXE1

Homozygous mutations in the *FOXE1* gene have been described in two pairs of siblings affected by Bamfort syndrome. This syndrome is characterized by cleft palate, bilateral choanal atresia, spiky hair, and congenital hypothyroidism with TD. The patients have been found to carry a homozygous missense mutation in the *FOXE1* gene, and because of this, the mutant protein was unable to bind DNA. All of the patients show athyreosis, whereas in mice the absence of Foxe1 causes either athyreosis or defects in thyroid migration. Because *FOXE1* mutations have been identified in only four patients, it is not known whether this discrepancy between humans and mice is significant or not.

TSHR

Mutations in the *TSHR* gene have been identified in patients affected by congenital hypothyroidism with thyroid hypoplasia and compensatory increased TSH secretion. The disease is inherited as an autosomal recessive trait, and the phenotype ranges from asymptomatic hyperthyrotropinemia to congenital hypothyroidism with severe hypoplasia of the thyroid. The different penetrance of the phenotype could be due to the amount of residual activity of the receptor as well as to the individual genetic background.

CONCLUSION

Although early in development TTF-1, Foxe1, Pax8, and Hhex are expressed in the thyroid primordium, none of them is essential for the initial steps of thyroid

morphogenesis. Genes required for thyroid anlage specification have not yet been identified. It is possible that the identification of the genes controlling TTF-1, Foxe1, Pax8, and Hhex expression can give us information on how thyroid precursor cells begin their differentiation. Mutations in genes involved during the initial steps of thyroid morphogenesis could be responsible for thyroid agenesis (i.e., absence of the formation of a thyroid anlage), a phenotype not found in any of the available animal models.

TTF-1, Foxe1, Pax8, and Hhex are transcription factors whose role is to control the expression of target genes that ultimately actuate a specific developmental program. The identification of these genes is still a matter of study. A number of cases of congenital hypothyroidism with TD could be due to mutations in genes that are targets of the transcription factors TTF-1, Foxe1, Pax8, and Hhex.

Most genes expressed in the developing thyroid are still expressed in the adult gland. The creation of animal models with a thyroid-specific, conditional knockout of these genes will be an invaluable tool in elucidating their role in a physiological context.

Figure 1 Schematic diagram of thyroid hormone biosynthesis and release. Subsequent metabolic steps are (a) iodide transport via the Na^+/I^- symporter (NIS) inhibited by ClO_4^- and SCN^- ; (b) oxidation of I^- to I^+ and iodination of tyrosine residues in thyroglobulin (Tg), and coupling of mono-iodotyrosine (MIT) and diiodotyrosine (DIT) to thyroxine (T_4) or triiodothyronine (T_3), catalyzed by thyroid peroxidase (TPO) and inhibited by propylthiouracil and methimazole; (c) colloid resorption, inhibited by lithium and I^- ; (d) proteolysis of Tg, inhibited by I^- ; (e) deiodination of MIT and DIT; and (f) deiodination of T_4 , inhibited by propylthiouracil.

or T_4). Approximately $150 \mu\text{g}$ of inorganic iodide is required daily for normal thyroid hormone biosynthesis. Iodine is an essential but rare element; it is mainly supplied in food, either naturally (especially in sea fish) or artificially, by the iodization of salt, bread, or milk. The thyroid gland accumulates iodide by an active energy-requiring transport mechanism: the Na^+/I^- symporter (NIS) is able to concentrate iodide from the serum against a large concentration gradient. Other proteins involved in thyroid hormone biosynthesis (schematically represented in Fig. 1) are thyroid peroxidase (TPO) and thyroglobulin. TPO (carbohydrate content 10%) contains four glycosylation sites that are important for the tertiary structure at the active site, and a prosthetic (heme) group; its main form is TPO-1 (103 kDa), but alternative splicing (by which exon 10 is spliced out) gives rise to the variant TPO-2 of 97 kDa, which is inactive with respect to iodination. Thyroglobulin is a large homodimeric glycoprotein (carbohydrate content 10%) containing 134 tyrosyl residues, of which 40 are available for iodination. Tyrosine residues 5, 1290, 2533, and 2746 are located in the amino terminus of the thyroglobulin molecule and are preferentially iodinated; these are known as the hormonogenic sites.

Once iodide is taken up in the thyrocyte, it rapidly moves to the apical surface and into the lumen. Thyroid hormone biosynthesis occurs within the thyroglobulin molecule at the apical surface. It involves two oxidative reactions, both catalyzed by

TPO located in the apical plasma membrane. The first is iodination of the tyrosyl residues in thyroglobulin, resulting in monoiodotyrosine and diiodotyrosine. The iodination requires prior peroxidation of I^- to form its more reactive form I^+ (or hypoiodite). The second is the coupling of iodotyrosines in the thyroglobulin: coupling of a donor diiodotyrosine residue to an acceptor diiodotyrosine results in T_4 and that of a donor monoiodotyrosine to an acceptor diiodotyrosine in 3,5,3'-triiodothyronine (T_3) (Fig. 2.) The hormonogenic sites are only partially used in the biosynthesis: under normal circumstances (at an iodine content of thyroglobulin of 0.5%, i.e., 26 atoms iodine per 660 kDa molecule of thyroglobulin), each thyroglobulin molecule contains 5 monoiodotyrosine, 4.5 diiodotyrosine, 2.5 T_4 , and 0.7 T_3 molecules. The thyroglobulin is stored in the colloid.

Release of T_4 and T_3 from the gland first involves resorption of stored thyroglobulin from the colloid. In a process called micropinocytosis, or coated vesicle-dependent endocytosis, there is an invagination of the apical plasma membrane into small vesicles, producing colloid droplets. The vesicles are transported to the basolateral surface of the thyrocyte via endosomes; internalized thyroglobulin that is poorly iodinated is, however, recycled back to the follicular lumen. Colloid droplets with highly iodinated thyroglobulin fuse with lysosomes. Intralysosomal peptidases catalyze the degradation of thyroglobulin, releasing T_4 , T_3 , monoiodotyrosine, and diiodotyrosine. Monoiodotyrosine

Figure 2 Structures of some iodotyrosines and iodothyronines.

and diiodotyrosine are deiodinated by an NADPH-dependent dehalogenase, and the liberated iodide is largely re-utilized for hormone synthesis, being only partly lost from the thyroid gland. The thyrocyte also contains 5'-deiodinase activity (type I), converting a small amount of hydrolyzed T₄ into T₃.

Thyroid hormone (and a small amount of thyroglobulin) is secreted from the basolateral surface of the thyrocyte into the circulation. Thyroxine is the main secretory product of the thyroid gland (~130 mol/day). Thyroidal T₃ secretion is much lower (~10 mol/day), providing only 20% of the daily T₃ production. Secretion of the inactive iodothyronine rT₃ (reverse triiodothyronine) is still smaller, because the conditions for its formation within the thyroglobulin molecule (requiring coupling of a donor diiodotyrosine residue to an acceptor monoiodotyrosine) are less favorable.

The iodide uptake in the thyrocyte, the iodide organification (i.e., the incorporation of iodine in tyrosines), and the formation of iodothyronines, the resorption of colloid, and the release of T₄, and T₃ are all stimulated by TSH. Specific transcription factors have been identified that bind to the promoter region of thyroglobulin and TPO genes: thyroid-transcription factors TTF-1 and TTF-2 (now called Foxe₁, Forkhead box e1) and PAX-8. They induce via transactivation expression of these genes, but they may also play a role in ontogenesis: during embryonic development they are expressed before thyroglobulin, TPO, and TSH receptor.

REGULATORY MECHANISMS

The activity of the thyroid gland is tightly regulated by feedback and feedforward control at the pituitary and hypothalamus. After being secreted into the bloodstream, thyroid hormone circulates predominantly bound to serum thyroid hormone binding proteins. Upon arrival at extrathyroidal target tissues, thyroid hormones enter cells via specific uptake mechanisms. Once inside the cell, thyroid hormones undergo a variety of metabolic reactions, most importantly deiodination. Thyroid hormone binds to specific nuclear binding sites, resulting in modulation of gene transcription.

hypothalamus–pituitary–thyroid axis, suppressing the production of thyroid-stimulating hormone (TSH or thyrotropin) in the anterior pituitary as well as that of thyrotropin-releasing hormone (TRH) in the hypothalamus. These signals lead to reduced hormone production by the thyroid. The central regulation of thyroid activity is therefore aimed at maintaining certain levels of thyroid hormone to ensure proper physiological function of virtually every tissue. Consequently, the general involvement of thyroid hormone becomes apparent only in disease states that lead to reduced or increased plasma hormone levels. Because of its diverse effects and essential role in normal physiology, thyroid hormone has been likened to a vitamin.

Perhaps not surprising, the mechanisms by which thyroid hormone exerts its myriad effects are complex and certainly not completely understood. A large number of processes are directly affected by thyroid hormone, but the full physiological effect is often the result of additional, secondary effects. As appears to be the case for various steroid hormones, nonnuclear actions may contribute to the full spectrum of direct effects of thyroid hormone, but evidence for this is relatively sparse. In contrast, following the seminal work of Tata and Oppenheimer in the 1960s and 1970s it was generally accepted by the early 1980s that regulation of gene expression, mediated by nuclear thyroid hormone receptors (TRs), is the principal mechanism of action of the hormone. The independent discoveries of multiple T_3 -binding nuclear receptors in 1986 opened the way to a detailed analysis of transcriptional regulation as the molecular basis of thyroid hormone action. This mode of action proves to be particularly complex, and together with an increasing amount of information on the role of local thyroid hormone metabolism in different tissues, it is becoming clear that thyroid hormone action can be modulated at the level of individual tissues throughout life.

EVOLUTION OF THYROID HORMONE ACTION

Information on the origins and earliest effects of thyroid hormone has increased our understanding of the effects in higher organisms. A brief overview of the evolutionary development of thyroid hormone action and its major effects is therefore given, followed by a description of the mechanisms of action and the tissue-specific effects of thyroid hormone in mammals, including man.

Synthesis of Thyroid Hormone in Invertebrates

Spontaneous iodination of tyrosine residues in proteins occurs in the iodine-rich marine environment. Subsequent coupling of two iodinated tyrosines and digestion of proteins may release iodothyronines, including T_4 and T_3 , and these thyroid hormones are indeed found in significant amounts in marine invertebrates. At least in some species of jellyfish, organification of iodine to form T_4 actually appears to play a role in the timing of the asexual reproductive cycle in a process called strobilation, which may be likened to metamorphosis in amphibians. T_4 production is therefore an ancient biochemical process with possibly a physiological role in the most primitive invertebrates, predating the evolution of specialized thyroid cells. Such cells are found in the immediate precursors of vertebrates, the protochordates (sea squirts). These cells actively form T_4 -containing proteins but are not yet organized in the typical thyroid follicle structure. Furthermore, release and subsequent absorption of T_4 appear to be dependent on digestion of the secreted proteins in the gut.

Synthesis of Thyroid Hormone in Vertebrates

Follicular thyroid cells, in which thyroid cells enclose a follicular lumen containing iodinated proteins (thyroglobulin), are found in the most primitive living vertebrates, the sea lampreys. At this point in evolution, thyroid cells have acquired a protein-digesting enzyme that allows the release of T_4 , and in adult lampreys the gland has become endocrine. Interestingly, during the larval stage of this organism, which lasts up to 5 years and constitutes the better part of its life, the thyroid cells are still nonfollicular and T_4 secretion is exocrine followed by absorption. Upon metamorphosis, these epithelial cells form thyroid follicles and secreted T_4 is then directly absorbed by the vascular system. Therefore, the development of the lamprey seems to recapitulate the evolutionary acquisition of the endocrine thyroid gland.

All vertebrates contain follicular thyroid cells, although the localization and organization into a discrete gland vary greatly, from scattered follicles in the subpharyngeal area in lampreys to follicles located mostly in the kidneys in fish, a disc-shaped gland next to the heart in turtles, two widely separated globules on either side of the trachea in birds, and a

bilobed gland connected by an isthmus straddling the trachea in lizards, as is also the typical structure of the thyroid gland in all mammals. Despite these differences, the circulating levels of free T_3 and T_4 are within one order of magnitude throughout the vertebrate lineage, with the exception of some species of fish.

Modes of Action and Effects of Thyroid Hormone in Invertebrates

The presence of T_4 or T_3 , particularly in marine organisms, is not proof of a physiological function given the spontaneous generation of iodothyronines under certain conditions. Nevertheless, iodothyronines appear to have effects in invertebrates as mentioned previously, although direct evidence for these effects is limited. A stronger case for a physiological role for thyroid hormone in primitive organisms is perhaps made by the presence of the specialized T_4 -producing cells in lampreys. This has interesting implications for the primordial mode of action of thyroid hormone. Phylogenetic analysis of the large family of DNA-binding nuclear receptors, of which the TRs are members, shows that the common ancestral proteins were DNA-binding factors without ligand-binding properties. The capacity to selectively bind hormones and other regulatory compounds evolved relatively late. In the case of the thyroid receptors, it appears to have occurred during the development of the vertebrate lineage. The earliest effects of thyroid hormone must then be assumed to be extranuclear, and this mode of action may still be relevant in higher organisms.

Modes of Action and Effects of Thyroid Hormone in Vertebrates

Development of the large diversity of effects in vertebrates is linked to the adaptive progression of tissue distribution of the T_3 receptors (TRs) and mutations within the receptors allowing interactions with other DNA-binding proteins or accessory factors. Genes may have developed thyroid hormone responsiveness by acquiring the specific sequence in their promoter region that is required for binding of TRs. In contrast, the part of the receptor that recognizes this six-base pair sequence is highly conserved in this family of receptors and therefore not a factor in the diversification of T_3 action. Further development of (variable) tissue responsiveness is probably also linked to the evolving expression patterns of the thyroid

hormone-metabolizing deiodinases, which are present throughout the vertebrate lineage.

Growth and Development

The receptor-mediated effects of thyroid hormone on growth and development are evident in all vertebrates. The most striking of these is the transition of the larval amphibian from an aquatic vegetarian organism to a terrestrial carnivore. This experiment can be done with a salamander by simply adding T_4 to the aquarium water. The ensuing metamorphosis leads to radical changes in the appearance of the animal, including replacement of the fin-like tail and appendages with legs and claws and a round tail; replacement of a smooth skin with a thicker keratinized skin; the loss of gills and acquisition of lungs; development of eyelids; complete restructuring of the mouth, tongue, and intestinal tract to allow a mostly carnivorous diet; and numerous biochemical changes to accommodate a different respiratory and metabolic physiology. The increase in thyroid activity and thyroid hormone levels at metamorphic climax in amphibians triggers and sustains the process. Cells in all tissues undergoing metamorphic changes express TRs, and thyroid hormone induces or represses the expression of many genes. In addition, responsiveness of tissues is actually increased by T_3 -dependent stimulation of the expression of TRs, as is the case in the restructuring of the tail. A surge in thyroid hormone levels is similarly critical in early growth and differentiation in fish, reptiles, and birds. All these effects have their counterparts in the fetal and perinatal development in mammals, particularly with respect to brain development. In humans, the critical involvement of thyroid hormone is illustrated by the striking and mostly irreversible effects of congenital hypothyroidism on growth, metabolism, reproduction, and mental development (cretinism). The surge in T_3 and T_4 levels reaches its peak in humans during the first 2 months after birth, coinciding with the phase of maximal cortical growth. This growth spurt starts during the third trimester when fetal thyroid activity increases and the dependence on maternal thyroid hormone wanes. However, thyroid hormone is required for central nervous system development beginning in the 10th week of fetal life, coinciding with the appearance of TRs in neuronal tissue. Relatively low levels of thyroid hormone are essential throughout intrauterine development to ensure proper timing and progression of the various phases of brain development. Studies in rats show that T_4 levels are critical because neurons preferentially take up this iodothyronine and then convert it to T_3 .

Metabolism

The basal metabolic rate (BMR), which is the sum of all energy-consuming processes of an individual when completely at rest, is reduced in humans by 40% in hypothyroidism, whereas it is increased by 50% in hyperthyroidism. Thyroid hormone has essentially the same stimulatory effect on metabolism and concomitant O_2 consumption in other mammals and birds. It was previously thought that this effect played a crucial role in the evolutionary development of endothermy since metabolism in cold-blooded animals appeared unresponsive to thyroid hormone. However, this effect proved dependent on body temperature and the BMR of fish, amphibians, and reptiles is similarly responsive to T_3 , albeit the extent of the effect is somewhat less than in mammals. Thyroid hormone does not appear to play a major role in thermoregulation in warm-blooded animals, and the effect on energy turnover, and hence heat production, is considered to be a second-order phenomenon.

The T_3 -dependent stimulation of the BMR is the sum of increased energy consumption and substrate metabolism. The major energy-consuming processes in all tissues at rest are maintenance of the mitochondrial proton (H^+) gradient; maintenance of the gradients of calcium (Ca^{2+}), sodium (Na^+), and potassium (K^+) over various cellular membranes; and synthesis of DNA, RNA, and proteins. The effect on the BMR is not primarily the result of the stimulation of a single process, as has long been maintained for the effect of thyroid hormone on the sodium–potassium pump ($Na^+K^+ATPase$). Cellular ion homeostasis is nevertheless an important aspect of the effect of thyroid hormone on the BMR. This homeostasis involves the energy-dependent transport of Ca^{2+} , Na^+ , and K^+ ions against gradients across the plasma membrane, as well as across intracellular membrane systems in the case of Ca^{2+} , to maintain their critical cytosolic concentrations. These processes account for a considerable part of the metabolic rate in mammals due to the passive and facilitated leak of ions through membranes. The expression and activity of the major ion-pumping ATPases are stimulated by thyroid hormone, as are the passive-leak characteristics of membranes. The proliferation of some intracellular membranes is also increased by thyroid hormone, and together these effects result in increased ion fluxes and ATP consumption. Proliferation of mitochondria as well as their capacity for oxidative phosphorylation are also stimulated by thyroid hormone, ensuring sufficient ATP production to meet the greater demand due to increased ion cycling and other processes.

To fuel the extra ATP turnover, thyroid hormone increases the rate of glucose production by the liver and increases the availability of the necessary substrates—amino acids, glycerol, and free fatty acids from proteins and fat. Thyroid hormone stimulates the breakdown of protein and fat, but at the same time it stimulates the synthesis of these compounds. This cycling of substrates, which consumes a considerable amount of energy, appears futile, but it allows for the regulated liberation of the substrates mentioned previously.

Which Iodothyronines Are Active in Mammals?

T_4 and T_3

The thyroid produces mainly T_4 , whereas 80% of circulating T_3 results from peripheral enzymatic deiodination of T_4 , predominantly in the liver. The protein-bound and free plasma levels of T_4 in all species that have been studied are substantially higher than those of T_3 . In humans, the difference is approximately 40-fold for total hormone and 5-fold for free hormone. Nevertheless, as noted previously, T_3 is considered to be the active form of thyroid hormone in mammals. Although T_4 can affect the expression of thyroid hormone-responsive genes, the affinity of the thyroid hormone receptors for T_4 is considerably lower compared to that for T_3 . In some thyroid hormone effects, such as the effect on neurons and the down-regulation of pituitary TSH production, T_3 cannot substitute for T_4 and T_4 appears to be the active form. In the latter case, as in neurons, the genes encoding the TSH α and TSH β subunits are indeed responsive to T_3 , but the pituitary cellular T_3 content is determined by T_4 uptake and subsequent deiodination rather than by the plasma T_3 levels.

Other Iodothyronines

Progressive deiodination of T_4 and T_3 by the three known deiodinases gives rise to a number of different triiodothyronines and diiodothyronines. Of these, reverse T_3 (3,3',5'-triiodothyronine) and 3,5- T_2 (3,5-diiodothyronine) have also been shown to elicit T_3 -like effects. Because the affinity of the TRs for these compounds is negligible and the effects do not require *de novo* protein synthesis, the mechanism of action must be extranuclear. In the case of stimulation of mitochondrial activity by 3,5- T_2 , it was indeed shown to involve a direct interaction of this iodothyronine with mitochondrial enzymes.

Enzymatic removal of the amino group (deamination) of T_4 and T_3 gives 3,5,3',5'-tetraiodothyroacetic acid (Tetrac) and 3,5,3'-triiodothyroacetic acid (Triac), respectively. Tetrac can be deiodinated to Triac, and Triac has an even higher affinity for TRs than T_3 . When administered at concentrations comparable to those of T_4 and T_3 , these compounds show T_3 -like effects.

Although it cannot be ruled out that in certain circumstances cellular concentrations of these metabolites may reach levels high enough to elicit significant effects, they are generally considered to be of little or no physiological relevance based on the known low plasma concentrations.

MECHANISMS OF THYROID HORMONE ACTION

In the following sections, the mechanisms of the primary actions of thyroid hormone are presented (i.e., those mediated by T_3 receptors and those that may involve direct interaction with a target). Additional actions may include effects on the stability of specific proteins or the messenger RNAs (mRNAs) encoding these proteins. However, there are few examples, and

the mechanism is not understood. Figure 1 summarizes the modes of action that are discussed here.

Extranuclear Action

Stimulation by T_4 and T_3 of the activity of the plasma membrane Ca^{2+} -pump (Ca^{2+} -ATPase) in red blood cells, which do not have a nucleus, is the best documented example of an extranuclear thyroid hormone effect. The *in vitro* effects correlate with increased activity of this enzyme in erythrocytes taken from hyperthyroid patients and decreased activity in those from hypothyroid patients. *In vitro* and *in vivo* studies also show that T_3 and T_4 stimulate glucose uptake in a variety of tissues, increase heart rate, and induce vasodilation, with effects appearing within minutes. Similarly, in various cultured cell types, the addition of physiological amounts of T_3 or T_4 almost instantly stimulates Ca^{2+} influx or the activity of proteins involved in cellular signaling processes. These effects, however, are transient and it is not clear whether they are relevant under normal conditions. The molecular mechanism underlying the mostly membrane-associated rapid effects is also unclear. There is evidence of a direct interaction of T_3 or T_4 with membrane-bound proteins, thereby altering their properties. Based on a large body

Figure 1 Modes of action of thyroid hormone. T_4 and T_3 are actively taken up by the cell by specific transporters. Deiodinases (DI) can convert T_4 to T_3 , adding to the cellular T_3 pool. T_3 binds to its nuclear receptor (TR) on the promoter of a T_3 -responsive gene and activates transcription of the gene by RNA polymerase (POL). Messenger RNAs (mRNA) are translated into protein constituents of the cell, including mitochondrial proteins. Extranuclear actions are indicated by dashed arrows. T_4 and T_3 may affect substrate uptake or ion fluxes across the outer membrane by direct interaction with the transport proteins or its lipid environment. The activity of mitochondrial enzymes may be similarly affected. Transcription and expression of genes encoded by mitochondrial DNA may be modulated by T_3 through specific TRs in mitochondria.

of data, an alternative hypothesis proposes that T_3 and T_4 affect membrane properties in a less specific way by becoming part of it. The physicochemical properties of the molecules are such that the lipophilic, iodinated phenolic part inserts readily in the outer leaflet of the lipid bilayer, whereas the hydrophilic amino and carboxyl groups prevent the molecule from crossing the membrane (it is for this reason that specific thyroid hormone transporters are required for cellular uptake). This partitioning in the membrane at normal levels of T_3 and T_4 reduces its fluidity, and this will affect the activity of membrane-associated enzymes.

Such a mechanism may also account for the immediate effects of T_3 and T_4 on many mitochondrial membrane-bound enzymes, although this is a matter of debate. Irrespectively, the number of mitochondria, mitochondrial membrane density, and mitochondrial activity generally increase with increasing thyroid activity. This may in part be a secondary response to greater ATP demand. However, the presence of high-affinity thyroid hormone-binding proteins in the inner mitochondrial membrane in hormone-responsive tissues, but not in refractory tissues such as testis and spleen, suggests a unique pathway of thyroid hormone action in mitochondria. These proteins are known to be truncated forms of the TR- α protein and indeed act as T_3 -dependent transcription factors of genes encoded in the mitochondrial genome. Apart from this relatively rapid receptor-mediated action, several nuclear-encoded mitochondrial enzymes are regulated via nuclear TRs.

Changes in thyroid status also lead to alterations in the lipid composition and properties of membranes, most notably affecting the saturation of fatty-acyl chains of the phospholipids. Such changes have also been shown to affect membrane-associated enzymes. These lipid alterations are thought to be related to the effects of thyroid hormone on the expression of lipid desaturases. Any subsequent effects on membrane-associated processes are therefore secondary to a nuclear-mediated action of the hormone.

Receptor-Mediated Nuclear Action

There are two known genes for thyroid hormone receptors (i.e., TR- α and TR- β). Multiple receptor isoforms and related proteins are expressed through alternative splicing of mRNAs. Of these, TR- α_1 , TR- β_1 , TR- β_2 , and TR- β_3 are bona fide TRs in that they bind T_3 and confer transcriptional regulation of target genes. Other forms, such as TR- α_2 (DNA binding but not hormone binding) and the Δ TR- α / Δ TR- β forms (hormone binding but not DNA binding), can act

as dominant negative factors interfering with TR action. These factors may increase the capacity for tissue-specific fine-tuning of thyroid hormone effects. Some *in vivo* data support such a role, but the precise physiological relevance in different tissues is unknown.

Studies of receptor knockout mice lacking either functional TR- α or TR- β receptors indicate a large degree of redundancy between both isoforms. The molecular mechanism of transcription regulation is considered identical for the TR- α and TR- β isoforms, which is supported by *in vitro* analyses. Some isoform-specific effects are observed in knockout mice as well as in cases of TR- β mutations in humans, including cardiac pacemaking (TR- α_1), development of hearing (TR- β_1), and thyroid hormone feedback regulation (TR- β_2). These dependencies reflect tissue-restricted expression of TRs rather than gene-specific regulatory mechanisms.

Regulation of Gene Transcription

Transcription of a gene's DNA into mRNA requires recruitment of the RNA polymerase complex to general transcription factors that are already bound to the promoter region of the DNA, immediately upstream of the coding sequence. The rate of expression of a gene is basically determined by the ease with which these complexes are formed. Promoter activity and transcription rate are therefore terms that describe the frequency with which transcription of a gene is initiated following assembly of the complex. Gene transcription is primarily modulated by factors that either facilitate and stabilize the assembly of the transcription machinery or disrupt it. The RNA polymerase complex that transcribes the gene is exceptionally large, containing more than 100 different proteins. In contrast, nuclear DNA in its compact form is not readily accessible for such large complexes. Every 200-base pair stretch of DNA is wrapped around a disc-shaped histone protein complex forming a string of so-called nucleosomes that compact the DNA further by combining with other proteins. The resulting chromatin structure, however, is dynamic and can be made accessible to large DNA-binding complexes by modification of the histone proteins. Addition of acetyl groups to histones relaxes the chromatin structure, whereas deacetylation closes it. Two classes of enzymes are responsible for this reversible chemical modification: histone acetyl transferases (HATs) and histone deacetylases (HDACs). These proteins are key factors in the regulation of gene expression because they can be recruited by transcription factors, including nuclear hormone receptors.

Thyroid Hormone Response Elements

The TRs belong to the large family of ligand-dependent transcription factors, which includes receptors for steroid hormones, retinoic acid and related retinoids, and vitamin D. Specific DNA sequences (response elements) are required in the promoters of genes to allow binding of these receptors, making the gene hormone responsive. Receptors in this family recognize the six-base pair element AGGTCA and interaction of two receptors (dimerization) is typically required for functional activity. The DNA motif to which each receptor binds is consequently referred to as a half-site, and the spacing and orientation of the half-sites determine receptor specificity of the response element. In the case of TRs, the optimal arrangement of half-sites in a thyroid hormone response element (TRE) is either a direct repeat spaced by four base pairs, a palindrome, or an everted repeat with a six-base pair gap (Fig. 2).

Deviations from the optimal half-site sequence and, to a lesser extent, from the optimal spacing between them are common in naturally occurring TREs. This variation is responsible for large differences between TREs in TR-binding affinity and stimulation of promoter activity. The relaxed constraints placed on TRE structures are evident in Fig. 3, which shows several natural TREs. TREs often consist of three or four half-sites allowing for binding of additional TRs, which further increases promoter activation. In addition, a promoter may contain several TREs contributing to the overall T_3 responsiveness.

TRs readily form heterodimers on TREs with the retinoid X receptor (RXR) with greater binding affinity than that of TR homodimers. Transcription activation by T_3 is also higher, requiring no ligand for RXR. RXRs are also considered the natural partner for TRs

Figure 2 The optimal half-site for TR binding is depicted as in double-stranded DNA. Only the top strand of DNA is depicted in the three TREs that confer high T_3 responsiveness to a promoter. The arrows indicate the orientation of half-sites in a TRE, and “n” can be G, A, T, or C. The hexamer sequence and optimal half-site arrangements are derived from studies of synthetic TREs.

in vivo because of the ubiquitous presence of these proteins.

Interactions between different hormone receptors within the family are possible given their similar structure and DNA-binding properties. *In vitro* studies support this, showing, for instance, that estrogen receptors can interfere with TR action on T_3 -responsive promoters, whereas TRs can bind to and block estrogen response elements. This so-called crosstalk may be relevant in tissues in which both hormone signaling routes are active, such as the hypothalamus in this example, but *in vivo* data are lacking.

Stimulation of Gene Transcription by T_3

One aspect of TRs that is unique in the nuclear receptor family is the fact that TRs and TR-RXR heterodimers are bound to TREs in the unliganded state, whereas the other receptors require ligand for DNA binding. Furthermore, binding of unliganded TRs results in a substantial repression of basal promoter activity. Activation of transcription is induced by binding of T_3 to the TR. This not only relieves the repression but also further stimulates promoter activity. Figure 4 summarizes the current model of the *in vivo* molecular mechanism underlying this action of T_3 . The essential classes of factors involved are depicted, but different proteins exist within each class, some of which show tissue-specific expression. Transcription is repressed in the absence of T_3 because the TR recruits a histone deacetylase to the promoter by means of a ubiquitous corepressor protein that serves as an adapter, having binding sites for both TR and the HDAC protein. Binding of T_3 induces a marked conformational change in the TR, which disrupts binding of the corepressor complex. Instead, binding of coactivator proteins is now possible. Several such proteins form a complex with histone acetylase activity. This in turn opens up the local chromatin structure, allowing the assembly of an active transcription complex. Additional direct interactions of the TRs with basal transcription factors appear to further facilitate this process.

Inhibition of Gene Transcription by T_3

The mechanism of T_3 -induced repression of transcription, such as in the case of the TSH- α , TSH- β , and TRH genes, is not understood. Corepressors and coactivators appear to be equally involved in this mode of regulation but with exactly opposite effects compared to the positively regulated genes (i.e., unliganded TRs stimulate transcription, which is abolished after T_3 binding). Although TRE-like binding sites or even single half-sites have been implicated in

Figure 3 A selection of natural TREs illustrating the variation in half-site sequence and spacing between half-sites. All indicated half-sites are functional in these TREs and the invariable central two Gs (Cs) are essential for TR binding. TREs from the rat growth hormone gene and the Ca²⁺-ATPase gene from rat skeletal muscle are examples of composite response elements. Both TREs from the human TRβ promoter contribute to the T₃ responsiveness of this gene. The TRE from the rat TSHα gene is an example of a half-site structure conferring a negative T₃ response.

some down-regulated promoters, a consensus negative TRE has not been defined.

Many genes are expected to be directly regulated by T₃ based on the responsiveness of expression under various conditions. The list of promoters that are shown to contain functional TREs is continuously growing. A selection of such genes are presented in [Table I](#) together with a short description of the function of each gene.

EFFECTS OF THYROID HORMONE ON TARGET TISSUES

The large number of different processes, factors, and mechanisms summarized in the previous sections provide an explanation for the variety of tissue-specific actions of thyroid hormone. The responsiveness of tissues with respect to transcription of specific genes is dependent on the mix of TRs and their numerous cofactors, the details of which are poorly understood. Furthermore, the rate of cellular T₃ and/or T₄ uptake and local activity of hormone-metabolizing deiodinases will determine a tissue's T₃ concentration. As noted previously, many of the physiological effects of altered thyroid hormone levels are secondary to a limited number of direct actions of T₃, and a large-scale analysis of gene expression indicates that the current list of genes that are directly regulated by T₃ is far from complete.

The effects of thyroid hormone on some of the major responsive tissues, based on both clinical and animal

experimental data, are described in the following sections. The emphasis is on the effects for which the primary targets of thyroid hormone are known.

Brain

The development of the central nervous system is severely impaired in the absence of sufficient levels of thyroid hormone. The incomplete maturation of the brain is evidenced by neurological defects and mental retardation in humans. The timing of connections between axons, dendrites, and their targets in the developing brain is critical for the formation of the neuronal network. Diminished axonal growth and reduced dendritic arborization are evident in cerebral cortex, hippocampus, and cerebellum and in the visual and auditory cortex of hypothyroid rats. The expression of many genes is dependent on T₃, but only a few have been shown to be directly regulated, such as myelin basic protein and brain-derived neurotrophic factor. The action of T₃ on the other genes may in part be permissive, which means that T₃ is essential for the action of another factor. For example, the stimulation of expression of ornithine decarboxylase by growth hormone (GH) in the brain is absolutely dependent on thyroid hormone. This enzyme is essential in nucleic acid and protein synthesis, and thyroid hormone alone has no effect on its expression. Interestingly, in hypothyroidism all enzymes that are dependent on thyroid hormone eventually reach normal levels of expression. It therefore appears that

Figure 4 Model of the T₃-dependent stimulation of transcription in a T₃-responsive gene. (A) Basal or repressed state in the absence of T₃. DNA is in its compacted form wound around histone proteins (nucleosomes) and bound to other ubiquitous proteins (not depicted). TR-RXR dimers are bound to the TRE. TR forms a complex with a protein with histone deacetylase activity (HDAC), which maintains the compact structure. The interaction is through a corepressor protein (CoRepr). (B) Activation. The corepressor complex is replaced by coactivator proteins (CoAct) upon binding of T₃ to its receptor. Histone acetylase activity (HAT) in the CoAct proteins opens up the nucleosome structure. The TATA box-binding protein (TBP) is a general transcription factor that binds to the DNA sequence TATA at the transcription initiation site. (C) Transcription. Following assembly of multiple general transcription factors (TF), which is stabilized by proteins that interact with the TR complex, the RNA polymerase complex (POL) is recruited to the promoter and transcription ensues.

the timing of thyroid action is critical, and that there is a transient period of hormone responsiveness during the development of the brain.

Bone

Development and growth of bone are critically dependent on thyroid hormone, as evidenced by the typical short stature of adults when neonatal hypothyroidism remains untreated. The cell types that are involved in bone formation (osteoblasts) and bone resorption (osteoclasts) are both stimulated by T₃, with effects on several critical enzymes. In hyperthyroid patients, increased bone formation and resorption result in a net loss of bone thickness and increase in porosity, leading to greater risk of fractures. Little

is known about the primary targets and mechanism of action of T₃ in bone cells, mainly because these cells are difficult to study in culture. Thyroid hormone is required for the effects of GH on bone growth and development, which involve the production of insulin-like growth factor 1. Some of the effects of T₃ may therefore result from this permissive action of thyroid hormone. However, studies using TR knockout mice indicate that many of the effects of T₃ on bone metabolism are nuclear mediated and independent of GH.

Heart

Cardiovascular effects are among the most prominent clinical manifestations of thyroid disease. The expression of key cardiac proteins is dependent on thyroid hormone, as evidenced by the profound changes in cardiac performance in the transition from hypothyroidism to hyperthyroidism. Thyroid hormone directly regulates the expression of genes involved in membrane depolarization, muscle contraction, Ca²⁺ handling, and adrenergic signaling (Table I). These actions include positive and negative regulation of transcription. In addition, extranuclear effects on membrane ion fluxes contribute to the increase in heart rate and a reduction in vascular resistance. All these effects combine to increase the performance of the heart, with a concomitant increase in energy turnover. A key factor is the stimulation of the Ca²⁺-pump of the sarcoplasmic reticulum (SR), whereas its inhibitory protein phospholamban is reduced. The SR membrane system is the intracellular store for Ca²⁺ required for each contraction. The higher Ca²⁺-pump activity increases the amount of Ca²⁺ that can be released from the SR as well as the speed with which it can be taken up again during relaxation. The result is an increased contractile capacity of the heart. Together with the increase in heart rate, the hemodynamic load placed on the heart increases with higher T₃ levels. Such mechanical load is a major independent stimulus for growth of the heart and responsible for the progressive cardiac hypertrophy seen with increasing thyroid hormone levels. The combined effects of T₃ on cardiac function and vascular resistance result in an increase in cardiac output adapted to the higher overall metabolic demand made by the organism.

Skeletal Muscle

The overall effect of thyroid hormone on skeletal muscle is similar to that described previously for the

Table I Genes Known to be Transcriptionally Regulated by Thyroid Hormone^a

| | Gene function |
|---|---|
| Gene transcription stimulated by T₃ | |
| BDNF | Brain-derived neurotropic factor. Stimulation of expression of this brain-specific regulatory factor may in part explain the critical role of thyroid hormone in brain development. |
| Myelin basic protein β ₁ -Adrenergic receptor | Major protein component of the insulating myelin sheaths surrounding axons. Stimulation of expression of this receptor accounts for the potentiating effect of thyroid hormone on the adrenergic responsiveness of many tissues, such as liver, fat, skeletal muscle, and heart. |
| TR-β ₁ | Thyroid hormone receptor β ₁ . Stimulation of expression of this TR is particularly important for the timing of brain development. |
| HCN2 | Hyperpolarization-activated cyclic nucleotide-gated channel. Cardiac ion channel involved in pacemaker activity. |
| MHC-α | Myosin heavy-chain α. One of the two ATPase proteins responsible for cardiac contraction. MHC-α imparts faster contraction at higher energy consumption than MHC-β. MHC-β is the predominant isoform in human heart. |
| SERCA2a | Sarcoplasmic reticulum (SR) Ca ²⁺ -ATPase. Ion pump that regulates intracellular calcium, playing a key role in the contraction-relaxation cycle of the heart. SERCA2a is also expressed in skeletal muscle. |
| SERCA1 | Isoform of SERCA2a but exclusively expressed in skeletal muscle. It can be expressed at much higher levels than SERCA2a and its activity may account for up to 50% of the total energy consumption of contracting muscle. |
| GLUT4 | Insulin-responsive glucose transporter. Responsible for insulin-stimulated uptake of glucose, particularly in skeletal and cardiac muscle and adipose tissue. |
| PEPCK | Phospho-enol-pyruvate carboxy kinase is a key enzyme in gluconeogenesis in liver and skeletal muscle. |
| Malic enzyme | Malic enzyme, or malate dehydrogenase, catalyzes the last oxidation step in the citric acid cycle in mitochondria. |
| Cholesterol hydroxylase | Cholesterol 7α-hydroxylase is a key enzyme in the hepatic degradation of cholesterol into bile acids. |
| Na ⁺ /K ⁺ -ATPase | Ubiquitous ion pump in the plasma membrane of cells responsible for maintaining the gradients of sodium and potassium between the extracellular and intracellular space. |
| MyoD and myogenin | Two different transcription factors that drive the expression of many muscle-specific genes during the differentiation of skeletal muscle (myogenesis). |
| rGH | Rat growth hormone. The TRE in this pituitary gene was the first to be analyzed in detail. A similar TRE has not been identified in the human GH gene. |
| Deiodinase type 1 | This enzyme is responsible for the peripheral production of T ₃ through deiodination of T ₄ . It is primarily expressed in liver and kidney. |
| UCP1 | Stimulation of expression of uncoupling protein 1 is responsible for the T ₃ -induced thermogenic response in brown adipose tissue. It uncouples mitochondrial respiration, thereby converting oxidative energy directly to heat. |
| Gene transcription inhibited by T₃ | |
| MHC-β | Myosin heavy-chain β. Slower and more energy-efficient isoform of the two myosin ATPases responsible for cardiac contraction. The hypothyroid rodent heart expresses almost exclusively MHC-β, which is nearly completely replaced by MHC-α in hyperthyroidism. This shift occurs to some extent in the hyperthyroid human heart. |
| TSH-α and-β | Both anterior pituitary genes encoding the α- and β-subunits of thyroid-stimulating hormone (TSH or thyrotropin) are negatively regulated by thyroid hormone. This is part of the negative feedback loop regulating plasma thyroid hormone levels. |
| TRH | Thyrotropin-releasing hormone, synthesized in the hypothalamus, is the principal positive regulator of TSH synthesis. Repression of transcription of this gene is another aspect of the feedback inhibition of thyroid hormone production. |

^aOne or more TREs have been identified in the promoters of these genes.

heart: that is, an increase in performance at the expense of a higher energy turnover. Stimulation of the rates of contraction and relaxation by thyroid hormone is a classic observation in thyroidology. Changes in expression of genes similar or identical to those in cardiac tissue underlie this effect, but multiple isoforms and cell-specific and innervation-dependent factors make for a less straightforward regulation by T_3 . Generally, T_3 induces a shift in the expression of myosin-ATPase proteins, which determine the rate of contraction, from the slow myosin heavy-chain form (MHC I) to faster MHC II forms. MHC I is identical to MHC- β in heart and this gene is also negatively regulated in skeletal muscle by T_3 at the promoter level. Direct regulation is not established for the multiple MHC II forms that are similar, but not identical, to cardiac MHC- α . As in heart, the relaxation rate is determined by the level of expression of the Ca^{2+} -pump of the SR. Muscle also expresses the SERCA2 form present in the heart, but T_3 preferentially stimulates the expression of a second isoform (SERCA1). This protein is virtually identical to the SERCA2 form, but the promoter of the SERCA1 gene is completely different, with different TREs allowing much higher expression of the protein compared to the SERCA2 form. Proliferation of the SR membrane is also stimulated by T_3 . The expression of the fast MHC isoforms and the high Ca^{2+} -pump levels increase the energy cost of contraction two- or threefold in the transition from hypothyroidism to hyperthyroidism. The economy of force production is consequently reduced by T_3 since absolute force production is not affected by these changes.

The timing of expression of a series of fetal and adult MHC isoforms during development is dependent on thyroid hormone. Similar to brain, the adult expression patterns are ultimately obtained irrespective of the thyroid status. This is not the case for the SERCA1 gene, which is absolutely dependent on thyroid hormone. Effects of neonatal hypothyroidism on muscle development in rats are fully reversible by treatment with thyroid hormone.

Liver

Plasma levels of cholesterol, particularly low-density lipoprotein (LDL) cholesterol, are increased in hypothyroid patients. This is the result of decreased LDL cholesterol uptake by the liver (due to reduced LDL receptor numbers) and reduced hepatic metabolism of cholesterol. These effects can be reversed by treatment with thyroid hormone. The enzyme cholesterol 7 α -hydroxylase is the rate-limiting step in the degradation

of cholesterol into bile acids, and its expression is stimulated by T_3 at the promoter level. Whether the expression of LDL receptors is also directly stimulated by T_3 is not known.

T_3 stimulates the expression of a number of enzymes involved in lipogenesis, including malic enzyme, glucose-6-phosphate dehydrogenase, and fatty acid synthase. Malic enzyme is particularly responsive and the promoter of this gene contains a strong TRE. Interestingly, the same enzyme is expressed in brain, but it is unresponsive to T_3 . In liver, several signal routes involved in energy metabolism, such as insulin signaling, converge on the promoter of this gene and interact with the T_3 signal. For instance, the stimulatory effect of T_3 on malic enzyme expression is increased 10-fold when a normal diet is replaced by a high-carbohydrate/fat-free (lipogenic) diet.

Synthesis of glucose (gluconeogenesis) from precursors such as amino acids and glycerol is an important liver function. T_3 stimulates the expression of key enzymes in this process, including pyruvate carboxylase, glucose-6-phosphatase, and phospho-enol-pyruvate carboxy kinase (PEPCK). A TRE has been identified in the promoter of the PEPCK gene.

In addition, T_3 stimulates the expression of the deiodinase type I gene, which converts T_4 to T_3 . This enzyme is responsible for most of the circulating T_3 in the body and its promoter contains several TREs.

Adipose Tissue

Differentiation of preadipocyte cells into mature white adipose tissue is dependent on thyroid hormone, and the same key enzymes involved in lipid metabolism in liver are influenced by T_3 in fat tissue. High levels of T_3 shift the balance between fat synthesis and breakdown to net lipolysis, resulting in generalized fat mobilization and loss of body fat stores. Although brown adipose tissue (BAT) is virtually absent in adults, as it is in most larger mammals, newborns have appreciable amounts of this type of fat tissue. It gets its color from the cytochromes in mitochondria, which are particularly abundant in these fat cells. In rodents, BAT is the site of the thyroid hormone-dependent extra heat production in response to prolonged cold exposure. Circulating thyroid hormone levels do increase, but this is not essential for cold adaptation and the action of the hormone appears to be permissive. Surprisingly, however, the adipocytes greatly increase their T_3 content by increasing the expression of deiodinase type II. Like type I, this enzyme converts T_4 to T_3 and its expression is stimulated by the higher levels of

circulating adrenergic hormones triggered by the cold stress. The increase in T_3 in the brown adipocyte in turn induces the transcription and expression of a protein called thermogenin or uncoupling protein 1, which uncouples respiration in mitochondria. This means that the energy produced by the numerous mitochondria in these cells is not stored in the form of ATP but rather directly released as heat. This mechanism is equally important in maintaining body temperature in newborns and it is an example of how thyroid hormone action may be regulated at the level of individual tissues.

Deiodinase activity in the pituitary thyrotroph cells controls the negative feedback regulation of thyroid hormones on thyrotropin synthesis and secretion.

INTRODUCTION

The roles of the essential trace element iodine and of the thyroid gland for development and normal function of vertebrate organisms, including humans, have been known for a long time, but it was not until 1915 that iodine containing prohormone thyroxine (T_4) was isolated by Edward C. Kendall. Charles R. Harington and George Barger performed the structure analysis and chemical synthesis of T_4 in 1927, and in 1952 Jack Gross and Rosalind Pitt-Rivers identified the bioactive thyroid hormone 3,3',5-triiodothyronine (T_3), the "real thyroid hormone" (Fig. 1). Various enzymes metabolizing the amino acid-derived thyroid hormones have been characterized during the past 60 years. These enzymes generate a complex pattern and network of T_4 -derived iodothyronine metabolites, some of which have specific biological functions that differ from those of the bioactive thyroid hormone T_3 . T_3 exerts its influence mainly by modulation of action of the ligand-dependent transcription factors, the nuclear T_3 receptors (TRs). In addition to this key mechanism of action, several other biological effects of T_4 and iodothyronines derived therefrom have been reported. However, these effects are less well characterized (e.g., activation of processes associated

with the plasma membrane of cells, modulation of the organization of the cytoskeleton, or direct influence of iodothyronines on mitochondrial function). Iodothyronines comprise iodinated metabolites of the prohormone T_4 that have an intact diphenylether structure that is generated by coupling of two iodinated tyrosines residues of thyroglobulin during biosynthesis of the hormone in the thyroid gland. The only source of T_4 is the thyroid gland, whereas the other iodinated metabolites are formed intracellularly in various organs and tissues. T_4 is a highly hydrophobic, lipid-soluble compound that circulates in the blood bound to three main transport or distribution proteins: thyroxine-binding globulin (TBG), transthyretin (TTR), and albumin. T_4 and its metabolites are excreted mainly via the bile and the feces. Iodide liberated from the iodothyronine metabolites by enzymatic deiodination, together with the fraction of iodide taken up by food, is excreted into the urine. Urinary iodide concentrations provide an indicator of the iodine supply of the organism.

T_4 and the iodothyronines are derivatives of the amino acid tyrosine and carry ionic charges in solution. Therefore, efflux of T_4 and T_3 from the thyrocytes and uptake of iodothyronines into target cells require transport processes such as facilitated transport or active or passive carrier-mediated transport, which is catalyzed by specific proteins not completely characterized. Tissue- and development-specific expression of these transporters of iodothyronines contributes to

Figure 1 Enzymatic deiodination of the prohormone T_4 to the thyromimetically active T_3 by type I or type II 5'-deiodinase and inactivation of T_4 to rT_3 by type III 5-deiodinase. 5'-D, 5'-deiodination (phenolic or outer-ring deiodination); 5-D, 5-deiodination (tyrosyl- or inner-ring deiodination). Numbers indicate substituent positions (n') at the phenolic (outer) ring or (n) at the tyrosyl (inner) ring.

the bioavailability of thyroid hormones in cells and organs and provides a first level of control for metabolism of iodothyronines by intracellular enzymes that depend on substrate availability. No enzymes metabolizing thyroid hormones in the blood or in the interstitial space have been identified. The free hormone concentrations in serum and interstitial space are very low due to the binding of T_4 and T_3 by the high-affinity distribution proteins TBG, TTR, and albumin. The other iodothyronine metabolites exhibit lower affinity for these proteins than T_4 and T_3 and thus might be more available to metabolic transformations.

ENZYMATIC DEIODINATION OF THYROID HORMONES

Sequential Monodeiodination Both Activates and Inactivates Thyroid Hormones

Reductive deiodination of the prohormone T_4 generates two iodothyronine metabolites with different biological function (Fig. 1). Deiodination in the 5' position of the phenolic (outer) ring of T_4 produces the thyromimetically active hormone T_3 . Deiodination in the 5 position of the tyrosyl ring (inner ring) generates reverse T_3 (rT_3), a metabolite devoid of thyromimetic action at the nuclear T_3 receptor but with the potential to act as a competitor to T_4 in the 5'-deiodination reaction. rT_3 circulates in the serum of normal persons in concentrations similar to those of T_3 . Deiodinase enzymes are expressed in a development-, tissue-, and cell-specific manner and are regulated by different factors. All three deiodinase enzymes belong to the class of selenocysteine-containing proteins and are encoded by three different genes. With few exceptions, selenium availability is not a limiting factor in humans for the expression of the three deiodinase selenoenzymes, which rank very high in tissue-specific selenium supply among the selenoproteins. However, *in vitro* and animal studies indicate selenium-dependent regulation of the three deiodinases. Only during severe selenium deficiency, under protein-free diets due to metabolic diseases (phenylketonuria), long-term total parenteral nutrition, or malabsorption syndromes may effects of selenium deficiency on the expression of deiodinase enzymes and T_3 formation be observed in children and adults.

Two 5'-Deiodinases Are Involved in Activating Thyroid Hormone Metabolism

5'-Deiodination at the phenolic ring is catalyzed by two enzymes, the type I and the type II 5'-deiodinase (5'-DI and 5'-DII, respectively), which differ in various aspects as indicated in Table I. 5'-DI is less selective in substrate specificity than 5'-DII, which preferentially deiodinates T_4 with a low-nanomolar Michaelis–Menten constant (K_m) for this substrate. 5'-DII produces T_3 mainly for the local supply in tissues expressing this enzyme, which renders these tissues independent from circulating T_3 . 5'-DII does not contribute significantly to circulating plasma T_3 , which is mainly provided by 5'-DI action on T_4 in liver, kidney, and thyroid tissues expressing high 5'-DI activity in normal healthy subjects. The extent to which thyroid 5'-DI activity contributes to T_3 secreted by the thyroid gland, which also produces T_3 apart from T_4 during thyroid hormone synthesis especially under conditions of iodine deficiency and in Graves' autoimmune thyroid disease, is unclear. In the latter constellation, 5'-DII activity also contributes to thyroid T_3 production from T_4 because 5'-DII expression in Graves' disease is stimulated by thyroid-stimulating autoantibodies, similar to thyrotropin (TSH) stimulation of 5'-DII in autonomous adenoma. 5'-DI also participates in the inactivation of T_4 by deiodination at the tyrosyl ring, generating rT_3 and degrading T_3 to 3,3'- T_2 . Sulfated iodothyronines are also substrates of 5'-DI.

Type III 5-Deiodinase Inactivates Thyroid Hormones

The third deiodinase, 5-deiodinase (5-DIII), removes iodine from the 5 position of the tyrosyl ring (inner-ring deiodination) (Fig. 1). 5-DIII is responsible for the majority of rT_3 formation and T_3 degradation and is considered the main thyroid hormone-inactivating enzyme. Expression of 5-DIII occurs in several tissues and cells that do not respond to thyroid hormone action. Thus, 5-DIII can be considered the one component of the "gatekeepers" of thyroid hormone action that prevents T_3 action from occurring at an inappropriate time, location, or concentration. Because 5-DIII can act on both T_4 (forming rT_3) and T_3 (forming 3,3'- T_2), it can perform the gatekeeping function in cell types that are exposed to T_4 and/or T_3 and thus might act independently of the expression pattern of cell type-specific thyroid hormone

Table I Properties of the Deiodinase Enzymes^a

| | Type I 5'-deiodinase (5'-DI) | Type II 5'-deiodinase (5'-DII) | Type III 5-deiodinase (5-DIII) |
|---------------------------------|--|--|---|
| Function | Systemic > local T ₃ production; degradation of rT ₃ and sulfated iodothyronines | Local > systemic T ₃ production | Inactivation of T ₄ and T ₃ |
| Expression | Liver, kidney, thyroid, pituitary; at low levels in heart and many other tissues; loss of expression in tumors | (Hypothyroid) pituitary, brain, brown adipose tissue, skin, placenta; thymus, pineal, and hardierian gland; glial cells and tanyocytes; overexpression in mesothelioma cell line | Placenta, brain; many other tissues, except normal adult pituitary and adult healthy liver, thyroid, kidney; reexpression in pathological organs (liver, pituitary); overexpression in hemangioma |
| Cosubstrate | DTT or DTE <i>in vitro</i> (K _m , 2–5 mM); not glutathione or thioredoxin <i>in vivo</i> | DTT or DTE <i>in vitro</i> (K _m , 5–10 mM); higher concentrations than for 5'-DI | DTT or DTE <i>in vitro</i> (K _m , 10–20 mM); higher concentrations than for 5'-DI |
| Subcellular location | Endoplasmatic reticulum in liver; inner plasma membrane in kidney and thyroid | Inner plasma membrane; p29 subunit associated with F-actin respectively perinuclear vesicles | Endoplasmatic reticulum |
| Human gene location | 1p32–p33 | 14q24.3 | 14q32 |
| Essential amino acid residues | Histidine, selenocysteine, cysteine, phenylalanine | Selenocysteine | Selenocysteine |
| Enzyme stimulation or induction | T ₃ , retinoids; TSH and cAMP in thyroid only; testosterone in liver; selenium, carbohydrate | cAMP; FGF; β-adrenergic agonists, nicotine; phorbolsters via PKC; ANP and CNP via cGMP in glial cells | T ₃ , FGF, EGF; selenium |
| Inhibition | PTU, iodoacetate, aurothioglucose, iopanoate, dexamethasone | T ₄ , rT ₃ , iopanoate | Iopanoate |

^aAbbreviations used: ANP, atrial natriuretic peptide; CNP, C-type natriuretic peptide; DTE, dithioerythreitol; DTT, dithiothreitol; EGF, epidermal growth factor; FGF, fibroblast growth factor; PKC, protein kinase C.

transporters, restricting the uptake of these hormones. On the other hand, the development-, tissue-, and cell-specific expression pattern of the two 5'-deiodinase enzymes provides a system of systemic or local production of the thyromimetically active nuclear receptor ligand T₃. Expression of the deiodinase enzymes in the thyrotroph cells of the anterior pituitary controls the local production and levels of T₃, which suppresses gene expression and secretion of TSH. Therefore, deiodinases play a key role in negative feedback regulation of TSH by circulating thyroid hormone levels.

INTRACELLULAR TARGETING AND COMPARTMENTALIZATION OF ACTIVE AND INACTIVE IODOTHYRONINES

Subcellular Location of Deiodinases

Because all three deiodinase enzymes are located inside the cell with active sites exposed toward the cytosol (Fig. 2), their action also depends on the

availability of the main substrate T₄, which reaches the cytosol via cell-type-specific T₄ carriers. T₃ entering the cells via T₃ transporters may therefore bypass the control exerted by the intracellular deiodinase network and gain direct access to the nuclear T₃ receptors. There is evidence that in some cells compartmentalization or distinction occurs for the two different T₃ pools. T₃ locally originating from the two 5'-deiodinases and T₃ taken up by plasma membrane T₃ transporters might be handled differently and might reach the nuclear T₃ receptors through distinct intracellular routes. Moreover, T₃ formed by the high activity of 5'-DI in liver, kidney, or thyroid might not be targeted to the nuclear T₃ receptor of the same cells but rather channeled toward efflux and export into circulation and thus reach (other) target cells only after its transient circulation in the blood pool of thyroid hormones.

The determination of the detailed subcellular location and extensive research on the intracellular compartmentalized fate of iodothyronines are required to clearly understand the molecular steps of thyroid hormone economy and action at the cellular level.

RXR, retinoic acid receptor; TR, T_3 receptor.

$5'$ -DI activity has been shown to be associated with the inner leaflet of the basolateral plasma membrane in proximal kidney tubular epithelial cells. The subcellular location of $5'$ -DI in the thyroid epithelial cells is not unequivocally clear, and in liver $5'$ -DI has been shown to be located in the rough and smooth endoplasmic reticulum with orientation toward cytosol, a finding that does not exclude an additional location at a lower concentration in the inner leaflet of the plasma membrane. $5'$ -DII activity has been demonstrated to be associated with the inner leaflet of the plasma membrane of several cell types. Type III 5D activity is also associated with cellular membranes. All three deiodinase enzymes are important membrane enzymes whose activity depends on membrane integration. Studies on the subcellular location of the three deiodinases using transient or stable overexpression of these selenoproteins, mainly in cell types that normally do not express deiodinase activity, have provided information on the different locations of these proteins, and data on the inactivation of the deiodinases by the ubiquitin-associated proteasome

protein degradation system have also been presented. However, these experiments should be interpreted with caution because overexpression models were used, an artificial cellular environment was chosen, and mainly marker enzymes or proteins were determined that do not correspond to classical and established integral membrane proteins of rough and smooth endoplasmic reticulum, cytosolic- or luminal-oriented microsomal proteins, plasma membrane-associated proteins, apical or basolateral plasma membrane protein markers, and intra- or extracellularly oriented integral plasma membrane proteins, which have not been systematically studied. In addition, the proteasome protein degradation system has not been studied in detail for integral membrane proteins and is not well understood for cell lines overexpressing proteins outside of the specific cellular context.

Iodothyronine Deiodinases Participate in the Control of Cell-Type-Specific Production and Action of Thyroid Hormone

It has long been known that thyroid hormone action, mainly exerted by the thyromimetically active T_3 , depends on the cellular expression pattern of T_3 receptors, which mediate thyroid hormone action on gene expression. The cloning of several isoforms of (nuclear) thyroid hormone receptors, encoded by two different genes (TR- α and TR- β), which occur in different splice forms that bind either both ligand and DNA (TR- α_1 , TR- β_1 , TR- β_2 , and several variants) or only DNA (TR- α_2), added to the complexity of the regulation of thyroid hormone action. This complexity has become even more complicated by the demonstration that in many instances the cellular location of the T_3 receptor differs from that of T_3 formation by the $5'$ -DI or $5'$ -DII enzymes. Two examples are the distinct location of $5'$ -DII-forming T_3 and the T_3 receptor-mediating T_3 action in the development of the cochlea of the inner ear of the mouse or the development of the frog eye. Whereas T_3 receptors are located in the sensory epithelium of the inner ear, the $5'$ -DII enzyme producing the active ligand T_3 is located in the surrounding connective tissue cells in a development-dependent manner. This implies that T_3 produced from T_4 must be released from the connective tissue cells and taken up by the sensory epithelial cells. Therefore, defects in both the time-dependent and the spatial organization of this network of ligand availability might lead to disturbed hearing function,

known to be affected by (fetal or congenital) hypothyroidism. In the development of the retina of the frog eye, a close correlation between the expression of T_3 receptors and 5-DIII is reported. Local overexpression of 5-DIII, removing the active ligand T_3 , disturbs the development of the eye. Compartmentalization of the T_3 receptors, the ligand-activating 5'-deiodinase, and the ligand-inactivating 5-DIII occurs at the implantation site of the embryo in the uteroplacental unit and the fetal epithelium. Again, the expression patterns of the three deiodinase enzyme forms appear strictly associated with different cell types in a time- and space-dependent manner, thus allowing for strictly controlled ligand availability to the developing fetus. In the latter case, the deiodinases, especially the T_3 - and T_4 -inactivating enzyme 5-DIII, are essential for the control of thyroid hormone transfer from the maternal to the fetal compartment because it is well-known that excessive exposure of the fetal tissues and the fetal brain to thyroid hormone leads to irreversible brain damage such as occurs in uncontrolled maternal hyperthyroidism during pregnancy.

Amphibian Metamorphosis Is a Paradigm of Spatial and Temporal Control of Thyroid Hormone Expression

The previous examples of spatial and temporal control of the active ligand T_3 relate to the developmental program of expression of T_3 receptors and deiodinase enzymes in amphibian metamorphosis that is under the central control of thyroid hormone. Although the thyroid gland provides the prohormone T_4 and a small amount of circulating T_3 (which might be needed to prime the metamorphic events), the local production and removal of the active ligand T_3 are under the control of the deiodinase network, which is expressed in a cell-type-specific manner. Whether T_4 and T_3 transporters also contribute to precursor or ligand availability remains to be determined. Several cell-type-specific transporters for thyroid hormones have been identified. Disruption of these organized networks of control of ligand availability for T_3 receptors might occur during various diseases, affecting either the cellular organization of tissues or the expression of the three deiodinase enzymes.

ABERRANT AND INAPPROPRIATE EXPRESSION OF DEIODINASES

The concept of the control of availability of the thyromimetically active ligand T_3 by appropriate expression of thyroid hormone deiodinases has gained

support as a result of the identification of several pathological constellations in which aberrant or inappropriate expression of deiodinase enzymes has been observed. The first example is the overexpression of 5-DIII in some infantile hemangiomas leading to extremely severe hypothyroidism that in some cases cannot be treated with excessive doses of administered T_4 —a syndrome called consumptive hypothyroidism. The opposite situation is found for some mesothelioma tumors, in which overexpression of 5'-DII leads to elevated T_3 production. For 5'-DI, no clear-cut alterations of expression have been described in humans. However, several animal experimental models with altered expression or regulation of 5'-DI activity have been described. Decreased (hepatic) expression of 5'-DI leads to constellations characterized by normal to elevated serum T_4 , decreased or normal serum T_3 , and elevated rT_3 . The latter parameter might be the leading sign of decreased expression of 5'-DI because it is almost exclusively degraded by 5'-DI, whereas its production occurs via 5-DIII and, to a minor extent, 5'-DI. Therefore, the ratio of serum T_3/rT_3 might be the most sensitive parameter of altered 5'-DI activity. No evidence of overexpression of 5'-DI has been reported in humans.

Two polymorphisms have been reported in the 5'-DI gene associated with altered plasma thyroid hormone levels and ratios. In combination with a further polymorphism of the TSH receptor gene, clear-cut alterations of the setpoint of the pituitary feedback control of thyroid hormone secretion and homeostasis are apparent. A polymorphism in the 5'-DII gene leading to an amino acid exchange in the enzyme has been found to be associated with obesity in diabetic patients, but no functional alterations of characteristics of the variant 5'-DII enzyme have been found.

LOW T_3 SYNDROME OR EUTHYROID SICK SYNDROME

A long-standing clinically relevant conundrum is the low T_3 syndrome or the euthyroid sick syndrome, characterized by low serum levels of T_3 , elevated rT_3 , and normal, elevated, or, in later stages, decreased serum T_4 without appropriate elevation of serum TSH levels. This peculiar hormone constellation has been explained by decreased hepatic T_3 formation by 5'-DI, normal or decreased thyroid hormone synthesis, and lack of pituitary stimulation of TSH secretion (Table II). Many facets of regulation of thyroid homeostasis contribute to this syndrome, which is

Table II Pathogenesis of Low Serum Levels of T₃ and T₄ in the Euthyroid Sick Syndrome of Nonthyroidal Illness

| |
|---|
| Low T ₃ state |
| Decreased hepatic Type I 5'-deiodinase activity |
| Increased hepatic Type III 5-deiodinase activity |
| Decreased concentrations of serum thyroid hormone-binding proteins |
| Circulating inhibitors of binding of T ₃ to serum proteins |
| Decreased tissue uptake of T ₃ by peripheral tissues |
| Decreased TSH secretion |
| Hypercortisolism |
| Elevated cytokines (IL-1, IL-6, and TNF-α) |
| Interference of drugs with serum binding, tissue uptake, and 5'-deiodination (dopamine, glucocorticoids, propranolol, and uremic compounds) |
| Low T ₄ state |
| Decreased serum concentration of T ₄ -binding proteins |
| Circulating inhibitors of binding of T ₄ to serum proteins |
| Decreased tissue uptake of T ₄ by peripheral tissues |
| Decreased TSH secretion |
| Hypercortisolism |
| Elevated cytokines (IL-1, IL-6, and TNF-α) |
| Interference of drugs with serum binding, tissue uptake, and 5'-deiodination (glucocorticoids, dopamine, amiodarone, salicylates, and uremic compounds) |

IL, interleukin; TSH, thyroid-stimulating hormone; TNF-α, tumor necrosis factor-α.

observed during carbohydrate starvation, acute and chronic illness, surgical intervention, trauma, infection, sepsis, or after administration of certain drugs that inhibit (hepatic) 5'-DI activity. In addition to decreased hepatic and, in some cases, impaired renal and thyroidal 5'-DI activity, the remarkable interruption of the normal negative feedback of thyroid hormones at the hypothalamic and pituitary level is a hallmark of this syndrome. Experiments using various animal models, including knockout mice models, suggest that elevated levels of proinflammatory cytokines (interleukins-1 and -6, tumor necrosis factor-α, and interferon-γ) in these conditions contribute to the inhibition of deiodinase activity and the interruption of the negative feedback at the central level. In addition, both thyroid hormone binding in serum and cellular uptake appear to be changed in these conditions. If recovery or causal treatment of the underlying disease are not possible, the condition may worsen because T₄ production decreases (low T₄ syndrome), a condition with a bad prognosis and high mortality rate. Attempted treatment or substitution with thyroid hormones (T₄ or T₃) were unsuccessful and even worsened the situation by generating a negative nitrogen balance or an even more catabolic constellation.

Important new information on the pathogenesis of this syndrome has become available. In a clinical study of intensive care patients, from a systematic analysis

of the activities of the three deiodinases in biopsies of postmortem tissues (liver and skeletal muscle) and corresponding serum levels of thyroid hormones, together with other routine clinical chemistry parameters, it became obvious that in critically ill patients a reexpression of hepatic 5-DIII occurs, which is similar to the pattern in fetal human liver. This finding may explain the rapid decrease in circulating T₃ and increase in rT₃ in combination with decreased hepatic 5'-DI activity. Lowest 5'-DI and highest 5-DIII activities were observed in patients who died from cardiovascular complications, suggesting that poor tissue perfusion alters the normal expression levels of these two deiodinases. No significant expression of 5'-DII activity was found in both kidney and muscle. In addition, successful disruption of this vicious cycle of the euthyroid sickness syndrome has been demonstrated in intensive care patients who received a combined stimulation by the hypothalamic-releasing hormones thyroliberin (TRH) and growth hormone-releasing peptide, whereas administration of either component alone was not successful in restoring the growth hormone-thyroid hormone axis in severe illness. Pulsatile secretion of the pituitary hormones growth hormone (GH), TSH, and prolactin was reamplified by this combination of releasing factors, which also substantially increased circulating levels of insulin-like growth factor-1, T₄, and T₃ while

avoiding an increase in rT_3 . Apparently, interference at the hypothalamic level of regulation enabled this metabolic improvement and the restoration of normal feedback loops. Whether this treatment regimen can be used for all variants of the euthyroid sick syndrome remains to be established. Independent support for this hypothesis derives from observations in children and adult patients treated with GH. This regimen led to decreased T_4 and rT_3 and increased serum T_3 levels independent of alterations in TSH and suggests stimulation of hepatic 5'-DI activity. This interpretation is supported by several studies of animal models indicating increased hepatic 5'-DI expression and activity after GH treatment. No data are available on a GH-dependent decrease in hepatic 5-DIII, which is normally not expressed in rodent liver.

TISSUE-SPECIFIC EXPRESSION PATTERNS OF DEIODINASE ENZYMES AND HOMEOSTASIS OF NET T_3 FORMATION

The observations of hepatic reexpression of 5-DIII and decreased activity of 5'-DI in severe illness suggest that the developmental pattern of expression of deiodinases can be reverted under certain conditions or that an alteration of the cellular composition of a given tissue results in marked alterations in the net balance of homeostasis of T_3 formation. Decreased expression of 5'-DI without evidence of a concomitant increase in 5-DIII expression is also found in tumors of the thyroid, kidney, prostate, and testis. In pituitary adenoma, decreased expression of 5'-DI is associated with elevated 5-DIII activity, whereas the normal pituitary shows only low levels of this enzyme. Depending on the type of pituitary tumor, 5'-DI expression is increased or reduced. Treatment of human cell lines derived from tumors expressing deiodinase activity with agents modulating DNA methylation or histone acetylation or administration of retinoic acid, an agent known to induce cell differentiation, leads to reexpression of 5'-DI activity, even in cell lines that have lost 5'-DI expression. These observations indicate that several regulatory factors involved in development and differentiation exert marked influence on the production and homeostasis of T_3 , which is essential for maintenance of the differentiated state and the metabolic function of various cell types, especially epithelial cells. Therefore, adequate production of thyromimetically active T_3 seems to be a key parameter of the normal cell and functional tissue, which is under a complex network

of control by potent factors involved in development, differentiation, and maintenance of function of a vertebrate organism.

METABOLISM OF THYROID HORMONES AT THE AMINO ACID SIDE CHAIN

Thyroid hormones and iodothyronines derived therefrom have an alanine amino acid side chain that can undergo oxidative decarboxylation and deamination, as found for other amino acids. Although no *in vivo* experimental evidence is available on decarboxylation of iodothyronines to yield metabolites with an amine side chain, oxidative decarboxylation of T_4 and T_3 seems to occur because relevant circulating levels of both tetraiodothyro-acetic acid (Tetrac) and the corresponding triiodothyro-acetic acid (Triac) can be measured in serum. The enzymes catalyzing these reactions have not been characterized in detail. However, the metabolites Tetrac and Triac are of potential relevance because Tetrac is a good substrate for the 5'-deiodinases and Triac is a potent ligand for nuclear T_3 receptors. Whether Triac reaches the nuclear T_3 receptor target *in vivo* and modulates the expression of T_3 -regulated genes is unclear. Triac has a short biological half-life compared to that of T_3 and is used in pharmacological doses for treatment of thyroid hormone resistance, for which it efficiently suppresses elevated TSH but does not lead to hyperthyroid conditions in heart, liver, and other organs due to its rapid degradation and lack of accumulation in tissues.

CONJUGATION OF THYROID HORMONES BY GLUCURONIDASES AND SULFOTRANSFERASES

Glucuronidation

Multiple UDP-glucuronyltransferases appear to be involved in the glucuronidation of thyroid hormones. The 4'-OH group of iodothyronines is rather acidic, depending on the iodine substitution pattern of the phenolic ring, and Tetrac and Triac are better substrates for glucuronidation than their parent compounds T_4 and T_3 . Glucuronidated iodothyronines show increased solubility in water and are rapidly excreted via the bile, but they may also undergo enterohepatic circulation. Drugs and agents interfering with UDP-glucuronyltransferases might therefore affect thyroid hormone metabolism and elimination

as indicated by findings on the effects of several halogenated aromatic compounds (PCBs and dioxins) in animal models. Compounds that increase T_4 glucuronidation decrease serum levels of T_4 (e.g., phenobarbital and several halogenated aromatic compounds).

Sulfation

The second important pathway of thyroid hormone conjugation of the phenolic hydroxyl group is catalyzed by sulfotransferases, which belong to a large superfamily of enzymes with tissue- and development-specific expression patterns. Sulfation accelerates the deiodination of different iodothyronines by the type I deiodinase and initiates irreversible hormone degradation. T_3 sulfate found during pregnancy in fetal and maternal circulation might function as a reservoir from which active T_3 is recovered by tissue sulfatase activity. T_2 sulfate, also found in fetal circulation, might represent an elimination form of excess thyroid hormone secreted toward the maternal circulation when fetal type I deiodinase activity is still low. Significant sulfotransferase activity has been found in fetal tissues. Relevant sulfatase activities that might liberate T_3 from circulating T_3 -sulfate have been observed in (maternal) placenta and liver during pregnancy as well as in other tissues.

DRUGS INTERFERING WITH THYROID HORMONE METABOLISM

Several drugs and agents interfere with thyroid hormone metabolism, especially the deiodination reactions. Many phenolic aromatic, mono- or polycyclic agents interfere with iodothyronine binding and deiodination by the deiodinases. With few exceptions, these agents specifically interfere with one or more of the deiodinase enzymes. Several drugs routinely used in clinics interfere with $5'$ -DI. Most efficient inhibition is observed for some iodinated oral cholecystographic X-ray contrast agents (ipodate or iopanoic acid), the antiarrhythmic drug amiodarone and its metabolites, the synthetic glucocorticoid dexamethasone, some antiphlogistic and anti-inflammatory agents, and the large group of plant secondary phenolic metabolites (flavonoids, isoflavonoids, aurones, and chalcones). The latter compounds are contained in significant amounts in daily consumed plant-derived food, but it is unclear whether their consumption contributes to goitrogenesis under conditions of inadequate iodide supply. Many of these deiodinase-inhibiting

compounds lead to a constellation of serum thyroid hormones reminiscent of the low T_3 syndrome: normal or elevated T_4 , low T_3 , elevated rT_3 , and normal TSH. The main effect of these compounds is inhibition of $5'$ -DI. Some agents are potent inhibitors of all three deiodinases (e.g., iopanoic acid). No selective or isoenzyme-specific inhibitors of $5'$ -DII and 5-DIII are known. The antithyroid drug 6-*n*-propyl-2-thiouracil is a selective inhibitor of $5'$ -DI in most species. However, its clinical use as an antithyroid drug is based mainly on its inhibition of thyroid hormone synthesis catalyzed by the thyroperoxidase and less so via inhibition of $5'$ -DI activity. The compound aurothioglucose is a potent inhibitor of $5'$ -DI but also inhibits the other deiodinases at higher concentrations due to the presence of a selenocysteine residue in their active sites. The synthetic flavonoid F21388 derived from natural compounds is a potent inhibitor of $5'$ -DI and $5'$ -DII and has been shown to modify transplacental thyroid hormone transfer and thyroid hormone transport to the fetal brain. The development of isoenzyme-specific inhibitors may provide the possibility for tissue- and cell-specific interference of thyroid hormone action in a manner similar to that of the steroid field, for which selective inhibitors of steroid activation (e.g., aromatase inhibitors) and inactivation are already in clinical use.

Figure 1 Schematic representation of the four thyroid hormone receptor (TR) isoforms. The receptor isoforms are shown with the tissues where their expression is most prominent. The differences between the isoforms are indicated by different shading symbolizing the different domains. The schematic domain structure is indicated at the bottom, with A/B signifying the N-terminal receptor domain, C the DNA binding domain, D the hinge region, and E/F the ligand binding domain.

has led to a better understanding of resistance to thyroid hormone, the possible mechanism of action of amiodarone, and the development of thyroid hormone agonist and antagonists.

TR ISOFORMS

Gene Structure

TRs are encoded by two different gene loci, TR- α [locus *c-erbA- α* on chromosome 17q11.2 (human), 10 (rat), and 11 (mouse)] and TR- β [locus *c-erbA- β* on chromosome 3p24.3 (human), 15 (rat), and 14 (mouse)]. The TR- α gene encodes for TR- α_1 and its splice variant TR- α_2 . Two further isoforms arise from the TR- α gene, namely TR- $\Delta\alpha_1$ and TR- $\Delta\alpha_2$. The TR- α gene contains 10 exons, and the alternative splice site for TR- α_2 is located on exon 9 (Fig. 2). The TR- α_2 splice variant, which is only found in mammals, has no intact ligand-binding domain (LBD) but can act as a constitutive repressor of TR action. An internal promoter located on intron 7 is responsible for the formation of TR- $\Delta\alpha_1$ and TR- $\Delta\alpha_2$ variants, which are unable to bind hormone and DNA and can act as constitutive repressors of the other TRs.

The TR- β locus encodes the isoforms TR- β_1 , TR- β_2 , TR- β_3 , and a truncated receptor TR- $\Delta\beta_3$ (unable to bind thyroid hormone), which are generated via alternative splicing and/or differential promoter usage (Fig. 2). They differ only in the amino-terminal part of the receptor (Fig. 1). The TR- β locus contains 11 exons, of which exons 3–8 are common to all TR- β s and also show high homology with the TR- α isoforms. Exons a, A, and B were discovered later. Alternative splicing of exons 1 and 2 results in the

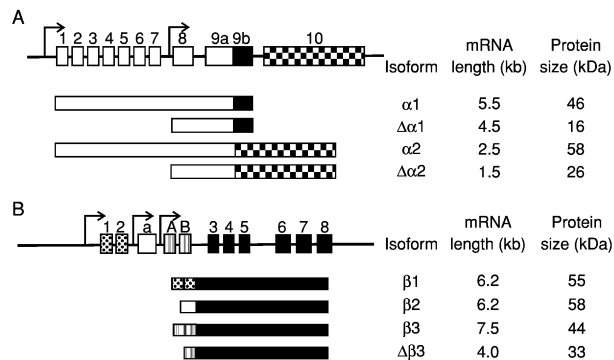

Figure 2 (A) Schematic representation of the transcripts generated by the *c-erbA α* locus. Exons common to the TR- α_1 and TR- α_2 isoforms are depicted as white rectangles. The black rectangles show the regions specific to the TR- α_1 isoforms and the black blocked rectangles show the regions specific to the TR- α_2 isoforms. The arrows indicate the different promoters used to generate the different TR- α isoforms. (B) Schematic representation of the transcripts generated by the *c-erbA β* locus. Exon 3–8, common to all TR- β isoforms, are shown as black rectangles. Exons 1 and 2, common to the TR- β_1 isoform, are shown as dotted rectangles. Exon a of the TR- β_2 isoform is depicted as a white rectangle, and exons A and B of the TR- β_3 and B of TR- $\Delta\beta_3$ are shown as gray rectangles. The arrows indicate the different promoters used to generate the different TR- β isoforms.

N-terminal part of TR- β_1 , exon a for TR- β_2 , and exons A and B for TR- β_3 and its Δ variant.

Protein Structure

The TRs have a domain organization similar to that of the other members of the nuclear receptor superfamily. There are four domains: the A/B domain (the amino-terminal part, which differs in TRs), the C domain (which contains the DNA binding domain), the D domain (hinge region), and the E/F domain (LBD) (Fig. 1). Each of these domains plays a different role in the interaction with proteins and DNA. Generally, it is believed that the A/B domain, together with the E domain, is involved in the interaction with coactivator proteins. DNA binding of the TRs is regulated by the C and E domains, and corepressor interaction sites are located mostly in the D and E domains. The protein sequence is highly conserved between rodents and humans.

The A/B domains of the TR- α and TR- β isoforms differ in size and sequence. The protein sequence of the amino-terminal part of TR- α_1 and TR- α_2 is the same, whereas it differs between TR- β isoforms. There is a high homology between the different isoforms of rat, human, and mouse, although the TR- β_2 isoform in rats is 38 amino acids longer than those in

mouse and human. TR- β_3 and TR- $\Delta\beta_3$ have only been found in rats.

The role of the A/B domain in transcriptional activation is poorly understood due to the fact that its activity is highly dependent on the species or cell types being studied. Some studies have shown that transcriptional activity is lost after deletion of the N-terminal amino acids of the TRs, suggesting that the most likely function of this domain is in regulation of the interaction of the TR with other proteins, such as transcription factors or coactivators.

The C domain possesses two zinc fingers (Fig. 3), each containing four cysteines coordinated by a zinc ion and four functional sites called P-, D-, T-, and A-boxes. The first zinc finger is important in the specific association with the TRE sequences. In the presence of DNA, the receptor dimerizes, followed by placement of the first zinc finger of the DNA-binding domain of each monomer in direct contact with the DNA major groove. The second zinc finger of each monomer is stabilized by direct interaction between

the this zinc finger and the TRE. The P-box is also important in sequence-specific recognition of response elements of other receptors, such as ER, RXR, RAR, and VDR. The D-box is involved in distinguishing the spacing between half-sites of hormone response elements. The T- and A-boxes are involved in heterodimerization. Because of their critical role, changes in the zinc fingers or boxes result in abrogation of DNA-binding and transcriptional activity.

The hinge region (D domain) links the C domain to the LBD (Fig. 3). It interacts with corepressors since mutation of this domain in the TR- β_1 receptor abolishes the basal repression. This indicates either that the hinge region of the unliganded TR can provide a contact surface with corepressor or that the hinge region has an allosteric effect on these interactions since the interaction with corepressors is also associated with sequences in the LBD.

TRs possess motifs called nuclear localization signals (NLSs). The consensus sequences mediating nuclear translocation consist of two clusters of two or three basic amino acids separated by two nonbasic amino acids [(K/R)(K/R)XX(K/R)(K/R)(K/R)]. For TR- β_1 , the KRLAKRK (amino acids 184–190) in domain D mediates the T₃-induced nuclear translocation. The TR- α isoforms also possess several NLSs in the D and E domains, and this receptor shows nuclear-cytoplasmic shuttling.

Ligand-Binding Domain (E Domain)

The LBD or E domain is required for nuclear localization, homo- and/or heterodimerization, and, most important, ligand binding and the ligand-induced change in transcriptional activity. In the case of the thyroid hormone receptor, the ligand T₃ is tightly packed inside the binding pocket (Fig. 3). The LBD in its inactive form is able to bind to so-called corepressor molecules that help the receptor keep the gene silent. The major event upon ligand binding is that helix 12, which is composed of the final amino acids of the receptor protein, moves into a different position, thus releasing the corepressor. It then forms a different surface that will allow binding of the coactivator, which helps the receptor in gene activation. Molecular studies have established that an LXXLL amino acid motif within the coactivators mediates the interaction with ligand-activated nuclear receptors.

The LBD domain also harbors important sequences such as the heptad repeats. These repeats form hydrophobic interfaces for TR homo- and heterodimerization. One of these conserved regions, the ninth heptad, is important for TR homodimerization

Figure 3 Impression of the combination of the three-dimensional (3D) structures of the TR- β DNA and ligand binding domain (from the NCBI-MMDB database, structure Nos. 1BSX and 2NLL). It can be seen that T₃ is tightly packed inside the molecule. The zinc fingers, hinge region, ligand binding domain (LBD), and helix 12 are indicated.

and RXR–TR heterodimerization since mutation of the ninth heptad decreases TR homo- and heterodimerization. For TR- α_2 the dimerization region is probably located in the DNA-binding domain (note that TR- α_2 has no ninth heptad).

Although sequence comparisons show great similarity between species and between TR- β and TR- α , an intriguing difference exists in the ligand-binding capacity for the T₃ analogue TRIAC between these isoforms. TR- β_1 binds TRIAC 1.5-fold stronger than does TR- α_1 . There are only a few amino acid alterations between the two receptor isoforms in the hormone-binding pocket. However, these changes allow a subtle change in the position of one of the arginine residues (Arg²²⁸ for TR- α_1 , and Arg²⁸² for TR- β_1), which explains the increased binding in TR- β_1 .

DISTRIBUTION AND FUNCTION OF THYROID HORMONE RECEPTORS

After the discovery of TR-encoding genes, developmental and tissue-specific patterns of TR expression were reported based on their mRNA. TR- α_1 , TR- α_2 , and TR- β_1 are expressed in almost all tissues. From studies of frogs, it appears that the TR- α isoforms are predominant during prenatal development, followed by expression of TR- β isoforms; it has been suggested that this may hold true for other species as well. In adult organisms, TR- α isoform mRNAs are highly expressed in skeletal muscle and the TR- $\Delta\alpha$ mRNAs are expressed in the intestine. TR- β_1 mRNA is most highly expressed in the liver, kidney, and brain. TR- β_2 mRNA expression is limited to certain hypothalamic areas, the pituitary, and the retina. TR- β_3 and TR- $\Delta\beta_3$ mRNA expression is restricted to the liver, spleen, heart, and lung. Even when different receptor isoforms are present, one is the major isoform in a particular tissue (Table I).

Other regulatory possibilities arise from the fact that many T₃-dependent genes are not distributed homogeneously in a tissue. In the liver, T₃-dependent genes, such as *PEPCK* and *Spot14*, are expressed around the portal vein or around the central vein, respectively (zonal distribution). Studies have shown that the TR isoforms in liver are not homogeneously expressed but are also expressed in a zonal fashion. From these studies, it appears that TR- β_1 is expressed in only a few cell layers around the central vein of the liver lobule (Fig. 4). Interestingly, the *Spot14* gene, which is expressed in the same subpopulation of cells around the central vein, is exclusively dependent on the TR- β_1 isoform for its regulation by thyroid

Table I Isoform-Selective TR Functions in Different Organs

| Thyroid hormone target | Receptor isoforms mediating actions |
|-----------------------------------|-------------------------------------|
| Hepatic gene regulation | TR- β > TR- α |
| Bone development | TR- α > TR- β |
| TSH suppression | TR- β > TR- α |
| Ligand-independent TSH elevation | TR- α > TR- β |
| Cochlear development and function | TR- β |
| Maturation of small intestine | TR- α = TR- β |
| Cardiac gene expression | TR- α > TR- β |
| Heart rate | TR- α |
| Retinal development | TR- β |
| Growth | TR- α > TR- β |
| Immune function | TR- α > TR- β |
| Temperature regulation | TR- α > TR- β |

hormone. The TR- α_1 and - α_2 isoforms are expressed in a wider area but are still clustered around the central vein. These findings indicate that when studying TR isoform-dependent effects, it is important to consider these effects not only *in vitro* but also *in vivo* in relation to the local expression of the different TR isoforms.

The elucidation of the TR isoform-dependent effects was greatly helped by the advent of mice devoid of one or more specific isoforms. The TR- α_1 knockout is fertile and shows a mild hypothyroid phenotype, reduced body temperature, and reduced heart rate. Selective ablation of TR- α_2 results in overexpression of TR- α_1 , low levels of thyroid hormones,

Figure 4 Zonal expression of TR- β_1 in rat liver. Rat liver slices were incubated with polyclonal anti-TR- β_1 . Monoclonal antiglutamine synthetase was used as a control to stain the central veins on a consecutive slice. It can be clearly seen that TR- β_1 is expressed in the same subset of cells that express GS. A schematic drawing depicting the position of the central (CV) and portal (PV) veins in the slices is shown on the right. Magnification, $\times 100$.

and normal levels of TSH. Interestingly, the phenotype of TR- α_2 mutant mice also shows signs of hyperthyroidism, such as decreased body weight, elevated heart rate, and increased body temperature. These data suggest that the balance between TR- α_1 and TR- α_2 may provide an additional level of adjustment of hormone responsiveness in certain tissues.

In mice missing the full-length TR- α_1 and TR- α_2 (but that have the $\Delta\alpha$ isoforms), the thyroid gland develops abnormally, there is arrested maturation of the intestine and reduced bone growth, and the mice die within a few weeks after birth. Interestingly, when all TR- α isoforms are deleted (both full-length and Δ), the phenotype is less severe. The selective inactivation of the TR- β gene results in thyroid hyperplasia, increased serum thyroid hormones and TSH, impaired T₃-dependent regulation of cholesterol metabolism, and defects in cochlear function (similar to the resistance to thyroid hormone syndrome in humans).

The TR knockout animal models emphasize two important features. First, the mice without all known isoforms are still viable. The existence of an unknown receptor isoform is a possibility that has not been clarified. Second, the deletion of a particular isoform can be partly compensated by other receptors. However, certain genes or processes will be influenced by the deletion of a particular isoform, as seen in the case of genes involved in lipid metabolism or inner ear development.

TR AGONISTS AND ANTAGONISTS

Solving the X-ray structure has allowed the development of TR isoform-specific agonists and antagonists. As for the knockouts discussed previously, it is not an all-or-nothing phenomenon but it is a matter of preferential stimulation or inhibition. One of the first isoform-specific agonists to be synthesized was GC-1, which showed a clear preference for TR- β_1 both *in vitro* and *in vivo*. The X-ray structure suggested that compounds with a 5'-aryl extension could act as antagonists because they would interfere with the proper folding of helix 12 (the lid on the box). However, many compounds based on GC-1 that have large extensions act as agonists with the exception of GC-14, which acts as a partial TR- β_1 antagonist. This can probably be explained by the fact that the side chains are not rigid enough and therefore allow helix 12 (the lid) to assume its proper position. Other synthetic ligands have been developed that behave as antagonists (DIBRT and NH-3) or partial antagonists (NH-4). Of these, NH-3 appears to be the first

high-affinity TR antagonist that also inhibits TR action in a *Xenopus* development model. It has been shown to block both coactivator and corepressor binding. The latter is strange since all known receptor antagonists promote the binding of these corepressors because although they block the proper positioning of helix 12, they leave the corepressor binding site intact. This means that as a result of NH-3 binding, helix 12 assumes a position that precludes both coactivator and corepressor binding. In light of the fact that the TRs are also able to bind without hormone and thus inhibit gene expression, this may be a beneficial property.

CONCLUSION

Solving the structure has allowed the design and understanding of the mechanism of action of antagonists and agonists. With the current knowledge of receptor structure, it can be envisaged that it may be possible to design receptor agonists that will correct the receptor defect in thyroid hormone resistance. For instance, it has been shown that the shift of 0.3 Å of helix 6 of the TR due to mutation of alanine-317 to threonine is the cause of decreased T₃ binding. If an agonist were found that could “live” with this small shift and thus activate the receptor, patients harboring this particular mutation could be treated. Furthermore, the fact that TRs are not homogeneously expressed in target tissues and the design of novel agonists and antagonists open up exciting possibilities for a directed interference in specific cellular processes.

^aTHBPs, thyroid hormone-binding proteins.

oligosaccharide chains with an average of 10 sialic acid residues. Carbohydrates affect the half-life of TBG in serum since deglycosylation is associated with rapid clearance of the protein by the liver. In addition, carbohydrate removal slightly reduces TBG immunoreactivity and T₄-binding activity and decreases its stability. TBG has only one binding site for iodothyronines, and it binds T₄ with a higher affinity than T₃. The very high affinity of TBG for thyroid hormones explains why TBG, although present in serum at a much lower concentration than TTR or HSA, carries approximately 65% of T₄ and 75% of T₃ (Table I).

TBG concentration in normal adult human serum ranges from 12 to 20 mg/liter (Table II), with a maximal T₄-binding capacity of 0.14–0.25 mg T₄/liter. TBG is detectable in the 12-week-old fetus; concentrations in newborns are higher than in adults, decline until midadulthood, and increase thereafter.

Transthyretin

TTR is a 56-kDa protein composed of four identical subunits, each containing 127 amino acids; it does not contain carbohydrates (Table II). It has two identical thyroid hormone binding sites, but normally only one of them is occupied. The normal serum TTR concentration is 250 mg/liter (Table II), corresponding to maximal binding capacity of 2 mg T₄/liter. TTR binds approximately 10% of T₄ and 10% of T₃. In addition to thyroid hormone, TTR also binds retinol-binding protein and is therefore involved in vitamin A transport. Synthesis of TTR occurs mostly in the liver, but the protein is also expressed in the pancreatic islet cells, the retina, and the epithelial cells of choroid plexus in both rats and humans. TTR synthesized in the choroid plexus may play an important role in brain develop-

^aAbbreviations used: TBG, thyroxine-binding globulin; TTR, transthyretin.

ment because it may help maintain the appropriate T₄ concentration in the central nervous system and favor its uniform distribution in different areas of the central nervous system.

The TTR gene exists in a single copy located on chromosome 18 and is composed of four exons spanning 7.3 kilobase pairs. The 5'-flanking region has a highly conserved DNA sequence among species, suggesting a crucial role in the regulation of TTR gene expression.

Albumin

Albumin is a 66-kDa protein composed of 585 amino acids (Table II). It has a relatively strong binding site for thyroid hormone and several additional sites with much lower affinity. It does not contain carbohydrates. Its serum concentration is very high (40 g/liter), and the percentage of thyroid hormone bound to albumin is approximately 20% of T₄ and 10% of T₃.

The human albumin gene consists of a single copy and is located on the long arm of chromosome 4, linked to vitamin D-binding α₂-globulin, whereas in mice the gene is located on chromosome 5, close to the α-fetoprotein gene. There is 90% homology between

the human albumin gene and the corresponding gene in rodents.

Lipoproteins

Lipoproteins are complex molecules composed of a protein moiety (apolipoproteins) and a lipid (both polar and nonpolar) moiety. They bind approximately 3% of T₄ and 6% of T₃. High-density lipoproteins are the major lipoprotein plasma carriers of thyroid hormones through a specific interaction with their apolipoproteins (A-I, A-II, A-IV, C-I, C-II, C-III, and E). These apolipoproteins have a single thyroid hormone binding site encoded by exon 3 (exon 2 for apolipoprotein A-IV) of the respective gene. The thyroid hormone binding site on apolipoproteins is distinct from the apolipoprotein portion that binds to cell lipoprotein receptors. The physiological role of thyroid hormone binding to lipoproteins remains to be defined, but lipoproteins may facilitate enterohepatic circulation, transplacental passage, and central nervous system distribution of thyroid hormones, and they may be involved in thyroid hormone delivery to target tissues with cell surface receptors for apolipoproteins.

VARIATIONS IN THYROID HORMONE-BINDING PROTEINS

Acquired Variations

TBG

Many drugs and pathophysiologic conditions (Table III) are associated with changes in serum TBG concentration related to variations in either TBG synthesis or metabolic clearance rate. Hyperthyroidism and hypothyroidism cause a slight decrease and increase, respectively, in serum TBG levels due to an effect on liver synthesis of the protein. Pregnancy and estrogen therapy cause an increase in serum TBG concentration. This appears to be related to the longer half-life of TBG in the circulation because of estrogen-induced increased sialylation of the protein. Serum TBG values are also increased in patients with acute or chronic hepatitis and in a significant proportion of cases of hepatocarcinoma. Whereas in hepatitis the increase in TBG is probably the consequence of TBG release from damaged liver cells, in hepatocarcinoma the underlying mechanism may be increased liver synthesis of TBG. Patients with nephrotic syndrome have a reduced TBG concentration due to massive renal protein loss. Losses of TBG through peritoneal membrane are likely to account for the

Table III Acquired Thyroxine-Binding Globulin (TBG) Variations

| Condition/drug | Serum TBG concentration |
|-----------------------------|-------------------------|
| Hyperthyroidism | Decreased |
| Hypothyroidism | Increased |
| Pregnancy | Increased |
| Acute and chronic hepatitis | Increased |
| Hepatocellular carcinoma | Increased |
| Nephrotic syndrome | Decreased |
| Chronic renal failure | Decreased |
| AIDS | Increased |
| Diabetic ketoacidosis | Decreased |
| Starvation | Decreased |
| Cushing's syndrome | Decreased |
| Acromegaly | Decreased |
| Oat cell carcinoma | Increased |
| Estrogens | Increased |
| Androgens | Decreased |
| Anabolic steroid | Decreased |
| Glucocorticoids | Decreased |
| Perphenazine | Increased |
| 5-Fluorouracil | Increased |
| Heroin, methadone | Increased |
| Clofibrate | Increased |
| L-Asparaginase | Decreased |
| Interleukin-6 | Decreased |

decrease in TBG concentration observed in patients with chronic renal failure undergoing regular peritoneal dialysis. Serum TBG (but not CBG) levels are increased in AIDS patients, possibly due to associated hepatitis or to a specific enhancement of TBG hepatic synthesis. Patients with diabetic ketoacidosis often have decreased serum TBG levels, which might be related to the lack of stimulation of liver protein synthesis by insulin. Starvation or extreme protein-calorie malnutrition cause a decrease in serum TBG concentration likely related to decreased hepatic synthesis of the protein. These effects, as well as the decrease in TBG that occurs in severe terminal illness, may be mediated by inhibition of TBG synthesis caused by interleukin-6. Minor variations in serum TBG concentration have been reported in several other pathophysiologic conditions (Table III).

In addition to estrogens, other drugs cause an increase in serum TBG concentration, including 5-fluorouracil, clofibrate, heroin, and methadone (Table III). Conversely, administration of androgens, anabolic steroids, glucocorticoids, and L-asparaginase has been associated with decreased TBG levels in the circulation (Table III).

TTR

Serum TTR concentration is often decreased in patients with severe nonthyroidal illness, particularly during protein-calorie malnutrition, nephrotic syndrome, liver diseases, and cystic fibrosis (Table IV). In such circumstances, serum TTR levels decrease, whereas TBG and albumin concentrations remain normal. Both decreased liver synthesis of TTR (possibly mediated by interleukin-6) and its accelerated degradation contribute to these changes. TTR may be increased in patients with pancreatic endocrine tumors (insulinomas or glucagonomas) or gastrointestinal carcinoids, probably due to TTR synthesis by the neoplasm. TTR levels are increased in the central nervous system but not in the serum of patients with endogenous depression or with Parkinson's disease (after adrenal medullary autotransplantation). These changes probably reflect an increased TTR synthesis by the choroid plexus. Many drugs affect serum TTR concentration, and the effect is often the converse of that on TBG. Thus, estrogens decrease serum TTR concentration and androgens, anabolic steroids, and glucocorticoids increase serum TTR concentration (Table IV). Although the underlying mechanisms are not completely understood, variations in TTR synthesis likely contribute to these changes.

Albumin

Albumin concentration is decreased in many acute and chronic nonthyroidal illnesses. These variations occur concomitantly and are always associated with the previously mentioned similar changes in serum TBG and TTR concentrations.

Table IV Acquired Transthyretin (TTR) Variations

| Condition/drug | Serum TTR concentration |
|------------------------------|-------------------------|
| Protein-calorie malnutrition | Decreased |
| Nephrotic syndrome | Decreased |
| Liver diseases | Decreased |
| Cystic fibrosis | Decreased |
| Insulinoma | Increased |
| Glucagonoma | Increased |
| Gastrointestinal carcinoids | Increased |
| Depression | Increased ^a |
| Parkinson's disease | Increased ^a |
| Estrogens | Decreased |
| Androgens | Increased |
| Anabolic steroids | Increased |
| Glucocorticoids | Increased |

^aTTR concentration is increased in cerebrospinal fluid but not in serum.

Inherited Variations**TBG**

Familial forms of TBG deficiency and TBG excess, both inherited as X-linked traits, exist. These defects involve the TBG gene rather than the rate of TBG disposal. Complete TBG deficiency, partial TBG deficiency, and TBG excess are distinguished according to serum TBG levels in hemizygous subjects. When TBG deficiency is complete, affected males have no detectable TBG in serum, whereas carrier females have half the normal serum TBG levels. In partial TBG deficiency, serum TBG concentration in heterozygous females is usually higher than half the normal value. In the presence of excess TBG, serum concentration of the protein is usually two- to fourfold higher than normal.

Complete TBG deficiency occurs in approximately 1 in 15,000 newborn males. Eleven TBG variants account for complete TBG deficiency. In most cases, a single nucleotide substitution, a frameshift due to nucleotide deletion, or multiple nucleotide deletions are the mechanisms leading to early termination of translation and truncation of the TBG molecule. Mutations may also occur outside the coding region of the TBG gene. In a family with complete TBG deficiency, no mutations were detected either in the coding or in the promoter regions of the gene.

Partial TBG deficiency occurs in 1 in 4000 newborns. Six different TBG variants cause variable degrees of decreases in serum TBG concentration. Some of these variants are unstable, have a reduced binding affinity for T₄ and T₃, or show an abnormal migration pattern on isoelectric focusing. A Japanese family with partial TBG deficiency has been reported with normal thyroid hormone-binding affinity, normal isoelectric focusing pattern, normal heat stability, and no mutations in the TBG gene coding region. In this family, the hereditary transmission appeared to be autosomal dominant.

Inherited TBG excess is a rare condition, occurring in approximately 1 in 25,000–30,000 newborns. The pathophysiological basis of TBG excess has been shown to be TBG gene amplification (duplication and triplication), whereas no mutations in the coding and promoting regions have been detected.

TTR

Many TTR variants characterized by single amino acid substitutions have been described, most in patients with familial amyloidotic polyneuropathy, amyloidotic cardiomyopathy, or senile systemic amyloidosis. Some of these TTR variants have a reduced binding

affinity for thyroid hormone. A different TTR variant characterized by an increased affinity for T_4 is responsible for a pattern of euthyroid hyperthyroxinemia (i.e., TTR-associated hyperthyroxinemia).

Albumin

A well-characterized inherited albumin variation transmitted as an autosomal dominant trait is familial dysalbuminemic hyperthyroxinemia (FDH), which is characterized by the presence in serum of an albumin variant with increased affinity for thyroid hormones. In many cases, the albumin variant has increased affinity for T_4 only; in other instances, an increased affinity for T_3 and/or reverse T_3 is also present. Three different single nucleotide substitutions have been identified as the molecular basis for the increased albumin affinity for thyroid hormone.

The inherited absence of albumin (analbuminemia) and the polymorphism called bisalbuminemia have negligible effects on thyroid hormone transport because the decrease in albumin levels is partially compensated for by a slight increase in TBG and TTR levels.

EFFECTS OF VARIATIONS IN THYROID HORMONE-BINDING PROTEINS ON THYROID FUNCTION TESTS

Variations in THBP concentration or affinity profoundly affect serum total thyroid hormone concentrations. This is particularly true for TBG because it has a major role in thyroid hormone binding. Accordingly, a decrease or an increase in serum TBG concentration lead to a decrease or an increase, respectively, in serum total thyroid hormone levels. Although the latter changes are similar to those found in hypothyroidism and hyperthyroidism, respectively, they do not reflect thyroid hypofunction or hyperfunction because they are not associated with variations in the metabolically active, free (unbound) thyroid hormone fraction. Similar considerations are tenable for FDH and TTR-associated hyperthyroxinemia. Therefore, TBG excess, FDH, and TTR-associated hyperthyroxinemia are among the most important causes of euthyroid hyperthyroxinemia. The latter may be independent of THBP variations and caused by drugs (e.g., amiodarone, propranolol, iodinated contrast agents, and L-thyroxine), resistance to thyroid hormones, or the acute phase of some psychiatric disorders (Table V).

Thus, should serum total thyroid hormone measurement provide results that are in contrast with the clinical picture, a THBP abnormality should be suspected and searched for. The correct definition

Table V Causes of Euthyroid Hyperthyroxinemia

| |
|--|
| TBG excess |
| Familial dysalbuminemic hyperthyroxinemia |
| Transthyretin-associated hyperthyroxinemia |
| Amiodarone |
| Propranolol |
| Iodinated contrast agents |
| L-Thyroxine |
| Resistance to thyroid hormone |
| Acute phase of psychiatric disorders |

of thyroid status requires measurement of serum free thyroid hormones and thyrotropin concentrations. This approach is particularly useful when THBPs (e.g., TBG excess or FDH) coexist with thyroid disorders, such as Graves' disease or Hashimoto's thyroiditis. In these circumstances, serum total thyroid hormone levels may be normal in hypothyroid patients, whereas the increased levels of hyperthyroid patients may not easily be distinguished from the increased concentrations due to THBP abnormalities.

Because serum free thyroid hormone determination is crucial for the assessment of thyroid status and to avoid inappropriate treatment for hyperthyroidism or hypothyroidism, it is essential to select methods for free thyroid hormone measurement that are not affected by the abnormal THBP concentration or affinity. The two-step methods in which free hormone is first separated from protein-bound hormone by dialysis, ultrafiltration, column adsorption chromatography, or immunoabsorption provide the most reliable results. In fact, in the second step (immunoassay) the tracer is not in contact with THBP, thus preventing interaction between the two and the consequent artifactual results.

CONCLUSION

THBPs exert functions that are important for thyroid physiology. They provide a buffering action, preventing abrupt changes in serum thyroid hormone levels; function as a storage system for thyroid hormones; and are involved in targeted delivery of thyroid hormone at the tissue level, thus facilitating thyroid hormone cellular distribution. TBG is the major THBP in serum since it binds approximately two-thirds to three-fourths of T_4 and T_3 . Both inherited and acquired variations of the major THBPs (TBG, TTR, and albumin) have been demonstrated. These variations do not modify thyroid status but do affect the results of serum total thyroid hormone measurement and

may lead to incorrect diagnosis and inappropriate treatment for hyperthyroidism or hypothyroidism. Thus, for a correct definition of thyroid status, determination of free T_4 and T_3 by assays that are not influenced by THBPs is required.

Table I Nuclides of Iodine with Clinical Relevance

| Nuclide of iodine (I) | Half-life | Dose | Clinical uses |
|-----------------------|----------------|---------------------------------|--|
| ¹²⁷ I | Nonradioactive | | Necessary for life; can be imaged by fluorescent scanning |
| ¹²³ I | 13 h | 100–300 μ Ci 3.7–7.4 MBq | For measurement of uptake, scanning of thyroid |
| ¹²³ I | 13 h | 1–5 mCi 37–185 MBq | For imaging thyroid cancer after surgical thyroidectomy |
| ¹³¹ I | 8 days | 1–10 mCi 37–370 MBq | For diagnostic images of thyroid cancer after surgical thyroidectomy |
| ¹³¹ I | 8 days | 30–>200 mCi 1.1–7.4 MBq | For imaging thyroid cancer days after radioiodine treatment |
| ¹²⁴ I | 4 days | 5 mCi 185 MBq | Positron emitter for imaging; provides functional and volumetric information |

tetrafosmin, ¹⁸F fluorodeoxyglucose (FDG), ¹¹¹In octreotide, and ^{99m}Tc demercaptosuccinate (DMSA). These are shown in Table II and their roles in imaging thyroid cancer are described later.

INSTRUMENTS

The optimal instrument is a gamma camera fitted with a pinhole collimator. This provides high-resolution scans and allows anterior and oblique views to be produced. Tomographic images, or single photon emission computed tomography, provide better resolution but do not provide additional relevant information. For whole-body imaging, a dual-headed whole-body camera is recommended. For imaging positrons, dedicated positron emission tomography

(PET) cameras have better resolution than hybrid PET–gamma cameras.

NORMAL THYROID GLAND

The adult thyroid gland has an average weight of 15–20 g and appears as two pear-shaped lobes connected by an isthmus. The appearance on scan is variable, with some degree of asymmetry being common (Fig. 1). Iodide that is not trapped by the thyroid gland is primarily excreted in the urine, with small amounts trapped by the salivary glands, stomach, choroid plexus, and lactating breast tissue. Iodine trapped by nonthyroidal tissues is not organified. Recent intake of iodine-rich foods and drugs decreases radioiodine trapping by the thyroid gland

Table II Properties of Radionuclides and Radiopharmaceuticals Used in the Diagnosis of Thyroid Disorders

| Radionuclide | Usual administered dose | Main clinical use |
|---|--------------------------|---|
| Thallium 201 | 3–5 μ Ci | Whole-body scan for thyroid cancer, usually when Tg positive and ¹³¹ I scan negative |
| ^{99m} Tc-sestamibi | 111–185 MBq | Has been used to differentiate malignant from benign nodules |
| | 20–25 mCi | Whole-body scan for thyroid cancer as above |
| ^{99m} Tc-tetrafosmin | 740–925 MBq | Has been used to differentiate malignant from benign nodules |
| | 20–25 mCi | Whole-body scan for thyroid cancer as above |
| ¹¹¹ In-octreoscan | 740–925 MBq | Has been used to differentiate malignant from benign nodules |
| | 1–10 mCi | Minimal value for differentiated thyroid cancer |
| ¹⁸ F-fluorodeoxyglucose | 37–370 MBq for scan | Moderately useful in medullary cancer |
| | 15 mCi | Whole-body scan for thyroid cancer useful in Tg-positive, ¹³¹ I-negative patients |
| | 555 MBq | Has been used to differentiate malignant from benign nodules Useful in medullary cancer |
| ^{99m} TcV dimercaptosuccinate (pentavalent DMSA) | 15–20 mCi 555–740 MBq | Useful for medullary cancer but not available in the United States |

Figure 1 A normal thyroid scan. The imaging was completed 24 h after the oral ingestion of 7.4 MBq ^{123}I . There is homogeneous uptake in both lobes, and the isthmus shows less uptake. The normal 24-h uptake is approximately 10–30% when the dietary iodine intake is approximately 500 μg daily.

and lowers the calculated uptake value. Similarly, administration of intravenous radiographic contrast agents impairs thyroidal iodine trapping.

NONTOXIC GOITER

The most common cause of goiter worldwide is iodine deficiency. In iodine-deficient regions, the uptake of radioiodine is increased. Imaging of a diffuse (endemic) goiter in regions of low iodine intake reveals a uniformly enlarged gland with a relatively homogeneous pattern of uptake. The most common form of goiter in the United States is Hashimoto's disease. The scan is seldom required for Hashimoto's disease, but when obtained the appearance can vary from a diffusely enlarged gland with normal uptake to that similar to Graves' disease, patchy uptake, or a gland with significantly reduced uptake. With increasing numbers of emigrants to the United States from iodine-deficient regions, multinodular goiter is becoming more common, especially in women and those of advanced age. Imaging typically demonstrates a markedly heterogeneous radioiodine distribution due to the presence of multiple nodules with varying degrees of function. This condition can progress to thyrotoxic nodular goiter if one or more of the nodules enlarge and develop autonomous function.

HYPERTHYROIDISM (THYROTOXICOSIS)

Thyrotoxicosis refers to the effects of excess thyroid hormone; hyperthyroidism implies that the excess hormones are produced and secreted by the thyroid. In the setting of thyrotoxicosis, diagnostic radioiodine studies are primarily used to differentiate low-uptake thyrotoxic conditions (e.g., silent thyroiditis), which are self-limited without treatment, from high-uptake conditions that persist unless treated (Table III). Uptake measurement of radioiodine can help determine optimal treatment doses of ^{131}I in the latter case.

Thyrotoxicosis with High Uptake of Radioiodine (Hyperthyroidism)

Graves' Disease

Graves' hyperthyroidism is caused by autoantibodies to the receptor for TSH (TSI). These autoantibodies cause continuous production of thyroid hormone, and the thyroid is unresponsive to normal inhibitory feedback mechanisms (i.e., it is nonsuppressible). Imaging of the thyroid in Graves' disease reveals a diffusely enlarged gland with uniformly increased accumulation of tracer throughout both lobes (Fig. 2). The 24-h uptake value is elevated, often in the range of 60–80%. Visualization of the pyramidal lobe is more

Table III Causes of Thyrotoxicosis

Figure 2 A thyroid scan 24h after ingestion of 7.4MBq ^{123}I in Graves' disease. The uptake is increased (usually $>40\%$) and the gland is larger and plumper.

common in cases of autoimmune thyroid disease, perhaps due to increased stimulation of otherwise minimally functioning remnant tissue, and it is seen in more than 50% of patients.

Toxic Multinodular Goiter

Toxic multinodular goiters are more common in older patients and in those from areas of endemic iodine deficiency. Unlike euthyroid multinodular glands, these are accompanied by symptoms and signs of hyperthyroidism due to the unchecked, autonomous overproduction of thyroid hormone by one or more of the nodules. Scans reveal heterogeneous uptake of tracer by nodules with varying degrees of functionality. At least one nodule demonstrates increased uptake, accounting for the toxic aspect of this condition. Because the uptake tends to be less elevated in this condition than in Graves' disease, and because the condition is more resistant to radiation than Graves' disease, higher doses of therapeutic radioiodine are required to achieve successful ablation.

Solitary Toxic Adenoma

In single toxic adenoma ("hot" nodule), imaging reveals high uptake within this nodule, with little or no uptake throughout the remainder of the gland due to suppression by low TSH (i.e., the remainder of the gland remains sensitive to the normal feedback mechanisms). Scans of toxic adenomas can also reveal

Figure 3 Examples of functioning hot nodules (A) in a euthyroid patient, (B) in a mildly hyperthyroid patient, and (C and D) in hyperthyroid patients. In C and D, there is suppression of normal thyroid. Figure 3C shows central degeneration, and Fig. 3D shows markers where edges of the nodule are palpated.

"cold" (i.e., relatively photopenic) regions within the otherwise intense uptake of the adenoma due to necrosis (degeneration). Figure 3 shows the range of scan findings in functioning thyroid nodules. The uptake in a solitary toxic adenoma is often only mildly elevated or near the upper limit of normal. A functioning euthyroid nodule is likely benign, and the rate of progression to thyrotoxicosis is usually slow but increases when the nodule is large (>3 cm) and the patient is advanced in age.

Thyrotoxicosis with Low Uptake of Radioiodine

Thyroiditis is a general term for a group of disparate conditions, several of which have thyrotoxic symptoms and signs and biochemical findings despite low iodine uptake by the thyroid gland. The excess thyroid hormones result from uncontrolled release of previously stored hormone from disrupted follicles. Imaging reveals minimal trapping of radioiodine by the thyroid gland, and uptake measurements are depressed (Fig. 4). Included in this category are subacute thyroiditis, silent thyroiditis, postpartum thyroiditis, and martial arts thyroiditis, which is also called traumatic thyroiditis. These conditions are usually transient and self-limited. Acute thyroiditis (thyroid abscess) also shows reduced uptake. Thyrotoxicosis with low uptake can also result from oversupply of thyroid hormone by exogenous sources. This can be intentional (thyrotoxicosis medicamentosa) in patients with thyroid cancer

Figure 4 A thyroid scan in a patient with subacute thyroiditis. There is no uptake by the thyroid. A radioactive marker over the sternal notch shows the expected site of the thyroid (arrow).

or factitious when the patient conceals ingesting the medication. Patients who need thyroid hormone commonly take slightly more than a physiological dose because it makes them feel better. This is not factitious thyrotoxicosis because both patient and physician recognize the deception. Thyroid imaging reveals a pattern similar to that seen in thyroiditis, with minimal uptake of radioiodine and a markedly suppressed uptake value. Low thyroglobulin is an indicator of factitious thyrotoxicosis.

In addition, hyperthyroidism can be secondary to ectopic overproduction of thyroid hormone (as in functioning thyroid metastases, trophoblastic disease, struma ovarii, or teratomas). Scanning outside the thyroid determines the source of thyroid hormone production. Excess intake of iodine can cause hyperthyroidism (Jod Basedow effect). This is more common in patients who have been chronically iodine deficient and then are exposed to excess iodine.

THYROID NODULES

Thyroid imaging using radiopharmaceuticals has a limited role in patients with a solitary thyroid nodule. Scintigraphy can be used to determine the functional status of such nodules, recognizing that nonfunctioning (cold) nodules have a greater likelihood of being malignant than do functioning (hot) nodules. The vast majority of nodules imaged, however, are nonfunctional (approximately 90%), and 10–15% of these

are malignant. Thus, the positive predictive value of scintiscan for thyroid cancer is low (on the order of 15%). This raises concern about the cost-effectiveness of scintigraphy. Because of the low positive predictive value of thyroid scan to diagnose cancer, patients with thyroid nodules who are euthyroid are better evaluated by fine needle aspiration (FNA). In contrast, when patients have a nodule and are hyperthyroid, scintigraphic imaging can be performed first to discriminate between a benign functioning nodule and a nonfunctioning nodule in the setting of Graves' disease. The latter case is relatively uncommon, but it warrants further evaluation by FNA. This discussion regarding the relative malignant potential of hot and cold nodules applies to adults only and does not hold for children, in whom functional nodules have a relatively high likelihood of malignancy. ^{123}I is preferred to $^{99\text{m}}\text{TcO}^4$ because it provides more physiologic information and predicts response to therapeutic ^{131}I for functional nodules. There are disparate results for ^{123}I and $^{99\text{m}}\text{TcO}^4$. A cold ^{123}I nodule that traps pertechnetate has a significant probability of being malignant.

ECTOPIC THYROID TISSUE

The thyroid begins its embryologic development in the posterior oral cavity and subsequently migrates downward toward its final destination in the neck base. This migration may be arrested, leaving thyroid tissue in ectopic locations ranging from the base of the tongue to the pericardium. Ectopic thyroid tissue is usually hypofunctional, and the resultant elevation in TSH stimulates the ectopic tissue to grow larger over time. When ectopic thyroid tissue is present (above the neck base), a normal cervical thyroid gland is almost always absent. Diagnosis should be made using a combination of thyroid function tests and radioiodine scintigraphy. The embryologic descent is marked by the thyroglossal duct, and cysts can develop along this route. Thyroglossal duct cysts generally do not take up radioiodine and are thus better confirmed with ultrasound or other anatomic imaging studies. The pyramidal lobe is a normal remnant of the thyroglossal duct tract and can rarely be seen scintigraphically in normal scans and in approximately two-thirds of scans in autoimmune hyperthyroidism.

THYROID CANCER

After thyroidectomy for thyroid carcinoma, radioablation with ^{131}I can be used to eradicate any

remaining thyroid tissue within the thyroid bed or metastases to lymph nodes or distant sites. Whole-body imaging has an important role in the postoperative management of the thyroid cancer patient. A diagnostic scan prior to treatment is useful to determine the dose of therapeutic ^{131}I to be prescribed based on uptake in the thyroid region and the presence or absence of uptake in lymph nodes or other metastatic sites. Opinions vary regarding the necessity of the diagnostic scan prior to the first radioablation, but follow-up using the diagnostic scan is well established. Imaging of the patient following ablation allows the physician to verify uptake of the radiopharmaceutical by the thyroid tissue and to identify any areas of uptake not seen on the diagnostic scan. Periodic follow-up imaging is performed to monitor for recurrence of thyroid cancer; the general guidelines proposed by some authorities recommend annual ^{131}I imaging until two consecutively negative studies are found. A TSH level $>25\text{--}30\text{ mU/liter}$ facilitates the detection of small amounts of thyroid tissue. We advise using a level of 50 mU/liter or higher. Levo-thyroxine is withdrawn for 4 weeks; alternatively, triiodothyronine (T_3), which has a shorter half-life, is substituted for 4 weeks, allowing time for T_4 to be metabolized, and then T_3 is discontinued for 2 weeks. The introduction of recombinant human TSH (rhTSH) has made it possible to image (and treat) with ^{131}I , without rendering the patient hypothyroid. Studies show that rhTSH is almost equivalent to endogenous TSH stimulation for determining the presence or absence of cancer, provided scan and serum thyroglobulin values are obtained. Peak serum TSH levels using rhTSH can be higher (the mean value in our experience with >100 patients is $140\text{ }\mu\text{m/liter}$) than those obtained after conventional withdrawal of thyroid hormone, but the time of stimulation is shorter. Patients prefer the rhTSH protocol because hypothyroidism is avoided. Since rhTSH has been studied extensively only in the diagnostic setting and patients scanned after surgery frequently require ^{131}I therapy, it may be prudent to reserve rhTSH for follow-up when it is anticipated that the scan will be negative. There are reports of the value of rhTSH in therapy. In any situation in which prolonged hypothyroidism and sustained elevation of TSH would be disadvantageous, rhTSH should be considered (e.g., when the metastases are in confined anatomic spaces, such as the spinal cord, and expansion of these could cause clinical problems).

The plasma inorganic iodine level is an important factor with regard to the amount of radioiodine that is trapped by the thyroid. Decreasing the intake of

iodine to $30\text{--}50\text{ }\mu\text{g/day}$ over 7–14 days increases the uptake two or three times, thus theoretically increasing the effectiveness of radioablation. A low-iodine diet is recommended for 2 weeks prior to radioiodine scanning (details of a low-iodine diet are available at www.Thyca.org). Diagnostic whole-body scanning is conducted 2–4 days after administration of $37\text{--}370\text{ MBq }^{131}\text{I}$. ^{131}I is used because its long half-life enables imaging after 48–96 h or more. Anterior and posterior whole-body images and spot scans of the neck with corresponding uptake measurements are obtained. Normal thyroid traps significantly more iodine than metastases; therefore, when there is a normal remnant it might have to be ablated prior to treating metastases. The importance of a skilled thyroid surgeon is emphasized. Lymph node metastases are usually in the lateral neck and less commonly in the mediastinum. Pulmonary metastases can be focal or diffuse, whereas skeletal lesions are focal in nature. The sensitivity of diagnostic ^{131}I scan for papillary cancer and follicular cancer has been reported to be 45–80%. The sensitivity of posttherapeutic ^{131}I scans is higher. Controversy exists regarding whether use of ^{131}I for diagnostic scan can cause “stunning,” which is the inability of the thyroid tissue to take up a therapeutic dose of ^{131}I secondary to radiation on the thyroid tissue by the diagnostic dose. Some investigators have not found the stunning effect after administration of 74 or 185 MBq of ^{131}I . Stunning appears to occur when larger diagnostic doses are prescribed and when there is a delay between testing and treatment. Reasons for lack of iodine uptake by cancers include genetic changes in the Na^+/I^- symporter, Hurthle cell types, and poorly differentiated follicular and papillary carcinomas. Retinoic acid has been used to promote redifferentiation and induce ^{131}I uptake in thyroid cancers with previously ^{131}I -negative papillary, follicular, and mixed cell-type tumors. These studies have shown mixed results, but overall this strategy appears to have minimal clinical impact.

Diagnostic Scanning with ^{123}I

^{123}I emits gamma rays at lower energies than does ^{131}I , and it does not emit beta particles and is unlikely to induce thyroid stunning. At least one study has demonstrated a higher rate of ablation after ^{131}I treatment when ^{123}I was used in the diagnostic scan, indicating the possibility that ^{123}I may replace ^{131}I for whole-body scintigraphy (Fig. 5). A dose of $74\text{ MBq }^{123}\text{I}$ has been shown to have the same overall effectiveness in diagnostic imaging as a dose of $74\text{ MBq }^{131}\text{I}$.

Figure 5 (A, right) Anterior and posterior whole-body scan 24 h after a dose of 74 MBq ^{123}I in a patient with thyroid cancer who had thyroidectomy and prior ^{123}I therapy. There are two metastases in the posterior image (arrows). These are seen faintly in a rib and sacroiliac joint on bone scan (left, arrows). (B) A whole-body scan 10 days after a therapeutic dose of 7.4 GBq ^{123}I . The two lesions seen on diagnostic scan are shown. In addition, there is a faint lesion in the low thoracic spine that was not imaged with ^{123}I (arrow). There is significant uptake in the salivary glands. Liver uptake is due to metabolism of radioactive thyroid hormones.

Posttherapy Scanning

A posttherapy ^{131}I scan is usually performed 5–7 days following radioiodine ablation. **Figure 6** shows whole-body ^{131}I scans—first a diagnostic scan followed by a posttherapy scan and a second diagnostic scan 12 months later to determine whether ^{131}I treatment was successful. There is a higher sensitivity and clearer delineation of lesions using posttherapy scans due to the higher dose of ^{131}I . Some authors report that as many as one-third of patients had metastases to the lymph nodes and lungs seen on posttherapeutic study that were not seen on the diagnostic scan. In fact, some clinicians perform only a posttherapeutic scan. We do not recommend this approach because in our experience, the diagnostic scan determines how much therapeutic ^{131}I to prescribe and the posttherapy scan seldom shows additional clinically relevant information.

Figure 6 (A) A diagnostic scan made 72 h after a dose of 74 MBq ^{123}I . There is uptake in the thyroid bed. Physiological uptake is present in the stomach and intestines. (B) Whole-body scan in the same patient 1 week after 3.7 GBq ^{123}I therapy. There is uptake in the thyroid bed and a left cervical node, and there is also uptake in the liver and gut. There is no stunning. (C) Whole-body scan in the same patient 1 year after I-131 treatment. The scan was made 48 h after a dose of 74 MBq ^{123}I . RhTSH was used to stimulate uptake. There is no evidence of disease. There is physiological uptake in the gut and nasopharynx.

False-Positive ^{131}I Scans

Physiologic uptake is seen in the salivary glands, nasal mucosa, gastric mucosa, small bowel, and colon. Excretion can also be identified in the bladder and bowel. These should not be confused with thyroid metastases. However, contamination by secretions or excretions can be misinterpreted as metastases. Other false positives have been reported in sinusitis, dental disease, tracheostomy, bronchiectasis, thymus, gallbladder, Meckel's and Zenker's diverticulum, psoriatic plaque, rheumatoid arthritis, hiatal hernia, and achalasia. Nonthyroidal cancers that have been mistaken as recurrent thyroid disease or metastases include salivary adenocarcinoma, meningioma, lung cancer, ovarian cancer, breast cancer, teratoma, neurilemoma, and gastric adenocarcinoma. Labeled thyroid hormone may also collect diffusely in the liver in the postablation scan, after sufficient production by residual thyroid tissue and concentration by hepatocytes.

Other Radionuclide Scanning Techniques

Other scanning procedures that do not depend on iodine trapping can be employed for cancers that do not trap iodine. PET appears to be the first choice. When used in patients who are Tg positive and ^{131}I scan negative, PET has a sensitivity of approximately 60–80%. False-positive results may be due to uptake of FDG in the tense cervical muscles of anxious patients and in brown fat. Thallous-201 chloride is taken up by all types of thyroid cancer. The maximal cancer to background ratios are obtained 10–15 min after injection. Anterior and posterior whole body images are obtained. Neither a low-iodine diet nor thyroid hormone cessation are necessary. The sensitivities range from 45 to 94%. In one study, the detection rate of recurrent or metastatic thyroid carcinoma using ^{201}Tl was similar to that of FDG PET, and the two modalities are mostly concordant as well as complementary to ^{131}I scintigraphy. However, FDG PET is capable of providing better image quality. Sestamibi has been used to identify thyroid cancers and metastases; anterior and posterior whole-body images are obtained 10–20 min after injection. More than 90% of the tracer is found in the inner mitochondrial matrix. The sensitivity is 70–90%. FDG PET was found to be more sensitive in the detection of recurrent thyroid cancer than $^{99\text{m}}\text{Tc}$ sestamibi. $^{99\text{m}}\text{Tc}$ tetrafosmin has properties similar to those of sestamibi. This radiopharmaceutical is used most often in the detection of local recurrence and cervical lymph node metastases. The sensitivity of tetrafosmin scanning for

Figure 7 PET scan 1 h after intravenous injection of 555 MBq ^{18}F fluorodeoxyglucose. The patient had an elevated Tg but negative ^{123}I diagnostic and three negative posttherapy scans. Abnormal uptake is seen in the left supraclavicular node. This node was removed surgically and Tg became undetectable.

the detection of metastases has been reported to be 70–90%. ^{111}In octreotide, an analogue of somatostatin, has been most useful in imaging residual or metastatic medullary thyroid cancer since these neuroendocrine tumors express somatostatin receptors. ^{111}In octreotide scans have occasionally been useful in imaging differentiated thyroid carcinomas, especially in the case of Hurthle cell carcinoma. **Figure 7** shows a positive PET scan in a patient who had an elevated Tg but negative diagnostic and posttherapy scans. Specificities are higher with $\text{Tg} \geq 5\text{--}10 \mu\text{g/liter}$ and have been correlated with increasing thyroglobulin levels. Misinterpretation of tense or active muscles in the neck and larynx has led to false positives; therefore, it is important that the patient remain relaxed during the procedure and avoid speaking or chewing. Incidental focal uptake seen in the thyroid during PET performed for other indications is highly suspicious for primary thyroid cancer.

IMAGING MEDULLARY THYROID CANCER

When calcitonin remains high following surgery, residual medullary cancer is present. Noninvasive methods of detecting and imaging medullary cancer include ^{201}Tl , $^{99\text{m}}\text{Tc}$ sestamibi, ^{111}In octreotide, radioiodinated meta-iodobenzylguanidine, ^{131}I anti-CEA, and $^{99\text{m}}\text{Tc}$ -labeled DMSA. PET is superior to computed tomography or magnetic resonance imaging in detecting metastatic and recurrent medullary thyroid cancer, and sensitivities as high as 76% have been reported. Patients with rapidly rising serum calcitonin levels during the first postoperative year benefit most from a PET scan.

Figure 1 Patient with a clinically solitary thyroid nodule located in the midline of the anterior neck.

role of specific candidate genes in the etiology of nodular thyroid disease have not provided a clear picture, mostly because too small and too few families have been studied. Although single genes may play a role in certain families, it is thought that genetic heterogeneity (i.e., no single gene is either necessary or sufficient for disease development) is highly likely.

The following sequence of events appears to lead to the development of nodular thyroid disease: First, iodine deficiency or other goitrogenic factors induce thyroid hyperplasia. Second, due to increased proliferation during this stage, mutagenesis is increased. In the case of hot or toxic nodules, these mutations confer constitutive activation of the cyclic AMP cascade (e.g., thyroid-stimulating hormone receptor and $G_s\alpha$ protein mutations). This eventually leads to stimulation of iodine uptake and metabolism, thyroid hormone synthesis and release, and hyperthyroidism. In the case of cold thyroid nodules, a similar mechanism, but with mutations in genes that favor dedifferentiation (e.g., *ras* oncogene), is suggested. These latter mutations initiate growth but not function of the affected thyroid cells.

EPIDEMIOLOGY

Unfortunately, our knowledge is hampered by a lack of population-based longitudinal studies using sensitive diagnostic imaging (e.g., ultrasound) allowing distinction between uninodular and multinodular disease and morphologic as well as functional characterization. Despite these shortcomings, there is a clear pattern of increased thyroid nodularity with decreasing iodine intake. The fact that nodules exist in the face of iodine sufficiency and even iodine excess emphasizes the importance of other environmental etiologic factors acting in concert with genetic factors.

In the Whickham survey (United Kingdom), a solitary thyroid nodule was present in 5.3% of women and 0.8% of men (6.6:1 ratio). Size and function of the nodules were not indicated. In the Framingham, Massachusetts, study, a solitary thyroid nodule was present in 6.4% of women and 1.6% of men. Both investigations used clinical evaluation (palpation) and were performed in an iodine-sufficient area. If ultrasound is used, the prevalence of thyroid nodules >10 mm is usually 20–30%, increasing with age and in areas with insufficient iodine intake. In autopsy studies, 50% or more have either single or multiple thyroid nodules. If investigated using isotope scintigraphy, approximately 10–15% of all nodules are autonomously functioning (taking up the isotope, hot or toxic), whereas 85–90% are nonfunctioning (cold, no isotope uptake). The incidence of clinical disease is estimated to be 0.1% by palpation, corresponding to a lifetime risk of 5–10%.

NATURAL HISTORY

The natural history with respect to growth and function varies and is difficult to predict in a given patient since no specific growth parameters exist. Therefore, it is difficult to decide whether a patient can be monitored without treatment or should be offered treatment before the nodule grows any more.

In the Framingham survey, new nodules appeared with an incidence of 1 per 1000 individuals per year, resulting in an estimated lifetime risk for developing a nodule of 5–10%. After exclusion of the minority of patients who have rapid growth and symptoms and clinical suspicion of malignancy, and who are therefore offered treatment, nodules on average do not change significantly over time. Nodules that increase in size are predominantly solid and carry a higher risk of harboring thyroid malignancy than those predominantly cystic, which are more prone to decrease in size or even disappear. In many patients, ultrasound

will identify additional nodules not evident at clinical investigation. Given time, many patients will be classified as having multinodular goiter.

In the subgroup of hot nodules, the rate of evolution into a toxic nodule is approximately 4% annually. The risk is closely related to nodule size. If the nodule is >3 cm, the risk is 20% within 6 years, whereas the risk is only 2–5% if nodule size is <2.5 cm.

DIAGNOSIS

Clinical Evaluation

There is no clear-cut relation between thyroid nodule size, morphology, and function, on the one hand, and the complaints of the individual patient, on the other hand. The majority of patients have few or no clinical symptoms. Therefore, given normal thyroid function and exclusion of malignancy, many need no treatment. A rough management algorithm for the majority of patients with a thyroid nodule is shown in Fig. 2.

Manifestations

When present, the most important symptoms and signs are caused by compression of structures in the neck or, rarely, in the upper thoracic cavity. In

addition to various degrees of neck disfigurement, which by itself can merit treatment, the symptoms are related to compression of the trachea or esophagus. The symptoms of tracheal compression are dyspnea, stridor, cough, and choking sensation, but respiratory distress is rare unless the nodule extends into the thoracic cavity. An acute exacerbation may be caused by hemorrhage into a nodule or by upper respiratory infections causing endotracheal swelling. Complaints due to esophageal compression are less common, as is vocal cord paralysis caused by stretching and/or compression of the recurrent laryngeal nerves.

A high proportion of functioning nodules cause slight or overt hyperthyroidism due to excessive secretion of thyroid hormones. This condition, with or without pressure symptoms or cosmetic complaints, may by itself merit treatment.

Clinical Examination

The evaluation of a patient with a thyroid nodule comprises a careful history and physical examination focusing on inspection of the neck, including regional lymph nodes, the upper thorax, and palpation of the thyroid. This clinical evaluation should preferably be

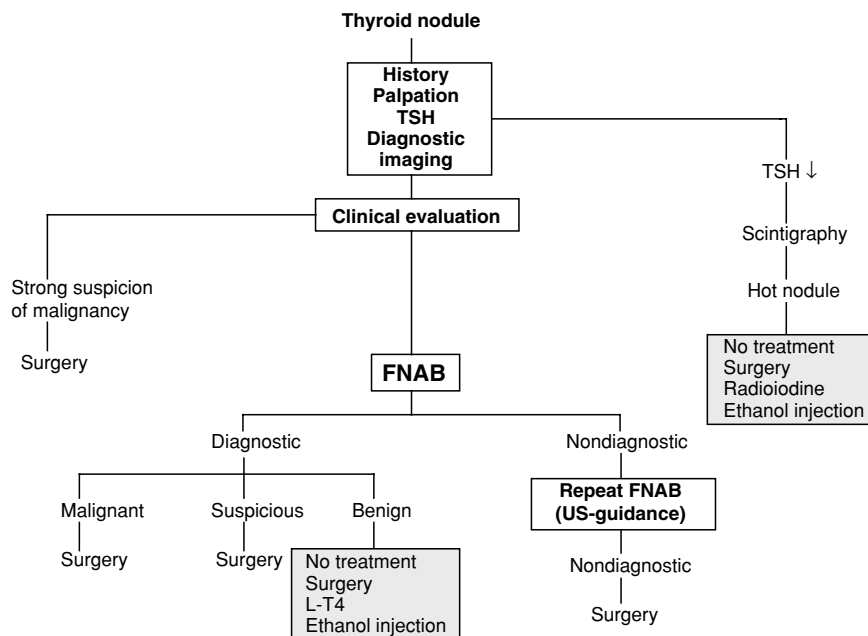

Figure 2 Management algorithm outlining a cost-effective evaluation and treatment of the solitary thyroid nodule. In case of strong suspicion of malignancy, surgery is advised irrespective of fine needle aspiration biopsy (FNAB) results. In case of a nondiagnostic result, repeat FNAB yields a satisfactory aspirate in 50% of patients. FNAB guided by ultrasonography (US-guidance) allows sampling from the periphery of a solid nodule or solid part of a mixed solid–cystic nodule, increasing the sufficiency rate. The options in case of a diagnostic FNAB include those for both solid and cystic nodules. In case of recurrent cysts, the possibilities are reaspiration, surgery, or ethanol injection. The shaded boxes indicate treatment options.

done with the patient swallowing gulps of water and the head tilted slightly backward. Observer variation is very high, and the specificity and sensitivity of the diagnosis of a thyroid nodule are low. Detection of nodules depends on their size, morphology, and location within the thyroid parenchyma; the anatomy of the patient's neck; and, most important, the training of the physician. The patient is usually unaware of the presence of a nodule smaller than 1.5–2 cm in diameter, and a nodule of 1.0 cm or less usually escapes detection by the physician.

Assessment of Risk of Malignancy

A family history of benign goiter suggests a benign disorder but is not proof thereof. Medullary thyroid carcinoma or even papillary or follicular thyroid carcinoma in the family should raise suspicion. The risk of harboring cancer is highest in the young and the old, and the risk is higher in men than in women. Head or neck irradiation during childhood for a number of benign conditions leads to clinically evident thyroid abnormality in 10–40% of these individuals 5–40 years later. Thyroid carcinomas, mainly papillary carcinomas, are seen in 30% of those with thyroid abnormality. The importance of fallout radiation is tragically evidenced by the epidemic of childhood papillary thyroid cancer seen in Belarus and Ukraine after the Chernobyl nuclear accident. Rapid nodule growth (weeks to months) and symptoms of local invasion, such as pain, dysphagia, hoarseness, or dyspnea, suggest a carcinoma; however, only a minority of patients have these symptoms. Growth during thyroid hormone therapy is particularly worrisome. Sudden growth is most likely a thyroid cyst or hemorrhage into a previously undetected nodule. A hard and immobile nodule is suggestive of thyroid carcinoma, as is same-sided lymphadenopathy. Virtually all patients with thyroid carcinoma have normal thyroid function, as do most patients with benign thyroid nodules. On the other hand, thyroid hyperfunction normally rules out thyroid malignancy. In case of a high clinical suspicion of malignancy (Table I), thyroid surgery should be recommended, irrespective of a benign needle biopsy, since the likelihood of malignancy is very high.

Laboratory Investigations

The only relevant biochemical test that is routinely needed is serum thyrotropin (TSH), which if normal indicates normal thyroid function. Subnormal serum TSH values should lead to determination of free

Table I The Most Important Clinical Factors Increasing the Likelihood of Thyroid Malignancy in a Patient with Normal Thyroid Function and a Solitary Thyroid Nodule

| |
|---|
| Family history of thyroid malignancy |
| Rapid nodule growth (especially during levothyroxine therapy) |
| Very firm or hard nodule |
| Fixation to adjacent structures |

| Compression symptoms (dysphagia, hoarseness, dyspnea) |

thyroxine (T_4) and free triiodothyronine (T_3) in serum. If serum TSH is decreased on repeat examination, treatment of this hypermetabolic state should be offered independent of whether free T_4 and/or free T_3 are elevated, especially in the elderly. Isotope scintigraphy is recommended and will most likely demonstrate a functioning nodule. Most patients have normal serum TSH, including those with thyroid malignancy. Elevated serum TSH with or without decreased serum free T_4 suggests that the patient has chronic autoimmune thyroiditis (Hashimoto's thyroiditis). This can be verified by demonstrating thyroid autoantibodies in serum.

Thyroid autoantibodies against thyroid peroxidase or thyroglobulin do not aid in the differentiation between malignant and benign nodules. However, they are markers of an increased risk of developing hypothyroidism (Hashimoto's thyroiditis) and hyperthyroidism (Graves' disease) spontaneously or secondary to surgery or treatment with radioactive iodine.

Calcitonin, a hormone produced by the parafollicular C cells of the thyroid gland, is the only clinically relevant biochemical marker of medullary thyroid carcinoma, which accounts for approximately 5% of all thyroid carcinomas. Basal or pentagastrin-stimulated serum calcitonin measurement is more sensitive than thyroid biopsy in detecting medullary thyroid carcinoma. However, there is no consensus on its routine use in patients with thyroid nodules.

Diagnostic Imaging

Neck palpation is very imprecise with regard to the determination of thyroid nodule morphology and size. For this reason, imaging methods are increasingly

used, although no imaging method can accurately differentiate benign and malignant nodules.

Ultrasonography

This very sensitive technique with a high resolution has had a dramatic impact on clinical practice. When used in patients with a goiter, it has been shown to alter management in more than half of these patients. The increasing and widespread use, whether initially or during follow-up, is related to high availability, low cost, little discomfort to the patient, and its nonionizing nature. It allows determination of total thyroid volume, individual nodule size and echogenicity, and morphology of extranodular tissue and the evaluation of regional lymph nodes. Color-flow Doppler provides additional information regarding regional blood flow and nodule vascularity (Fig. 3). It distinguishes solid from cystic lesions and aids in the performance of accurate biopsies, punctures, and therapeutic procedures, such as percutaneous ethanol injection and laser therapy. Although there is no ultrasonographic pattern, alone or in combination with other techniques that may be considered specific for thyroid malignancy, characteristics such as hypoechogenicity, microcalcifications, and increased nodular flow are all predictive of malignancy to some extent. However, fine needle aspiration biopsy, preferably guided by ultrasonography, is far more accurate for this distinction.

Figure 3 Various appearances (morphological patterns) of a thyroid nodule using ultrasonography. (A) Normal thyroid tissue. (B) Solitary solid hypoechoic (dark) thyroid nodule in the right thyroid lobe (left) surrounded by normal thyroid tissue (medium gray). (C) Solitary cyst (black area) surrounded by normal thyroid tissue. (D) Multiple nodules with varying echogenicity (multinodular gland).

Scintigraphy

Although the resolution of isotope imaging can be enhanced to 5–10 mm by tomography, this resolution is still far below that of ultrasonography. Therefore, scintigraphy is not so much used for evaluation of morphology as for evaluation of the regional uptake of the isotope and thereby the determination of functionality of the thyroid nodules (Fig. 4). Nodules with uptake by scintigraphy (hot or toxic) almost never harbor clinically important malignancy, although rare exceptions do exist. In an unselected population of patients with a thyroid nodule, 80–90% of the nodules were nonfunctioning (cold). The a priori risk of malignancy is probably no higher than 5% for such a nodule. Scintigraphy is inaccurate in estimating thyroid and nodule size as well as in diagnosing malignancy.

Computed Tomography and Magnetic Resonance imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) are expensive, time-consuming, and not readily available for imaging thyroid nodules. Their major strength is their ability to diagnose and assess the extent of substernal/intrathoracic thyroid tissue much more precisely than any other method. Both methods are well suited for visualizing the trachea and demonstrating narrowing of the tracheal

Figure 4 Various appearances (morphological patterns) of a thyroid nodule using scintigraphy. (A) Normal uptake in two thyroid lobes. area or a decrease in its volume. However, this measure correlates poorly with lung function.

Fine Needle Aspiration Biopsy

Fine needle aspiration biopsy (FNAB) provides the most direct and specific information about a thyroid nodule and is used by virtually all thyroid specialists in the initial evaluation of a patient with a solitary thyroid nodule or a dominant nodule in a multinodular goiter. It is without complications, inexpensive, and easy to learn to perform. Use of FNAB has reduced the number of thyroid surgeries by approximately 50%, doubled the surgical yield of thyroid cancer, and reduced the overall cost of medical care for these patients by 25%.

The technique involves the use of a 5- to 20-ml plastic syringe with a 22- to 27-gauge needle. The skin is cleaned with alcohol, and sometimes skin infiltration with 1 or 2 ml of 1% lidocaine is used. The needle attached to the syringe is inserted perpendicular to the anterior surface of the neck. Negative pressure is applied, and as soon as bloody fluid in the hub of the needle appears, pressure is released and the needle withdrawn. No fluid should enter the syringe. If the nodule is a cyst or partly cystic, the aspiration should be followed by FNAB of any residual solid component. Investigation of the cyst sediment rarely aids in the diagnosis of malignancy. After withdrawal, the needle is detached and the specimen is evacuated onto a slide. The specimen should be smeared immediately. Often, air drying is used and a number of staining methods are available.

Diagnostically useful FNAB specimens are obtained in approximately 80% of the cases and rebiopsy typically reduces the number of insufficient samples by half. The number of sufficient samples increases with operator experience, use of ultrasound guidance, the number of aspirations, when the nodule is solid, and with increasing cytopathologist experience, but it is highly dependent on the criteria used for adequacy of a sample. The relative distribution of FNAB results is given in Table II.

Diagnostic accuracy of FNAB at large depends on the classification of the 10–15% of suspicious lesions, of which 15–25% are malignant. If regarded negative, sensitivity will decrease and specificity will increase. If regarded positive, the converse is true. Patients with suspicious, malignant, and nondiagnostic FNAB results (after reaspiration) should be operated on (Fig. 2). If this strategy is followed, the risk of postponing the diagnosis of malignancy in the approximately

Table II Etiology of Thyroid Nodules and the Relative Distribution of Fine Needle Aspiration Biopsy Results^a

| Etiology | Distribution (%) |
|---|-------------------------|

^aData are representative of the author's institution.

^bThe number of nondiagnostic results can be halved by rebiopsy.

70% of cases in which nonsurgical therapy is an option can be reduced to 1%. Repeat FNAB during follow-up of nodules left untreated will virtually eliminate the risk of overlooking thyroid malignancy. Neither elaborate classification systems for suspicious FNAB findings nor the use of large-needle biopsy increase diagnostic accuracy. Attempts to include biochemical analysis of thyroid cyst fluid or immunodetection of various candidate molecules, such as thyroid peroxidase or lectin-related molecules, in the evaluation of thyroid cytology are still in the experimental stage.

TREATMENT

There is no ideal treatment for the thyroid nodule. The optimal therapy varies depending on the size and morphology of the nodule and whether it is functioning (Fig. 2; Table III). Although nodules 1–1.5 cm or larger should undergo FNAB, treatment is often not necessary once malignancy has been ruled out. In the subcentimetric nodule, FNAB need not routinely be performed and treatment is rarely indicated.

Levothyroxine Therapy

Although on the decline, it is still common practice to use thyroid suppression with levothyroxine (L-T4) in the management of solid thyroid nodules in the euthyroid patient. The aim is to shrink existing nodules, considered to be a favorable sign indicating that the

Table III Advantages and Disadvantages of the Treatment Options for the Solitary Thyroid Nodule

| Treatment | Advantages | Disadvantages |
|--------------------------|--|---|
| Levothyroxine | Outpatient Low cost May slow nodule growth Possibly prevents new nodule formation | Low efficacy Lifelong treatment Regrowth after cessation Adverse effects (bone and heart) Not feasible with TSH suppressed |
| Surgery ^a | Prompt relief of symptoms Nodule ablation Definite diagnosis | Inpatient High cost Anesthesiological risk Surgical risk Vocal cord paralysis Hypoparathyroidism Hypothyroidism Bleeding and infection Scar |
| Radioiodine ^b | Outpatient Low cost | 40% size reduction Contraceptives needed in fertile women Side effects Radiation thyroiditis Graves' disease Hypothyroidism Long-term cancer risk unknown |
| Ethanol injection | Outpatient Relatively low cost Thyroid function preserved | Repeat injections needed Low efficacy in large nodules Operator dependency Side effects ^c Pain Transient dysphonia Thyroiditis Extranodular fibrosis Complicates subsequent cytological interpretation |

^aIn this case, unilateral operation limiting the risk of side effects.

^bIt can only be used in the nodule with uptake, whether thyroid function is increased or not.

^cExcept for various degrees of pain, side effects are rare.

nodule is benign. TSH suppression seems most beneficial in the subgroup of patients with small, solid nodules. Approximately 20% of solitary solid nodules actually regress as a result of L-T4 therapy, and cessation of therapy leads to rapid regrowth. On average, long-term therapy is without significant nodule-reducing effect. Growth can be suppressed or slowed, and the formation of new nodules may be prevented. However, this necessitates that serum TSH is suppressed to subnormal values, which may have adverse effects. This degree of TSH suppression, called mild or subclinical hyperthyroidism, is associated with an increased risk of atrial fibrillation, other cardiac side effects, and reduced bone density, potentially leading to osteoporosis. It is without effect in the cystic nodule

and in patients with spontaneously low serum TSH with or without elevated thyroid hormone levels. For these reasons, its use is questionable; at most, it can be used in younger patients with small nodules, in whom treatment is least necessary.

Surgery

When there is malignant or suspicious cytologic features and/or symptoms due to the nodule, surgery is often recommended, especially for younger patients and in cases in which there are large nodules. The preferred operation is a unilateral removal of the affected lobe. The frequency of complications decreases with increasing experience and specialist

training and is generally low. Complications include temporary and permanent unilateral vocal cord paralysis (1–2 and 0.5–1.0%, respectively), temporary and permanent hypocalcemia (1.0 and 0.5%, respectively), and wound hematomas and infections (0.5 and 0.3%, respectively). The risk of complications increases with the extent of operation. In the patient with normal thyroid function postoperatively, there is no indication for routine L-T₄ treatment since this does not seem to hinder thyroid growth in the long term, at least in iodine-sufficient regions.

Although an option, surgery is rarely used in the hyperthyroid patient with a toxic nodule. Radioactive iodine treatment is the preferred treatment.

Radioactive Iodine

If the patient has hyperthyroidism (toxic nodule), antithyroid drugs (propylthiouracil or methimazole) can normalize thyroid function but disease recurrence is the rule when medication is stopped. With the exception of a few patients who have a large nodule, in which case surgery may be indicated, radioactive iodine is the treatment of choice. This is also the case for the clinically euthyroid patient with a functioning (hot) nodule without hyperthyroidism, in whom treatment may be dictated by the nodule size, which may cause compression or cosmetic disturbances. In addition, radioactive iodine treatment is used to prevent hyperthyroidism (annual risk of approximately 4%).

A cure rate (i.e., normalization of thyroid function and the appearance on a thyroid isotope scintigram) of 75% is seen, and the nodule shrinks 30–40% following a single dose of radioactive iodine. Side effects are few, with rare cases of radiation thyroiditis and transition to Graves' disease. The risk of hypothyroidism is approximately 10% after 5 years and unrelated to the dose of radioactivity. The long-term risk of malignancy is unknown but considered negligible.

Radioactive iodine has no effect in the nonfunctioning (cold) thyroid nodule, whether solid or cystic. In the future, the possibility of stimulation with recombinant human TSH before radioactive iodine treatment may lead to an increased iodine uptake and also an effect in the solid, cold nodule.

Ethanol Injection

Ethanol (70–100%) causes local small vessel thrombosis and coagulative necrosis, leading to fibrosis and permanent tissue ablation. It has been used in both

autonomously functioning thyroid nodules and nonfunctioning thyroid nodules, whether solid or cystic. If multiple injections are used, complete cure (normal serum TSH and isotope scintigraphy) can be achieved in 60–70% of patients with toxic nodules and 70–80% with hot nodules. A single ethanol instillation (after aspiration) in thyroid cysts reduces recurrence to approximately 20% compared to approximately 50% after aspiration alone. In solitary solid, nonfunctioning thyroid nodules, approximately 50% of patients are relieved of their clinical symptoms based on a 50% nodule volume reduction. Additional injections have little effect. It is an option for patients who do not wish to undergo radioiodine treatment or surgery. However, it often necessitates repeat treatment to obtain complete cure. The long-term effects are unknown, and the treatment is not devoid of side effects. The procedure, often used in Italian centers, is not a routine option, should still be classified as experimental, and requires the special technical skill that can be obtained only at a center familiar with interventional ultrasound.

Ultrasound-guided interstitial laser photocoagulation for solid solitary, benign, nonfunctioning thyroid nodules was recently introduced. One treatment lasting approximately 10 min resulted in a nodule reduction of approximately 40% and significant reduction of pressure symptoms. These results are similar to those obtained using ethanol therapy. The fact that the spread of energy with a laser (thermal destruction) can be controlled, as opposed to chemical destruction by injection of ethanol, may favor laser therapy in the long term. This treatment option is experimental.

reactions: Iodotyrosine is formed at the active site of TPO through the reaction of iodide radicals with tyrosine radicals. In particular, TPO catalyzes two-electron oxidation of tyrosine and iodide and forms an iodinating intermediate (TPO-I^+) that reacts with tyrosine and produces monoiodothyrosine (3-iodotyrosine; MIT) with TPO. As another possibility, Taurog proposed a reaction between oxidized TPO and I^- to produce hypoiodite (OI^-), which also involves a two-electron change.

Oxidative Coupling by TPO

TPO catalyzes two-electron oxidation of iodide and tyrosine to form MIT; further reaction of the MIT radical with iodide (one-electron oxidation) gives diiodotyrosine (3,5'-diiodotyrosine; DIT) through formation of DIT radicals. No matter the precise nature of the iodinating species, it is clear that iodide is oxidized by H_2O_2 and TPO and transferred to the tyrosyl group within the Tg peptide chain. Not all of Tg's tyrosyls are equally accessible to iodination. Isolated from the thyroid, Tg rarely contains more than 1% iodine, or approximately 56 atoms of iodine per 660-kDa molecule of Tg. The molecule has approximately 134 tyrosyl residues among its two identical chains; thus, at most, only one-third of the tyrosyls are iodinated. After DIT and MIT formation, two residues of DIT couple to make L-thyroxine (tetraiodothyronine; T_4) or one DIT and one MIT make L-triiodothyronine (triiodothyronine; T_3), all still within the Tg molecule. In this reaction, further oxidation mediated by TPO and H_2O_2 produces an iodophenyl free radical, leaving T_4 or T_3 at the acceptor site and dehydroalanine at the donor position.

Regulation of Thyroid Hormone Synthesis by TPO

From the kinetic data on the iodinating and coupling reactions of free tyrosines catalyzed by TPO, it has been concluded that the mechanism of the enzyme action fits the preferential formation of T_4 , even though the formation started from free tyrosine. The native structure of Tg plays an important role in the preferential formation of T_4 . This is supported by the fact that a specific peptide structure of Tg is involved in the biosynthesis of thyroid hormone: The hormonogenic tyrosine residues are iodinated in rigid sequential order, resulting in the formation of DIT derivatives via MIT, which subsequently undergo one-electron oxidation to form T_4 . It is important to note

that thyroid hormones formed in Tg are prevented from further oxidation by TPO, whereas free iodothyronines are readily oxidized by TPO.

GENE STRUCTURE OF TPO

The cDNAs encoding TPO have been isolated in man, pig, rat, and mouse. Kimura *et al.* cloned two different cDNAs of hTPO: one of 3048 nucleotides [base pairs (bps)] called *TPO1* and the second (*TPO2*) of 2877 bps. *TPO1* coded for a protein of 933 residues and a molecular mass of 103 kDa, whereas *TPO2* was identical except that it lacked exon 10 and had 1 bp change, coding for a protein of 96 kDa. Both forms occur in normal and abnormal human thyroid tissue. *TPO2* appears enzymatically inactive because it does not bind heme, degrades rapidly, and failed to reach the cell surface in experiments with stable cell lines. There are different degradative pathways for the two forms. The TPO gene resides on chromosome 2p13, spans more than 150 kbps, and has 17 exons. It contains domains similar to those of acetylcholinesterase, low-density lipoprotein receptor, and insulin-like growth factor receptor. Several types of mutations of the TPO gene cause diminished iodide organification. TPO shares with NIS, Tg, and the TSH receptor the regulation of its gene expression by thyroid-specific transcription factors (TTFs), such as *TTF-1*, *TTF-2*, and *Pax-8*. Tg and TPO have the same binding sites for *TTF-1*, *TTF-2*, and *Pax-8* in their promoters, and the genes for both have *TTF-1* binding sites in their enhancer regions. TPO is synthesized on polysomes and transported to the Golgi, where it undergoes glycosylation; it is then packaged into exocytotic vesicles along with Tg. These vesicles fuse with the apical membrane in a process stimulated by TSH, and TPO is then found in the membrane associated with microvilli. Yokoyama and Taurog suggest that the C-terminal portion of the TPO molecule is in the cell cytoplasm, that the portion from residues 845 to 870 is in the apical membrane, and that the remainder, including residues 1–844, lies in the thyroid follicular lumen. TPO enzymatic activity is restricted to the apical membrane, but most of the thyroid's total amount of TPO is intracellular at the endoplasmic reticulum and perinuclear membrane. This intracellular protein is inactive due to improper folding and contains only high-mannose-type carbohydrate units; in contrast, the membrane TPO has complex carbohydrate units, essential for enzymatic activity. Chronic TSH stimulation increases the amount of TPO and its concentration at the apical membrane.

MUTATIONS OF THE TPO GENE

Defective organification of iodine is due to abnormalities of Tg and TPO synthesis or H₂O₂ production. Organification defect in iodine caused by abnormal H₂O₂ production is rare, so abnormal Tg and TPO synthesis is thought to be the major cause of defective organification of iodine. The prevalence of neonatal hypothyroidism is approximately 1/4000, one-fifth of which is caused by genetically determined thyroid dyshormonogenesis. Because defective TPO activity is one of the two major causes of defective organification of iodine, approximately 1 in 40,000 newborns has hypothyroidism due to defective TPO. The results of clinical observations, however, suggest that compensatory hyperplasia of the thyroid tissue partially compensates hypothyroidism when TPO activity is borderline. Therefore, more than 1 in 40,000 newborns may have milder forms of hypothyroidism caused by defective TPO. Defects of TPO are both quantitative and qualitative; the latter include impaired binding to heme, impaired binding to Tg or iodine substrates, abnormal localization in thyrocyte, and abnormal susceptibility to inhibition. More than 110 cases of hereditary defective organification of iodine ascribable to defective TPO have been reported, and the hereditary form is autosomal recessive. Pedigree maps of these families show consanguineous marriage in many cases. The TPO gene mutations responsible for congenital goitrous hypothyroidism have been identified, causing either abnormal TPO with low or absent enzymatic activity or complete absence of TPO protein formation. It has been shown that Pendred's syndrome (an autosomal recessive disease characterized by defective iodine organification with goiter and congenital neurosensory deafness) is due to mutations of the pendrin gene. The decreased organification activity of this condition may be due to abnormal pendrin-TPO interactions of the apical membrane of thyroid follicular cells.

TPO AS AUTOANTIGEN

TPO, Tg, and TSH receptor are the major thyroid autoantigens identified at the biochemical and molecular levels. In particular, TPO was identified in 1985 as the "thyroid microsomal antigen" reacting with thyroid microsomal autoantibodies, first described in the late 1950s. Anti-TPO autoantibodies (TPO-Ab) are detected together with anti-Tg (Tg-Ab) and anti-TSH receptor (TR-Ab) autoantibodies in sera of patients with autoimmune thyroid diseases (AITD); the majority of TPO-Ab are IgG₁ or IgG₄.

Epitopes recognized by autoantibodies have been extensively studied using synthetic peptides, recombinant DNA molecules, and recombinant Fabs specific for TPO. B-cell epitopes are generally conformational, whereas T-cell epitopes are short, linear peptide fragments. In studies of B-cell epitopes with recombinant TPO, it has been found that many B-cell epitopes are located on the latter half of the COOH end of the TPO molecule and that the region between amino acids 590 and 767 contains an epitopic hotspot; approximately 80% of TPO-Ab recognize two conformational epitopes. TPO-Ab are detected in almost all patients with Hashimoto's thyroiditis and in the majority of those with Graves' disease. Although TPO-Ab mediate *in vitro* complement-dependent lysis and antibody-dependent, cell-mediated cytolysis of thyroid cells, they are probably devoid of cytolytic activity *in vivo* due to the inaccessibility of the apical membrane of the thyroid follicular cell. Some, but not all, TPO-Ab are able to inhibit TPO enzymatic activity *in vitro*, but the relevance of this phenomenon *in vivo* is probably minimal. Taken together, these data strongly support the concept that serum TPO-Ab are markers of thyroid autoimmunity but are not directly involved in thyroid cell damage.

Sera of AITD patients also contain autoantibodies that recognize cross-reacting epitope(s) between Tg and TPO (TGPO-Ab). The exact nature of TGPO-Ab remains to be clarified. Results of primary lymphocyte cultures with synthetic peptides have produced a degree of consensus regarding the TPO T-cell epitopes recognized in patients. Three regions of TPO protein probably contain T-cell epitopes: amino acid residues 110–250, 414–589, and 841–901. Amino acid residues 119–126 of TPO have been predicted from algorithms to be a T-cell epitope common to both TPO and Tg, and they have been proven to aid in the activation of thyroiditogenic cells. Porcine TPO can induce thyroiditis in mice. Interestingly, murine strains with a high incidence of thyroiditis induced by porcine TPO are quite different from those developing thyroiditis after immunization with Tg.

Thyroid-Stimulating Hormone

see TSH

amiodarone, iopanoic acid, propranolol, and glucocorticoids), or decreased TSH secretion (e.g., dopamine and its agonists, octreotide and glucocorticoids). Hypothyroidism and thyrotoxicosis may develop during therapy with iodine-containing drugs, and subclinical or overt hypothyroidism may be observed with long-term lithium therapy. Cytokines (e.g., interferon- α or interleukin-2) may precipitate hypothyroidism, thyrotoxicosis, or the biphasic pattern of silent thyroiditis, especially in the presence of preexisting thyroid autoimmunity. In hypothyroid patients taking L-T4, drugs such as ferrous sulfate, cholestiramine, cholestipol, and soybean formulations may interfere with L-T4 absorption.

THYROID DISEASES IN THE ELDERLY

Hypothyroidism

The prevalence of hypothyroidism in the elderly is high (0.5–6% for overt and 4–15% for subclinical hypothyroidism). Autoimmune thyroiditis is the main cause, but iatrogenic hypothyroidism (radioiodine administration, thyroid surgery, head and neck radiation, and antithyroid drugs) is also common. Excess iodine from amiodarone or iodinated radiographic contrast agents may induce hypothyroidism, preferentially in glands with preexisting autoimmunity. Hypothyroidism in the elderly develops insidiously and often lacks classic clinical features, and some manifestations may be erroneously attributed to “normal” aging or age-associated diseases. Unexplained increases in serum cholesterol, macrocytic anemia, severe constipation, congestive heart failure with restrictive cardiomyopathy, and subtle neurologic signs are the most common manifestations. Severe depression, lethargy, memory loss, apathy, and, rarely, psychosis or irreversible dementia may be observed. Elderly patients are more susceptible to myxedema coma, which may be precipitated by intercurrent NTI or cold exposure. The diagnosis of primary hypothyroidism is based on increased serum TSH, although the nonspecific effects of NTI and/or drugs must be taken into account. Decreased thyroid hormone concentrations may be observed in both hypothyroidism and NTI, but low FT4 is more frequent in thyroid failure. Anti-thyroid antibody tests help to differentiate autoimmune from nonautoimmune causes of hypothyroidism.

Subclinical hypothyroidism (increased serum TSH with normal FT4 concentration) occurs frequently in the elderly. Like overt thyroid failure, most cases are due to autoimmune thyroiditis or to previous treatment of hyperthyroidism. Progression to overt

hypothyroidism occurs in 2–18% of cases per year, with the highest percentages observed for subjects with high serum thyroid antibody titers. Subclinical hypothyroidism is associated with a slight but significant increase in serum lipids.

Therapy should be initiated with low doses of L-T4 (12.5–25 $\mu\text{g}/\text{day}$) followed by incremental increases (12.5–25 $\mu\text{g}/\text{day}$ every 4–8 weeks) until full replacement (1.1 or 1.2 $\mu\text{g}/\text{kg}$ body weight) after several months. Particular attention should be paid to patients with coronary disease to avoid angina or myocardial infarction. Indication for therapy in subclinical hypothyroidism is controversial. Serum TSH >10 mU/liter and/or high thyroid antibody titers favor treatment, particularly when hypercholesterolemia and hypothyroid symptoms are present. Careful consideration of potential adverse reactions is always required.

Hyperthyroidism

The prevalence of hyperthyroidism in the elderly is 0.5–2%, mostly due to Graves' disease, toxic nodular goiter (TNG), and toxic adenoma. The relative frequency of TNG is higher than in young patients, especially in areas of iodine deficiency. Iodine-induced hyperthyroidism occurs frequently in elderly patients using iodine-containing medications or radiographic contrast media, and amiodarone-induced thyrotoxicosis is the most frequent form. Elderly hyperthyroid patients frequently display few signs and symptoms, hence the terms apathetic or masked hyperthyroidism. Eye signs are often lacking, but Graves' ophthalmopathy, when present, is usually worse. Tachycardia is less common, but a high prevalence (25–35%) of atrial fibrillation is found in thyrotoxic elderly male patients. Weight loss is often associated with anorexia rather than increased appetite; muscle wasting and weakness are common, and the high risk of osteoporosis and bone fracture typical of old age is increased. Neuropsychiatric symptoms may be reported as primary manifestations. Elevated serum FT4 and/or FT3 and low TSH levels by sensitive assay establish the diagnosis. Serum TSH may be low in euthyroid severely ill patients with coexistent NTI, but undetectable rather than low serum TSH by third-generation assays strongly suggests hyperthyroidism. However, discrimination between the two conditions may not be possible without concomitant FT3 and FT4 assay.

Subclinical hyperthyroidism (low TSH and normal FT3 and FT4) must be distinguished from other

causes of low serum TSH, such as NTI. The prevalence of low serum TSH among elderly people is high (1.5–12.5%), but the number of cases progressing to overt hyperthyroidism is low (2–10%). Subclinical hyperthyroidism may be due to “subclinical” Graves’ disease, autonomously functioning thyroid nodules, or excessive/inappropriate thyroid hormone therapy. Subclinical hyperthyroidism in the elderly is associated with increased risk of atrial fibrillation and mortality from cardiovascular diseases, as well as reduced bone density in postmenopausal women.

Long-term therapy with antithyroid drugs is not recommended for elderly patients because of the high relapse rate after withdrawal and the increased incidence of adverse effects. Radioiodine (^{131}I) is the treatment of choice since it results in a definitive cure and avoids the risks of surgery. Euthyroidism should be restored with antithyroid drugs before ^{131}I therapy, and control of heart rate with beta-blockers (or calcium channels blockers) should be obtained before and after therapy, as long as the patient remains thyrotoxic. Long-term follow-up of thyroid function is mandatory and eventual hypothyroidism must be corrected. Most cases of subclinical hyperthyroidism in the elderly require active treatment due to cardiovascular and bone complications.

Nontoxic Goiter and Thyroid Carcinoma

An age-dependent increase in thyroid volume and nodularity has been documented by echography, reaching a prevalence after 60 years of age of approximately 50% in iodine-deficient areas. Because surgical risks are higher in the elderly, most nontoxic nodular goiters are managed conservatively, unless there is strong suspicion of malignancy or significant airway obstruction. In patients with contraindications to surgery, radioiodine has been used successfully, with

partial reduction in thyroid size and relief of pressure symptoms.

The ratio of papillary/follicular thyroid carcinoma is lower in the elderly (2:1) than in younger patients (3 or 4:1). Differentiated thyroid carcinoma is more aggressive in older patients, especially males. Anaplastic thyroid carcinoma is almost exclusively observed in patients older than 65 years of age, similar to other rare thyroid neoplasms, such as sarcomas and primary thyroid lymphomas. The therapeutic approach for differentiated thyroid cancer is similar to that followed for younger persons.

Figure 1 The skin incision in a thyroidectomy is made 1 cm below the cricoid and follows normal skin lines. A 00 silk suture is pressed against the neck to mark the incision site. Reprinted from Clark (1985), with permission.

crease for optimal cosmetic effect. Thus, the incision is directly over the isthmus of the thyroid gland. The gentle curve of the Kocher incision is then marked using a taut silk suture (Fig. 1). The length of the incision is dependent on the existing pathology and the size of the patient's neck. It may vary from approximately 3 to 5 cm.

The skin incision is extended through subcutaneous fat and the platysma muscle. The superior flaps are created by dissection in an avascular plane just deep to the platysma muscle and superficial to the anterior jugular veins up to the level of the thyroid cartilage. The lower flap is mobilized in a similar fashion to the level of the suprasternal notch. The wound edges are protected with moistened drapes, and one or two self-retaining retractors are placed.

MIDLINE DISSECTION

Excellent exposure is obtained by a midline incision through the median raphe of the superficial layer of the deep cervical fascia between the strap muscles. The midline is most easily identified low in the neck. The incision is extended superiorly to the thyroid cartilage and inferiorly to the suprasternal notch. Crossing veins in the lower neck may need to be ligated.

The sternohyoid muscle is dissected from the sternothyroid muscle laterally to provide better exposure of the thyroid gland. This can usually be done with blunt dissection. The sternothyroid muscle is then dissected from the underlying thyroid. The middle thyroid vein(s) is identified, divided, and ligated. This dissection is facilitated by medial retraction of the thyroid gland and lateral retraction of the strap muscles and carotid sheath.

Attention is turned to the superior pole. Retracting the thyroid in a caudal direction identifies the superior thyroid artery and veins. The tissue adjacent to the superior pole vessels can usually be swept from the thyroid with a peanut sponge. The space between the thyroid gland and cricothyroid muscle is opened, allowing the superior pole vessels to be skeletonized, triple clamped, ligated, and divided. The external branch of the superior laryngeal nerve is at risk of injury during this maneuver; there is a 10% reported injury rate. It has a variable course and is a thin nerve. The external branch of the superior laryngeal nerve is best preserved by not attempting to directly identify it but, rather, individually ligating the superior pole vessels close to the thyroid as opposed to mass ligation of the pedicle (Fig. 2).

The tissue posterior to the pole can now be easily swept from the thyroid gland by blunt dissection. The upper parathyroid gland is usually identified at

Figure 2 The superior pole vessels are identified and individually ligated using three right-angle clamps placed with tips away from the external branch of the superior laryngeal nerve. Reprinted from Clark (1985), with permission.

the level of the cricoid cartilage, where the RLN enters the larynx posterior to the cricothyroid muscle. It should be preserved on its vascular pedicle. The area cephalad to the cricoid cartilage is considered relatively safe because the recurrent laryngeal nerve enters the cricothyroid muscle below the cricoid cartilage.

The pyramidal lobe, which is present in approximately 80% of patients, should be identified and mobilized to the level above the thyroid cartilage with the dissection plane immediately adjacent to this lobe. There are often numerous small vessels supplying the pyramidal lobe. When the pyramidal lobe is freed of all its lateral attachments, it is gently avulsed or divided from its superior attachment at the hyoid bone.

IDENTIFICATION OF THE RECURRENT LARYNGEAL NERVE

Both right and left RLNs enter the larynx posterior to the cricothyroid muscle just above the cricoid cartilage. The right RLN takes a more oblique course in the neck and may pass anterior or posterior to the inferior thyroid artery (Fig. 3). In approximately 1% of patients, the right RLN is nonrecurrent and may

Figure 3 The recurrent laryngeal nerve may run anterior, posterior, or between the branches of the inferior thyroid artery. The inferior parathyroid gland is usually identified within 1 cm of this junction. Reprinted from Clark (1985), with permission.

enter the thyroid from a superior or lateral direction. The left RLN almost always runs in the tracheoesophageal groove because of its deeper origin from within the thorax. Both recurrent nerves may branch before entering the larynx; this occurs more frequently on the left. Preservation of the medial branch is of utmost importance because it usually contains the motor fibers.

Retraction of the carotid sheath laterally and the thyroid medially and anteriorly places tension on the inferior thyroid artery, which helps to identify the RLN where it crosses the midportion of the thyroid gland. It is usually safe to identify the RLN low in the neck and then follow it to where it enters the cricothyroid muscle through the ligament of Berry. The tertiary branches of the inferior thyroid artery are individually ligated with fine ties and divided, mobilizing the thyroid lobe medially, away from the RLN.

The most difficult part of the dissection during a thyroidectomy usually involves the ligament of Berry. The ligament is situated at the posterior lateral portion to the thyroid gland just caudal to the cricoid cartilage. A small branch of the inferior thyroid artery traverses the ligament, as do one or more veins from the thyroid gland. These vessels are usually readily identified and ligated. Should bleeding occur, it should be controlled by pressure with no clamping until the RLN is identified. A small amount of persistent bleeding at the end of the case can be controlled with the placement of a small pledget of thrombin-soaked gel foam. A tubercle of Zuckerkandl may extend over the RLN at the ligament of Berry. In addition to having a consistent relationship with the location of the RLN, the upper parathyroid gland may be situated at the tip of this protruding portion of thyroid tissue.

PRESERVATION OF THE PARATHYROID GLANDS

Eighty-five percent of people have four parathyroid glands usually situated immediately adjacent to the thyroid gland on the posterior lateral capsule. The upper parathyroid glands are most commonly lateral to the recurrent laryngeal nerve at the level of the ligament of Berry in a posterior position and are usually the easiest to preserve during thyroidectomy. The lower parathyroid glands are almost always situated anterior to the RLN and within 1 cm caudal to where the RLN crosses the inferior thyroid artery. If not observed here, they are usually in the thymus or

perithymic fat. Preservation of the blood supply to the parathyroid glands is best achieved by meticulous dissection from the thyroid capsule. Should it not be feasible to preserve the blood supply to a parathyroid gland, it should be biopsied to confirm it is parathyroid and autotransplanted into the contralateral sternocleidomastoid muscle.

In general, parathyroid glands should be preserved rather than transplanted if possible. The parathyroid glands should not be mobilized extensively because they may be devascularized. The thyroid gland should also be examined after its removal to ensure that a parathyroid gland has not been removed.

REMOVAL OF SPECIMEN

Always keeping in mind the location of the RLN, the inferior thyroid vessels are dissected free, clamped, and ligated. The thyroid gland is retracted medially to expose the trachea. The thyroid lobe and isthmus are then easily dissected off the trachea with electrocautery. For a lobectomy, the isthmus is divided between two Colodny clamps on the side contralateral to the thyroid pathology, and the isthmus is suture ligated. The operative field is irrigated with warm saline and any bleeding is controlled.

The strap muscles and then platysma muscle are reapproximated with interrupted 4-0 absorbable suture, and the skin is closed with butterfly clips. The wound is dressed with sterile gauze bandages.

FUTURE DIRECTIONS

Except for improved lighting and magnification, the fundamental approach to thyroid surgery, with

preservation of the RLN and parathyroid glands, has remained relatively unchanged during the past century. Minimally invasive surgery has evolved to include thyroid surgery. Endoscopic parathyroidectomy using CO₂ insufflation has been demonstrated to be technically feasible, and similar techniques have been applied to thyroidectomy. The development of highly sensitive nerve probes is under investigation. Its utility in avoiding injury to the external branch of the superior laryngeal nerve and preservation of the RLN in redo surgery has had promising preliminary results. Regardless of these new developments, the importance of adequate training, expertise, and knowledge of anatomy and techniques are fundamental to ensuring good outcomes.

Clinical Presentation and Diagnosis

Bacterial thyroiditis is often preceded by an upper respiratory infection, which may induce inflammation of the fistula and promote the transmission of pathogens to the thyroid, and it is more common in the late fall and late spring months. More than 90% of patients present with thyroidal pain, tenderness, fever, and local compression resulting in dysphagia and dysphonia, and signs and symptoms of systemic toxicity may be present. The thyroid is tender to palpation, with unilateral or bilateral lobar enlargement, and it is associated with erythema and warmth of the skin. Cervical lymphadenopathy is not a prominent feature unless there is a predisposing pharyngitis.

The differential diagnosis of bacterial thyroiditis can be divided into nonthyroidal and thyroidal causes (Table I). Essentially all of the nonthyroidal causes are

infectious in origin and present as discrete painful masses. Subacute thyroiditis is the most common cause of the painful thyroid and often results in both local and systemic symptoms similar to those seen in bacterial thyroiditis.

Thyroid function tests in the normal range are the most common finding in patients with bacterial thyroiditis (Table II), although thyrotoxicosis and hypothyroidism have been reported. Fine needle aspiration biopsy is the best laboratory test in the evaluation of infectious thyroiditis and is diagnostic in most cases, especially when tenderness is limited to a solitary nodule or a localized area and subacute thyroiditis has been ruled out. Gram stain and culture of the fine needle aspirate will reveal the causative organism in more than 90% of cases. Most imaging studies are adjunctive and are best reserved for patients for whom the diagnosis is unclear.

In the adult, *Staphylococcus aureus* and *Streptococcus pyogenes* are the offending pathogens in more than 80% of patients and are the sole pathogen in more than 70% of cases. In children, α - and β -hemolytic *Streptococcus* and a variety of anaerobes account for ~70% of cases, whereas mixed pathogens are identified in >50% of cases.

Management and Prognosis

Treatment of acute bacterial thyroiditis requires admission to the hospital, drainage of any abscess, and parenteral antimicrobial therapy aimed at the causative agent. If no organisms are seen on the gram stain, nafcillin and gentamycin or a third-generation cephalosporin is appropriate initial therapy in adults, whereas a second-generation cephalosporin or clindamycin is reasonable in children. Since a pyriform sinus fistula is the most

Table II Diagnostic Tests in the Evaluation of Infectious Thyroiditis

| Test | Comments |
|--------------------------------|--|
| Fine needle aspiration biopsy | Diagnostic in 90% of cases; test of choice; special stains considered necessary |
| Thyroid function tests | Usually normal; rare case reports of hypothyroidism and thyrotoxicosis |
| Erythrocyte sedimentation rate | Usually elevated; nonspecific test |
| Leukocyte count | Usually elevated; nonspecific test |
| Radionuclide imaging | Adjunctive test; radioiodine best; provides information regarding overall gland function |
| Neck radiograph | Adjunctive test; presence of gas indicates abscess with anaerobic organisms |
| Magnetic resonance imaging | Adjunctive test; helpful in identifying pyriform sinus fistulae |
| Ultrasonography | Adjunctive test; helpful in identifying pyriform sinus fistulae |
| Computed tomography | Adjunctive test; helpful in identifying pyriform sinus fistulae |
| Barium swallow | Adjunctive test; helpful in identifying pyriform sinus fistulae |

common route of infection in bacterial thyroiditis, a barium swallow, computed tomography, or magnetic resonance imaging of the neck should be performed to search for communicating fistulae in most patients, especially children, with the first episode and all patients with recurrent episodes. Such fistulae must be surgically excised for definitive cure and prevention of recurrent infection.

Mortality from acute bacterial thyroiditis has markedly improved from the 20–25% reported in the early 1900s. A 1983 review by Berger *et al.* estimated an overall mortality of 8.6%. Reviews involving more than 100 patients failed to list mortality as a complication of acute bacterial thyroiditis. However, the mortality is close to 100% if the diagnosis is delayed and antimicrobial therapy is not initiated. In survivors, complete recovery is the norm, although there have been reports of transient hypothyroidism, vocal cord paralysis (which may also be transient), and recurrence of infection as sequelae of acute bacterial thyroiditis.

FUNGAL INFECTIONS

Although rare, fungal infections of the thyroid are the next most common cause of infectious thyroiditis, comprising 15% of cases reported through 1980. The predominant offending organism is *Aspergillus* species, with at least 26 documented cases. Virtually all of the affected patients were immunocompromised and had disseminated disease; most cases of thyroidal infection were determined postmortem. Asymptomatic infection of the thyroid with *Pneumocystis carinii* is found in up to 20% of AIDS patients with disseminated *Pneumocystis* infection at autopsy. The diagnosis of *P. carinii* infection is made by performing Gomori's silver methenamine stain on specimens obtained by fine needle aspiration biopsy. Case reports of fungal infections of the thyroid have included *Coccidioides immitis*, *Histoplasma capsulatum*, *Candida albicans*, *Allescheria boydii*, and *Nocardia asteroides*.

MYCOBACTERIAL INFECTIONS

The true incidence of infection of the thyroid with *Mycobacterium tuberculosis* is difficult to determine. Using strict pathological criteria, only 19 cases have been reported in the literature. Thyroidal tuberculosis is associated with disseminated or miliary disease and symptoms are usually present for months. Although at least three of the reported patients with tuberculous thyroiditis died and recurrent laryngeal

nerve paralysis has been described, resolution without sequelae usually follows appropriate antituberculous therapy. Infections with atypical mycobacteria, including *M. chelonii*, *M. intracellulare*, and *M. avian-intracellulare*, have also been described—the latter in patients with AIDS in the setting of widely disseminated disease. Although acid fast organisms have been found in the thyroid of individuals with disseminated *M. leprae*, symptomatic thyroid infection has not been described.

PARASITIC INFECTIONS

Several parasitic agents have involved the thyroid on rare occasions. *Echinococcus granulosus* has been reported in the setting of a chronic goiter, with the diagnosis being made at the time of surgery. If echinococcal infection is suspected, biopsy of the lesion is contraindicated due to spillage and rupture of the cyst contents, and specific serologic testing should be performed. Surgical removal is the preferred mode of treatment, with antiparasitic agents useful as adjunctive therapy and for inoperable cases. Involvement of the thyroid with *Strongyloides stercoralis* has been described only in the setting of disseminated disease in immunocompromised patients. Mortality with disseminated *Strongyloides* infection is high due to both the infection and the immunocompromised status of the patient.

SYPHILITIC INFECTION

Historically, secondary syphilis was frequently associated with pain and swelling of the thyroid that responded to antisiphilic therapy, which commonly included iodides. However, microbiologic evidence of syphilitic infection of the thyroid is lacking in most of these cases; thus, a direct relationship between treponemal infection and thyroid dysfunction cannot be determined. Indeed, only seven cases of gummata of the thyroid, presenting as painless nodules, have been reported in the world's literature.

VIRAL INFECTIONS

The most common infectious organism found in the thyroid at postmortem examination in patients with AIDS is cytomegalovirus (CMV), occurring in the setting of disseminated CMV infection. However, symptomatic thyroidal infection with CMV has not been reported. Thyroiditis has been associated with mumps parotitis, although this is rare.

CONCLUSION

Infectious thyroiditis is uncommon and the diagnosis often requires a high index of suspicion. A rational approach to such patients, including history, physical examination, laboratory evaluation, and fine needle aspiration biopsy, will allow the appropriate diagnosis to be made in the vast majority of cases.

pregnancy, with postpartum increases in helper T cells and cytotoxic T cells.

The hormonal changes that occur during pregnancy have a profound effect on the production of immune tolerance. Increased corticotropin-releasing hormone production by the placenta stimulates the maternal adrenal glands to produce a state of hypercortisolism. There is activation of the sympathetic system with increased production of catecholamines. A moderate increase in 25-hydroxy vitamin D₃ and more significant increases in 1,25-dihydroxy vitamin D₃ also occur. Through intermediate mechanisms, these changes suppress proinflammatory cytokine formation and promote a shift from Th1 to Th2. The increase in plasma estrogen and progesterone levels may enhance this effect. These changes help to conserve the fetus and reduce chances of rejection.

Maternal immune mechanisms return to a normal nonpregnant state in the first few months to 1 year after delivery. However, there may be a rebound increase in some elements of the autoimmune reaction (e.g., antibody production or CD4:CD8 ratio), which may aggravate existing autoimmune disease or precipitate it for the first time in predisposed women.

Women with PPT

The “immune rebound” hypothesis may explain some of the autoimmune mechanisms that form the basis of PPT. The behavior of antibodies to thyroglobulin (TgAb) and thyroid peroxidase (TPOAb) during pregnancy and the postpartum period has been well documented. This heightened immune response in the first few months of the postpartum period may be caused by several factors.

Microchimerism

There is a considerable influx of fetal cells into the maternal circulation at the time of delivery. These cells may persist for short or long periods of time in the maternal host. Evidence suggests that these “chimeric” cells may induce an immune reaction in the host by causing a breakdown in immune tolerance. One short-term effect may be the rebound immune enhancement seen in the postpartum period, which may cause an exacerbation or new onset of some autoimmune diseases.

T-Cell Changes

Evidence suggests that activation of both circulating and intrathyroidal T cells occurs in PPT. Both Walfish and Stagnaro-Green demonstrated the expression of MHC class II molecules and a higher percentage of increased CD4:CD8 ratios in subjects who developed

PPT. In a prospective study of TPOAb-positive women, Kuijpers showed a higher percentage of MHC II-expressing T cells in subjects who subsequently developed PPT compared to those who did not. However, Jansson’s group did not demonstrate a difference in circulating subsets of T lymphocytes in thyrotoxic and hypothyroid PPT subjects compared with normal controls. This group demonstrated a relative increase in intrathyroidal B cells and a relative decrease in CD8 cells (resulting in an increased CD4:CD8 ratio) in subjects with PPT.

PPT as an Immune-Mediated Disease

Several features of PPT point to the central importance of immune mechanisms in the pathogenesis of PPT (Table I). The majority of women who develop PPT are positive for serological markers of thyroid autoimmunity (i.e., TPOAb and TgAb). In our experience, all such women have TPOAb during early pregnancy. Evidence suggests that antibodies with a dual specificity for Tg and TPO may also be found in PPT at a higher prevalence than in normal control subjects. However, several investigators have reported PPT in TPOAb-negative women. In such women, the etiology of PPT is unclear. The histological changes occurring within the thyroid gland, with immune cell infiltration typical of autoimmune thyroid disease, give further credence to the immune pathogenesis of the disease. Biopsy of the thyroid gland in women with PPT shows lymphocytic infiltration and follicle formation reminiscent of those of Hashimoto’s thyroiditis. Several studies have shown HLA haplotype restrictions in PPT, which are commonly seen in autoimmune thyroiditis such as Hashimoto’s and Graves’ disease.

The subclasses of TPOAb that are able to activate the complement cascade (IgG₁–IgG₃) increase during

Table I Immunohistological Features of PPT

| | |
|--|--|
| Presence of thyroid antibodies | TPOAb (majority) Thyroglobulin antibodies and antibodies with dual specificity (minority) |
| Postpartum increase in TPOAb subclasses capable of activating complement | IgG ₁ –IgG ₃ |
| Histological changes | Lymphocyte infiltration and follicle formation within the thyroid gland |
| HLA haplotype restriction | Similar to autoimmune thyroiditis |

Figure 1 Biologically active TPOAb levels in antibody-positive women who were euthyroid or had transient or persistent postpartum hypothyroidism. Antibody concentrations returned to normal in those with PPT but remained elevated in subjects with persistent hypothyroidism.

the postpartum period (Fig. 1) and are associated with both phases of PPT. Jansson reported an increase in IgG₁ in hypothyroid PPT. Hall demonstrated an increase in IgG₂ and IgG₃ in biphasic PPT, with the increase in IgG₃ coinciding with the thyrotoxic phase. Briones-Urbina confirmed the IgG₁ and IgG₂ changes but found low IgG₃ levels. However, these investigators also confirmed that IgG₄, which is incapable of influencing the complement cascade, remains relatively unchanged. This raises the interesting possibility of a pathogenetic role for these antibodies in PPT, perhaps through complement activation. A sublethal antibody-directed, complement-mediated attack on thyroid cells may result in increased secretion of thyroid hormones, producing the thyrotoxic phase of the disease. However, a more severe complement-mediated attack may produce damage to the follicular architecture of the gland and produce hypothyroidism. Conclusive evidence for such complement activation in PPT is lacking; studies have been unable to demonstrate terminal complement complexes (markers of complement activation) in TPOAb-positive women who developed PPT and who were followed weekly during the postpartum period.

CLINICAL FEATURES AND MANAGEMENT OF PPT

Prevalence

There is a wide variation in the reported worldwide prevalence of PPT. This variation may be explained by true geographic differences in prevalence (reflecting genetic heterogeneity and other factors) or by

methodological discrepancies in studies reported from different locations. Variability of factors such as diagnostic criteria, length of follow-up after delivery, frequency of postpartum blood sampling, and differences in hormone assay methodology may have contributed to this variation. An average prevalence of 5–7% is acceptable for unselected pregnant women from most iodine-replete populations.

Predisposition to PPT

Women with TPOAb (and TgAb alone in less than 5%), type 1 diabetes mellitus, and previous PPT are at increased risk of developing PPT. We previously mentioned this increased risk in TPOAb-positive women. Studies in Cardiff show that approximately 50% of women with TPOAb during the early stages of pregnancy develop PPT. Other studies have shown this proportion to vary between 30 and 52%. Therefore, TPOAb is a marker of risk for the development of PPT but remains a weak predictor. There is a higher prevalence of PPT in subjects with type 1 diabetes mellitus. Gerstein followed up 40 of 51 pregnant subjects with type 1 diabetes, of whom 10 developed thyroid dysfunction (1 due to Graves' disease), and Alvarez-Marfany followed up 28 of 41 similar women, of whom 7 developed thyroiditis. Therefore, the incidence is approximately 25% in this group of women. However, the highest incidence of PPT is found in women who have had a previous episode of the disease. Sixty-nine percent of women who have TPOAb and had PPT following a previous pregnancy will develop a similar disease during the next pregnancy. However, only 25% who are TPOAb positive and remain euthyroid will develop thyroid dysfunction during the next pregnancy.

There is evidence of a role for environmental factors, such as the presence of a goiter and smoking and a family history of thyroid disease, in the causation of PPT. However, additional studies are needed to confirm this finding.

Types of PPT and Clinical Features

Classically, PPT occurs after a full-term delivery. However, there are reports of postpartum thyroiditis occurring after early loss of pregnancy between 5 and 20 weeks of gestation.

PPT is typically a biphasic disease (Fig. 2). A transient thyrotoxic phase is followed by a period of recovery and then a hypothyroid phase. The thyrotoxic phase occurs at a median of 13 weeks postpartum and lasts 1 or 2 months; it is probably due to the release of

Figure 2 Clinical types of PPT. The thyrotoxic phase usually precedes the hypothyroid phase.

performed thyroid hormone resulting from destruction of thyroid follicles. The hypothyroid phase that follows occurs at a median of 19 weeks postpartum, lasts longer (approximately 4–6 months), is accompanied by significant symptoms, and results from autoimmune follicular destruction and reduced hormone synthesis. Some women may require thyroxine replacement therapy during this phase. Rarely, the hypothyroid phase may precede the thyrotoxic phase. In some women, the two phases of PPT may occur independently of each other and either clinical or biochemical evidence of thyrotoxicosis or hypothyroidism alone develops during approximately the same postpartum periods as described previously. Significantly, as many as 30% of women who have TPOAb and PPT may develop permanent hypothyroidism requiring thyroxine replacement therapy by the end of the first postpartum year.

The symptoms of the thyrotoxic phase are mild and self-limiting. Fatigue, palpitations, weight loss, irritability, and heat intolerance are more commonly found in subjects with thyrotoxic PPT than in euthyroid postpartum women. They may also have tremor, nervousness, and psychological symptoms. The mild and nonspecific nature of these symptoms may cause diagnostic confusion, and they may be missed if a high index of suspicion is not maintained.

The hypothyroid phase lasts longer and may cause considerable morbidity. Fatigue, loss of concentration, constipation, muscle and joint pains, and stiffness are common complaints. Some of these symptoms may occur before the abnormalities in biochemical thyroid function become evident and also persist after euthyroidism is achieved. Studies from The Netherlands and United Kingdom have demonstrated a significant

excess of symptoms of minor and major depression. However, a study from Spain was unable to confirm this finding. The mechanism of depression in hypothyroid PPT is speculative but may be related to the reduced 5-hydroxytryptamine drive seen in this condition or to known cytokine release associated with this phase, affecting neurotransmission.

Management of PPT

The temporal relationship to pregnancy and delivery, the presence of thyroid antibodies in the majority of women who develop symptoms, and the pattern and timing of biochemical thyroid dysfunction should alert clinicians to PPT in women at risk. Symptoms and the presence of a goiter are unhelpful in differentiating PPT from other causes of thyroid dysfunction in the postpartum period. The presence of eye signs in the thyrotoxic phase, however, favors a diagnosis of Graves' disease.

The thyrotoxic phase is distinguished from an exacerbation of quiescent or a new onset of Graves' disease relatively easily by radioiodine uptake scanning. Uptake is consistently low in PPT but high in Graves' disease. When postpartum thyrotoxicosis occurs in women with previously known Graves' disease, a low uptake confirms PPT (on the background of quiescent Graves' disease). However, care needs to be taken in the use of radioiodine as a diagnostic tool in nursing mothers. Technetium scans may be preferable. The presence of thyroid-stimulating hormone (TSH) receptor antibodies favors the diagnosis of Graves' disease. Thyroid ultrasonography, thyroglobulin estimation, and IL-6 measurement are of little practical value. Specific antithyroid drug therapy is not required in the thyrotoxic phase because symptoms and biochemical thyroid function return to normal in a few weeks. Occasionally, a beta-blocker may be indicated for symptom relief.

The hypothyroid phase usually follows the thyrotoxic phase and should be anticipated with periodic follow-up. An elevated TSH level at the appropriate time postpartum in women who are most likely TPOAb positive should alert clinicians to the diagnosis. This phase lasts longer and is associated with considerable morbidity. It may result in early permanent hypothyroidism, as described previously. Thyroxine therapy is indicated with a trial of withdrawal at 9–12 months. It is possible to withdraw thyroxine therapy in the majority of women at the end of this period, but a recurrence of symptoms associated with increased TSH levels on follow-up indicates the need for permanent replacement therapy.

LONG-TERM OUTCOME FOLLOWING PPT

The long-term outcome of PPT has been examined in several studies (Table II). In our series, permanent hypothyroidism occurred as early as 9 months postpartum in approximately 30% of subjects who were TPOAb positive and had PPT. These women required thyroxine replacement therapy to maintain normal clinical and biochemical thyroid function. A review of long-term follow-up studies of PPT from geographically different locations reported a 12–61% prevalence of permanent hypothyroidism. The variability may in part be due to differences in the definition of PPT and long-term thyroid dysfunction, length of follow-up, and ascertainment. We followed 98 TPOAb-positive women (of whom 48 developed PPT) and 70 TPOAb-negative controls for 66–140 months. Forty-six percent of women who developed PPT were hypothyroid (some subclinically) at the end of the follow-up period compared to only 4% of women who were TPOAb positive but did not develop PPT and 1.4% of women who were TPOAb negative. The rate of conversion to hypothyroidism in women who were TPOAb positive and developed PPT was 7.1% per year, higher than that reported for women in community-based follow-up studies. Investigators from different areas of the world have confirmed a high prevalence of hypothyroidism at the end of variable follow-up periods in women who developed PPT. In a study of Japanese women with a similar length of follow-up after PPT (mean, 8.7 years), Tachi found a 29% prevalence of permanent hypothyroidism. In a Swedish study, Jansson found a 30% prevalence of hypothyroidism at 5 years. In Brazil, Barca found a 61% prevalence of hypothyroidism at the end of a 2-year

period of follow-up after PPT. The reason for this high prevalence of relatively early hypothyroidism is unclear.

These studies raise the interesting issue of the nature of thyroid damage following the initial episode of PPT. Several investigators have indicated the distinct possibility of a persistent but subtle abnormality (probably autoimmune in nature) of thyroid function and morphology in these women. Iodine perchlorate discharge tests were abnormal in 41% of Italian and 64% of Welsh women studied 3 and 7 years, respectively, following PPT, suggestive of a persistent organification defect. Furthermore, we found a significantly higher prevalence of thyroid ultrasound hypoechogenicity (due to autoimmune destruction) at 4–8 weeks postpartum in women who were TPOAb positive and developed PPT (45%) compared to antibody-positive women who did not develop PPT (17%) and to antibody-negative women (1.5%). There was a significantly higher prevalence of persistent abnormalities in the first group after 66–144 months of follow-up (although mildly reduced from the postpartum period), indicative of persistent autoimmune destruction following the initial episode of PPT. It seems likely that a persistent but low-grade immune destructive process severe enough to produce echogenic changes in the thyroid gland continues to occur in these women, although maximal damage occurs at the time of PPT.

These findings indicate the need for long-term follow-up of women who are TPOAb positive and who develop PPT. A relatively high incidence of early permanent hypothyroidism in these women and a higher than normal annual conversion rate to hypothyroidism (compared to that of TPOAb-positive

Table II Long-Term Follow-Up of PPT

| Author | Follow-up (years) | No. of subjects | Thyroid dysfunction (includes subclinical hypothyroidism/abnormal TRH test) |
|---------------|-------------------|-----------------|---|
| Nikolai | 3 | 25 | 6 |
| Vargas | 1 | 42 | 8 |
| Tachi | 5–16 | 44 | 10 |
| Lervang | 2 | 23 | 2 |
| Jansson | 5 | 50 | 13 |
| Othman | 2–4 | 43 | 10 |
| Solomon | 0.9–3.7 | 55 | 20 |
| Kuijpers | 2.5–3 | 14 | 6 |

| Lucas | 3.3 | 42 | 5 |
| Barca | 2 | 49 | 30 |

women who do not develop PPT and women from community surveys), indicate the need for long-term follow-up. An increased TSH level with or without symptoms of hypothyroidism on annual (or more frequent) thyroid function testing is an indication for thyroxine replacement therapy.

SCREENING FOR PPT

There is no consensus about screening for PPT. This relates as much to the absence of a highly sensitive and specific marker for prediction as to the lack of appreciation of the clinical problem and the long-term effects of PPT. The significant morbidity of PPT in the first postpartum year, the likelihood that approximately three-fourths of women who have PPT will have an episode in a future pregnancy, the high prevalence of long-term thyroid dysfunction following PPT, and the availability of effective treatment should make a screening strategy useful. Some authorities recommend a selective screening strategy aimed at only those women who have a high risk of developing PPT (i.e., women with type 1 diabetes mellitus and those who have had PPT in a previous pregnancy). However, a screening strategy should take into account the fact that PPT may occur in TPOAb-negative women. It is salutary to remember that the prevalence of diseases for which antenatal screening is currently recommended is considerably lower than that of PPT in women of childbearing age.

TPOAb has been proposed as a marker for the prediction of PPT. As mentioned previously, when measured in early pregnancy, TPOAb is present in approximately 10% of women. However, only approximately half of these develop PPT, raising questions about the sensitivity of TPOAb as a predictor. Ten studies have examined TPOAb as a predictor of PPT. No firm conclusions can be drawn from these studies for several reasons. Most investigators measured microsomal antibodies, whereas some measured antibodies to TPO (the specific microsomal antigen). The assay methods used and the timing of antibody measurement were variable. Whereas some investigators measured antibodies in the antepartum period, others measured them at delivery and in the postpartum period. These studies, however, showed that thyroid antibodies have a sensitivity of 0.45–0.89 and specificity of 0.91–0.98. Positive predictive value and relative risk were 0.31–0.78 and 20–50.7, respectively. A report confirmed the cost-effectiveness of a screening program. It is not known whether screening

will be improved by thyroglobulin estimation, measuring ultrasound thyroid volume, or assessment of complement activation.

CONCLUSION

PPT is a common endocrine disorder affecting young women. The exact mechanisms of cellular damage have not been determined, although the autoimmune destructive nature of the disease has long been recognized. The immune perturbations of pregnancy and the postpartum period account for the modulation of thyroid autoimmunity, which is the hallmark of the disease, and the timing and nature of clinical and biochemical changes. Although the majority of patients have a short and self-limited illness, some have a prolonged and symptomatic disorder that requires specific therapy. The recognition of short- and long-term morbidity, and the need for permanent thyroxine supplementation in a significant minority of subjects following PPT, has raised the important but unsettled issue of screening for PPT, targeted perhaps at those at highest risk. We await the discovery of a sensitive and specific screening tool.

Table I Differential Diagnosis of Subacute Thyroiditis

| |
|--|
| Subacute thyroiditis |
| Acute hemorrhage into cyst or nodule |
| Infected thyroglossal duct cyst |
| Infected branchial cleft cyst |
| Acute pyogenic thyroiditis |
| Cellulitis of the anterior neck |
| Rapidly enlarging thyroid cancer |
| Painful Hashimoto's thyroiditis |
| Cervical adenitis |
| Radiation thyroiditis |
| Infected cystic hygroma |
| Rare infections (e.g., <i>Pneumocystis carinii</i>) or other inflammatory disorders (e.g., amyloidosis) |
| Globus hystericus |

all of whom were positive for HLA-Bw35. Two of the patients lived near each other but developed the disorder 1 year apart, and the third sibling lived several hundred miles away and had not been in contact with either of the other two when they had subacute thyroiditis. Thus, HLA-Bw35 appears to render individuals genetically susceptible to the development of the disorder.

An interesting cluster of subacute thyroiditis was reported in 12 patients in a single town in The Netherlands. Affected individuals bore clinical similarities to subacute thyroiditis, although only 1 patient was positive for HLA-Bw35, much less than would be expected. However, 5 of 11 patients tested positive for HLA-B15/62, a markedly greater frequency than expected. This suggests both genetic and clinical heterogeneity in subacute thyroiditis.

Although thyroid autoimmunity is not believed to play a role in subacute thyroiditis, autoimmune abnormalities associated with the disorder have been described. Antibodies directed against the thyroid-stimulating hormone (TSH) receptor have been reported. Also, a report of sensitization of T lymphocytes against thyroid antigen suggests the possibility of an autoimmune component, although it is believed that this is likely the result of released antigen during the active inflammation phase. Low titers of thyroid autoantibodies are sometimes detectable in patients with subacute thyroiditis.

CLINICAL FEATURES

Subacute thyroiditis is more common in women (80% of cases) between the ages of 40 and 50 years. As mentioned previously, a viral prodrome is common,

as are symptoms of sore throat, weakness, low-grade fever, myalgias, and, frequently, dysphagia. Symptoms may develop gradually over a few weeks, although patients frequently describe the disorder as coming on within a few days. Anterior neck pain is usual and is generally more significant on one side. It frequently radiates to the ear, the mandible, the occiput, or even the upper chest. Commonly, the patient initially consults an ear, nose, and throat physician or a dentist because of pain in the area of the throat or mandible. Frequently, the pain will migrate from one side to the opposite thyroid lobe after a few weeks. Symptoms of hypermetabolism are frequent since thyrotoxicosis occurs in approximately 50% of affected individuals; symptoms may include diaphoresis, palpitations, tachycardia, and weight loss. Rarely, the clinical presentation of subacute thyroiditis may be so dramatic in onset and so pronounced in severity that obstructive symptoms may develop (Fig. 1).

Physical examination may disclose signs of hypermetabolism, with tachycardia, diaphoresis, and tremor. Palpation of the neck generally reveals a very firm to hard, exquisitely tender, ill-defined mass in one lobe of the thyroid gland, although there is frequently thickening and tenderness of the contralateral lobe as well. Tenderness may be so pronounced that patients may try to prevent palpation by the examiner. The overlying skin is occasionally erythematous.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of subacute thyroiditis is shown in Table I and includes both thyroid and non-thyroid disorders. As mentioned previously, it is the most common thyroid etiology of anterior neck pain, with hemorrhage into a cyst or other benign nodule the second most common thyroidal cause of neck pain. Clinically, the two can readily be distinguished from each other since hemorrhage into a nodule is not accompanied by either viral symptoms or thyrotoxicosis. Moreover, hemorrhage is generally sudden in onset, and the mass tends to be very smooth on palpation. In addition, the radioactive iodine uptake in patients with hemorrhage is normal, and a radionuclide scan would reveal a filling defect. Pyogenic thyroiditis is characterized by features of an abscess, with a tender, palpable, fluctuant mass. In addition, the patient would likely have a high fever and a significantly higher white blood cell count than would the patient with subacute thyroiditis, and a radionuclide scan would reveal similar radionuclide findings as those for the patient with acute hemorrhage into a cyst. Patients with pyogenic thyroiditis are not thyrotoxic, nor are those with

Figure 1 A 52-year-old man with severe subacute granulomatous thyroiditis with threatened airway obstruction. Note the pronounced retropharyngeal edema (A) and its dramatic resolution following intravenous administration of methylprednisolone (B). From Singer, P. A. (1991). Thyroiditis: Acute, subacute, and chronic. *Med. Clin. North Am.* 75, 61–77.

cellulitis of the anterior neck. Also, patients with cellulitis have features of infection and do not have discreet masses on palpation. The patient with an infected thyroglossal duct cyst or branchial cleft cyst may present with a painful mass, which may be fluctuant. Such lesions also may be distinguishable from subacute thyroiditis by virtue of their more superior (thyroglossal duct cyst) or lateral (branchial cleft cyst) locations. In addition, patients with such lesions are euthyroid.

Rapidly growing thyroid cancer is an unusual cause of anterior neck pain, but when it occurs patients complain more of an achy-type pain, often accompanied by symptoms of tracheo-esophageal pressure. Patients do not have features of acute inflammation, and on palpation the mass is nontender and usually rock hard. Painful Hashimoto's thyroiditis is also very uncommon and is accompanied by elevated titers of thyroid antibodies and, frequently, hypothyroidism.

Radioactive iodine administration, either for treatment of thyrotoxic Graves' disease or for remnant ablation in patients with differentiated thyroid cancer, may cause anterior neck pain and thyroid tenderness. The etiology of the inflammation is always obvious.

Several years ago, infection of the thyroid with *Pneumocystis carinii* was confused with subacute thyroiditis. We reported on three patients with biopsy-proven *P. carinii* infection who presented with anterior neck

pain and suppressed radioiodine uptake values; two of the patients were thyrotoxic. Other workers also reported similar cases at approximately the same time. What made most of the cases unique was the history of using inhaled aerosolized pentamidine for pneumocystis pneumonia prophylaxis, which may well have resulted in the pneumocystis organism seeking another primary target. Since pentamidine is no longer used for prophylaxis, no further cases of pneumocystis thyroiditis have been reported.

Thyroid amyloidosis associated with systemic amyloid has been reported, with tender goiters, low thyroid radioactive iodine uptake values, and elevated erythrocyte sedimentation rates but without thyrotoxicosis.

LABORATORY FINDINGS

Biochemical thyrotoxicosis occurs in approximately half of patients with subacute thyroiditis. Serum T_4 (free T_4) and T_3 (free T_3) levels are elevated and serum TSH concentrations are suppressed. There is a disproportionate elevation of T_4 relative to T_3 since serum levels of thyroid hormones are due to "dumping" of preformed hormone into the circulation and therefore reflect intrathyroidal T_4 and T_3 content. This is in contrast to the thyroid hormone levels in

patients with Graves' disease, in which there is a disproportionate increase of serum T_3 relative to serum T_4 . In addition, impaired peripheral conversion of T_4 to T_3 due to the illness may contribute to the relatively lower T_3 concentrations. In general, the thyrotoxicosis associated with subacute thyroiditis is mild or at most modest in its severity.

Radioactive iodine uptake is always suppressed, usually to less than 2% after 24 h. Indeed, if the radioactive iodine uptake is more than 5% after 24 h, the diagnosis of subacute thyroiditis is unlikely. The absent uptake of iodine by the thyroid is due to destruction of the iodine-trapping mechanism from the inflammatory process as well as from inhibition of TSH secretion by excess circulating thyroid hormone. It is important to perform a radioactive iodine uptake test in patients with suspected subacute thyroiditis in order to rule out other causes of anterior neck pain as well as other types of thyrotoxicosis.

The erythrocyte sedimentation rate is almost always >50 mm/h. A normal sedimentation rate in a patient with a painful anterior neck mass places the diagnosis of subacute thyroiditis in question. A mild normochromic, normocytic anemia is frequently present, as is a slightly elevated total white blood cell count.

The serum thyroglobulin concentration is always elevated during the acute phase of subacute thyroiditis, reflecting the destruction of the thyroid follicular architecture and release of thyroglobulin into the circulation. However, the serum thyroglobulin is not recommended as a routine test in the evaluation of patients with suspected subacute thyroiditis since it is elevated in virtually all other thyroid disorders as well. It may be a helpful test when anterior neck discomfort is present, and when the diagnosis of subacute thyroiditis is in question, a normal serum thyroglobulin would cast serious doubt on the diagnosis.

Fine needle aspiration is not routinely recommended in the evaluation of suspected subacute thyroiditis but may be employed in patients in whom the diagnosis of a painful neck mass is not clear. The principal disorders to exclude in such circumstances include acute pyogenic thyroiditis and hemorrhage into either a malignant or benign thyroid nodule. Fine needle aspiration in subacute thyroiditis shows giant cells and pseudogranulomas.

Ultrasonography has been employed as an adjunct in the diagnosis of subacute thyroiditis; findings show diffuse areas of hypoechogenicity. However, ultrasound is not routinely used in the evaluation of patients with suspected subacute thyroiditis. [Table II](#) summarizes typical clinical and laboratory manifestations of subacute thyroiditis.

Table II Clinical and Laboratory Characteristics of Subacute Thyroiditis

| |
|--|
| Symptoms |
| Viral-type prodrome (fever, myalgias, sore throat) |
| Dysphagia |
| Anterior neck pain (frequently with radiation) |
| Symptoms of hypermetabolism (palpitations, tachycardia, weight loss) |
| Signs |
| Fever |
| Tachycardia |
| Tender, hard thyroid mass |
| Laboratory findings^a |
| Serum free T_4 elevated |
| Serum TSH suppressed |
| Erythrocyte sedimentation rate elevated |
| Thyroidal radioactive iodine uptake suppressed |
| Serum thyroglobulin elevated |

^aAll of the tests on this list, except the thyroglobulin, should be included in the routine evaluation of subacute thyroiditis. The thyroglobulin is helpful when it is unclear if the neck pain is thyroid in origin.

TREATMENT AND CLINICAL COURSE

Treatment of subacute thyroiditis is directed toward relief of pain and inflammation and control of thyrotoxic symptoms. Salicylates and nonsteroidal anti-inflammatory agents have been advocated by some physicians as preferred treatment, although they tend to be effective in only the mildest cases of the disorder. Most thyroid specialists recommend the use of glucocorticoids, which are effective at relieving pain within hours after oral administration. A divided dose of 30–60 mg of prednisone daily usually suffices. Lack of significant improvement within 24 h after initiation of steroids is uncommon since dramatic relief of pain usually occurs within hours. Indeed, the absence of rapid improvement would call into question the original diagnosis. The prednisone can begin to be tapered after approximately 1 week and discontinued within 3 or 4 weeks. Pain and swelling recur, often in the contralateral lobe, in approximately 20% of patients. When this occurs, prednisone should be resumed but with a lower dose. Approximately half of the original starting dose usually suffices. The tapering process can then begin anew.

Thyrotoxic symptoms may be controlled by the use of beta-blocking agents, with the dose depending on severity of symptoms. Propranolol in a dose of 10–40 mg three or four times per day or atenolol in a dose of 25–50 mg once daily is usually sufficient to control the hypermetabolic symptoms.

Thionamide agents are of no use in the management of subacute thyroiditis and are not recommended since the thyrotoxicosis results from release of preformed hormone rather than from increased synthesis. Therefore, drugs that inhibit thyroid hormone synthesis, such as thyroid-blocking agents, have no beneficial effect.

Sodium ipodate has been shown to be effective in correcting thyrotoxicosis more rapidly, although few physicians have reported using it. Cases have been reported in which radioactive iodine ablation, or even thyroidectomy, has been employed for patients with prolonged, disabling pain, but such circumstances are rare.

The clinical course of subacute thyroiditis generally follows four phases (Fig. 2). The initial or "acute" phase is characterized by pain, tenderness, and thyrotoxicosis, and it may last 2–12 weeks. It is during this phase, called

the thyrotoxic phase, that treatment with glucocorticoids is necessary. Following the thyrotoxic phase, a several-week interval of euthyroidism occurs. A hypothyroid period then follows, which may last from a few weeks to a few months. During the hypothyroid phase, levo-thyroxine therapy may be necessary. An asymptomatic recovery phase then follows, during which the thyroid is restored to normal function.

Not all patients with subacute thyroiditis progress through all four phases of the disorder since only approximately 50% of patients develop transient hypothyroidism. In most cases, the entire episode of subacute thyroiditis lasts no more than 6 months.

Late recurrences of subacute thyroiditis are uncommon but may occur, even years later. Typically, a repeat bout of subacute thyroiditis is milder than the original occurrence.

Figure 2 Representation of changes observed during a typical bout of subacute thyroiditis. From Emerson, C. H., and Farwell, A. P. (2000). Sporadic silent thyroiditis, postpartum thyroiditis, and subacute thyroiditis. In "Werner & Ingbar's The Thyroid: A Fundamental and Clinical Text" (L. E. Braverman and R. D. Utiger, eds.), 8th ed., pp. 578–589. Lippincott Williams & Wilkins, Philadelphia.

Virtually all patients with subacute thyroiditis achieve restoration of normal thyroid function, although permanent hypothyroidism has been reported in 1–5% of patients. Moreover, it has been shown that patients who have suffered a bout of subacute thyroiditis may have subtle, permanent thyroid abnormalities. For example, patients have been shown to be sensitive to the inhibitory effects of exogenously administered iodides by exhibiting elevations in serum TSH concentrations, even years after having had subacute thyroiditis. Thus, perhaps patients with a history of subacute thyroiditis should be screened with serum TSH levels a few weeks after receiving exogenous iodides in pharmacologic quantities.

phosphatase (ALP), osteocalcin, and osteopontin. Thyroid hormone receptors are central to conferring T_3 responsiveness to cells by binding to target genes either as homodimers or as heterodimers complexed with the *cis*-acting factor 9-*cis*RXR. Transcriptional regulation by thyroid hormones is mediated by ligand-dependent transcription factors called TRs (e.g., TR α 1, TR β 1, TR β 2). In osteoblasts, TRs are coexpressed with the *cis*- and *trans*-acting factors 9-*cis*RXR (RXR) and all-*trans* RAR (RAR) where they modify the regulation of endogenous gene expression (e.g., ALP, osteocalcin, osteopontin) by T_3 .

The cellular osteoblast-like lineage hOb displays lower cytokine secretion, reduced immunostaining of TR- and T_3 -binding sites, and decreased thyroid receptor function than does another osteoblast-like cell line, BMS; therefore, it seems that hOb cells play a lesser role and BMS cells play a greater role than previously envisaged in T_3 regulation of bone remodeling. Although it is premature to extend these observations to the situation *in vivo*, this nonetheless highlights the potential importance of human bone marrow cells in future studies of T_3 action on bone.

Osteoblast/Osteoclast Function

Interference of Thyroid Hormones in Osteoblast/Osteoclast Function

Thyroid hormones increase osteoclastic bone resorption by acting indirectly on osteoblasts; a direct response of osteoclasts to T_3 is disputed, and most actions of T_3 in bone are thought to be mediated via osteoblasts. Osteoclasts are the primary cell type that can resorb bone. They are highly motile, giant, multinucleated cells derived from hemopoietic tissue. The osteoclast precursor cells are closely related to cells of monocyte macrophage lineage. The formation of osteoclasts takes place only in the close vicinity of mineralized bone, and the multinucleated osteoclasts never appear in the circulation. The activity of osteoclasts is essential for the physiological resorption of bone during skeletal remodeling as well as for the maintenance of calcium homeostasis. Enhanced osteoclast activity is apparent in the excessive bone loss seen in a variety of pathological conditions such as thyrotoxicosis. Studies on the expression of the receptors for the stimulators of bone resorption, parathyroid hormone (PTH), and calcitriol [1,25(OH) $_2$ D $_3$, vitamin D $_3$] reveal, surprisingly, that they are not present on osteoclasts or on their precursor cells but rather are expressed in bone-forming osteoblasts. The osteoblast/stromal cell ratio is crucial for the development and differentiation of the osteoclast via

a mechanism involving cell-to-cell contact. The osteoblastic stromal cells produce osteoclast-differentiating factors in response to a variety of stimuli that are essential for the formation of mature osteoclasts. One of these factors has been identified as RANKL (receptor activator of nuclear factor kappa B [NF- κ B] ligand), which is a membrane protein expressed in the osteoblastic stromal cells and belongs to the tumor necrosis factor (TNF) family of growth factors. Osteoclast progenitors express RANK, the receptor for RANKL, at their cell surfaces, and the interaction between RANK and RANKL stimulates the development and differentiation of osteoclasts. T_3 induces the expression of RANKL mRNA in primary osteoblastic cells (POB). This effect is amplified when cells are costimulated with calcitriol.

In addition to RANKL, the osteoblastic stromal cells produce osteoprotegerin, (OPG), which serves as a decoy receptor for RANKL, inhibiting osteoclastogenesis by preventing the interaction between the osteoblastic stromal cell and the osteoclast progenitor (Fig. 1).

The regulation of osteoclast apoptosis is a further mechanism by which osteoclast activity can be controlled. In fact, many resorptive agents are able to alter osteoclast life span and/or apoptotic rate. Osteoclast viability is increased by agents that stimulate resorption (e.g., macrophage colony-stimulating factor [M-CSF], interleukin-1 [IL-1]) that are produced by monocyte macrophage cell lines and also by the effect of thyroid hormones.

In conclusion, thyroid hormones, like other resorption agents, stimulate osteoclast activity in cocultures with osteoblasts but do not stimulate activity in highly purified osteoclast preparations. The primary effect of thyroid hormones is to stimulate osteoblastic production of downstream effectors that activate the osteoclast. These downstream effectors can act either in a paracrine fashion to directly activate osteoclast activity or in an autocrine fashion to further stimulate osteoblasts to produce the paracrine factors that directly activate the osteoclasts.

Local Bone Marrow Factors (Cytokines) Modulating Bone Remodeling in Thyrotoxic Bone Disease

The release of cytokines by osteoblasts provides a mechanism by which osteoblasts could mediate the action of T_3 on osteoclast resorption. In the microenvironment of the bone marrow, the cytokines IL1, M-CSF, and TNF can stimulate bone formation and resorption and play a critical role in regulating osteoclast formation and activity. Furthermore, it has been

Figure 1 Schematic representation of the role of the RANK/RANKL/OPG system in osteoclast development. RANKL is expressed on the surface of the osteoblastic stromal cell and serves as a ligand for RANK, which is expressed on the surface of the osteoclast progenitor cell. The interaction between RANK and RANKL triggers the development of the mature osteoclast. OPG, produced by the osteoblastic stromal cell, serves as a decoy receptor for RANKL and inhibits osteoclastogenesis, preventing the interaction between the osteoblastic stromal cell and the osteoclast progenitor.

shown that cell cultures of human bone marrow stromal cells, containing osteoblast progenitor cells, release IL-6 and IL-8 in response to T_3 . The former regulates osteoclast proliferation and recruitment, whereas the latter regulates osteoclast development and activity. In addition, IL-8 receptors have been identified in osteoclast cells. Other cytokines induced by thyroid hormones are also implicated in high-turnover bone resorption. Serum IL-6 and IL-8 are produced by a number of sources, including blood monocytes and bone tissue. IL-6 mRNA is present in thyroid follicles, but high levels of cytokines, independent of the thyroid gland, are also reported in patients with ablated thyroids. The soluble serum receptor for IL-6 (sIL-6R) regulates the biological activity of IL-6, and the levels of this receptor correlate well with those of serum thyroid hormones and may prove to be a better determinant of thyrotoxic bone resorption.

High levels of serum IL-6 have been demonstrated previously in thyrotoxicosis, including Graves' disease, and also in other conditions unrelated to autoimmunity such as toxic nodular goiter and iatrogenic

subclinical thyroid excess. The elevations in serum IL-6 and IL-8 in thyrotoxicosis seem to result from the chronic effect of thyroid hormone excess rather than from the accompanying autoimmune inflammatory response produced by Graves' thyroid or eye disease.

In hyperthyroidism, as in osteoporosis from estrogen deficiency, there is an inverse relationship between the IL-6 concentration and BMC values as well as between cytokines and deoxypyridinoline (Udpd) excretion. It is possible that the same mechanism, mediated by IL-6, induces osteopenia in two conditions with high bone turnover as in postmenopausal osteoporosis and thyrotoxicosis.

Serum levels of IL-6 and IL-8, as well as markers of bone remodeling, are elevated in untreated thyrotoxicosis but fall as thyroid hormone levels normalize with treatment. The normalization of Udpd precedes that of serum cytokine concentrations; although many studies have not found a correlation between serum cytokines and Udpd, the interaction of T_3 with IL-6 and other cytokines should continue to be a focus in future investigations.

Evidence of a role for cytokines in T_3 -associated bone resorption is lacking; this is due partly to an interference of their effects by a variety of other growth systemic factors such as PTH, calcitriol, and prostaglandin E_2 (PGE_2).

Systemic Factors Regulating Osteoblast/Osteoclast Function in Thyrotoxic Bone Disease

Thyroid hormones, at concentrations approaching those that occur in thyrotoxicosis, also stimulate bone resorption and increase sensitivity to PTH. This causes a marked increase in bone resorption in bone organ cultures and stimulates osteoclast formation in both murine and human marrow cell cultures. Many of the calciotropic hormones and cytokines appear to act through a dual capacity to inhibit production of OPG and to stimulate the RANK system. The RANKL/RANK interaction is essential for the effect of PTH, calcitriol, and PGE_2 . This is demonstrated by the ability of anti-RANKL antibodies to inhibit the bone resorption activity of these known inducers of bone resorption; in contrast, estrogen appears to inhibit RANKL production.

Studies have demonstrated that PTH regulates systemic levels of IL-6 in experimental animals. Furthermore, IL-6 has been shown to be an important mediator of the bone-resorbing activity of PTH *in vivo* and also plays a role in coupling PTH-induced bone resorption; IL-6 can stimulate proliferation of early osteoblast precursors, and PTH induces the differentiation and fusion of the precursors to form multinucleated osteoclasts.

The treatment of bone cell cultures with thyroid hormones produces a gradual increase in the concentration of PGE_2 . This effect is abolished by indomethacine, which also reduces thyroid hormone-induced bone resorption.

In mouse bone cell cultures, the effect of calcitriol on the IL-6-dependent formation of osteoclast-like cells is also subject to modulation by T_3 . The mechanism of interaction of these two hormones appears to involve the joint stimulation of the prostaglandin system. T_3 alone does not induce osteoclast formation in cocultures of marrow cells with POB; rather, it enhances the calcitriol-induced osteoclast formation. In addition, calcitriol induces the expression of deiodinase, an enzyme that converts the prohormone 3,5,3',5'-tetraiodothyronine (T_4) into its active form (T_3). These data facilitate an understanding of the mechanism of osteoclast formation and suggest a novel interaction between thyroid hormones and calcitriol.

The addition of calcitriol to unfractionated bone cells produces a dose-dependent increase in osteoblast survival. Calcitriol also acts indirectly on osteoclasts via the production of IL-1 and IL-6 by osteoblasts, stimulating osteoclast resorption.

THYROTOXIC BONE DISEASE

Biochemical Markers of Bone Remodeling in Thyrotoxic Bone Disease

Thyroid hormones stimulate both osteogenesis and osteolysis to induce an acceleration in bone remodeling. Early biochemical studies attempted to quantify the calcium balance in hyperthyroidism. Mean serum calcium and phosphorus concentrations were found to be higher than those in normal controls. The relative hypercalcemia reduces serum PTH and calcitriol levels, both of which are negatively correlated with free T_4 (FT_4), but these levels are normalized when the hyperthyroidism is treated.

Biochemical markers of bone formation and bone resorption, such as osteocalcin, ALP, bone isoenzyme, and urinary collagen pyridinoline (Upyr) or Udpd cross-links, are elevated in thyrotoxic patients and indicate increased bone formation and osteoclastic bone resorption. The binding of T_3 to its nuclear receptor in osteoblasts directly stimulates the osteoblasts to produce ALP, osteocalcin, and the propeptide of type I collagen. Furthermore, osteoblast activity mediates the T_3 activation of osteoclasts, leading to bone resorption and the release of markers such as collagen pyridinoline and Udpd cross-links.

Total ALP and osteocalcin are elevated in 30% and 65 to 90% of thyrotoxic patients, respectively. Early studies found a significant correlation between ALP and T_4 serum levels and osteoid volume. Conflicting data have been published on the potential correlation between osteocalcin and bone ALP and free T_3 (FT_3), so the precise relationship of osteocalcin to bone ALP remains unclear.

Novel markers related to collagen have been established as specific markers of bone resorption: the non-reducible cross-links of mature collagen, serum and urinary pyridinoline and deoxypyridinoline (Udpd/creatinine), and serum carboxyterminal telopeptide type I collagen. Urinary pyridinoline levels are raised in 99% of thyrotoxic patients but are less specific for bone than are urinary Udpd cross-links. Udpd accurately indicates thyrotoxic and subclinical advanced thyrotoxic bone resorption. Humoral markers of bone metabolism, such as bone ALP, osteocalcin, and Udpd, are more important to judge the early

effects of antithyroid treatment than is BMD, whose changes occur too slowly.

It is important to predict which patients are likely to suffer a long-term deficit in bone mineral mass so as to increase the efficacy of the therapy. Longitudinal and cross-sectional studies confirm that bone turnover is balanced within 2 to 3 weeks of therapy, and after 4 to 8 weeks of euthyroidism, a peak in the level of ALP occurs and Udpd levels return to within the normal range. However, continued increased serum ALP levels after 1 year of therapy may indicate continuing bone formation and, therefore, provide a marker for low bone mass, even in the presence of normalized Udpd excretion levels. This should be related to high levels of PTH; prior to treatment, endogenous PTH is slightly suppressed but increases significantly during the first year of therapy. The elevation of PTH seems to play a role in maintaining the high bone turnover rate despite the euthyroidism, conserving the bone calcium levels mediated by calcitriol, and increasing bone formation by an anabolic effect on osteoblasts.

Patients with Graves' disease exhibit suppressed serum thyroid-stimulating hormone (TSH) levels and often display elevated levels of TSH receptor antibody (TRAB). Cross-sectional studies indicate that markers of bone metabolism (e.g., ALP, Udpd, Upr) are more strongly correlated with TRAB than with TSH in Graves' clinical and subclinical patients as well as in Graves' patients with normal TSH levels. These data could support the clinical usefulness of TRAB as a marker of bone metabolism in Graves' patients. Because TRAB correlates with neither FT₃ nor FT₄ but is closely correlated with biochemical markers of bone metabolism, TRAB might directly affect bone metabolism independently of thyroid function. This hypothesis is supported by a recent study demonstrating that osteoblasts possess functional TSH receptors.

Bone Histomorphometry in Thyrotoxic Bone Disease

After the first report by von Recklinghausen, the histological bone changes in thyrotoxicosis were described as being similar to those of osteite fibrosa, osteoporosis, and osteomalacia.

More recently, histomorphometric analysis has shown that the bone hyperthyroid changes occurring in thyrotoxicosis are, in fact, specific and characterized by increased turnover in trabecular bone and increased remodeling and porosity in cortical bone. The predominant changes are related to bone

destruction where the osteoclast activity is increased and the osteolytic activity induces and surpasses the osteogenic activity.

In Graves' bone disease, bone mineralization is initially slightly greater than bone formation; however, subsequently, the equilibrium between the increase in bone mineralization and bone formation is restored. Osteoid production can even exceed the rate of mineralization; consequently, an osteomalacia-like, osteoid-rich pattern can be observed on histological analysis of bone biopsy specimens.

Because the rate of bone formation does not always equal that of bone resorption, trabecular thickness may decrease, giving rise to trabecular perforations and higher cortical porosity.

In conclusion, the thyrotoxic histomorphometric pattern is unique and characterized by increased osteoblast and osteoclast activity, giving rise to a net loss of bone volume. These changes are present in both cortical and trabecular bone, although they are more evident in cortical bone, whereas a reduction of the absolute bone volume occurs less often in cortical bone.

Bone Mineral Density Markers in Thyrotoxic Bone Disease

Between 1970 and 1980, BMD was measured only in peripheral sites in patients with hyperthyroidism. However, a newer and more superior method, dual energy X-ray absorptiometry (DEXA), has been developed for evaluating bone mass, where measurements are taken in lumbar vertebrae or femoral neck, typical sites of osteoporosis-related morbidity. Longitudinal studies of thyrotoxic patients demonstrate that even a slight excess of thyroid hormones, regardless of the cause, is associated with decreased BMD in cortical and trabecular bone. In thyrotoxic patients, the baseline percentage BMD of vertebrae is 92.6% as compared with that of normal controls ($0.91 \pm 0.03 \text{ g/cm}^2$ and $0.85 \pm 0.2 \text{ g/cm}^2$, respectively). After 12 months of antithyroid therapy, the mean lumbar spine BMD increases from an initial value of 1.01 g/cm^2 to 1.07 g/cm^2 and increases by 6.6% per year ($P < 0.001$). The femoral neck BMC increases by 1.2% per year, and increases in femoral trochanter bone mineral of 3.2% per year have also been documented. No significant difference is observed between the BMDs of male and female patients. A significant reduction in BMD is seen in postmenopausal women affected by thyrotoxicosis or long-term treatment with L-T₄ suppressive therapy. Some authors, but

not others, have found a significant correlation between markers of bone formation and BMD. Conflicting results have also emerged regarding the correlation between BMD and the duration of hyperthyroidism, with some findings sustaining that percentage BMD is inversely correlated with levels of the TRAB. In addition, premature hair graying may be a weak marker for reduced BMD in women with a history of Graves' disease, although that is not the case in normal women. Hyperthyroid patients display a general reduction of bone mass in the axial skeleton that is only partially corrected, mainly at the femoral neck, after 5 to 7 months of biochemical euthyroidism. In children, severe osteopenia is observed on diagnosis of Graves' disease, with a preferential loss of cortical bone and the BMD reduced significantly, but this is rapidly corrected after 1 year of euthyroidism.

After surgical treatment for Graves' disease, thyrotoxicosis-associated bone loss in premenopausal women is fully restored, and subclinical hypothyroidism post-thyroidectomy may even result in higher BMD than in controls. In contrast, surgical thyroidectomy does not produce a similar result in postmenopausal women due to the influence of the menopause on bone resorption. T₄ therapy alone does not represent a significant risk factor for bone loss or, therefore, for osteoporotic fracture. Nonetheless, it is clear that there is a potential risk of bone loss in postmenopausal females.

CLINICAL ASPECTS OF THYROTOXIC BONE DISEASE

Clinical studies have shown that hyperthyroidism is one of the major causes of secondary osteoporosis; however, unlike osteoporosis, it affects more than trabecular bone. The imbalance of the resorption/formation ratio reduces BMD and, therefore, constitutes a risk of thyrotoxicosis-associated osteoporotic fractures.

The etiology and duration of thyrotoxicosis do not seem to play a role in the severity of thyrotoxic bone disease, but the clinical manifestations of Graves' disease for bone may differ depending on the age of the patient, particularly for pre- and postmenopausal female patients.

Several humoral markers reflect osteogenesis. T₃ enhances the functional activity of mature osteoblasts but suppresses the differentiation of osteoprogenitor cells to osteoblasts. The marker of osteoblast activity at all stages (ALP) and the marker of mature osteoblast activity (osteocalcin) are increased in thyrotoxic bone disease.

The osteolytic humoral marker, Udpd cross-links/creatinine excretion, is a highly sensitive marker of increased bone metabolism in thyrotoxicosis, whereas there are only relatively small increases in osteocalcin and bone ALP determinants.

After 1 year of euthyroidism, thyrotoxicosis-associated bone loss may be reversible. The normalization of thyroid hormone levels with antithyroid drugs is followed by a significant increase in lumbar spine BMD, which is preceded by a significant attenuation of increased bone turnover. This recovery is sometimes incomplete in the lumbar spine and Ward's triangle after 5 to 7 months euthyroidism; therefore, it is important to identify hyperthyroid patients who are at risk for insufficient recovery.

Some longitudinal studies suggest that high ALP levels 1 year after the initiation of antithyroid therapy are associated with reduced BMD values and could predict poor restoration of BMD. During this phase, PTH rises and insulin-like growth factor-1 (IGF-1) bioactivity could be insufficient to restore bone mass despite euthyroidism. In addition, the use of antiresorptive drugs could be encouraged in these patients.

In postmenopausal thyrotoxic women, many factors in serum and the bone microenvironment unit interact to increase osteoclast activity and subsequent bone loss. This is due to the effect of increased thyroid hormone production together with a lack of skeletal protection by estrogen. The relative dehydroepiandrosterone (DHEA) and IGF-1 insufficiency that occurs during the postmenopausal period may constitute additional risk factors for developing enhanced bone loss. The high-turnover state of the early postmenopausal stage could predispose bone to the detrimental effects of hyperthyroidism, and postmenopausal women are most sensitive to accelerated bone loss from excessive T₄ therapy.

Conversely, other studies have demonstrated no significant difference in BMD expressed as a Z score between pre- and postmenopausal female hyperthyroid patients. This could suggest that the impact of thyrotoxicosis is great enough to surpass the effect of the menopause on bone mass, at least during the late postmenopausal period. The effect of thyroid hormones could aggravate the evident high bone turnover state during the early postmenopausal period. In contrast, during the late postmenopausal period, characterized by slow bone loss, thyroid hormone could produce a less detrimental effect on bone remodeling. This argues in favor of the early use of hormonal replacement therapy in early postmenopausal thyrotoxic women and, moreover, for the thyroid hormone replacement or suppressive therapy to be of

the smallest possible dose to produce the desired clinical effect.

Special discussion is required for the impact of thyrotoxicosis on bone metabolism in three specific situations: thyrotoxicosis in men, bone disease in subclinical hyperthyroidism, and thyrotoxicosis in children.

Thyrotoxic Bone Disease in Men

There is little information on the effect of thyroid hormones on bone mass and the risk of fractures in men; however, it is clear that thyroid hormones have a smaller effect on bone in men than in women. Nonetheless, many experts believe that hyperthyroidism is one of the most important causes of osteoporotic fractures in men occurring after alcohol abuse, glucocorticoid excess, and hypogonadism.

Previous studies have shown that thyrotoxic patients display a lower radial BMD, compared with age-matched controls, and have a twofold increased risk of hip fractures.

In male patients with recent-onset Graves' disease, BMD values are reduced to levels similar to those reported in female hyperthyroid patients. As in women, this is more marked in cortical bone where there is a significant relationship with T₄ levels. This is consistent with an improvement of BMD in Graves' patients on recovery from the hyperthyroidism and with partial recovery of bone mass after attainment of euthyroidism.

The presence of greater concentrations of total ALP and osteocalcin in men affected by Graves' disease suggests the beginning of the bone mass recovery period during the early months of effective treatment.

The effect of long-term suppressive T₄ therapy for thyroid cancer on BMD is similar to that produced by Graves' disease. Nonetheless, the bone loss in Graves' disease is reversible to some extent, whereas the bone loss in patients on suppressive therapy is reasonably continuous. The prior administration of pamidronate could be used to prevent a thyroid hormone-induced increase in bone resorption.

The effect of excess endogenous and exogenous thyroid hormones is mildly deleterious in the axial bone mass in male patients. In another study, the same suppressive therapy caused only a small increase in the markers of bone metabolism without detectable changes in the BMD.

In hypothyroidism, thyroid hormone replacement therapy does not produce a difference in BMC, thereby excluding the possibility of a significant loss of cortical bone mineral by thyroid hormones.

Normal BMD is reported in male patients on T₄ substitutive therapy.

Major evidence is emerging for the existence of male osteoporosis; therefore, male patients with a history of TSH suppression and thyrotoxicosis should be included in the preventive program of skeletal status assessment.

Bone Disease in Subclinical Hyperthyroidism

Endogenous subclinical hyperthyroidism is identified by suppressed values of TSH in the presence of normal T₄ levels. This is also observed during suppressive T₄ treatment and is referred to as exogenous subclinical hyperthyroidism.

BMD and bone biochemical parameters may be influenced by the duration of subclinical hyperthyroidism and by the menopausal status of the patients. For subclinical thyrotoxicosis, it appears that the appendicular, rather than the axial, skeleton is more susceptible to minor thyroid hormone excess. In premenopausal women affected by the endogenous subclinical hyperthyroidism associated with Graves' disease or multinodular goiter, biochemical bone markers are not increased and BMD is not reduced. Conversely, long-term endogenous subclinical hyperthyroidism (2 years or more) may be a contributing factor for the development of osteoporosis and accelerated bone loss in postmenopausal women, mostly at sites where cortical bone predominates. A subtle increase in thyroid hormone, together with the lack of skeletal protection by estrogen and relative postmenopausal insufficiency of DHEA and IGF-1, is an additional risk factor for bone loss.

Antithyroid treatment of endogenous subclinical hyperthyroidism has a beneficial effect on bone loss in postmenopausal women. This is substantiated by significantly higher BMD values at the distal site of the forearm in treated patients, as compared with untreated patients, during the second year of treatment. The difference is small but cumulative over many years and could result in a decreased risk of fracture. The stabilization of the decline in BMD is remarkable considering the postmenopausal status. In premenopausal women affected by subclinical hyperthyroidism for Graves' disease, the antithyroid drug treatment produces a significant increase in bone mass and reduces the risk of secondary osteoporosis. It still appears to be important to achieve normal TSH levels in Graves' patients during the treatment so as to normalize their bone metabolism.

The T₄ treatment could produce exogenous subclinical hyperthyroidism. The T₄ dose that renders a patient euthyroid, as shown by normal TSH values, rarely produces an adverse effect.

The slightly suppressive T₄ administration can activate bone turnover but does not constitute a risk factor for bone loss or for osteoporosis in pre- and postmenopausal women with nontoxic goiter.

Two meta-analysis studies have shown a significant reduction in BMD, but only in postmenopausal women on long-term L-T₄ suppressive therapy; this was more marked in cortical bone than in trabecular bone. In postmenopausal women, the bone loss appears early during the suppressive treatment. Long-term suppressive doses of TSH produce BMD reduction at various skeletal sites and increase the risk of fractures. TSH suppressive doses should be prescribed only when appropriate and no longer than necessary so as to minimize the adverse effects of excessive doses of thyroid hormone on bone. The magnitude of bone loss, also during long-term therapy, depends on the serum levels of thyroid hormones as well as on the functional state of thyroid hormone receptors in bone tissue. However, other risk factors should be studied to prevent the possible loss of bone mass (e.g., age, weight, calcium intake in postmenopausal women, low physical activity in premenopausal women).

T₄ therapy represents a significant risk factor for BMD loss only in postmenopausal women with a previous history of thyrotoxicosis. In this condition, the smallest possible dose of thyroid hormone to produce the desired clinical effect must be used. Postmenopausal women taking both thyroid and estrogen hormones exhibit BMD values comparable to those observed in women taking only estrogen. The estrogen replacement therapy abolishes the reduction in femoral and vertebral BMD in postmenopausal women on L-T₄ therapy. The potential beneficial influence of estrogen replacement therapy suggests that estrogen administration should be encouraged in those patients. Anti-osteoclastic agents may also be appropriate as a preventive treatment in postmenopausal women at high risk for osteoporosis during T₄ therapy.

Thyrotoxic Bone Disease in Children

Graves' disease is a rare condition during childhood and adolescence, with only 1 to 5% of all patients being children. The incidence of juvenile Graves' disease ranges from 0.1 in 100,000 patients in young children to 3.0 in 100,000 patients in adolescents. Only a few investigations in children and adolescents

have been published during the past decade or so. Accelerated growth and bone maturation is observed in prepubertal children; growth acceleration is present for several months before diagnosis, and the bone age is advanced by 1.5 to 2.5 years compared with the chronological age, irrespective of weight. During this phase, the bone maturation is affected by growth hormone (GH) and thyroid hormone, whereas at puberty, it is influenced mainly by sex hormones. This may explain the failure to observe similar growth acceleration and bone maturation in the pubertal patients for whom bone age corresponds to anagraphic age. In prepubertal children, the epiphysis is also significantly altered due to the exposition to high levels of thyroid hormones.

In growing children, untreated thyrotoxicosis and inappropriate T₃ replacement therapy can increase osteopenia in the short term but generally results in short-stature adults relative to predicted heights.

The severe osteopenia in children that is observed on diagnosis of Graves' disease is rapidly corrected after 1 to 2 years of treatment. Furthermore, antithyroid treatment dramatically reduces the bone resorption in pubertal girls and increases significantly both spinal and total body BMD, providing the physiological conditions to obtain optimal peak bone mass.

OUTLINE OF THERAPY FOR THYROTOXIC BONE DISEASE

Experimental animal studies demonstrate that excess thyroid hormone induces cortical bone loss associated with high bone turnover that is higher in tibia than in vertebra. This is due to the effect of alendronate, evident in tibia but not in vertebra, that interferes with the recruitment of osteoclasts and increases bone volume by inhibiting osteoclast activity. In vertebra, the lack of effect of thyroid hormone and alendronate may be ascribed to a lower basal bone turnover.

The pamidronate is effective at preventing bone mineral loss in ovariectomized rats, both T₄ treated and untreated. This finding may have clinical relevance in estrogen-depleted patients for whom a treatment other than the reduction of T₄ administration would be desirable.

In normal men subjected to mild thyroid hormone excess for 8 days, the prior administration of pamidronate is useful in the prevention of thyroid hormone-induced increased bone resorption or induced osteopenia. Alendronate also produces an increase in BMD and a corresponding decrease in serum osteocalcin levels in both pre- and postmenopausal women.

A recent study assessed the effect of antiresorptive therapy with nasal calcitonin on bone metabolism in recently diagnosed hyperthyroid patients. The effect of exogenous calcitonin was greater in the patients than in normal controls.

The significant reduction in axial BMD in thyrotoxic patients was partially restored after attainment of the euthyroid state. Nonetheless, recovery was incomplete, with a 5% deficit compared with controls. The treatment with nasal calcitonin had no additional effect after attainment of the euthyroid state.

In postmenopausal women, estrogen replacement therapy is effective at preventing an increase in bone mineral metabolism in high-dose T₄ treatment as in thyrotoxicosis.

For the treatment of bone thyrotoxic disease in children, the antithyroid drug therapy dramatically reduces the bone resorption and increases significantly both spinal and total BMD, providing physiological conditions for the achievement of the peak bone mass.

In summary, published evidence indicates that TSH suppresser therapy for subclinical Graves' disease, and even minimally excessive thyroid hormone replacement or chronic suppression therapy, can be accompanied by a decrease in cortical bone mass. This raises important questions about the use of lifelong replacement therapy, especially for young patients. These data should also provoke caution in the use of traditional suppressive therapy for thyroid nodules. The correct interpretation of studies such as these requires keeping in mind the concept of remodeling space. Predictable changes in bone density will be observed simply by increasing or restricting the remodeling space. However, after some months, a new equilibrium will be achieved. To evaluate the clinical impact of such changes, it is necessary to carry out longer term studies than those that have been

reported, but for the present time, the smallest possible dose of thyroid hormones to achieve an euthyroid state or to suppress thyroid gland activity is advisable.

The critical effect of suppressive T₄ treatment on bone in thyroid cancer could be balanced by pamidronate administration. In these patients, it is also critical to assess bone mineral metabolism.

2-h radioiodine uptake, although it should be feasible to obtain the result of serum T4 determination within a few hours on an emergency basis in most hospitals today. However, initiation of therapy should not be postponed when there is a high index of suspicion merely because one is awaiting laboratory confirmation of the diagnosis.

Other laboratory abnormalities often include modest hyperglycemia in the absence of diabetes mellitus. Moderate leukocytosis with a mild shift to the left is common even in the absence of infection. Increased serum calcium levels may be seen, perhaps due to both hemoconcentration and the known effects of thyroid hormone on bone resorption, but other serum electrolytes are usually normal. Hepatic dysfunction in thyrotoxic storm will result in elevated levels of serum lactate dehydrogenase, aspartate aminotransferase, and bilirubin.

Because serum cortisol levels are usually elevated in thyrotoxic individuals, a normal value may be interpreted as being inappropriately low. In view of the known coincidence of adrenal insufficiency with Graves' disease, one should maintain a reasonably high index of suspicion for this disorder, particularly if there is hypotension and suggestive electrolyte abnormalities. It would be prudent to obtain a serum sample for cortisol determination prior to the administration of corticosteroid. Even in the absence of adrenal insufficiency, adrenal reserve may be exceeded in thyrotoxic crisis due to the inability of the adrenal gland to meet the demand placed on it as a result of the accelerated turnover and disposal of glucocorticoids that occur in thyrotoxicosis.

PATHOGENESIS

The precise pathogenesis underlying the precipitation of thyrotoxic storm is likely not to be the same in all cases and remains incompletely understood, although the magnitude of serum hormone levels per se does not appear to be critical. However, acute discharge of hormone resulting in rather sudden changes of its concentration, in the appropriate clinical setting, certainly can trigger crisis. This may be seen after ¹³¹I therapy, withdrawal of propylthiouracil (PTU) therapy, vigorous palpation of the thyroid, or administration of lithium, stable iodine, or iodinated contrast dyes.

A possible interaction between the effects of excessive levels of circulating thyroid hormone and the catecholamines has been proposed. This is evidenced by the dramatic clinical improvement that follows the use

of agents that either deplete their tissue levels, such as reserpine, or block β -adrenergic receptors, such as propranolol. Although these agents are useful adjuncts to therapy, they should not be used by themselves because they might not prevent the occurrence of storm.

TREATMENT

We believe that to avoid a fatal outcome, it is important to implement a four-pronged approach to the management of thyrotoxic storm. The relative importance for survival of each arm of therapy will vary in a given patient. First, specific antithyroid drugs must be used to decrease the increased thyroid production and release of thyroxine (T4) and T3. The second part of management consists of treatment intended to block the effects of the remaining, but excessive, circulating concentrations of free T4 and T3. The third component addresses any underlying precipitating illness such as infection or ketoacidosis. The final arm of therapy is composed of those several specific treatments that are directed against the underlying systemic decompensation that may be characterized by fever, congestive failure, shock, and the like. In view of the poor prognosis associated with incompletely treated thyrotoxic storm, no one component of this four-pronged therapeutic approach should be neglected.

Therapy Directed against the Thyroid Gland

Inhibition of new synthesis of the thyroid hormones is achieved by administration of thionamide antithyroid drugs, such as PTU and methimazole (Tapazole), given orally. There are no available parenteral preparations of these compounds. Either methimazole or PTU may also be administered via the rectum if necessary. In view of the gravity of thyrotoxic storm, thionamide doses are much higher than those for otherwise uncomplicated thyrotoxicosis. Some experienced clinicians believe that PTU will provide more rapid clinical improvement because it has the additional advantage of inhibiting conversion of T4 to T3, a property not shared by methimazole. Separate treatment must be administered to inhibit the continuing release of T4 and T3 into the blood because thionamides act to reduce new hormone synthesis but have no effect on thyroidal secretion of preformed stores of hormone. Either inorganic iodine or lithium carbonate may be used for this purpose. Iodides may be given either orally as Lugol's solution or as a saturated solution of potassium iodide (eight

drops every 6 h). When iodine is administered together with full doses of antithyroid drugs, dramatic decreases in serum T₄ can be seen. The sequence of administration of these agents is extremely important. Use of iodine without prior thionamide dose is contraindicated because the iodine will provide extra substrate to enrich hormone stores within the gland, thereby generating the potential for further exaggeration of thyrotoxicosis.

In patients who may be allergic to iodine, lithium carbonate may be used as an alternative agent to inhibit hormonal release, although some caution has been raised in regard to its use in the setting of storm. This drug also may be used in thyrotoxic patients who are known to have serious toxic reactions to the thionamides.

Therapy Directed against Ongoing Effects of Thyroid Hormone in the Periphery

For the purpose of acutely reducing the circulating hormones, peritoneal dialysis and plasmapheresis have been employed, as has experimental hemoperfusion through a resin bed or charcoal columns. Such aggressive management should be considered in severe cases.

Beta blockers are also commonly used. Propranolol is the agent most commonly used in the United States today. Large doses, such as 60 to 120 mg every 6 h, are used in crisis or impending crisis. Indeed, because of the more rapid metabolism of the drug in severe thyrotoxicosis, even larger oral doses, or preferably intravenous doses, should be given. Initial intravenous doses should be given cautiously, whereas the patient's cardiac rhythm is monitored continuously. Added benefits of β -adrenergic blockade in these patients include improvement in agitation, convulsions, psychotic behavior, tremor, diarrhea, fever, and diaphoresis.

Therapy Directed against the Precipitating Illness

In most cases of thyrotoxic storm, therapy is not complete unless a diagnosis of the possible precipitating event is made and early treatment as indicated for that underlying illness is implemented.

It is important to be alert to the fact that conditions such as ketoacidosis, pulmonary thromboembolism, and stroke may underlie thyrotoxic crisis, particularly in the obtunded or psychotic patient, and require the same vigorous management ordinarily indicated. In the patient with thyrotoxic crisis in whom none of the latter precipitating factors is apparent, a diligent search for some focus of infection must be carried out. Empirical,

broad-spectrum antibiotic coverage may be warranted while awaiting results of cultures. In most patients who survive thyrotoxic crisis, clinical improvement is dramatic and demonstrable within 12 to 24 h.

Therapy Directed against Systemic Decompensation

Fluid depletion caused by the hyperpyrexia, diaphoresis, vomiting, or diarrhea must be vigorously replaced to avoid vascular collapse. Fluid management must be individualized. Shock may be refractory to cautious fluid resuscitation in younger patients, whereas judicious replacement of fluids is necessary in elderly patients with congestive heart failure or other cardiac compromise. Intravenous fluids containing 10% dextrose in addition to electrolytes will allow repletion of the depleted hepatic glycogen. For fever, acetaminophen, rather than salicylates, is the preferred antipyretic because salicylates inhibit thyroid hormone binding and could increase free hormone, thereby transiently worsening the thyrotoxic crisis.

Vasopressor therapy may become necessary on a temporary basis to provide adequate hemodynamic support if hydration with intravenous fluid replacement is not effective. Stress dose glucocorticoids have been given on empirical grounds on the basis of postulated relative adrenal insufficiency. This approach has the added benefit of further blockade of peripheral conversion of T₄ to T₃, and this is an additional justification for their use.

Table II Differential Diagnosis of Main Forms of Thyrotoxicosis with Low/Suppressed Thyroidal Radioactive Iodine Uptake

| | Subacute thyroiditis | Iodine-induced thyrotoxicosis | Thyrotoxicosis factitia |
|-----------------------------|--------------------------------------|-------------------------------|-------------------------|
| Serum-free thyroid hormones | Increased | Increased | Increased |
| Serum TSH | Suppressed | Suppressed | Suppressed |
| Serum thyroglobulin | Increased | Increased | Low/Undetectable |
| Serum interleukin-6 | Increased | Increased | Low |
| Urinary iodine excretion | Normal | Increased | Normal |
| Thyroid echogenicity | Markedly reduced and not homogeneous | Slightly reduced | Normal |
| Thyroid vascularity | Reduced | Reduced | Reduced |
| Thyroid pain/tenderness | Present | Absent | Absent |

CLINICAL FEATURES

The clinical picture of thyrotoxicosis factitia does not differ from that of classical spontaneous hyperthyroidism. Patients complain of tachycardia, tremors, loss of weight, increased perspiration, heat intolerance, extreme anxiety and nervousness, increased bowel activity, and/or insomnia (Table I). Goiter and ophthalmopathy, as seen in Graves' disease, are absent. Likewise, thyroid pain and tenderness, commonly observed in subacute thyroiditis, are absent (Table I). Cardiovascular complications (e.g., tachyarrhythmias, heart failure, myocardial infarction) as well as bone loss (osteopenia) may occur as a consequence of prolonged excess thyroid hormone ingestion. These complications are more likely to take place in older patients.

Laboratory evaluation reveals the typical increase in free T4 (FT4) and free T3 (FT3) concentrations associated with undetectable serum thyrotropin (TSH) levels. An isolated increase in serum FT3 concentration associated with suppressed serum FT4 levels indicates that the ingested thyroid hormone preparation contained only T3. Circulating autoantibodies to thyroglobulin or thyroperoxidase, as well TSH receptor autoantibodies responsible for Graves' disease, are usually absent. Thyroidal radioactive iodine uptake (RAIU) is characteristically very low or suppressed (Table I). Serum thyroglobulin concentration is typically markedly reduced or undetectable in thyrotoxicosis factitia (Table I). Accordingly, its measurement is a useful tool for differentiating thyrotoxicosis factitia from other thyrotoxic conditions associated with low RAIU values (Table II). Serum interleukin-6, a marker of thyroidal destructive processes, is also undetectable in thyrotoxicosis factitia (Table II). Measurement of thyroid hormones in stools may be useful for identifying the abnormally high fecal excretion of ingested thyroid hormones.

Urinary iodine excretion is normal (Table II). Color flow Doppler sonography of the thyroid shows an absent vascularity and normal–low peak systolic velocity in spite of the thyrotoxic state (Table II).

If the patient denies the surreptitious thyroid hormone intake, it may be necessary to hospitalize him or her to be sure that the deliberate ingestion does not continue. Under strict medical controls, a rapid improvement in the clinical and laboratory features of thyrotoxicosis is usually observed. However, recurrency of thyrotoxicosis is frequently observed after hospital release unless reasons for surreptitious thyroid hormone intake are identified.

TREATMENT

Treatment of thyrotoxicosis factitia obviously requires withdrawal of thyroid hormones. It may be useful to associate a short-term treatment with β -adrenergic blocking drugs to control tachycardia and tremors promptly. However, for a full recovery of the patient, psychiatric aid or counseling is mandatory in all cases.

Table I Classification of Known Causes of Thyrotoxicosis, Epidemiology, and Distinctive Diagnostic Features

| Group | Disease | Relative frequency (percentage) | Distinctive features | Neck RAIU | Serum TSH | Serum thyroglobulin | |
|---------------------------------------|---|--|---|--|-----------------|---------------------|------|
| Thyrotoxicosis of thyroidal origin | Associated with hyperthyroidism | Graves' disease | 70 | Diffuse goiter Ophthalmopathy Positive TRABs | High | Undetectable | High |
| | | Toxic adenoma | 5 | Single "hot" nodule at thyroid scan | High | Undetectable | High |
| | | Toxic multinodular goiter | 20 | Multiple "hot" nodules at thyroid scan | High | Undetectable | High |
| | Associated with thyroid destruction | Iodine-induced thyrotoxicosis | <1 | High urinary iodine | Low to high | Undetectable | High |
| | | TSH-secreting adenomas | <1 | Inappropriately high TSH level | High | Normal to high | High |
| | | Familial gestational hyperthyroidism | Extremely rare | Pregnancy-associated DNA analysis | Presumably high | Undetectable | High |
| | | Trophoblastic tumors | <1 | High chorionic gonadotropin | High | Undetectable | High |
| | | Neonatal thyrotoxicosis | <1 | Positive TRABs | High | Undetectable | High |
| | | Non-autoimmune congenital and familial hyperthyroidism | Extremely rare | TSH receptor gene mutations by DNA analysis | High | Undetectable | High |
| | | Subacute thyroiditis | 3 | Neck pain High erythrocyte sedimentation rate | Low | Undetectable | High |
| Thyrotoxicosis of nonthyroidal origin | Silent thyroiditis | 3 | Positive thyroid autoantibodies | Low | Undetectable | High | |
| | Type II amiodarone-induced thyrotoxicosis | <1 | High urinary iodine High serum interleukin-6 | Low | Undetectable | High | |
| | Factitious thyrotoxicosis | <1 | History Low serum thyroglobulin | Low | Undetectable | Low | |
| | Thyroid hormone intoxication | <1 | History Low serum thyroglobulin | Low | Undetectable | Low | |
| | Dermoid tumors (struma ovarii) | Very rare | Abdominal RAIU | Low | Undetectable | High | |
| | Metastatic differentiated thyroid cancer | Very rare | Bone RAIU | Low | Undetectable | High | |

and overproduction and release of thyroid hormone that lead to hyperthyroidism. In some cases, thyroid nodularities can be felt as a consequence of either long-standing disease or preexisting nodular goiter. Physical examination reveals signs of Graves' ophthalmopathy in 30 to 45% of patients, and when studied with imaging techniques, suggestive findings can be observed in up to 70% of cases. Local myxedema is a peculiar and rare skin manifestation of Graves' disease characterized by edema, inflammation, and lymphocytic infiltration localized mostly to the pretibial dermis. It occurs almost exclusively in patients who also have Graves' ophthalmopathy.

Toxic Adenoma

Toxic adenoma is a quite frequent cause of hyperthyroidism, especially in iodine-deficient countries, where its prevalence has been reported to be as high as 4.5% (10% of all cases of thyrotoxicosis). A lower prevalence (2.7%) has been reported in iodine-sufficient areas.

Toxic adenomas are benign isolated thyroid tumors that function autonomously. The nodular tissue acquires the capability of producing thyroid hormones independently of TSH stimulation. The increased thyroid hormone secretion first suppresses pituitary TSH secretion and eventually leads to overt hyperthyroidism. Because of TSH suppression, the extranodular thyroid tissue becomes functionally quiescent and may undergo some degree of atrophy. Toxic adenomas are more frequent in the aged population and in females. The natural history of toxic adenoma is characterized by slow growth over many years with a progression of its functional properties through various stages. During the early stages, the excess of secretion of thyroid hormones is not sufficient to completely suppress TSH secretion (partial autonomy) and the extranodular tissue. With further growth of the nodule, TSH suppression becomes complete, whereas circulating thyroid hormones are in the upper range of normality (complete autonomy). Eventually, overt thyrotoxicosis ensues with frankly elevated thyroid hormone levels. Recent studies have shown that somatic mutations of the TSH receptor gene are the cause of 20 to 80% of toxic adenomas. In other cases, the Gs- α -subunit of the TSH receptor-coupled adenylcyclase is mutated. Both kinds of mutations cause permanent activation of the TSH receptor intracellular signaling pathway in the absence of the natural ligand (TSH); therefore, they fully explain the autonomous functioning of the nodules.

Toxic Multinodular Goiter

Toxic multinodular goiter is also more frequent in iodine-deficient countries and primarily affects women. Epidemiological studies have clearly shown that toxic multinodular goiter represents the long-term outcome of many long-standing nontoxic goiters; therefore, it is most often found in aged persons. Somatic activating mutations of the TSH receptor have been observed occasionally in toxic multinodular goiter as well. The natural history of toxic multinodular goiter is similar to that of toxic adenoma, with a slow formation of multiple autonomously functioning nodular areas in the setting of an overall nodular goiter. Progression of autonomous function may lead to subclinical hyperthyroidism and overt thyrotoxicosis. The clinical manifestations are scanty due to the advanced age of patients and the slow progression of thyrotoxicosis.

TSH-Secreting Adenoma

Hyperthyroidism caused by excessive TSH secretion by a pituitary adenoma (central hyperthyroidism) is very rare. TSH-secreting adenomas completely or partially lose feedback regulation by thyroid hormone and, therefore, cause sustained stimulation of the thyroid gland, leading to the development of goiter and hyperthyroidism. The severity of thyrotoxicosis is highly variable, ranging from modest elevations to very high levels of thyroid hormones; therefore, the patient may report few or no symptoms or may present with overt thyrotoxic symptoms. TSH-secreting adenomas may cosecrete growth hormone (GH) and prolactin, with clinical presentation of acromegaly and galactorrhea. Most TSH-secreting adenomas are macroadenomas and may lead to hypopituitarism and visual field defects.

Human Chorionic Gonadotropin-Dependent Hyperthyroidism

Human chorionic gonadotropin (hCG) is secreted in large amounts by placental tissue in normal pregnancy and also by trophoblastic tumors such as hydatidiform mola. hCG has a partial homology with TSH and can act as a weak TSH agonist. Therefore, large amounts of hCG in the bloodstream can overstimulate the thyroid gland and cause hyperthyroidism.

Trophoblastic Tumors

In hydatidiform mola, hyperthyroidism is caused by tumor secretion of large quantities of hCG. However, overt thyrotoxicosis is observed in only a minority (10%) of patients with extraordinarily high levels of hCG (>3 million IU/L).

Hyperemesis Gravidarum

Hyperemesis gravidarum is characterized by prominent nausea and vomiting, weight loss ketosis, and electrolyte abnormalities. It is a poorly understood early complication of pregnancy associated with inappropriately high levels of circulating hCG that causes clinical or subclinical hyperthyroidism in about one-third of cases.

Familial Gestational Hyperthyroidism

This inherited pregnancy-associated form of hyperthyroidism has been described in one family. Hyperthyroidism was due to a mutation in the TSH receptor gene, causing increased sensitivity of the receptor to the effect of hCG. For this reason, hyperthyroidism manifests only during pregnancy and recurs every time an affected woman becomes pregnant.

Fetal and Neonatal Thyrotoxicosis

TSABs in the serum of mothers with Graves' disease can cross the placenta and cause fetal and neonatal hyperthyroidism through direct stimulation of the fetal thyroid. The disease can be very severe and is characterized by tachycardia, jaundice, heart failure, and failure to thrive. A goiter is usually present. The thyrotoxicosis is transient and resolves within 3 months after birth because there is no source of TSABs in the neonate.

Nonautoimmune Congenital and Familial Hyperthyroidism

Recently, a new form of congenital hyperthyroidism has been reported. The disease is caused by a germ line *de novo* mutation of the TSH receptor gene, causing constitutive permanent activation of the receptor and, therefore, diffuse goiter and overproduction of the thyroid hormone, in turn causing severe hyperthyroidism in the neonate. The clinical presentation is similar to the presentation of neonatal thyrotoxicosis, and the diagnosis should be suspected when no history of Graves' disease is present in the mother.

Familial nonautoimmune hyperthyroidism has been described in two kindreds. In this case, hyperthyroidism is due to dominant inherited activating mutations of the TSH receptor, but because the effect of the mutation is mild, hyperthyroidism and goiter develop only during adult age. The clinical manifestations are mild and variable in patients bearing the same mutation.

Causes of Destructive (low-RAIU) Thyrotoxicosis

Subacute Thyroiditis

Transient thyrotoxicosis occurs in approximately 50% of patients with subacute thyroiditis (ST). ST is an inflammatory disorder of the thyroid, probably due to a viral agent. The viral origin is suggested by the frequent association with a history of recent upper respiratory tract infection. Clinically, patients with ST present with pain in anterior neck, variable degrees of thyroid swelling, and systemic symptoms such as malaise and fever. From a histopathological point of view, the thyroid gland indicates a leukocytic and granulomatous infiltrate with follicles disruption. Thyrotoxicosis results from the destruction of thyroid follicles by the inflammatory process with release of preformed thyroid hormones. When present, thyrotoxicosis lasts for 3 to 8 weeks and is sometimes followed by a phase, also transient, of mild hypothyroidism. Complete recovery of thyroid function eventually occurs, but permanent hypothyroidism has also been reported.

Painless Thyroiditis

Painless thyroiditis is probably due to an autoimmune thyroid disorder that can generate an inflammation of the gland with chronic lymphocytic infiltration closely resembling that of Hashimoto's thyroiditis. Similar to subacute thyroiditis, the disease is characterized by a transient phase of thyrotoxicosis, but neck pain and general symptoms are usually absent. Circulating thyroid autoantibodies are found in the majority of cases, and the progression to spontaneous permanent hypothyroidism is observed in as many as 20% of cases in long-term follow-up. In some cases, painless thyroiditis is precipitated by radiotherapy in the region of the neck for a variety of neoplasms that induce thyroid damage with discharge of preformed thyroid hormone. Cytokine treatments, particularly with interferon-1 alpha and interleukin-2, have also been shown to cause a clinical syndrome resembling classical painless thyroiditis. These cytokines may also cause classical Graves' disease by acting as generic triggers of thyroid autoimmunity in predisposed individuals. The most likely mechanism in these cases is activation of preexisting thyroid autoreactive T-cell clones.

Findings suggestive of painless thyroiditis are the presence of a goiter, low radioiodine uptake with transient thyrotoxicosis, and occasional progression toward hypothyroidism. These cases may be classified as a variant of Graves' disease with predominant

cytotoxic aspects, quickly leading to a clinical picture of Hashimoto's thyroiditis. Painless thyroiditis may be seldom associated with Graves' ophthalmopathy.

Postpartum Thyroiditis

Postpartum thyroiditis is a subacute thyroid inflammation that occurs during the early postpartum period in susceptible woman. It represents a variant of painless thyroiditis. Postpartum thyroiditis is a rather common disorder, occurring in 5 to 10% of pregnancies. Most women with postpartum thyroiditis have circulating antithyroglobulin and antithyropoxidase antibodies before or during the onset of the disease. Some human leukocyte-associated antigen (HLA) haplotypes, such as B35, confer a clear-cut predisposition to the disorder, making it distinct from classical Hashimoto's thyroiditis. From a clinical point of view, the disease is similar to painless thyroiditis with absence of nonspecific or local symptoms and with transient thyrotoxicosis that occurs in approximately 50% of cases. Approximately one-third of cases present with a second phase of transient hypothyroidism that may develop up to 10 years later. The risk of recurrent postpartum thyroiditis in subsequent pregnancies is as high as 70% in women who have already had an episode.

Other Forms of Destructive Thyrotoxicosis

Rarely, destructive thyrotoxicosis can be precipitated by anterior neck injuries. Thyrotoxic crises following thyroid surgery were frequent at the beginning of thyroid surgery era. It has become extremely rare considering the optimal preparation of patients with antithyroid drugs and the refinement of surgical procedures. Finally, thyrotoxicosis may transiently worsen or recur in patients who are treated with radioiodine for Graves' disease, toxic adenomas, and multinodular toxic goiter. This phenomenon can be explained with two mechanisms: ongoing thyroid hyperfunction before radioiodine fully takes effect and radiation-induced thyroid destruction.

Iodine- and Amiodarone-Induced Thyrotoxicosis

Iodine-induced thyrotoxicosis, secondary to the consumption of large amounts of iodine through the diet or other routes (some medications and diagnostics [e.g., contrast media, disinfectants, drugs] and some foods), has been recently reported with increased frequency. Thyrotoxicosis can precipitate through several mechanisms. When high doses of iodine are

Table II Thyroid Disorders Predisposing to Iodine-Induced Thyrotoxicosis

| |
|---|
| • Autonomous or pretoxic thyroid adenoma |
| • Nontoxic, autonomous, or pretoxic multinodular goiter |
| • Euthyroid or "latent" Graves' disease |
| • Graves' disease in remission after or during antithyroid drug treatment |

administered, the normal thyroid responds with inhibition of organification. This is an autoregulatory defense mechanism known as the Wolff–Chaikoff effect. Eventually, an escape phenomenon ensues and thyroid hormone synthesis resumes. The protection mechanism appears to be defective in autonomous thyroid tissue, and excess iodine or even simple dietary supplementation may precipitate hyperthyroidism in patients with a preexisting thyroid disorder through the "jodbasedow" phenomenon. Most of these disorders (Table II) are characterized by thyroid autonomy; therefore, iodine-induced thyrotoxicosis is by far more prevalent in areas of iodine deficiency and in aged patients.

Among drugs, the antiarrhythmic amiodarone deserves a special mention due to the dual mechanism by which it can cause thyrotoxicosis. One tablet of 200 mg of amiodarone contains approximately 75 mg of organic iodide and will release approximately 8 mg of free iodine, a tremendous amount when compared with the daily recommended dose of 200 μ g. This amount of iodine can precipitate hyperthyroidism in predisposed patients simply through the jodbasedow phenomenon in a manner similar to that of iodine of other sources (type I amiodarone-induced thyrotoxicosis). However, amiodarone has been shown to be directly cytotoxic to thyroid follicular cell *in vitro* and can precipitate a form of thyrotoxicosis similar to that observed in subacute thyroiditis and due to the release of preformed hormones (type II amiodarone-induced thyrotoxicosis). The distinction between the two forms is crucial because the treatments are quite different. A mixed form of amiodarone-induced thyrotoxicosis may occur.

Thyrotoxicosis of Extrathyroidal Origin

Thyrotoxicosis Factitia

Thyrotoxicosis factitia is due to the voluntary surreptitious ingestion of excess thyroid hormone preparations with the purpose of mimicking thyrotoxicosis. It should be distinguished from iatrogenic thyrotoxicosis, which is caused by excessive doses of thyroid

hormones administered by the physician or inadvertently taken by the patient. However, the term has been widely applied to all forms of thyrotoxicosis due to the ingestion of thyroid hormone. True thyrotoxicosis factitia is most often observed in women with psychiatric disturbances. Very often, thyroid hormone is taken to reduce weight or to receive medical attention. Denial of thyroid hormone assumption may be extreme in these patients, and the diagnosis is rarely obtained at history taking. Sometimes, thyroid hormone is inadvertently taken as a component of “herbal” or “alternative” medications, usually for weight-reducing purposes. Finally, accidental grinding of cattle thyroids in hamburger meat has been reported to be the cause of an outbreak of thyrotoxicosis among hamburger consumers in the United States.

Struma Ovarii

Struma ovarii is a rare teratoma of the ovary that may contain functional thyroid follicular tissue, among others. Struma ovarii causes overt thyrotoxicosis only rarely, depending on the amount of follicular tissue present in the neoplasia. Because complete TSH suppression occurs in struma ovarii, the neoplastic thyroid tissue is assumed to be functionally autonomous to cause thyrotoxicosis. A suspicion of the struma ovarii can be confirmed at the time of RAIU by scanning the pelvic area with the probe. The presence of functional thyroid tissue can be demonstrated by the finding of significantly increased uptake of iodine in the ovarian region. Computed tomography (CT) or ultrasound scan will confirm the presence of an ovarian mass.

Functional Metastatic Thyroid Cancer

Differentiated thyroid cancer, even when metastatic and with large tumor burdens, rarely produces physiologically relevant amounts of thyroid hormone. On the other hand, thyroid follicular cancers with extensive bone metastases may cause thyrotoxicosis.

Table I Systemic Effects of Thyrotoxicosis

| System | Effects |
|------------------|--|
| General | Weight loss, fatigue, heat intolerance, insomnia, nervousness, tremulousness |
| Skin | Fine, warm, and moist; hyperpigmentation; hyperhidrosis; onycholysis; fine and friable hair; urticaria |
| Eye | Exophthalmos, lid edema, lid lag, globe lag, chemosis, ophthalmoplegia, optic nerve involvement |
| Cardiovascular | Tachycardia, overactive heart, widened pulse pressure, bounding pulse; occasionally cardiomegaly, signs of congestive heart failure, paroxysmal tachycardia, atrial fibrillation |
| Gastrointestinal | Hyperphagia, increased thirst, increased frequency of stools or diarrhea, elevated liver function tests, hepatomegaly |
| Muscular | Tremulousness, weakness of proximal muscles, quickened and hypermetric reflexes, myopathy, muscle atrophy, periodic paralysis |
| Nervous | Anxiety, inability to concentrate, irritability, restlessness, lability, depression, psychiatric reactions |
| Respiratory | Dyspnea |
| Renal | Mild polyuria, polydipsia |
| Skeletal | Osteopenia or osteoporosis |
| Hematopoietic | Anemia (usually normochromic or normocytic), lymphocytosis, splenomegaly, lymphadenopathy, enlarged thymus |
| Endocrine | Irregular menses or amenorrhea, gynecomastia, decreased fertility |
| Metabolic | Elevated serum calcium, decreased serum magnesium, increased bone alkaline phosphatase, hypercalciuria |

frequent in all forms of thyrotoxicosis and is responsible for the bright-eyed “stare” or “fish eyes” of the patient with thyrotoxicosis (Fig. 3). Lid lag is caused

Modified from Nodyke, R. A., Gilbert, F. I., Jr., and Harada, A. S. M. (1988). Graves' disease: Influence of age on clinical Findings. *Arch. Int. Med.* **148**, 626–631.

^aThe presence of atrial fibrillation was not assessed in controls.

by the fact that the upper lid lags behind the globe when the patient is asked to gaze downward; globe lag occurs when the globe lags behind the upper lid when the patient gazes slowly upward. These ocular manifestations appear to be the result of increased adrenergic activity. It is important to differentiate these ocular manifestations from those of infiltrative ophthalmopathy characteristic of Graves' disease.

Cardiovascular System

The vascular manifestations of thyrotoxicosis constitute some of the most profound and characteristic symptoms and signs of the disorder. Tissue blood flow is increased in response to accelerated metabolism and increased oxygen consumption. Hemodynamic changes in thyrotoxic patients are characterized by an elevated cardiac output and a decreased peripheral vascular resistance. The mechanism responsible for the reduced vascular resistance is unclear. Thyroid hormone itself may be involved directly through its action on smooth muscles of blood vessels. Moreover, the finding in thyrotoxic patients of elevated levels of plasma adrenomedullin and proadrenomedullin-N-terminal 20-peptide, which have a potent vasodilatory activity, raises the possibility that these substances might also be involved in the decrease of vascular resistance in these patients.

Tachycardia is nearly always present, even at rest. The heart rate is also elevated during sleep; this helps to distinguish tachycardia of thyrotoxic origin from that of psychogenic origin. The pulse pressure is widened as a result of both an increase in cardiac

Figure 1 Dermopathy of Graves' disease. Marked thickening of the skin is noted, usually over the pretibial area. Thickening will occasionally extend downward over the ankle and the dorsal aspect of the foot but almost never above the knee.

output and a decrease in peripheral vascular resistance. Other common cardiovascular symptoms include exercise intolerance and dyspnea on exertion. The latter is usually present with sustained activity but may also arise with an activity as limited as climbing a flight of stairs. Because of the diffuse and forceful nature of the apex beat, the heart may appear to be enlarged on physical examination, but echocardiography is usually normal.

In aged thyrotoxic patients, the cardiovascular manifestations may be limited to resting tachycardia. Other classic thyrotoxic symptoms may be absent, possibly due to the relative paucity of adrenergic activity.

Thyrotoxic patients may have chest pain similar to angina pectoris in nearly all respects, probably caused by either relative myocardial ischemia or coronary artery spasm. However, in older patients, the increased

Figure 2 Thyroid acropachy. Photograph of the hands in a patient with acropachy shows clubbing and swelling of fingertips.

myocardial oxygen demand due to thyrotoxicosis may unmask coronary artery disease. The plasma level

Figure 3 Clinical presentation of Graves' ophthalmopathy. Photograph shows proptosis, marked conjunctival injection and chemosis, and retraction of lower eyelids.

of homocysteine, an independent risk factor for cardiovascular disease, in thyrotoxic patients did not differ significantly from that in controls.

Heart sounds are loud and ringing, and a systolic murmur—or even a late diastolic or presystolic murmur—may be present at apex. Auscultation may reveal a systolic ejection murmur and a gallop rhythm caused by rapid flow of blood through the aortic outflow tract. Systolic murmurs may arise from valve prolapse, left ventricular dilatation, or dysfunction of the mitral valve apparatus. Mild edema sometimes occurs in the absence of heart failure. Heart failure rarely occurs in thyrotoxic patients unless an underlying cardiac disease is also present.

Cardiac arrhythmias are common with thyrotoxicosis and are almost invariably supraventricular. Approximately 10% of patients with thyrotoxicosis have atrial fibrillation, and a similar percentage of patients with otherwise unexplained atrial fibrillation are thyrotoxic. This manifestation may be the presenting symptom of thyrotoxicosis, particularly in the elderly, and the risk of developing persistent atrial fibrillation is approximately three times that in normal individuals. Paroxysmal supraventricular tachycardia may be demonstrable or may be suggested by the history. Ventricular premature contractions are rare. Angina pectoris and myocardial infarction may occur rarely in the absence of coronary artery disease.

Nonspecific electrocardiographic changes may occur in thyrotoxicosis. A shortening of the PR interval is common, secondary to the increased rate of conduction through the atrioventricular node.

Thyrotoxicosis alone may determine heart failure in both old patients and (much less often) young patients. In large clinical studies, thyrotoxic patients with heart failure were generally old and, therefore, at risk for underlying heart disease and had chronic thyrotoxicosis. Elderly patients with rhythm disturbances, including atrial fibrillation, are at the greatest risk for heart failure. In the absence of atrial fibrillation, heart failure is rare. In the absence of underlying heart disease or in young patients, the heart failure is thought to be “high output.” High-output heart failure might not be a true heart failure; instead, it might be a circulatory congestion caused by fluid retention. In thyrotoxicosis, cardiac output is potentially near to maximal at rest and cannot increase in response to exercise, stress, surgery, or pregnancy. As a consequence, atrial filling pressures rise, leading to pulmonary and peripheral edema. This situation may be worse if atrial fibrillation is present. Left ventricular function is impaired because the persistent tachyarrhythmia alters this function. Sustained

tachycardia causes abnormal ventricular systolic and diastolic function that resolves when arrhythmia is treated. β -adrenergic receptor blockade-mediated slowing of the heart rate can rapidly reverse even severe degrees of left ventricular dysfunction in thyrotoxic patients.

Gastrointestinal System

The classical gastrointestinal manifestations of thyrotoxicosis are rapid intestinal transit, increased frequency of semiformal stools, and weight loss from increased caloric requirement or malabsorption. These changes are not necessarily frequent. An increase in appetite, both during and between meals, is a common symptom but is usually not seen in patients with mild disease. In severe disease, the increased intake of food is usually inadequate to meet the increased caloric requirements, and weight loss occurs. Anorexia, rather than hyperphagia, sometimes accompanies severe thyrotoxicosis. It occurs in approximately one-third of elderly patients and contributes to the picture of “apathetic” thyrotoxicosis.

Frequent bowel movements are significantly more common in thyrotoxic patients than in normal controls. Diarrhea is rare. When constipation is present before the development of thyrotoxicosis, bowel function may become normal. More often, stools are less well formed and the frequency of bowel movements is increased. Gastric emptying and intestinal motility are increased, and these changes appear to be responsible for slight malabsorption of fat. Gluten enteropathy and Graves' disease may coexist more frequently than can be accounted for by chance due to their common autoimmune origin.

Hepatic dysfunction occurs in thyrotoxicosis, particularly when the disease is severe; hypoproteinemias and increased serum alkaline phosphatase and transaminase levels may be present. In severe cases, hepatomegaly and jaundice may be found.

Nervous System

Hyperactivity, emotional lability, distractibility, and anxiety observed in thyrotoxicosis may reflect changes in the nervous system, but the pathogenetic mechanisms remain obscure. The reaction to all sorts of stimuli is distinctly excessive. Examination reveals a fine rhythmic tremor of the hands, tongue, or slightly closed eyelids. Emotional lability causes patients to lose their tempers easily and to have episodes of crying without any apparent reason. Crying may be evoked by merely questioning patients about the

symptom. In rare cases, mental disturbance may be severe. Rarely, patients develop visual or auditory hallucinations or a frank psychosis. It is probable that thyrotoxicosis makes manifest an abnormality already present rather than inducing a psychosis *de novo*. Anxiety is characterized by restlessness, shortness of attention span, and a compulsion to be moving around despite a feeling of fatigue.

Fine hand tremor is a frequent finding and may sometimes mimic that of Parkinsonism, and a preexisting Parkinsonian tremor can be accentuated. Chorea seldom appears as a manifestation of thyrotoxicosis. The neurological manifestation of thyrotoxic crisis rarely includes coma and status epilepticus. Patients with a convulsive disorder may become more difficult to control with the usual medications, and seizures may appear in patients who never manifested such symptoms previously.

The electroencephalogram of most thyrotoxic patients reveals an increased fast wave activity. The basal metabolic rate tends to correlate with the frequency of brain waves, but the correlation is usually poor at the extremes of thyroid abnormality.

Muscle

Muscle weakness and fatigue are frequent. In most instances, they are not accompanied by objective evidence of local disease of muscle except for the generalized wasting associated with weight loss. Weakness is often most prominent in the proximal muscles of the limbs, causing difficulties in climbing stairs or in maintaining the leg in an extended position. In severe untreated cases, muscle wasting occasionally occurs as a predominant symptom (thyrotoxic myopathy). In extreme forms, the patient may be unable to rise from a sitting or lying position and may be virtually unable to walk.

Muscle manifestations affect men with thyrotoxicosis more commonly than they do women and may overshadow other manifestations of the syndrome. In severe forms, the myopathy involves mainly distal muscles of extremities and the muscles of the trunk and face. The involvement of ocular muscles may mimic myasthenia gravis. Graves' disease occurs in approximately 3 to 5% of patients with myasthenia gravis, and approximately 1% of patients with Graves' disease develop myasthenia gravis. Myasthenia gravis associated with Graves' disease has a mild expression characterized by preferential involvement of the eye muscles. Another myopathy sometimes observed in association with thyrotoxicosis is hypokalemic periodic paralysis. It is characterized by sporadic attacks

(which may last from minutes to many hours), most commonly involving flaccidity and paralysis of legs, arms, and/or trunk, although any muscle can be involved. Episodes can occur spontaneously, after carbohydrate ingestion, or after exercise. Hypokalemic periodic paralysis is most frequent in Asians.

Respiratory System

Dyspnea is present in the large majority of severe thyrotoxic patients, and several factors may contribute to this condition, including reduction of vital capacity, decreased pulmonary compliance, weakness of the respiratory muscles, and increase in respiratory dead space ventilation. In some cases, it is difficult to separate patients with pure respiratory muscle weakness from patients who have only decreased lung compliance. Manifestations of respiratory muscle dysfunction include rapid shallow respirations, respiratory dyskinesia, hypoventilation, respiratory acidosis, and easy fatigability. Most patients with overt thyrotoxicosis have diminished proximal muscle strength. Pulmonary function returns to normal when the eumetabolic state is restored.

Renal System

Most of the renal effects in thyrotoxic patients produce no symptoms except mild polyuria. Renal plasma flow and glomerular filtration rate are increased in thyrotoxicosis, probably because of the increase in cardiac output and decrease in peripheral resistance. Intrarenal vasodilation also occurs. The mean 24-h urine creatinine excretion is significantly lower in thyrotoxic patients than in normal individuals. The latter finding has been attributed to loss of muscle mass and occurs despite an increase in urea clearance. These changes are normalized when a normal metabolic state is restored.

Thyrotoxicosis is generally not associated with abnormalities in water metabolism. Serum electrolytes are usually normal. Some thyrotoxic patients have polydipsia, with 24-h urine volumes up to 3 to 4 L. Polyuria in these patients is due to increased thirst, as in primary polydipsia, and could be secondary to an increase of plasma angiotensin II concentration.

Skeletal System: Calcium and Phosphorus Metabolism

Thyrotoxicosis is associated with an increase of bone turnover and eventually bone loss, especially in

postmenopausal women. Patients with a long-standing history of thyrotoxicosis may have overt osteoporosis and an increased risk of fractures. Bone turnover is increased, but the increase in bone resorption is relatively greater than that of bone formation, so the urinary excretion of calcium, phosphorus, and hydroxyproline is increased. As a consequence of this acceleration in bone resorption, hypercalcemia may occur in a significant proportion of patients with thyrotoxicosis. Total serum calcium may be slightly increased in up to 27% of these patients, and the ionized serum calcium level may be increased in up to 47%. The concentration of alkaline phosphatase and osteocalcin is also frequently increased. Parathyroid hormone and 1,25-dihydroxy-vitamin D3 levels tend to be low as a result of the increased calcium released from bone. Excretion of calcium in the feces is also increased in thyrotoxic patients. The secretions of the gastrointestinal tract are altered in thyrotoxicosis, and the transit time of calcium in the intestine is shortened.

Hematopoietic System

The red blood cells are usually normal, but the red blood cell mass is increased. The increase in erythropoiesis appears to be due both to a direct effect of thyroid hormones on the erythroid marrow and to an increased production of erythropoietin. A parallel increase in plasma volume also occurs; therefore, hematocrit value is normal.

The most common red blood cell morphological abnormality is microcytosis, which is found in at least 37% of patients. The cause of this change is unclear. Iron deficiency is occasionally reported in thyrotoxic states. Microcytosis usually resolves with the restoration of euthyroidism. Some patients with severe thyrotoxicosis may develop a normocytic anemia. Defective iron use has been shown to occur in thyrotoxic patients and may be responsible for the development of anemia. Approximately 3% of patients with Graves' disease have pernicious anemia, and a further 3% have antibodies to intrinsic factor but normal absorption of vitamin B12. Autoantibodies against gastric parietal cells are present in about one-third of patients with Graves' disease, and the requirements for vitamin B12 and folic acid appear to be increased.

The total white blood cell count is often low because of a decrease in the number of neutrophils. The absolute lymphocyte count is normal or increased,

leading to a relative lymphocytosis. The numbers of monocytes and eosinophils may also be increased.

Blood platelets and the intrinsic clotting mechanism are normal. However, the concentration of factor VIII is often increased and returns to normal when thyrotoxicosis is treated. Furthermore, there is an enhanced sensitivity to coumarin anticoagulants because of an accelerated clearance of vitamin K-dependent clotting factors.

Endocrine System

Thyrotoxicosis affects the secretion of most pituitary hormones, in particular the secretion of growth hormone (GH), prolactin (PRL), adrenocorticotropin (ACTH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH).

Children with thyrotoxicosis grow more rapidly than do normal children. Growth acceleration in thyrotoxicosis suggests that GH secretion might be greater than normal. However, serum GH concentrations are lower in thyrotoxic patients than in normal individuals. This decrease is probably due to the increased metabolic clearance rate. Serum insulin-like growth factor-1 (IGF-1) concentration is higher in thyrotoxic patients and returns to normal values after restoration of the euthyroid state.

Thyrotoxicosis has several effects on adrenocortical function and adrenocortical hormone metabolism, with an increased clearance of the latter. The half-life of cortisol is shortened, but both the number of bursts of ACTH and the resulting burst of cortisol secretion are increased and maintain serum cortisol levels. The plasma concentration of corticosteroid-binding globulin is normal. The urinary excretion of the free cortisol and 17-hydroxycorticosteroids is normal or slightly increased, whereas the urinary excretion of 17-ketosteroids may be reduced. The rate of turnover of aldosterone is increased, but its plasma concentration is normal. Plasma renin activity is increased, and the sensitivity to angiotensin II is reduced.

β -adrenergic receptor blockade ameliorates most of the cardiovascular manifestations of thyrotoxicosis. This suggests that catecholamines play a role in their genesis, but the secretion rate and plasma levels of epinephrine and norepinephrine are normal in thyrotoxic patients. Indeed, the apparent sympathetic hyperactivity appears to be the consequence of a direct effect of thyroid hormones on peripheral tissues.

Thyrotoxicosis during early life may cause delayed sexual maturation, although physical development is normal and skeletal growth may be accelerated.

Reproductive System

Thyrotoxicosis, after puberty, influences the reproductive function, especially in women. An increase in libido occurs in both genders. The intermenstrual interval may be prolonged or shortened, and menstrual flow initially diminishes and ultimately ceases. Fertility may be reduced. In some women, menstrual cycles are predominantly anovulatory with oligomenorrhea; however, in most women, ovulation occurs. With treatment, menstrual cycles return to their regular pattern. Thyrotoxicosis in prepubertal girls may result in slightly delayed menarche. In premenopausal women with thyrotoxicosis, basal plasma concentrations of LH and FSH are normal but may display an enhanced responsiveness to LH-releasing hormone.

An increase in sex hormone-binding globulin (SHBG) is a prominent feature of thyrotoxicosis and is responsible for many of the alterations in steroid metabolism. Because of the increase in SHBG, the metabolic clearance rates of testosterone and (to some extent) estradiol are decreased. Testosterone levels are elevated because of the increased concentration of SHBG. Free testosterone levels tend to be normal. The metabolic clearance rate of estradiol is normal, suggesting that tissue metabolism of the hormone is increased. Conversion rates of androstenedione to testosterone, estrone, and estradiol, as well as conversion rates of testosterone to dihydrotestosterone, are increased. Extragonadal conversion of androgens to estrogens is increased, and this could be the mechanism responsible for gynecomastia observed in a consistent minority of thyrotoxic men.

Energy Metabolism: Protein, Carbohydrate, and Lipid Metabolism

One of the most prominent symptoms in the hyperthyroid patient is heat intolerance. The symptom reflects an increase in the basal metabolism of many substrates. The increase in metabolic activity results in increased consumption of adenosine triphosphate (ATP) and oxygen. Despite the increased food intake, a state of chronic caloric inadequacy often ensues, depending on the degree of increased metabolism, and becomes more pronounced with age. In addition to losing fat stores, there is often a loss of muscle mass, making weakness a common complaint. Both synthesis and degradation of proteins are increased, with the latter increased to a greater extent than the

former, so that there is a net decrease in tissue protein content.

The oral glucose tolerance test is often abnormal. The most common abnormality is a faster rise in plasma glucose after glucose ingestion, but some patients have a delayed peak plasma glucose or a peak value that is higher than that in normal individuals. These abnormalities may reflect changes in glucose absorption rather than metabolism given that many patients who have abnormal oral glucose tolerance have normal responses to intravenous glucose administration. Preexisting diabetes mellitus is aggravated by thyrotoxicosis, with one cause being increased degradation of insulin.

Both synthesis and clearance of cholesterol and triglycerides are increased, but the latter effect predominates, so that serum levels are generally low. Plasma phospholipid and low-density lipoprotein cholesterol concentrations fall, whereas high-density lipoprotein cholesterol levels increase. Finally, thyroid hormones may influence cholesterol metabolism by increasing its conversion to bile acid and its clearance through the membrane surface low-density lipoprotein receptors. Although fatty acid synthesis is increased in both adipose tissue and liver, degradation of most lipids appears to be stimulated out of proportion to synthesis; consequently, body lipid deposits become depleted and plasma concentrations of various lipid components fall.

Several studies have investigated the relationship between leptin level and thyroid status. With the exception of a couple of reports suggesting a relative hypoleptinemia, most clinical studies have found no effect of thyrotoxicosis on leptin levels.

Modified from Cooper, D. S. (1996). Treatment of thyrotoxicosis. In "Werner and Ingbar's The Thyroid" (L. E. Braverman and R. D. Utiger, eds.), 7th ed., pp. 713–734. Lippincott-Raven, Philadelphia.

problem, may be observed with both MMI and PTU, but a low dose of MMI is safer than a high dose of either drug. Agranulocytosis may develop suddenly and usually occurs during the first months of therapy. It typically presents with fever and evidence of infection. In addition to prompt discontinuation of the antithyroid drug, treatment of agranulocytosis involves the administration of broad-spectrum antibiotics and growth factors to stimulate recovery of bone marrow. Patients usually recover within 2 to 3 weeks, but a few deaths from this complication have been reported. Hepatitis, vasculitis, and lupus-like syndromes are rare complications but make the discontinuation of antithyroid drugs mandatory. Minor side

effects are much more frequent, occurring in 1 to 5% of patients. Among them, pruritus, rash, and (less commonly) urticaria are the most prominent manifestations. These side effects may resolve spontaneously despite continued therapy, but they generally call for substitution of one thionamide for the other, although cross-sensitivity to these drugs may occur.

β-Adrenergic Antagonist Drugs

These drugs are an integral part of the management of hyperthyroidism. Blockade of β-adrenergic receptors rapidly ameliorates some manifestations of thyrotoxicosis such as tremor, palpitation, and anxiety. β-adrenergic antagonists do not affect thyroid hormone synthesis and release; therefore, they should not be used alone except for short periods before and/or after radioiodine therapy in selected patients preparing for thyroid surgery or in patients with self-limited forms of thyrotoxicosis. Since the introduction of propranolol, a number of new agents with a longer duration (e.g., atenolol, metoprolol, nadolol), or with greater cardioselectivity (e.g., atenolol, metoprolol, bisoprolol), have become available. The usual contraindications of β-adrenergic antagonists, such as asthma, should be considered. Despite the initial concern, propranolol or other β-adrenergic antagonists are widely used in thyrotoxic heart disease in view of the notion that tachycardia and tachyarrhythmias are the most prominent factors involved in this condition.

Iodide and Iodine-Containing Agents

Inorganic iodide given in pharmacological doses (as Lugol's solution or as saturated solution of potassium iodide [SSKI]) decreases its own transport into the thyroid, inhibits iodide organification (the Wolff-Chaikoff effect), and rapidly blocks the release of T4 and T3 from the gland. However, after a few days or weeks, its antithyroid action is lost and thyrotoxicosis recurs or may worsen. The usual dose of Lugol's solution is three to five drops three times daily and that of SSKI is one drop three times daily. Short-term iodide therapy is used to prepare patients for surgery, usually in combination with a thionamide drug. Iodide is also used in the management of severe thyrotoxicosis (thyroid storm) because of its ability to inhibit thyroid hormone release acutely.

Iopanoic acid and sodium ipodate, widely used in the past as oral cholecystographic agents, may be useful in the management of thyrotoxicosis. These compounds have a dual action: they produce a fall

in the serum concentration of thyroid hormones (resulting from the block of thyroid hormone secretion due to the inorganic iodide released from the drug) and inhibit the peripheral conversion of T4 to T3. Some reports have confirmed the efficacy of these compounds as a primary therapy of hyperthyroidism. These agents may be particularly useful when a rapid decrease in T3 levels is desired. Although an early escape from the therapeutic effect has been suggested, other studies have not found this to be the case for up to nearly 2 years of therapy.

Perchlorate

Perchlorate interferes with accumulation of iodide by the thyroid. In conjunction with thionamides, it has been used successfully in the treatment of amiodarone-induced hyperthyroidism. Gastric irritation and toxic reactions (aplastic anemia) limit the long-term use of perchlorate in the management of hyperthyroidism.

Glucocorticoids

Glucocorticoids in high doses inhibit the peripheral conversion of T4 to T3. In Graves' hyperthyroidism, glucocorticoids appear to decrease T4 secretion by the thyroid, but the efficiency and duration of this effect are unknown. In severe hyperthyroidism, short-term glucocorticoid administration may be used as a general supportive treatment. The immunosuppressive effect of glucocorticoids in high doses is commonly exploited in the treatment of ophthalmopathy and dermopathy of Graves' disease but not in the management of uncomplicated Graves' hyperthyroidism.

RADIOIODINE

Among different radioactive isotopes of iodine, ^{131}I is the agent of choice in the treatment of thyroid hyperfunction. After oral administration, radioiodine is completely absorbed, rapidly concentrated, oxidized, and organified by thyroid follicular cells. The destruction of thyroid cells produced by radioiodine results from the ionizing effects of β -particles that have a path length of 1 to 2 mm. Specifically, $1\ \mu\text{Ci}$ of ^{131}I retained per gram of thyroid tissue delivers approximately 70 to 90 rads. Biological effects of radioiodine include necrosis of follicular cells, shorter survival and impaired replication of nondestroyed cells, and vascular occlusion. In the long run, there is atrophy and fibrosis, as well as a chronic inflammatory response, that ultimately may result in thyroid failure.

The goal of radioiodine therapy of hyperthyroidism is to destroy sufficient thyroid tissue to cure hyperthyroidism with one dose of ^{131}I . The administered dose is calculated on the basis of thyroid size and uptake of ^{131}I using the following formula:

$$\begin{aligned} \text{Dose (mCi)} &= \text{Estimated Thyroid Weight(g)} \\ &\times \text{Planned Dose } (\mu\text{Ci/g}) / \\ &\text{Fraction 24-h Radioiodine Uptake} \\ &\times 1000. \end{aligned}$$

In other centers, standard fixed doses are given. Because of radiation safety restrictions, in some centers, especially in Germany, repeated 2- to 3-mCi doses of radioiodine are administered. It is a common experience that small glands appear to be destroyed more readily by radioiodine than do larger ones and that toxic adenomas or toxic multinodular goiters are usually more radioresistant than Graves' glands.

The therapeutic effect of radioiodine is delayed, and in some patients up to several months may be required for the complete control of hyperthyroidism. Thus, a course of antithyroid drugs before the administration of radioiodine is frequently used, particularly in cases of severe thyrotoxicosis, to avoid the inconveniences of persistent hyperthyroidism. In selected patients with significant comorbidity, antithyroid drugs may also be administered following radioiodine, but doing so may decrease the efficacy of treatment.

Radioiodine therapy may lead to worsening of Graves' ophthalmopathy when present. This worsening can be prevented by concomitant glucocorticoid therapy, beginning after radioiodide administration.

In the past, the major concerns with radioiodine therapy derived from the possible carcinogenic effects of ionizing radiation and from the risks of congenital malformations in offspring of women treated during their childbearing years. No association was found between radioiodine administration and thyroid cancer in large epidemiological studies. Similarly, there is no evidence that radioiodine therapy for hyperthyroidism increases the risk of leukemia or solid tumors. No association between radioiodine treatment for hyperthyroidism and congenital abnormalities in subsequent offspring has been observed.

THYROIDECTOMY

Subtotal or near-total thyroidectomy is performed in Graves' disease and toxic multinodular goiter, whereas lobectomy is the procedure of choice in toxic adenoma. Restoration of euthyroidism before surgery is mandatory. The classical approach combines a course of

thionamide treatment to restore and maintain euthyroidism and the preoperative administration of iodide for approximately 10 days to decrease blood flow of the gland. Care must be taken not to discontinue or decrease the dose of antithyroid drugs when iodide is added. We do not favor a preoperative program based only on the use of a β -adrenergic antagonist associated with iodide. Euthyroidism is not restored in these patients because iodide alone normalizes the concentration of thyroid hormones in serum only a few days before the operation but does not produce "tissue" euthyroidism. Furthermore, the risk of thyroid storm is not completely prevented even when high-dose propranolol is administered for several days after surgery.

Possible complications of thyroid surgery include thyroid storm (which is extremely rare nowadays), bleeding, injury to the recurrent laryngeal nerve, and hypoparathyroidism. In particular, the risk of laryngeal nerve injury and hypoparathyroidism cannot be disregarded. Although an incidence of these complications of less than 2% is reported from clinics with wide experience in thyroid surgery, much higher figures of up to 10 to 15% are encountered in some series. These complications are, of course, less frequent when lobectomy for toxic adenoma is performed.

CHOICE OF THERAPY

The choice of treatment for Graves' hyperthyroidism involves both physician's prejudice and patient's preference. Our policy is to give radioiodine as a first-choice treatment for Graves' hyperthyroidism once euthyroidism has been restored and maintained by a short course (3–6 months) of antithyroid drugs. We do advise this type of treatment for all middle-aged and elderly people, and we offer this option to young adults as well. Our preference for this treatment strategy derives from two considerations. First, the recurrence rate of hyperthyroidism after antithyroid drugs is high. Second, radioiodine therapy for hyperthyroidism is effective, inexpensive, and safe.

If we take into account the possible side effects of long-term thionamide administration, the risks of recurrent thyrotoxicosis, and/or the complications of thyroid surgery, radioiodine appears to be a relatively safe form of treatment for Graves' hyperthyroidism. Acute complications of radioiodine are extremely rare if patients are rendered euthyroid with antithyroid drugs for a period of time sufficient to deplete intrathyroidal stores of hormones.

In patients with Graves' hyperthyroidism and ophthalmopathy, we favor the rapid restoration of

euthyroidism by antithyroid drugs, followed by radical treatment of hyperthyroidism by thyroidectomy or radioiodine, as indicated. In patients with mild or moderate ophthalmopathy, we favor protection from possible exacerbations of ophthalmopathy after radioiodine or surgery with a short-term course of glucocorticoids. In patients with severe ophthalmopathy, we favor radical treatment of hyperthyroidism associated with specific therapy for eye disease consisting of orbital irradiation and high-dose systemic glucocorticoids.

Thionamides are the first-choice treatment in pregnant women with hyperthyroidism. Radioiodine therapy is contraindicated during pregnancy, and surgery is restricted to exceptional cases. Both PTU and MMI cross the placenta and, in excessive doses, may cause hypothyroidism and goiter in the fetus and the neonate. Because PTU is less lipid soluble and more highly protein bound, its placental transfer appears to be lower, so that the preferential use of this drug in pregnancy has been advocated by some, mainly in the United States. However, one study showed no difference between PTU and MMI in suppressing fetal thyroid function. The drug chosen should be given at the lowest possible dose (but not higher than 10 mg MMI or 100 mg PTU daily as maintenance dose) to maintain maternal-free T₄ and free T₃ in the high-normal range.

Graves' disease is the main cause of hyperthyroidism in children and adolescents. In this age group, the peak incidence of the disease is between 11 and 15 years of age, but it may occur in children under 5 years of age. Antithyroid drugs, radioiodine, and surgery have been successfully used in children, but we favor thionamides as the first-choice treatment.

Hyperthyroidism due to toxic adenoma responds well to radioiodine, and the nodule is partially reduced by this form of therapy. In severe hyperthyroidism, pretreatment with thionamides is indicated, but radioiodine should be given before restoration of extra-nodular thyroid function by thyrotropin-stimulating hormone (TSH).

Surgery is a more appropriate choice in large (>5 cm) nodules with associated pressure symptoms (Table III). Young age also favors surgery with respect to radioiodine. Lobectomy is indicated in classic toxic adenoma in otherwise normal thyroid glands. When single hyperfunctioning thyroid nodules occur in a multinodular goiter, subtotal or near-total thyroidectomy is indicated.

Toxic multinodular goiter is more frequent in patients over 50 years of age who may have other non-thyroidal illnesses adding a risk to surgery (Table III).

Table III Factors Favoring Specific Forms of Treatment of Toxic Adenoma and Uninodular and Toxic Multinodular Goiter

| |
|---|
| Surgery |
| Young-adult age |
| Large goiter or adenomas greater than 5 cm |
| Low radioiodine uptake and large areas of poorly functioning tissue within the goiter |
| Airway obstruction or compression of other structures |
| Refusal to take radioiodine |
| Radioiodine |
| Small adenomas (< 5 cm) |
| Old age |
| Contraindications to surgery |

Therefore, many patients with toxic multinodular goiters receive radioiodine. Hyperthyroidism is cured in virtually all cases, although more than one dose of ^{131}I may be required. However, the reduction in thyroid size is only partial because of the presence of intrathyroidal calcifications, fibrosis, and large areas of nonfunctioning tissue. Nevertheless, in patients with large mediastinal goiters but contraindications to surgery, radioiodine may be used with benefit and partial relief of pressure symptoms.

Surgery is generally regarded as a better option in patients with large goiters, especially if there is evidence of substernal extension and compression of airways and blood vessels. Surgery is also indicated in those instances when radioiodine uptake by the gland is relatively low, as frequently occurs in large multinodular goiters.

satisfactory. In most iodine-sufficient countries, a single FT4 measurement is sufficient to confirm or reject the suspicion of thyrotoxicosis. In contrast, in iodine-deficient countries, a significant proportion of hyperthyroid patients (up to 12%) may have normal FT4 levels with elevated FT3 levels (T3 toxicosis). Conversely, FT4 can be falsely elevated in conditions causing reduced peripheral conversion of T4 to T3 such as amiodarone or high-dose propranolol treatment. We prefer to assess both FT4 and FT3 levels together with TSH to obtain a complete baseline panel of the thyroid function status in every patient where the diagnosis of thyrotoxicosis is suspected.

A condition characterized by low or undetectable TSH level and normal free thyroid hormone levels, detected occasionally at routine thyroid function testing or in patients complaining of mild thyrotoxic symptoms, is termed "subclinical thyrotoxicosis."

DIFFERENTIAL DIAGNOSIS OF THYROTOXICOSIS: LABORATORY AND INSTRUMENTAL INVESTIGATIONS

History and physical examination are usually sufficient to identify the cause of thyrotoxicosis. However, in some cases, a careful differential diagnosis is needed to establish an etiological diagnosis. This is necessary to plan the correct treatment. For many years, radioiodine uptake (RAIU) has represented a mainstay of the differential diagnosis of thyrotoxicosis. RAIU is easily performed by administering a minimal (tracer) dose of radioactive iodine and then measuring the percentage of administered radioactivity accumulated in the thyroid. The upper normal limit of RAIU in iodine-sufficient countries, 24h

after the administration of the tracer, is approximately 25%, whereas it may reach 40% in areas with mild to moderate iodine deficiency. RAIU represents an indirect method of estimating the thyroidal intracellular mechanisms for iodine trapping and organification. Whenever excessive active formation of thyroid hormone takes place in the thyroid gland, RAIU is increased. Therefore, a high RAIU readily identifies true hyperthyroidism (e.g., with thyroid hyperfunction). In contrast, thyrotoxicosis with a low RAIU indicates either thyroidal destruction, with release of preformed hormone, or an extrathyroidal source of thyroid hormone. In thyroid destruction, the damaged follicular cell loses its capability of iodine trapping. Conversely, when exogenous hormones are administered in excess, the suppression of the pituitary secretion of TSH causes a block of the trapping capacity of follicular cells. The only exception to this rule is iodine-induced thyrotoxicosis, in which a low RAIU can be observed because of dilution of the tracer dose in the large body pool of iodine in spite of true hyperthyroidism.

Nowadays, RAIU is not universally performed in the initial assessment of a thyrotoxic patient, and a vast array of laboratory and imaging techniques are available to accurately identify the cause of thyrotoxicosis. However, RAIU may still be used as a starting point to broadly define forms of thyrotoxicosis according to their pathogenesis before proceeding with the use of adjunctive diagnostic tools.

Graves' Disease

Anti-TSH Receptor Antibodies

A mainstay in the diagnosis of Graves' disease resides in serum detection of TSH receptor antibodies (TRABs). TRABs can be measured by different methods. TRABs were originally detected with *in vivo* bioassays, but this method has been replaced by *in vitro* systems. The most commonly used assay is based on the displacement of radiolabeled TSH from its receptor by the patients' sera. Antibodies detected with this method have been termed "TSH binding-inhibiting immunoglobulins" (TBIs). This test does not provide any information on the biological activity of the detected antibodies and, therefore, cannot distinguish between antibodies with stimulating activity (TSABs) and those with blocking activity (TSHBAs) that can also be detected in thyroid autoimmune disorders. The stimulating activity of TRABs can be tested by employing cellular systems carrying a functional TSH receptor (e.g., Chinese hamster ovary cells transfected with cloned human TSH receptor) and detecting the

release of cyclic AMP (cAMP) in the culture medium on challenge with serum or purified immunoglobulins (TSAB assay). In a modification of the assay, TSHBABs can be detected as well. TSABs are the cause of hyperthyroidism in Graves' disease. Unfortunately, the assay is quite expensive and requires cell culture capabilities, making it available only to research centers. For clinical purposes, the TBII assay is used most often. By past-generation assays, positive TBII tests are found in 75 to 95% of patients, with a high specificity (99%). Therefore, the TBII test represents an excellent tool in the diagnosis of Graves' disease. In spite of its efficiency, a TBII test is needed only in the minority of cases where the clinical picture is unclear, for example, in the differential diagnosis of hyperemesis gravidarum, in the nodular variants of Graves' disease that must be differentiated from toxic nodular goiter, and in patients with exophthalmos without thyrotoxicosis (euthyroid Graves' disease). Therefore, the TBII test should be considered a second-line test in the diagnosis of Graves' disease. The finding of TBII after long-term treatment with antithyroid drugs may be useful to identify patients prone to recurrence of hyperthyroidism.

Antithyroid Peroxidase and Antithyroglobulin Antibodies

Antithyroid peroxidase (AbTPO) antibodies can be found by commercial radioimmunoassays in up to 90% of patients with untreated Graves' disease, whereas antithyroglobulin (AbTG) antibodies are less frequently positive (in about 50–80% of cases). However, both antibodies are also present in other forms of thyroid autoimmune disorders, some of which may cause thyrotoxicosis, such as postpartum thyroiditis and silent thyroiditis. A relatively high percentage (up to 25%) of positive tests is also found in normal individuals, especially women. Thus, anti-TPO and anti-TG tests do not establish the diagnosis of Graves' disease as the cause of thyrotoxicosis but may be useful as complementary tests in confirming the presence of thyroid autoimmunity.

Thyroid RAIU and Scan

A high value of RAIU at the 24th hour is always found as a distinctive feature in untreated hyperthyroid Graves' disease patients. In some cases, the 3rd- or 6th-hour value can be even higher than the 24th-hour value, as an expression of an extremely high iodine turnover. The test is very useful for ruling out transient thyrotoxicosis due to hashitoxicosis or painless or subacute thyroiditis, factitious thyrotoxicosis, and type II amiodarone-induced thyrotoxicosis.

Figure 1 Thyroid scanning (performed with radioiodine) in Graves' disease.

Thyroid scanning in Graves' disease is useful when coexisting nodules are detected by palpation and their functional status needs to be evaluated. Thyroid imaging can be performed with radioiodine at the time of RAIU or by using ^{99m}Tc perchnetate (Fig. 1).

Thyroid Ultrasound

The thyroid gland in Graves' disease hyperthyroidism has a typical ultrasound pattern. Because of both the reduction in the colloid content and the lymphocytic infiltrate, the gland becomes diffusely hypoechoic. A similar pattern is also observed in goitrous autoimmune thyroiditis. Therefore, thyroid ultrasound can be useful for confirming the suspicion of thyroid autoimmunity during the evaluation of thyrotoxicosis. Moreover, thyroid ultrasound scanning allows an accurate measurement of the goiter size. This information is important in choosing the most appropriate treatment. Finally, thyroid ultrasound accurately distinguishes true thyroid nodules from the lobulations that can be felt occasionally at palpation in Graves' disease glands. Therefore, the information provided by thyroid ultrasound is quite useful in the initial evaluation of Graves' disease patients, although it is not strictly needed from a diagnostic standpoint.

The measurement of blood flow to the thyroid gland by color flow Doppler ultrasound has also been used experimentally in Graves' disease patients. In untreated Graves' disease, the color Doppler pattern is characterized by markedly increased signals with a patchy distribution. In the setting of a hypoechoic pattern at ultrasound, the detection of an

increased blood flow allows the distinction from Hashimoto's thyroiditis. Therefore, color Doppler studies of the thyroid gland can be useful, as is RAIU, in distinguishing Graves' disease from other forms of thyrotoxicosis such as amiodarone-induced destructive thyrotoxicosis, subacute thyroiditis, and painless thyroiditis (in which the blood flow is reduced or absent).

Toxic Adenoma

The presence of a toxic adenoma must always be suspected in a thyrotoxic patient with a single thyroid nodule revealed at neck palpation. In confirming the diagnosis of thyrotoxicosis, it is important to measure both FT4 and FT3 levels because T3 toxicosis is distinctly frequent in toxic adenomas.

At 99m technetium or radioiodine thyroid scanning, the nodule will appear "warm" when only partial autonomy is present, with the extranodular thyroid tissue clearly visible. In this case, parallel thyroid function tests will show a low but detectable TSH and thyroid hormone levels that are normal or at the upper limit of the normal range. When TSH is completely suppressed (e.g., complete autonomy, overt thyrotoxicosis), the scan will show only the autonomous nodule with complete suppression of the extranodular tissue. Ultrasound scanning of the neck provides no direct diagnostic information on the functional property of the nodule, but it is useful in detecting coexisting nodules (which can eventually be cold at scan) and accurately defines the size of the nodule. Preliminary reports have shown a distinctive color Doppler pattern in autonomously functioning thyroid nodules, characterized by an increased blood flow in the nodular tissue, in good correlation with radionuclide scans. This technique is not able to distinguish benign nodules from malignant ones; therefore, it is of limited value. Fine needle aspiration biopsy is not useful in the evaluation of a thyroid hot nodule and provides inconclusive findings that often show undetermined follicular neoplasm. The risk of malignancy in hot nodules is extremely low, although they are occasionally reported. Therefore, in the presence of a low TSH, fine needle aspiration is needed only when coexisting nodules detected by palpation or ultrasound are cold at radionuclide scanning.

In the past, T3 in suppressive doses was administered for 5 to 7 days to patients with warm nodules to completely suppress TSH secretion, and a scan was performed thereafter (Werner's test). The purpose of the test was to show autonomous radionuclide uptake in the nodular tissue only, confirming the suspicion of

nodular functional autonomy. This test has become obsolete with the availability of ultrasensitive TSH assays.

Further imaging, such as neck X rays, barium swallow, and computed tomography (CT) scans, may be needed in selected patients with large nodules to evaluate the presence of significant tracheal and/or esophageal compression. It is important to remember that CT scan, when done with this purpose, should always be performed without the administration of iodinated contrast media because these may worsen thyrotoxicosis or precipitate it in partially autonomous nodules.

Toxic Multinodular Goiter

The same alterations of thyroid function tests described in toxic adenomas can be observed in toxic multinodular goiter. Physical findings and history are often sufficient to suspect the presence of a toxic multinodular goiter. Thyroid radionuclide scanning is quite useful for identifying and mapping autonomous nodules and cold nodules that are often coexistent (Fig. 2). Scanning is also useful as an adjunct to TRAB measurement in distinguishing true toxic multinodular goiter from Graves' disease hyperthyroidism superimposed on a preexisting nontoxic multinodular goiter. RAIU is always elevated, unless iodine overload is present, but is not always necessary to establish the diagnosis.

Figure 2 Thyroid scanning (performed with 99m perchnetate) in toxic multinodular goiter.

Thyroid ultrasound scan is also useful in measuring the size of the goiter. Moreover, relative to radio-nuclide scanning images, it is helpful in identifying cold nodules. Fine needle biopsy should be performed in any palpable dominant nodule that is cold at scan.

TSH-Secreting Adenomas

Patients with TSH-secreting adenomas present a detectable TSH in the presence of clearly elevated circulating thyroid hormone levels (inappropriate secretion of TSH).

The first step in the evaluation of inappropriate secretion of TSH is making sure that interferences in the measurement of TSH (by heterophilic antibodies) or thyroid hormone levels (by thyroid hormone antibodies) are not the cause of the laboratory findings. Once these interferences are ruled out, further investigations are required to differentiate patients with TSH-secreting pituitary adenomas from those with resistance to thyroid hormone.

TSH-secreting adenomas abnormally secrete the α -subunit of TSH in molar excess with respect to TSH. A serum α -subunit/TSH ratio greater than 1 is observed in approximately 90% of patients with TSH-secreting adenomas. High ratios can also be observed in postmenopausal women and even in normal individuals, making this test alone unable to establish the diagnosis. Growth hormone (GH), insulin-like growth factor-1 (IGF-1), and prolactin serum measurements are useful because approximately 30% of TSH-secreting adenomas cosecrete these hormones.

Dynamic tests may be useful for demonstrating the unresponsiveness of TSH in patients with TSH-secreting adenomas. In most TSH-secreting tumors (92%), the TSH level fails to increase in response to a standard TRH stimulation test, whereas a normal or increased response is observed in resistance to thyroid hormone. It can be useful to investigate the response of pituitary TSH to exogenous T₃. T₃ is administered

orally, and the dose is increased every 3 days (up to 200 mg daily). Before every increase, basal and TRH-stimulated TSH levels are measured together with peripheral markers of thyroid hormone action. Only partial or no suppression of TSH secretion is observed in TSH-secreting adenomas, whereas complete suppression is observed in resistance to thyroid hormone. The test is contraindicated in elderly patients and in patients with arrhythmias and/or coronary artery disease. Available tests in the differential diagnosis of the syndrome of inappropriate secretion of TSH are described in Table II.

Pituitary imaging is very important in confirming the diagnosis. Fully 90% of TSH-secreting adenomas are larger than 1 cm at diagnosis and, therefore, are easily detected at pituitary magnetic resonance imaging (MRI) scanning. As a complement, radiolabeled octreotide pituitary scintigraphy can be used and may be particularly useful for detecting small tumors.

Human Chorionic Gonadotropin-Dependent Thyrotoxicosis

The diagnosis of thyrotoxicosis during hyperemesis gravidarum can be particularly difficult. Because of weight loss and malnutrition, FT₃ levels may be disproportionately low or even normal in comparison with FT₄ levels due to a reduced peripheral conversion of T₄ to T₃. The TSH level is often low during early normal pregnancy, but it is seldom undetectable as it is in true thyrotoxicosis. The only distinctive laboratory feature is an inappropriately high human chorionic gonadotropin (hCG) level, but a large overlap with normal pregnancies exists. Therefore, the diagnosis of thyrotoxicosis in hyperemesis gravidarum relies mainly on the clinical picture and on appropriate exclusion of other more common forms of hyperthyroidism by specific testing. It is important to remember that RAIU, as well as any other *in vivo* radioisotopic procedure, is absolutely contraindicated during pregnancy.

Table II Laboratory Investigations in the Differential Diagnosis of the Syndrome of Inappropriate Secretion of TSH

| Test | TSH-secreting adenomas | TRH | Comment |
|--|-------------------------------|-------------------------------|--|
| Peripheral markers of thyroid hormone action | High | Normal-high | Nonspecific |
| α -subunit/TSH molar ratio | >1 | 1 | High during menopause |
| TSH after T ₃ suppression test | Unchanged or slightly reduced | Frankly reduced or suppressed | Hazardous in elderly and cardiopathic patients |
| TSH after TRH | Unchanged | Increased | |
| Pituitary imaging | Positive | Negative | Confirmatory |

The presence of a trophoblastic tumor should be suspected when thyrotoxicosis is diagnosed in an amenorrheic woman, especially when a palpable abdominal mass is present. The diagnosis is readily confirmed by the finding of extremely high circulating hCG levels and a pelvic mass at ultrasonography.

Given the extreme rarity of the disorder, no diagnostic guidelines are available for familial gestational hyperthyroidism. The diagnosis can be suspected only on a history of recurrent pregnancy-associated hyperthyroidism and can be confirmed only by the demonstration of a mutation of the TSH receptor gene, available in very few research laboratories worldwide.

Fetal and Neonatal Hyperthyroidism

Mothers with a past or current history of Graves' disease should be carefully monitored throughout pregnancy. The persistence of high TRAB levels in the maternal serum by the end of pregnancy, when the transplacental passage is maximal, is a predictor of hyperthyroidism in the neonate. Fetuses of mothers with Graves' disease who have been previously treated with radioiodine or surgery may be at higher risk because they lack the protective effect of antithyroid drugs administered to the mothers. The presence of a fetal heart rate greater than 160 beats per minute, in the absence of other fetal abnormalities, is suggestive of fetal hyperthyroidism. It is very useful to test neonatal cord blood at the time of delivery for thyroid function tests and TRABs. When the mother has been treated with high-dose antithyroid drugs, the neonate should be retested 10 days after birth given that transplacental passage of methimazole or propylthiouracil may initially mask hyperthyroidism. A TRAB-negative neonatal hyperthyroidism, in the absence of a maternal history of Graves' disease, should direct diagnosis to the suspicion of nonautoimmune congenital hyperthyroidism. Nowadays, the diagnosis can be confirmed only by sequencing of the TSH receptor gene.

Iodine-Induced Thyrotoxicosis

Iodine urinary excretion in patients with thyrotoxicosis due to excessive iodine consumption is always high, and excessive iodine consumption should always be suspected when hyperthyroidism appears abruptly in patients with a history of nodular thyroid disease. A careful history often identifies the source of iodine, and all patients should be asked about recent exposure to any of the compounds listed in Table III. With the

Table III Common Sources of Iodine Contamination

| | |
|------------------------------|--|
| Foods | Seaweed and seaweed containing foods (Japanese cuisine) |
| Food supplements | Kelp and other seaweed derivatives Vitamin supplements |
| Radiological contrast agents | Intravenous and oral (e.g., Gastrografin, Renografin, iopanoic acid, sodium ipodate) |
| Antiseptics | Betadine Iodoform gauze |
| Drugs | Amiodarone Expectorants |
| Iodine solutions | Lugol's solution, SSKI, KI |

exception of type II amiodarone-induced thyrotoxicosis, RAIU is usually low in thyrotoxic patients with heavy iodine contamination, but it is almost never less than 1%, a feature that allows distinction from subacute and painless thyroiditis.

Amiodarone-Induced Thyrotoxicosis

In the presence of amiodarone-induced thyrotoxicosis, further testing is required to distinguish between the type I (nondestructive) and type II (destructive) forms given that treatments may be radically different. Because of the concomitant underlying presence of thyroid disease, such as Graves' disease or nodular thyroid disease, type I amiodarone-induced thyrotoxicosis differs somewhat from other forms of iodine-induced thyrotoxicosis. It usually can be diagnosed with appropriate tools. Accordingly, RAIU is usually low but by definition never less than 1%. In contrast, in type II amiodarone-induced thyrotoxicosis, RAIU is always less than 1% and often no clear underlying thyroid disorder can be identified. High circulating interleukin-6 levels have been proposed as a useful marker of thyroid tissue destruction, and color flow Doppler ultrasound imaging shows a distinctive absence of vascularization in the gland.

Subacute, Painless, and Postpartum Thyroiditis

Subacute, painless, and postpartum thyroiditis are classically characterized by a low (<1%) RAIU during the thyrotoxic phase. This test alone, in

the presence of a suggestive clinical presentation, allows the diagnosis in nearly all cases. High-titer anti-TG and anti-TPO antibodies are usually found in postpartum and painless thyroiditis as a marker of prominent thyroid autoimmunity, whereas only weakly and transiently positive tests are occasionally found in subacute thyroiditis. A very high (> 50 mm/h) erythrocyte sedimentation rate is an additional distinctive diagnostic feature in subacute thyroiditis. Other inflammation indexes may be high in subacute thyroiditis, and a mild leukocytosis is often observed. As in other thyroidal destructive processes, interleukin-6 levels are elevated in all three disorders and, therefore, have no differential values. Ultrasound findings are generally characterized by patchy areas of hypoechogenicity in subacute thyroiditis, whereas a more diffuse hypoechoic pattern, closely resembling Hashimoto's thyroiditis, is found in postpartum and painless thyroiditis. The color flow Doppler pattern shows reduced vascularity in all three disorders. Occasionally, and especially when patients are first seen during the recovery or hypothyroid phase, a more subtle picture can emerge from testing, with a low but not nil RAIU and with only mild elevations of the erythrocyte sedimentation rate, making the differential diagnosis more difficult.

Thyrotoxicosis of Extrathyroidal Origin

An extrathyroidal source of thyroid hormone should always be suspected when more frequent causes of low RAIU thyrotoxicosis have been ruled out. When thyrotoxicosis factitia is suspected, a serum thyroglobulin measurement can be extremely useful in confirming the diagnosis because this disorder represents the only condition (in absence of AbTG) in which thyrotoxicosis is associated with an undetectable thyroglobulin level. Indeed, the presence of AbTG may cause falsely low thyroglobulin levels. Given the high prevalence of thyroid nodules in the general population, especially in iodine-deficient areas, it is also useful to perform ultrasound scanning of the neck because, in the presence of thyroid nodules, thyroglobulin may be elevated in spite of the assumption of exogenous thyroid hormone.

The suspicion of struma ovarii can be confirmed at the time of RAIU by simply scanning the pelvic area with the probe. The presence of functional thyroid tissue is demonstrated by the presence of significantly increased uptake of iodine in the ovarian region. Further imaging (CT or ultrasound scan) will confirm the presence of an ovarian mass.

When the source of thyroid hormone is metastatic thyroid follicular cancer, the presence of the latter is usually evident from the history. Because all patients with differentiated thyroid cancer after thyroidectomy take L-T4 in TSH-suppressive doses, thyroid function tests should be repeated after tapering the medication to rule out iatrogenic thyrotoxicosis. Confirmation is obtained with whole body radioiodine scanning that will show multiple foci of uptake in several skeletal regions.

the technique by blocking axonal transport with colchicine led to the disclosure of TRH-containing neurons in the rat telencephalon and brain stem. The olfactory bulb, hippocampus, periaqueductal gray, medulla oblongata, and dorsal horn of the spinal cord are among the extrahypothalamic brain areas containing TRH-positive cells and fibers, suggesting a physiological role for TRH as a neurotransmitter or neuromodulator in the central nervous system (CNS) in addition to its neuroendocrine role in TSH release. In fact, the majority of total brain TRH is found in extrahypothalamic brain areas. The pituitary gland, gastrointestinal tract, pancreatic islets, and reproductive tract also contain some TRH.

TRH RECEPTORS AND TRH-DEGRADING ENZYME

The TRH receptor TRH-R1, originally cloned from a pituitary cDNA library, was the only TRH receptor known until recently. Many studies suggest that this receptor belongs to the family of G protein-coupled membrane receptors acting via the inositol phospholipid-calcium-protein kinase C signal transduction pathway. In spite of the wide distribution of TRH in the rat CNS, there is only little TRH-R1 mRNA expression in the brain. In contrast, TRH-binding sites are present in a large number of rat and human brain areas. Part of this discrepancy has been clarified by the demonstration of another TRH receptor, TRH-R2, which was cloned from a rat brain cDNA library. It has approximately 50% amino acid homology with rat TRH-R1 and may be a key component of TRH signaling within the CNS.

The termination of TRH signals is probably mediated by a membrane-bound ectoenzyme designated pyroglutamyl peptidase II, which has a remarkable specificity to hydrolyze only TRH and closely related peptides. Therefore, this enzyme has been termed TRH-degrading ectoenzyme (TRH-DE). The highest activity is present in rat brain. In the pituitary, the enzyme is localized on lactotrophs, where TRH-DE activity and mRNA levels are tightly regulated by estrogen and thyroid hormone. In peripheral tissues, the enzyme is present in retina, lung, and liver. Studies have compared the distribution of TRH-R1, TRH-R2, and TRH-DE in rat brain, showing that TRH-R1 is predominantly expressed in hypothalamic regions and the anterior pituitary, in accordance with the known neuroendocrine functions of TRH. TRH-R2 is widely distributed throughout a number of brain areas, including the thalamus, cerebral and cerebellar

cortex, and habenulae. The complementary expression of both receptor subtypes and the overlapping expression of both receptors with TRH-DE strongly suggest that the two receptors serve highly specific functions in discrete neuroanatomical pathways.

FUNCTIONS OF TRH

Ever since its discovery, TRH has been known as the major neuropeptide stimulating the anterior pituitary to synthesize and release TSH. It also stimulates release of prolactin from the anterior pituitary. Changes in serum concentrations of thyroid hormone have a strong effect on TRH gene expression in the hypothalamic PVN but not elsewhere, as demonstrated by mRNA *in situ* hybridization studies. TRH immunocytochemical staining intensity and mRNA expression increase in hypothyroidism, with reverse changes in hyperthyroidism. In addition, lesions of the PVN reduce serum TSH concentrations and prevent the increase in serum TSH in primary hypothyroidism. Studies in mice have demonstrated an important role for the TR β 2 isoform in this negative feedback effect of thyroid hormone on TRH cells in the PVN. Neuroanatomical tracing studies using transsynaptic viral tracers have identified multisynaptic autonomic connections between neurons in the PVN and the thyroid gland. Because some of these neurons are TRH immunoreactive, TRH cells in the PVN may be involved in thyroid regulation via both classical neuroendocrine and novel neural pathways.

It has been known for many years that serum concentrations of thyroid hormone decrease during food deprivation. The way in which the brain orchestrates this adaptation to starvation has become increasingly clear. In a food-deprived condition, TRH gene expression in the PVN is markedly decreased. The fat-derived hormone leptin plays a pivotal role in this neuroendocrine response to starvation. A decrease in serum leptin signals via the leptin receptor in the hypothalamic arcuate nucleus (Arc) to agouti-related peptide (AgRP) and α -melanocyte-stimulating hormone (MSH)-containing neurons. These neurons have monosynaptic connections with TRH cells in the PVN that express the melanocortin-4 receptor (MC4R). The MC4R is stimulated by α -MSH and is inhibited by AgRP. A number of *in vitro* and lesion studies in rats have clearly demonstrated the importance of these pathways for the integrity of the neuroendocrine response to fasting. The effects of starvation on TRH cells in the PVN are less dependent on TR β 2 than are the effects of hypo- and

hyperthyroidism, underlining the different roles for TRH cells in the PVN in these two conditions.

In extrahypothalamic brain areas, TRH may be involved in blood pressure regulation, temperature regulation, and carbohydrate metabolism. In TRH knockout mice, hyperglycemia and impaired insulin secretion in response to glucose support the latter. Experimental studies involving the administration of TRH suggest a role for TRH in attention and mood.

TRH AND PATHOLOGY

Within hours after the onset of a severe physical stressor such as a surgical procedure or trauma, the serum concentration of triiodothyronine (T3) decreases, mainly due to decreased peripheral conversion of thyroxine (T4) to T3. The magnitude of the change in serum T3 roughly correlates with the severity of the illness. Similarly, serum T3 decreases during food deprivation. Serum TSH is typically within the normal range, with a strongly attenuated nocturnal TSH surge. These changes are known as nonthyroidal illness (NTI), as well as the sick euthyroid syndrome and low-T3 syndrome, and they have been interpreted as an attempt of the organism to reduce energy expenditure during illness and starvation. Patients treated in intensive care units for prolonged periods of time have decreased serum T3 and T4 in combination with low-normal serum TSH and dramatically diminished pulsatility. Postmortem studies in human brain have shown decreased gene expression of TRH in the PVN, correlating with the decrease in serum T3 and TSH in serum samples taken just before death, pointing to a role of hypothalamic TRH in the resetting of the thyroid axis during illness.

Van den Berghe and colleagues studied the neuroendocrine component of the decreased activity of the thyroid and somatotrophic axes in critical illness by the intravenous infusion of TRH, growth hormone-releasing peptide-2 (GHRP-2), and growth hormone-releasing hormone. Patients who had been critically ill for several weeks showed a dramatic augmentation of nonpulsatile TSH release by TRH infusion and increased pulsatile TSH secretion after TRH plus GHRP-2 infusion. TRH infusion also increased serum T4 and T3 by 40 to 110%. In subsequent placebo-controlled studies, the same group demonstrated near-normalized serum concentrations of thyroid hormone, increased markers of anabolism, and decreased markers of catabolism after infusion of TRH and GHRP-2 over 5 days. Thus, the hypothesis

of inappropriately decreased neuroendocrine drive in critically ill patients can be tested in randomized clinical trials assessing clinical outcome.

Another clinical condition involving changes in the set point of the hypothalamus–pituitary–thyroid axis is major depression. Some 25% of these patients have serum T4 higher than the reference value, probably resulting from increased T4 production. Serum T3 is often normal but may be decreased in a proportion of patients. Serum TSH is low, but it is mostly within the normal range and shows an attenuated diurnal variation. The latter observation points to changes in hypothalamic function given that the hypothalamic SCN drives the diurnal variation in thyroid hormones. Both increased and unchanged cerebrospinal fluid (CSF) levels of TRH have been reported in depression. Based on the neuroendocrine changes in depression and earlier observations of central effects of TRH, a number of studies have addressed the possibility of a therapeutic role for TRH in depression. The results of these studies have been largely inconsistent, possibly due in part to the pharmacokinetics of orally administered TRH-like peptides. One double-blind crossover study reported strong and positive effects of intrathecal TRH in refractory depressed patients, but the number of patients was rather small.

CONCLUSION

TRH is a classical neuropeptide originally identified as a hypothalamic-releasing factor for TSH. It is important for thyroid physiology and a key element of thyroid set point regulation. Studies in TRH knockout mice and the identification of a TRH receptor mutation in a patient with central hypothyroidism have confirmed these assumptions. Studies during the past decade or so have shown an important role for hypothalamic TRH in the neuroendocrine response to food deprivation. This response includes changes in serum leptin concentrations mediated via the hypothalamic melanocortin system to TRH neurons in the PVN. Studies in critically ill patients have revealed a role for TRH in the neuroendocrine response to disease. Major depression is another example of a pathological condition in which TRH plays a role.

the 311 bp Alu-repeat sequence in intron 8. Another eight polymorphisms of the t-PA gene have been described and characterized by a single nucleotide substitution. Among these, three were found in linkage disequilibrium with the Alu-repeat polymorphism, namely, a C-7351T substitution in the enhancer region, a T20099C substitution in exon 6, and a T27445A substitution in intron 10. *In vitro* studies failed to demonstrate any influence of the Alu-repeat polymorphism on basal endothelial synthesis of t-PA. No correlation between the Alu-repeat I/D genotype and circulating levels of both t-PA antigen and activity was observed *in vivo*. In contrast, a relationship between this polymorphism and the net local t-PA release rate, as well as an influence on t-PA release after venous occlusion, was seen in healthy subjects. Conflicting results have emerged from studies dealing with the relationship between the Alu-repeat I/D polymorphism of t-PA and the risk of myocardial infarction.

SYNTHESIS AND SECRETION OF t-PA

t-PA has been isolated from many tissues, such as endothelial cells and smooth muscle cells of vascular

walls, monocytes, mesothelial cells, megakaryocytes, mast cells, cardiac fibroblasts, and neuronal cells. The principal site of t-PA synthesis is the endothelial cell, where the protease is stored in the cytoplasm and released through a constitutive secretory pathway. Moreover, t-PA can be released in the circulation within a few minutes in response to different stimuli through a regulated secretory pathway, suggesting the presence of a cytoplasmic storage pool rather than a *de novo* synthesis of the protein.

Several stimuli have been found to induce *in vivo* acute t-PA release, such as venous occlusion, exercise, 1-desamino-8-D-arginine-vasopressin (DDAVP) infusion, mental stress, and sympathoadrenal activation; in this last case, t-PA may be also coreleased with catecholamines by chromaffin cells. Moreover, *in vitro* stimulation of endothelial cells with thrombin, fibrin, bradykinin, histamine, and acetylcholine is associated with enhanced t-PA secretion; also, an arterial shear stress of 14 to 28 dyn/cm² applied to the culture may increase the production of t-PA.

By immuno- and electromicroscopic techniques in human umbilical vein endothelial cells, the site of cytoplasmic storage of t-PA has been identified in small and dense vesicles that are different from the

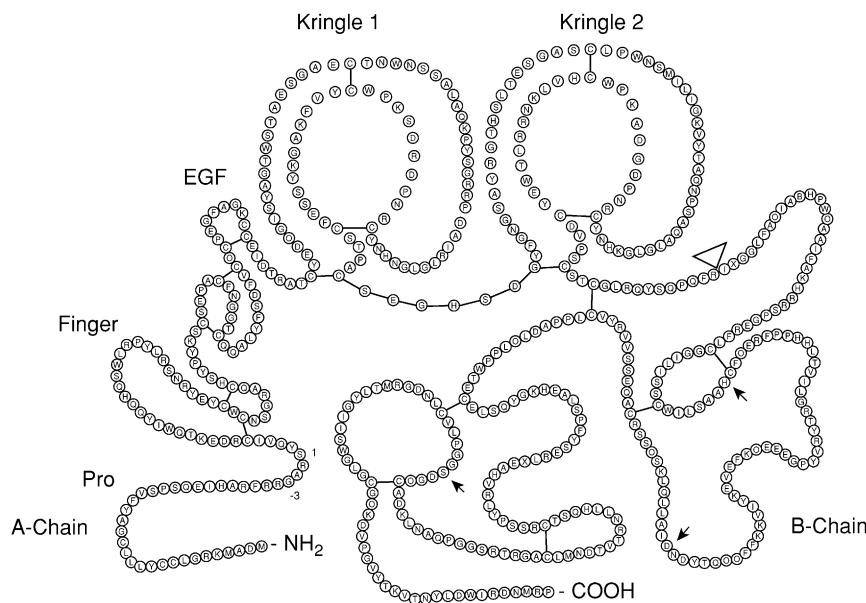

Figure 3 Molecular structure of t-PA. The cleavage of the Arg275-Ile276 peptide bond (open arrowhead) transforms the single-chain t-PA in a double-chain molecule. The solid arrows indicate the catalytic triad His-322, Asp-371, and Ser-478. EGF, epidermal growth factor. Adapted from Ny T. *et al.* (1984), with permission.

Weibel-Palade bodies, where t-PA may also be accumulated together with von Willebrand factor. Concomitant release of t-PA and von Willebrand factor *in vivo* is commonly observed after DDAVP infusion, whereas patients with severe von Willebrand's disease are deficient in acute t-PA release.

The t-PA concentration in normal plasma is approximately 5 $\mu\text{g/liter}$. Since most of the protein circulates in a complex with its inhibitor, PAI-1, the amount of free enzyme activity is usually approximately 0.5 U/ml, corresponding to 1 $\mu\text{g/liter}$.

ACTION AND INHIBITION OF τ -PA

The sole substrate of t-PA is represented by plasminogen, in which t-PA cleaves the Arg561-Val562 peptide bond, thus generating the active protease plasmin. In the absence of fibrin, however, t-PA is a weak activator of plasminogen; conversely, in the presence of fibrin, the affinity of t-PA for plasminogen is greatly increased, leading to an enhanced plasminogen activation of at least 2 orders of magnitude. This finding can be explained by an assembly of both t-PA and plasminogen on the fibrin surface, thus forming a ternary complex; moreover, fibrin-bound plasminogen exhibits an open conformation that favors its activation. The single-chain t-PA has a lower catalytic activity than the double-chain t-PA in the absence of fibrin, but this difference disappears when the molecules bind to fibrin. During lysis of the fibrin clot,

the appearance of additional plasmin-generated carboxyl-terminal lysine residues further promotes the binding of t-PA.

The main physiological inhibitor of t-PA is PAI-1, even though other serpins are known to potentially inactivate the t-PA. An interaction between the positively charged t-PA sequence 298-302 and the negatively charged PAI-1 sequence 350-355 precedes the irreversible reaction between the Arg346-Met347 reactive site of the inhibitor and the serine residue of the t-PA active site. This reaction occurs rapidly in plasma, although fibrin-bound t-PA may also be inhibited by PAI-1. Both free t-PA and t-PA-PAI-1 complexes are rapidly cleared from the circulation; the liver is the main organ involved in this process. In particular, liver endothelial cells and Kupffer cells provide t-PA clearance via a mannose receptor, whereas the hepatocytes may remove both t-PA and t-PA-PAI-1 complexes via the lipoprotein receptor-related protein/ α 2-macroglobulin receptor (LRP). The half-life of free t-PA is approximately 3-4 min, whereas the formation of complex with PAI-1 is associated with an increase in the LRP-mediated clearance of approximately 1 order of magnitude.

CLINICAL ASPECTS OF τ -PA

A physiological fluctuation of t-PA activity during a 24 h period, with a marked decrease in the early morning hours, is tightly associated with the circadian

rhythm of PAI-1, which is characterized by a significant increase in the inhibitor's levels early in the morning.

Congenital t-PA deficiency has never been described in humans, suggesting a lethal condition. In contrast, mice with a complete deletion of the t-PA gene revealed normal development and mild glomerulonephritis; after endotoxin injection, t-PA⁻/t-PA⁻ mice showed more extended thrombotic lesions than t-PA⁺/t-PA⁺ mice. A bleeding diathesis due to an excess of t-PA has been reported in only a few cases. An overexpression of annexin II, a cell receptor for t-PA, on acute promyelocytic leukemia cells seems to be involved in the pathogenesis of the hyperfibrinolytic state typical of this disease.

The endothelial release of t-PA is part of the thromboprotective properties of the vascular surface and represents a counterregulatory mechanism to prevent the progression of a clotting process into occlusive thrombus. A lower level of t-PA production has been observed in the calf veins with respect to the proximal veins, suggesting a possible role in the onset of deep venous thrombosis. An impaired fibrinolytic capacity due to reduced t-PA release or, more often, to PAI-1 excess has been found in up to 40% of patients with deep venous thrombosis; however, the predictive value of both t-PA and PAI-1 levels for the risk of thrombotic events and recurrences has not been confirmed. A predictive value for major cardiovascular events has been ascribed to high t-PA antigen values. This apparently paradoxical finding, however, depends mainly on concomitant increased PAI-1 levels

Table I Clinical Application of Thrombolytic Therapy with Recombinant t-PA

| |
|---|
| Major indications |
| Acute myocardial infarction |
| Hemodynamically unstable massive pulmonary embolism |
| Indications suggested in highly selected cases |
| Acute peripheral artery occlusion |
| Massive iliofemoral vein thrombosis |
| Acute ischemic stroke |
| Cerebral sinus vein thrombosis |
| Budd-Chiari syndrome |
| Central retinal artery and/or vein thrombosis |

Note. The risk of bleeding must be carefully excluded before treatment.

leading to high concentrations of protease-inhibitor circulating complexes but low free active t-PA.

Several drugs may enhance t-PA synthesis and secretion, such as DDAVP, sodium nitroprusside, epinephrine, isoproterenol, sodium butyrate, and triazobenzodiazepines.

Using recombinant DNA technology, the human t-PA molecule (rt-PA) has been produced for therapeutic thrombolysis. The efficacy of this agent in the treatment of acute myocardial infarction and massive pulmonary embolism has been clearly demonstrated. Even though rt-PA has fibrin-selective properties, its use is not completely devoid of the risk of systemic fibrinolysis or of hemorrhagic complications. Therefore, therapeutic thrombolysis is indicated in selected life-threatening cases (Table I). Variants of rt-PA have been constructed with modified pharmacokinetic or functional properties, but clinical trials have failed to demonstrate any superiority to the original molecule.

Figure 1 tRAAS and heart valve leaflets (V). By *in situ* hybridization, renin mRNA (A) expression is markedly increased in leaflets as contrasted with surrounding tissue. Shown is the tricuspid valve of the rat heart. Using *in vitro* autoradiography, high-density binding for ACE (B) and Ang II receptors (C) is found in valve leaflets. Shown is the aortic valve of the normal rat heart. Reprinted from Sun and Weber (2003), with permission.

Katwa has shown that cultured leaflet myoFb express (mRNA and protein) requisite components for Ang peptide formation, including angiotensinogen (Ao)

an aspartyl protease (cathepsin D), and ACE. Their ACE and kinase activities include conversion of substrates such as Ang I, bradykinin, and substance P, respectively. Ang II generated by these cells is involved in the autocrine induction of type I collagen expression via up-regulation of TGF- β_1 expression. This is an angiotensin receptor type I (AT $_1$) receptor-mediated event. Contraction of leaflet myoFb grown on a flexible substratum and mediated by α -smooth muscle actin microfilaments in these myoFb can be induced by Ang II, catecholamines, endothelin-1, or serotonin through the binding of their respective receptors and ligands; papaverine induces relaxation.

Diseased Hearts

Compared to nonfailing donor heart tissue, the number of ACE transcripts is increased in tissue homogenates prepared from explanted failing human hearts. ACE and TGF- β_1 expression is likewise increased in myocardium obtained from patients undergoing aortic valve replacement for aortic stenosis and correlate with the extent of fibrosis found in these tissue samples. ACE and Ang II are present in the fibrous tissue that contributes to the sclerosis and the stenosis of diseased human aortic valves. In keeping with the expression of ACE in heart valve leaflets and Ang II in regulating leaflet collagen turnover, Atalar *et al.* have suggested that the ACE-DD genotype is associated with a greater risk of valve deformity following a bout of acute rheumatic fever.

The aorta–coronary sinus concentration gradient for Ang II is decreased in patients with heart failure with increased Ang II appearing in this venous effluent and is accompanied by increased mRNA expression of angiotensinogen and ACE in noncardiomyocyte cells found in explanted failing hearts. ACE-dependent Ang II formation is increased in the infarcted segment of scarred myocardium in autopsied hearts and it has also been reported that expression of angiotensinogen, renin, ACE, and Ang II receptor genes is present in adult cardiomyocytes and up-regulated in response to myocardial ischemia.

Temporal and spatial responses in autoradiographic ACE binding have been assessed by Sun *et al.* in a rat heart model of myocardial infarction (MI). Other forms of injury involving various tissues are present in this model. They include the heart, visceral pericardium, kidneys, and skin. Each serves as a positive control in the analysis of ACE and tissue repair. Low-density ACE binding is present in normal rat myocardium, where renin mRNA expression is not found. High-density ACE binding and renin mRNA

expression appear at the site of anterior MI on day 7 following left coronary artery ligation and are coincident with the appearance of fibrillar collagen. As a fibrillar collagen network forms scar tissue over 8 weeks, the density of ACE binding and the expression of renin (see Figs. 2A and 2B) at this site increase progressively. A large transmural MI in the rat heart is associated with high-density ACE binding and the appearance of fibrosis at sites remote to the infarct, including the noninfarcted left ventricle, interventricular septum, and right ventricle (see Fig. 2B). The appearance of fibrosis at these remote sites is directly related to the extent of infarct injury. When an infarct injury is extensive, the entire myocardium, including infarcted and noninfarcted ventricular tissue, is involved in tissue repair and subsequent structural remodeling by fibrotic tissue.

Noninfarct-related sites of injury serve to further address the relationship between the appearance of ACE and repair. Sham operation includes manual handling of the heart and this leads to inflammation and subsequent fibrosis of the visceral pericardium. Silk ligature placement around the left coronary artery or within skin to close a surgical incision is associated with a foreign-body fibrosis at each site. The appearance of a mural thrombus in the infarcted left ventricle is associated with subsequent endocardial fibrosis and on occasion leads to thromboembolic renal infarction. At each of these sites of injury and repair, high-density autoradiographic ACE binding is temporally and spatially concordant with fibrous tissue formation. Angiotensinogen, renin, ACE, and TGF- β_1 mRNA levels are increased in the rat right ventricle at 3 and 6 weeks after monocrotaline-induced pulmonary injury. In mice with desmin-deficient cardiomyopathy, areas of cardiac fibrosis are colocalized with up-regulated expression of ACE and TGF- β_1 .

Potential differences in healing and thereby ACE expression could occur as a result of ischemic versus nonischemic injury. Permanent coronary artery ligation, for example, can impede the delivery of circulating cells and signals to the site of injury and can limit said delivery to that provided by collateral vessels. Nonischemic models of cardiac myocyte necrosis have been examined. They include the following: the endogenous release of catecholamines that accompanies Ang II infusion from implanted minipump or exogenous administration of isoproterenol, and chronic (>3 weeks) administration of aldosterone by minipump in uni-nephrectomized rats on a high-salt diet and which is accompanied by enhanced urinary potassium excretion and subsequent cardiac myocyte

Figure 2 Renin, ACE, and Ang II receptor expression in the infarcted rat heart. Following MI, high-density renin mRNA expression is observed at the site of MI, as well as in the inflamed pericardium and endocardium at week 1 (A) and remains elevated over the course of 4 weeks (not shown). ACE and Ang II receptor-binding density was also markedly increased at the same sites. (B) ACE and (C) Ang II receptor-binding densities in the infarcted heart at week 4 post-MI. Reprinted from Sun and Weber (2003), with permission.

potassium depletion with cell necrosis. At each site of nonischemic myocyte loss, and irrespective of its etiologic basis, the temporal and spatial appearance of high-density ACE binding is coincident with the deposition of fibrous tissue and resembles the aforementioned responses observed in the infarcted heart following permanent coronary artery ligation. Thus, irrespective of the etiologic basis of injury, the tissue involved in repair, or the presence of ischemic versus nonischemic repair, marked autoradiographic ACE binding is coincident with fibrous tissue formation.

Furthermore, examination of serial heart sections of the infarcted rat heart demonstrates high-density ACE binding to be spatially concordant with marked autoradiographic Ang II (see Fig. 2C) and TGF- β receptor-binding densities and mRNA expression of renin TGF- β_1 and type I collagen by *in situ* hybridization at these sites of fibrosis. Collectively, these findings in various injured tissues indicate that both Ang II and TGF- β_1 are part of a common signaling pathway involved in promoting repair.

The mRNA expression of ALDO synthase (CYP11B2), integral to the biosynthesis of ALDO, and ALDO production have been demonstrated in rodent heart and vascular tissue. ALDO generation is regulated by Ang II, a low-Na⁺ or high-K⁺ diet, or adrenocorticotrophic hormone. ALDO is extracted by the heart following MI and the transcardiac ALDO gradient (between aorta and coronary sinus) correlates with a serologic marker of collagen turnover (i.e., procollagen type III amino-terminal peptide) found in coronary venous effluent and associated with left ventricular (LV) dilation and impaired function. ALDO is extracted by the chronically failing human heart of diverse etiologic origins, a response that is blocked by spironolactone. Others have reported that ALDO production is increased in the failing human left ventricle based on coronary sinus levels of ALDO that exceed those found in the aorta. There exists an up-regulated expression of CYP11B2 in the left ventricle of the failing human heart of diverse etiologic origins. Additionally, 11 β -hydroxysteroid dehydrogenase, an enzyme that is critical to maintaining the specificity of the mineralocorticoid receptor, given its equal affinity for mineralocorticoids and glucocorticoids, has been found in human cardiac tissue.

CELLS EXPRESSING tRAAS

Normal Heart

Cells expressing ACE in normal rat heart valve leaflets have been identified by immunolabeling with a

monoclonal antibody: endothelial cells lining atrial and ventricular leaflet surfaces and fibroblast-like cells residing within the leaflet matrix or myoFb. TGF- β_1 induces ACE synthesis in cultured rat heart interstitial fibroblasts and is accompanied by their differentiation into myoFb.

Diseased Hearts

The ACE-positive cells involved in the response to renin expression seen at and remote to the infarct site include macrophages that invade the infarct site and myoFb. Within 24 h of MI, macrophages appear at the interface between viable and necrotic myocardium; by day 3, stromal fibroblasts coaggregate with macrophage clusters bordering on the infarct site. Thereafter, fibroblast differentiation follows, resulting in an α -smooth muscle actin (α -SMA)-positive myoFb phenotype; the myoFb then proliferate and migrate into the site of necrosis during the remainder of week 1. A combination of cell growth with spatial control of growth and fibrillar collagen assembly governs the rebuilding of infarcted tissue.

Macrophages and myoFb found at the infarct site also express Ang II receptors, TGF- β_1 , and TGF- β_1 receptors. Beyond day 14, only myoFb and endothelial cells are renin- and ACE-positive, coincident with the gradual disappearance of macrophages from the infarct site. Persistent renin expression and high-density ACE and Ang II receptor binding are present at the infarct site in rat hearts for 8 weeks or more post-MI. This is primarily due to α -SMA-positive myoFb, which remain in infarct scar tissue for prolonged periods of time. In the infarcted human heart, these myoFb persist at the site of MI for years.

Gabbiani *et al.* have shown that myoFb have considerable phenotypic and functional diversity. Immunolabeling with α -SMA, vimentin, and desmin defines their phenotype at the infarct site. Fibroblast-like cells express vimentin (V). ACE-labeled fibroblasts found in the infarct scar and involved in the expression of fibrillar collagen mRNA are positive for the cytoskeletal proteins α -SMA and vimentin. These vimentin/actin (VA)-positive myoFb, instrumental to tissue repair including wound contraction, are likewise found in the connective tissue that comprises endocardial fibrosis, pericardial fibrosis, renal infarction, and sites of foreign-body fibrosis. Unlike incised skin, where myoFb contribute to tissue repair and then progressively disappear through programmed cell death (apoptosis) coincident with wound closure and scar tissue formation at week 4, the VA phenotype at the infarct site remains for prolonged periods.

Whether pathologic fibrosis at and remote to MI found in the infarcted heart is related to its persistent myoFb is uncertain.

In vitro emulsion autoradiography identifies VA-positive myoFb as expressing Ang II receptors. Together with displacement studies using either an AT₁ receptor antagonist, losartan, or an AT₂ receptor antagonist, PD123177, the great majority of these receptors in the infarcted rat heart are of the AT₁ subtype. MyoFb found at sites of microscopic scarring involving both infarcted and noninfarcted tissue also express mRNA for the fibrogenic cytokine TGF- β ₁ and TGF- β receptors. This has implicated locally produced Ang II at sites of injury in regulating collagen turnover, which has been further suggested by the cardioprotective actions of losartan, an AT₁ receptor antagonist, in attenuating fibrous tissue formation at and remote to the MI. Locally produced Ang II is also involved in regulating *de novo* ALDO production in the infarcted heart, which likewise may contribute to tissue repair. Increased expression of ALDO synthase and ALDO tissue levels, together with increased concentrations of Ang II, have been observed in noninfarcted rat myocardium following coronary artery ligation. Treatment with losartan prevented these responses related to *de novo* ALDO production.

tRAAS AND TISSUE REPAIR

Normal Heart

ACE imparts connective tissue with metabolic activity. Its substrate utilization involves factors participating in a reciprocal regulation of cell behavior—stimulators or inhibitors of cell growth and functions integral to the formation and degradation of fibrillar collagen. Loose and dense connective tissue formation is a dynamic process during the early growth and development of newborn rats. The contribution of Ang II to this process has been examined in young rats, where treatment of 4-week-old rats with enalapril attenuated the cardiac and vascular accumulation of collagen involving the right and left ventricles, aorta, and systemic arteries compared to untreated, age-matched control rats. No such study has yet been conducted with an Ang II receptor antagonist. In rats with a genetic predisposition to hypertension, treatment with either quinapril or hydralazine during early growth and development prevented the appearance of hypertension in adulthood. However, only quinapril attenuated the expected development of connective tissue seen in age-matched hypertensive controls.

Diseased Hearts

High-density ACE binding in connective tissue that appears in response to tissue repair indicates that there is marked ACE activity at such sites. ACE activity has been examined in tissue obtained from the failing, infarcted, and noninfarcted human heart tissue. Homogenates of blocks of transmural tissue adjacent to visible scar tissue and obtained at the time of aneurysmectomy were prepared for analysis. Such samples, it was noted, may have contained scar tissue. The ACE activity of this homogenate was compared to that prepared from noninfarcted ventricular tissue obtained at necropsy from persons dying of noncardiac causes. Infarct tissue ACE activity exceeded that of such control tissue severalfold and the extent of activity was related to the severity of tissue damage. In rat heart tissue homogenates prepared from sites remote to a large transmural anterior MI, ACE activity is increased and the extent to which substrate conversion is increased correlates with infarct size. The importance of fibrous versus nonfibrous tissue ACE in determining this heightened ACE activity at infarcted and remote sites could not be determined from these studies.

A paradigm of tissue repair in which ACE and local Ang II are integral to the orderly and sequential nature of repair that eventuates in fibrosis has been proposed by Weber. As shown in Fig. 3, ACE is involved in a two-part *de novo* generation of Ang II within granulation tissue that forms at sites of injury. The first component of local Ang II generation is provided by macrophages. In an autocrine manner, ACE regulates the expression of the fibrogenic cytokine TGF- β ₁ that determines the phenotype conversion of coaggregating stromal fibroblasts. VA-positive myoFb then generate Ang II, whose autocrine induction of TGF- β ₁ regulates collagen turnover at sites of fibrous tissue formation, including infarcted and noninfarcted myocardium. It is suggested that Ang II generation at the infarct site is related to the extent of the myoFb response and accordingly the degree of myocyte necrosis and subsequent healing response. An extensive transmural MI and the accompanying inflammatory cell response generate a large amount of Ang II, which reaches distant or remote sites via its diffusion through tissue fluid to promote fibrosis. Accordingly, activation of fibrogenesis is greatest at sites closest to the anterior MI (e.g., interventricular septum) and less so at more remote sites (e.g., right ventricle). Expression of type I and III collagens is greater and persists longer in the septum than in the right ventricle in rat hearts following left coronary artery ligation.

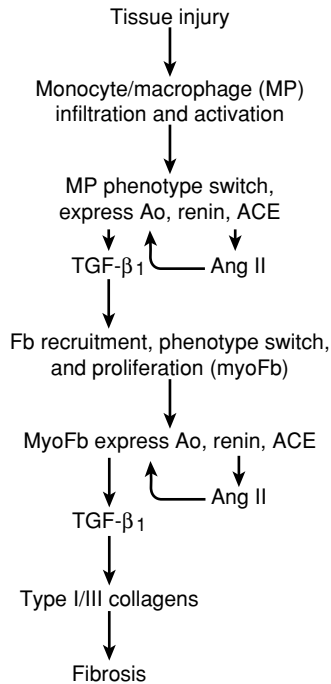

Figure 3 A schematic representation of the two-part *de novo* generation of Ang II involved in tissue repair following MI. See text for discussion and abbreviations. Adapted from Weber (1997), with permission.

The fibrogenic signals generated at a site of MI are transferred to remote sites through the heart's common interstitial space. These signals (e.g., Ang II) promote postinfarct remodeling at and remote to the site of MI. The persistence of VA-positive, active myoFb perpetuates such remodeling. Circulating and locally generated Ang II contributes to myocardial remodeling post-MI. Elevations in circulating Ang II, due to RAAS activation, represent a signal that gains entry to tissue where it further promotes postinfarct fibrosis by AT₁ receptor binding. Diastolic dysfunction is an outcome of such exuberant, unbridled tissue fibrosis. Ang II, whether derived locally or from the circulation, may further contribute to abnormal tissue stiffness through its induction of myoFb and thereby fibrous tissue contraction.

MyoFb persist in the infarct scar. Furthermore, these cells remain active, expressing ACE, Ang II receptors, TGF- β receptors, type I collagen, and TGF- β ₁. Prolonged stimulation of collagen production and adverse myocardial remodeling by fibrosis long after the acute phase of healing post-MI are reminiscent of progressive valvular sclerosis that appears years after acute rheumatic valvulitis and where valvular deformity (e.g., leaflet and chordal shortening) is related to contractile myoFb. The persistence of myoFb in

injured kidneys is accompanied by progressive interstitial fibrosis, renal dysfunction, and poor prognosis.

Treatment with either losartan or spironolactone prevents the accompanying accumulation of collagen at sites remote to the MI, suggesting the involvement of Ang II-driven local ALDO production in regulating tissue repair. In circumstances where circulating ALDO is not increased, spironolactone attenuates neointimal thickening following vascular barotrauma, tissue repair at sites of fibrous tissue formation, and vascular injury in stroke-prone rats. These observations further suggest that the autocrine/paracrine properties of locally produced ALDO participate in tissue repair, as proposed by DelCayre and co-workers.

Salutary clinical responses to ACE inhibition are likely to be multifactorial in origin. One important component relates to the prevention of adverse structural remodeling of infarcted and noninfarcted myocardium by fibrous tissue. Evidence supporting a contribution of locally produced Ang II in regulating myoFb collagen synthesis is obtained using pharmacologic probes that interfere with local Ang II generation (i.e., ACE inhibition) or occupancy of its AT₁ receptor prior to circulating RAAS activation. Captopril or enalapril, begun at or close to the onset of MI, reduces infarct size, infarct expansion, and thinning and attenuates the rise in hydroxyproline concentration at the infarct site in dogs with permanent coronary artery occlusion. The potential additional contribution of reduced bradykinin degradation to tissue repair and which would accompany ACE inhibition is under investigation. Bradykinin (BK) is released post-MI and a BK₂ receptor antagonist (Hoe140 or icatibant) accentuates collagen accumulation remote to the MI site.

Losartan, begun on day 1 after coronary artery ligation and at a dose that reduced AT₁ receptor binding by 50%, reduces the infarct scar area. Moreover, the expected rise in tissue Ang II concentration found at the infarct site 3 weeks after coronary artery ligation is markedly attenuated by either delapril or TCV-116, an AT₁ receptor antagonist, introduced on postoperative day 1. These findings raise the prospect that the number of myoFb or their Ang II-generating activity per cell at sites of repair may be influenced by Ang II. Other studies have not found such antagonists to influence fibrosis post-MI. The reason for these divergent findings is unclear.

Fibrous tissue formation at sites remote to MI is also influenced by these pharmacologic interventions. Perindopril, given 1 week after MI, attenuates the endocardial fibrosis that appears in the nonnecrotic

segment of the rat left ventricle. Captopril, commenced at the time of coronary artery ligation, attenuates the expected fibrosis of noninfarcted rat left and right ventricles and proliferation of fibroblasts and endothelial cells that appears at remote sites 1 and 2 weeks following MI. In these circumstances, captopril prevents the rise in LV end diastolic pressure that appears in untreated rats and which does not occur in propranolol-treated rats. Captopril also reduces the inducibility of ventricular arrhythmias in this model. When initiated 3 weeks post-MI, well after the tissue repair process has commenced and progressed, captopril does not prevent fibrosis remote to the infarct site or the rise in ventricular stiffness. Losartan prevents fibrosis at remote sites, but not the cellular proliferation that appears. Others did not find an inhibition of type I and III collagen mRNA expression at remote sites and have suggested posttranslational modification in collagen turnover to explain why fibrosis fails to appear at remote sites.

These favorable tissue protective effects of ACE inhibition or AT₁ receptor antagonism are not confined to the infarcted heart. These interventions prevent the appearance of fibrosis in diverse organs with experimentally induced or naturally occurring tissue injury and where circulating RAAS is not activated. These include the following: pericardial fibrosis post-pericardiectomy; tubulointerstitial fibrosis associated with unilateral ureteral obstruction, toxic nephropathy, cyclosporine, remnant kidney or renal injury following irradiation; cardiovascular sclerosis and glomerulosclerosis that appear in stroke-prone spontaneously hypertensive rats; interstitial pulmonary fibrosis that follows irradiation or monocrotaline administration; and subcutaneous pouch tissue in response to croton oil. The attenuation of fibrous tissue formation by these interventions in diverse organs with various forms of injury supports the importance of local Ang II in promoting fibrosis. A more detailed discussion of Ang II and tissue repair involving systemic organs can be found elsewhere.

A structural remodeling of the cardiovascularity by fibrous tissue accompanies aldosteronism derived from either endogenous or exogenous sources. This fibrogenic phenotype includes intramural arteries of the heart, kidney, pancreas, mesentery, and vasorum of the aorta and pulmonary artery. Cotreatment with a receptor antagonist (e.g., spironolactone, eplerenone), in either nondepressor or depressor dosage, prevents this remodeling, indicating its independence of elevations in blood pressure. In a substudy to the RALES trial, Zannad *et al.* found that a survival benefit was associated with a reduction in

circulating markers of collagen synthesis that presumably reflected an attenuation in ongoing vascular fibrosis. In this regard, urinary excretion of hydroxyproline, a marker of collagen turnover, is increased in adrenalectomized rats treated with ALDO, 1% dietary NaCl, and cortisone. Glucocorticoids, on the other hand, are known to reduce urinary hydroxyproline excretion and their inhibition of collagen formation in bone is associated with osteoporosis.

SUMMARY

The tRAAS serves to regulate local concentrations of various mediators of inflammation and tissue repair in the heart and other organs. MyoFb-bound ACE is integral to *de novo* generation of Ang II that modulates the expression of TGF- β_1 and whose autocrine/paracrine properties regulate collagen turnover in heart valve leaflets, in an exteriorized portion of the normal extracellular matrix, and at sites of fibrous tissue formation that appear in response to various forms of injury involving diverse tissues. Persistent myoFb and their ACE at the infarct site or diseased heart valve leaflets contribute to a sustained metabolic activity that can account for a progressive fibrosis at these sites. It is such adverse structural remodeling by fibrous tissue that eventuates in ischemic cardiomyopathy, a major etiologic factor in the appearance and progressive nature of chronic cardiac failure, or in heart valve deformity, a major cause of chronic circulatory failure.

Figure 1 Signal transduction in an autonomously functioning thyroid cell. The cAMP cascade is stimulated by the constitutively activated TSH receptor (or less frequently by the $G_{s\alpha}$ protein). cAMP stimulates thyroid function and growth, ultimately resulting in a phenotype of hyperthyroidism and goiter.

At this stage, serum levels of thyroid hormones are usually still normal but the TSH level is already reduced and the function in normal thyroid tissue is suppressed (subclinical hyperthyroidism). If this stage is passed by further autonomous growth and/or function, which causes an excess in the serum thyroid hormone level, thyrotoxicosis becomes clinically manifest (Fig. 2).

Over the past years, several European studies suggested that somatic activating TSH receptor mutations constitute the most frequent molecular cause

of toxic adenoma. An overall prevalence of ~50% was reported for somatic TSH receptor mutations, whereas mutations in the $G_{s\alpha}$ protein were found to occur in less than 10% of TA. Figure 3 shows a compilation of activating TSH receptor mutations identified in toxic adenoma. It should be noted that ~20% of TA are monoclonal but do not harbor a TSH receptor or a $G_{s\alpha}$ protein mutation, which suggests the presence of further, as yet unknown mutations in other genes.

CLINICAL FEATURES—DIAGNOSIS

Clinical features and presenting complaints in a patient with toxic adenoma can be attributed to (1) the nodule or, if present, a goiter and (2) symptoms of hyperthyroidism. Thus, a patient may present to the doctor because of a lump in the neck, intolerance of tight necklaces, or an increase in collar size. Moreover, mechanical symptoms such as difficulty in swallowing and, very rarely, difficulty in breathing due to local esophageal or tracheal compression by the nodule may be apparent. However, more often, the patient presents with features suggestive of hyperthyroidism, such as nervousness, hyperactivity, weight loss despite increased appetite, palpitations, tremor, and heat intolerance (Table I). Of note, these classical symptoms of hyperthyroidism are frequently absent in elderly patients with TA or TMG.

Figure 2 Development of thyroid autonomy. A thyroid cell with a somatic gain-of-function TSH receptor mutation has a growth and functional advantage over unaffected thyrocytes. The autonomous nodule increasingly contributes to the production of thyroid hormone by the thyroid independent of the TSH level, which in turn starts to decrease. If the nodule reaches a critical mass, thyrotoxicosis becomes clinically manifest, TSH levels become low, and surrounding tissue is suppressed. On scintiscan, the toxic adenoma appears as a “hot” nodule with suppression of surrounding thyroid tissue.

Figure 3 Full spectrum of TSH receptor mutations identified in toxic adenoma, toxic multinodular goiters, and patients with autosomal dominant nonautoimmune hyperthyroidism (information can be accessed from the TSH receptor database at <http://www.uni-leipzig.de/~innere/TSH>).

Table I Clinical Manifestations of Thyrotoxicosis

Complaints

- Nervousness
- Fatigue
- Increased perspiration
- Heat intolerance
- Tremor
- Hyperactivity
- Palpitation
- Appetite change (usually increase)
- Weight change (usually loss)
- Menstrual disturbances

Clinical features

- Hyperactivity
- Tachycardia/arrhythmia
- Systolic hypertension
- Warm, moist smooth skin
- Tremor
- Hyperreflexia
- Muscle weakness

Note. Classic features of hyperthyroidism are often absent in the elderly.

Diagnosis of a toxic adenoma is based on three characteristics: (1) Abnormal results are obtained on thyroid function tests. Typically, there is overt hyperthyroidism {suppressed TSH, elevated thyroid hormones [triiodothyronine (T3) and (T4)]}. However, dependent on the autonomous cell mass, TA can also be associated with subclinical hyperthyroidism (TSH suppressed, T3 and T4 normal) or may even be present in a still euthyroid patient (TSH normal, T3 and T4 normal). (2) A palpable and/or sonographically localized thyroid nodule is present. (3) There is increased radioiodine or ^{99m}Tc-pertechnetate uptake in the nodule concomitant with a decreased uptake in the surrounding extranodular thyroid tissue. This typical scintiscan finding of a TA has led to the notion of a “hot” nodule (Fig. 4). If a TA is suspected in a patient with euthyroid function, it is sometimes necessary to induce an artificial state of TSH suppression by administration of thyroid hormones. In this state, a “suppression” scan can be performed, in which all normal tissue, but not the autonomous tissue, will show decreased uptake of the

administration of excessive amounts of iodine, e.g., in form of contrast medium widely used for angiography or computer tomography scanning. Iodine-induced hyperthyroidism is a common problem in regions with iodine deficiency. Thereby, “iodine contamination,” which can be easily demonstrated by the elevated urinary iodine excretion, may even trigger the onset of a life-threatening thyroid storm.

Due to the somatic molecular defect, there is practically no spontaneous cure in toxic adenoma, which indicates that once the TA becomes clinically manifest, definite treatment is indicated. Importantly, ~97% of TA are benign thyroid lesions, so that patients can be confidently reassured about the “good nature” of the toxic nodule.

TREATMENT

The treatment of a toxic adenoma involves (1) symptomatic treatment of hyperthyroidism and (2) ablation of the autonomously functioning nodule.

The first step is to render a thyrotoxic patient euthyroid. This is achieved by the administration of so-called thyrostatic drugs, e.g., carbimazole, that inhibit thyroperoxidase, an enzyme essential for the production of thyroid hormones. Due to the long half-life of the predominantly produced thyroid hormone T₄ (7 days) and the intrathyroidal storage of large amounts of thyroid hormone, normalization of thyroid hormone levels usually takes several weeks. Frequent side effects of thyrostatic treatment are skin rashes (1–5%), whereas effects on the bone marrow (leukocytopenia or thrombocytopenia) constitute a rare (<0.5%) but potentially life-threatening complication (in the case of agranulocytosis), which requires immediate cessation of the thyrostatic drug.

Classical symptoms of hyperthyroidism, such as nervousness, sweating, tremor, and palpitations, are relieved faster and controlled by the additional administration of beta-blockers, preferably propranolol. Beta-blockers antagonize the autonomous sympathetic nervous system (and inhibit the peripheral conversion of T₄ to T₃), which is greatly stimulated by the excess of thyroid hormones.

Once euthyroidism has been achieved, ablation of the toxic adenoma can be achieved either by thyroid surgery, usually in form of a hemithyroidectomy, if it is a solitary nodule, or by ¹³¹I radioiodine therapy. The major advantage of thyroid surgery is that it immediately “cures” thyrotoxicosis; the obvious drawback is that it involves an invasive procedure with

potential side effects from anesthesia and/or thyroid surgery-specific complications, such as hypoparathyroidism and laryngeal nerve palsy.

In contrast, radioiodine treatment takes advantage of the characteristic feature of the “hot” nodule, i.e., increased iodine uptake. Thus, ¹³¹I is preferentially accumulated in the autonomous tissue, which is progressively destroyed by the ¹³¹I beta radiation. As a consequence, abrogation of hyperthyroidism by radioiodine therapy is a gradual process and may take several months, during which the patient requires further symptomatic treatment of hyperthyroidism.

As an alternative procedure, percutaneous ethanol injection of the toxic nodule has been employed and more than 200 patients with toxic nodules have been studied. The treatment usually involves three to eight ethanol injections into the nodule under ultrasound control. Studies from specialist centers have demonstrated that it is a cost-effective, reliable, and safe strategy if performed in experienced hands. Since there is only limited follow-up and evaluation in comparison with standard therapy of toxic adenoma, percutaneous ethanol injection is widely regarded as an alternative treatment for patients with contraindications to surgery or radioiodine therapy (e.g., old age, severe nonthyroidial illness, hemodialysis, pregnancy).

Thus, the clinician’s decision regarding the discussed treatment options for toxic adenoma will be based on several criteria, e.g., the patient’s age, the severity of hyperthyroidism, the size and structure of the thyroid gland, concomitant other medical conditions, and the patient’s personal preference.

Figure 1 Scintiscan of a patient with toxic multinodular goiter and subclinical hyperthyroidism. Note areas of increased uptake (arrows) in the right thyroid lobe and the isthmus region and decreased uptake in the surrounding thyroid tissue.

Diffuse goiters often undergo nodular transformation later in life and evolve into euthyroid multinodular goiter. If autonomously functioning nodules within these nontoxic multinodular goiters produce thyroid hormones in excess, the serum hormone level increases and causes thyrotoxicosis. Similar to solitary toxic thyroid adenomas, somatic mutations in the TSH receptor have also been detected in hot nodules of toxic multinodular goiters (see Fig. 4). Moreover, these mutations have also been identified in microscopic autonomously functioning areas of euthyroid goiters. Growth advantage as the result of an advantageous somatic mutation (e.g., in the TSH receptor or $G_{s\alpha}$ protein) appears in a single thyrocyte and induces monoclonal growth. Thus, a monoclonal origin has also been demonstrated in nodules within a toxic multinodular goiter. However, other nodules within

the same goiter appear to be polyclonal. As yet, their precise etiology is unknown but epigenetic, e.g., environmental, effects that cause a growth advantage in a number of cells simultaneously have been proposed to explain polyclonal thyroid nodules.

TOXIC MULTINODULAR GOITER VERSUS GRAVES' DISEASE

In iodine-deficient areas, the distinction between toxic autoimmune and nonautoimmune forms of hyperthyroidism (e.g., Graves' disease and toxic multinodular goiter) is often complicated by findings that do not correspond to typical diagnostic criteria. In this regard, several possibilities may be encountered. (1) The disorder may be incorrectly classified as

Figure 2 Hypothesis for the evolution of clonal thyroid nodules in multinodular goiters. Hyperplasia due to iodine shortage increases the likelihood for somatic mutations that may confer a growth and functional advantage. Further expansion of cell clones ultimately results in “hot” and “cold” nodules that characteristically prevail together in multinodular goiters. Modified with permission from Krohn, K., and Paschke, R., *J. Clin. Endocrinol. Metab.* **86**(7), 3336–3345, 2001, The Endocrine Society.

nonautoimmune hyperthyroidism due to the failure to detect TSH receptor antibodies (TRAB) with the routinely used *in vitro* assays (TBII assay). This is illustrated by the detection of TRAB with more sensitive cell culture assays in sera of hyperthyroid patients who show a scintiscan compatible with toxic multinodular goiters (e.g., Graves' disease superimposed on a preexisting nodular thyroid gland, which is prevalent in iodine-deficient regions) or in patients who show a scintiscan with diffuse uptake and have no other clinical signs of Graves disease (termed “diffuse” autonomy). (2) Nonautoimmune hyperthyroidism occurring as the result of TSH receptor germline mutations without detectable TSH receptor antibodies might clinically masquerade as Graves' disease.

AUTOSOMAL-DOMINANT NONAUTOIMMUNE HYPERTHYROIDISM AS A RARE FORM OF TOXIC MULTINODULAR GOITER

Unusually, in some patients there may be a family history of thyroid autonomy and a characteristic course of frequent relapses of hyperthyroidism following thyrostatic therapy or partial thyroidectomy. Depending on the age of onset (neonatal period

to adulthood), these patients may present with a diffusely enlarged goiter or a TMG. The underlying cause of this condition is an activating germline mutation in the TSH receptor gene, which can be confirmed through molecular analysis from leukocyte DNA extracted from a routine blood sample. Patients with an activating TSH receptor germline mutation require ablative thyroid treatment in the form of a total thyroidectomy and sometimes in addition an ablative dose of radioiodine to prevent further relapses. Genetic counseling is also mandatory as the condition is autosomal dominantly inherited.

CLINICAL FEATURES AND DIAGNOSIS

The diagnosis of TMG may be suggested by clinical inspection, thyroid palpation, or ultrasound examination. Generally, toxic multinodular goiter is seen more often in the elderly. In this patient group, the clinical features of hyperthyroidism are often not apparent to the clinician; i.e., often the main concern for consultation is that of weight loss and worry about cancer, and tremor, sweating, and hyperkinesia are absent. The presence of atrial fibrillation and congestive heart failure in the presence of a nodular goiter should alert the clinician to the diagnosis, especially

when there is accompanying weight loss. Biochemical diagnosis of hyperthyroidism is achieved with standard thyroid function tests.

Examination of the goiter and neck structures reveals the degree of enlargement and multinodularity of the gland as does ultrasonography. Imaging by scintiscan indicates which nodules are functional and helps to ascertain the extent of possible retrosternal extension of the goiter. Fine-needle aspiration cytology should be performed on prominent cold nodules within a TMG.

TREATMENT

The management of patients with TMG will to some extent depend on the age of the patient, the severity of hyperthyroidism, the size of the thyroid gland, the presence of additional nonfunctioning thyroid nodules, and the coexistence of other medical illness. The first requirement must involve measures to render the patient euthyroid as well as arrange for treatment of a multinodular goiter that may be large and compressive. There is controversy as to whether treatment for the subclinical hyperthyroidism in such patients is indicated. There is evidence, however, that bone mineral density is reduced in postmenopausal women with TMG and there is also an increased risk of atrial fibrillation. In these situations, anti-thyroid treatment

is beneficial although the effect on bone density has yet to be established.

Therapy for the toxic nodular goiter patient is either by radioiodine (^{131}I) administration or by surgical resection of the gland (see Fig. 3). If the patient is hyperthyroid, appropriate anti-thyroid drug therapy must be given so that euthyroidism is present prior to operation. If heart failure is present, this can be managed with standard therapy, including anticoagulants if atrial fibrillation is present.

Surgical treatment is indicated for large goiters with or without compressive features especially in the younger age group. A hemithyroidectomy, subtotal thyroidectomy, or near-total thyroidectomy may be performed depending on the extent of disease as assessed preoperatively and at surgery. Relative contraindications to surgery include advanced age and general ill health. Following surgery, recurrent hyperthyroidism will occur in less than 10–20% of patients but hypothyroidism will be seen in up to 70% of patients, depending on the extent of surgery. Potential long-term complications of surgery include hypocalcemia due to hypoparathyroidism or hoarseness due to laryngeal nerve lesion, both of which are rare ($\leq 1\%$) if the operation is performed by an experienced thyroid surgeon.

Radioiodine therapy is effective in terms of both eradicating hyperthyroidism and reducing thyroid

Figure 3 Clinical features influencing the treatment strategy of toxic adenomas and toxic multinodular goiters.

gland volume. Usually, anti-thyroid drugs must be given before and after ^{131}I therapy (generally for weeks up to few months) to ensure euthyroidism. Postradioiodine hypothyroidism occurs in approximately 31% of patients after an 8-year follow-up period and must be checked for on a regular basis because it evolves gradually.

A review of 253 patients with toxic multinodular goiter treated at the Mayo Clinic over a period of 18 years showed that both surgery and ^{131}I treatment are effective for this condition. Surgery was effective sooner, thereby minimizing cardiac effects of coexisting tachycardia. The surgical approach also rarely required re-treatment and did remove any coexisting malignancy. ^{131}I was associated with a 20% requirement for a second treatment. Posttreatment hypothyroidism was higher in the surgical group but this can be readily treated by oral L-thyroxine administration.

The long-term management of patients with toxic multinodular goiter is directed at the detection of thyroid dysfunction (hypothyroidism or a relapse of the hyperthyroid state), relapse of goiter, and treatment of surgical complications, e.g., calcium administration in the case of hypoparathyroidism. After surgery, thyroxine is often administered routinely, independent of thyroid function, although there is no evidence to suggest that this is beneficial unless the patient is hypothyroid. Follow-up of patients with toxic multinodular goiter (as well as other forms of thyroid disease) should be performed on a routine basis by experienced doctors or thyroid specialists.

composed of exons 1 to 6, variant I is composed of exons 1 to 5 and 6B, and variant II is composed of exons 1 to 5, α , and 6B. The main transcript (NCBI accession no. NM_003236) is observed at approximately 4.5 to 4.8 kb. Poorly characterized shorter transcripts of 1.6 and 0.35 kb have been reported in some cultured cell lines, but their importance is unclear. The half-life of TGF- α mRNA varies widely and can be decreased or increased, for example, by the von Hippel-Lindau tumor suppressor in the 786-0 renal cell carcinoma line or by autoinduction in keratinocytes, respectively. In adult tissues, TGF- α mRNA is present in numerous cell types of endodermal, ectodermal, and mesodermal origin. Expression is highly variable and inducible, for example, in the nervous system following damage. Similarly, expression is induced during inflammation and repair in activated fibroblasts, macrophages, monocytes and neutrophils, and eosinophils. The role of TGF- α in various tissues is discussed in more detail later. TGF- α is also expressed during embryonic development in numerous tissues, including lung, liver, digestive tract, testis, ovary, mammary gland, and several areas of the central nervous system (CNS). Finally, TGF- α expression is up-regulated in several disease states, including multiple types of carcinoma, psoriasis, cystic fibrosis, idiopathic pulmonary fibrosis, palmar fibromatosis, and Menetrier's disease of the gastric mucosa.

Maturation

Precursor

Although soluble human TGF- α is a 50-amino acid polypeptide, it is synthesized as a 160-amino acid, 18-kDa, type 1 membrane protein termed pro-TGF- α (Fig. 1). The N-terminal 99-amino acid region of the precursor undergoes heterogeneous N- and O-linked glycosylation, raising the apparent size to 20 to 22 kDa. N-linked glycosylation is required for maturation in some, but not all, cell types. This structural heterogeneity is observed in the soluble TGF- α , which varies in apparent size from 6 to 20 kDa. In addition to glycosylation and disulfide bridge formation, pro-TGF- α is covalently modified by palmitoylation (C16:0) of two cysteine residues (153 and 154) located near the C terminus.

Secretory Pathway

The C terminus of wild-type pro-TGF- α contains a class I PDZ-binding motif (TVV), which is required for export from the endoplasmic reticulum. Therefore, different export signals may operate for the C-terminal splice variants, both of which are also expressed on the cell surface. Early in the export

Figure 1 Human TGF- α polypeptides. The cytoplasmic domain of pro-TGF- α (residues 125–160) contains a putative basolateral sorting motif (dileucine 146 and 147), the palmitoylation sites (dicysteine 153 and 154), and a C-terminal type I PDZ-binding motif (residues 158–160) that are required for export from the endoplasmic reticulum. The schematics of human TGF- α , based on the annotation in the SwissProt database entry TGFA_HUMAN, illustrate the various forms arising during maturation, including the N-terminal signal peptide (residues 1–23, vertical lines), propeptide (residues 24–39), EGF-like domain (residues 40–89, solid), and transmembrane region (residues 99–124, hatched lines). One consensus N-linked glycosylation site exists at Asn(25) in the propeptide. Sizes to the right of each form are apparent values in kilodaltons reported for various cell types using gel electrophoresis.

pathway, the C terminus of wild-type pro-TGF- α binds a protein termed TACIP18 (pro-TGF- α cytoplasmic domain-interacting protein 18). This protein is also known by several other names, including mda-9 (melanoma differentiation-associated gene-9) and SNTA1 (syntenin 1) or SDCBP (syndecan-binding protein) because it binds syndecans among several other proteins as well as the lipid phosphatidylinositol(4,5)bisphosphate. The interaction with pro-TGF- α appears to require both PDZ domains in TACIP18, although the role of this multifunctional protein in pro-TGF- α trafficking remains to be elucidated. A cytoplasmic protein with two PDZ domains, termed p59, also binds the C-terminal residues of pro-TGF- α , although the N-terminal PDZ domain of p59 alone is sufficient for binding. This protein is the human orthologue of the murine GRASP55 protein, which has been implicated in the assembly and stacking of

intermediate Golgi cisternae. As with TACIP18/syntaxin 1, it remains to be shown whether or not p59/GRASP55 is involved in the trafficking of pro-TGF- α through the early Golgi compartment and what its function is in this process. On leaving the Golgi compartment, pro-TGF- α , like its receptor, is sorted to the basolateral surface in polarized epithelial cells. Targeting appears to employ more than one intrinsic sorting signal in the cytoplasmic region, but the C-terminal PDZ-binding motif is not required.

Proteolysis–Ectodomain Shedding

At the cell surface, mature TGF- α is released from pro-TGF- α by proteolysis (Fig. 1). Proteolytic release of extracellular domains is a feature of many different cell surface proteins and is generically termed ectodomain shedding. The soluble TGF- α released from the cell surface can stimulate either the host cell (autocrine) or proximal cells (paracrine). Although the relative rates of proteolysis at the N- and C-terminal sites can vary, current genetic and biochemical data indicate that the tumor necrosis factor- α -converting enzyme (TACE), also known as ADAM17 (a disintegrin and metalloprotease 17), is responsible for both events. The rate of proteolysis is increased via intracellular protein kinase C and mitogen-activated protein (MAP) kinase signaling pathways induced by a variety of factors, including phorbol esters, growth factors, serum, and retroviral transformation. In contrast, overexpression of the tetraspanin protein CD9, which binds the ectodomain of pro-TGF- α , inhibits the increase in shedding in response to phorbol esters or serum. However, the recent identification of a complex containing CD9, pro-heparin-binding (HB)-EGF, and the HB-EGF shedding protease ADAM10 suggests the possibility that CD9 overexpression may artifactually disrupt pro-TGF- α proteolysis. In gastric juice, the seven C-terminal residues of TGF- α are removed by pepsin to produce TGF- α (1–43), thereby reducing its biological activity by more than 50%.

Structure

The three-dimensional structure of the mature TGF- α polypeptide has been determined in a solution using nuclear magnetic resonance spectroscopy. The crystal structure of TGF- α bound to its receptor is described later. TGF- α belongs to the type I subset (InterPro IPR006210) of the large family of EGF-like domains (InterPro IPR006209). The solution structure possesses the set of three disulfide bonds, which link cysteine residues 8–21, 16–32, and 34–43, and two pairs of antiparallel β -sheets (composed of residues 19–33 and 38–46) that characterize EGF-like domains.

Receptor

At the cell surface, the EGF receptor (also termed HER or ErbB) family binds TGF- α . The EGF receptor (HER1 or ErbB1), as either a homo- or heterodimer with other members of the family, binds TGF- α with the highest affinity (low nanomolar range), similar to its affinity for six other structurally similar ligands: EGF, HB-EGF, amphiregulin, betacellulin, epiregulin, and epigen. TGF- α appears to bind certain other members of the EGF receptor family, but the affinity is several orders of magnitude lower. High-affinity binding by the EGF receptor can be inhibited in trans, termed transmodulation (e.g., via agonists that stimulate protein kinase C activity).

Expression

The EGF receptor is ubiquitously expressed on adherent cell types, but with the exception of certain early progenitors, it is absent from most hemopoietic cells. The levels of receptor expression vary widely among cell types, during development, and in several disease states such as psoriasis and multiple types of solid tumor.

Ligand Binding

Structure

The crystal structure of TGF- α bound to a soluble fragment of the EGF receptor comprising the N-terminal 501 residues has allowed resolution to 2.5 Å. More than one-third of the accessible surface area of TGF- α is buried on binding to the receptor, and nearly two-thirds of the amino acid residues of TGF- α make contact with the receptor. In the back-to-back, 2:2 (TGF- α :EGF receptor) complex, the TGF- α molecules are bound on opposite sides and separated by more than 70 Å. Binding appears to stabilize the structure of TGF- α relative to the form in free solution; a short third β -strand is generated (residues 4–6) as part of the principal β -sheet formed by residues 19 to 33 and the C terminus becomes more ordered. Ligand binding stabilizes an active conformation of the receptor, which favors dimerization and in which allosteric inhibition of the intracellular protein tyrosine kinase domain by the extracellular region is relieved and the kinase activity is enhanced.

Pro-TGF- α as an EGF Receptor Ligand

Early studies gave rise to the conclusion that soluble mature TGF- α or pro-TGF- α can directly activate EGF receptors. Accordingly, the soluble form was

suggested to mediate autocrine and paracrine signaling, whereas the membrane precursor was suggested to stimulate EGF receptors located on neighboring cells, a mechanism termed juxtacrine signaling. In some studies, including inhibition of shedding by CD9, stimulation by pro-TGF- α was reported to be even more effective than that by soluble TGF- α . However recent studies have questioned this idea and indicated instead that although pro-TGF- α can bind the EGF receptor, this interaction does not lead to receptor signaling in the absence of shedding. Thus, although it is clear that pro-TGF- α binds to the EGF receptor, it remains unclear whether juxtacrine signaling by pro-TGF- α can occur in some cell-cell interactions or whether it only appears to exist and localized shedding at cell-cell contacts actually leads to signaling.

Intracellular Signaling

It has been suggested that pro-TGF- α itself may be able to act as a receptor and stimulate intracellular signals at the cell surface in response to a juxtacrine interaction with the EGF receptor. Although protein serine, threonine and tyrosine kinase activity, and proteins of 86 and 106 kDa associate with pro-TGF- α at the surface of Chinese hamster ovary (CHO) cells overexpressing pro-TGF- α , the identity of these proteins and whether or not they transduce signals from a pro-TGF- α -EGF receptor complex are unclear. A review of the multiple intracellular signaling pathways stimulated by the EGF receptor in various cell types is beyond the scope of this article, although a recent review is cited in the Further Reading section.

Internalization and Degradation

Although in many cellular assays, including receptor autophosphorylation, TGF- α and EGF produce very similar results, in some cases TGF- α and EGF have been found to possess differential potency. One suggestion as to why this should occur arises from the observation that TGF- α and EGF cause the EGF receptor to follow different internalization pathways. Whereas EGF causes signaling to be terminated by degradation of the ligand and receptor within the lysosomal compartment, TGF- α dissociates from the receptor at less acidic conditions, and this in turn causes a smaller amount of ligand and receptor degradation and allows a fraction of the internalized ligand and receptor to recycle back to the cell surface. However, in some cell types, TGF- α is degraded very efficiently by insulin-degrading enzyme (IDE) within the mildly acidic endosomal compartment.

PHYSIOLOGICAL FUNCTIONS IN HEALTH AND DISEASE

Much is derived from animal, particularly rodent, models and *in vitro* studies with cell lines. These are not always apparently consistent with *in vivo* results, and it is clear that growth and differentiation can differ among cell types and be fundamentally affected by the context in which they are analyzed. Furthermore, in transgenic mutant lines, compensatory activity by other EGF receptor ligands may affect phenotypic presentation.

Tissue Distribution

TGF- α and the EGF receptor are expressed in many developing and adult tissues, where TGF- α has been implicated in cell migration, growth, and differentiation. The physiological importance of TGF- α is equally pleiotropic, encompassing the organization, homeostasis, protection, and repair of several types of tissues. Notable among the targets of TGF- α are various epithelial cells, and often also associated mesenchymal cells, in the gastrointestinal tract, lung, liver, kidney, mammary gland, dermis, gonads, skeletal muscle, and nerve cells within the central and peripheral systems. Although TGF- α commonly acts via autocrine or paracrine signaling in solid tissues, it can also mediate paracrine signaling by activated macrophages, monocytes, neutrophils, and eosinophils. Many studies have taken advantage of murine strains containing either decreased or increased levels of TGF- α . A TGF- α -deficient line termed waved-1 (*wa-1*) carries a naturally occurring mutation that causes a 5- to 30-fold decrease in TGF- α expression. TGF- α knockout lines have also been engineered. In addition, various lines have been engineered to overexpress TGF- α under the control of a variety of promoters.

Cancer

TGF- α is a potent mitogen for many different types of epithelial and mesenchymal cells, whose transgenic overexpression under a variety of different nonspecific or tissue-specific promoters causes different types of hyperproliferative and preneoplastic lesions, including benign papillomas, adenomas, cysts, and fibroses. However, in most tissues, tumorigenesis is absent without secondary oncogenic factors such as treatment with chemical carcinogens, altered expression of *bona fide* cellular and viral oncogenes, and viral

infection (particularly hepatitis B and hepatitis C). Nonetheless, a few types of epithelial tumors have been reported as a consequence of transgenic TGF- α overexpression, notably hepatocellular carcinoma, mammary adenocarcinoma, pancreatic carcinoma, and coagulation gland carcinoma *in situ*. Increased expression of TGF- α has been reported in numerous primary epithelial tumors, including carcinomas of the liver, pancreas, breast, kidney, lung, epidermis, prostate, larynx, gallbladder, gastrointestinal tract, and ovary. In several studies, the importance of autocrine growth stimulation was suggested by increased EGF receptor expression, for example, in gastric and ovarian carcinomas. Furthermore, blocking autocrine stimulation with an anti-TGF- α antibody inhibits growth of primary ovarian cancer cells and the GEO colon carcinoma cell line. Finally, increasing or decreasing TGF- α expression by expression of sense or antisense cDNA increases or decreases the tumorigenicity of GEO cells, respectively. The level of TGF- α expression alone is not prognostic for most carcinomas, including breast, larynx, gallbladder, lung, and colon, but it is apparently indicative of longer, progression-free survival of ovarian carcinoma patients. Other factors must be considered before productive TGF- α signaling is assumed. For example, studies have shown that TACE, which is required for shedding a variety of growth factors such as TGF- α , is also required for tumorigenesis in a rodent model. Finally, TGF- α is chemotactic for vascular endothelial cells and promotes angiogenesis in experimental models. However, there is no direct evidence of an angiogenic role in primary tumors.

Role in Specific Tissues

Hemopoietic System

TGF- α plays a role in wound repair and is differentially secreted by granulocytes during inflammatory responses in many different tissues. Expression is induced in activated macrophages that are recovered, for example, from wound sites or that are stimulated in culture from which soluble TGF- α is released. Monocytes and neutrophils store TGF- α in poorly characterized cytoplasmic granules. Eosinophils constitutively produce TGF- α , and transcription is increased by treatment with the cytokines interleukin-3 (IL-3) and granulocyte-macrophage colony-stimulating factor (GM-CSF). However, secretion of soluble TGF- α is increased by GM-CSF but not by IL-3. Eosinophils are a major source of TGF- α at malignant sites in the oral epithelium. Finally, TGF- α is

expressed in bone marrow by progenitor cells in the myeloid lineage, consistent with the observation that progenitor cells within this lineage are the only hemopoietic cells to express the EGF receptor.

Gastrointestinal System

Many parts of the gastrointestinal tract synthesize TGF- α to enhance the epithelial cell migration and proliferation required to compensate for continual cell loss and to protect the integrity of the epithelium from lesions caused, for example, by low pH or oxidation. Consequently, transgenic overexpression of TGF- α causes foveolar hyperplasia, and TGF- α -knockout mice and overexpressing mice have an increased and decreased susceptibility, respectively, to experimentally induced colitis. Hyperplasia similar to that seen in transgenic mice and TGF- α overexpression by the gastric epithelium occur in Menetrier's disease, although the etiology of this condition is unknown. Although TGF- α stimulates cell division, migration, and prostaglandin estradiol (PGE₂) synthesis in gastric epithelial cells in culture, the protective effect against mucosal injury in rodent models appears to be mediated indirectly by stimulation of calcitonin gene-related peptide (CGRP) release from capsaicin-sensitive sensory neurons. TGF- α also inhibits stimulated secretion of gastric acid (e.g., by gastric mucosa treated with histamine) and of chloride ions (e.g., by intestinal epithelial cells treated with carbachol). The latter has been shown to occur by transactivation of the EGF receptor via increased shedding of TGF- α and subsequent autocrine signaling.

Lung

In the lung, TGF- α is expressed in different epithelial and mesenchymal cell types throughout fetal development and is likely to regulate growth and maturation. In the adult lung, TGF- α , arising also from alveolar macrophages, reduces acute damage caused, for example, by inhalation of noxious substances at least in part by attenuating inflammation. Transgenic overexpression of TGF- α by murine lung epithelial cells causes pulmonary fibrosis and remodeling, including enlarged airspaces, whereas TGF- α knockout mice exhibit reduced pulmonary fibrosis following chemical insult.

Liver

Most studies on the role of TGF- α in the liver have focused on neoplasia and regeneration. The level of TGF- α mRNA increases after partial hepatectomy, and the level of TGF- α in the serum correlates with the degree of regeneration. In animal models,

autocrine mitogenic stimulation arises from expression induced in hepatocytes. In fetal liver, TGF- α is expressed by bile ducts and hepatocytes, whereas in adults, the expression of TGF- α , but not the EGF receptor, is lost in hepatocytes. The mitogenic action of bile acids toward bile duct cholangiocytes arises from a stimulation of TGF- α ectodomain shedding. Constitutive expression of TGF- α in transgenic mice leads to increased hepatocyte proliferation, liver enlargement, and neoplasia. In addition to its mitogenic activity, TGF- α has been shown to possess antiapoptotic activity by virtue of its ability to inhibit Fas-mediated hepatic apoptosis.

Kidney

Expression of TGF- α in the fetal and adult kidney is detectable but low. Expression in rodents has been reported to be complicated by antibody cross-reactivity and to be localized to the proximal tubules of the adult renal cortex. Transgenic overexpression of TGF- α in the kidney causes renal enlargement, glomerular mesangial expansion, and cyst formation. Furthermore, early-stage lesions in adult polycystic kidney disease are positive for a proximal tubule marker protein and display increased levels of TGF- α , although end-stage cysts show markers for different tubule regions.

Mammary Tissue

TGF- α is expressed in mammary epithelial cells and plays a role in mammary development and lactation. Overexpression of TGF- α in mice causes abnormal duct morphology and hyperplasia and can lead to failure of lactation and mammary adenocarcinoma formation. In regard to lactation itself, the production of whey acidic protein (WAP) by rodent mammary epithelial cells is inhibited by TGF- α produced when the alveolar extracellular matrix is disrupted. TGF- α is present in milk, but at a much lower concentration than is EGF. Transgenic overexpression of TGF- α in mammary epithelia under the WAP promoter restricts high-level expression to pregnancy and lactation and increases the incidence of preneoplastic and neoplastic lesions with strain-dependent penetrance.

Reproductive Organs

In human oocytes the level of TGF- α is greatest in primordial follicles, but expression by theca and granulosa cells increases with development, reaching a maximum at the lutein cell stage of the mid-luteal phase. Expression by rodent theca cells is indirectly enhanced by follicle-stimulating hormone (FSH) via increased estradiol synthesis by granulosa cells.

TGF- α overexpression in a murine transgenic line attenuates the action of gonadotropins on ovarian steroidogenesis, although in the brain an opposing mechanism, possibly acting on hypothalamic release of luteinizing hormone-releasing hormone (LHRH), enhances female sexual maturation. In the latter example, the action of TGF- α on hypothalamic astrocytes is proposed to stimulate PGE₂ release by glial cells, followed in turn by LHRH release by neurons in response to PGE₂ stimulation. In the testes, expression is strongest in Leydig cells, and weak expression has been reported in other cell types, although the testes appear normal in TGF- α null mice.

Skin

TGF- α is produced by embryonic epidermal layers and in the adult stratified epidermis. It stimulates keratinocyte migration *in vitro*, and an autocrine pathway induces gene expression of TGF- α and other EGF receptor ligands, although the increased level of TGF- α mRNA is more stable and persists far longer than do the amphiregulin and HB-EGF transcripts. The level of TGF- α in cutaneous exudates increases after damage caused by abrasion or ultraviolet irradiation, consistent with an autocrine role in wound repair. The phenotypes of mice overexpressing TGF- α under the control of a keratin K14 or K1 promoter suggest a developmental role for TGF- α in controlling epidermal growth, with overexpression causing increased epidermal thickness in some areas of skin or wrinkling, respectively. TGF- α -deficient mice develop abnormal external and middle ear epidermal morphology, deranged hair follicles causing curly whiskers and wavy fur, and prematurely opened eyes at birth. A similar phenotype occurs in wavy-2 mice, which carry a mutant EGF receptor gene, and is exacerbated by TACE deficiency. In studies using primary tissue from psoriasis patients, the level of TGF- α was increased in all layers of the epidermis relative to nonpsoriatic skin, although mRNA was increased only in the subcorneal layers. Finally, although several previous studies found no evidence of linkage, when considered as a single group, different mutations located in conserved regions of the 3' UTR of the human TGF- α gene show a weak link with nonsyndromic cleft lip with or without cleft palate and nonsyndromic cleft palate only.

Muscle

Smooth muscle cells in several different types of embryonic and adult tissue have been shown to express TGF- α . Early reports suggested that TGF- α affects contractility in addition to its mitogenic action on

myocytes. Transgenic overexpression of TGF- α leads to a decrease in skeletal muscle mass, and a role in the early differentiation of myoblasts and in pyloric muscle hypertrophy also has been proposed.

Nervous System

TGF- α is widely expressed in numerous different neuronal and glial cells of the CNS as well as in the peripheral nervous system, where it has roles in growth, development, and repair. For example, TGF- α regulates the proliferation of neural stem cells in the forebrain subependyma and is also a tropic factor for cultured mesencephalic dopaminergic neurons, which are severely depleted from the substantia nigra in TGF- α null mice. TGF- α regulates the differentiation of cultured retinal precursor cells. A role in neuronal damage and repair is indicated by the ability of TGF- α to indirectly reduce damage caused by neuronal excitotoxicity via glial cell stimulation and by the rapid and transient up-regulation of TGF- α expression by motor neurons following nerve crush in rodents. Mutation of the TGF- α open reading frame has been excluded from Alström syndrome and autosomal dominant Parkinson's disease, although the latter is linked to chromosome 2p13.

Several roles for TGF- α in controlling behavior have been reported using rodent models. Transgenic male mice overexpressing TGF- α are more aggressive and less able to cope with stress, although transgenic females display the opposite phenotype relative to nontransgenic individuals. An endocrine link is suggested by the observation that the aggressive behavior of males is lost following castration. Intriguingly, TGF- α exhibits rhythmic expression in the supra-chiasmatic nucleus (SCN) of the hypothalamus, where it appears to inhibit daily cycles of locomotor activity by paracrine stimulation of proximal neurons in the subparaventricular zone.

Endocrine Glands

In addition to the endocrine tissues already mentioned, TGF- α is synthesized by the anterior pituitary, thyroid, parathyroid, adrenal cortex and medulla, and pancreas. In the pituitary gland, TGF- α synthesized locally mediates the mitogenic activity of estrogen *visa paracrine* signaling, but much remains to be understood regarding the physiological role of TGF- α in the other endocrine glands.

Figure 1 Molecular structure of trichlormethiazide. Note the common thiazide backbone of 1,2,4-benzothiadiazine-1,1-dioxide, with additional radicals, including a CHCl_2 group at position R3 and a Cl at R6.

This increases the stability and duration of action to approximately 24 h, with a relative oral natriuretic maximal response in human of approximately 2.1-fold above chlorothiazide at a dose of 1–4 mg/day and an equieffective intravenous chloruretic response of 0.01 mg/kg in the dog.

BIOAVAILABILITY, PHARMACODYNAMICS, AND DOSAGE

Whereas chlorothiazide is poorly absorbed in the gastrointestinal tract, the uptake of other thiazides is more efficient, with a diuretic response occurring within 1 h of administration. The plasma half-life of thiazides ranges from 6 to 44 h, with TCMZ displaying a duration of action of approximately 24 h. Uptake of thiazides into erythrocytes, where they likely bind to carbonic anhydrase, may slow plasma clearance. The recommended dosage of TCMZ is 1 to 4 mg/day, with initial doses given twice daily. The onset of diuretic action is usually seen at 2 h, with the maximum effect at 4 h. Antihypertensive effects are long-lasting, requiring as with most other thiazides only one dose per day. Such a response is probably related to natriuresis and not to diuretic potency, since equivalent doses of loop diuretics have weaker antihypertensive activity. The reason may be traced to the fact that thiazide-induced natriuresis is persistent for several hours, thus resulting in efficient control of Na^+ balance in hypertensive subjects. In contrast, loop diuretics with a shorter duration of action promote greater natriuresis for 6 to 8 h (up to 20–25% of the filtered load of Na^+); thereafter, they paradoxically enhance Na^+ reabsorption by a mechanism involving volume depletion and stimulation of the renin–angiotensin–aldosterone system through the remainder of the day. This often

results in a net positive Na^+ balance over time, if repeated doses are not given and the patient is not placed on a Na^+ -restricted diet.

Another interesting feature of TCMZ and other thiazides is that since their site of action is distal to that of furosemide and other loop diuretics, chronic treatment does not induce the compensatory adjustments that tend to offset their efficacy by inducing hypertrophy of distal tubular Na^+ transporters. This translates into distal reuptake of Na^+ and Cl^- ions that have escaped reabsorption in the thick ascending loop of Henle. This is indeed the rationale for combination therapy employing a loop diuretic in conjunction with a thiazide or K^+ -sparing agent to potentiate the diuretic response in massively edematous patients.

Dose reduction may be appropriate for TCMZ in chronic renal failure, although a substantial lack of activity is common for thiazides in such a setting.

SIDE EFFECTS AND TOXICITY

TCMZ (LD_{50} orally in rats: >20,000 mg/kg) shares with other thiazides a number of minor side effects, seldom requiring withdrawal of therapy. These side effects include hypokalemia with metabolic alkalosis (linked to volume depletion), hyperuricemia (also resulting from volume contraction with enhanced urate reabsorption), and hypotension (particularly if the patient is aggressively diuresed through combination treatment with loop agents or is concurrently treated with other antihypertensives). Rarely, volume depletion is such that prerenal azotemia may occur, which is usually reversible on rehydration and/or volume expansion. Most of these effects are seen within the first few weeks of treatment, so that prolonged surveillance of serum K^+ or urate levels is usually not needed if the patient has not experienced major side effects from the outset. Thiazides may also promote hypercalcemia, hypophosphatemia, hyponatremia, and hypomagnesemia, with the last side effect resulting in dizziness, lethargy, confusion, and muscle weakness. TCMZ may impair glycemic control in diabetics, through a host of mechanisms involving impaired glyconeogenesis, reduced glycogenolysis, and possibly diminished insulin responsiveness to an oral glucose load. Thiazides also increase cholesterol and triglyceride levels in plasma, possibly enhancing atherosclerotic risk.

DRUG INTERACTIONS

Hypotension may occur when TCMZ is associated with angiotensin-converting enzyme (ACE) inhibitors. Beta-blockers may increase hyperglycemia in type II

diabetes mellitus. Bile acid-binding resins are known to impair gastrointestinal absorption of thiazides. Nonsteroidal anti-inflammatory drugs antagonize diuretic potency and the antihypertensive effects of thiazides, likely by blocking the natriuretic activity of endogenous prostanoids. As a matter of fact, this interaction is not unique to thiazides, but rather applies to most antihypertensive agents. Lithium toxicity may result from impaired lithium excretion during concurrent therapy. Cyclosporin toxicity and the risk of gout are increased by thiazides, so that concurrent therapy should possibly be avoided.

CLINICAL USE

TCMZ [Achletin (Toyama); Anatron (Tobishi); Anis-tadin (Maruko); Aponorin (Kodama); Carvacron (Taiyo); Diurese (American Urologicals); Esmarin (Merck); Fluitran (Shionogi); Flutra (Schering); Intromene (Teikoku); Kubacron (Kayaku); Metahydrin (Merrell Dow); Naqua (Schering); Salurin (Syntex); Tachionin (Sana); Tolcasone (Rhone-Poulenc Rorer); Triflumen (Serono)] has been extensively used for the treatment of hypertension and edematous states. Its efficacy has been validated by a number of clinical trials, in which it was compared with other diuretics, calcium channel blockers, beta-blockers, ACE inhibitors, and other drugs. All studies confirm a mild but significant antihypertensive efficacy, although combination treatment is often necessary, with the exception of some subsets of hypertensives, such as African Americans or volume-expanded individuals, who show brisk responses to thiazide therapy. The latter concept has been highlighted by several trials that emphasized the cost-to-benefit ratio of thiazides as first-line agents in antihypertensive therapy compared to the much more expensive drugs that have been introduced. However, a major limitation to the use of TCMZ and other thiazides is renal insufficiency, in which reduced filtration and tubular delivery impair activity in NaCl transport, markedly diminishing their clinical effectiveness.

Another area of interest in the use of TCMZ and related compounds is the prevention of recurrent nephrolithiasis, with particular emphasis on calcium oxalate stones. The agent has been shown to markedly reduce calciuria in patients with primary or secondary hypercalciuria, thus effectively reducing the recurrence of stones. The mechanism of action involves the enhanced uptake of Ca^{2+} by distal tubular cells once they become hyperpolarized by intracellular Cl^- depletion.

An uncommon but useful indication of thiazide diuretics is symptomatic treatment of polyuria in

nephrogenic diabetes insipidus, either the X-linked or the autosomal-recessive form. Here, TCMZ and other thiazides have been shown to reduce the free water clearance by diminishing the volume delivered to the distal tubule. Natriuresis appears once again to be responsible, by reducing plasma volume and enhancing proximal tubular reabsorption of salt and water, thus decreasing the flow through the distal nephron.

THYROID FUNCTION IN THE FETUS AND INFANT

Fetal Thyroid Physiology

During the first 8 to 16 weeks of gestation, the human fetal thyroid synthesizes only minute amounts of thyroxine (T_4) and triiodothyronine (T_3). There is limited transfer of maternal T_4 and T_3 to fetal blood, and serum total T_4 and T_3 levels in the early gestational fetus are low. Although the relative placental barrier to thyroid hormone transfer is maintained throughout pregnancy, the transplacental passage of some thyroid hormone may preserve fetal central nervous system development and function in the infant with thyroid agenesis. After mid-gestation, fetal hypothalamic expression of TSH-releasing hormone (TRH) and the production of TSH and T_4 rise progressively to peak during the month prior to term. Total T_3 levels in fetal blood remain low until 26 to 30 weeks of gestation, reflecting the immaturity of type I deiodinase activity (which converts T_4 to T_3) and the high levels of type III deiodinase activity (which converts T_4 to the inactive reverse T_3 and converts T_3 to diiodothyronine) in fetal and placental extrathyroidal tissues. Type II deiodinase mediates the local production of T_3 from T_4 in selected fetal tissues such as the brain.

Neonatal Thyroid Physiology

At delivery, the sudden cool temperature stimulates a dramatic rise in plasma TSH during the first hour of life. The levels of TSH rise to a peak of more than $50 \mu\text{U/ml}$ at 30 min of age, stimulating a rise in serum total and free T_4 (FT_4) and T_3 (FT_3). In full-term infants with normal thyroid function, TSH levels are generally below $20 \mu\text{U/ml}$ at 24 h of age and are 1.3 to $16.0 \mu\text{U/ml}$ by 4 days of age. By 6 weeks of age, TSH concentrations approximate those of adults. In full-term infants, serum T_4 and FT_4 concentrations fall gradually during the subsequent 4 to 6 weeks, and serum T_3 levels rise gradually after the neonatal period to achieve mature levels by 2 to 12 weeks of age. By 6 months of age, the levels of T_4 and FT_4 remain slightly higher than those of older children and adults, and the circadian pattern of TSH secretion begins to appear. These observations suggest that hypothalamic-pituitary regulation of TSH secretion matures gradually until 6 weeks to 6 months of postnatal age.

Thyroid Function after Premature Birth

In preterm infants, the neonatal rise of TSH and the rise in T_4 , FT_4 , and FT_3 are blunted. By 4 days of age, TSH levels have declined to 0.8 to $6.9 \mu\text{U/ml}$. T_4 and FT_4 levels in preterm infants exceeding 30 to 32 weeks gestation increase progressively over the ensuing 4 to 8 weeks to values comparable to those of term infants. In contrast, levels of T_4 and FT_4 in very low-birthweight infants (less than 30 weeks or less than 1200–1500 g) decline progressively after day 1, reaching a nadir at 1 to 2 weeks of age. TSH is low at 5 to 7 days of age ($0.8 \mu\text{U/ml}$) and increases to $6.1 \mu\text{U/ml}$ at 5 weeks of age, paralleled by an increase in FT_4 and FT_3 . This relative hypothyroxinemia is most profound in those infants born most prematurely. In the majority of cases, serum TSH concentrations are not elevated.

TSH STRUCTURE AND GLYCOSYLATION

TRH has been shown to be necessary for TSH synthesis, posttranslational glycosylation, and secretion of a fully bioactive TSH molecule from the pituitary. TSH is composed of an α -subunit (identical to that of luteinizing hormone [LH], follicle-stimulating hormone [FSH], and human chorionic gonadotropin [hCG]) and a unique β -subunit. Both of these subunits undergo posttranslational glycosylation in response to TRH. The glycosylation patterns influence the bioactivity of the TSH molecule. There are two oligosaccharide chains on the α -subunit and one on the β -subunit. Highly sialated chains (as in recombinant TSH) have decreased bioactivity, decreased hepatic clearance, and longer half-life. Altered TSH glycosylation resulting in altered bioactivity is seen in the following:

1. Mixed hypothyroidism (central hypothyroidism with elevated TSH): oligosaccharide chains having increased mannose with decreased TSH bioactivity
2. Primary hypothyroidism: increased sialation, decreased TSH bioactivity, and elevated TSH levels
3. Resistance to thyroid hormone: increased galactose N-acetylglucosamine and increased TSH bioactivity
4. TSH-secreting pituitary adenomas: variable biological activity

5. Nonthyroidal illness: transient central hypothyroidism due to decreased TRH secretion, decreased TSH surge, and decreased TSH bioactivity

The TSH β -subunit gene was cloned in 1988, allowing research leading to production of recombinant TSH. Key domains of the β -subunit allowing ligand receptor interaction were identified, potentially permitting engineering of TSH molecules with increased bioactivity. Glycosylation patterns affect bioactivity; the endogenous TSH β -subunit has oligosaccharides with sialic acid and galactose, or sulfate and N-acetylgalactosamine, whereas recombinant TSH has sialated oligosaccharides only. For TSH to act, both the α - and β -subunits interact with the G protein-coupled receptor.

REGULATION OF TSH SYNTHESIS AND RELEASE

TSH-Releasing Hormone

Like GH, TSH is synthesized in anterior pituitary cells in response to a releasing hormone. TRH is secreted from the hypothalamus and transported to the pituitary via the venous portal system. Dopamine and somatostatin (both of which inhibit TSH release) are also transported from the hypothalamus. The TRH (G protein-coupled) receptor has been identified on pituitary cells and also in the central and peripheral nervous systems.

Circadian Variation in TSH Concentration

In persons of all ages after infancy (6 months), TSH secretion normally occurs in a circadian pattern with lower concentrations in the afternoon, a nocturnal surge beginning after 1900 h, and higher concentrations between 2200 and 0400 h. Peak TSH levels between 2200 and 0400 h are followed by a gradual decline between 0400 and 1000 h to nadir TSH values. Small frequent pulses occur as an overlay on this overall "sin wave"-shaped circadian pattern. Thus, at least one-third of the trophic influence of TSH on the thyroid gland occurs during the hours of sleep.

Despite the clear description of the daily pattern of TSH variation in the literature, the neuroendocrine influences that result in this circadian pattern have not yet been fully characterized. Factors regulating the timing and amplitude of the TSH surge may include an endogenous surge in hypothalamic TRH secretion at night, onset of sleep, and/or altered pituitary sensitivity to endogenous TRH. Substances that appear

to influence pituitary sensitivity to TRH include α -adrenergic stimuli, somatostatin, endogenous opiates, dopamine, cortisol, leptin, and GH concentrations.

TSH FUNCTION AT THE RECEPTOR

TSH Receptor Binding

TSH is secreted from the pituitary into the blood, stimulating synthesis and release of T_4 and T_3 from the thyroid gland as well as influencing uptake of iodine. Both subunits of TSH interact with the G protein-coupled cell membrane receptor to generate cyclic AMP (cAMP) within the cell. The TSH receptor has an extracellular glycosylated portion and an intracellular portion with a cytoplasmic "tail" involved in G protein coupling and signal transduction. Both portions undergo posttranslational processing, influencing receptor-binding affinity of TSH. Mature complex glycosylation of the extracellular portion is required for TSH binding; if there are only manose-type sugars, TSH binds with only low affinity.

Results of TSH Receptor Binding

TSH receptor binding leads to increased synthesis of iodothyronines and to their storage in thyroid colloid in association with thyroglobulin. TSH receptor binding also leads to increased release of fully formed T_4 and small amounts of T_3 from the colloid. Plasma T_4 and T_3 circulate in the serum bound to thyroid-binding globulin and albumin, with only small amounts that are "free" or unbound. FT_4 undergoes intracellular deiodination to FT_3 , which interacts with DNA to influence cellular mRNA and protein synthesis. Both T_4 and T_3 provide negative feedback at the hypothalamus and pituitary to modulate TRH and TSH secretion.

TSH Receptor Mutations

A TSH receptor mutation database has been established to allow easy access to the many identified TSH receptor mutations and their clinical consequences. At least 12 loss-of-function mutations have been found in patients with partial resistance to TSH or in rare cases of congenital hypothyroidism. A truncated TSH receptor with complete inactivation has been identified in infants with congenital hypothyroidism from an inbred kindred. Their thyroid glands were hypoplastic but not ectopic. Activating mutations of the TSH receptor in focal tissue may result in hyperfunctioning thyroid nodules or multinodular goiter. Expression of

the mutation in all thyroid tissue may result in thyrotoxicosis presenting during the neonatal period (and persisting beyond 6 months of age), late infancy, childhood, or adulthood.

ELEVATED TSH SECRETION

Primary Hypothyroidism

Congenital Hypothyroidism

Primary hypothyroidism (reduced function of the thyroid gland itself with low FT₄ and high TSH) is the most common form of hypothyroidism both in the general population and in cancer survivors. There is now universal screening for congenital primary hypothyroidism in the United States. American newborn screening programs measure either TSH or total T₄ by radioimmunoassay in blood spot samples obtained after 24 h of age. Hypothyroxinemia is defined as a total T₄ value below 90% of the samples screened on that day. Measurement of TSH in hypothyroxinemic infants identifies those with primary hypothyroidism. TSH values often exceed 50 to 100 μ U/ml in infants with thyroid agenesis and other forms of permanent primary hypothyroidism. TSH levels exceeding 16 to 20 μ U/ml between 24 and 96 h of age, or 5.0 to 7.7 μ U/ml between 1 and 12 months of age, may reflect primary thyroid dysfunction.

Hypothyroidism in Preterm Infants

It should be recognized that very low-birthweight infants are at an eightfold increased risk for the development of transient primary hypothyroidism with low T₄ levels and marked elevations in TSH. Transient primary hypothyroidism in preterm infants may, in some cases, be induced by transdermal absorption of iodine antiseptics. On the other hand, in iodine-deficient geographic regions, transient hypothyroidism is more likely related to insufficient iodine intake. Transient primary hypothyroidism may be accompanied by a delayed rise in TSH that is not detected until several weeks after birth; thus, a number of investigators now recommend rescreening very low-birthweight infants (<1500 g or <30 weeks gestation) at 2 to 6 weeks of age. The prevalence of permanent congenital primary hypothyroidism in preterm infants is comparable to that in term infants.

Acquired Primary Hypothyroidism

Primary hypothyroidism may be acquired after infancy and may represent a partially functioning ectopic or hypoplastic thyroid gland or be associated with thyroid peroxidase antibodies (as in Hashimoto's

thyroiditis). In acquired primary hypothyroidism, TSH may be as elevated as 1800 μ U/ml. The frequency of primary hypothyroidism is increased in chromosome abnormality syndromes such as Turner, Klinefelter, and Down syndromes. Most patients with mildly elevated TSH concentrations have been considered to have mild or "compensated" hypothyroidism. However, mild primary hypothyroidism has potential clinical importance given that children with mild TSH elevation and T₄ levels within normal limits typically grow less well than do other children. In addition to slow growth, mild hypothyroidism causes fatigue, dry skin, constipation, increased sleep requirement, and cold intolerance. Thyroid replacement therapy in mild hypothyroidism improves growth velocity, lipid profile, and energy level.

Primary Hypothyroidism after Cancer

Primary hypothyroidism (with TSH elevation) is most likely to occur in patients who have received mantle irradiation for Hodgkin's disease, craniospinal radiation for medulloblastoma, or total body irradiation prior to bone marrow transplantation. Primary hypothyroidism is rarely isolated in cancer survivors, who may also have GH deficiency, adrenocorticotrophic hormone (ACTH) deficiency, and/or pubertal disorders.

Thyroid Hormone Resistance and TSH-Secreting Adenoma

In thyroid hormone resistance and TSH-secreting adenoma, TSH is measurable (inappropriately) in the presence of elevated T₄ and elevated FT₄. In resistance, this biochemical picture is associated with few or no symptoms of hyperthyroidism. Patients may be euthyroid or even hypothyroid. In contrast, in TSH-secreting adenomas, patients are clinically hyperthyroid. Pituitary TSH-secreting adenomas are uncommon in general and are particularly rare in the pediatric age group.

DEPRESSED TSH SECRETION

Hyperthyroidism

Low serum TSH concentration is an appropriate response to excessive thyroid hormone levels resulting from either endogenous or exogenous source. Graves' hyperthyroidism is a result of antibodies to the TSH receptor binding in a manner that activates the intracellular G protein signaling pathway as if TSH were binding at the receptor. Hyperthyroidism in

McCune–Albright syndrome is an example of a chronically activated G protein pathway.

Central Hypothyroidism

Reduced TSH Surge

A blunted or absent nocturnal TSH surge is a characteristic of central hypothyroidism, suggesting a loss of the normal circadian variation in TRH (and thus a reduction in total TSH release) and loss of one-third to one-half of the daily trophic stimulus to the thyroid gland. In central hypothyroidism, FT₄ is low or in the lowest third of the normal range, with a normal daytime TSH. Measurement of the nocturnal TSH surge has improved sensitivity for detection of central hypothyroidism compared with the TRH test.

Low-Normal T₄ and FT₄

Many patients with central hypothyroidism maintain normal daytime TSH concentrations and iodothyronine concentrations that are just below the normal range or in the lowest third of the normal range. These patients remain clinically puzzling and, therefore, are often not treated with thyroid replacement medication. Failure to recognize and treat central hypothyroidism can result in poor growth in children and in a less than optimal state of health in children and adults. Subtle hypothyroidism may be associated with depression and mild hyperlipidemia.

A Cause of Short Stature

In children referred to endocrinology for evaluation of apparent idiopathic short stature, approximately 13% had isolated central hypothyroidism (a blunted TSH surge associated with low or low-normal FT₄ in the absence of any other pituitary hormone disturbance). The incidence was 33% of children with height shorter than -2 SD who had an FT₄ in the lowest third of the normal range. Growth velocity significantly improved in children during treatment with levothyroxine compared with that in children who had a normal TSH surge and who were otherwise clinically similar. Children with known hypopituitarism also show blunting of the nocturnal TSH surge. In these conditions, delayed TSH response to TRH is not always observed.

Thyroid Function after Head Injury

Disturbances in thyroid function are commonly observed in head-injured patients, including low T₃ and low T₄, usually with a normal level of TSH. Reverse T₃ is often elevated. Thyroid axis injury may still be

quite difficult to identify in newly injured patients because of the prolonged half-life of T₄ (7 days).

Central Hypothyroidism after Cancer

TRH testing in children after radiotherapy suggests that hypopituitarism is more common than was suspected previously. Central hypothyroidism is recognized in as many as 65% of patients after brain tumor or nasopharyngeal tumor, in more than 35% after bone marrow transplant, and in as many as 15% after leukemia, suggesting that central hypothyroidism (hypothalamic–pituitary–thyroid dysregulation) may be quite common in cancer survivors. In contrast, primary hypothyroidism occurs most commonly after total body radiation or radiation to the nasopharynx, neck, or spine. Central and mixed hypothyroidism both occur in patients after radiation to the head and include brain tumors, nasopharyngeal tumors, and total body radiation. Chemotherapy alone can cause primary or central hypothyroidism, but the frequency of this occurrence is much less than that after radiotherapy. If TSH secretion is not tested until GH deficiency becomes apparent, the diagnosis of hypothyroidism may be delayed in approximately one-third of patients.

Central Hypothyroidism in Adults

Central hypothyroidism can be quite difficult to recognize in adults where slowed growth rate is not available as a sign. Symptoms of central hypothyroidism (e.g., asthenia, edema, drowsiness, adynamia, skin dryness) may be of gradual onset and be unrecognized until therapy is begun and the patient feels better.

Mixed Hypothyroidism

Mixed hypothyroidism consists of central hypothyroidism with TSH elevation. It has been described in survivors of childhood cancer and in women with Sheehan syndrome (postpartum pituitary necrosis). With reduced TRH from the hypothalamus, TSH may be abnormally glycosylated and of lower biological activity. Thus, mild elevation of serum TSH concentrations (5–14 mU/L) may be seen in central hypothyroidism; the differentiation from primary hypothyroidism can be made by documentation of a blunted or absent TSH surge. In Sheehan syndrome patients, elevated 24-h TSH was observed with blunting of the TSH surge, suggesting dysregulated release of biologically inactive TSH.

Mixed hypothyroidism may reflect either separate injuries to the thyroid gland and hypothalamus (e.g.,

radiation injury of both structures) or central hypothyroidism in which the biological activity of the secreted TSH is reduced. Using baseline FT₄ and TSH alone, 92% of those with central hypothyroidism and 27% of those with mixed hypothyroidism may remain undiagnosed.

DIAGNOSIS OF HYPOTHYROIDISM

Individual Set Point for TSH and FT₄

FT₄ is currently the best measure of thyroid status along with serum TSH. FT₄ remains fairly stable in an individual over the years at an optimal “set point” for thyroid function. If FT₄ production from an injured thyroid gland declines (as in mild primary hypothyroidism), the intact pituitary secretes more TSH. Thus, in primary hypothyroidism, a serum sample for TSH at 0800 h is the best test. In contrast, in central hypothyroidism, hypothalamic–pituitary release of TSH is itself impaired, and as a result, FT₄ declines; the patient is just as hypothyroid, but the TSH concentration is not usually elevated.

Free Thyroxine

FT₄ below the normal range without TSH elevation is clearly suggestive of central hypothyroidism. However, FT₄ concentration may, alternatively, be in the lowest third of the normal range. FT₄ and T₄ values are similar to those seen in mild primary hypothyroidism. The “red flag” of an elevated TSH is absent because the ability to increase TSH secretion is impaired; however, daytime serum TSH is not usually low. A blunted or absent nocturnal TSH surge in central hypothyroidism suggests loss of the normal circadian variation in TRH release. Central hypothyroidism can be difficult to diagnose because of this subtle clinical and laboratory presentation. Decline in FT₄ over time (years) after injury or radiation therapy can be the most important observation; however, baseline (prior to radiation therapy) measurements of FT₄ are not always available for comparison. It is important to maintain a high index of suspicion and to recognize that FT₄ levels in the lowest third of the normal range are compatible with thyroid dysfunction.

Monitoring

Yearly measurements of TSH and FT₄ and growth surveillance are recommended in children at risk for hypothyroidism such as girls with Turner syndrome, children with Down syndrome, and childhood cancer

survivors. Earlier diagnosis of mild hypothyroidism will allow earlier intervention to improve growth velocity and quality of life. In a healthy person with slow growth or other symptoms of hypothyroidism, criteria for starting thyroid hormone therapy without further diagnostic testing include (1) TSH above 4 mU/L at 0800 or 0900 h or above 3 mU/L between 1000 and 2000 h (regardless of the FT₄ value) and (2) FT₄ at or below the lower limits of the normal range for the assay (regardless of the TSH value). If FT₄ is in the upper two-thirds of the normal range and TSH does not meet the preceding criteria, no thyroid therapy is needed, and thyroid status and growth (in children) should be reviewed in 1 year in patients at risk. If FT₄ is in the lowest one-third of the normal range without TSH elevation, both the TRH test and the TSH surge should be performed. The combination of history of head injury or cranial or total body radiation, slow growth rate, normal weight gain, no intercurrent illness, delayed bone maturation, and declining FT₄ or FT₄ below the lower limits of normal or TSH above the upper limits of normal should be diagnostic of hypothyroidism.

THERAPY FOR HYPOTHYROIDISM

Starting Thyroid Hormone Therapy

Thyroid hormone doses at initiation of therapy are much higher in infants (10–12 μg/kg BW/day) and toddlers (5–8 μg/kg BW/day) than in children (3 μg/kg BW/day) and adolescents or adults (1.25–1.50 μg/kg BW/day). These doses approximate 100 μg per meter squared per day.

Typical initial thyroid replacement dose in healthy young people with TSH of less than 30 mU/L and without risk of cardiac decompensation is 3 μg levothyroxine per kilogram body weight given daily in the morning. If TSH is more elevated or if there are concerns about medical stability, starting with one-quarter of this dose and increasing by a quarter dose each month can permit more gradual physiological and psychological adjustment to the new metabolic state. In general, because levothyroxine has a long half-life of 5 to 6 days, it is useful to measure thyroid levels only after 4 weeks.

Thyroid Dose Adjustment

Thyroid dose should then be adjusted as follows. In primary hypothyroidism (initial TSH elevation above normal with no evidence of central hypothyroidism), TSH is the most useful test to monitor during

therapy. The target should be a TSH of 0.5 to 1.5 mU/L (or $\mu\text{U}/\text{ml}$), without symptoms of overreplacement. In central or mixed hypothyroidism, therapy with levothyroxine rapidly suppresses TSH before resolution of clinical symptoms, so TSH is not useful to measure unless the initial TSH was elevated. The recommendation is to monitor FT_4 during therapy, adjusting the dose to achieve FT_4 just above the middle of the normal range and without symptoms of hypo- or hyperthyroidism.

Thyroid Replacement and Adrenal Function

Because thyroid therapy can result in improved metabolic clearance of many substances such as cortisol, thyroid hormone replacement can result in clinical decompensation of patients with unrecognized adrenal insufficiency. In patients at risk, it is necessary to evaluate for primary adrenal insufficiency and/or hypothalamic ACTH deficiency and to provide such patients with hydrocortisone prior to initiating thyroid therapy.

Figure 1 Schematic representation of the TSHR. The holoreceptor (left) and the two-subunit receptor (right) are shown.

of 8 and 50 aa unique to TSHR as compared with LHR and FSHR are included in this domain (aa 38–45 and 317–367). The second domain is the transmembrane/cytoplasmic region, a characteristic of the G protein-coupled receptor superfamily.

TSHR undergoes a variety of posttranslational modifications, including glycosylation, intramolecular cleavage, disulfide formation, tyrosine sulfation, and palmitoylation.

There are six potential N-linked glycosylation sites (N_xS/T) on TSHR, all of which appear to be actually glycosylated. The TSH holoreceptor can be detected by Western blotting as a doublet of ~100 and 120 kDa. The ~100 kDa protein is a precursor with mannose-type oligosaccharides located in the endoplasmic reticulum, which gradually is transformed into the ~120 kDa mature protein with complex oligosaccharides in the Golgi apparatus and then is expressed on the cell surface. Thus, TSHR is heavily glycosylated and contains an ≈25 kDa glycan, which corresponds to 40% of the molecular mass of the A subunit (see below).

TSHR undergoes intramolecular cleavage into two subunits: the TSH-binding A-subunit and the transmembrane B-subunit. This cleavage apparently occurs at multiple sites on the cell surface of the mature receptor, presumably by a membrane-associated matrix metalloproteinase, resulting in the removal of a peptide corresponding to an approximately 50 aa insertion

(C peptide). These subunits are linked by disulfide bridges that are reduced by a cell surface enzyme, possibly protein disulfide isomerase, to release the A-subunit, a phenomenon called “receptor shedding.” Shedding may also involve the removal of the cysteine residues at the N terminus of the B-subunit by cleavage. Cleavage does not affect the receptor function in terms of high TSH-binding and TSH-mediated signal transduction. However, it is of interest that TSAb appear to preferentially recognize the shed A-subunit.

There are 11 cysteines in the ectodomain, clustering in three distinct regions: the N and C termini of the A-subunit and the N terminus of the B-subunit. Two additional cysteines are also present in the extracellular loops. Although it has not been confirmed which cysteines form disulfide bridges with each other, it is likely that cysteines in the second and third clusters link the A- and B-subunits.

Other posttranslational modifications include the following: (1) sulfation of the tyrosine at aa 385 in the ectodomain, which is required for high-affinity binding for TSH, but not TSAb; (2) palmitoylation of the cysteine at aa 699 in the C-terminal cytoplasmic tail of the receptor, which positively controls the rate of intracellular trafficking of the receptor; and (3) the formation of oligomers, which rapidly dissociate into monomers on TSH binding.

TSH and presumably also autoantibodies bind to the TSHR ectodomain with high affinity. The binding site(s) appears to be highly conformational and consists of multiple, discontinuous amino acid sequences, which span the entire ectodomain. The binding sites for TSH and the autoantibodies likely overlap but may not be identical. For example, the midregion of the ectodomain (particularly aa 201–211 and 222–230) is a TSH-binding site, whereas the N and C termini of the ectodomain seem to be critical for TSAb and TBAb binding, respectively. As mentioned above, the TSHR A-subunit rather than the holoreceptor may be the primary autoantigen in Graves' disease.

Because of its highly complex tertiary structure and because of a variety of posttranslational modifications, the functional receptor can be expressed only in mammalian cells. In addition to the full-length receptor, the entire ectodomain linked to the single transmembrane region of CD8 or a glycosylphosphatidylinositol anchor and the soluble, truncated receptor, approximately corresponding to the A-subunit, but not the whole ectodomain itself, have also been functionally expressed.

Neither the three-dimensional structure of TSHR nor the mechanisms for transmembrane signaling are known. However, the LRR region of the TSHR ectodomain is modeled based on the known structure of LRRs in ribonuclease inhibitor (RI). This region appears to have a nonglobular, horseshoe shape whose concave surface likely interacts with TSH.

TSHR GENE

The TSHR gene consists of 10 exons and 9 introns and spans > 60 kb on human chromosome 14q. Exons 1–9 encode most of the ectodomain, with each exon corresponding to a LRR, and exon 10 encodes part of the ectodomain and the transmembrane/cytoplasmic region. These findings indicate that the TSHR gene is derived from the integration of multiple genes, each encoding a LRR into a prototypic intronless G protein-coupled receptor gene. The full-length TSHR cDNA is approximately 4kb long and contains a single open reading frame of 2292 bp.

Multiple TSHR mRNAs are detected in the thyroid tissue; there are major transcripts of ~4kb and several other minor transcripts. The former correspond to the full-length receptors with distinct 3'-untranslated regions and the latter correspond to alternatively spliced, truncated receptors lacking the transmembrane/cytoplasmic region.

The promoter region of the TSHR has characteristics typical of those of housekeeping genes with multiple transcription start sites. TSH induces a transient increase and subsequent down-regulation of TSHR expression under *in vitro* culture conditions, whereas TSHR mRNA levels are relatively stable *in vivo*. The minimal sequence required for thyroid-specific expression and negative regulation by TSH is located at –195 to –39 bp of the 5'-flanking region.

TSHR is primarily expressed in the basolateral membrane of thyroid follicular epithelial cells, but extrathyroidal expression including fat tissues and retro-orbital fibroblasts is noted, which may be relevant for extrathyroidal manifestations of Graves' disease.

AUTOIMMUNITY

As mentioned above, the TSHR autoantibodies act as agonists in most patients with Graves' disease (TSAb) or as antagonists in some patients with autoimmune hypothyroidism (TBAb). To detect these antibodies, two assays have become available. One is a bioassay for TSAb that measures agonist-mediated cAMP production using thyroid cells of various species or mammalian cells stably expressing recombinant TSHR. The other is competition of antibodies for radiolabeled TSH binding to TSHR [TSH-binding inhibiting antibody (TBIAb)]. Although the TBIAb assay has long used porcine thyroid membrane as an antigen, a highly sensitive TBIAb assay with recombinant human TSHR has become commercially available. However, this assay cannot discriminate between stimulating and blocking antibodies.

New methods to detect direct binding of TSHR autoantibodies to TSHR have also been developed with recombinant receptors. These assays detect any type of antibody, not only TSAb and TBAb, but also neutral antibodies with no biological activities. The results obtained with these direct binding assays are closely correlated with TBIAb values.

TSHR autoantibodies can be experimentally elicited by traditional immunization approaches using the soluble TSHR protein with classical adjuvants, which, however, do not usually have TSAb activities. In contrast, immunization of mice with syngeneic cells coexpressing TSHR and major histocompatibility complex class II antigen or genetic immunization with plasmid- or adenovirus-encoded TSHR can effectively induce TSAb and Graves'-like hyperthyroidism. Since Graves' disease is an antibody-mediated disease, it has been widely believed that the T helper 2 cell (Th2)-based immune response

is predominant in Graves' disease. However, studies with these animal models challenge this concept, suggesting that the Th1 immune response may be more critical than previously anticipated or that the Th1/Th2 paradigm may be too simplistic to explain the pathogenesis of Graves' disease.

NATURALLY OCCURRING MUTATIONS

Numerous mutations in the TSHR gene causing loss- or gain-of-function have been identified. Constitutively activating mutations were found in hyperfunctioning thyroid adenomas and autosomal-dominant congenital nonautoimmune hyperthyroidism. Most of the mutations are point mutations and are localized in transmembrane/cytoplasmic regions. TSHR is "noisy," that is, it displays significant constitutive activity even in the absence of agonist. Unliganded ectodomain likely constrains the receptor activity. In contrast, loss-of-function mutations in congenital hypothyroidism associated with resistance to TSH can be found in any region of the receptor. Furthermore,

a unique mutation (K183R), which increases the sensitivity to human choriogonadotropin and causes a type of familial gestational hyperthyroidism, has also been identified.

peptides that include TRH and flanking and intervening sequences. These peptides themselves have important intracellular or extracellular actions, notably prepro-TRH, which can stimulate TSH gene expression. In fact, the potentiating effects of prepro-TRH on TRH-induced TSH secretion may be mediated by folliculostellate cells in the anterior pituitary.

The hypothalamus exerts a dominant stimulatory role on TSH secretion, and this effect is mediated by TRH. Evidence for this comes from a number of observations. TRH exerts a dose-dependent increase on TSH secretion *in vivo* and *in vitro*, and TSH levels decrease following lesions to the hypothalamus or after hypothalamic-pituitary dissociation. The presence of TRH in hypophyseal portal blood in physiologically relevant concentrations and the occurrence of hypothyroidism in animals treated with a neutralizing antibody to TRH add further substance to the importance of TRH in the regulation of TSH secretion and the maintenance of normal thyroid function. In humans, TSH levels increase within 2 to 5 min of intravenous TRH administration, peak at 20 to 30 min, and gradually return to normal by 2 to 3 h. This increase is paralleled later by a rise in serum T₃ and T₄ concentrations, which peak at 3 and 8 h, respectively. However, TRH does not exert its effects simply by stimulating TSH release; rather, it also stimulates TSH synthesis through the induction of TSH subunit gene transcription and translation. This action involves calcium influx and activation of protein kinase C and is modulated by both cyclic AMP (cAMP) and the pituitary-specific transcription factor Pit-1, which also regulates the expression of the prolactin (PRL) and growth hormone (GH) genes and mediates the action of TRH on PRL gene expression in cultured GH₃ cells. As a result, mutations of this factor result in congenital TSH deficiency as well as deficient lactotroph and somatotroph function.

TRH regulates TSH by acting at a posttranslational level as well as at a transcriptional level and by modifying the processing of the oligosaccharide groups of TSH. TSH needs to be fully glycosylated for maximal biological activity, and this observation explains the clinical finding that some patients with central hypothyroidism and slightly elevated basal TSH concentrations secrete TSH with reduced biological activity that increases after TRH administration.

Interactions between TRH and Thyroid Hormones

The stimulatory effect of TRH on the synthesis and secretion of TSH is counteracted by the direct

pituitary inhibition of TSH synthesis and release by thyroid hormones, a process involving the intrapituitary conversion of T₄ to T₃. However, thyroid hormones can also modulate the expression of the TRH and TRH receptor genes. For example, the number of TRH receptors on thyrotrophs increases in hypothyroidism and can be reduced by thyroid hormone replacement. In contrast, in pituitary tumor GH₄C₁ cells, TRH reduces T₃ receptor number and T₃ responsiveness, and this may represent a further site of feedback interaction between T₃ and TRH at the level of the pituitary. The levels of TRH mRNA in hypothalamic paraventricular nuclei also increase in hypothyroidism and are reduced by thyroid hormone treatment. Furthermore, rats that have lesions of their hypothalamic paraventricular nuclei do not have the normal rise of TSH and TSH subunit mRNA after induction of primary hypothyroidism. These observations indicate that the paraventricular nuclei are another target for the action of thyroid hormones in the regulation of TRH gene expression and secretion, providing a further mechanism for the thyroidal control of TSH secretion.

Role of Somatostatin

Somatostatin was initially isolated and characterized on the basis of its ability to inhibit GH release from the anterior pituitary gland. It has since been shown to inhibit the secretion of TSH in both animals and humans. Somatostatin inhibits both basal and TRH-stimulated TSH secretion from cultured rat anterior pituitary cells, and this effect is greater in the presence of hypothyroidism. These observations led to the hypothesis that TSH release was regulated by the hypothalamus through a dual-control system involving stimulation by TRH, on the one hand, and inhibition by somatostatin, on the other. The biological relevance of this proposal was confirmed in studies using antiserum directed against somatostatin. For example, administration of antisomatostatin antiserum to rats increases both basal serum TSH concentrations and the serum TSH response to cold stress and TRH. In humans, somatostatin reduces the elevated TSH concentrations in patients with primary hypothyroidism, reduces the serum TSH response to TRH, and prevents the release of TSH after administration of dopamine antagonist drugs. Despite these acute effects, chronic treatment with somatostatin or its analogues does not cause hypothyroidism, presumably because the sensitivity of thyrotrophs to any reduction in thyroid hormone concentration overrides the inhibitory effect of somatostatin in the long term.

Role of Neurotransmitters

An extensive network of neurotransmitter neurons, projecting from the midbrain and other regions, terminates on the cell bodies of the hypophysiotropic neurons and within the interstitial spaces of the median eminence where they regulate neuropeptide release into hypophyseal portal blood. However, these interacting neural networks are complex, and it is not surprising that attempts to dissect the relative contributions of different neurotransmitter systems on the regulation of TSH release have proved to be difficult. Nevertheless, consensus views have developed about the roles of several different neurotransmitter pathways, notably the catecholaminergic system.

Studies using central neurotransmitter agonist and antagonist drugs have identified the existence of stimulatory α -adrenergic and inhibitory dopaminergic pathways in the control of TSH secretion in rats, and although the precise central effects of these pathways are uncertain, it is clear that dopamine and epinephrine exert opposing actions on TSH release directly at the pituitary level. Furthermore, both of these molecules are present in hypophyseal blood in physiologically relevant concentrations and in higher concentrations than in peripheral blood. Dopamine causes a dose-dependent inhibition of TSH release from cultured rat and bovine anterior pituitary cells, mediated by the DA₂ class of dopamine receptors that are negatively coupled to adenylate cyclase, and also inhibits α -subunit and TSH- β -subunit gene transcription. In contrast to dopamine, adrenergic activation causes dose-dependent stimulation of TSH release in cultured anterior pituitary cells, an effect that is mediated by high-affinity α -1 adrenoreceptors. Quantitatively, the adrenergic release of TSH is nearly equivalent to that induced by TRH, and together they have additive effects on TSH secretion, suggesting activation of separate intracellular pathways.

In humans, it is well recognized that dopamine exerts a physiological inhibitory effect on TSH release, and some data suggest a stimulatory α -adrenergic pathway. However, the catecholaminergic control of TSH secretion in humans appears to be a fine-tuning mechanism rather than a matter of primary importance, and as with somatostatin analogues, chronic administration of catecholaminergic agents does not result in alterations in thyroid status, reflecting the presence of compensatory mechanisms to maintain TSH secretion and euthyroidism.

The effects of a number of other substances on the release of TSH have been studied, and actions have

Figure 1 Schematic representation of the principal primary and secondary modulators of thyrotroph function. DA, dopamine; SS, somatostatin. been described for serotonergic pathways; opioid peptides; neuropeptides such as neurotensin, neuromedin B, vasopressin, and vasoactive intestinal polypeptide; and cytokines such as tumor necrosis factor and interleukin-1. However, in the majority of cases, adequate physiological studies have not been undertaken, and the precise roles of these substances in the regulation of TSH release are unclear. The major factors regulating the release of TSH are illustrated in [Fig. 1](#).

PHYSIOLOGICAL ALTERATIONS IN TSH RELEASE

Alterations in TSH secretion may be apparent in the pattern or degree of change in basal TSH concentration or in the pattern and degree of TSH responses to TRH or dopamine receptor blockade.

Serum TSH concentrations show clear circadian and ultradian variation. In humans, serum TSH concentrations begin to rise before the onset of sleep, reaching a peak between 2300 and 0400 h and declining thereafter to reach a nadir at approximately 1100 h. Furthermore, a seasonal variation in serum TSH concentrations has been reported in patients with primary hypothyroidism receiving thyroxine replacement, and some of these patients have higher TSH concentrations during winter than during summer. However, the central mechanisms underlying TSH pulsatility and rhythmicity are unknown, and although pulsatile TRH release can influence

TSH pulse amplitude, the major input may be from the suprachiasmatic nuclei in the hypothalamus.

Serum TSH concentrations can also vary according to changes in body temperature, age, and caloric restriction. Exposure to cold in rats induces an increase in hypothalamic TRH secretion and a subsequent rise in serum TSH concentrations. A similar response is apparent in human neonates, although this increase is unusual in adults and is usually small when present. Aging causes a slight reduction in TSH secretion due to a readjustment of the threshold of TSH inhibition by thyroid hormones secondary to increased pituitary conversion of T_4 to T_3 , increased uptake of T_4 by thyrotrophs, or reduced T_4 and T_3 clearance. These observations highlight the need for caution in using TSH assays alone when assessing thyroid function in the elderly. Caloric restriction induces a small reduction in basal and TRH-stimulated serum TSH concentrations despite a decrease in serum T_3 concentrations, which in the extreme condition of anorexia nervosa may be secondary to increased serum cortisol concentrations. Recent evidence also indicates a critical role for leptin in mediating hypothalamic responses to caloric withdrawal.

PATHOLOGICAL ALTERATIONS IN TSH RELEASE

Apart from thyroid and hypothalamic-pituitary disease, stress, nonthyroidal illness, and neuropsychiatric disease all can modify TSH secretion. In humans, surgical stress causes both a transient acute lowering of TSH release and chronic abolition of the nocturnal increase in serum TSH concentration. This occurs despite a fall in serum-free T_3 concentrations, whereas serum-free T_4 concentrations do not change. As with the effects of caloric restriction, these stress phenomena are similar to the altered neuroregulation of TSH that can occur in nonthyroidal illness and in some neuropsychiatric disorders such as anorexia nervosa and depression. Although basal serum TSH concentrations are usually normal in patients with both acute and chronic nonthyroidal illness, they can be either low or slightly raised. However, the mechanisms involved in the central suppression of thyrotroph function apparent in severe nonthyroidal illness are unclear, although alterations in glucocorticoid, cytokine, leptin, opiodergic, dopaminergic, and somatostatinergic activity all have been implicated.

The development of highly sensitive assays for the measurement of TSH has rendered TRH testing

obsolete and enabled thyrotoxicosis and euthyroidism to be reliably distinguished. With the exception of thyrotoxicosis secondary to inappropriate TSH secretion (from a TSH-secreting pituitary tumor or thyroid hormone resistance), serum TSH concentrations are low or undetectable in patients with thyrotoxicosis, irrespective of the cause, as a result of increased negative feedback of thyroid hormones on the thyrotrophs. However, following treatment, serum TSH concentrations remain low or undetectable for 4 to 6 weeks after T_4 and T_3 levels have returned to normal, reflecting a delay in synthesis or secretion of TSH by the previously suppressed thyrotrophs. In primary hypothyroidism, serum TSH concentrations are usually in excess of 20 mU/L in patients who are symptomatic, whereas concentrations between 5 and 20 mU/L are usually associated with serum thyroid hormone concentrations in the lower part of their normal ranges. After initiation of T_4 replacement, serum TSH concentrations fall slowly (4–8 weeks) in comparison with the increase in T_4 concentrations (days). This differential response allows the identification of poorly compliant patients where raised T_4 and TSH values may be observed following T_4 ingestion only for the few days before the clinic visit. Low serum TSH in the presence of normal thyroid hormone concentrations, termed “subclinical hyperthyroidism,” is common in patients with multinodular goiter. Such patients were not usually treated in the past, although the observation that osteopenia and atrial fibrillation are associated with subclinical hyperthyroidism now favors early treatment. In contrast, the treatment of subclinical hypothyroidism, where TSH levels are elevated in the presence of normal T_4 and T_3 concentrations, is more contentious.

In the majority of patients with pituitary disease, basal serum TSH concentrations and serum TSH responses to TRH or dopamine receptor blockade are normal or reduced; an absent TSH response to TRH is suggestive of a pituitary lesion. Occasional patients with a pituitary tumor causing stalk compression and mild hyperprolactinemia have a delayed TSH response to TRH. In patients with hypothalamic disease, TSH responses to TRH can be normal, suppressed, or delayed, with peak TSH responses not occurring until 60 min after TRH administration. In patients with prolactin-secreting pituitary tumors, thyroid status depends on the size of the tumor. Patients with macroadenomas may have impaired TSH responses to TRH and dopamine antagonism or, less commonly, to overt hypothyroidism. However, patients with microprolactinomas are almost invariably euthyroid, although the serum TSH response

to dopamine receptor blockade is characteristically exaggerated. Clinically important disruption of the hypothalamic–pituitary–thyroid axis is uncommon in patients with acromegaly or Cushing’s disease. In acromegaly, central hypothyroidism is rare and usually confined to large tumors. In hypercortisolism, a slight lowering of free T_4 and TSH levels, secondary to inhibition by cortisol, is not uncommon but recovers quickly with treatment of the pituitary disease.

thyroid ablation by surgery or radioiodine. This aggressive transformation of the pituitary tumor resembles that occurring in Nelson's syndrome after adrenalectomy for Cushing's disease.

By light microscopy, tumoral thyrotropes generally appear to be chromophobic, with atypical nuclei and mitoses, and so they are often mistakenly recognized as pituitary malignancy or metastasis from distant carcinomas. By electron microscopy, these tumors are monomorphous and characterized by a poorly developed Golgi apparatus and a low number of small secretory granules aligned mainly under the plasma membrane.

Approximately 75% of TSH-omas secrete TSH alone, which is often accompanied by an unbalanced hypersecretion of the α -subunit of glycoprotein hormones. Hypersecretion of growth hormone (GH) and/or prolactin (PRL), resulting in acromegaly and/or amenorrhea/galactorrhea syndrome, is present in approximately 25% of tumors, whereas the occurrence of mixed TSH/gonadotropin adenomas is rare and no association with adrenocorticotropic hormone (ACTH) hypersecretion has been documented. This may be due to the fact that GH and PRL share with TSH the common transcription factor Pit-1.

As for most pituitary tumors, the pathogenesis of TSH-omas remains largely unknown. Screening studies for genetic abnormalities that may be responsible for tumor formation were generally negative. Anecdotal reports showed overexpression of the Pit-1 gene, absence of thyroid hormone receptor isoforms, and (recently) mutations in the beta isoform of the receptor leading to an altered feedback mechanism that is possibly responsible for the tumor formation. However, available data concern only a low number of tumors and are too preliminary to draw definite conclusions on transcriptional and/or expression abnormalities in TSH-omas.

CLINICAL MANIFESTATIONS

Patients with TSH-omas present with signs and symptoms of hyperthyroidism that are sometimes milder than expected on the basis of circulating thyroid hormone levels. Signs and symptoms of hyperthyroidism are frequently associated with those related to the mass effects of the pituitary adenoma. The latter frequently prevail over those of thyroid hyperfunction. Visual field defects are present in approximately 41%, headache in 23%, and partial or total hypopituitarism in 25% of patients (Table I).

Most patients have a long history of thyroid dysfunction, often misdiagnosed as Graves' disease, and

Table I Clinical Features of Patients with TSH-omas

^aData include women with or without hyperprolactinemia.

approximately one-third had inappropriate thyroidectomy or radioiodine thyroid ablation. In some acromegalic patients, signs and symptoms of hyperthyroidism may be clinically missed because those of acromegaly overshadow them. The presence of goiter, frequently uni- or multinodular (~90% of reported cases), is the rule. Also, in patients with previous thyroidectomy, thyroid residue may regrow as a consequence of TSH hyperstimulation. Progression toward functional autonomy or differentiated carcinomas seems to be infrequent. Bilateral exophthalmos occurred in a few patients who subsequently developed autoimmune thyroid disorders, whereas unilateral exophthalmos due to orbital invasion by pituitary tumor was reported in three patients with TSH-omas.

DIAGNOSIS

Serum Thyroid Hormone and TSH Levels

Serum total and free thyroid hormone levels are definitely high in patients with TSH-omas, whereas TSH levels may be elevated or in the normal range (Table II). In some patients with TSH-omas, the findings of normal TSH in the presence of high levels of free thyroxine (FT4) and free triiodothyronine (FT3) were demonstrated to be due to an increased biological activity of secreted TSH molecules.

Particular clinical situations and possible laboratory artifacts causing a biochemical profile similar to that characterizing central hyperthyroidism should be considered. Measuring free, instead of total, thyroid hormones may recognize most of the confusing conditions, including genetic alterations or drugs that may cause quantitative/qualitative alterations of

Table II Differential Diagnosis between TSH-omas and RTH

| Parameter | TSH-omas | RTH | P |
|---|----------------|------------|-------|
| Female/Male ratio | 1.29 | 1.41 | NS |
| Familial cases (percentages) | 0 ^a | 86 | <0.01 |
| TSH (mU/L) | 2.9 ± 0.5 | 2.4 ± 0.4 | NS |

Note. Only patients with intact thyroid were taken into account. Data are obtained from patients followed at our institute and are expressed as means \pm SE.

^aExcluding the three families with Men-1 reported in the literature.

^bWerner's test (80–100 μ g T3 for 8–10 days). Quantitatively normal responses to T3 (i.e., complete inhibition of both basal and TRH-stimulated TSH levels) have never been recorded in either group of patients. Although abnormal in quantitative terms, TSH response to T3 suppression test was qualitatively normal in RTH patients.

T4-binding globulin, albumin, or transthyretin leading to increases in thyroid hormone levels, particularly T4. Laboratory artifacts, such as those caused by circulating anti-T4 and/or anti-T3 autoantibodies that interfere in most immunometric assays, may cause falsely high levels of free thyroid hormones, whereas heterophilic antibodies directed against or cross-reacting with mouse immunoglobulin G (IgG), as well as anti-TSH autoantibodies in patients previously treated with bovine TSH or contaminated pituitary extracts, may lead to incorrect evaluation of the actual TSH concentrations.

Pituitary Glycoprotein Hormone α -Subunit

A helpful diagnostic tool for the diagnosis of TSH-omas is the determination of serum concentrations of the α -subunit, the subunit common to all pituitary glycoprotein hormones. Secretion of the α -subunit in these tumors is in excess not only of the TSH- β subunit but also of the intact TSH molecule, resulting in an α -subunit/TSH molar ratio generally higher than that recorded in controls matched for age and sex and with similar circulating levels of TSH, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) (Table II).

Parameters of Peripheral Thyroid Hormone Action

Because patients with central hyperthyroidism may present with mild signs and symptoms of thyroid

hormone overproduction, the measurements of several parameters of peripheral thyroid hormone action have been proposed to quantify the degree of hyperthyroidism. Some of these parameters, and in particular sex hormone-binding globulin (SHBG) and cross-linked carboxyterminal telopeptide of type I collagen (ICTP), have been used to differentiate hyperthyroid patients with TSH-omas from those with RTH (Table II); patients with TSH-omas have levels of these indexes into the hyperthyroid range, whereas they are into the normal range in RTH patients.

Dynamic Testing

Several stimulatory and inhibitory tests are useful for the diagnosis of TSH-omas. Classically, the T3 suppression test has been used to assess the presence of a TSH-oma because complete inhibition of TSH secretion after T3 (80–100 μ g/day for 8–10 days) has never been recorded in patients with TSH-omas (Table II). It is worth noting that in patients with previous thyroid ablation, T3 suppression seems to be the most sensitive and specific test in assessing the presence of a TSH-oma. In approximately 93% of patients, TSH levels do not increase after TRH injection. The lack of TSH response to TRH may also be useful in unusual situations where TSH-omas coexist with primary hypothyroidism.

The majority of patients with TSH-omas maintain the sensitivity to native somatostatin or its analogues, and these tests may be predictive of the efficacy of long-term treatment in most patients.

Imaging Studies

When considering the diagnosis of a TSH-oma, full imaging studies, particularly nuclear magnetic resonance imaging (MRI) or high-resolution computed tomography (CT), are mandatory. Various degrees of suprasellar extension or sphenoidal sinus invasion are present in two-thirds of cases. The positivity of Octreoscan (scintigraphy with $^{111}\text{Indium-pentetreotide}$) may also be helpful in the diagnostic workup of particular cases.

Differential Diagnosis

In a patient with signs and symptoms of hyperthyroidism, the presence of elevated thyroid hormone and detectable TSH levels rules out primary hyperthyroidism. When the existence of central hyperthyroidism is confirmed and the presence of methodological interferences is excluded, several diagnostic steps have to be carried out to differentiate a TSH-oma from RTH (Table II). Indeed, the possible presence of neurological signs and symptoms (e.g., visual defects, headache) or clinical features of concomitant hypersecretion of other pituitary hormones points to the presence of a TSH-oma. Furthermore, the presence of alterations of pituitary content at MRI or CT scan strongly supports the diagnosis of a TSH-oma. Nevertheless, the differential diagnosis may be difficult when the pituitary adenoma is undetectable by MRO or CT scan or in the case of confusing lesions such as empty sella or pituitary incidentalomas. In these cases, elevated α -subunit concentrations or high α -subunit/TSH molar ratios and TSH unresponsiveness to TRH stimulation and/or to T3 suppression tests favors the presence of a TSH-oma. Moreover, in contrast to RTH patients, familial cases of TSH-omas have never been documented. Finally, an apparent association between TSH-oma and RTH was recently reported in a young Japanese woman, although genetic investigations of possible mutations in T3 receptor $\beta 1$ were not carried out. Nonetheless, the occurrence of TSH-omas in RTH patients is theoretically possible and, therefore, should be carefully considered.

TREATMENT AND FOLLOW-UP

Surgical resection is the recommended therapy for TSH-producing pituitary tumors. However, a radical removal of large adenomas, which still represent the majority of TSH-omas, is particularly difficult due to the local invasion of the tumor. Particular attention has to be paid to presurgical preparation of the

patient. Antithyroid drugs or octreotide along with propranolol should be used to restore euthyroidism. If surgery is contraindicated or declined, as well as in the case of surgical failure, pituitary radiotherapy may be undertaken with the recommended dose of no less than 45 Gy fractionated at 2 Gy per day or 10 to 25 Gy in a single dose if a stereotactic gamma unit is available. The criteria of cure of patients operated and/or irradiated for TSH-omas have not been clearly established due to the rarity of the disease and the great heterogeneity of parameters used. In particular, clinical remission of hyperthyroidism with normalization of thyroid hormones, TSH, and α -subunit or α -subunit/TSH molar ratio, and with the disappearance of neurological symptoms, has been considered for the evaluation of the efficacy of surgery or radiotherapy in patients with TSH-omas. In our experience, undetectable TSH levels 1 week after surgery are likely to indicate complete adenectomy provided that presurgical treatments were stopped at least 10 days before surgery. The most sensitive and specific test to document the complete removal of the adenoma remains the T3 suppression test. In fact, only patients in whom T3 administration completely inhibits basal and TRH-stimulated TSH secretion appear to be truly cured. No data on the recurrence rates of TSH-omas in patients judged to be cured after surgery or radiotherapy have been reported. Although earlier diagnosis has improved the surgical cure rate of TSH-omas, several patients require medical therapy to control the hyperthyroidism. Dopamine agonists, and particularly bromocriptine, have been employed in some TSH-omas with variable results, with positive effects being observed mainly in some patients with mixed PRL/TSH adenomas. Today, the medical treatment of TSH-omas rests on long-acting somatostatin analogues such as octreotide LAR and lanreotide SR. Treatment with these analogues leads to a reduction of TSH and α -subunit secretion in nearly all cases, with restoration of the euthyroid state in the majority of them. During octreotide therapy, tumor shrinkage occurs in approximately half of patients and vision improvement occurs in 75%. Resistance to octreotide treatment has been documented in only 4% of cases. Whether somatostatin analogue treatment may be an alternative to surgery and irradiation in patients with TSH-omas remains to be established.

| TNFSF18 | AITRL | TL6 | | Inhibits T-cell receptor-dependent apoptosis |

immune function. CD95 ligand (CD95L, FasL) plays an important role in several types of physiological apoptosis. TNF-related apoptosis-inducing ligand (TRAIL, Apo-2L) is a potent endogenous activator of the cell death pathway. TNF-related activation-induced cytokine (TRANCE, RANKL) mediates survival of dendritic cells and is required for osteoclast differentiation and activation in the skeleton.

The receptors for these proteins also constitute a TNF receptor (TNFR)-related gene superfamily (Table II). Molecular studies and databases permitted the identification of a group of factors with structural similarities and diverse functions, and the term TNF-TNFR superfamily evolved. The TNF-TNFR superfamily is evolutionally highly conserved.

Two types of TNFRs have been described: TNF receptor I (TNFRSF1A, p55-R in mice; p60-R or TNFR60 in humans; CD120a) and TNFR II (TNFRSF1B, p75-R, p80-R, TNFR80, CD120b). TNF receptor I contains a death domain (DD) and TNF receptor II has a TNFR-associated factor (TRAF) domain. The extracellular ligand-binding region of all TNF superfamily receptors is characterized by a variable number of cysteine-rich domains,

permitting the formation of trimeric structures. TNFRs can be cleaved proteolytically and exist as soluble receptors. Most DD-containing genes derive from a common ancestor, and a subsequent diversification occurred in the TRAF domain.

The cytoplasmic domains of TNFS function as docking sites for signaling molecules. Signaling occurs through two cytoplasmic adaptor proteins, TRAFs and DD molecules. The binding of TNF to TNF receptor I causes the association of adaptors such as TNFR-associated DD protein (TRADD) and Fas-associated death domain (FADD) that ultimately causes caspase activation and cell death. Like other TNF family members, CD95L (FasL) is a homotrimeric molecule. Because DD molecules associate with one another, CD95L binding leads to clustering of the DDs of CD95 (Fas). FADD then binds through its own DD to the clustered receptor DDs.

TRAFs are critical mediators of the cell-activation and antiapoptotic functions of the TNFR superfamily. In particular, TRAF2 is important for protection from apoptosis, as is clear from the observation that cells from TRAF2-deficient mice are overly sensitive to TNF-induced apoptosis.

Table II TNF Receptor Superfamily

| Superfamily no. | Receptor name | Other names | Phenotypes associated with mutations | Functional observations |
|-----------------|---------------|---------------------------------|--|-----------------------------------|
| TNFRSF1A | TNFR1 | CD120a, p55-R, TNFR60, TNF-R-I | Impaired clearance of bacterial pathogens | |
| TNFRSF1B | TNFR2 | CD120b, p75-R, TNFR80, TNF-R-II | Increased sensitivity to bacterial pathogens | |
| TNFRSF3 | LT- β R | TNFR2-RP, TNF-R-III | Absence of lymphonodi | |
| TNFRSF4 | OX40 | CD134, ACT35, TXGP1L | Defective T-cell responses | |
| TNFRSF5 | CD40 | | Defective Ig class switching | |
| TNFRSF6 | FAS | CD95, APO-1, APT1 | Autoimmunity | |
| TNFRSF6B | DeR3 | | | Secreted decoy receptor |
| TNFRSF7 | CD27 | Tp55, S152 | Defective T-cell responses | |
| TNFRSF8 | CD30 | Ki-1 | | |
| TNFRSF9 | 4-1BB | CD137, ILA | | Probable role in T-cell responses |
| TNFRSF11A | RANK | TRANCE-R | Osteopetrosis, abnormal B-cell development | Mammary gland development |
| TNFRSF12 | DR3 | TRAMP, WSL-1, APO-3 | | |
| TNFRSF14 | HveA | HVEM, ATAR, TR2 | | T-cell proliferation |

| TNFRSF17 | BCMA | BCM | | B-cell responses |
| TNFRSF18 | AITR | | | |
| TNFRSF19 | Troy | Taj | | |

BIOLOGICAL ACTIVITIES OF TNF

Cells of the macrophage/monocyte lineage are the predominant source of TNF *in vivo*, but a number of other cell types are capable of producing TNF (Table III). The most potent stimulus for TNF production is bacterial lipopolysaccharide (LPS). The macrophage is sensitive to LPS so that maximal rates of TNF production are observed when LPS is present in barely detectable concentrations. TNF is also produced by exposure to a wide variety of exogenous and endogenous factors (Table III). The exogenous factors include molecules associated with infectious pathogens, such as enterotoxins, fungal cell walls, and viral envelopes. Chemicals such as phorbol esters and calcium ionophores are also active in TNF induction. The endogenous factors that induce TNF include cytokines such as TNF, interleukin (IL)-1, IL-2, granulocyte macrophage colony-stimulating factor, and MIP-1 α . TNF production occurs as part of the conserved response to a wide range of cell stressors and threatening stimuli.

The biological effects of TNF are summarized in Table IV. TNF is a key mediator of inflammation and host defense against microbes, parasites, or neoplasia.

Endothelial cells significantly regulate the coagulation and fibrinolytic pathways via the expression of

tissue factor and thrombomodulin. TNF causes endothelial cells to have procoagulant activity by enhancing the expression of tissue factor and suppressing cofactor activity for the anticoagulant protein C. The effects of TNF eventually result in increased thrombin formation and decreased fibrinolysis and thus promote the intravascular deposition of fibrin. TNF also induces the enhanced expression of HLA antigens and adhesion molecules that participate in the adherence of leukocytes and platelets to the endothelial surface. Endothelial leukocyte adhesion molecule-1 is synthesized rapidly by endothelial cells in response to TNF and significantly mediates neutrophil adhesion. Vascular adhesion molecule-1 induced by TNF interacts specifically with lymphocytes but not neutrophils. Importantly, TNF up-regulates the expression of several adhesion molecules on endothelial cells that interact with lymphocytes, macrophages, and neutrophils and therefore promotes the recruitment of these cells to inflammatory sites.

The activation of T cells requires the presentation of antigen in conjunction with HLA class I or class II antigens. TNF up-regulates MHC class I expression on a number of cells as well as macrophages. Treatment with TNF alone causes a minor induction of MHC class II expression on macrophages, but

TNF can augment synergistically the effects of interferon- γ on MHC class II expression. TNF causes increased phagocytosis and the release of oxygen radicals from macrophages and neutrophils.

TNF causes fever and anorexia because it crosses into the region of the hypothalamic center that regulates body temperature and appetite. The inflammatory effects of TNF are important in the development of cerebral inflammation and edema during meningitis. TNF also participates in the development of the characteristic plaques in multiple sclerosis.

TNF-induced activation of pulmonary endothelium and margination of neutrophils with degranulation lead to the development of adult respiratory distress syndrome, characterized by pulmonary edema, hypoxia, and high mortality.

TNF-treated adipocytes are depleted of lipids and exogenous lipid uptake is blocked. TNF up-regulates the expression of acute-phase proteins in serum and suppresses albumin biosynthesis. TNF stimulates the biosynthesis of circulating lipids, and excessive lipogenesis may contribute to the hypertriglyceridemia observed in the acute-phase response.

TNF has proved to be sufficient to elicit profound biological effects as an autocrine, paracrine, and endocrine mediator. One of the principal biological effects of TNF is that it triggers the release of other cytokines that enhance the biological activities of TNF. TNF operates as a part of the cytokine network system.

TNF AND DISEASES

TNF displays diverse biological effects, including the ability to modify immunological, metabolic, and physiological responses. The local effects of TNF improve host defense systems by increasing immune function and stimulating inflammation. However, its overproduction may cause immunological and inflammatory diseases. TNF has been closely linked to the pathophysiological processes of many acute and chronic human diseases (Table V). TNF is rapidly released in large amounts in response to a wide variety of endogenous and exogenous stimuli. TNF may be the most important mediator of metabolic changes in the host compared to other cytokines. TNF triggers a cascade of subsequent mediators that enhance cellular and humoral changes. Thus, many consequences of TNF release, which may be beneficial when restricted to a local site, can be harmful to the host.

TNF is produced in patients with septic shock, and in some cases serum levels of TNF predict mortality. TNF is the main mediator of tissue injury and septic shock. Administration of inhibitors of TNF prevents the development of tissue injury and septic shock. The protection conferred by TNF inhibitors is believed to result from the combined effect of inhibiting TNF toxicity and interrupting the cytokine cascade.

Cachexia is frequently observed in cancer patients and infectious diseases. Cachexia may be caused by chronic exposure to TNF. Cachexia is characterized by catabolism of proteins and lipid stores that leads to a loss of body weight. Increased serum triglyceride levels have been reported in severe malaria. Since serum TNF levels in malaria increase in relation to illness severity, and serum triglyceride levels increase when TNF is administered to the host, TNF seems to be involved in malarial hypertriglyceridemia. Severe anemia is a major component of malarial pathology. TNF makes an important contribution to the anemia of malaria. Dyserythropoiesis and

erythrophagocytosis seen in mice infected with malaria can be reproduced by administration of TNF. Erythropoiesis in mice infected with malaria can be increased by the injection of anti-TNF antibody.

Endogenous TNF released in response to infection triggers the characteristic manifestations of bacterial meningitis since mortality from cerebral meningitis correlates with the levels of TNF detected in the serum and cerebrospinal fluid.

There is convincing evidence that TNF plays an important role in the pathogenesis of autoimmunity. Genetically associated differences in TNF production and polymorphisms in the promoters of TNF have been associated with predisposition to or severity of various autoimmune diseases. TNF has been implicated in the cytotoxicity to islet cells. TNF injection induces a state of insulin resistance that is similar to the metabolic effects of diabetes.

TNF production in the inflamed joint has been implicated in the mediation of rheumatoid arthritis. Clinical investigations in which the activity of TNF in

Table V Diseases Associated with TNF

rheumatoid arthritis patients was blocked with anti-TNF monoclonal antibody have provided evidence that TNF regulates the production of other cytokines, angiogenesis, and recruitment of inflammatory cells

into joints. The important causal role of TNF in rheumatoid arthritis is also suggested by the prolonged period of remission following anti-TNF antibody therapy.

division, instead of longitudinal cell division (leading to an isochromosome), major and minor deletions of either the long arm or the short arm of the X chromosome, or by the formation of a ring X chromosome.

Features of TS may also be seen in cases where, in addition to one of the cell lines mentioned, cells with material from the Y chromosome are also present (e.g., karyotype 45,X/46,XY). The presence of Y chromosome material may cause the development of gonadoblastoma. Therefore, probing for Y chromosome material should be performed in any TS patient with evidence of virilization or when a marker chromosome (a sex chromosomal fragment of unknown origin, i.e., X versus Y) is found. This can be achieved by DNA hybridization or fluorescence *in situ* hybridization using a Y centromeric or short arm probe and may require probing of multiple tissues.

Karyotype/Phenotype Correlation

The wide range of developmental abnormalities in TS suggested that a number of different X-localized loci are responsible for the complete Turner phenotype. It is widely accepted that dosage (haploinsufficiency) of specific X-Y homologous genes that escape X inactivation causes the characteristic Turner somatic features and associated cognitive defects.

The important studies of the relationship between karyotype and phenotype in TS by Ferguson-Smith, published in 1965, first suggested that genes responsible for the TS phenotype could be assigned to specific regions on the X chromosome. Subsequent studies using chromosome banding techniques have shown: (1) a locus near the tip of the X chromosome involved in short stature; (2) proximal loci on Xp (short arm) involved in other TS anatomic features; (3) the association of the proximal long arm (Xq) with greater viability; and (4) a “critical region” for normal ovarian function from Xq13–q26, excluding part of Xq22. A rough phenotype map is shown in Fig. 2. With the further development of molecular techniques, it became possible to refine the short stature critical region to the extreme tip of the short arm of the X and Y chromosomes, the pseudo-autosomal region (PAR1). Subsequently, the PAR1 SHOX (short stature homeobox) gene was identified. It has been suggested that haploinsufficiency of this gene

Table 1 Some Typical Chromosome Changes and Their Relative Frequency in Patients with Turner Syndrome ($n = 649$)

leads to the growth failure seen in TS. A number of lines of research have suggested other candidate genes for some TS phenotypes.

CLINICAL FEATURES

General

In addition to short stature and gonadal dysgenesis, there are a multiplicity of findings in patients with TS, occurring with varying frequencies (Table II, Fig. 3). The degree of the severity of the abnormal appearance seems to be partially dependent on the underlying chromosome disorder and is usually most marked when there is a complete loss of an X chromosome (karyotype 45,X). A number of features listed in Table II are considered a part of a skeletal growth disturbance, whereas other features can be explained by lymphatic obstruction or germ cell chromosomal defects. The growth failure and ovarian dysgenesis are the features occurring with the highest frequency in TS.

Growth Failure

Growth is reduced in virtually all of the patients. Newborns with TS delivered at term are smaller than average girls; body length is reduced by approximately 3 cm and body weight by approximately 500 g. Postnatal growth rate appears to be in the normal

range during the first 2 to 3 years of life. Thereafter, height velocity shows a gradual decrease compared with healthy girls. In most girls, there is a lack of pubertal growth spurt because the ovaries are non-functional. Due to the delayed epiphyseal fusion, most untreated girls continue to grow until their late teens or beyond. The mean adult height of women with TS of white European origin ranges from approximately 142 to 147 cm in northwestern Europe; this is approximately 20 cm smaller than the mean of the normal female population. Figure 4 shows the Dutch–Swedish–Danish reference values for height in TS, which are based on data from a large multinational study. Convincing evidence that patients with a 45,X karyotype differ from those with another chromosomal pattern has not been documented. Although the absence of one of the X chromosomes results in the typical features of TS, such as short stature, the mechanisms leading to the stunted growth in girls with TS are still unknown. Growth failure in TS is not due to growth hormone (GH) deficiency but resistance to GH or growth factors might play a role.

Ovarian Dysgenesis

In TS, the ovaries develop apparently normally during the first 3 months *in utero*. Thereafter, oocytes are rapidly lost and connective tissue transformation takes place. However, there is wide variation in the loss of germ cells in girls with TS, such that 5–10% retain sufficient ovarian function for puberty to commence spontaneously, though in most girls incompletely. Only in a few cases does spontaneous menstrual bleeding occur and in most of these cases it persists for only a short period of time. Occasionally, “spontaneous” pregnancies have been reported.

DIAGNOSIS

Prenatal

Most prenatally detected cases of TS are discovered incidentally during chorionic villous sampling or amniocentesis performed for unrelated reasons, the most common being advanced maternal age, which itself is not associated with an increased incidence of TS. Certain ultrasound findings (such as increased nuchal translucency, coarctation of the aorta, renal abnormalities) or an abnormal maternal multiple-marker screening (α -fetoprotein, hCG, inhibin A, and unconjugated estriol) are frequently seen in TS, but should not be considered diagnostic of the disorder, however. Even when the prenatal diagnosis has been made by karyotype, chromosomes should be reevaluated postnatally.

Table II Physical Features and Their Frequency in Turner Syndrome

| Feature | Frequency ^a | Feature | Frequency ^a |
|---|------------------------|--|------------------------|
| Eyes | 20–39% | Start of hair growth in nape of neck pointing upward | |
| Ptosis | | Pterygium colli | |
| Epicanthus (“Mongol-fold”) | | Chest | 60–79% |
| Myopia | | Scutiform thorax | |
| Strabismus | | Nipples apparently wide apart (not real, appearance results from scutiform thorax) | |
| Nystagmus | | Inverted nipples | |
| Ears | 40–59% | Skeleton | 40–59% |
| Deformed auricles | | Wide angle of arm (cubitus valgus) | |
| Otitis media | | Short metacarpal bones (e.g., fourth metacarpal) | |
| Impaired hearing | | Spongiose bone structure | |
| Mouth, jaw | 60–79% | Scoliosis | |
| High arched palate (palatus arcuatus) | | Heart vessels | 40–50% |
| Small lower jaw (micrognathia) | | Stenosis of aortic isthmus | |
| Defective dental development | | Bicuspid aortic valve | |
| Skin, skin appendages | 60–79% | Aortic dilation/aneurysm | |
| Lymphedema of hands and feet | | Kidneys | 40–59% |
| Increased number of pigmented naevi | | Renal malformation (e.g., horseshoe kidney) | |
| Increased body hair growth | | Renal aplasia | |
| Fingernail and toenail dysplasia | | Changes in the renal pelvis and ureters | |
| Increased skin ridge patterns (dermatoglyphics) | | Vessel abnormalities | |
| Alopecia | | Ovaries | 80–100% |
| Vitiligo | | Gonadal dysgenesis | |
| Neck | 60–79% | Growth | 80–100% |
| Short, thick neck | | Small for gestational age | |
| Low nape of neck/hairline | | Growth retardation after birth | |

^aFrequencies reported in the literature show some variation. Ranges are therefore given for frequency, rather than exact figures.

Postnatal

TS is most frequently discovered during childhood. The age at which the diagnosis is confirmed depends on the severity of the symptoms. The physical features are not always immediately obvious in every girl with TS or might even be absent in some cases (Table II). Clinicians should always consider the diagnosis in any female patient with unexplained growth failure or pubertal delay.

MANAGEMENT IN CHILDHOOD, ADOLESCENCE, AND ADULTHOOD

Short Stature

Although girls with TS are not GH deficient, treatment with biosynthetic recombinant human GH accelerates height velocity. To determine the effect of GH on adult height, the attained adult height is

compared to the individually predicted adult height at the start of GH treatment based on references for untreated girls with TS. The method of choice for predicting adult height in patients with TS is the Projected Adult Height method. This method assumes that the standard deviation (SD) score of the adult height is equal to the SD score of height for chronological age in girls with TS at any moment before final height is reached. In many countries, TS is an accepted indication for GH treatment although controversy exists regarding the effects of GH treatment on adult height since the mean increase in adult height varies between 0.2 and 16.0 cm in different reports. For most girls, a minimal gain in adult height of approximately 10 cm can be achieved when GH is started before the age of approximately 8 or 9 years with a daily GH dose of approximately 0.045 mg/kg/day (1.4 mg/m²/day ~ 4 IU/m²); the standard daily GH dose for children with GH deficiency is 0.023 to 0.032 mg/kg/day. Higher GH doses (0.06 or

Figure 3 Girl with Turner syndrome.

0.09 mg/kg/day) or the addition of the synthetic anabolic steroid oxandrolone to GH may be more effective, but the efficacy on adult height has yet to be proven.

Although supraphysiological GH dosages are given for several years, no negative side effects of clinical importance of long-term GH treatment have been found, other than a very slight increase in the incidence of edema in the first weeks of the treatment and in the incidence of kyphoscoliosis, diabetes mellitus type 2, and benign intracranial hypertension. During GH treatment, a disproportionately greater increase in foot size than in height is often found in girls with TS. Since it has been shown that untreated adult women with TS have relatively large feet as well, this disproportionate growth of feet must be considered mainly a part of the natural development in TS. GH had no adverse effects on glucose levels, but did induce higher levels of insulin that decreased after

Figure 4 Reference curve for healthy Dutch girls (3rd, 10th, 50th, 90th, and 97th percentiles, indicated by solid lines) and for untreated girls with Turner syndrome (northern European references: 3rd, 50th, and 97th percentiles, indicated by dashed lines).

discontinuation of GH. Long-term GH treatment seems to be safe, but continued observation into adulthood is required.

Gonadal Dysgenesis

Induction of Puberty

To induce puberty, continuous treatment with estrogens must be given to girls with TS. Although 5–10% retain sufficient ovarian function for puberty to start spontaneously, most girls show a progressive ovarian failure and need estrogen therapy for complete breast development and withdrawal bleeding. The authors prefer the use of the natural estrogen 17β -estradiol over synthetic estrogens. The optimal age to start estrogen therapy is a point of discussion. Although it has been shown that lower doses may stimulate growth, it has been suggested that estrogen therapy be postponed to delay closure of the epiphyseal growth plates and, consequently, to prolong the growth phase. However, delay of pubertal development may have

serious psychosocial consequences. Therefore, it is important to maximize the growth before higher levels of estrogens, required for complete pubertal development, will result in epiphyseal fusion. In the authors' view, when GH treatment has been optimized, that is, starting early (before 8–9 years of age) and with an adequate dose (0.045 mg/kg/day), it is not necessary to delay the induction of puberty: treatment can start at approximately 12 years of age with low-dose estrogens [5 to 10 μ g 17 β -estradiol/kg/day or 50 to 100 ng ethinyl-estradiol/kg/day or Premarin (a conjugated estrogen used particularly in the United States) at a dose of 0.3 to 0.625 mg]. The dose must be adjusted to the response of the individual patient. However, the progression of puberty (from Tanner breast stage 2 to stage 4–5 with regular withdrawal bleeding) should take a similar length of time as in spontaneous puberty, that is, approximately 2–3 years. Cyclic progestin, such as medroxyprogesterone or dydrogesterone, at 5–10 mg daily for 12–14 days each month, should be added in order to induce withdrawal bleeding and consequently prevent endometrial hyperplasia. It should be started in accordance with normal pubertal development, that is, before Tanner breast stage 4 is reached, which is usually after 2 years on estrogen.

Hormonal Replacement Therapy in Adulthood

To treat the short- and long-term consequences of estrogen deficiency in women with TS, continuation of hormonal replacement therapy (HRT) is highly recommended. The available studies indicate that HRT has beneficial effects on bone density, risk of cardiovascular disease, and hyperinsulinism. In addition, HRT might have positive effects on general well-being, cognition, and psychosocial functioning. Natural estrogens are recommended either orally, at least (the equivalent of) 2 mg 17 β -estradiol, or transdermally, 25–50 μ g/24 h, combined with cyclic progestin. Since overweight and hypertension can be exacerbated by exogenous estrogen, particularly when administered by the oral rather than the transdermal route, blood pressure should be checked at regular intervals.

Fertility

Ninety-five percent of women with TS are infertile. Abnormal germ cell development combined with accelerated oocyte loss results in a percentage of only 5–10% of Turner girls who will have oocytes remaining in their ovaries at the age of puberty. Those with follicles remaining may develop ovulatory cycles and will have a short period of fertility prior to entering into a premature menopause. In general, outcomes of

spontaneous pregnancy in Turner women are poor, with miscarriage rates of 30% and a high incidence of structural and chromosomal abnormalities that may affect 25% of live births.

The availability of oocyte donation combined with *in vitro* fertilization offers these women a realistic change of conceiving and delivering a healthy child. Although some case series indicate that conception rates rival those obtained in non-Turner women, the pregnancies are more frequently complicated by miscarriage and the need for caesarean section.

Pregnancy is associated with maternal morbidity. Those with cardiovascular abnormalities may be at risk of aortic dissection, and prepregnancy screening for preexisting dilation of the aortic root is therefore recommended. In addition to possibly increasing the rate of miscarriage, the hypoplastic uterus frequently observed in adult TS may be prone to rupture in late pregnancy. Furthermore, an increased risk of cephalopelvic disproportion at delivery exists. The mechanical and physiological stresses of pregnancy may be reduced by avoiding multiple pregnancy.

The future may offer additional fertility options for Turner women. The ability to cryopreserve, thaw, and mature oocytes *in vitro* makes it feasible to preserve for later fertilization those few oocytes remaining at prepuberty and technique is being extensively investigated. Although it is still only a research tool, this technique may provide the possibility of pregnancy with the patient's own oocytes. Though it is an attractive proposition, it would not overcome the high risk of fetal abnormalities observed in spontaneous pregnancies in Turner women.

Other Medical Problems

Cardiovascular Disease

The most frequently observed major congenital cardiovascular abnormality in TS is the coarctation of the aorta, which can be corrected completely by surgical intervention. Morphological abnormalities of the aortic valves, which are often found, are mostly not of clinical significance in childhood. The incidence of hypertension is higher in girls and adults with TS than in healthy peers. The mechanisms leading to hypertension in these individuals are unknown and not clearly related to the cardiac or renal congenital abnormalities. Obesity, common in adolescent and adult individuals with TS, contributes to high blood pressure. Rupture of an aneurysm or dissection of the aorta in childhood has been rarely described and is associated with hypertension. However, even in the

absence of predisposing factors such as aortic valve abnormalities or hypertension, this life-threatening event occurs more frequently than in the normal population and can even occur at a younger age. Therefore, evaluation and follow-up of the cardiovascular dimensions and blood pressure are required, with adequate treatment when indicated.

The chronic estrogen deficiency known to affect many adult women with TS is likely to be associated with increased cardiovascular morbidity, since it is becoming clear that estrogens not only confer cardioprotectivity by lowering harmful circulating lipids, but also through direct antioxidant effects, through a change in the vascular reactivity, and through its interaction with smooth vascular muscles.

Ocular and Hearing Problems

The eyes often show slight changes in the position and form of the palpebral fissure or ptosis can be observed; this does not affect function. It is important that visual disorders and squinting should be diagnosed and treated as early as possible to prevent further deterioration or permanent damage.

Conductive hearing loss and sensorineural hearing loss are common in girls and women with TS. The outer ear, middle ear, and inner ear are all affected and hearing problems and ear malformations correlate with the karyotype. Frequent periods of otitis media are found in 50–80% of patients. With audiometric measurements, a sensorineural dip in the midfrequencies is

often found. In a young Turner girl, this seldom leads to hearing impairment, but the dip broadens and the depth progresses over time, leading to social hearing problems later. A high-frequency hearing loss (presbycusis) is also added to the dip at >35 years of age, leading to rapid hearing loss and social hearing problems at a younger age than in the normal population.

Skin and Neck

Swelling of the backs of the hands and dorsum of the feet due to lymphedema is not exclusive to TS but is a striking feature, particularly in the newborn. In most girls, the lymphedema shows a tendency to regress after birth. Some patients have an increased number of pigmented naevi, which are usually benign but often show a tendency to grow during puberty. Some clinical evidence has shown that when recombinant human growth hormone is administered for short stature, the growth of melanocytic naevi is boosted without signs of malignant transformation. The patient's neck often appears short and thick-set. In addition, a pterygium colli (webbed neck) can be found (Fig. 5) and can be corrected by surgery. However, keloid scars develop more often than usual after surgical interventions.

Skeleton and Bone Mineral Density

In addition to the "classical" sign of cubitus valgus, occasionally Madelung's deformity of the wrist (the ulna projects beyond the level of the hand because

Figure 5 Turner girl with pterygium colli (webbed neck).

the wrist is displaced toward the palm of the hand) or some other minor deformities of the hands and feet are found. In addition, girls and women with TS have relatively large hands and feet relative to their height. Bone mineral content (BMC) is decreased in adults with TS, whereas BMC is normal in prepubertal girls with TS. It is well known that treatment with estrogens is pivotal in order to avoid rapid bone mineral loss in adolescents and young adults. Furthermore, studies have shown that GH-treated Turner girls receiving low-dose estrogens do not have osteopenia. There have been suggestions that the reduced BMC and bone mineral density (BMD) are a function of the syndrome per se in combination with the estrogen deficiency. Both clinical and epidemiological data show that the reduced BMD does indeed lead to increased fractures and osteoporosis. Gravholt and co-workers observed that the increased risk of fractures in TS was already present in childhood and persisted throughout all age groups, favoring the explanation that chromosomal aberrations contribute at least to some extent to the decreased BMD and increased risk of fractures. Furthermore, there are indications that other multiple discrete hormone insufficiencies in women with TS contribute to the low BMD and high risk of fractures.

Renal Disorders

Renal disease occurs up to nine times more frequently in girls and women with TS. Up to one-third of individuals with TS have structural renal malformation. Rotational abnormalities and double-collecting systems are found most frequently. Although many of these abnormalities are without significant major renal complications, some may result in an increased risk of hypertension, urinary tract infections, or hydro-nephrosis. Usually a renal ultrasound was carried out at the time of diagnosis.

Thyroid Disease

Ample clinical and epidemiological evidence shows that the risk of endocrine disease and especially thyroid disease is increased in TS. Up to 50% of women with TS have anti-thyroid antibodies, and autoimmune thyroiditis is common: almost one-quarter of adult patients have hypothyroidism compared with 1% in the general population. Thyreotoxicosis does not occur more frequently in TS.

Glucose Metabolism and Insulin Sensitivity

Increased frequency of abnormal glucose tolerance, reduced insulin sensitivity, hyperinsulinemia, and inappropriately low insulin secretion are seen in TS. In

a register study covering the entire population in Denmark, an increased relative risk of 4.38 was found. A new and unexpected association was that not only type 2, but also type 1 diabetes is more prevalent in TS. Adiposity, which is seen in a large proportion of the adult Turner population, and sometimes decreased physical fitness are important factors in the development of type 2 diabetes.

Hepatic Function

Higher serum levels of hepatic enzymes, such as alanine aminotransferase, γ -glutamyl transferase, and alkaline phosphatase, have been found in adult Turner women than in controls. These elevated levels of hepatic enzymes and proteins do not seem to be associated with overt hepatic disease. Epidemiological evidence, however, suggests that cirrhosis of the liver is more frequent in TS.

Cancer

The relative risk of most cancers is low in TS and comparable to that of the general population, with the exception of the colon and rectum. In two separate registers in Denmark, it was found that the relative risk of these cancers was five to seven times that of the background population. Since sex hormone substitution may lead to an increased risk of cancer of the breast and reproductive organs, concerns have been raised about a possible increased risk in Turner women on HRT. However, no increased risk in the two Danish registers have been found. Gonadoblastoma might develop in the ovaries of girls and women with TS with Y chromosome material. The risk of this occurring has previously been estimated as 25–40%, although newer data suggest a lower risk of only 7–10%. Nevertheless, gonadectomy is still recommended to exclude malignancy with absolute certainty.

COGNITIVE AND PSYCHOSOCIAL ABILITIES

No increase in the prevalence of mental retardation is associated with TS, except for a few patients with a small ring X chromosome that fails to undergo X inactivation. Numerous studies have documented that girls with TS have a neurocognitive profile consisting of visuospatial information processing deficits in the context of relatively preserved verbal skills. In particular, persons with TS are impaired in the coding and transforming of visuospatial information. Relative to typically developing controls, girls with TS also are described as exhibiting difficulty with tasks of left/

right discrimination, road map skills, mental rotation, line orientation, and integration of motor and visual/perceptual skills.

It has been reported that girls with TS are vulnerable to specific behavioral problems, particularly hyperactivity and inattention, as well as learning disabilities.

In conjunction with behavioral problems, girls with TS often exhibit difficulties with social development and functioning. They have been described as showing delayed emotional maturity, difficulty understanding social cues, needing more structure to socialize, poor peer relations, shyness, and poor body image. Impairments in self-concept and self-esteem increase during adolescence but interestingly improve with initiation of estrogen replacement therapy. Abnormalities in cognitive and psychosocial abilities in persons with TS likely reflect underlying atypical brain development and function.

Girls with TS have a typically female pattern of development, with unambiguous female gender identification. Dating and initiation of sexual activities, however, may be somewhat delayed or infrequent. It is not clear whether this reflects some underlying genetic or hormonal influence on behavior or simply discomfort, because of the issues of short stature, physical anomalies, and infertility with which women with TS must cope.

to need any further attention. For clinical studies, a more exact location of the testes than “scrotal,” “subinguinal,” or “inguinal” should be used, preferably by measuring the distance in millimeters between the testis and a defined point (e.g., the pubic tubercle or the external inguinal orifice).

The term cryptorchidism is often used to describe the condition of undescended testes. This term implies that the testes are “hidden,” that they can neither be seen nor palpated. Since in clinical practice even inguinal or subinguinal palpable testes should be considered undescended, the term cryptorchidism is not always correct. “Nondescended” and “retained” (Latin: *retentio testis*) are synonyms of undescended testes that are sometimes used.

The term ectopic testis has been coined to describe a position of the testis that is outside the normal path of the testis during descent. This diagnosis generally cannot be made before surgery. Only after surgery can the true differentiation between a low inguinal and an ectopic testis be made.

It is difficult to distinguish bilaterally retained testes from testicular atrophy. The differentiation between the two may be aided by a human chorionic gonadotropin (hCG) stimulation test. Significantly increased testosterone levels indicate the presence of testes. During the first 2 years of life, measurement of inhibin B in serum is valuable since in boys this hormone is only produced in Sertoli cells. It is more common to find uni- rather than bilaterally undescended testes, and unilaterally retained testes have a better prognosis for future fertility.

INCIDENCE

The classical epidemiological studies by Scorer in the late 1950s in England are often cited. Using his quite strict definitions, 2.7% of boys with a birth weight of > 2.5 kg had undescended testes at birth, but testicular descent proceeded during the first postnatal months so that at age 3 months only 0.9% were considered to have incompletely descended testes. In premature infants, the incidence is much higher (21% if < 2.5 kg), reflecting the late normal descent *in utero*. When Scorer’s study was repeated 20 years later using the same methodology, the incidence at birth and at 3 months was 3.4 and 1.4%, respectively, suggesting a negative trend in fetal testicular development during this period.

In a recent report, the incidence of undescended testes was found to be twice as high in Denmark as in Finland using the same criteria for diagnosis. This

remarkable geographical difference is paralleled by a similar difference in the incidence of testicular cancer during the past few decades, suggesting a possible common environmental cause of testicular maldevelopment.

MECHANISMS OF TESTICULAR DESCENT

The translocation of the fetal testes from the lower abdominal wall to their final destination in the scrotum is lead through the inguinal canal by the gubernaculum, one end of which is anchored in the epididymal tail and the other in what is to become the bottom of the scrotum. Initially, the gubernaculum fills the canal, and through successive shortening and swelling of its intra- and extracanalicular parts it is believed to aid the testis through the canal. The precise hormonal regulation of this series of events is incompletely known. In addition to nonhormonal homeobox genes, some endocrine factors have been suggested to have a crucial role in one or several of the events leading to testicular descent.

Undescended testicles are often found in boys with hypogonadotropic hypogonadism or androgen insensitivity. This indicates a role of androgenic hormones in the final passage through the inguinal canal. Patients with persistent Müllerian duct syndrome due to a loss of function of anti-Müllerian hormone or its receptor also have retained testicles. Therefore, this hormone has been suggested to be a key factor for testicular descent. However, since in this syndrome the testes are closely linked to the uterus and fallopian tubes, this may in itself hinder descent. It has been found that in mice the newly described *Ins13* gene is important for gubernacular development and testicular descent. No human disease has yet been ascribed to this factor.

ABNORMAL FUNCTIONS OF UNDESCENDED TESTICLES

Spermatogenesis

Numerous animal experiments have proven that spermatogenesis is blocked at a premeiotic stage if the testes are retained in or moved into the abdomen at any time after birth. This spermatogenic arrest is reversed if the testes are transferred to the scrotum or even if they are cooled in an abdominal position with a cooling device. These experiments prove that a temperature less than 37°C is needed to complete

spermatogenesis. In man, the difference between abdominal and scrotal temperature is 2 or 3°C. Germ cells, including spermatogonia and spermatoocytes, seem to be the most temperature-sensitive cells, but impaired Sertoli cell function at 37°C may also be of importance.

On the other hand, not all undescended testicles will attain normal spermatogenesis if they are transferred to the scrotum by surgery or by hormonal treatment. As many as 40% of successfully treated men with primary undescended testicles are reported to have grossly subnormal sperm quality. Although the treatment may be harmful, this suggests that a number of undescended testicles have other deficiencies in spermatogenesis unrelated to their abdominal or inguinal position. However, it is not possible to distinguish the testes with primary defects in spermatogenesis from those that will normalize when put in a scrotal position.

Steroidogenesis

Animal experiments have demonstrated that even if the testes are translocated to the abdomen, normal blood levels of testosterone can be maintained. However, there is a subtle difference: The Leydig cells are enlarged and have a lower sensitivity to stimulation by Lutropin (synonyms: luteinizing hormone, LH, interstitial cell-stimulating hormone) or hCG. It is not known whether this is due to a primary effect of temperature on the Leydig cells or if it is secondary to damage to the seminiferous tubules, causing an abnormal paracrine hormonal milieu.

In man, normal testosterone levels in blood are generally seen even when the testicles are undescended. Thus, a stimulation test with hCG can be used to differentiate between bilaterally nonpalpable retained testicles and the complete absence of testes (testicular atrophy). It is important to remember that even a small testis that has a poor prognosis with regard to spermatogenesis should not be removed if the other testis is absent. This small testis may mean the difference between lifelong testosterone replacement and no medication.

Malignancies

It is frequently cited that undescended testicles often develop malignancies and therefore should either be placed into the scrotum or removed. The basis for this assumption lies in the finding of an overrepresentation of undescended testicles (with or without successful

treatment) in cohorts of patients with testicular cancer. Five to 10% of men with testicular tumors have a history of undescended testes. However, the true incidence of testicular cancer in a group of men with undescended testes has not been well documented. In a Swedish retrospective study, all 3000 boys with undescended testes from a defined geographical area were operated on. These patients, as well as 30,000 boys operated on for inguinal hernia, were searched for in the Swedish Cancer Registry when they were adults. In the cryptorchidism cohort, 4 cases of testicular cancer occurred versus 0.54 expected, yielding a relative risk of 7.4 (95% confidence interval, 2.0–19.0). The hernia controls had no increased risk. The most prevalent testicular cancer was seminoma, which has a good prognosis following modern treatment. This figure contrasts with the observation by the Copenhagen group of scientists that as many as 1 or 2% of previously undescended testicles show microscopic carcinoma *in-situ* (CIS) cells. Such testes are known to often develop cancer at a later stage. Small dysgenetic testicles are more prone to develop CIS cells than normal-sized testes. Thus, it is recommended that an undescended testis should be brought into a palpable position so that tumor formation can be detected at an early stage, even in cases in which there is little hope of spermatogenesis. Since testosterone production might be maintained even in a small and soft testicle, it should not be removed unless the contralateral testis is normal.

TREATMENT

There is much controversy regarding the methods of treatment of undescended testicles, despite the numerous articles that have been published. The major controversies relate to the method (hormonal or surgical) and the timing of treatment.

Hormonal Treatment

Probably based on the common finding of undescended testicles in boys with hypogonadotropic hypogonadism or androgen insensitivity, stimulation of the testes through administration of hCG or gonadotropin-releasing hormone (GnRH) has been advocated as the logical treatment. Direct administration of systemic testosterone has the drawback of treating the whole body as much as the testis and its surroundings and in a few trials has not been shown to be very effective.

Human Chorionic Gonadotropins

In many countries, injection of hCG for 3–5 weeks is the recommended treatment of undescended testicles. The following is a typical treatment regimen: injection of 500 IU hCG intramuscularly twice weekly for 5 weeks for boys younger than 6 years old and doubling the dose for older boys. In uncontrolled studies, this treatment is reported to result in testicular descent in approximately 50% of patients; the nonresponders are referred for surgery. However, a meta-analysis of randomized controlled studies indicates that the success rate is only 19%, compared to 5% for placebo groups.

The short-term side effects of hCG include pain of injections, increased frequency of erections, and sometimes development of pubic hair. Animal experiments and some clinical observations have raised concern regarding possible long-term adverse effects of hCG on the testis. Thus, impaired spermatogenesis has been noted in dogs treated with hCG at the time of puberty. In rats, injection of hCG or LH causes an acute inflammatory response in the testicular interstitium, with increased intratesticular pressure, extravasation of leukocytes, and signs of edema. A similar microscopical picture has been reported in testicular biopsies taken within a few days of completed unsuccessful hCG treatment. Furthermore, it has been shown that the number of apoptotic spermatogonia is markedly increased following a course of hCG treatment compared to that in biopsies taken from boys operated on without prior hCG treatment. In one study, a positive correlation was found between the number of apoptotic spermatogonia within 1 month after treatment in childhood and the follitropin, follicle-stimulating hormone, levels as adults, approximately 20 years later. Testicular volume in adulthood was negatively correlated with the initial spermatogonial apoptosis, suggesting a quantitative difference in spermatogenesis secondary to the post-hCG apoptosis.

Gonadotropic-Releasing Hormone

When this hormone became available as a therapeutic modality, several studies demonstrated good results on undescended testicles. However, later controlled studies were unable to repeat these results, and it has been concluded that GnRH treatment is most successful in boys with retractile or high scrotal testes. If results of the professional examination during the neonatal period are available, such information is of great help for predicting whether hormonal treatment (hCG or GnRH) will be effective: Only boys who had palpable testes at birth will respond to hormonal

treatment. Also, success is rare if the testicle is not palpable at the time of later examination. The mechanism of action seems to be increased release of pituitary gonadotropins, similar to the hCG treatment but with a more moderate stimulation of Leydig cell testosterone production. Thus, it can be considered similar to a mild hCG treatment. No side effects of GnRH treatment of undescended testes have been reported.

Surgery (Orchidopexy)

Open surgery is the most direct way of transferring an abdominal or inguinal testis into the scrotum. This method has been used for a very long time. The major complications are surgical: In addition to the small risk of general anesthesia, the blood supply to the testis might be damaged during surgery. A high incidence of testicular atrophy after surgical orchidopexy has been reported. The latter complications may occur in departments in which “scrotal and inguinal surgery” (including orchidopexy and hernia repair) is considered to be an activity for surgeons in training. In skilled hands, this complication should be rare if the testis is not situated very high in the abdomen. Surgery has the added advantage that it provides opportunities for direct observation of the testis and, in selected cases, biopsy for microscopical investigations.

Comparison between Hormonal and Surgical Treatment

The main advantages of hormonal treatment are that it is inexpensive and hospitalization and the trauma of anesthesia and surgery are avoided (when successful). This method also provides an opportunity to test the capacity of the testicles to produce testosterone if blood samples are taken at the end of hormone administration.

The major reason for treating undescended testicles is to save future fertility. Unfortunately, there are no published studies in which patients have been randomized to surgical or hormonal treatment and followed up into adulthood. Therefore, a scientifically based conclusion regarding the advantages of the two approaches in terms of future fertility cannot be made. The possible adverse effects of hCG on future spermatogenesis and the poor efficacy of hCG or GnRH argue against this as the first-line therapy; instead, a primary surgical approach is favored, provided that a skilled surgeon is available.

AGE AT WHICH UNDESCENDED TESTICLES SHOULD BE TREATED

Again, the scientific foundations for recommendations are weak. The single classical report by the Swiss pathologist Hedinger is generally referred to as an argument for early treatment. He compared microscopical sections from undescended and normally descended testicles of boys who had died suddenly. The number of spermatogonia per seminiferous tubular cross section was determined. He noted that in normally descended testicles, there was a steady decline in the number of spermatogonia from birth until 1 or 2 years of age, followed by a slow increase that continued until puberty. In the undescended testes, the initial decline was similar, but the normal increase in spermatogonia after age 2 years did not occur.

The Hedinger study seems to show that undescended testes should be brought into the scrotum before the age of 2 years. It is assumed that spermatogenesis will be improved after successful treatment. Repeat biopsies have been studied in only two publications: One showed improved spermatogenesis, one did not. It is not known whether the catch-up of spermatogenesis is more complete after early rather than after later treatment. Nevertheless, treatment before age 2 has become the standard of treatment in many countries. If this approach is followed, initial surgery is to be preferred rather than hormonal treatment since the latter seems to be even less effective at ages younger than 4 years.

Final recommendations about the most suitable age for treatment of undescended testes must await results of controlled, randomized studies of treatment at various ages. The final outcome to be evaluated in such studies should be spermatogenesis and fertility in adulthood. This requires very long-term prospective studies. Careful measurements of testicular size during the first years after treatment may to some extent predict spermatogenesis and should be performed in future studies.

CONCLUSIONS

The condition of undescended testicles is the most common inborn developmental abnormality in boys,

affecting approximately 1% of the entire male population. The cause may be hormonal deficiencies or, in most cases, unknown. Untreated, undescended testicles always have severely impaired spermatogenesis, but testosterone production is generally acceptable. The risk of malignancy in undescended testicles is increased. If the testes are moved into the scrotum, future spermatogenesis will be improved but not to the full extent. Both the choice of treatment (hormonal or surgical) and the most appropriate age of treatment (1–4 years) are controversial. However, based on current knowledge, skilled surgery at an early age, rather than hormonal treatment, seems to be advisable.

Figure 1 Structure of 1,25(OH)₂D and the principal pathways for its production and metabolism.

D in some foods are widely different from those claimed on the packaging.

Transport

Following its synthesis in the skin or absorption from the gastrointestinal tract, vitamin D circulates bound to vitamin D-binding protein. Vitamin D-binding protein is encoded by a gene located on chromosome 4 and is structurally related to α -fetoprotein and albumin. It circulates at a concentration of 4–8 μ M and there is one binding site for a vitamin D metabolite on each molecule. Thus, only approximately 5% of the binding sites are usually occupied. The affinities of the vitamin D metabolites for vitamin D-binding protein are in the following order: 25(OH)D₃ > 24,25(OH)₂D₃ > vitamin D₃ \approx vitamin D₂ > 1,25(OH)₂D₃ > 1,24,25(OH)₃D₃.

Most circulating vitamin D-binding protein is synthesized in the liver. Its circulating concentrations are increased by pregnancy and estrogen therapy and are decreased under hypoproteinemic conditions (e.g., liver disease, malnutrition, nephrotic syndrome). The role of vitamin D-binding protein is probably to

prevent rapid fluctuations in the levels of the vitamin D metabolites. Vitamin D-binding protein deficiency in humans has not been identified but a knockout mouse does exist. This animal is more susceptible to hypocalcemia when fed a vitamin D-deficient diet than is a wild-type animal. Despite its size (58 kDa), vitamin D-binding protein appears to be filtered at the glomerulus and is then reabsorbed in the proximal tubule via the receptor protein, megalin, a member of the low-density lipoprotein receptor family. Mice deficient in megalin who survive long enough to develop a bone phenotype have severe rickets. Approximately 10% of vitamin D metabolites circulate bound to albumin. Once vitamin D metabolites have entered their target cell, their transport to the appropriate intracellular organelle may be facilitated by a different group of intracellular vitamin D-binding proteins, related to the heat shock proteins.

Activation

The first step in the activation of vitamin D is its 25-hydroxylation, to form 25-hydroxyvitamin D [25(OH)D]. This takes place in the parenchymal

cells of the liver and is mediated by the enzyme from the cytochrome P450 family, coded for by the gene CYP27. This enzyme was originally characterized as providing 27-hydroxylation of cholesterol in the synthesis of bile acids. It is likely that other enzymes are also involved in 25-hydroxylation. There appears to be very little regulation of the 25-hydroxylase and only in very advanced liver failure does its activity become limiting to normal vitamin D metabolism.

25(OH)D formed in the liver returns to the circulation bound to vitamin D-binding protein. If it is to be further hydroxylated, this takes place in the proximal tubular cells of the kidney. The entry of 25(OH)D into these cells is dependent on the action of megalin. Further activation of 25(OH)D is accomplished by 25-hydroxyvitamin D 1 α -hydroxylase, which is also a mitochondrial P450 enzyme encoded by the CYP1 α gene. It shows significant homology to the 25-hydroxylase. The proximal tubular cells that contain the 1 α -hydroxylase have parathyroid hormone (PTH) receptors, which stimulate enzyme activity. This accounts for the increased levels of 1,25-dihydroxyvitamin D [1,25(OH)₂D] in states of hyperparathyroidism. The 1 α -hydroxylase is also expressed in distal tubular cells and, again, megalin is present in these cells. In contrast to the proximal tubule, the PTH receptor is not present, but the receptor for calcitonin is and appears to have a stimulatory effect on 1 α -hydroxylase activity. 1,25(OH)₂D directly inhibits the expression of the CYP1 α gene at both sites in the renal tubule.

The kidney is clearly the most important site of 1,25(OH)₂D synthesis since anephric individuals have dramatically reduced concentrations of the hormone. However, 1,25(OH)₂D is still measurable in such patients, suggesting that there is extrarenal synthesis of the hormone. This 1 α -hydroxylase gene is expressed in skin but even patients who are deficient in the gene still have measurable levels of 1,25(OH)₂D, suggesting that other enzymes might mediate 1-hydroxylation of 25(OH)D. Extrarenal synthesis of 1,25(OH)₂D clearly occurs in granulomatous diseases and in some lymphomas, where unregulated production of the hormone results in hypercalcemia. During pregnancy, the placenta produces 1,25(OH)₂D.

An alternative fate for 25(OH)D is to be hydroxylated on C-24, to produce 24,25-dihydroxyvitamin D. This conversion is mediated by vitamin D 24-hydroxylase, encoded by the gene CYP24. This enzyme can also 24-hydroxylate 1,25(OH)₂D and is regarded as the principal pathway for deactivating vitamin D metabolites. As a consequence, it is widely expressed throughout the body, particularly in vitamin

D target tissues, including the proximal and distal tubules of the kidney. Vitamin D metabolites then undergo further hydroxylations and side chain cleavage, resulting in the production of water-soluble calcitric acid, which has no biological activity.

REGULATION OF VITAMIN D METABOLISM

The key points of regulation of vitamin D metabolism are the 1 α -hydroxylase and the 24-hydroxylase (Table I). As noted above, the 1 α -hydroxylase gene is directly regulated by PTH, calcitonin, and 1,25(OH)₂D, the latter two hormones having the predominant effect under normocalcemic conditions, whereas the effect of PTH predominates over that of calcitonin under hypocalcemic conditions. Phosphate concentration is also an important regulator of 1 α -hydroxylase activity, which is suppressed by high concentrations of phosphate and stimulated by low concentrations. Calcium concentration impacts on 1 α -hydroxylase activity, mainly through its effect on circulating levels of PTH, though there is some evidence that it can directly influence enzyme activity as well. There is also evidence for effects of other growth-related hormones, such as estrogen, prolactin, and growth hormone, but these appear to be relatively minor.

1,25(OH)₂D is the principal regulator of 24-hydroxylase activity. This is a genomic effect mediated by vitamin D-response elements in the promoter for the 24-hydroxylase gene. In the renal proximal tubule, PTH inhibits 24-hydroxylase activity, though it may have an opposite effect in the distal tubule. The induction of 24-hydroxylase by 1,25(OH)₂D also leads to accelerated catabolism of 25(OH)D. This explains the low levels of this metabolite seen in patients treated with calcitriol and in those suffering from primary hyperparathyroidism.

Table I Physiological Regulators of the Principal Enzymes in Vitamin D Metabolism

| 1 α -Hydroxylase | 24-Hydroxylase |
|--------------------------------------|------------------------------------|
| PTH \uparrow | 1,25(OH) ₂ D \uparrow |
| Phosphate \downarrow | PTH \downarrow |
| 1,25(OH) ₂ D \downarrow | |
| Calcitonin \uparrow | |

Note. Arrows indicate the effect of the regulatory factors on enzyme activity.

ACTIONS OF VITAMIN D AND ITS METABOLITES

Mechanisms of Action

The classic mechanism of action of vitamin D metabolites on their target tissues is similar to that of other steroid hormones and is mediated by the vitamin D receptor (VDR), a member of the steroid hormone receptor superfamily. Both $1,25(\text{OH})_2\text{D}$ and $25(\text{OH})\text{D}$ bind to this receptor, though the affinity of $1,25(\text{OH})_2\text{D}$ for the receptor is 1000-fold higher. However, it should be remembered that $25(\text{OH})\text{D}$ circulates in concentrations 1000-fold higher than those of $1,25(\text{OH})_2\text{D}$, so both may contribute to receptor activation. The vitamin D metabolites bind to the VDR, which then forms a heterodimeric complex with the retinoic acid X receptor. This complex then interacts with vitamin D-response elements associated with a variety of genes (see Fig. 2). The VDR gene contains nine exons and encodes a protein of 427 amino acids. In humans, the gene is located on chromosome 12q. The DNA-binding domain is located in the amino-terminal region and consists of a double zinc-finger structure. The ligand-binding domain is in the C-terminal region of the molecule. Mutations of the VDR have been identified in humans and result in vitamin D resistance, producing the clinical picture of rickets. Polymorphisms of the VDR gene have also been observed. These variations in nucleic acid sequence do not result in differences in the amino acid sequence of the expressed protein, but may impact on the transcription or stability of the mRNA for the VDR. Despite extensive clinical studies, it remains unclear whether these polymorphisms are consistently associated with changes in calcium metabolism or bone mass.

In addition to this classic mechanism of action of vitamin D metabolites, rapid responses, which are thought to occur too rapidly to be accounted for by a genomic mechanism of action, have been observed. These rapid responses include changes in intracellular calcium and transcalcitachia, which is a rapid transport of calcium from the intestinal lumen to the circulation. The structure-activity relationships of vitamin D metabolites in stimulating these rapid effects are different from that for the classic genomic effects of vitamin D and some of these effects have been demonstrated in cells lacking the VDR. These observations have raised the possibility of a different vitamin D receptor being present on the cell membrane.

Calcium Metabolism

$1,25(\text{OH})_2\text{D}$ is one of the classic calcitropic hormones. In humans and animals lacking the vitamin D receptor, the only abnormality observed at birth is in hair follicle development. Subsequently, however, hypocalcemia and the development of rickets are observed. The abnormalities in bone development can be prevented by restoration of normal serum calcium concentration, suggesting that maintenance of normocalcemia and maintenance of normophosphatemia are the principal biological roles of the vitamin D metabolites. It is likely that this is achieved primarily by increasing the absorption of calcium in the small intestine. Vitamin D receptors are found throughout the small intestine but are most abundant in the duodenum. Administration of calcitriol to animals or humans leads to increases in intestinal calcium absorption, though the precise mechanism by which this occurs is not fully understood. $1,25(\text{OH})_2\text{D}$ regulates the production of a calcium-binding protein, calbindin D8k, within the intestinal epithelial cell. This is mediated by a vitamin D-response element in the gene for calbindin D9k. It is thought that this calcium-binding protein facilitates the transport of calcium through the intestinal epithelial cells. $1,25(\text{OH})_2\text{D}$ may also facilitate the entry of calcium from the intestinal lumen into the epithelial cell, possibly through a channel. $1,25(\text{OH})_2\text{D}$ also stimulates the activity of an ATP-dependent calcium pump at the basolateral membrane. $1,25(\text{OH})_2\text{D}$ also stimulates intestinal phosphate absorption, though this mostly takes place in the distal small bowel.

The direct effects of $1,25(\text{OH})_2\text{D}$ on bone work in concert with those already described in the intestine, to maintain or increase serum calcium concentrations. $1,25(\text{OH})_2\text{D}$ acts on osteoblasts and their precursors, causing the production of RANK-L, which binds to preosteoclasts to stimulate their development into osteoclasts. This leads to an increase in osteoclastic bone resorption. $1,25(\text{OH})_2\text{D}$ also directly stimulates alkaline phosphatase activity and the production of osteopontin and osteocalcin by osteoblasts. Although it has been suggested that $1,25(\text{OH})_2\text{D}$ may directly influence skeletal mineralization, the majority of evidence suggests that this occurs indirectly, as a result of vitamin D effects on serum calcium and phosphate concentrations.

In the kidney, it is clearly established that $1,25(\text{OH})_2\text{D}$ induces its own catabolism by the 24-hydroxylase and that it inhibits its own production.

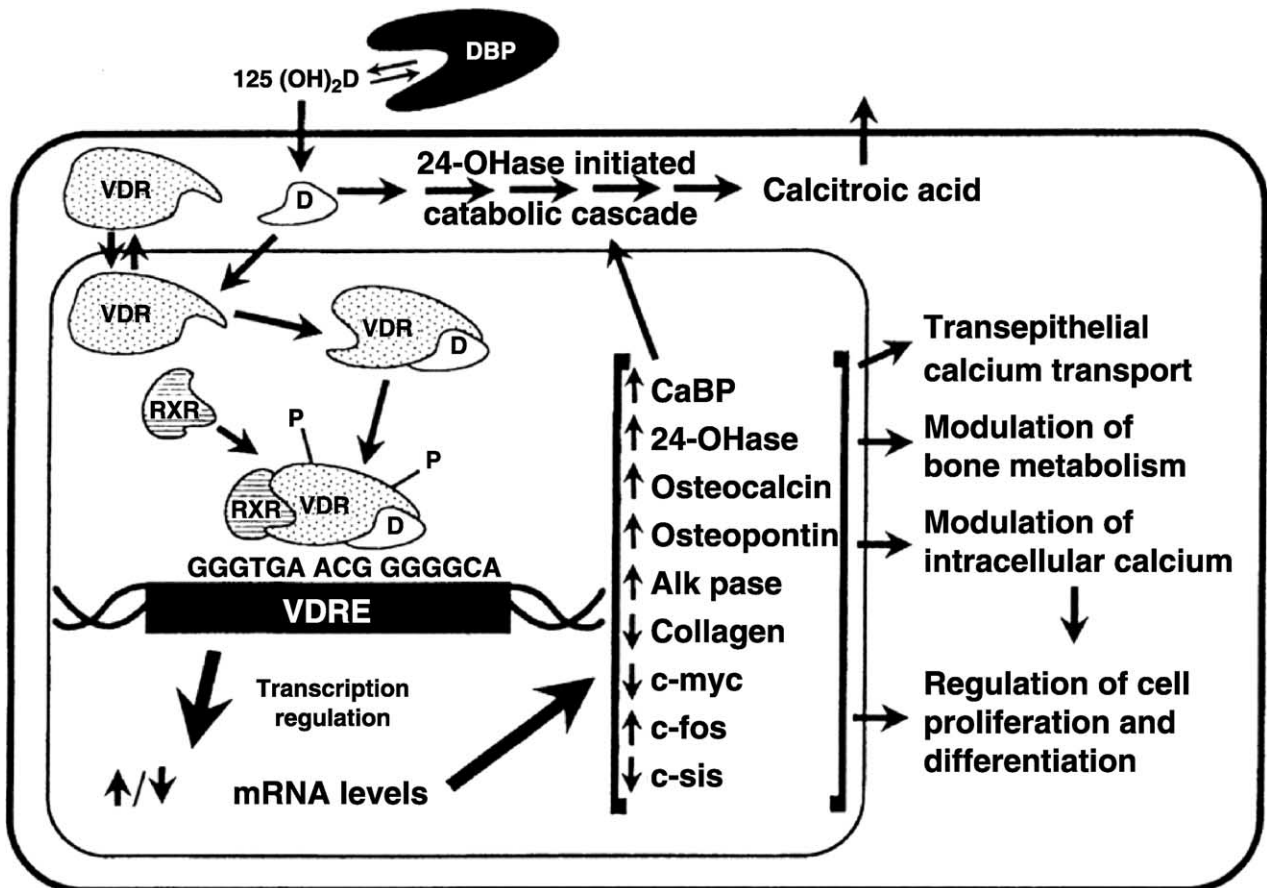

Figure 2 Mechanism of action of $1,25(\text{OH})_2\text{D}$ in target cells. Free $1,25(\text{OH})_2\text{D}$ enters cells and interacts with the vitamin D receptor (VDR), which becomes phosphorylated. A complex is formed with the retinoic acid X receptor (RXR), which then interacts with the vitamin D-response elements (VDRE) of a number of genes regulated by this hormone. Reprinted from Holick, M. F. (1999). Vitamin D: Photobiology, metabolism, mechanism of action and clinical applications. In "Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism" (M. J. Favus, ed.), 4th ed., pp. 92–98. American Society of Bone and Mineral Research, Philadelphia, with permission.

It has been suggested that it has effects on calcium and phosphate reabsorption in the renal tubule but this remains uncertain.

$1,25(\text{OH})_2\text{D}$ also acts on the parathyroid glands, where its binding to the vitamin D receptor directly decreases expression of the PTH gene. This genomic effect is reinforced by the action of $1,25(\text{OH})_2\text{D}$ to increase serum calcium and thus diminish PTH secretion. The direct effects of vitamin D metabolites on PTH secretion are particularly important in the management of the secondary hyperparathyroidism of chronic renal failure. They may also be important in the prevention and treatment of primary hyperparathyroidism, since this condition may be exacerbated by the low levels of $25(\text{OH})\text{D}$ with which it is frequently associated.

Other Tissues

$1,25(\text{OH})_2\text{D}$ receptors are expressed in a wide variety of tissues other than those classically involved in mineral and bone homeostasis. In keratinocytes and in some white blood cells or their precursors, $1,25(\text{OH})_2\text{D}$ has anti-proliferative and pro-differentiation effects. Thus, in psoriasis, it appears that the hyperproliferative state of skin cells can be controlled with the use of vitamin D analogues. There is also experimental evidence that some leukemic cell lines show similar responses to vitamin D metabolites. As a result, there has been an interest in using $1,25(\text{OH})_2\text{D}$ for treating leukemias and other tumors, such as those of the breast, colon, and prostate. Despite the existence of promising preliminary results

in these areas for a number of years, the vitamin D metabolites are not yet established as having a therapeutic role in any of these malignant conditions. Vitamin D metabolites may also have direct actions on muscle cells, on adipocytes, in immune regulation, and on endocrine tissues, such as the pancreatic beta cell.

ASSESSMENT OF VITAMIN D STATUS

25(OH)D is the principal circulating vitamin D metabolite and it is the entity that should be assessed when determining an individual's vitamin D status. Because ingested or endogenously produced calciferols are converted to 25(OH)D with very little regulation, serum levels of this metabolite accurately reflect both excess and deficiency states. As noted above, 25(OH)D circulates bound to vitamin D-binding protein, so any condition associated with hypoproteinemia may produce falsely depressed levels of 25(OH)D. Caution is required in interpreting measurements of vitamin D metabolites in this situation, because it is uncommon to measure vitamin D-binding protein in routine clinical practice.

When assessing vitamin D status, it is important to consider whether the "normal" range—which varies with latitude—can be regarded as optimal. This has been addressed by Malabanan *et al.*, who demonstrated that vitamin D supplementation suppressed parathyroid hormone levels only in subjects whose baseline serum 25-hydroxyvitamin D was less than 50 nmol/liter. This suggests that 50 nmol/liter is a more appropriate target concentration for serum 25-hydroxyvitamin D, though some cross-sectional studies suggest that it may be as high as 100 nmol/liter.

Measurements of serum 1,25(OH)₂D are also widely available. The value of measurement of 1,25(OH)₂D in clinical medicine is relatively small. It is sometimes helpful in elucidating the cause of hypercalcemia, being high when hypercalcemia is a direct consequence of overproduction of 1,25(OH)₂D, as in some granulomatous conditions and lymphomas. The widespread impression that 1,25(OH)₂D is the only biologically active vitamin D metabolite frequently leads to the inappropriate use of vitamin D assays. This belief results in the expectation that levels of 1,25(OH)₂D are all that will influence calcium metabolism, whereas this is clearly not the case. As vitamin D deficiency develops, serum 25(OH)D declines. In response to this decline, secondary hyperparathyroidism develops and with it there are increases in serum 1,25(OH)₂D. Thus, the paradoxical situation can develop, wherein patients who have clinical and

histological evidence of osteomalacia have a serum 1,25(OH)₂D level that is either normal or supranormal.

In summary, measurement of serum 25(OH)D suffices for the detection of vitamin D deficiency or vitamin D intoxication and measurement of 1,25(OH)₂D is usually indicated only in the diagnosis of difficult cases of hypercalcemia.

THERAPEUTIC USE OF VITAMIN D AND ITS METABOLITES

Vitamin D Deficiency and Osteoporosis

It is becoming increasingly recognized that vitamin D deficiency is common in the elderly, particularly those who are no longer fully independent and therefore less exposed to sunlight. The problem is often greater at higher latitudes, though it can also occur in very hot climates where the sun is often avoided because of the heat. Vitamin D deficiency leads to secondary hyperparathyroidism and a resulting increase in bone loss.

Physiological supplements of calciferol (e.g., 400 IU/day) reduce parathyroid hormone concentrations in elderly subjects and lead to increases in bone density, particularly at the femoral neck. Similar changes in biochemical end-points can be achieved with regular sunlight exposure for 15–30 min daily. Two large studies have assessed the effect on fracture rates of calciferol supplementation alone. Lips *et al.* showed no difference in fracture incidence in 2578 Dutch men and women over the age of 70 years randomized to calciferol 400 IU/day or placebo, whereas Heikinheimo *et al.* showed that 150,000 IU of vitamin D annually reduced symptomatic fracture rates by 25% in a cohort of 800 elderly subjects in Finland. Two other major studies have been reported in which calcium was coadministered with calciferol to elderly subjects. Chapuy *et al.* demonstrated a reduction of more than 25% in nonvertebral and hip fracture rates in a cohort of 3000 elderly women studied over a period of 3 years. Dawson-Hughes *et al.* demonstrated a reduction of nonvertebral fracture rates by more than 50% in 400 older men and women randomized to calcium 500 mg/day plus 700 IU vitamin D or to placebo. It is not possible to determine whether the calcium, the vitamin D, or the combination of the two was the component essential to the success of these two studies, but the findings do point to the possibility of a major reduction in morbidity in elderly patients using a safe and inexpensive intervention. Vitamin D supplementation seems to produce no benefit in early postmenopausal women

or those who are already vitamin D replete, as defined above.

The dose–response relationship between calciferol intake and serum 25(OH)D levels is relatively flat up to intakes of several thousand international units per day. Thus, this intervention is safe and doses of 400–1200 IU/day are routinely used. Calciferol is stored in adipose tissue and has a half-life of many weeks. Therefore, it can be administered in larger doses less frequently. Doses of at least 500,000 IU can be given at once to correct deficiency and the authors routinely maintain normal vitamin D status with monthly oral supplements of 50,000 IU. There are anecdotal reports of wide variability in the bioavailability of different preparations of calciferol and dietary vitamin D intakes also vary widely from country to country. Therefore, each region needs to determine what regimen of replacement is safe and effective in that environment.

The use of vitamin D as a physiological supplement is fundamentally different from the use of high doses of calciferol or 1 α -hydroxylated vitamin D metabolites (e.g., alfacalcidol, calcitriol) to pharmacologically manipulate intestinal calcium absorption. Both of these strategies bypass the normal homeostatic controls of vitamin D metabolism and therefore carry a significant risk of hypercalcemia and hypercalciuria. The use of pharmacological doses of calciferol has not been demonstrated to confer any beneficial effects on bone density. Trials of the use of alfacalcidol or calcitriol in the prevention and treatment of osteoporosis have shown mixed results, including both significant increases and significant decreases in bone density and fracture rates. Adverse outcomes have been most common in studies of osteoporosis prevention in women and in studies in males. This variability in results may be attributable to a different balance of the potentially beneficial effects on intestinal calcium absorption versus the potentially damaging effects on osteoclast recruitment in the different populations studied. As a result, vitamin D metabolites are not regarded as a first-line therapy for osteoporosis.

In conclusion, suboptimal vitamin D status is very common in the elderly, mainly because of reduced sunlight exposure. The provision of a daily intake of 400–800 IU is a straightforward, safe, and inexpensive means of prevention and appears to produce substantial reductions in fracture rates.

Other Conditions

Failure of the 1 α -hydroxylation of 25(OH)D is probably the single most important contributor to the

hypocalcemia of renal failure and the resulting development of renal bone disease. Thus, the availability of 1,25(OH)₂D (calcitriol) and 1 α -hydroxyvitamin D (alfacalcidol) as pharmaceuticals has revolutionized the management of calcium metabolism in renal failure. The development of hypercalcemia can be dose-limiting when using vitamin D metabolites to reverse secondary hyperparathyroidism in renal failure. This has led to the development of synthetic vitamin D analogues that suppress parathyroid hormone secretion but have less effect on serum calcium.

The 1 α -hydroxyvitamin D metabolites have also revolutionized the management of other conditions associated with either hypocalcemia (e.g., hypoparathyroidism) or hypophosphatemia (e.g., X-linked-hypophosphatemia, oncogenic osteomalacia). Previously, these conditions were managed with very large doses of calciferol. Because of its long half-life, any overdosage resulted in sustained hypercalcemia, often leading to renal failure.

As noted above, the anti-proliferative actions of the vitamin D metabolites are being used in the management of psoriasis and experimental work is continuing regarding their use in some cancers. There is also epidemiological evidence suggesting that high vitamin D levels are associated with a lower incidence of cardiovascular disease. This work is potentially subject to a number of biases (e.g., people who are more physically active and therefore at lower risk of cardiovascular disease spend more time outdoors and therefore have better vitamin D status). Intervention studies will be necessary before the significance of these findings can be determined and vitamin D supplementation is not a standard part of cardiovascular disease prevention at the present time.

SAFETY OF VITAMIN D AND ITS METABOLITES

The use of replacement doses of calciferol is a very safe intervention, as would be expected since the intention is to restore circulating levels of 25(OH)D to the levels that are present in the ambulant population. Thus, in the study by Chapuy in which more than 1600 women were treated with calciferol, the only individual who developed hypercalcemia was subsequently found to have primary hyperparathyroidism. A similar zero-incidence of significant hypercalcemia has been reported by other investigators using low-dose regimens of calciferol administration.

Figure 3 Dose–response relationship between daily vitamin D intake and mean 25(OH)D concentration. The solid points show mean results for groups of adults consuming the indicated doses of vitamin D, usually vitamin D₃. Results for groups of adults that were definitely consuming vitamin D₂ are shown by the circled points. The results represented by × are for individuals who had hypercalcemia as a result of vitamin D consumption. The toxic intakes were of vitamin D₂, not D₃. Reprinted from Vieth, R. (2001). In “Nutritional Aspects of Osteoporosis” (P. Burckhardt, R. Heaney, and B. Dawson-Hughes, eds.), pp. 173–195. Academic Press, San Diego, CA, with permission.

In contrast, with the use of pharmacological doses of calciferol, there are case reports of severe hypercalcemia, often of long duration and sometimes associated with renal failure. Vieth reviewed this issue and concluded that the relationship of vitamin D dose to serum 25(OH)D concentration is relatively flat up to a daily calciferol intake of 10,000 IU (Fig. 3). It is likely that doses of up to 10,000 IU/day are safe in individuals who have no conditions that predispose them to hypercalcemia (e.g., primary hyperparathyroidism, sarcoidosis) and fully documented cases of toxicity have occurred only with intakes of 40,000 IU/day or more. Calcitriol and alfacalcidol frequently cause hypercalcemia and hypercalciuria, but their short half-lives result in this being readily corrected by dose adjustment. However, close monitoring is necessary when these drugs are being introduced or their doses increased. Changes in calcium intake can also affect serum calcium concentrations in patients using these compounds.

The hypercalcemia of vitamin D intoxication has usually been attributed to increased intestinal calcium absorption, but it has been demonstrated that bisphosphonates are effective in treating some cases, indicating that increased bone resorption may also contribute. Hyperresorption of bone has certainly been demonstrated in animal models of hypervitaminosis D. The long duration of hypercalcemia associated with calciferol intoxication means that this compound is substantially less safe at high doses than its more active and shorter half-life metabolites, such as alfacalcidol and calcitriol.

failure or delay of mineralization in the growth plates and joints as well as in other skeletal sites.

VITAMIN D DEFICIENCY

Calcium is absorbed in the upper small intestine under the control of the active vitamin D hormone, 1,25-dihydroxyvitamin D₃ [1,25(OH)₂D₃], also known as calcitriol. In this article, we use these terms interchangeably. Vitamin D is synthesized in the skin with the aid of sunlight or it is ingested in the diet. The distribution of vitamin D in food is quite restricted, being substantial mainly in oily fish. Because dietary vitamin D is so limited, some countries have fortified various foods (milk, cereals, orange juice, etc.) in order to avoid widespread vitamin D deficiency. Even in these countries, nutritional sources of vitamin D may be limited and exposure to sunlight is critical for adequate endogenous production of vitamin D.

Vitamin D deficiency is characterized by undermineralized bone and excess osteoid. Normally, most osteoid is rapidly mineralized and a small rim of unmineralized matrix can be found on bone trabeculae. However, in rickets or osteomalacia, the level of unmineralized osteoid is increased. Initially, osteoid surface and volume are increased, but osteoid thickness and lag times (delay in mineralizing osteoid) are normal. In more severe cases, osteoid thickness exceeds 15 μm and mineralization lag time exceeds 100 days. In the most florid cases, no mineralization may be detected. The strength of unmineralized osteoid is greatly diminished compared to that of normally mineralized bone, leading to metabolic bone disease and increased susceptibility to fracture. In the case of childhood rickets, a number of additional skeletal abnormalities are found, including bowing of the long bones, joint pain and swelling, bone pain, and abnormalities of the teeth. In severe vitamin D insufficiency, infants may show delayed development and even respiratory failure because breathing is impaired due to involvement of the thoracic cage with rickets.

Any step in the pathway of calcitriol synthesis or action that is defective can result in rickets/osteomalacia. The usual causes of rickets/osteomalacia are listed in Table I and the pathway involved is shown in Fig. 1. The most common cause of rickets/osteomalacia worldwide is vitamin D deficiency due to inadequate vitamin D ingestion combined with insufficient synthesis in the skin. This can be caused by inadequate amounts of vitamin D in the diet and/or by malabsorption of vitamin D in the gastrointestinal tract in association with inadequate sunlight

Table I Etiology of Rickets or Osteomalacia

| |

exposure. Since vitamin D supplementation of milk or other dietary products reduces nutritional causes of rickets/osteomalacia in the United States and some other developed countries, other etiologies are becoming more important in the developed world. However, avoidance of dairy products and the use of sunscreens or the wearing of traditional clothing that prevents sunlight exposure contribute to vitamin D deficiency even in developed countries. Furthermore, the elderly or others confined to an indoors existence in nursing homes has led to an upsurge in vitamin D deficiency.

Other causes of rickets/osteomalacia include the inability to synthesize calcitriol due to renal failure or a genetic defect in 1α-hydroxylase, the key enzyme involved in calcitriol synthesis. Abnormalities that cause excess loss of phosphate include genetic defects or tumors that produce phosphaturia. Finally, mutations in the vitamin D receptor (VDR), the protein that mediates calcitriol actions in the intestine and other target tissues, can cause rickets in children. Each of these entities is described later.

MECHANISM OF VITAMIN D ACTION

Vitamin D Receptor

Although called a vitamin, 1,25-dihydroxyvitamin D (calcitriol) is actually a member of the steroid

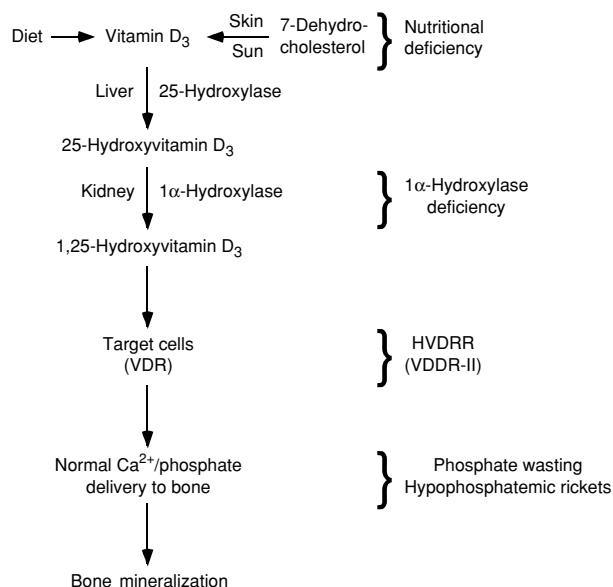

Figure 1 Pathways of calcitriol synthesis and action. The synthetic pathway of calcitriol (1,25-dihydroxyvitamin D₃) is shown. Defects in the pathway that interfere with normal mineralization of bone and cause osteomalacia or rickets are indicated. From Feldman, D., and Malloy, P. J. (2003). "Encyclopedia of Hormones," Vol. 3, pp. 620–628. Reprinted with permission from Elsevier.

hormone family. Together with PTH, it regulates calcium metabolism and bone mineralization. Calcitriol also promotes other physiologic activities, including exerting prodifferentiation, antiproliferative, and immunosuppressive actions. Calcitriol acts through the VDR, a member of the steroid–thyroid–retinoid receptor gene superfamily, although some data suggest a rapid nongenomic action as well. The VDR acts as a ligand-activated transcription factor and regulates gene transcription. The VDR has a modular structure comprising an N-terminal DNA-binding domain (DBD) and a C-terminal ligand-binding domain (LBD). The DBD enables the VDR to interact with vitamin D response elements (VDREs), specific nucleotide sequences located in promoter regions of vitamin D-responsive genes. The VDR LBD specifically binds calcitriol and triggers a series of molecular events leading to the activation of target genes. Gene transactivation by the VDR requires its binding as a heterodimer with the retinoid X receptor (RXR). RXR heterodimerizes with a number of other receptors in the steroid–thyroid–retinoid receptor gene superfamily, including thyroid hormone receptor, retinoic acid receptor, and the peroxisome proliferator activating receptor. Coactivator proteins are also recruited to the VDR following ligand binding. These proteins act as bridging factors linking the

VDR–RXR heterodimer to the preinitiation complexes and RNA polymerase II. Coactivators include a family of closely related p160 proteins, such as SRC1/NcoA1, TIF2/GRIP1/NcoA2/SRC2, and pCIP/RAC3/ACTR/AIB1/SRC3. Other coactivators include a group of proteins collectively called vitamin D receptor-interacting proteins (DRIPs). These coactivator proteins associate with nuclear receptors in a ligand-dependent manner to enhance transactivation of target genes.

Pathway of Calcitriol Action

How do cells respond to calcitriol? After the hormone is produced and secreted by the kidney, it is transported in the blood either bound to vitamin D-binding protein (DBP) or in the free state. The free hormone is lipid soluble and readily gains entry into cells by permeating the lipid bilayer of the cell membrane, although evidence of an active step in cell entry is currently being developed. Cells that respond to calcitriol have VDRs located in the cell nuclear compartment, where they are loosely associated with RXR. Once inside the cell, calcitriol encounters the VDR, where it becomes bound in the ligand-binding pocket within the LBD. The binding causes the VDR to bind more tightly to RXR and to interact with VDREs on target genes. When calcitriol occupies the ligand-binding pocket, helix H12 in the VDR LBD swings into a new position, locking the hormone inside the receptor. The repositioning of helix H12 forms a binding cleft for interaction with coactivators. The coactivators that are recruited by the VDR, such as SRC-1, are then able to remodel the chromatin so that assembly of the transcriptional apparatus can occur. The VDR can then recruit the DRIP complex and begin activating gene transcription.

ACQUIRED CAUSES OF RICKETS AND OSTEOMALACIA

Nutritional Deficiency

Vitamin D deficiency causes a sequence of metabolic abnormalities that combine to cause osteomalacia or rickets. The insufficiency of vitamin D, if severe, can result in diminished intestinal calcium absorption and hypocalcemia. The calcium-sensing receptor present in the parathyroid gland detects the low serum calcium level. This leads to an increase in PTH synthesis and results in secondary hyperparathyroidism. The elevated levels of PTH attempt to correct the hypocalcemia by three actions

on bone and kidney. One action aimed at correcting the calcitriol deficiency is the stimulation of renal 1α -hydroxylase activity to cause increased renal production of calcitriol. However, this step requires adequate vitamin D and 25-hydroxyvitamin D substrate, which is absent in vitamin D deficiency. Therefore, this compensation fails to correct the deficiency. A second PTH action on bone is to increase bone resorption to raise calcium and phosphate flux from bone to serum. In other words, bone is sacrificed in an attempt to maintain normal serum calcium, thus contributing to the metabolic bone disease caused by calcitriol deficiency. A third PTH action is to increase renal calcium reabsorption and decrease calciuria. However, while decreasing calciuria, PTH increases phosphaturia, thus reducing the availability of this mineral component for bone mineralization. The overall result of vitamin D deficiency is hypocalcemia, secondary hyperparathyroidism, and defective mineralization of osteoid leading to the development of osteomalacia.

It is clear that adequate calcium and vitamin D are required for bone health. The vitamin D requirement is estimated to be a minimum of 400 IU per day, although elderly subjects may require 600 IU or more. Most infants and children in the United States have adequate vitamin D intake because of vitamin D supplementation of milk. During adolescence, when consumption of milk and dairy products diminishes, decreased dietary vitamin D may adversely affect calcium absorption and thereby lead to impaired skeletal health. Vitamin D insufficiency is greatly increased in the elderly population, which is at risk for both osteoporosis and osteomalacia. This problem is worse in countries that do not supplement milk or other foods with vitamin D and where sunlight exposure may be inadequate.

Vitamin D is not present in substantial levels in many foodstuffs except for oily fish. In the United States, milk is ostensibly fortified with 400 IU of vitamin D per quart, although actual amounts vary. Ultraviolet (UV) radiation from sunlight is necessary for endogenous production of vitamin D in the skin. Since dietary vitamin D is so limited, sunlight is essential for most individuals to achieve normal vitamin D status. The solar irradiation causes photolysis of the precursor 7-dehydrocholesterol in the skin and allows for its conversion to vitamin D. However, many individuals have reduced intake of milk or dairy products and also do not have adequate sun exposure, leading to vitamin D insufficiency. This problem is exacerbated by several modern trends, including avoidance of dairy products to control weight or elevated

cholesterol levels and avoidance of sunlight to reduce the risk of skin cancer. Also, many elderly individuals have limited mobility and do not have the opportunity for adequate sunlight exposure. These circumstances have led to a substantial increase in the frequency of osteomalacic bone disease and fractures in the elderly, especially among the nursing home population. Some populations wear traditional dress covering most of the body and preventing UV rays from reaching the skin. During winter, reduced sunlight further diminishes vitamin D synthesis, especially in the northern latitudes, and worsens the tendency toward vitamin D insufficiency. Races with dark skin have additional difficulty obtaining adequate vitamin D synthesis because the melanin in the skin is a natural sunscreen that reduces the penetration of UV rays to the layers of the dermis where vitamin D is formed.

Deficient dietary calcium intake may also cause osteomalacia or exacerbate the problem of vitamin D insufficiency. There exists a spectrum of etiologies ranging from pure vitamin D deficiency with normal calcium intake to adequate vitamin D sufficiency with inadequate calcium intake. Many cases worldwide are due to vitamin D insufficiency combined with relative calcium insufficiency. Certain dietary habits, especially common in selected populations, may exacerbate vitamin D insufficiency by inhibiting vitamin D absorption or increasing the metabolic clearance of 25-hydroxyvitamin D, including the consumption of chapattis, an East Asian bread made from wheat flour with high phytate levels that impairs calcium and vitamin D absorption. Increased risk of osteomalacia is associated with a number of factors, including inadequate sunlight exposure, living at high altitude, vegetarianism, calcium-deficient diets, and high-fiber diets. A combination of inadequate dietary vitamin D and lack of UV light exposure and exacerbated by other factors determines the risk and severity of the osteomalacic bone disease.

Renal Osteodystrophy

Renal failure is associated with complex abnormalities of vitamin D, secondary hyperparathyroidism, and calcium metabolism. Phosphate retention due to inadequate kidney function causes hypocalcemia by complexing calcium and inhibiting renal 1α -hydroxylase activity and therefore causes diminished calcitriol synthesis. Also, as kidneys shrink and renal functional tissue declines, 1α -hydroxylase activity is further diminished, leading to deficiency of calcitriol production. These changes combine to

cause secondary hyperparathyroidism, compounding the bone abnormality. The constellation of hypocalcemia, secondary hyperparathyroidism, and calcitriol deficiency causes osteomalacia and renal osteodystrophy. Recognition of this sequence of events has led to important changes in the medical management of renal failure in an attempt to prevent the development of renal osteodystrophy. Two major therapeutic measures are (i) the use of phosphate binders to minimize and/or prevent the development of phosphate retention with elevated phosphate concentration and its consequent hypocalcemia and (ii) supplementation with calcitriol to avoid deficiency of active vitamin D.

Gastrointestinal Problems and Malabsorption of Vitamin D

In areas of the world that do not fortify foodstuffs with vitamin D, diet is estimated to contribute only one-fourth to one-third of the daily requirement of vitamin D. Therefore, gastrointestinal malabsorption may worsen vitamin D insufficiency but often is not the sole cause of osteomalacia. Some gastrointestinal problems are also associated with increased metabolic clearance of vitamin D metabolites, compounding the malabsorption problem. Gastrointestinal diseases associated with osteomalacia include celiac disease (gluten enteropathy), cirrhosis, biliary obstruction, pancreatic insufficiency, inflammatory bowel disease, and postgastroectomy or jejunioileal bypass surgery. Patients receiving total parenteral nutrition, usually because of chronic bowel disease, develop osteomalacia due to inadequate mineral or vitamin D supplementation. Anticonvulsant therapy increases the metabolic clearance of vitamin D metabolites, requiring vitamin D supplementation.

Tumor-Induced Osteomalacia

Some small mesenchymal tumors (hemangiopericytomas, fibromas, angiosarcomas, etc.) can cause phosphaturia and hypophosphatemia, leading to osteomalacia. The syndrome is known as tumor-induced osteomalacia (TIO) or oncogenic osteomalacia. The mechanism involves the synthesis and secretion of excessive amounts of a phosphaturic factor called phosphatonin. The major candidates for this role are FGF23 and frizzled-related protein 4 (FRP-4). How FGF23 and FRP-4 causes phosphaturia is not completely understood. However, findings from the study of X-linked hypophosphatemia (XLH) and autosomal dominant hypophosphatemic rickets (ADHR)

shed light on TIO and the mechanism for all three phosphaturic entities is discussed below. The tumors causing TIO originally were thought to be benign and of mesenchymal origin, but malignant tumors have also been reported to cause the syndrome. Often, the tumors are small and difficult to locate. The levels of calcitriol are inappropriately low (hypophosphatemia should stimulate calcitriol production) and so the tumor product is also thought to interfere with renal 1α -hydroxylation. The osteomalacia responds to treatment with large phosphate supplements to restore phosphate levels to normal. The syndrome can be cured by successfully removing the tumor.

GENETIC CAUSES OF RICKETS

Hypophosphatemic Rickets

X-Linked Hypophosphatemic Rickets

XLH is an X-linked dominant disorder caused by renal phosphate wasting and results in severe skeletal abnormalities and growth retardation. The primary mechanism is defective phosphate reabsorption in the renal proximal tubule that results in excessive phosphaturia. The clinical presentation is usually not apparent until 6–12 months of age and ranges from mild abnormalities of the bones to severe rickets and osteomalacia. Children exhibit rachitic bone deformities, including enlargement of the wrists and knees and bowing of the lower extremities. Defects in tooth development and premature cranial synostoses may also be present. Low or inappropriately normal circulating levels of calcitriol are found, despite the hypophosphatemia (Table II). The low serum phosphate normally should cause an increase in 1α -hydroxylase activity and enhanced calcitriol production, suggesting that XLH may also result in abnormal regulation of 1α -hydroxylase.

The gene causing XLH has been cloned and named *PHEX*, which is a phosphate-regulating gene with homologies to endopeptidases located on the X-chromosome. The *PHEX* gene is homologous to a family of endopeptidases that includes endothelin-converting enzyme-1 and neutral endopeptidase. The *PHEX* gene encodes a 749-amino acid membrane-bound protein that is expressed in bone, adult ovary, lung, and fetal liver. A number of genetic defects in the *PHEX* gene have been found in patients with XLH. Since many of the mutations are inactivating mutations, the X-linked dominant expression of the disorder is likely caused by a haploinsufficiency rather than the result of a dominant negative effect. The hypothesis for action is that the *PHEX* enzyme

Table II Comparison of Genetic Causes of Rickets^a

| | VDDR-I | HVDRR | XLH | ADHR |
|--------------------------------------|----------------|-------|-----------------------|-----------------------|
| Gene | <i>CYP27B1</i> | VDR | <i>PHEX</i> | <i>FGF23</i> |

^bInappropriately normal relative to decreased serum phosphate concentration.

inactivates a phosphaturic factor (phosphatonin) important for reabsorbing phosphate from the glomerular filtrate. Inactivating mutations lead to excessive phosphaturia due to inadequate destruction of phosphatonin and therefore excess urinary phosphate loss.

Autosomal Dominant Hypophosphatemic Rickets

ADHR is an autosomal dominant disorder caused by urinary phosphate wasting that has findings commonly seen in other phosphate-wasting disorders. Patients have short stature, bone pain, rickets, and osteomalacia. Patients also have inappropriately normal serum calcitriol concentrations (Table II).

The gene causing ADHR has been cloned and named *FGF23*. It is one of the phosphatonins. The *FGF23* gene is a member of the fibroblast growth factor family. The *FGF23* gene encodes a 251-amino acid protein that is expressed in bone, heart, lymph node, thymus, and liver. Three unique mutations have been found in the *FGF23* gene in patients with ADHR. These mutations occur in two arginine residues located in a consensus proteolytic cleavage site. The mutations provide a gain-of-function activity that results in the autosomal dominant negative transmission. Excessive *FGF23* activity causes phosphaturia and hypophosphatemic rickets.

Mechanism of Phosphate Loss in XLH, ADHR, and TIO

How are *PHEX* and *FGF23* involved in the pathophysiology of XLH, ADHR, and TIO? One hypothesis is that under conditions of normal phosphate regulation the *PHEX* enzyme regulates the bioavailability of *FGF23*, *FRP-4*, and possibly other putative phosphatonins. As phosphatonins are secreted from cells, some of

them are degraded to inactive metabolites by the membrane-bound *PHEX* endopeptidase. The remaining active phosphatonin enters the circulation and interacts with a receptor protein on the renal tubule cells. Binding of *FGF23* transmits a signal to down-regulate the activity of the sodium-dependent phosphate cotransporter (NPT2) in the kidney, thus decreasing phosphate reabsorption. In XLH patients, the mutant *PHEX* protein, or lack thereof, is unable to degrade phosphatonin. This leads to excess amounts of *FGF23* in the circulation. As a result, the signal to down-regulate NPT2 activity is magnified, leading to renal phosphate wasting. In ADHR, on the other hand, mutations in *FGF23* prevent the proteolytic processing step by *PHEX* and therefore there is an overabundance of active *FGF23* that then leads to down-regulation of NPT2 activity, which causes phosphate wasting. In TIO, tumors overexpress *FRP-4* and *FGF23* and elevated secretion by the tumors also leads to phosphate wasting in this condition. In all three diseases, phosphate wasting results in hypophosphatemia and undermineralization of bone, causing rickets.

Vitamin D-Dependent Rickets I

Vitamin D-dependent rickets type I is also known as pseudo-vitamin D deficiency type I and pseudo-vitamin D deficiency rickets. We refer to the entity as 1 α -hydroxylase deficiency since it has been shown to be caused by mutations in the cytochrome P450 enzyme, 25-hydroxyvitamin D-1 α -hydroxylase (1 α -hydroxylase). The human 1 α -hydroxylase gene (*CYP27B1*) is located on chromosome 12 near the gene encoding the VDR. A number of mutations that disrupt 1 α -hydroxylase activity are found scattered throughout the entire region of the *CYP27B1* gene. 1 α -Hydroxylase deficiency is a rare autosomal recessive disease that is manifested at an early age. Patients with 1 α -hydroxylase deficiency exhibit hypocalcemia, elevated PTH levels, increased alkaline phosphatase, and low urine calcium (Table II). Affected children present with hypotonia, muscle weakness, growth failure, and rickets. Tetany and convulsions may occur with severe hypocalcemia. Patients have normal serum concentrations of 25-hydroxyvitamin D₃ but low levels of 1,25(OH)₂D₃ due to the defective synthesis of 1,25(OH)₂D₃. PTH infusion does not increase circulating 1,25(OH)₂D₃ levels, consistent with a defect in 1 α -hydroxylase activity. Very large doses of vitamin D or 25-hydroxyvitamin D₃ are required for adequate treatment of 1 α -hydroxylase deficiency; often, 20,000 to more than 100,000 IU of vitamin D daily is needed.

On the other hand, modest doses of the active hormone $1,25(\text{OH})_2\text{D}_3$ ($0.25\text{--}2\ \mu\text{g}/\text{day}$) tend to be sufficient to restore calcium to normal and heal the rickets. Since mutations in 1α -hydroxylase block $1,25(\text{OH})_2\text{D}_3$ synthesis, treatment with calcitriol bypasses the defect and reverses the abnormalities caused by the disease.

Hereditary 1,25-Dihydroxyvitamin D-Resistant Rickets

Hereditary 1,25-dihydroxyvitamin D-resistant rickets (HVDRR) is also known as vitamin D-dependent rickets type II or pseudo-vitamin D deficiency type II. HVDRR is an autosomal recessive disease characterized by early onset rickets, hypocalcemia, secondary hyperparathyroidism, and normal or elevated serum $1,25(\text{OH})_2\text{D}$ levels. Some patients also have total body alopecia (Table II).

HVDRR is caused by mutations in the VDR. A number of mutations have been found throughout the VDR. Missense mutations in the DNA-binding domain usually occur in highly conserved amino acids and prevent the VDR from binding to DNA. Nonsense mutations have been found that result in truncation of the VDR protein and loss of hormone responsiveness. Mutations that cause exon skipping or affect RNA splicing also result in truncation of the VDR. A number of missense mutations have been identified in the ligand-binding domain. Some of these mutations occur in amino acids that are contact points for $1,25(\text{OH})_2\text{D}_3$. In one patient, Arg²⁷⁴, the contact point for the 1-hydroxyl group of $1,25(\text{OH})_2\text{D}_3$, was mutated to leucine (Arg²⁷⁴Leu), whereas in a second patient histidine³⁰⁵, the contact point for the 25-hydroxyl group of $1,25(\text{OH})_2\text{D}_3$, was mutated to glutamine (His³⁰⁵Gln). Other mutations, such as Phe²⁵¹Cys, Gln²⁵⁹Pro, and Arg³⁹¹Cys, have been identified that prevent RXR heterodimerization with VDR. A mutation in helix H12 (Glu⁴²⁰Lys) was found to prevent coactivator binding. All these mutations cause some degree of vitamin D resistance.

Interestingly, one patient exhibited all the signs of HVDRR including alopecia but no mutations in the VDR. Vitamin D resistance in this patient was apparently due to the abnormal expression of a hormone response element-binding protein. This case highlights the fact that proteins other than VDR are involved in $1,25(\text{OH})_2\text{D}_3$ signaling and that defects in these proteins may also cause the HVDRR syndrome.

Most children with HVDRR do not respond to supraphysiological doses of calcitriol. However,

these children can be successfully treated for their hypocalcemia by normalizing their serum calcium using chronic intravenous infusions of calcium. The intravenous calcium infusions are given nightly over a period of many months. This treatment bypasses the intestinal defect in calcium absorption caused by the mutant VDR. The treatment eventually results in normalization of serum calcium levels, correction of secondary hyperparathyroidism, and normal mineralization of bone and healing of rickets on X-ray. The clinical improvement can be sustained if adequate serum calcium and phosphorus concentrations are maintained. Some patients can sometimes be maintained thereafter by oral calcium. However, patients do not show improvement in their alopecia with treatment.

SUMMARY

Proper supply of calcium and phosphate to the skeleton is critical for the synthesis of normal bone and the prevention of rickets or osteomalacia. Calcitriol and PTH regulate mineral metabolism and adequate delivery of calcium and phosphate to the bone-forming sites. The most common cause of rickets/osteomalacia worldwide is vitamin D deficiency. Fortification of dietary foodstuffs or vitamin D supplements given to individuals at risk would greatly reduce the impact of this devastating disease of the skeleton. Also, defects at any stage in the pathway of hormone synthesis or action can cause rickets or osteomalacia. Other important causes are calcium deficiency, chronic renal failure with inadequate synthesis of calcitriol and gastrointestinal diseases that result in malabsorption of calcium or vitamin D. Many forms of rickets are due to genetic errors in the synthesis or action of calcitriol or in conditions that cause renal phosphate loss. Improvements in our understanding of the molecular mechanisms by which these defects cause rickets or osteomalacia have led to improved diagnostic and treatment strategies.

by neurologic complications of brain hemangioblastomas or by metastatic renal cell cancer.

Significant advances have been made in the understanding of the VHL gene and its pathway. These advances have led to improvements in genetic diagnostics, the availability of presymptomatic screening, and new treatment methods, including organ-sparing surgeries, with the intent of increasing the quality of life and life-span of affected individuals.

History

More than 100 years ago, incomplete clinical descriptions of the disorder of what has come to be known as VHL were first reported. Illustrations of angiomas of the eye and similar vascular lesions of the cerebellum began appearing in reports as early as the 1860s. By 1904, Eugen von Hippel (1867–1938), a German ophthalmologist, published descriptions of retinal angiomas in several generations of family members in a small number of kindreds. In 1926, Arvid Lindau (1892–1958), a Swedish pathologist in Lund, published his thesis recognizing that retinal angiomas and cerebellar hemangioblastomas as well as cysts in the kidney, pancreas, and epididymis were part of a familial syndrome. Among the subsequent reports that refined the clinical understanding of VHL, Melmon and Rosen's landmark summary in 1964 established the first diagnostic criteria and included renal cancer. Linkage of the VHL gene to the short arm of chromosome 3 was reported by Seizinger and colleagues in 1988. Finally, in 1993, Latif and colleagues identified the VHL tumor suppressor gene by positional cloning strategies.

GENETICS

Molecular Genetics

The VHL gene is located at chromosome 3p25–p26 and is a tumor suppressor gene. This gene is also conserved in many species, including insects through mammals, and thus its functions are considered to be fundamental to life. Mutations causing loss or inactivation of the wild-type allele from the unaffected parent are thought to transform a cell into the clonal progenitor of a tumor.

Mutations causing VHL have been detected in all three exons and some intronic regions of the VHL gene. Mutation types identified include missense mutations, nonsense mutations, and partial and complete deletions of the gene. In 1996, Zbar and international collaborators reported more than 137 different *VHL*

mutations identified from patients in North America, Europe, and Japan. It is possible that exon 2 of the VHL gene may have a specific role in RCC development, as 45% of patients with mutations in exon 2 have RCC.

VHL Complex

The VHL gene product (pVHL) binds with elongin C, which binds elongin B, Cul2, and RBX1 to form a multimeric complex. The VHL complex targets the hypoxia-inducible factors (HIF) HIF1- α and HIF2- α for ubiquitin-mediated degradation. Under normoxic conditions, the complex degrades HIF. Under hypoxic conditions, HIF is not degraded and it overaccumulates. Increased levels of HIF are associated with increased transcription of a number of downstream genes, including vascular endothelial growth factor (VEGF), erythropoietin, platelet-derived growth factor, Glut1, and transforming growth factor- α . Mutations of the VHL gene in the α -domain (elongin C binding) or the β -domain (HIF targeting) have been shown to be associated with increased HIF levels. VEGF is a known promoter of tumor angiogenesis, which may account for the vascular nature of VHL tumors.

Genetic Counseling, Family Screening, and Molecular Diagnosis

VHL is transmitted in an autosomal-dominant pattern of inheritance with reproductive consequences. Each offspring of an affected parent has a 50% chance of inheriting the mutated copy of the VHL gene, putting them at risk for VHL tumors and for transmitting the trait. Offspring who inherit the affected parent's wild-type allele are not at risk for VHL and cannot transmit the trait for VHL.

Detection of the *VHL* mutation was possible in 93 of 93 VHL families, as reported by Stolle and colleagues in 1998. Laboratories utilize multiple molecular techniques, including DNA sequencing, for the detection of *VHL* point mutations. Gene deletions may be detected by quantitative Southern blotting and, in some instances, fluorescence *in situ* hybridization is available for *VHL* mutation analysis in a growing number of Clinical Laboratory Improvement Amendment (CLIA)-certified clinical laboratories.

Genetic testing should occur within the context of genetic counseling as recommended by the American Society of Human Genetics, the American Society of Clinical Oncologists, and other medical societies. Before being tested, patients make the decision to be

Table I Approach to Diagnosis of von Hippel-Lindau Syndrome Assisted by DNA Testing

Obtain a geneticist, genetic counselor, and/or physician to assist:

- (1) Clinically document von Hippel-Lindau syndrome (VHL) in a family member.
- (2) Analyze the member's peripheral blood lymphocyte DNA for a mutation in the VHL gene.
- (3) If a mutation is identified,^a the DNA-tested family member's first-degree relatives who wish are counseled, sign informed consent, and have their blood cells' DNA tested for the same mutation. All those found positive for the VHL gene mutation, then have DNA testing offered to their remaining first-degree relatives.
- (4) Clinical screening is offered to all those found to carry the VHL gene mutation.

Note. VHL penetrance has been estimated at > 90%.

^a*De novo* VHL in sporadic cases may have clinical manifestations, but patients may not have a mutation identified in their peripheral blood leukocyte DNA. The offspring of patients are considered to be at risk unless they are shown to have a normal VHL gene.

tested, after discussing the medical and psychosocial implications for themselves and their families. Post-test genetic counseling continues through disclosure of genetic results.

Discovery of a germ-line genetic mutation is an indication for a lifetime of periodic screening for VHL tumors and cysts. Early detection and management of VHL-related tumors may result in decreased morbidity and mortality and improved quality of life. At-risk biological relatives need genetic counseling, clinical screening, and/or genetic testing to clarify VHL risk. Presymptomatic detection of this highly treatable disease is aided by genetic diagnostic testing (see Table I). The choice to be tested must be entirely voluntary after informed consent is given and a consent document is then signed.

De novo mutations present a special challenge in genetic counseling and genetic diagnostic testing. The frequency of new germ-line mutations in *VHL* is not known. Sgambati and co-workers in 2000 reported that in a registry of 181 kindreds, 42 (23%) included a first in family diagnosis. When 2 (4.8%) of the 42 were further analyzed by additional molecular investigations, VHL mosaicism was demonstrated. New mutations may arise as any one of three types of sporadic VHL mosaicism, depending on which tissues have cells with a *VHL* mutation. Mosaicism is present in varying degrees and may include VHL gene mutations in somatic tissue only, in somatic plus germ tissue (spermatocyte, oocyte), or in germ tissue only.

CLINICAL MANIFESTATIONS

Common manifestations of VHL are renal cell carcinoma and cysts, pheochromocytoma, pancreatic neuroendocrine tumors, benign cysts of the pancreas, hemangioblastomas of cerebellum or spinal cord and medulla, retinal angiomas, endolymphatic sac tumor, and papillary cystadenomas of the epididymis and broad ligament.

The VHL clinical phenotypic expression is variable among families, which is thought to be mainly attributable to genotypic differences. Variability within families is also seen with regard to age of onset and severity of disease. In the latter case, other influencing factors, including modifier genes and lifestyle choices, such as cigarette smoking, are being studied. Classification of VHL into phenotypic subtypes has been correlated with genotypes to the extent possible (Table II). Type I, type IIA, and type IIB were initially described, and type IIC has been described in a number of reports and was the focus of the report from the laboratory of Kaelin and colleagues in 2001.

Age of onset of VHL is variable, with a mean age of onset of 25, 30, and 37 years for patients with tumors of the eye, CNS, and kidney, respectively. However, there are reports of children with retinal angioma at 1 year of age, with CNS hemangioblastoma at 11 years of age, and clear cell RCC at 16 years of age. Pheochromocytomas can occur in children as young as 6 years of age. In contrast, VHL expression can be very delayed; the diagnosis can occasionally be delayed until the eighth decade, supporting the need for lifelong monitoring of individuals at risk.

Table II Von Hippel-Lindau Syndrome (VHL) Classification

- I. VHL *without* pheochromocytomas
- II. VHL *with* pheochromocytomas
 - A. Pheochromocytomas, retinal angiomas, and CNS hemangioblastomas
 - B. Pheochromocytomas, retinal angiomas, CNS hemangioblastomas, clear cell RCC, and pancreatic neoplasms and cysts
 - C. Pheochromocytomas only

Note. VHL type I and type IIB differ only by the absence (I) or presence (IIB) of pheochromocytoma. Endolymphatic sac tumors and cystadenomas of the epididymis and broad ligament have not been assigned to specific VHL types.

Table III Screening^a Guidelines for Von Hippel-Lindau Syndrome (VHL)

| Test | Age |
|----------------------------------|--|
| Ophthalmoscopy yearly | From infancy |
| Fluorescein angiography | As needed |
| Urinary catecholamines | From age 2 years, every 1–2 years |
| Enhanced MRI, brain/spine | From age 11 years, every 2 years; ^b after age 60 years, every 3 years |
| Abdominal CT w/ and w/o contrast | From age 18 years, every 2 years |
| Abdominal US | Yearly from age 11 to 18 years when abdominal CT begins |
| Neurotology examination | Any age if there is hearing loss, tinnitus, or vertigo |

^aScreening tests of specific organ sites are modified and may be increased in frequency at sites where VHL tumors or cysts are detected.

^bExamine area of internal auditory canals for signs of endolymphatic sac tumor.

When clinical evidence of VHL is unclear, genetic testing (in all but some mosaic cases) should detect a mutation in the VHL gene when there is a risk for VHL. Identified risk indicates a need for age-appropriate baseline clinical screening and a lifetime of periodic monitoring (Table III), as well as a 50% chance for each offspring to inherit the trait and carry the risk for VHL.

Treatment of any one VHL manifestation must be prioritized along with knowledge of the other VHL tumors and cysts present in the patient. In particular, pheochromocytoma must be ruled out before any surgery. In the case of abdominal surgery, preoperatively, one must also consult the neurosurgeons to evaluate for unstable CNS masses.

Clear Cell Renal Cell Carcinoma: Solid and Cystic Disease

Renal cell carcinoma is detected in approximately 24–45% of individuals with VHL disease. Males and females are affected approximately equally, unlike sporadic RCC, which occurs more often in males.

Multiple bilateral VHL clear cell renal lesions develop, within which a few have scattered granular cells. These tumors tend to be low grade and minimally invasive when they are small and become more aggressive as they enlarge. Only 1 of 66 malignant lesions examined by Poston and colleagues in 1995 was found to have sarcomatoid renal cell carcinoma with clear and granular cells. Although microscopic invasion of the pseudo-capsule was common (52%), no tumor extension through the pseudo-capsule was identified in a study of 161 renal lesions. There is wide variation in the growth rate of solid tumors in VHL, which Choyke and colleagues in 1992 have shown to be 0.2–2.2 cm/year (mean 1.6 cm/year). There is a single case report of metastatic disease occurring in

VHL with a primary renal tumor less than 3 cm in diameter.

As many as 63% of people with VHL have renal cysts. Complex renal cysts in VHL disease have been shown to harbor clear cell RCC in many cases. Although renal cystic disease in VHL may have the appearance of polycystic kidney disease, in VHL, periodic monitoring of renal cystic disease is recommended, as malignancy may be present.

A high prevalence of microscopic lesions in grossly normal renal parenchyma was identified and reported by Walther and colleagues in 1995. Based on extrapolations from grossly normal renal parenchyma removed at the time of partial nephrectomy, up to an estimated 600 microscopic “tumorlets” and 1100 microscopic cysts with clear cell lining may be present in the kidney of a 37-year-old with VHL. In the follow-up study reported in 1996 by Lubensky and colleagues, allelic deletion of the VHL gene was present in microscopic clear cell renal lesions. They identified loss of the wild-type VHL allele and retention of the inherited mutated VHL allele early in the development of renal clear cell lesions.

Diagnosis

Primary kidney tumors may grow for many years before symptoms manifest. In a screened population, renal tumors are often diagnosed incidentally during imaging studies for another purpose. The classic triad of pain, palpable mass, and hematuria is very rare and when seen is often associated with large renal masses. Presymptomatic screening protocols (Table II) for individuals at risk for VHL are recommended to identify tumors at a stage when they may be managed with good outcome.

Computed tomography (CT) remains the gold standard for diagnosis of renal involvement in VHL. Contrast-enhanced CT in thin sections of 3–5 mm before and after intravenous non-ionic iodinated

contrast medium is essential for best detection and spiral geometry may decrease the chances of missing lesions (Fig. 1). Ultrasound is less sensitive than CT and is not considered reliable for lesions smaller than 2 cm. However, ultrasound is often useful in determining whether a lesion is cystic or solid. Magnetic resonance imaging (MRI) may be used in cases in which CT is contraindicated, for example, when there is impaired renal function. Patients with VHL commonly have normal renal function even when there are multiple tumors and cysts in their kidneys. Renal lesions in patients with VHL are most often considered suspicious for cancer and it is recommended that they be followed if they are not yet large enough to warrant immediate treatment.

Treatment

Nephron-sparing surgery was designed to minimize the risk of metastasis yet preserve kidney function. Walther and colleagues reported in 1999 their 10-year experience with preserving kidney function by using a 3 cm threshold for renal parenchymal-sparing surgery. In 52 patients with VHL who had partial nephrectomies and a median follow-up of 60 months (ranging from 6 to 205 months), there were no metastases and none of these patients needed dialysis or transplantation.

Each patient's treatment may be tailored according to the location and sizes of renal masses on imaging studies. Preoperative evaluation in VHL includes evaluations for pheochromocytoma and

hemangioblastomas of the central nervous systems as both lesions in these locations have the potential to cause significant adverse consequences in the operative and perioperative period if undetected.

Radiofrequency ablation, a newer treatment modality, is being evaluated in VHL patients as an alternative to surgery. Early results are encouraging for this method of tumor ablation, which may have significantly reduced morbidity compared to surgery. However, it is too early to determine the role of this method of treatment for patients with VHL-associated renal cell carcinoma.

Kidney transplantation after bilateral nephrectomy is performed when the option of nephron-sparing surgery is no longer viable. In addition to the usual protocol rules guiding organ transplantation for individuals who have had cancer, the hereditary nature of VHL adds another dimension in selecting a living related donor. It is recommended that potential related donors be screened with genetic testing. Furthermore, the long-term effects of immunosuppression in VHL with regard to tumor development are incompletely understood.

Sporadic Clear Cell Renal Carcinoma and VHL Gene Mutations

Approximately 60% of tumors from patients with sporadic clear cell renal cancers unrelated to VHL have been found to have mutations in the VHL gene. Somatic mutations in both alleles of the VHL

Figure 1 A CT scan of a 44-year-old female with VHL and severe renal manifestations, including bilateral renal cell carcinomas (arrows) and numerous bilateral renal cysts.

gene have been shown in many clear cell RCCs. This is strong evidence supporting the VHL gene as being important in the development of clear cell carcinoma of the kidney.

Phenocopies

In kindreds with VHL, sporadic clear cell RCC may arise even in the absence of the VHL gene mutation. This has been observed in individuals from two kindreds. One family member with clear cell RCC who was a heavy cigarette smoker was shown to be negative for the VHL germ-line mutation present in her relatives with VHL. These phenocopies apparently represent sporadic cases of renal cancer occurring in families with VHL.

Risk Factors in RCC

Environmental factors, as well as heritable genetic factors, have been shown to be associated with mutations in the VHL gene. It has been widely reported that cigarette smoking may be a risk factor for the development of kidney cancer. In addition, in 1999, Brauch and colleagues reported high cumulative trichloroethylene (TRI) exposure in workers who later developed RCC with a unique mutation pattern found in the VHL gene. In the past, TRI was used in industrial solvents.

Pheochromocytoma

The exclusion of pheochromocytoma prior to any surgery and before the onset of labor and delivery can be a life-saving measure. Pheochromocytomas are one of two types of VHL tumors that can occur before age 10. It is recommended that for children who are at risk for VHL screening should begin at an early age.

VHL has been subclassified based on the tendency to develop pheochromocytomas. Type I VHL is not associated with pheochromocytomas, whereas type II VHL predisposes to pheochromocytomas. Type IIA has a high prevalence of pheochromocytomas. For example, 57% of VHL-affected children and adults had pheochromocytomas, as seen in early studies of a type IIA large multigenerational family with mild CNS hemangioblastomas and retinal angiomas and a missense germ-line mutation in *VHL*. Type IIB, however, predisposes to pheochromocytomas along with the entire spectrum of VHL disease. Atuk *et al.* in 1998 reported a large multigenerational type IIB VHL family with pheochromocytoma having its onset between the ages of 5 and 25 years. Type IIC has been designated as familial pheochromocytoma only,

without renal cell carcinoma and hemangioblastomas, in five or more reports since 1995 of kindreds with mutations in the VHL gene.

Pheochromocytomas in VHL arise from chromaffin cells, usually in the adrenal medulla. Less than 2–10% of pheochromocytomas in VHL become metastatic. In 1999, Walther and colleagues reported on 64 patients with VHL pheochromocytomas and noted that missense mutations in the VHL gene tended to be associated with extra-adrenal pheochromocytoma, younger age at presentation, and the only patient in the study with metastases.

Diagnosis

Pheochromocytomas in VHL are frequently multiple and bilateral in the adrenal medulla or may be extra-adrenal (Fig. 2). Ectopic or extra-adrenal pheochromocytomas (paragangliomas) are not uncommon and may be located in the glomus jugulare, carotid body, peri-aortic sites, spleen, kidney, and organ of Zuckerkandl (bifurcation of aorta and femoral arteries). Metastatic disease to nodes and distant organs has been seen with pheochromocytomas in VHL. CT or MRI is helpful in identifying adrenal and peri-adrenal masses, but extra-adrenal sites may require a radionuclide study called metaiodobenzylguanidine (MIBG). Patients with VHL and pheochromocytomas can have CT scans with intravenous non-ionic iodinated contrast without adverse effects. Pheochromocytomas arise from neural crest tissue and produce catecholamines that are stored in neurosecretory granules. Symptoms are variable and may include intermittent or sustained hypertension, palpitations, tachycardia, nervousness, irritability, headaches, episodic sweating, pallor, nausea, and anxiety attacks. Pheochromocytomas may cause life-threatening hypertensive crisis, myocardial infarction, cardiac failure, or metastatic disease. However, VHL-associated pheochromocytomas are often diagnosed by presymptomatic screening of family members. Walther and colleagues reported in 1999 that 35% (13 of 37) of newly diagnosed patients, detected by screening kindreds with the pheochromocytomas, had no symptoms, normal blood pressure, and normal catecholamine test results. Median tumor doubling time was 17 months.

Laboratory tests for pheochromocytoma often provide the foundation for the diagnosis. These functional tests may show activity of a pheochromocytoma when there is no adrenal or extra-adrenal tumor seen on imaging, thus prompting further studies, possibly including MIBG scintigraphy, to locate the site of tumor activity. For many years, 24h urinary measurements of catecholamines have been the practice in testing for functional pheochromocytoma.

Figure 2 Bilateral pheochromocytomas in a 28-year-old male with VHL. There is a 4 cm pheochromocytoma (short arrow) on the left and a 1 cm pheochromocytoma on the right (long arrow), ectopically located behind the inferior vena cava.

A very sensitive serum test for catecholamine precursors was developed by Eisenhofer and colleagues in 1999. The sensitivity for normetanephrines and metanephrines is 97% and the specificity is 96%, whereas the sensitivities of other biochemical tests ranged from 47 to 74%. Patients with VHL had high plasma concentrations of normetanephrines; this contrasts with multiple endocrine neoplasia type 2 (MEN2) patients, who had high concentrations of metanephrine. Measurements are made of epinephrine, norepinephrine, normetanephrines, and total metanephrines. Twenty-four-hour urinary testing additionally measures dopamine and vanillylmandelic acid. It may also be necessary to perform provocative testing by glucagon stimulation and/or clonidine suppression tests to assess for functional changes that would occur under stress.

Treatment

Surgical resection is often the most common treatment for pheochromocytoma. Partial adrenalectomies and enucleations are increasingly being recommended to preserve adrenal function. Prior to surgery for pheochromocytoma, systemic treatment may be required for pharmacologic control with a combination of α - and β -adrenergic blockade. Blockade may be initiated with phenoxybenzamine, an alpha-blocker, followed by beta-blockade with propranolol or methyparatyrosine. Adrenergic blockage may be employed before, during, and even after surgery. Asymptomatic VHL

pheochromocytomas found during screening before catecholamine levels are elevated are sometimes followed at intervals of 6 months to 1 year with imaging and functional tests. Walther and colleagues provided surgical decision guidelines in 1999 that include tumors with abnormal function or size greater than 3.5 cm.

Sporadic Pheochromocytomas

Brauch *et al.* in 1999 reported their study of germ-line VHL gene mutations and RET gene mutations in 62 patients with pheochromocytomas with no history of hereditary disease. They found 2 patients (3%) with VHL gene mutations and none with mutations in the RET proto-oncogene at exons 10, 11, and 13. Neumann and colleagues in 1993 reported 19.5% of unselected patients with what appeared to be sporadic pheochromocytomas, who actually had VHL as the etiology. Walther *et al.* in 1999 found pheochromocytomas in VHL to be smaller and less functional than sporadic pheochromocytomas.

Pancreatic Neuroendocrine Tumors

Solid VHL neoplasms of the pancreas are commonly nonfunctional neuroendocrine tumors. Histologically, the tumor may show a trabecular and/or glandular architecture and nests of tumor cells have been demonstrated. Pancreatic and gastrointestinal hormones

were negative by staining in the study of Libutti and colleagues reported in 1998, whereas Lubinski *et al.*, also in 1998, examined 30 tumors and found that fewer than 4 stained positive for pancreatic polypeptide, somatostatin, insulin, and/or glucagon.

A Mayo Clinic study of patients with VHL, enrolled at the clinic during a 10-year period, found neuroendocrine tumors in 17% of patients. An association with pheochromocytomas was also noted. Libutti and colleagues in 1998 studied 17 patients with surgically resected pancreatic neuroendocrine tumors and their ages ranged from 18 to 48 years.

Diagnosis

CT imaging performed pre- and post-contrast may identify a neuroendocrine tumor of the pancreas as an enhancing mass (Fig. 3). The CT is often obtained during the arterial (early) phase after contrast administration as these tumors enhance early and briefly and then become isodense with the surrounding pancreatic parenchyma. The tumors frequently occur in the pancreatic head, but are also found in the body or tail. They may be multiple and metachronous; thus, monitoring of the remaining pancreas is continued after resection of a tumor. Because these tumors are characteristically non-functional, detection may require periodic scanning of asymptomatic individuals at risk for VHL.

VHL neuroendocrine tumors in some series have been shown to have the potential to metastasize, most often to the liver and regional lymph nodes.

Therefore, it is considered important to carefully evaluate the liver by CT and MRI in patients with VHL and PNETs.

Neuroendocrine tumors may sometimes be difficult to distinguish from multicystic cystadenomas, which are considered to be benign VHL pancreatic masses, which may also show enhancement on CT or MRI. Pancreatic neuroendocrine tumors usually enhance uniformly and intensely, whereas serous or multicystic cystadenomas are more heterogeneous and enhance to a lesser degree.

Treatment

Surgical resection is often the treatment of choice. The surgical approach is generally dictated by the location and size of the tumor. Resection may be by enucleation, pylorus-preserving pancreaticoduodenectomy (Whipple's procedure), or partial or rarely total pancreatectomy with replacement therapy. Neuroendocrine tumors of the pancreas in VHL may be slow-growing. Libutti and colleagues in 1998 found the size of the primary tumor to be correlated with the presence of metastases. Tumors less than 1 cm in size were monitored with serial scanning at intervals of 12–24 months. Management of larger tumors, 1–3 cm, depended on their location. However, preserving pancreatic functional tissue is often balanced with the known malignant potential.

Metastatic foci in the liver have been treated by therapies such as isolated hepatic perfusion with

Figure 3 Pancreatic neuroendocrine tumor in a 40-year-old female with VHL. There is a large hyperenhancing mass in the pancreatic head (solid arrow) and a right pheochromocytoma (open arrow). A cyst is present in the pancreatic tail.

Melphalan, hyperthermia, radiofrequency ablation, and wedge resection.

Pancreatic Cysts and Cystadenomas

Benign cysts and cystadenomas are the most common VHL lesions in the pancreas. The frequency of individuals affected varies in different studies; frequencies ranging from 17 to 56% have been reported. Rarely, these lesions may be associated with endocrine or exocrine insufficiency. Some very large benign cysts may require treatment to relieve symptoms due to compression of the stomach outlet, intestine, or bile ducts (Fig. 4).

Hemangioblastoma of Brain and Spinal Cord

A common presenting tumor of VHL, found in 44–72% of patients, is hemangioblastoma of the CNS. This tumor is most often detected using clinical imaging. A mean age of onset of 29 years has been estimated, but affected individuals as young as 11 years and as old as 78 years with CNS hemangioblastoma have been reported.

The central nervous system is often affected by multiple tumors, each of which may have an associated cyst. Within the fixed intracranial space, growing tumors or their more rapidly expanding associated cysts impinge

on normal brain structures and may cause obstructive hydrocephalus, increased intracranial pressure, and death, if they are not identified and treated.

Hemangioblastoma is a vascular tumor with histopathology demonstrating channels lined by cuboidal epithelium, nests of foamy stromal cells, and pericytes. Loss of heterozygosity of the VHL gene has been found in the stromal cell, indicating that it is the likely cell of origin of these tumors. Hemangioblastomas express excess VEGF. Berkman and colleagues demonstrated that these tumors express a large amount of VEGF. Rarely, a patient with hemangioblastoma in the CNS may have polycythemia associated with elevated erythropoietin and the erythropoietin levels decrease after removal of the tumor. Erythrocytosis or secondary polycythemia has been seen even more rarely in VHL.

Diagnosis

MRI with gadolinium demonstrates hemangioblastomas as circumscribed, brightly enhancing, spherical tumors that often arise at several sites in the cerebellum, spinal cord, intrathecal nerve roots, and brainstem. Thus, in screening evaluations, both the brain and spinal cord are imaged. Commonly, the tumors are found in the cerebellum, where they may be silent until they reach a large size. Spinal cord, brainstem, and supratentorial sites of hemangioblastomas are more problematic for treatment. Rarely, tumors occur in the temporal lobe where they may

Figure 4 Severe pancreatic cystic disease. In this 34-year-old female with VHL, the pancreas is markedly enlarged by innumerable small and large pancreatic cysts including a large multilobulated cyst in the tail of the pancreas (arrow). This patient had poor gastric emptying due to extrinsic compression on the stomach.

Figure 5 Multiple hemangioblastomas in a 26-year-old female with VHL. One hemangioblastoma (h) is entirely solid and the other (h') is surrounded by a cyst.

cause seizure activity. Also rare are hemangioblastomas that arise in the tuber cinereum, near the pituitary, or in the optic nerve or chiasm, where impingement on the optic nerves or chiasm may produce loss of vision, even though the retina may be free of angiomas. When cysts are associated with the CNS tumors, they may necessitate treatment sooner because of rapidly accumulating fluid enlarging the cyst and causing pressure on normal tissue. In fact, Lindau's original description of the typical CNS lesion was a vascular mural nodule that may be difficult to locate in a large fluid-filled cyst (Fig. 5).

Spinal cord hemangioblastomas arise mainly in the cervical and thoracic regions of the spinal cord and less often in the lumbar region. In the important Melmon and Rosen report of 1964, 80% of intramedullary hemangioblastomas were accompanied by syringomyelia. These cysts in the spinal cord (Fig. 6) can cause pressure on adjacent normal tissue and symptoms such as weakness, sensory loss, urinary disturbance, and loss of balance may result. In addition

Figure 6 Multiple cervical hemangioblastomas with a syrinx. This 36-year-old male has undergone prior neurosurgical procedures to remove hemangioblastomas. A syrinx (open arrow) and several hemangioblastomas (arrows) are present.

to headaches, symptoms may include vertigo, nausea, vomiting, slurred speech, nystagmus, dysmetria, wide-based gait, ataxia, and motor or sensory deficits.

Treatment

Surgical resection remains the mainstay of treatment. Because these tumors are benign and do not metastasize, neurosurgical resection is sometimes not considered until there are symptoms or signs that functional compromise may be impending. The timing of surgery is often selected to avoid neurologic deficits. In the surgical treatment of enlarging or symptomatic cysts or syrinxes, neurological surgeons often locate and remove the hemangioblastoma producing the fluid, because if the cyst is only drained and the tumor is left in place, the cyst may recur in a few days. Intraoperative color Doppler ultrasound often is used to aid the neurosurgeon in localizing small mural tumors in the cerebellum and tumors in the spinal cord.

A small fraction of cerebellar hemangioblastomas are treated with high-dose focused radiation (gamma knife surgery, linac, or other stereotactic radiosurgical ablation). In a setting of multiple tiny hemangioblastomas, on rare occasions, selected doses of conventional external-beam radiotherapy targeting the posterior fossa or spinal axis have achieved tumor control for many years.

Retinal Angiomas

Retinal angiomas (hemangioblastomas) are the commonest VHL tumor, occurring in 59% of individuals with VHL. Approximately 5% of the cases present under age 10 years, with the earliest age of onset being reported in a 1-year-old.

The histology of retinal angiomas appears to be identical to that of hemangioblastomas of the CNS and they are also considered benign. Molecular studies by Chan and colleagues in 1999 were undertaken to determine the cell of origin of hemangioblastomas. They concluded that vacuolated stromal cells represent the true neoplastic cell in retinal angiomas.

Diagnosis

Direct or indirect ophthalmoscopy may identify most retinal angiomas. Prominence of feeder vessels may be seen leading to and from some tumors. Tonometry periodically may be recommended to detect any associated glaucoma. Screening examinations are often recommended at least yearly. A pediatric ophthalmologist will often be involved in the management early in the life of individuals at risk for VHL.

Multifocal and bilateral (approximately 50%) retinal angiomas may occur. Asymptomatic lesions may be found in the periphery of the retina. However, it is not uncommon to have the tumor on the optic disc, in which case the ophthalmologist might recommend monitoring the lesion, as treatment itself could have the potential to damage the optic nerve head.

Symptoms resulting from untreated retinal angiomas may be the result of retinal detachment, capillary leak with fluid exudates, hemorrhage, macular edema, neovascularization glaucoma, and cataract. Partial or total vision loss occurs in some individuals with VHL retinal disease.

Other causes of vision loss in VHL are hemangioblastomas of the optic nerve or chiasm, increased intracranial pressure from homangioblastoma of the brain resulting in optic nerve atrophy, and postneurosurgical damage to the occipital lobe.

Treatment

Most clinicians recommend laser photocoagulation for the treatment of retinal tumors or cryotherapy for larger lesions. However, tumors on the optic disc are often monitored without treatment, which itself can be associated with damage. When tumors are diagnosed and treated early, vision loss or blindness may be prevented. Enucleation may be necessary for irreversible glaucoma with severe pain associated with ocular angiomatosis. Vitrectomy may play a role in a few cases. Further investigations are needed for the role of systemic antitumor agents. Various radiotherapy modalities have been applied on a compassionate or an experimental basis in cases of severely affected eyes not responding to the usual treatments.

Endolymphatic Sac Tumor

Manski and colleagues reported in 1997 their study of the association of an inner ear tumor with VHL. The ELST was the consensus name given for the previously diverse nomenclature of the tumor. ELSTs were detected in 13 (11%) of 121 individuals with VHL and in none of 253 patients without VHL. Hearing loss occurred at a mean age of 22 years, with the range being 12 to 50 years of age. Additional patients from the collection at the Air Force Institute of Pathology were reviewed by Manski and included a 7-year-old with ELST. Bilateral ELSTs seem to be found exclusively in patients with VHL.

The ELST is characterized by a papillary-cystic adenomatous growth, but lacks generally accepted histologic features of malignancy. However, because of its locally aggressive behavior of eroding the surrounding temporal bone, Heffner *et al.* classified it as a low-grade adenocarcinoma.

Diagnosis

Common presenting symptoms of ELST are hearing loss, tinnitus, vertigo/disequilibrium, and facial paresis. Sudden onset of complete hearing loss on the side of the tumor was found in 38% of patients with ELST. There is no clear correlation between tumor size and symptoms.

Audiologic assessment is added when there is a suspicion of a tumor. MRI of the brain may reveal a lesion, but the specific studies used for diagnosis are CT and MRI of the internal auditory canals. On CT scans, ELST is seen as an expansile and/or osteolytic lesion centered around the vestibular aqueduct in the posterior petrous bone. On MRI scans, it is characterized by heterogeneous foci of low and high

Figure 7 Endolymphatic sac tumor. This 32-year-old female with VHL developed sensorineural hearing loss on the left due to an endolymphatic sac tumor (arrow) on T2-weighted sequence MRI (A). A CT scan (B) of the same lesion demonstrates bony erosions due to the tumor (arrow).

intensities in both T1- and T2-weighted sequences (Fig. 7).

If no ELST is identified in patients with symptoms of hearing loss, tinnitus, vertigo or unexplained imbalance, repeated monitoring including audiologic and imaging studies is often advised.

Treatment

The indication and timing of surgical treatment take into consideration the slow but variable growth rate of ELSTs, preoperative hearing level, and severity of vestibular symptoms. Due to a high incidence of sudden sensorineural hearing loss associated with ELST, an early surgical intervention may be recommended for a patient with serviceable hearing as long as the tumor has not extended into the bony labyrinth. A surgical treatment may be indicated to control recalcitrant vestibular symptoms from ELST.

Surgical treatment of ELST may be curative when the tumor is completely excised via a combined retro-labyrinthine and retrosigmoid approach. Partial resection with or without radiation therapy has been reported as having a high incidence of recurrence. With complete resection, the preoperative level of hearing has been preserved in most cases and the tumor-associated vestibular symptoms can be effectively controlled.

Papillary Cystadenoma

Epididymal Papillary Cystadenomas

Choyke and colleagues in 1997 reported that 30 (54%) of 57 males with VHL had epididymal abnormalities consistent with epididymal cystadenoma, commonly 15 to 20 mm solid masses in the head of

the epididymis. Onset has been seen in the teenage years. Ultrasounds of the scrotum may be used to distinguish cystadenomas of the epididymis found in males with VHL from cysts of the epididymis found in approximately one-fourth of all males (Fig. 8). The tumors are papillary cystadenomas that may be multiple and bilateral and are often identifiable on physical examination. Because these tumors are benign and most often asymptomatic, treatment is rarely required. One case of VHL with bilateral clear cell papillary cystadenoma of the epididymis that presented as infertility has been reported.

Broad Ligament Papillary Cystadenomas

In females with VHL, papillary cystadenomas of the broad ligament have been reported in rare cases, but may be unrecognized in many more cases. In 1994, Gaffey and colleagues in their report pointed out the histological similarity of papillary cystadenomas of the middle ear/temporal bone and of the female pelvic adnexa in patients with VHL. They referred to the broad ligament tumors of VHL as adnexal papillary cystadenoma of probable mesonephric origin (APMO). In 2000, Shen *et al.* reported allelic deletion of the VHL gene detected in papillary tumors of the broad ligament, thus confirming it as a VHL tumor. Reports in the literature include descriptions of women with VHL who had diagnoses of broad ligament cystadenomas between the ages of 22 and 46 years. However, in the VHL registry of the authors of this article, one patient was a teenager when she had surgery twice within a few years for resection of papillary cystadenomas of the paratubal region of the broad ligament.

Figure 8 Cystadenoma of the epididymis. This 28-year-old male with VHL presented with a rock-like mass in the right scrotum. A longitudinal ultrasound of the scrotum reveals a normal testicle (T) and a solid mass in the head of the epididymis, which is typical of a cystadenoma of the epididymis in VHL.

FUTURE PROSPECTS

The genetics of VHL have relevance to a number of sporadic neoplasms. Of particular importance is the genetic similarity of most clear cell renal cancers. This has led to diverse molecular studies of VHL being initiated although the syndrome itself is a rare disease. Most VHL tumors have been shown to make VEGF and, as a result, VHL has become a model for the study of tumor angiogenesis and the development of anti-angiogenic agents. Investigations of the role of pVHL, elongin B/C, and Cul2 and their role with HIF in oxygen sensing may lead to therapies to restore normal function to important biochemical pathways. This may lead to the development of anti-tumor agents or modalities for use in the prevention or treatment of VHL and sporadic tumors arising due to VHL gene somatic mutations.

von Recklinghausen's Disease

see Neurofibromatosis

progresses. Hyperreflexia in the lower extremities with a positive Babinski sign is elicited in all patients. Peripheral neuropathy is manifest in the lower extremities with relative sparing of the hands. Patients show an abnormal wear pattern to their shoes. In most cases, the brain MRI is normal at the time of initial diagnosis, but approximately one-third of AMN patients demonstrate cerebral white matter involvement and probably carry a worse prognosis. Somatosensory-evoked potentials and BAEPs are often abnormal and nerve conduction velocities in the lower extremities may be delayed.

As the neurologic disease progresses over the course of 10–30 years, cerebral involvement becomes more apparent in most patients and signs of subcortical dementia supervene. In addition to the adrenal disease, patients often show diminished testicular function with decreased testosterone levels in combination with elevated luteinizing hormone and follicle-stimulating hormone levels. Nevertheless, many patients have fathered children prior to the onset of neurologic symptoms or early in its course. AMN patients frequently develop premature thinning of their scalp hair.

In addition to CCALD and AMN, there are several less common ALD phenotypes. Some males have adolescent or adult-onset forms of cerebral ALD, with a rapid progression of neurologic disease similar to that seen in CCALD. A small number of X-ALD patients exhibit Addison's disease only and lack neurologic symptoms. By screening families of X-ALD probands, a significant proportion of asymptomatic males who carry the gene, but lack neurologic or adrenal symptoms have been identified. Most of these males are still young and will probably develop AMN or other neurologic variants.

Although males express the full spectrum of symptoms, 20% of female heterozygotes ultimately develop mild spastic paraparesis, similar to AMN males, in the fourth to sixth decades of life. A greater proportion shows subtle signs of neurologic disease, such as hyperreflexia and decreased vibratory sensation in the lower extremities. However, female heterozygotes rarely develop adrenal insufficiency.

A perplexing observation is the lack of consistency in the X-ALD phenotypes within families. Approximately one-half of X-ALD kindreds have patients with CCALD and AMN, even though these patients share the same ALD mutation. This argues strongly for the presence of other genetic or environmental factors that modify the clinical expression of X-ALD. Genetic studies implicate the existence of a modifier gene, which has yet to be identified.

GENETIC DEFECT

ALD is inherited as an X-linked trait and the gene has been mapped to chromosome Xq28. The gene spans 26 kb and is composed of 10 exons that code for a 745-amino-acid protein (ALDP), which is localized to the peroxisomal membrane. ALDP is a member of the ATP-binding cassette (ABC) family of membrane transport proteins and shows homology to several other ABC proteins that are located within peroxisomal membranes, including ALDR and PMP70. ALDP is a half-transporter that is active when it forms a dimer with itself, ALDR, or other ABC half-transporter proteins. The exact function of ALDP is not known, but the biochemical consequence of its deficiency is an impaired ability to oxidize very-long-chain fatty acids (VLCFAs). The protein has been speculated to act in the intraperoxisomal transport of VLCFA, VLCFA-coenzyme A (CoA) esters, very-long-chain acyl CoA synthetase, or other essential factors for VLCFA oxidation.

More than 200 mutations have been found in the ALD gene, including missense mutations, deletions, insertions, and splicing defects. Most of these mutations result in the absence of immunologically detectable ALDP. It is notable that there is no correlation between the type of mutation and the associated X-ALD phenotype or the severity of the VLCFA oxidative defect.

BIOCHEMICAL ABNORMALITIES

Patients with X-ALD are deficient in VLCFA metabolism. The biochemical defect is at an early step in peroxisomal β -oxidation in which the free fatty acid form of VLCFA is activated to its acyl-CoA ester. This reaction is catalyzed by a peroxisome-specific very-long-chain acyl-CoA synthetase but, as noted above, it is dependent on functional ALDP, which is missing in X-ALD. As a consequence, VLCFAs are diverted through an alternate pathway, where they are acted on by an analogous synthetase enzyme in the endoplasmic reticulum that provides VLCFA-CoA substrates for biosynthesis of other lipids, including phospholipids, cholesterol esters, and sphingolipids. Fatty acid analyses of the tissue lipids of X-ALD patients reveal abnormal elevations in saturated VLCFAs that are longer than 22 carbons. In the adrenal cortex and brain, cholesterol esters containing saturated VLFA (C24:0 and C26:0) are almost undetectable in normal controls, whereas in CCALD they may account for over 50% of the fatty acid composition. VLCFA elevations are seen in other

lipid fractions as well, but to a lesser extent. In plasma from X-ALD patients, C26:0 and C24:0 levels are increased by two- to sixfold and 50%, respectively.

PATHOGENESIS

The pathogenesis of endocrine and neurologic disease in X-ALD is complex and poorly understood. Pathologic mechanisms must account for the extraordinarily diverse clinical phenotypes and the intrafamilial variation in symptoms. Nevertheless, an excess of saturated VLCFAs is the cardinal biochemical feature of X-ALD. Although the extent of lipid abnormality and the types of VLCFA-containing lipids vary from one tissue to another, the vulnerable organs in X-ALD are those that show the greatest accumulation of VLCFAs in cholesterol esters. In electron micrographs, these cholesterol esters are manifest as lamellar lipid inclusions in adrenal cortical cells, Leydig cells, Schwann cells, and brain macrophages.

The major neuropathologic differences between cerebral forms of X-ALD and pure AMN are the active cerebral inflammatory demyelination observed in the former and the prominent axonal degeneration observed in the latter. The brain in CCALD exhibits decreased myelinated axons and oligodendrocytes, reactive astrocytosis, sudanophilic lipid deposits in macrophages, and a striking perivascular lymphocytic infiltration. Both T and B cell lymphocytes are present. Inflammatory mediators, such as tumor necrosis factor α and interleukin-1, are produced in regions of active demyelination. Lipid analysis of autopsy brain shows that the fatty acid abnormality precedes demyelination, but the antigenic determinants have not been identified. VLCFA accumulation may initiate in phosphatidylcholine and later spread to other lipids as demyelination proceeds. Actively demyelinating lesions show the highest level of cholesterol esters containing VLCFAs, but these are unlikely to elicit an antigenic response. In addition, myelin proteins have been shown to be acylated with VLCFAs. Irrespective of the mechanism, the inflammatory demyelinating lesions in the brain of ALD are not seen in other lipidoses associated with white matter disease.

In contrast to the cerebral forms of X-ALD, AMN seems to lack an immune component to the neurologic disease. In AMN, the spinal cord is mainly involved with loss of myelinated axons in the ascending and descending tracts. The peripheral nerve is usually less severely affected. The mechanism for axonal degeneration is unclear.

In all forms of X-ALD, VLCFA accumulation in adrenocortical cells is thought to be solely responsible for the adrenal gland dysfunction, but more than one pathogenic mechanism may be in play. Addition of saturated VLCFAs to cultured adrenocortical cells has been shown to blunt adrenocorticotrophic hormone (ACTH) receptor responsiveness, probably by increasing plasma membrane microviscosity. Cholesterol esters containing VLCFAs, which accumulate in the adrenal gland, are poor substrates for hydrolyzing enzymes to provide free cholesterol precursors for steroidogenesis. In time, adrenocortical cells become ballooned and striated from lipid accumulation and then die. In contrast to autoimmune forms of Addison's disease, anti-adrenal antibodies are missing in X-ALD. Whether analogous pathogenic mechanisms occur in Leydig cells and are responsible for testicular dysfunction is not known.

DIAGNOSIS

The diagnosis of X-ALD may be challenging because of its rare occurrence and striking clinical variation. Identification of X-ALD is often delayed until symptoms involving the nervous system and adrenal gland appear together, a condition that is lacking in a significant proportion of patients. AMN males and symptomatic heterozygote females are frequently misdiagnosed as having multiple sclerosis or familial spastic paraparesis.

Because neurologic symptoms are missing or can develop many years after the onset of adrenal disease, X-ALD should be suspected in any male with isolated primary adrenal insufficiency. In adults, adrenal insufficiency is often caused by other etiologies, but a significant proportion of boys who present with Addison's disease in childhood have X-ALD. In those who initially present with neurologic symptoms, however, adrenal disease might be suspected only after a diagnostic work-up for leukodystrophy has been initiated. In these patients, a 60 min ACTH stimulation test will usually detect adrenal involvement. Measurement of a morning serum cortisol concentration alone is not an adequate screening test, because basal cortisol levels may be maintained in the face of diminished adrenal reserve. In contrast, plasma ACTH is usually elevated before hypocortisolemia develops.

Owing to its wide clinical variation, the diagnosis of X-ALD is critically dependent on laboratory confirmation. The most convenient test is measurement of VLCFAs in plasma, which is noninvasive, is relatively inexpensive, and detects abnormal elevations of

VLCFAs in patients long before symptoms develop, even at the time of birth. Affected patients accumulate C26:0 and C24:0, but have normal C22:0. The C26:0/C22:0 and C24:0/C22:0 ratios are particularly useful for discriminating X-ALD patients from non-ALD controls. In males, there are very few conditions, such as a ketogenic diet, that give rise to false-positive results and false-negative results are uncommon. In circumstances where the plasma VLCFA results are equivocal, fatty acids can be measured in cultured skin fibroblasts grown from a patient. Female carriers for X-ALD tend to show intermediate elevations in plasma VLCFAs, but interpretation of a normal test result is problematic because plasma VLCFAs are elevated in only 85% of carriers. A normal test result, therefore, does not completely eliminate the possibility that the female is carrying the X-ALD gene. DNA testing is more reliable for heterozygote detection if the mutation is known in the family, but the lack of a common mutation in the X-ALD gene hampers the development of simple DNA screening tests for routine diagnosis.

The diagnosis of X-ALD has profound implications for genetic counseling, disease prevention, and potential treatment. Family studies indicate that only approximately 5% of the X-ALD probands represent new mutations. It is therefore important to screen at-risk family members by measuring plasma VLCFA or by DNA analysis. This frequently leads to the identification of asymptomatic males who should be counseled and monitored for the appearance of symptoms. It is not possible to predict which X-ALD phenotype they may develop.

Prenatal diagnosis affords the ability to prevent X-ALD. Affected fetuses can be identified by DNA analysis or by measuring VLCFA content of chorionic villi cells obtained at 8.5 to 10 weeks gestation and in amniocytes obtained during the second trimester.

MANAGEMENT

The adrenal cortical insufficiency in X-ALD is easily treated with hormone replacement, but it has no effect on the progression of neurologic disease. Hydrocortisone is typically used alone or in combination with fludrocortisone, depending on the severity of mineralocorticoid deficiency. The glucocorticoid dosage should be increased in response to stressful occasions. Patients lacking adrenal insufficiency at the time of diagnosis should be monitored yearly by measuring plasma ACTH in combination with a morning serum cortisol. Elevations in ACTH level

precede a decline in cortisol to alert the physician of impending adrenal disease. As a practical matter, patients are often treated with replacement doses of glucocorticoids once diminished adrenal reserve is discovered. No therapy has been found to prevent or reverse the adrenal insufficiency.

Therapeutic options for the serious neurologic symptoms of X-ALD have emerged over the past decade. Bone marrow transplantation (BMT) has been shown to stabilize, or even reverse, the neurologic disease in CCALD. To receive clinical benefit, however, patients need to be transplanted at the earliest sign of neurologic involvement when only cognitive symptoms are predominant. Even then, all patients do not respond. Given the risks of BMT, the procedure is not recommended for asymptomatic or AMN patients.

Other therapeutic approaches have not proven useful, including attempts to modify the inflammatory reaction in the brain with immunosuppressive drugs, by intravenous administration of gamma globulin or β -interferon. Dietary restriction of saturated VLCFAs has no effect on the disease. Dietary supplementation with monounsaturated fatty acids (Lorenzo's oil) normalizes plasma C26:0 by inhibiting saturated VLCFA synthesis, but has no significant clinical impact once neurologic symptoms develop, probably because fatty acids in the brain are not altered. Studies are ongoing to determine whether Lorenzo's oil can delay the onset of neurologic or adrenal disease in presymptomatic boys.

Pharmacologic approaches to increase the peroxisomal VLCFA-oxidizing activity using 4-phenylbutyrate or statin drugs are under investigation. These drugs act to stimulate VLCFA oxidation by up-regulating peroxisomal ALDR protein, which forms functional ABC protein heterodimers in place of the missing ALDP protein. In this regard, the availability of mouse X-ALD gene knockout animals is essential for future therapeutic investigations.
