girl who is pathologically short with no other established diagnosis should always obtain chromosomes, irrespective of the presence or absence of secondary sex characteristics. Other genetic causes of severe short stature include Down syndrome, pseudohypoparathyroidism, Lawrence–Moon–Biedl syndrome, Weaver syndrome, and Prader–Willi syndrome.

MANAGEMENT

For the patient with CDG, the following points are important to keep in mind:

1. The diagnosis is one of exclusion of other problems.
2. There is often a familial history of this growth pattern.
3. The child has short stature, but normal growth velocity after 3 years of age, and absent or early sexual development.
4. There is modest bone age delay (within 75% of the chronological age).
5. After careful investigation, it is determined that the child has an absence of systemic or endocrine disease.

After establishing the diagnosis of CDG by excluding pathological causes of short stature, no pharmacological treatment is usually necessary. The parents and patient should be thoroughly educated about normal patterns of growth and development and should be given realistic projections of the expected range of adult height. The patient should be followed for assessment of the growth rate and pubertal development. If the growth rate is abnormally low or if

puberty is markedly delayed, more detailed biochemical and radiological investigations may become indicated. In some instances in CDG, pubertal development may be so late that it becomes a major psychological problem to the patient, and so giving hormonal therapy to induce the onset of puberty may become indicated.

buried within the GC-A ECD, consistent with observations that ANP binding to GC-A appears to depend on Cl⁻ concentration.

The KHD has substantial amino acid sequence identity to the catalytic domain of protein kinases, but no intrinsic protein kinase activity has been

reported. The KHD has been proposed to function as an inhibitory regulator of the CYC given that deletion of the KHD from GC-A and GC-B renders constitutively active enzymes. GC-A and GC-B KHDs contain adenosine triphosphate (ATP)-binding motif-like sequences (GxGxxxG and LxGxxxG, respectively), and it has been suggested that ATP binding to these sequences is essential for ligand-induced activation of GC-A and GC-B.

Two other potential subdomains have been defined in pGCs: the hinge region and the C-terminal tail (Fig. 1). The hinge region is a putative, amphipathic α -helical region connecting the KHD and the CYC, and it has been suggested to function in dimerization of pGCs. GC-C, GC-D, GC-E, and GC-F have extended C-terminal tails. GC-C, having the longest tail, appears to associate with the cytoskeleton through this subdomain.

Soluble GCs possess two subunits, α and β , and two isoforms have been identified for each subunit: α_1 , α_2 , β_1 , and β_2 . In the human, two subunits named α_3 and β_3 are actually the orthologues of rat α_1 and β_1 (Table II). Soluble GCs contain a heme-binding domain within the N terminus and the CYC near the C terminus (Fig. 1). Heterodimer formation is essential for full sGC activity; one heme molecule is bound

Figure 1 The structure of guanylyl cyclases. “P”, “ATP” in the ellipse, and “Fe” in the rectangle indicate phosphorylation, ATP binding, and a heme moiety, respectively.

Table II Human Gene Loci, Human and Mouse Gene Symbols, and Tissue Expression of No Transmembrane-Segment Forms of Guanylyl Cyclase

| Cyclase | Human locus | Human (mouse) gene symbol | Expression in normal tissues ^a |

^aDetermined by Northern blotting or RT-PCR.

per heterodimer and serves as the nitric oxide (NO)-binding site. The central region (i.e., the region between the heme-binding domain and the CYC) of sGC isoforms is amphipathic α -helical and could function as a dimerization domain. $\alpha_1\beta_1$ and $\alpha_2\beta_1$ heterodimers have been detected *in vivo*. NO-induced cGMP generation of $\alpha_2\beta_1$ or $\alpha_1\beta_2$ was reportedly one-third of $\alpha_1\beta_1$ *in vitro*, and a dominant negative effect of β_2 isoform on $\alpha_1\beta_1$ activity has been suggested.

Expression of GCs in various tissues has been examined in humans, monkeys, rats, and mice (Tables I and II). GC-A and GC-B are expressed widely but not equally throughout the body. GC-A is abundant in the cardiovascular system (kidney, heart, and aorta), whereas GC-B expression is high (greater than GC-A expression) in the cerebellum, pituitary gland, pineal gland, and growth plate of bone. GC-C is found mostly in the intestine and colon, but GC-C mRNA is detected in the rat nephron by reverse transcriptase–polymerase chain reaction (RT-PCR). GC-C mRNA is detected also in the regenerating liver and in metastatic tumors of colon cancer. GC-D is expressed in a limited number of sensory neurons in the olfactory neuroepithelium. GC-E and GC-F are expressed in the outer segment of photoreceptor cells in the retina. GC-G is expressed in the lung, skeletal muscle, jejunum, and kidney.

Soluble GC α_1 and β_1 isoforms are expressed almost ubiquitously (Table II). α_2 isoform expression is detected in various but more limited tissues than are α_1 and β_1 isoforms. β_2 isoform expression is found in the kidney and liver and in human gastric carcinomas (Table II).

CHROMOSOMAL LOCALIZATION AND ORGANIZATION OF GC GENES

As shown in Table I, pGC genes are located on separate chromosomes. The genes for sGC α_1 and β_1 isoforms are located on the same chromosome in mice and humans, with the other isoform genes (α_2 and β_2) located on separate chromosomes (Table II).

Rat sGC α_1 and β_1 loci are located on chromosome 2, closely linked to Na⁺, K⁺-ATPase α_1 isoform, and calmodulin-dependent protein kinase II δ loci, which have been reported to flank a quantitative trait locus for blood pressure in Dahl rats. The rat sGC β_2 locus located on chromosome 5 also cosegregates with the systolic blood pressure in Dahl rats.

Structures of GC-A, GC-B, and GC-E genes have been reported along with the NPR-C genomic structure. The rat GC-A gene of approximately 17.5 kb consists of 22 exons and 21 introns. Each functional domain is encoded by a group of exons; the ECD, the TM, the KHD, the hinge region, and the CYC are encoded by exons 1–6, 7, 8–15, 16, and 17–22, respectively (Fig. 2A). The structure is conserved in the human GC-B gene (Fig. 2B). The human GC-B gene contains a GT microsatellite repeat polymorphism within the second intron, and the (GT)₁₁ allele significantly associates with essential hypertension. The bovine NPR-C gene shares quite similar exon–intron organization with the ECD-encoding regions of GC-A and GC-B genes except for greater intron length (Fig. 2C). The overall structure of the bovine GC-E gene is similar to the overall structures of the GC-A and GC-B genes: an additional intron exists in each of the 5'- and 3'-noncoding

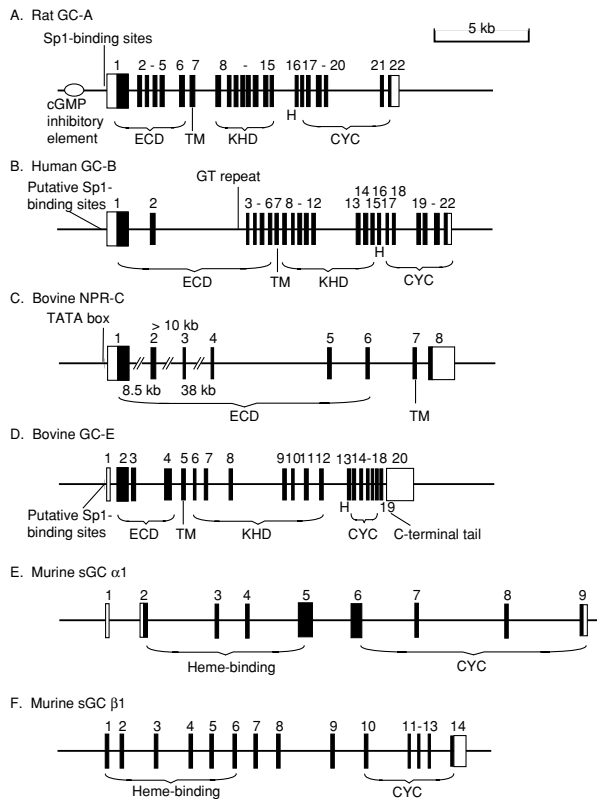

Figure 2 The structure of guanylyl cyclase (GC) genes. The genomic structure is shown for rat GC-A (A), human GC-B (B), bovine NPR-C (C), bovine GC-E (D), murine sGC α_1 (E), and murine sGC β_1 (F). Boxes with numbers represent exons; coding regions are filled. H, the hinge region.

regions; 3 introns, 1 intron, and 1 intron are missing from regions encoding the ECD, the KHD, and the CYC, respectively; and the C-terminal tail is encoded in a separate exon (Fig. 2D). Three murine sensory organ pGC genes (GC-D, GC-E, and GC-F) share identical exon-intron boundaries, at least within the region encoding the ECD. At least some intron positions of the murine GC-G gene are the same as those of the NPR genes.

The murine sGC α_1 isoform gene is at least 26.4 kb and consists of 9 exons and 8 introns (Fig. 2E), and the murine β_1 isoform gene consists of 22 kb and contains 14 exons and 13 introns (Fig. 2F). The structures are quite different from those of pGC genes.

The promoter region has been sequenced for the GC-A, GC-B, GC-C, GC-E, and GC-F genes. These genes have no typical TATA boxes. The NPR-C gene contains a TATA box in the promoter region (Fig. 2C) but is not essential for gene transcription. The rat GC-A gene contains three Sp1-binding sites that appear to be essential for basal transcription of the

gene in the proximal promoter region and a cGMP-inhibitory element in the distal promoter region (Fig. 2A). The human GC-C gene promoter contains a binding site for hepatocyte nuclear factor (HNF)-4, a key regulator of intestinal-specific gene expression.

REGULATION OF GC ACTIVITY

Regulation of Gene Expression

Particulate GCs

Some reports indicate that natriuretic peptides and transforming growth factor- β attenuate gene expression of GC-A and GC-B in isolated cell lines. It has been suggested that ANP suppresses GC-A gene expression through a cGMP pathway, consistent with the presence of a cGMP-inhibitory element in the GC-A gene promoter.

Signaling through GC-A or GC-B also may be modulated by the NPR-C expression given that NPR-C participates in ligand clearance. The β_2 -adrenoceptor/cyclic adenosine 3',5'-monophosphate (cAMP) pathway or GC-B/cGMP pathway down-regulates NPR-C gene expression. Fibroblast growth factors (FGF-1 and FGF-2) and platelet-derived growth factor (PDGF)-BB, which activate receptor tyrosine kinases and subsequently mitogen-activated protein (MAP) kinases, inhibit NPR-C gene expression in rat pulmonary artery smooth muscle cells (SMCs).

Prolonged exposure of human colonic carcinoma T84 cells to 4 β -phorbol 12-myristate 13-acetate, a potent protein kinase C (PKC) activator, results in a decrease of GC-C gene expression. The element responsible for the down-regulation has been located in a 129-bp region of the human GC-C gene promoter, which contains an HNF-4-binding site.

Soluble GC

NO and nerve growth factor have been reported to decrease sGC α_1 and β_1 isoform mRNA levels in cultured rat vascular SMCs and rat pheochromocytoma PC12 cells, respectively.

Stimulation of cAMP/protein kinase A pathways has been shown to decrease mRNA levels of both α_1 and β_1 isoforms and α_1 protein levels in rat aortic SMCs. Lipopolysaccharide and interleukin-1 β reportedly attenuate sGC α_1 gene expression in rat vascular SMCs and β_1 gene expression in rat cerebellar astrocyte-enriched primary cultures. It is also reported that estradiol reduces sGC α_1 and β_1 mRNA levels within 1 h in the rat uterus.

Regulation by Posttranslational Modification

GC-A and GC-B

Receptor desensitization by posttranslational modification of the receptor molecule has been proposed for both GC-A and GC-B, where ANP and CNP desensitize GC-A and GC-B, respectively. Both GC-A and GC-B are phosphorylated on specific serine and threonine residues in the KHD, and ligand-induced desensitization is associated with dephosphorylation of the phosphoserine and phosphothreonine residues.

Desensitization of GC-A and GC-B by signaling molecules other than ligands has been reported as well. This type of desensitization can also generally be correlated with dephosphorylation of phosphoserine and phosphothreonine residues. Angiotensin II (AII) and arginine vasopressin can attenuate ANP-induced cGMP generation in rat vascular SMCs, glomerular mesangial cells, and adrenocortical carcinoma cell lines. Endothelins (ETs) can attenuate ANP- and CNP-induced cGMP generations in rat vascular SMCs and murine astrocytes, respectively. AII and ETs appear to cause this desensitization through stimulation of PKC.

Serum, PDGF-BB, and FGF-2 desensitize GC-B rapidly (within a few minutes) and extensively. In various kinds of cells, these agents activate MAP kinases and subsequently proliferation. It has been shown that this sequence of events can, in turn, be inhibited by CNP or ANP via cGMP-dependent mechanisms.

GC-C

STa and uroguanylin cause attenuation of subsequent STa-induced cGMP generation in human colonic carcinoma cell lines (T84 and Caco2). A significant portion of the refractoriness seems to be caused by desensitization of GC-C. In clear contrast to GC-A and GC-B, phosphorylation of the C-terminal tail by PKC appears to enhance GC-C activity.

Soluble GCs

Both very rapid (within 10 s) and slow (within 2 h) desensitization have been reported for sGCs. The mechanism of the very rapid desensitization has not been elucidated, but a cellular factor appears to be essential for this phenomenon. The mechanism of the slow desensitization also has not been revealed, but oxidation of the enzyme by free radicals derived from NO is suggested as being responsible.

Regulation by Binding Proteins

GC-A and GC-B

Protein phosphatase-5 and heat-shock protein 90 have been reported to bind to the GC-A KHD, but neither has been shown to regulate GC-A activity. Visinin-like protein-1 (VILIP-1), a member of the intracellular neuronal calcium sensor (NCS) family, was shown to bind to GC-A and GC-B in the CYC and can enhance ANP- and CNP-induced cGMP generation in PC12 pheochromocytoma and C6 astrocytoma cell lines, respectively. A guanylyl cyclase regulatory protein (GCRP) was also identified in the rat brain as a protein that binds to GC-A and enhances ANP-induced GC-A activation. The physiological significance of VILIP-1 and GCRP, however, has not been elucidated.

GC-E and GC-F

GC-activating proteins (GCAP-1, GCAP-2, and GCAP-3) have been identified as regulatory proteins for GC-E and GC-F; they also belong to the NCS family. A GCAP-binding site has been identified within the GC-E CYC. Bleaching of rhodopsin by light results in activation of cGMP-specific phosphodiesterase (PDE6) mediated by transducin. The PDE6 decreases intracellular cGMP, causing closure of the cGMP-gated Ca^{2+} channel and subsequently hyperpolarization, which leads to visual sensations. In response to the resultant decrease in intracellular Ca^{2+} , GCAPs activate GC-E and GC-F to increase cGMP levels and restore the dark state. Targeted disruption of both GCAP-1 and GCAP-2 genes reportedly eliminates the Ca^{2+} -dependent GC regulation and reduces the capability of photoreceptors to adjust their sensitivity to light.

Other Mechanisms

Complexes of ANP and GC-A are internalized after ANP binding to GC-A in murine Leydig tumor cells. This could explain a portion of the ANP-induced down-regulation of GC-A activity. Some studies have suggested that activation of cGMP-PDE (PDE5) or GC-C internalization by STa explain, at least to some extent, the STa-induced refractoriness to subsequent STa stimulation in T84 cells.

PHYSIOLOGICAL ROLES OF GCS

GC-A

GC-A null mice show blood pressure elevation independent of dietary salt intake and prominent cardiac

hypertrophy with cardiac fibrosis. Systolic blood pressure decreases as GC-A gene copy number is increased from 0 to 4 by targeted disruption and duplication of the gene. Intravenous infusion of ANP or isoconic solution, which leads to an increase of plasma ANP concentrations, does not cause an increase of water and sodium excretion in GC-A null mice, whereas it has significant effects in wild-type mice. Thus, it has been suggested that GC-A plays important physiological roles in blood pressure regulation, diuresis, and natriuresis.

The GC-A system also functions as a local regulatory system to directly inhibit myocyte hypertrophy and fibrosis in the cardiac ventricle. The cardiac myocyte-specific overexpression of GC-A does not alter blood pressure and heart rate, but it reduces myocyte size in ventricles of both wild-type and GC-A null mice. Normalization of blood pressure by chronic treatment with antihypertensive drugs reportedly fails to attenuate left ventricular hypertrophy in GC-A null mice.

ANP inhibits aldosterone secretion from bovine adrenal glomerulosa cells via activation of cGMP-stimulated cAMP-PDE. GC-A null mice show 1.5- to 2-fold higher plasma aldosterone concentrations than do wild-type mice on a low-salt (0.008% NaCl) or a normal-salt (1% NaCl) diet, whereas a high-salt (8% NaCl) diet reduces plasma aldosterone levels to under the detectable limit in both genotypes. Plasma renin activities in GC-A null mice are 20 to 50% of those in wild-type mice on the normal-salt diet. An increase in circulating aldosterone levels due to loss of suppression by the ANP/GC-A system may contribute to hypertension with cardiac hypertrophy and fibrosis and to suppressed plasma renin activities.

Another endocrinological role of GC-A has been suggested. Serum testosterone concentrations are elevated, and ANP-induced testosterone secretion from Leydig cells is augmented, as GC-A gene copy number increases.

GC-B

Studies on knockout mice of CNP, NPR-C, and cGKII have suggested that the CNP/GC-B/cGKII system is important for normal endochondral ossification and skeletal growth. CNP null mice exhibit dwarfism as a result of impaired endochondral ossification; proliferation and differentiation of chondrocytes in the growth plate of long bones, where CNP, GC-B, NPR-C, and cGKII transcripts are expressed, are markedly reduced. Dwarfism has also been observed in mice lacking cGKII. Targeted disruption

and three independent loss-of-function mutations that naturally occur in the murine NPR-C gene result in skeletal overgrowth; a decrease in endogenous CNP clearance by NPR-C appears to activate the CNP/GC-B pathway.

The CNP/GC-B signaling pathway has been proposed to play an important role in regulating proliferation and migration of vascular SMCs in proliferative vascular lesions such as atherosclerosis and restenosis after coronary angioplasty. It is suggested that both CNP secretion from endothelial cells and GC-B expression in proliferating vascular SMCs are augmented in these lesions.

GC-C

Disruption of the murine GC-C gene results in resistance to pathogenic bacteria that secrete STa and cause acute secretory diarrhea. In enterocytes of the intestinal villi, intracellular cGMP elevation caused by STa binding to GC-C stimulates cGKII. Cystic fibrosis transmembrane conductance regulator (CFTR) is activated by cGKII and promotes massive intestinal fluid secretion and diarrhea. Mice deficient in cGKII are resistant to STa, and a report indicates that CFTR null mice show lesser responses to STa than do wild-type mice. GC-C null mice display no prominent abnormal phenotypes other than the STa resistance in a disease-free, highly controlled environment, and physiological roles of GC-C still remain unclear.

GC-E

A series of studies has shown that signaling through GC-E is essential for normal retinal function. In GC-E null mice, a decrease in the number of cone photoreceptors occurs as mice age, whereas rod photoreceptors appear to remain normal. Missense and frame-shift mutations in the human GC-E gene are associated with Leber's congenital amaurosis (LCA), in which early-onset widespread degeneration of rod and cone photoreceptors occurs. A dominant form of cone-rod dystrophy (CORD6) is also associated with GC-E mutations in humans.

Other pGCs

GC-D may be important to sense a particular subset of odorants or pheromones. A subset of olfactory neurons selectively expresses GC-D, a cGMP-stimulated PDE (PDE2), and a subunit of a cGMP-gated channel that is identified in cone photoreceptors. This subset of neurons also appears to

innervate atypical glomeruli in the olfactory bulb known as necklace glomeruli, which have been suggested to mediate some pheromone responses.

GC-F is thought to play an important role in the visual signal transduction because of its retina-specific expression and homology to GC-E. However, no direct evidence has been uncovered to support this hypothesis. Neither endogenous ligands nor regulatory molecules have been found for GC-G, and the physiological role(s) of GC-G remains unknown.

Soluble GCs

The NO/sGC pathway appears to play important roles in blood pressure regulation and renal excretion. Disruption of the murine inducible NO synthase gene results in systemic and pulmonary blood pressure elevation. It has been suggested that the NO/sGC system enhances glomerular filtration and inhibits tubular reabsorption in the kidney. In the kidney of the Dahl salt-sensitive rat, gene expression of the sGC β_2 isoform is augmented and that of the β_1 isoform is repressed compared with the Dahl salt-resistant rat. The dominant-negative effect of the β_2 isoform on the α_1/β_1 heterodimer might be responsible for blood pressure elevation in the Dahl salt-sensitive rat on high salt intake.

Soluble GC β_2 gene expression is detected in human gastric carcinoma tissues but not in the normal gastric tissue where the α_1 and β_1 isoforms are expressed. The dominant-negative effect of the β_2 isoform may have a role in tumorigenesis.

estimate is that approximately half of boys will develop some degree of gynecomastia during puberty. Gynecomastia generally has its onset between 10 and 12 years of age and peaks between 13 and 14 years of age. The gynecomastia usually involutes within 18 months and is completely resolved by 16 to 17 years of age in most male adolescents. The final peak of gynecomastia is during adulthood, when up to two-thirds of males between 50 and 80 years of age are found to have some degree of gynecomastia when carefully examined.

PATHOLOGICAL CAUSES OF GYNECOMASTIA

[Table I](#) outlines the broad categories of causes of gynecomastia. Gynecomastia may be found either in patients with germ cell tumors of the testicle, which secrete human chorionic gonadotropin (hCG), or in patients with Sertoli cell or Leydig cell tumors, which secrete excessive quantities of estrogens. Feminizing adrenocortical adenomas or carcinomas also either directly produce high quantities of estrogens or cause hyperestrogenemia through excessive production of estrogen precursors, such as androstenedione, that are aromatized to estrogens. Some tumors, such as giant cell carcinomas of lung, hepatoblastomas, and gastric or renal carcinomas, may secrete hCG, which stimulates the testes to produce excessive quantities of estrogen, resulting in gynecomastia.

Primary hypogonadism, which is due to a testicular pathology, results in a lowering of testosterone and, in some instances, an elevation of estrogen concentrations. A mild degree of testicular failure can be found in some men as part of the aging process. This may be accompanied by gynecomastia, which in the past has been termed “involutional gynecomastia.” Secondary hypogonadism, which is due to a defect in the

pituitary or hypothalamus and results in a loss of appropriate gonadotropin stimulation of the testes, is a rare cause of gynecomastia.

Androgen insensitivity from a defect in the intracellular androgen receptor leads to an inability of androgens to act at the target tissues. This results in unopposed estrogen activity and is a rare cause of gynecomastia. Approximately a quarter of males with hyperthyroidism from Graves' disease may develop gynecomastia due to an increase in the concentration of SHBG, which binds testosterone more avidly than it binds estrogen, leading to a greater lowering of the free, biologically active testosterone level relative to the free, biologically active estradiol level.

As noted previously, the majority of circulating estrogens in males are derived from peripheral extraglandular aromatization of estrogen precursors. Increased aromatization is found in a variety of clinical situations, including aging, obesity, hyperthyroidism, liver disease, congenital adrenal hyperplasia, and Klinefelter's syndrome, and as a primary defect with excessive aromatase activity from persistence of an unregulated fetal aromatase enzyme.

A variety of drugs are also associated with gynecomastia, and the broad groups are listed in [Table II](#). A strong relationship between the occurrence of gynecomastia and medication use has been shown for androgens and anabolic steroids, estrogens and estrogen agonists, antiandrogens such as flutamide, the antibiotic ketoconazole, cimetidine, spironolactone, and alkalating agents. There are a number of other sources of estrogen that occasionally cause gynecomastia. These include the use of over-the-counter phytoestrogens and androstenedione used by athletes. In addition, there may be occupational exposure and percutaneous absorption from anti-balding creams or a sexual partner's use of an estrogen-containing vaginal cream.

EVALUATION OF THE PATIENT WITH GYNECOMASTIA

The first question that must be answered is whether the breast enlargement is gynecomastia. The proper way in which to examine the male breast is to have the patient lie down with arms extended over or behind the head and for the examiner to take his or her thumb and forefinger and place them spread apart over the patient's breasts with the nipple centered in between. When the two digits are gently moved toward the nipple, gynecomastia will be detected as a firm or rubbery, mobile, round mound of tissue that arises concentrically from beneath the nipple and areola. The two most important conditions that should be differentiated from gynecomastia are pseudogynecomastia, which represents fatty enlargement of the breast without glandular proliferation, and breast carcinoma. With pseudogynecomastia, there will be no mound of tissue felt as the fingers close in on the nipple. Some of the features of breast carcinoma that distinguish it from gynecomastia include an eccentric location; mass that is hard, firm, and possibly fixed to underlying tissues; skin dimpling; retraction or crusting of the nipple or a frank nipple discharge; and the presence of axillary lymphadenopathy.

Once it is determined that the patient indeed has gynecomastia, the next question is whether medications are involved. A very careful history concerning medications, herb and vitamin intake, illicit drug use, and possible sources of environmental exposure to estrogens should be taken. If the patient is taking a medication known to be associated with gynecomastia, it should be stopped and the patient should be reexamined in 1 month.

The next question is whether the patient is pubertal. Because pubertal gynecomastia occurs frequently and is self-limited, its presence requires only reassurance that gynecomastia is a normal part of the pubertal process as well as a follow-up at 6 months or longer if the gynecomastia persists.

Another important question concerns whether the gynecomastia is of recent onset or is painful or tender. Gynecomastia of any cause undergoes the same pattern of histological evolution. The "florid phase" is found during the first 6 months. The breast ducts proliferate and exhibit epithelial hyperplasia, and there is an increase in the periductal and stromal constructive tissue, increased vascularity, and a substantial degree of periductal edema. Between 6 and 12 months is a transitional phase. The "involutional phase" is seen in patients with long-standing gynecomastia that has been present for 1 year or longer.

There is a marked reduction in the epithelial proliferation and increased stromal hyalinization, dilation of the ducts, and fibrosis. The presence of pain or tenderness indicates that the patient is in the florid phase and that the gynecomastia has been of relatively recent onset. It is also during this phase that medical therapy directed toward the gynecomastia is most likely to be effective. Once the tissue has entered the inactive or fibrotic stage, medical therapy is unlikely to be beneficial.

The patient should undergo a full physical examination, with particular attention given to the breast exam as described previously, the thyroid for signs of hyperthyroidism, an abdominal examination for signs of cirrhosis or adrenocortical masses, and a careful testicular examination, evaluating for the presence of masses and consistency, especially looking for the reduced size or decreased consistency consistent with hypogonadism.

If the patient is not in the pubertal age group and is not ingesting medications known to be associated with gynecomastia, laboratory investigation should include measurements of hCG, luteinizing hormone (LH), estradiol, and testosterone. An elevated hCG should lead to a testicular ultrasound, looking for a mass that would be compatible with a germ cell tumor. A normal ultrasound suggests that the patient has either an extragonadal germ cell tumor or an hCG-secreting nontrophoblastic neoplasm, which should be evaluated through additional imaging studies. An elevated LH and a decreased testosterone are compatible with primary hypogonadism, whereas a low LH and a low testosterone suggest secondary hypogonadism. In that instance, a serum prolactin should be measured to evaluate the patient for a prolactin-secreting pituitary tumor. If the prolactin is normal, the serum concentration of androstenedione and estrone should be determined. A normal or low level suggests secondary hypogonadism, whereas elevation of these hormones is indicative of the rare 17-ketosteroid reductase enzyme deficiency.

An elevated LH and an elevated testosterone are compatible with either hyperthyroidism or androgen resistance due to an androgen receptor defect. These can be discriminated through measurements of thyroid function tests, including free T₄ and thyroid-stimulating hormone (TSH). An elevated thyroxine (T₄) and a suppressed TSH are diagnostic of hyperthyroidism, whereas normal thyroid function tests indicate that the patient has androgen resistance.

A testicular ultrasound should be carried out in patients who have an elevation of the estradiol concentration and a decreased or normal LH level.

A testicular mass in this setting is indicative of a Leydig or Sertoli cell tumor. If the testicular ultrasound is normal, an adrenal CT scan or MRI should be performed, looking for an adrenal neoplasm. A normal result from that exam suggests that the patient has increased extraglandular aromatase activity. If all results are normal, it is likely that the patient has idiopathic gynecomastia with enhanced sensitivity of the breast tissue to normal amounts of estrogen or that the inciting factor that initiated the gynecomastia has been corrected.

TREATMENT

The indication for therapy includes anxiety, embarrassment, and pain. It should be noted that approximately 85% of patients who have gynecomastia of recent onset will undergo a spontaneous resolution, whereas patients with long-standing gynecomastia will have an approximately 10% chance of spontaneous resolution. Also, as noted previously, long-standing gynecomastia is less likely to respond to medical therapy than is gynecomastia of recent onset due to the presence of fibrosis in the breast tissue when the gynecomastia has been present for more than 1 year.

There are several therapies that have been tried for gynecomastia. Although there are many anecdotal reports of improvement on various therapies, there are few well-designed studies that have critically examined the different therapies. Many of the studies have been hampered by small numbers and lack of placebo controls. The medical therapies that have been tried include administration of testosterone and its metabolites, danazol (an impeded androgen with

weak androgenic and progestational activity), estrogen receptor antagonists such as clomiphene citrate and tamoxifen, and aromatase inhibitors such as testolactone and anastrozole. The best studied of these therapies is tamoxifen, which does appear to be superior to placebo in regard to reduction of breast pain and tenderness as well as breast size.

In a patient who has long-standing gynecomastia or who fails to have an adequate response to medical therapy, surgical removal of the breast glandular tissue should be considered. There are a number of approaches and methods that include sharp excision, liposuction, or a combination of these methods. The approach that is most commonly used currently involves a periareolar incision, a sharp excision of the breast glandular tissue, and liposuction for contouring the breasts. Complications of the procedures include nipple-areolar numbness, hematomas, seromas, scarring, inverted nipples, nipple necrosis, and depressive deformities of the chest wall as well as inadequate tissue removal along with redevelopment of the gynecomastia.

- Types Ia and Ib are generally small pedunculated hamartomas that are attached to the tuber cinereum (Ia) or to the mammillary bodies (Ib) and are usually associated with precocious puberty.
- Types IIa and IIb are relatively large lesions that displace the hypothalamus slightly (IIa) or markedly (IIb) and are usually associated with gelastic or other types of seizures. Surgery has been recommended for types Ia, Ib, and IIa, especially when epileptic activity and behavioral abnormalities are severe and difficult to control.

A further classification has been proposed based on magnetic resonance imaging (MRI):

- The parahypothalamic type, attached to the floor of the third ventricle or suspended from the floor by a peduncle, is generally associated with precocious puberty.
- The intrahypothalamic type, enveloped by the hypothalamus to displace the third ventricle, is more likely to be associated with gelastic seizures.

HISTOLOGY AND PATHOPHYSIOLOGY

Hypothalamic hamartoma is thought to be a developmental aberration, but its origin is unclear. Remnants of brain tissue left along the floor of the third ventricle when the chorda withdraws may account for its origin in the central nervous system (CNS). Histologically, it consists mainly of normal brain elements: neurons, glial cells, and fiber bundles that are frequently myelinated and connected to surrounding hypothalamic structures. Frequently, however, hamartomas do not reproduce the normal architecture of neighboring tissue.

The hypothalamic hamartoma functions as an ectopic luteinizing hormone-releasing hormone (LHRH) pulse generator that escapes the intrinsic CNS inhibitory mechanism. In the mouse, monkey, and human, LHRH neurons originate in the medial olfactory placode of the developing nose, migrate across the nasal septum, and enter the forebrain with the nervus terminalis, arching into the septal-preoptic area and hypothalamus. In hypothalamic hamartoma, a significant number of LHRH neurons migrate beyond the medial basal hypothalamus to the region of the mammillary bodies and tuber cinereum and form one of the constituents of the heterotopic mass of CNS tissue. The defect in migration could be related to an imbalance of diffusible chemotrophic factors that are secreted by restricted cell populations within the brain or to neural cell adhesion

molecules, which play an important role in axonal path-finding.

Since the number of LHRH neurons is limited, it is possible that a majority of the LHRH neurosecretory neurons may migrate into the hamartomas during CNS development. On the other hand, hypothalamic hamartoma may be related to aberrant differentiation among other cell types of neural primordia, including progenitor cells with the capacity to form LHRH neurosecretory neurons.

Histological specimens observed after surgery reveal hamartomas of low cell density containing irregularly structured groups of ganglionoid cells with variably sized unipolar and bipolar neurons interspersed among glial cells with myelinated and unmyelinated fibers connected to surrounding hypothalamic structures. The tissue is highly vascular and many of the vessels have fenestrated endothelium and double basement membranes. Each vessel is almost totally surrounded by axons. There is no or very little tendency to proliferation.

Immunohistochemical studies confirm the neuronal origin of hypothalamic hamartoma, showing positive staining for neuron-specific enolase, synaptophysin, and neurofilament protein.

Different immunohistochemical studies demonstrate the presence of membrane-bound, electron-dense granules (100 nm in diameter), which contain LHRH within the perikarya, the axons, and the axons terminals and which are the elements of an independent neuroendocrine unit.

The examination of two hypothalamic hamartomas associated with sexual precocity revealed that they contained astroglial cells expressing transforming growth factor- α (TGF- α), but not LHRH neurons. These findings indicate that some hypothalamic hamartomas induce sexual precocious puberty by activating endogenous LHRH secretion via astroglial-derived factors, such as TGF- α and/or TGF- β . This activation appears to require a close proximity of the hypothalamic hamartoma to either LHRH neurons or their axonal processes in the median eminence. In some cases, the hamartoma itself does not initiate precocious sexual maturation due to its location, but rather a lesion of the adjacent hypothalamic tissue resulting from surgery may cause the activation of astroglial cells, which may then lead to increased LHRH secretion from hypothalamic LHRH neurons.

A number of findings suggest that hamartomas are themselves epileptogenic. Electroencephalography (EEG) recordings revealed focal spikes arising from the depth contacts within hypothalamic hamartomas,

whereas electrical stimulation studies reliably reproduce gelastic episodes, suggesting a close relationship between hamartomas and the generation of laughing attacks. The most fascinating studies based on ictal single-photon-emission computed tomography demonstrated marked blood flow in the hypothalamus and thalamic structures during gelastic events. Improvement in intractable epilepsy has been reported in some cases after the resection of the hamartoma.

Clinical and experimental evidence suggests that the hypothalamus and adjacent structures, in particular the mammillary bodies and their immediate connections, may constitute an important subcortical pathway for seizure propagation. Sessile hypothalamic hamartomas with displacement of the hypothalamus are associated with seizures.

Evidence shows that, unlike laughing and focal seizures, slow spike-and-wave discharges and associated tonic and atonic seizures do not arise directly from the hamartoma. Indeed, postoperatively, these seizures may progressively “run down” after removal of the hamartoma, suggesting that they are the result of secondary epileptogenesis.

CLINICAL PRESENTATION

Endocrine Aspects

Hypothalamic hamartoma is considered the most common organic cause associated with CPP. The incidence of hypothalamic hamartoma in determining CPP varies widely, ranging from 2 to 28%.

The age of onset of the first signs of CPP has been reported as being between 0 and 4 years (frequently before 2 years of age), whereas CNS lesions (gliomas, germinomas, arachnoid cysts) tend to occur in association with CPP later in life.

CPP associated with hypothalamic hamartoma has all of the hormonal hallmarks of puberty, including plasma β -estradiol (E2) levels, a pubertal pattern of pulsatile luteinizing hormone (LH), and a pubertal LH response after gonadotropin-releasing factor administration. Higher levels of peak LH response and a peak LH/follicle-stimulating hormone (FSH) ratio after LHRH administration have been reported in girls with CPP associated with hypothalamic hamartoma compared to idiopathic precocious puberty.

Neurological and Behavioral Aspects

The classic presentation of hypothalamic hamartoma is represented by gelastic seizures, which begin in infancy, often in the neonatal period, and are later

followed by the development of seizures with focal motor features and autonomic manifestations, such as flushing and cardiorespiratory changes. Partial seizures, suggestive of a temporal or frontal lobe origin, may also occur. In many children, a generalized epileptic encephalopathy develops, with tonic and atonic seizures with slow spike-and-wave discharges on interictal EEG, intellectual deterioration, and sometimes with marked behavioral disturbances including rage attacks.

Several studies reported a characteristic, recognizable epileptic syndrome that shows a typical evolution over time. The syndrome begins with laughing attacks; the resemblance to normal laughter is so close in some patients that delayed diagnosis is possible. The pattern is quite stereotyped, with some variations over time. After a few years, the laughing attacks are associated with momentary loss of awareness, facial myoclonus, and/or abnormal eye movements. Autonomic phenomena are common. In later childhood, typically between the ages of 4 and 10 years, features of secondary generalized epilepsy appear with multiple seizure patterns including tonic, atonic, and tonic-clonic seizures and progressive cognitive impairment.

The occurrence of cognitive deficits is significantly associated with the presence, severity, and frequency of gelastic/complex partial seizures. In a study with a large cohort of patients, it has been demonstrated that patients with hamartomas display a statistically significant increase in comorbid psychiatric conditions, including oppositional defiant disorders, attention-deficit/hyperactivity disorder, high rates of conduct disorders, speech retardation/learning impairment, and anxiety and mood disorders. There are no definitive data to indicate exactly how the epileptic pathology interferes with a patient's development and behavior and why a majority of patients have a cognitive-behavioral deficit, which often worsens with age.

Brief infantile attacks are not associated with any significant change in EEG. However, in later childhood, with the progression of the epileptic syndrome, EEG abnormalities develop with generalized suppression of background rhythm, generalized low-voltage fast activity, or both. Interictally, there are generalized slow spike-and-wave discharges and background activity that is abnormally slow for the child's age as hallmarks of secondary generalized epilepsy.

MAGNETIC RESONANCE IMAGING

MRI has become the diagnostic method of choice in the detection of hypothalamic hamartoma. In general,

hamartomas are uniformly isointense to gray matter on T1-weighted MRI scans and slightly hyperintense or isointense on T2-weighted images. They are not enhanced by gadolinium (Figs. 1A and 1B). There are some cases where hypothalamic hamartomas appear slightly hyperintense on T1-weighted images and, very rarely, they may appear hypointense in the center of the lesion with normal isointensity at the periphery. The variance in myelinated axons and the presence of gliosis can affect the variability of the T2 signal.

Another characteristic feature of hypothalamic hamartomas is their relative stability in size, shape, and signal in long-term MRI follow-up during and after medical treatment. Signal or cystic changes have occasionally been observed; in these cases, the differential diagnosis should include low-grade astrocytomas and gangliogliomas. The MRI findings that commonly indicate hypothalamic hamartoma are as follows: an isointense mass with a pedunculated or sessile attachment to the hypothalamus without contrast enhancement, stable in size and shape during follow-up, associated with endocrinological and clinical features of CPP, occurring mostly before 2 years of age, and associated with gelastic seizures.

TREATMENT

Precocious Puberty

The aims of treatment are to arrest physical maturation, to prevent early menarche or sexual adult psycho-physical maturation, and to improve adult height to within the range of target height combined with normal body proportions.

Successful suppression treatment with gonadotropin-releasing hormone (GnRH) analogue preparations has been reported by several groups for a duration of up to 8 years with a homogenous endocrinological response characterized, after an initial phase of increased serum LH and FSH levels (flare-up), by a reduction to prepubertal ranges of basal LH, FSH, testosterone, and E2, a prepubertal peak LH and FSH response to GnRH stimulation test, and a prepubertal LH/FSH ratio with improvement of adult height toward predicted final height and close to target height; no adverse events have been reported.

A controversial outcome of precocious puberty has been reported after surgical resection of hamartomas. It has been suggested that surgery is safe and can be considered an option when compared to the cost of medical treatment, monthly treatment (or every 3 months) administration until puberty (sometimes

Figure 1 Sagittal T1-weighted MRI shows sessile hamartoma in the typical location in the third ventricle, isointense with gray matter before (A) and after (B) gadolinium administration (white arrow).

poorly tolerated), painful injections in some cases, the psychological implications, and, in some rare cases, an intolerance to treatment. Total resection, however, cannot be achieved in all hamartomas.

Females with hypothalamic hamartoma have a higher incidence of irregular menses, obesity, and neurological and behavioral problems with a normal reproductive axis within 4–5 years after discontinuation of GnRH analogue therapy; pregnancies resulted in normal, live infants.

Seizures

It has become clear that epileptic encephalopathy associated with hypothalamic hamartoma is a treatable condition. Strong evidence exists that removal, destruction, or disconnection of the hamartoma leads to remarkable control of the seizures, as well as to an improvement in behavior and probable cessation of cognitive decline.

Gelastic seizures are resistant to all available medications. Rarely, treatment of the focal seizures and of tonic and atonic attacks can be moderately successful with conventional anti-epileptic drugs. However, experience suggests that long-lasting control of these seizures can be effected by the complete removal, destruction, or disconnection of the hamartoma, thanks to important improvements in imaging and surgical techniques. There exist various possible surgical approaches to the lesion and the debate is focused on the best technique to use (i.e., it must be tailored to the specific surgical anatomy of the hamartoma) in order to guarantee, in each single case, the possibility of total removal or disconnection of the lesion. The transcallosal approach (suited to intraventricular lesions) appears to be the technique with the highest rate of success, with 90% of cases free or virtually free of all seizures at 1 year post-surgery. Prolonged follow-up is necessary to evaluate the real effects on cognitive impairment, whereas behavioral abnormalities tend to show marked improvement in many patients. Other surgical choices include the pterional approach (particularly useful for peduncular lesions) and the transventricular endoscopic approach or destruction of the lesion with radiofrequency or gamma knife radiosurgery.

Secondary effects of surgery that have been described are small strokes with good recovery, encephalomalacia, third-nerve palsy, transient memory impairment, and transient diabetes insipidus. Postoperative mortality has also been reported.

ASSOCIATED CONDITIONS

Pallister-Hall Syndrome

Pallister-Hall syndrome was first described in 1980 as a lethal congenital malformation syndrome associated with hypothalamic hamartoblastomas, postaxial polydactyly, craniofacial malformations, and imperforate anus. Additional abnormalities include developmental and postnatal retardation; holoprosencephaly; pituitary agenesis/dysgenesis with hormone dysfunction leading to micropenis, cryptorchidism, hypopituitarism, or panhypopituitarism; laryngeal clefts; bifid epiglottis; buccal frenula; small nose/anteverted nares; low-set/posteriorly angulated ears and microphthalmia; limb/skeletal malformations such as short fourth metacarpals and nail dysplasia; involvement of other organs with abnormal lung lobulation; renal agenesis and/or dysplasia; and congenital heart defects (Figs. 2A and 2B). The syndrome is considered a clinical, variable “iceberg” disorder with wide phenotypic variability in which adrenal insufficiency is the most common cause of perinatal death.

This disorder is inherited as an autosomal-dominant trait and has been reported in association with an unbalanced chromosome translocation between chromosomes 3p and 7q and it was mapped to chromosome 7p13. Mutations in the transcription regulator gene *GLI3* have been identified in patients with Pallister-Hall syndrome, but also in four other different autosomal-dominant phenotypes: the Greig cephalopolysyndactyly syndrome, preaxial polydactyly type IV, postaxial polydactyly type A, and postaxial polydactyly type A/B.

Consensus guidelines in 1996 developed diagnostic criteria for the delineation of familial Pallister-Hall syndrome, which include the presence of a hypothalamic hamartoma, central polydactyly most commonly affecting the third or fourth digit, and, in the first-degree relatives of an index case, a hypothalamic hamartoma or similar digital abnormalities associated with an autosomal dominant. An association with endocrine dysfunction requires hormone replacement treatment. Adult height above the target height has been reported in a patient treated with growth hormone for up to 7 years. Surgical correction of visceral abnormalities is mandatory.

Other Conditions

Hamartomas may be found in syndromes of midline defects such as oral–facial–digital syndrome or solitary maxillary incisor or in association with CNS malformations including agenesis of the corpus

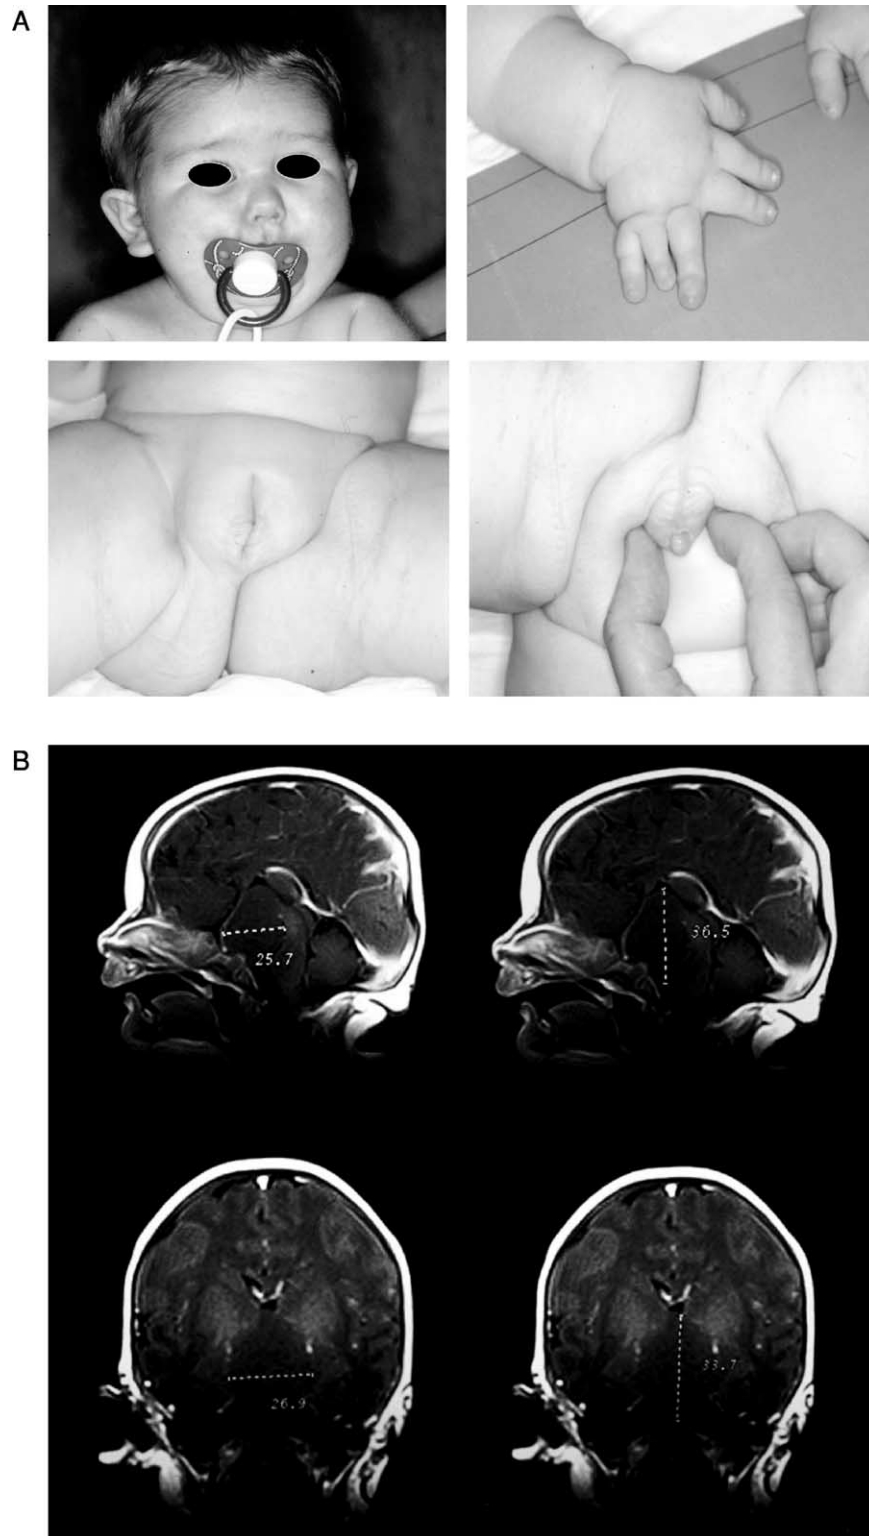

Figure 2 (A) Frontal view showing a phenotype suggestive of congenital hypopituitarism. Note the hands with polydactyly; micropenis and cryptorchidism are associated with panhypopituitarism. light of a higher prevalence of autoimmune hypothyroidism in iodine-sufficient regions as compared with iodine-deficient regions. Overt hypothyroidism in patients on a very rich iodine diet (e.g., seaweed, kelp) can be reversible on avoiding the source of the iodine excess. Otherwise, lifelong treatment with T_4 is indicated.

In the atrophic variant of chronic autoimmune thyroiditis (atrophic myxedema), fibrosis is the predominant feature along with lymphocytic infiltration. In the less common goitrous variant originally described by Hashimoto, the histology remains essentially unaltered after 20 years. The goiter is diffuse and has a firm "rubbery" consistence; it does not regress in 43% of patients despite T_4 treatment. Some patients have an initial transient hyperthyroid stage labeled as Hashitoxicosis. It disappears in a few months along with the decline in the causative TSH receptor-stimulating antibodies, which may give way to TSH receptor-blocking antibodies.

Figure 1 Structure and biological functions of HGF. Schematic structures of HGF mRNA, prepro-HGF, and mature HGF are shown in the upper half. Binding of HGF to the c-Met receptor evokes various biological effects on cellular behavior in a target cell-specific manner. See text for details.

product highly homologous to HGF. HGF-like protein was later shown to be identical to macrophage-stimulating protein. HGF-like protein specifically binds and activates Ron receptor tyrosine kinase, a family of the *c-Met* receptor.

The receptor encoded by *c-met* protooncogene is synthesized as a single polypeptide chain of 1436 amino acids that is cleaved into a 50-kDa α -chain and a 145-kDa β -chain (Fig. 1). The α -chain is exposed extracellularly, whereas the β -chain is a transmembrane subunit containing an intracellular tyrosine kinase domain. Binding of HGF to the Met receptor induces activation of tyrosine kinase, resulting in the subsequent phosphorylation of C-terminally clustered tyrosine residues and recruitment of various intracellular signaling molecules (Fig. 1).

Studies on the structure–function relationship in the HGF molecule revealed a functional domain for receptor binding and subsequent biological activities. Both NK1 and NK2, smaller N-terminal variants of HGF, can bind the *c-Met* receptor; thus, NK1 serves a minimum set of domains responsible for binding to the *c-Met* receptor. Interestingly, NK1 and NK2 exhibit antagonistic activity on HGF-induced mitogenesis, whereas they function as agonists in terms of cell motility activity. On the other hand, NK4, composed of N-terminal hairpin and four kringle domains, was characterized as a competitive antagonist for HGF.

BIOLOGICAL ACTIVITIES

HGF exhibits multiple biological activities for a wide variety of cells (Fig. 1). Target cells of HGF include most epithelial cells (e.g., hepatocytes, renal tubular cells, neurons, keratinocytes), vascular endothelial cells, and several mesenchymal/stromal cell types.

HGF is mitogenic for differentiated epithelial cells (e.g., hepatocytes, renal tubular cells, bronchial and alveolar epithelial cells, gastric epithelial cells, keratinocytes), vascular endothelial cells, mesenchymal/stromal cells (e.g., cardiomyocytes, articular chondrocytes, osteoclast-like cells), and stem cells such as hepatic stem cells, hematopoietic progenitor cells, and skeletal satellite cells, precursor cells that differentiate into myocytes. On the other hand, HGF inhibits growth of several distinct types of cancer cells and cell lines (e.g., HepG2 hepatocellular carcinoma cells, B16F1 melanoma cells). HGF as “motogen” stimulates motility and migration of various cells. Among the multipotent characteristics of HGF, the morphogenic activity of HGF is unique. HGF induces branching tubulogenesis in epithelial

cells, including renal tubular cells, mammary gland epithelial cells, and hepatic bile duct epithelial cells.

HGF has potent antiapoptotic activity in several types of cells, including hepatocytes, renal epithelial cells, vascular endothelial cells, cardiac myocytes, and neurons. HGF increases activity and/or gene expression of proteases involved in the breakdown of extracellular matrix components, including urokinase-type plasminogen activator and matrix metalloproteases. Induction of these proteases plays an important role in branching tubulogenesis, migration, or invasion of cells. It is notable that HGF is involved in a phenotypic transition between epithelial and mesenchymal cell types in a cell type-specific manner; HGF induces epithelial-to-mesenchymal transition of dermomyotome cells in embryos, whereas it inhibits transition of renal tubular epithelial cells to myofibroblasts.

DEVELOPMENTAL ROLES

Interactions between the epithelium and mesenchyme (i.e., epithelial–mesenchymal interactions) mediate crucial aspects of normal development, affecting tissue induction, morphogenesis, and organogenesis. Growth, differentiation, and morphogenesis of developing epithelia are regulated either inductively or permissively by neighboring mesenchyme in the developing kidney, lung, pancreas, placenta, mammary gland, salivary gland, tooth, and so forth. During rat and murine development, the *c-Met* receptor gene is predominantly expressed in epithelia, whereas the HGF gene is in mesenchymal cells in close vicinity to epithelia in various organs, including the kidney, pancreas, liver, lung, intestine, stomach, salivary gland, limb bud, and tooth. Several distinct approaches indicate that HGF plays roles in the development and morphogenesis of organs as a mediator in epithelial–mesenchymal interactions.

Essential roles of HGF in the development of mammalian fetal tissues were defined by targeted disruption of HGF or the *c-Met* receptor gene. These knockout mice are embryonic lethal due to impaired organogenesis of the placenta and liver. In the placenta, the number of epithelial trophoblasts in the labyrinthine layer is markedly reduced, leading to impaired exchange of oxygen and nutrients between maternal and embryonic bloodstreams. The embryonic liver is reduced in size and shows extensive apoptotic cell death, indicating that hepatoblasts/hepatocytes in the embryonic liver require HGF for proliferation and/or survival. An essential role for HGF in organogenesis was also demonstrated in the amphibian *Xenopus*.

Table I Developmental and Physiological Roles of HGF and Potential Clinical Application

| | |
|---|--|
| Developmental roles | |
| Growth, antiapoptosis, and/or morphogenesis | |
| Growth and morphogenesis of the liver | |
| Growth of the placental labyrinthine layer | |
| Morphogenesis of the kidney (tubulogenesis) | |
| Morphogenesis of the lung | |
| Morphogenesis of the mammary gland | |
| Morphogenesis of the tooth germ | |
| Migration | |
| Migration of myogenic precursor cells from the demomyotome to the limb and diaphragm | |
| Migration and proliferation of myogenic precursor cells to the tongue | |
| Chemoattractive and/or neurotropic | |
| Attraction of axons of motor neurons to the limb | |
| Guidance or attraction of cranial motor neurons | |
| Physiological roles | |
| Liver regeneration following partial hepatectomy, ischemia, or administration of hepatotoxins | |
| Renal regeneration following unilateral nephrectomy, ischemia, or administration of nephrotoxins | |
| Lung regeneration following partial pneumonectomy or chemical injury | |
| Cardiac protection following ischemia | |
| Epithelia of the stomach and intestine | |
| Cutaneous wound healing | |
| Angiogenesis | |
| Enhancement of insulin secretion and antiapoptosis in pancreatic beta-cells | |
| Potential therapeutic application | |
| Hepatic diseases: acute hepatitis, fulminant hepatitis, fatty liver, transplantation, liver cirrhosis | |
| Renal diseases: acute renal failure, chronic renal failure, transplantation | |
| Lung diseases: acute lung, lung fibrosis, transplantation | |
| Gastrointestinal: gastric ulcer, diabetes mellitus | |
| Cardiovascular diseases: cardiac infarction, cardiomyopathy, arteriosclerosis obliterans | |
| Nervous system: cerebral ischemia, amyotrophic lateral sclerosis | |
| Others: graft versus host-disease, cartilage defect | |

Involvement of HGF in morphogenesis of organs was also revealed in organ culture experiments. Cultured embryonic organs undergo morphogenic steps that mimic their development *in vivo*. In organ cultures, neutralizing anti-HGF antibody inhibited morphogenesis of developing lung epithelia and branching tubulogenesis of developing epithelia in the kidney and mammary gland. In tooth germ culture, antisense oligonucleotide to HGF induced impaired morphogenesis of tooth epithelium. Thus,

HGF is a mesenchymal-derived paracrine factor that supports morphogenesis of developing epithelia during organogenesis of the lung, kidney, and tooth.

One of the interesting developmental functions of HGF is the decisive role in generation of skeletal muscle that derives from long-range migrating muscle precursor cells. Ablation of HGF or the *c-met* gene in mice results in complete absence of skeletal muscles of the limb and diaphragm, whereas other muscle groups form normally. In these mice, the long-range migration of c-Met-positive myogenic precursor cells from dermomyotome in the somite to limb buds and diaphragm is impaired. Because HGF is strongly expressed in limb bud mesenchyme and septum transversum (which develops into the diaphragm), HGF provides spatially defined chemoattractant-like motogenic signals for migration of myogenic precursor cells. Similar chemoattractant-like function of HGF was noted in migration of myogenic precursor cells into the tongue.

In the nervous system, HGF has chemoattractant-like functions. Developing axons can be guided to their targets by diffusible molecules and factors bound to the cell surface that act as chemoattractants or repellents. Transplanted limb buds attract motor axons in amphibians and birds, and similarly, explanted mouse limb bud mesenchyme attracts axons of motor neurons. HGF was identified to be a chemoattractant factor derived from limb bud mesenchyme. Developmental and morphogenic roles of HGF are summarized in [Table I](#).

PHYSIOLOGICAL FUNCTIONS

Regeneration of the liver is a most dramatic phenomenon in higher animals. When 70% of the liver is resected, the cells in the remaining liver rapidly proliferate and the original liver mass is restored within a week. Given that HGF was initially implicated to be a hepatotropic factor that enhances liver regeneration, the hepatotropic roles of HGF have been demonstrated extensively. HGF and the c-Met receptor, both expressed in a variety of tissues, play a role in regeneration and/or protection of other tissues and organs besides the liver.

In rats and mice, a range of hepatic injuries (e.g., partial hepatectomy, acute hepatitis, ischemia, physical crush) increase blood HGF levels and HGF mRNA expression in the injured liver and in intact distant organs such as the lung, kidney, and spleen. Similarly, increases in plasma HGF levels and HGF gene expression in injured and noninjured organs occur following various types of injuries (e.g., partial

resection, ischemia, chemical injury) of other organs such as the kidney, lung, heart, muscle, and pancreas. Local injury to the gastric mucosa and skin increases local expression of HGF and the c-Met receptor.

Involvement of endogenous HGF in tissue regeneration and/or protection was demonstrated by approaches using a neutralizing antibody against HGF. Neutralization of endogenous HGF in rats or mice increased tissue damage and cellular apoptosis while it suppressed tissue regeneration in cases of hepatic, renal, and lung injuries. In case of cardiac ischemia reperfusion injury, neutralization of HGF resulted in increased apoptosis of cardiomyocytes and expansion of infarcted area, leading to cardiac dysfunction in rats. Local injection of anti-HGF antibody delayed gastric ulcer healing. Importantly, when endogenous HGF was neutralized in mice with renal injury, mice were susceptible to renal fibrosis, indicating that HGF is antifibrotic.

It is worth noting that increased HGF levels in sera or tissue fluid were noted in patients with distinct types of diseases, including acute hepatitis, fulminant hepatitis, acute renal rejection after transplantation, pneumonia, cardiac infarction, severe acute pancreatitis, and Crohn's, Huntington's, Parkinson's, and Alzheimer's diseases. Increased HGF levels in sera or tissue fluids are likely to reflect physiological responses to tissue and cellular damage.

Vascular endothelial cells from various tissues express the c-Met receptor, and HGF is a potent angiogenic growth factor that stimulates growth and migration of endothelial cells. HGF induces new blood vessel formation *in vivo*. However, because abnormal vascular formation was not seen in knock-out mice of HGF or the *c-met* gene, HGF might not play a major role in neovascularization during embryogenesis. Physiological roles of HGF are listed in [Table I](#).

INVOLVEMENT IN TUMORIGENESIS AND TUMOR PROGRESSION

Ligand-dependent or-independent constitutive activation of receptor tyrosine kinases is often associated with the tumorigenic transformation of cells. Genetic analysis of papillary renal carcinoma in patients indicated that missense mutations in the *c-met* gene are the causative genetic disorder in inherited and some sporadic papillary renal carcinomas. All mutations that occur in the *c-met* gene are missense, and the c-Met receptor with these mutations had enhanced

tyrosine kinase activity, indicating that these c-Met receptor mutations are likely to be a gain-of-function mutation. In addition to genetic mutation, aberrant activation of the c-Met receptor through establishment of an autocrine loop between HGF and the c-Met receptor, or overexpression of the c-Met receptor, is likely to be involved in tumorigenesis and/or tumor progression toward metastatic tumor. Overexpression of the c-Met receptor was noted in a wide variety of tumor cells and tissues, including carcinoma, lymphomas, and soft tissue tumors.

Although aberrant activation of the c-Met receptor is involved in the tumorigenic transformation of cells, a more definite significance of the c-Met receptor activation in tumor cells is likely to be in progression to invasive and metastatic tumor. Invasion of tumor cells is regulated by distinct cellular functions, including cell-cell adhesion, cell-extracellular matrix association, proteolytic breakdown of the extracellular matrix, and cellular locomotion. Because HGF affects these processes, HGF exhibits profound effects on the invasive behavior of a wide variety of tumor cells. Gene transfer experiments that involve autocrine activation of the c-Met receptor confer invasive and metastatic behavior in cancer cells. Furthermore, although tumor-stromal interaction closely affects invasive and metastatic behavior of carcinoma cells, HGF is a predominant stromal-derived mediator in tumor-stromal interaction. HGF is a critical factor for tissue regeneration, whereas cancer cells use the HGF-c-Met pathway toward tumorigenic and/or metastatic progression. The simile that "cancer is a never-healing wound" seems pertinent here.

THERAPEUTIC APPROACHES

Based on evidence that activation of the c-Met receptor leads to tissue protection and repair against tissue injury, whereas it also leads to invasive and metastatic progression of cancer cells in tumor tissues, two distinct therapeutic approaches can be considered. One is application of HGF (i.e., c-Met agonist) for treatment of organ injuries, and the other is application of an antagonistic or inhibitory molecule against HGF-c-Met pathway to inhibit cancer invasion and metastasis. Experiments to explore the therapeutic potential of HGF for treatment of diseases have been extensive, and various disease models and experimental animals have been used ([Table I](#)). Several approaches were done using HGF gene therapy.

Approaches Using HGF or HGF Gene Transfer for Therapeutic Purposes

Administration of human recombinant HGF into mice or rats stimulates proliferation of hepatocytes after liver insult caused by partial hepatectomy or hepatotoxins. Through its antiapoptotic action, HGF abrogated the onset of acute hepatitis and fulminant hepatic failure. Likewise, administration of HGF accelerated tissue regeneration and/or attenuated tissue injury in other organs. HGF suppressed the onset of acute renal failure caused by administration of nephrotoxic drugs or renal ischemia. HGF enhanced the mitogenesis of bronchial and alveolar epithelial cells following lung injury caused by partial pneumonectomy or hydrochloric acid. HGF administered to rats with cardiac ischemia reperfusion injury reduced the extent of apoptosis in cardiac myocytes, thereby reducing the infarcted area. The submucosal application of HGF accelerated gastric ulcer healing in rats. Mice with the transgenic expression of HGF in pancreatic beta cells were resistant to type 1 diabetes. In articular tissues, HGF effectively repairs osteochondral defects in a rabbit model.

Chronic inflammatory diseases are characterized by fibrotic changes in tissues, including liver cirrhosis, chronic renal failure, lung fibrosis, and cardiomyopathy. These fibrotic diseases are progressive and currently incurable. Administration of HGF into rats with liver cirrhosis decreased the accumulation of hepatic extracellular matrix components and abrogated the mortality rate due to hepatic dysfunction. HGF prevented renal fibrosis and concomitant renal dysfunction in models for chronic renal failure or renal fibrosis. Likewise, HGF administration prevented lung fibrosis caused by bleomycin. Although mechanisms responsible for antifibrotic action of HGF are not fully understood, HGF does suppress key events leading to tissue fibrosis. HGF suppresses expression of transforming growth factor- β , a key growth factor whose overexpression induces tissue fibrosis. HGF is antiapoptotic and mitogenic for epithelial cells (e.g., hepatocytes, renal tubular cells, alveolar epithelial cells) and endothelial cells, whereas HGF enhances protease activities responsible for the degradation of extracellular matrix components.

Neurotropic actions of HGF were expanded to therapeutic approaches for the treatment of injury or diseases of the nervous system. Infusion of HGF into the brain prevents neuronal death in the hippocampus and in the cerebral cortex. Transgenic expression of HGF in neurons resulted in retardation of disease progression and prolongation of the life span in a

transgenic mouse model for amyotrophic lateral sclerosis, a fatal neurodegenerative disorder characterized by the progressive loss of motor neurons and the degeneration of motor axons.

HGF gene therapy induces angiogenesis in models for hind limb ischemia and cardiac infarction. In 2001, the first clinical trial of HGF gene therapy for treatment of patients with arteriosclerosis obliterans was initiated, and validity of this therapy has been confirmed.

Approaches Using an HGF Antagonist for Cancer Treatment

The antagonistic molecule designated NK4 was isolated as a competitive inhibitor for binding of HGF to the c-Met receptor. NK4 is composed of N-terminal 447 amino acids of the α -chain of HGF and so contains the N-terminal domain and subsequent four kringle domains. NK4 has receptor-binding domains (i.e., NK1 or NK2) but has no agonistic activities after binding to the c-Met receptor.

Treatment with NK4 protein or HGF gene therapy inhibited tumor growth, invasion, and/or metastasis in experimental cancer treatment models, including pancreatic, breast, lung, gallbladder, colon, and ovarian cancers. Likewise, NK4 treatment prolonged the survival of mice with pancreatic, ovarian, and colon cancers.

An alternative approach to block c-Met-dependent signaling events was demonstrated using synthetic tripeptide inhibitors that block association of GRB2 with the c-Met receptor. These compounds inhibited migration, invasion, and the morphogenesis induced by HGF. Thus, these compounds are potential candidate molecules to inhibit c-Met-dependent cancer invasion and metastasis.

PERSPECTIVE

Developmental and morphogenic roles of HGF may facilitate understanding as to how HGF orchestrates organogenesis and morphogenesis, including spatial and timely expression of HGF and the *c-met* gene in distinct cell types as well as specific changes in signal transduction and gene expression toward morphogenic processes. These studies are closely related and recapitulated in tissue regeneration in adult tissues. Further studies on mechanisms for HGF-related tissue regeneration will lead to a fundamental understanding of growth factor-network and cellular interactions involved in tissue regeneration and homeostasis.

Approaches for potential therapeutic use of both agonists and antagonists in the HGF-c-Met system will explore new therapeutic methods for treatment of patients with various diseases and malignant tumors.

Table I Etiologies of Adult Hypogonadism

| |
|------------------------------------|
| Primary |
| Testicular trauma |
| Chemotherapy |
| Radiation |
| Klinefelter's syndrome |
| Mumps orchitis |
| Malnutrition |
| Excessive heat exposure |
| Drugs or medications |
| Environmental toxins |
| Surgical manipulation |
| Autoimmunity |
| Granulomatous disease |
| Secondary |
| Cushing's syndrome |
| Hyperprolactinemia |
| Panhypopituitarism |
| Isolated gonadotropin deficiency |
| Biologically active adrenal tumors |
| Obesity |
| Hypothyroidism |
| Primary or secondary causes |
| Medications |
| Hemochromatosis |
| Hypercortisolemia |
| Severe systemic illness |
| Sickle cell disease |
| AIDS |
| Uremia |
| Cirrhosis |

primary gonadal disorders, secondary disorders that reflect dysfunction at the level of the hypothalamic-pituitary axis, and defects with both primary and secondary hypogonadism components (Table I). Among the more common causes are hyperprolactinemia, hypercortisolemia, obesity, and medications. The medications most commonly noted to contribute to hypogonadism are ketoconazole, glucocorticoids, spirinolactone, cimetidine, phenytoin, and alcohol. As pituitary radiation becomes more common as a treatment for various pituitary tumors, its role in secondary hypogonadism and perhaps panhypopituitarism must be considered.

Testosterone Decline in the Aging Male

There is no male equivalent to female menopause, although some comparison can be made to declining testosterone production and increased gonadotropin levels with increasing male age. However, the loss of

testosterone production in men is gradual and relatively subtle. Both total and free (unbound) testosterone may decrease by approximately 1 to 2% per year from 30 to 40 years of age. Several reports suggest that there is also an alteration in the testosterone/estradiol ratio in that estradiol levels remain the same while testosterone production decreases over time. This results in an increase of SHBG, leading to even further decreases in unbound testosterone. The increases in gonadotropins in this setting are relatively modest. Older men with low to low-normal serum testosterone will have LH and FSH levels slightly above or comparable to the upper range of normal in young adult men.

DIAGNOSIS

Recognition of the manifestations and physical findings, such as loss of libido, erectile dysfunction, decreased bone density, gynecomastia, and small testes, leads to further evaluation by laboratory testing. Initial testing should include a morning plasma total testosterone performed by radioimmunoassay and gonadotropin levels. In approximately 30% of normal males, levels of testosterone are highest in the morning and are decreased by up to one-third by afternoon and evening, owing to the natural circadian rhythm of testosterone production and release. A low to low-normal morning total testosterone level, usually 200 to 250 ng/dl in most laboratories, warrants further investigation with determination of the free or unbound fraction of testosterone. It should be remembered that testosterone values, even in young men, can vary greatly and can appear to be in the low range of normal despite normal sexual function.

For those with testosterone levels that are clearly in the hypogonadal range, ascertainment of the etiology of hypogonadism is important and the gonadotropin levels are helpful in this respect (for etiologies of hypogonadism, see Table I). In older men with subtle symptoms of testosterone deficiency due to age, the diagnosis may be somewhat difficult. Although levels of total testosterone less than 200 to 250 ng/dl are generally considered hypogonadal, low-normal levels present a dilemma. Partial androgen deficiency in the aging male is an entity of growing interest, owing to a fair proportion of older men with subtle symptoms of hypogonadism and less than clear biochemical evidence of classic hypogonadism. In addition, it is unknown whether the requirements of elderly males are similar to those of younger men. Currently, there is no one parameter that adequately reflects biological

activity. Consequently, one must use good clinical judgment when evaluating hypogonadism, with treatment aims to alleviate symptoms and improve quality of life.

INDICATIONS FOR HORMONE REPLACEMENT

Patients with elevated gonadotropins and decreased testosterone (hypergonadotropic hypogonadism) have primary hypogonadism and warrant therapy with testosterone. However, most patients with primary hypogonadism have associated failure of spermatogenesis, and so androgen replacement cannot provide fertility.

Patients with low levels of gonadotropins and low testosterone (hypogonadotropic hypogonadism) have secondary hypogonadism. Testosterone is indicated to reverse hypogonadism. However, if fertility is desired, it is possible with the use of human chorionic gonadotropin (hCG) or recombinant LH to raise testosterone as well as human menopausal gonadotropin (hMG) or recombinant FSH to induce spermatogenesis. In patients with hypothalamic disorders resulting in hypogonadotropic hypogonadism, fertility can be induced with either administration of GnRH or the use of gonadotropins. The one caveat in this situation is the possibility of GnRH receptor defect as the etiology, thereby precluding effective treatment with the use of GnRH.

Although the treatment is controversial, older men with normal to borderline elevated levels of gonadotropin and normal to low-normal levels of testosterone, but with suggestive symptoms of hypogonadism, have been administered testosterone. Use of testosterone in this situation has not proved to be beneficial to sexual function, prevention of osteoporosis, or prevention of muscle loss. Although some features of male aging resemble the signs and symptoms of young hypogonadal men, the significance of the partial and gradual declines of testosterone levels in older men remains unclear from observational studies. Without guidance from more rigorous clinical trials, potential benefits of androgen administration must be weighed against potential adverse effects.

Although not strictly in the realm of androgen replacement, androgens are also used to treat adolescents with constitutional delay of puberty, to treat infants with micropenis, and as a preventive agent in cases of hereditary angioedema (C1 esterase inhibitor deficiency).

TREATMENT EFFECTS

The goals of androgen replacement therapy are alleviation of symptoms and maintenance of secondary sexual characteristics, sexual function, libido, muscle strength, and mass. Changes and improvement in sexual function and libido often begin within days to weeks of initiating therapy, whereas appearance changes evolve over a period of several months to years. Treating frank hypogonadism with androgens generally has significant effects, whereas treatment of the androgen decline of the aging male has effects that are more modest. As mentioned earlier, several studies have noted an increased sense of well-being, only modest changes in muscle mass and lean body mass, and no improvement in strength.

Hypogonadism is a significant risk factor for osteoporosis in men, and androgen replacement can arrest further bone loss and restore bone density. However, it must be pointed out that androgen replacement in osteoporosis is worthwhile only after other secondary causes of bone loss have been ruled out. In addition to probable direct effects, androgen is converted to estradiol, which also acts to decrease bone resorption and increase bone density.

There is evidence that lipid metabolism may be affected by androgens. Men generally have lower high-density lipoprotein (HDL) cholesterol, higher triglycerides, and higher low-density lipoprotein (LDL) cholesterol than do premenopausal women. It is also noted that during adolescence, HDL cholesterol levels decrease with concomitant increases in triglyceride and LDL cholesterol in males. Abuse of exogenous androgens by young men can likewise result in decreased HDL cholesterol levels. On the other hand, this is not necessarily seen with hormone replacement therapy. Reasons for this include the supraphysiological doses of androgens used by abusers and the use of androgens not aromatizable to estrogen. Studies of nonaromatizable androgens in normal men have shown that HDL cholesterol and apolipoprotein A-I levels decreased, whereas LDL cholesterol levels increased. However, the effect of testosterone on lipid profiles is not clearly understood. Most clinical trials of intramuscular testosterone therapy in older men show little, if any, effect on HDL cholesterol. Conversely, numerous cross-sectional studies report a positive association between exogenous testosterone and HDL cholesterol.

There may be other potential effects of androgens based on smaller studies. A tendency toward

decreased arterial pressure and improved insulin sensitivity has been reported. A decrease in abdominal fat, an increase in lipolysis, inhibition of lipoprotein lipase, and mobilization of triglycerides have also been reported in association with androgen administration. Future investigations might help to further define the physiology of testosterone's precise role in lipids and cardiovascular disease.

Although not commonly used in this manner today, androgens can be beneficial for various forms of anemia. In the kidney, androgens stimulate erythropoietin production, whereas synthesis of clotting factors is increased in the liver. Availability of commercially produced erythropoietin makes androgen use for the treatment of anemia rare. Patients with hypogonadism can often see increases in hematocrit with androgen therapy.

PRECAUTIONS

For individuals over 45 years of age, prostate-specific antigen and digital rectal exam are recommended. Untreated hypogonadal men generally have smaller prostates than do age-matched eugonadal men. With androgen replacement, prostate size can be expected to increase to match their eugonadal counterparts. However, caution should be exercised when considering treatment in men with known benign prostatic hyperplasia. Men with symptoms of urinary obstruction should not be treated with androgen given that benign prostatic hyperplasia can be hastened with the use of this therapy. Prostatic carcinoma is an absolute contraindication to the use of androgen replacement.

Several other precautions must be noted due to the effects of testosterone on various tissues. In older men, testosterone can have a profound effect on hematocrit and can cause polycythemia in as many as 25% of patients under treatment, often resulting in termination of therapy. Sleep apnea can also be precipitated or worsened. Fluid retention, gynecomastia, and cardiovascular disease have been noted to some degree, especially with higher doses and with nonaromatizable androgens. Although it is commonly believed that androgen administration may lead to behavioral disturbances, this has not been borne out in studies, especially when maintaining eugonadal levels of testosterone. Aggressive behavior can be monitored with patient self-reports with the aid of spouses or partners. In summary, evaluation prior to treatment should include a history for potential sleep apnea, prostate-related disorders, behavioral disturbances, and measurement of hematocrit.

ANDROGEN PREPARATIONS

Multiple forms of testosterone therapy for male hormone replacement have been produced through biochemical modification due to the bioavailability characteristics of naturally occurring testosterone. When administered by mouth, testosterone is promptly degraded by the liver once it enters the portal circulation, and relatively little reaches the systemic circulation. Parenterally, testosterone is both absorbed and degraded rapidly, making it unfavorable for treatment. As a consequence, a variety of chemical modifications have resulted in the currently available forms of androgen replacement (Table II). Most of

Table II Androgen Preparations

| Form | Agent | Usual dose |
|---------------|--|--|
| Oral | Fluoxymesterone | 5–20 mg daily |
| | Methyltestosterone | 10–50 mg daily |
| | Testosterone undecanoate | 80–160 mg daily |
| Intramuscular | Testosterone propionate | 25–50 mg three times per week |
| | Testosterone cypionate | 200 mg every 10–14 days |
| | Testosterone enanthate | 200 mg every 10–14 days |
| | Human chorionic gonadotropin (can also be given subcutaneously) | 2500–5000 IU two or three times per week |
| | Human menopausal gonadotropin | 75–100 IU three times per week |
| Transdermal | Testosterone patch | 1 patch (4 or 6 mg) daily |
| | Testosterone gel | 5–10 g daily |
| | Dihydrotestosterone gel | 5–10 g daily |
| Miscellaneous | GnRH pump | 5–20 µg every 120 min |

Figure 1 Testosterone.

the modifications involve esterification of the 17β -hydroxyl group; alkylation of the 17β -position; alteration of the ring structure at the 1, 2, 9, or 11 carbons; or a combination of these changes (Fig. 1).

Esterification of the 17β -hydroxyl group allows formation of fat-soluble compounds prepared as injectable testosterone esters. Commonly available preparations include testosterone propionate, testosterone cypionate, and testosterone enanthate. The main difference among these compounds is the length of the carbon chain in the ester. Longer chain modifications make the compounds more fat soluble, prolonging the action of the ester through slow release. Testosterone propionate has the shortest half-life and requires administration every 2 to 3 days. Testosterone cypionate and enanthate have a longer half-life, are used more often, and have a dosing frequency of 7 to 21 days. In hypogonadal men 20 to 40 years of age, 200 mg of testosterone cypionate or enanthate leads to supraphysiological levels of total testosterone at 1 to 5 days, with subnormal levels typically by 14 days. Anecdotally, this is supported by patients who feel a pronounced effect of therapy during the first week after testosterone injection and who feel occasional diminished libido during the last few days before an injection. Testosterone ester injections are relatively low in cost and are known to be safe and effective through years of clinical experience. However, this form of therapy also entails the need for regular intramuscular injections, a non-physiological pattern of testosterone levels over the dosing interval, and potentially wide variations in mood and libido over the dosing interval.

The testosterone patch and testosterone gel are two forms of the more recent transdermal testosterone delivery systems. Testosterone patches are applied to either scrotal or non-scrotal skin. Patches are applied daily to clean intact skin without hair and provide physiological testosterone levels. However,

application to scrotal skin results in higher levels of DHT, owing to the higher levels of 5α -reductase enzyme in the scrotum, and the long-term effects on the prostate are not known. Difficulties encountered with the testosterone patch include local skin reactions, cosmetic unacceptability, and relatively high cost, all leading to discontinuation in 30 to 50% of men who try the patch.

Testosterone gel has become particularly popular since its introduction. Packaged as a once-daily application, it consists of a hydroalcoholic gel that dries quickly when applied to the skin surface. Absorption occurs quickly, and increased serum testosterone levels can be seen within 30 min of application. Similarly to the testosterone patch, steady physiological levels are achieved. However, testosterone gel is potentially transferable via prolonged skin contact. Clinical studies have shown that as little as 15 min of skin contact within up to 12 h of application can result in dermal transfer. Thus, patients must be warned to apply the gel to clean intact skin that is not easily in contact with others. Although most men on transdermal testosterone achieve eugonadal levels of testosterone, the peak level achieved is significantly less than that achieved with intramuscular injections. Consequently, there are occasional patients who favor the intramuscular administration if they are accustomed to the effects of a supraphysiological dose that is often felt during the first week after an injection. Local skin reactions can occur, although not as commonly as with the testosterone patch.

Although not currently available in the United States, testosterone undecanoate is an orally active ester that is absorbed via intestinal lymphatics. Shortcomings of this preparation include short duration of action, the need to administer three times per day, and variable absorption, with consequent variations in levels of measured testosterone within the same patient and among different patients.

Other oral preparations for male hypogonadism include fluoxymesterone and methyltestosterone. Formed from 17α substitution, these agents should be avoided in the treatment of hypogonadism. They are known to cause cholestatic jaundice, abnormal liver function tests, and (rarely) tumors of the liver and peliosis hepatitis.

In addition to testosterone, its metabolites (e.g., DHT) have been developed for use in hypogonadal men. DHT is a selective androgen produced from testosterone by the 5α -reductase enzymes 1 and 2 that is not aromatized to estrogen. In Europe, DHT is marketed as a 2.5% hydroalcoholic gel that is applied transdermally. Because DHT is the major androgen

within the prostate, there is very little role for its use in men as hormonal replacement therapy.

For patients desiring fertility who have hypothalamic or pituitary lesions or any congenital or acquired defect involving GnRH, spermatogenesis can be achieved and maintained assuming that the gonads are capable of functioning. This requires treatment with LH and FSH to drive Leydig cell function and Sertoli cell function, respectively. Conventional therapy includes the use of hCG for its LH activity, followed by the use of hMG, a purified extraction from the urine of postmenopausal women providing FSH activity. Therapy is applied in two phases. The induction phase begins with hCG alone at doses of 2500 to 5000 IU two or three times per week, either subcutaneously or intramuscularly, for a period of 4 to 6 months. The dose may need titration, with a goal of testosterone in the normal range. Once this phase has been completed successfully, hMG (75–150 IU) is administered three times per week intramuscularly. hCG doses need to be monitored and adjusted further at this point because dose reductions are often necessary. Treatment should be carried out for at least 4 months, owing to the lengthy cycle of spermatogenesis. Potential complications that require consideration during therapy include local skin reactions, hypersensitivity and anaphylactic reactions, and thromboembolism.

Pulsatile GnRH therapy is also available to those with hypothalamic dysfunction resulting in hypogonadotropic hypogonadism. Treatment requires a portable pump attached to the skin via a subcutaneous butterfly needle. Doses range from 5 to 20 μg every 120 min. Efficacy is noted by induction of sperm in the ejaculate and an increase in testicular size.

MONITORING

So long as patients can be monitored for potential adverse effects, therapy should be lifelong. As with any treatment, goals, benefits, and risks must be reassessed continually. In general, the continuing assessment of androgen replacement therapy relies on the clinical response. In addition, levels of testosterone can be obtained with initiation of treatment and the timing of testing based on the anticipated peak or trough, depending upon the androgen preparation. Digital rectal exam and prostate-specific antigen should be checked at initiation of treatment and at frequent intervals thereafter. Hematocrit, lipid profile, and liver function tests (if indicated) should also be

examined prior to therapy, after 1 to 2 months, and at yearly intervals thereafter.

CONCLUSION

Hormone replacement therapy for the hypogonadal man is fairly straightforward. Once an etiology is ascertained, treatment with testosterone for those who are clearly hypogonadal has proven benefits regarding libido, sexual function, muscle mass and body habitus, and (for those with osteoporosis) bone mass. There are also a number of preparations available, with promising results shown in the newer transdermal gel preparations so far as ease of use and physiological effects are concerned. However, what is unclear is the effect of hormone replacement therapy in those with low-normal testosterone levels or the so-called partial androgen deficiency of aging males. The signs and symptoms of aging often seem similar to those of hypogonadal young men. Unfortunately, although testosterone and its metabolites can be measured, there is no clinically useful measure of the biological activity of androgens. Data on aging males reveal only modest, if any, positive effects. However, caution must be exercised when considering androgen replacement therapy for the aging male. Experience with hormone replacement therapy in postmenopausal women has shown that data from initial small series can be misleading or, at the very least, do not provide sufficient information until larger trials are performed. This was borne out recently by the data from the Women's Health Initiative Study. It is hoped that the future will offer the promise of further study in the matter of hormone replacement in the aging male and will delineate more clearly the risks and benefits of androgen supplementation.

Table I Transdermal Hormone Patches

| Name | Active hormone | Doses available |
|-------------|---|---|
| Alora | Estradiol 17- β | .05, .075, and 1 mg/day |
| Climara | Estradiol 17- β | .025, .05, .075, and .1 mg/day |
| Vivelle | Estradiol 17- β | .0375, .05, .075, and .1 mg/day |
| Vivelle-Dot | Estradiol 17- β | .0375, .05, .075, and .1 mg/day |
| CombiPatch | Estradiol 17- β ; norethindrone acetate | 50 μ g/140 μ g and 50 μ g/250 μ g |

(e.g., Alora, Climara, Vivelle, Esclim), and each allows for delivery of varying doses of estradiol (0.025–0.1 mg/day) (Table I). Twice-weekly application of most of these patches is recommended due to the pharmacokinetics of these preparations. A gel containing estradiol is in development for marketing in the United States.

Estrogens can also be prescribed for transvaginal absorption with the indication of vaginal atrophy. Creams containing estradiol (e.g., Estrace cream) and conjugated equine estrogens (e.g., Premarin cream) are designed for application into the vagina. Estrogen-containing rings (e.g., Estring) and estradiol vaginal tablets (e.g., Vagifem) have also been developed for treatment of vaginal atrophy.

TRANSDERMAL PROGESTIN THERAPY

There is no approved product for transdermal administration of progestin only. Progesterone-containing creams are marketed, but they have not been documented to prevent the increased risk of endometrial cancer that may result from unopposed estrogen treatment. Although the preparation of vaginal progesterone (e.g., Crinone) has not been traditionally used for hormone replacement, it remains a viable option that is under study for prevention of endometrial hyperplasia associated with estrogen replacement. The vehicle in this vaginal gel is an emulsion of water, oil, and polycarbophil polymer. This preparation has been known to cause some vaginal irritation in patients who use this product. However, vaginal administration of progestins may allow for an alternative treatment for those women who do not tolerate oral progestins.

COMBINED THERAPIES ADMINISTERED TRANSDERMALLY

A patch that delivers both estradiol and a progestin is convenient for women with uteri; unopposed estrogen is not desirable in these women. One system (CombiPatch) delivers estradiol and a progestin, norethindrone (Table I). This patch is available in two

different dosing combinations. The hormones are contained within a matrix system similar to that of the newer estrogen patches. Twice-weekly application is required.

TRANSDERMAL TESTOSTERONE THERAPY

Transdermal preparations for testosterone replacement have been marketed for men who experience hypogonadism. A transdermal testosterone patch that delivers lower and more physiological androgen levels for women is in development.

Testosterone has been thought to enhance libido and the sense of well-being, but the adverse effects of oral testosterone on circulating lipids has led to concerns about its use in women. Transdermal therapy may be optimal because it will alleviate a first-pass androgen effect on the liver; moreover, in one study, it led to no significant changes in circulating lipoprotein levels.

If studies support a benefit for testosterone replacement in women, it will be important to determine which groups of women will benefit from this therapy. It will also be essential to better delineate the risks of androgen replacement in women.

CONCLUSIONS

Transdermal hormone replacement offers another avenue for hormone replacement for postmenopausal women and their physicians. The available preparations are outlined in Table I. This route of administration avoids a first-pass liver effect. In addition, new preparations that allow for the administration of a progestin along with the estrogen therapy are now available. Advances in this area of hormone replacement are likely to be greatly beneficial to this growing population.

Table 1 The Clinical Continuum of a Hot Flash

| Symptom/Sign | Description |
|----------------------|--|
| Core temperature | A small (0.03°C) temperature elevation preceding the hot flash; temperature then drops (0.1–0.7°C) several minutes after the hot flash starts; felt as a chill |
| Sensation | Sudden feeling of intense heat sometimes accompanied by anxiety and feeling of suffocation |
| Heart rate | Increases by 5–35 beats per minute; sense of palpitations |
| Cutaneous blood flow | Increases due to vasodilatation; observed as flushing |
| Sweating | Rapid onset and profuse over head, face, and chest |
| Sleep disturbances | Night sweats |

menopausal, whether naturally or as a result of interventions such as ovariectomy, chemotherapy, and radiation or following administration of gonadotropin-releasing hormone (GnRH) agonists and antagonists. Rarely, premenopausal women report experiencing hot flushes during the postpartum period. Hot flushes have also been reported by men on abrupt decline of androgens such as occurs following orchiectomy or treatment with GnRH agonists and antagonists.

Most epidemiological studies in North America and Europe have found that the majority of women had at least some hot flashes with the onset of menopause. The incidence of hot flashes is highest during the first postmenopausal years, ranging from 58 to 93%. The incidence of hot flashes in perimenopausal women ranges from 28 to 65%. Surgically induced menopause is characterized by a somewhat higher prevalence of hot flashes as compared with natural menopause. Hot flashes typically last from 6 months to 5 years after natural menopause, with an average duration of 2 years. There is a direct correlation between severity of symptoms and duration of symptoms; thus, moderate to severe vasomotor flashes tend to persist for a longer time.

There is a large cross-cultural variability in the reported prevalence of vasomotor symptoms among menopausal women. Hot flashes are reported to be much less common among Mayan women in Mexico, Indonesian women (10–20%), and Chinese women (10–25%). The reasons for the differences of prevalence between Eastern and Western countries might be attributed to different cultural perspectives of the events or to a phytoestrogens-rich diet.

No significant association has been found between the occurrence of hot flashes and sociodemographic variables such as employment status, social class, income rate, and marital status or between the occurrence of hot flashes and gynecological factors such as age of menarche and number of pregnancies. However, mean body weight seems to relate to hot

flashes, as asymptomatic women usually have higher mean body weight and higher blood level of total circulating estrogens than do women with hot flashes.

PHYSIOLOGY OF HOT FLASHES

The underlying physiological mechanisms of the hot flash are not completely understood. Estrogen withdrawal at menopause is clearly the precipitating factor for hot flashes, but the relationship that might exist between estrogen and hot flashes is still illusive. Postmenopausal women suffering from severe vasomotor symptoms were found to have lower levels of circulating estrogens, and a smaller fraction of free estradiol (unbound to sex hormone-binding globulin), as compared with asymptomatic women. However, the presence of low blood estrogen level does not always lead to hot flashes. Other hypoestrogenic states, such as prepuberty, anorexia nervosa, and gonadal dysgenesis, are not characterized by hot flashes. It seems that the rapid decline in blood estrogen level is responsible for the occurrence of vasomotor symptoms. The onset of hot flashes after oophorectomy or after GnRH analogue administration supports this contention. So does the observation that although estrogen therapy usually improves hot flashes, they often return when estrogen therapy is discontinued. The influence of estrogen on temperature regulation is still not fully understood; however, it was demonstrated that estrogen can modulate the firing rate of thermosensitive neurons in the preoptic area of the hypothalamus in response to thermal stimulation in the rat. The responsiveness of vascular smooth muscle to catecholamines is modulated by estrogen, and it has been shown to be greater in women with hot flashes. Estrogen appears to enhance α_2 -adrenergic activity, so estrogen withdrawal may result in reduced α_2 -adrenergic activity and increased vasomotor function. Thus, estrogen may play both peripheral and central roles in the physiology of hot flashes. It was once believed that hot flashes were triggered by a sudden

downward resetting of the hypothalamic set point because there was no evidence of increased core body temperature. Recently, however, a central noradrenergic mechanism was asserted to be responsible for small core body temperature elevations that precede menopausal hot flashes. The thermoneutral zone within which sweating, peripheral vasodilatation, and shivering do not occur was virtually nonexistent in women with hot flashes. It was suggested that a small increase in core body temperature, acting within a narrowed thermoneutral zone, triggers a hot flash.

DIFFERENTIAL DIAGNOSIS OF HOT FLASHES

Most perimenopausal women presenting with hot flashes do not require further investigation. Menstrual cycle irregularity usually corresponds with fluctuating hot flashes, but regular menses should not defer the diagnosis. In a few cases where the diagnosis of menopause is unclear, measurements of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) may be of value. The levels of the gonadotropic hormones tend to fluctuate, especially in the premenopause; thus, repeated measurements may be needed. Conditions such as hyperthyroidism, panic attacks, carcinoid syndrome, pheochromocytoma, and niacin flush may mimic menopausal hot flashes and should be considered in the differential diagnosis of hot flashes that do not resolve following estrogen therapy.

SEX STEROID THERAPY

The available therapies do not “cure” hot flashes; rather, they provide symptomatic relief. Sometimes, the hot flashes are totally eliminated, at least for the duration of the treatment; other times, they are significantly relieved and enable women to maintain an acceptable quality of life.

Comparison of various therapies for hot flashes with placebo demonstrates considerable effectiveness of the latter; therefore, all data regarding effectiveness of various drug regimens for hot flashes should originate from randomized, double-blind, placebo-controlled crossover studies.

Hormonal replacement therapy (HRT) is by far the most effective therapy for treating estrogen-deficient hot flashes. For women who have absolute contraindications to HRT, hot flashes can be reduced with other medications and alternative approaches.

Estrogen

Estrogen treatment has been used in many forms, including crude extracts, for approximately 100 years. It was suggested as a treatment for hot flashes due to the co-appearance of these symptoms with declining blood estrogen levels and not due to understanding the physiology and pathogenesis of hot flashes. The effect of estrogens on climacteric symptoms is not always noted immediately and might be fully realized only after several weeks. Women on a cyclic estrogen regimen might experience recurrence of hot flashes during the intervening days between two cycles of therapy. Sometimes, the hot flashes recur following complete discontinuation of the treatment, and it is not known whether the treatment only postpones the climacteric symptoms or whether the women would have had the hot flashes for that duration regardless of the treatment. However, the effect on hot flashes may persist for several weeks after discontinuation of therapy because some estrogen formulations, such as conjugated equine estrogen, are stored in fatty tissue that serves as a reservoir for the drug.

The “traditional” estrogen therapy for relief of hot flashes, which remains the most commonly used one in the United States, is oral conjugated equine estrogen (CEE) in doses ranging from 0.375 to 1.25 mg. Other oral preparations are available, including 1 to 2 mg of 17- β estradiol. Transdermal preparations are also available and liberate 25 to 200 μ g/day of estradiol. Estrogen is also available as subcutaneous implants, injectables, and vaginal creams; most are effective at relieving climacteric symptoms. We

recently examined the efficacy of a vaginal ring delivering estradiol and progesterone in relieving climacteric symptoms and found that this modality is indeed effective in relieving hot flashes and might serve as a promising method for long-term HRT.

However, the most studied therapeutic regimen for hot flashes is the oral route, and it has been shown repeatedly that oral estrogen relieves approximately 90% of hot flashes within 3 months as compared with approximately 60% relief achieved with placebo (Fig. 1). Furthermore, estrogens were also efficient in relieving other climacteric symptoms such as vaginal dryness, sleep disturbances, anxiety and irritability, and memory loss. The first studies used doses as high as 1.25 mg of CEE (not commonly used today), whereas more recent studies demonstrated effectiveness in relieving hot flashes using doses as low as 0.375 mg of CEE or other estrogens in equivalent doses (Fig. 2). Long-term HRT is associated with adverse side effects such as breast tenderness and irregular vaginal bleeding, which are often given as reasons for discontinuation of therapy. To overcome this obstacle, a tendency toward lowering the dose used has been studied and encouraged recently. The hypothesis behind this attitude is based on the intuitive feeling that lowering the dose of HRT would be associated with reduced risk. There are indications from oral contraceptive experience that lowering the dose significantly decreased severe side effects, such as

thromboembolic phenomena and arterial occlusion events, without interfering with contraceptive effectiveness. For the time being, healthy, nonobese, postmenopausal women experiencing severe vasomotor symptoms should be treated with the lowest dose of estrogen shown to be effective.

Another route for delivering estrogens to relieve hot flashes is the transdermal approach. Avoiding the first pass in the liver is associated with significantly less effect on the angiotensin–renin system as well as with significantly less induction of triglyceride production. Thus, the transdermal approach may be the “route of choice” for hypertensive women, for those with hypertriglyceridemia, or for patients at increased risk for thromboembolism. Transdermal estrogen patches that provide continuous delivery of estrogens have been shown to be effective at relieving hot flashes in a dose–response manner. Transdermal patches delivering 25 to 200 $\mu\text{g}/\text{day}$ of estrogens were studied in regard to relieving hot flashes. All doses of estradiol reduced hot flashes; however, the highest dose (200 $\mu\text{g}/\text{day}$) was found to be the most efficient and resulted in 91% reduction in the number of hot flashes. The objectively monitored reduction in hot flashes has been reported to be higher than the subjectively reported reduction (85 vs 74%), and this is explained by the fact that estrogens relieve mainly hot flashes and, to a lesser degree, other climacteric symptoms that have a significant adverse effect on women’s well-being.

Progesterone

The combination of estrogen and progesterone is recognized as necessary treatment for postmenopausal women with intact uteri. The addition of progestin is aimed at providing protection against endometrial hyperplasia and adenocarcinoma. The inclusion of progesterone often raises concerns as to whether the beneficial effect of estrogen will be compromised. However, in regard to symptoms reduction, it has been suggested that progestin not only will not interfere with the estrogenic effect but might have independent benefits (Fig. 3). Several double-blind, placebo-controlled studies have shown that medroxyprogesterone (MPA), a C-21 nonestrogenic steroid, decreased the frequency of hot flashes. It has been shown that 150 mg/month of MPA injected intramuscularly reduced climacteric symptoms. A rate of 75% reduction effect was achieved with a 50 mg dose, rising to 90% following 150 mg of MPA by week 4 of treatment. Another study demonstrated a 74% decline in the number of hot flashes following 20 mg/day of MPA taken orally by the third month of treatment, as compared with a 26% reduction achieved with placebo. The same effect was achieved by megestrol acetate (MA), a synthetic derivation of natural progesterone, taken orally at a dose of 20 mg twice daily for 4 weeks. Norethindrone was also shown to significantly reduce hot flashes in a double-blind, crossover design study.

Androgens

Cotreatment of androgens with estrogen is specifically intended to increase low libido. The use of this combination therapy may also be an option for patients whose vasomotor symptoms are not adequately controlled with estrogen monotherapy. The additive effect of methyltestosterone in estrogen replacement therapy was demonstrated in a double-blind placebo-controlled trial. The lower dose of estrified estrogens plus methyltestosterone provided greater relief of menopausal symptoms than did corresponding estrified estrogens, and the extent of relief was similar to that observed with a higher dose of estrified estrogens alone.

CONCLUSIONS

Hot flashes are commonly experienced during menopause. For many women, vasomotor symptoms are severe enough to significantly compromise the overall quality of life and the general sense of well-being. Standard HRT is effective and results in alleviation of symptoms within days to a few weeks. Lower doses of estrogen treatment have also been shown to be

Figure 3 Rates of occurrence (means \pm SEs) of hot flashes in the study groups and premenopausal women (Premeno) before and during transdermal estradiol administration. Reproduced by permission from The Endocrine Society (Steingold, K. A., Laufer, Y., Chetkowski, R. J., et al. (1985). Treatment of hot flashes with transdermal estradiol administration. *J. Clin. Endocrinol. Metab.* **61**, 630).

effective. Progesterone probably has an independent effect on alleviation of hot flashes. For some women, an estrogen–androgen combination therapy might provide sustained relief. Only modest and delayed improvement of symptoms could be expected by alternative nonhormonal preparations.

Table 1 Methods for the Identification of Endocrine Controls of Eating

If a particular control of eating ("the effect"; for example, meal initiation or satiation) is under the control of a hormone, then:

- Intravenous infusion of the hormone, or agonists or secretagogues for it, should produce the effect (for example, for satiation, perception of fullness and a reduction in meal size). Furthermore, infusion of doses that produce levels of the hormone that occur in the blood when the effect normally occurs (for example, for a satiation effect, at meal end) should be sufficient.
- Intravenous infusion of a selective and potent antagonist to the hormone at the time the effect normally occurs should reverse the effect (for example, if the hormone produces satiation, administration of the antagonist during the meal should increase meal size).
- Local infusion of the hormone and of its antagonist at the site of the hormone's action should produce the effect and reverse it, respectively.
- Removal of the hormone or of the receptors mediating the effect should prevent the effect (for example, for a satiation effect, increase meal size). Classically, this is done by removal of the gland producing the hormone; it is now possible to engineer transgenic animals lacking the gene for the hormone or its receptor.
- When the hormone but not its receptor, has been removed, replacement of the hormone in physiological patterns should normalize the effect.

whether the organism gains or loses stored energy. In the adult, this translates into increases or decreases in body adiposity. This loop is closed by negative feedback signals related to body adiposity that affect eating behavior. Again, endocrine signals are the best understood of such feedback signals (see Fig. 1).

Finally, eating is also subject to influences, such as stress and reproduction, that are independent of feedback signals from ingested food. Endocrine signals are also important mediators of these influences.

SATIATION

Cholecystokinin

The gut peptide hormone cholecystokinin (CCK) is synthesized by endocrine cells dispersed along the small intestine and is released by preabsorptive food stimuli. CCK, which was discovered and named by the pioneering gut endocrinologist Andrew Ivy in 1928, has long been accepted as the major physiological control of gall bladder contraction and enzyme secretion from the exocrine pancreas. It now appears that CCK is also responsible for a substantial fraction of the satiating effect of ingested food.

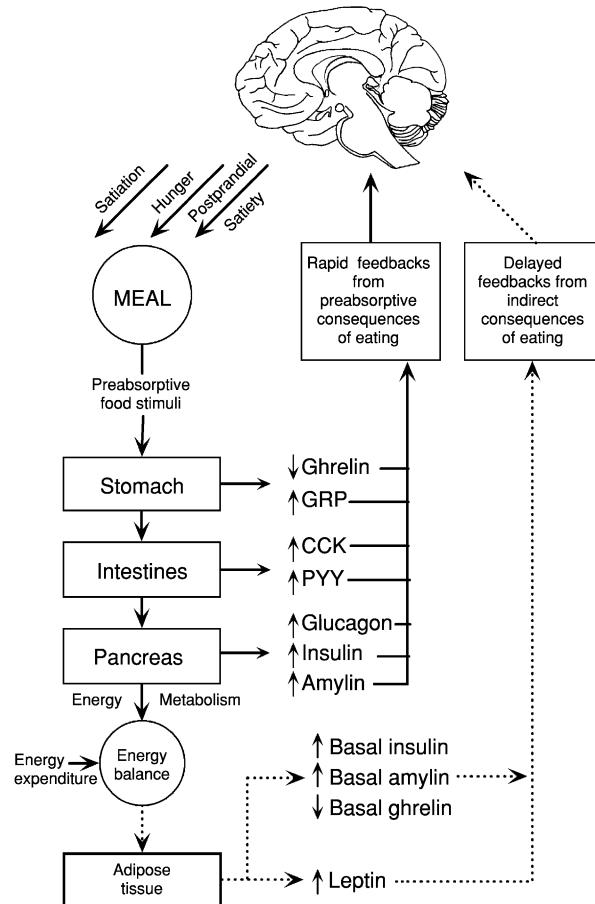

Figure 1 Schematic overview of endocrine feedback signals controlling eating. The diagram begins with eating (i.e., a meal) under way (upper left). The best-understood endocrine controls of eating are CCK, GRP, glucagon, and amylin, which are released from the gut during the meal by preabsorptive actions of ingested food signals and provide immediate direct negative feedbacks to the brain that contribute to meal termination (i.e., produce satiation) (arrows in solid lines). Absorbed nutrients affect energy balance and body adiposity, and several hormones are secreted in proportion to body adiposity. These contribute delayed negative feedbacks inhibiting eating, again apparently mainly by acting on brain processes of satiation (arrows in dashed lines). Some endocrine signals, such as ghrelin, PYY, and basal amylin, may affect hunger or postprandial satiety, but these contributions are not yet well understood.

Exogenous CCK and Satiation

In 1973, Gerard Smith, James Gibbs, and their colleagues at Cornell University Medical College in New York began publication of a series of classic studies that both advanced the operational sophistication of the study of eating and identified CCK as a putative endocrine control of satiation. CCK is one of a number of gut hormones that is released during meals. These investigators intraperitoneally injected a CCK-rich porcine gut extract that had been prepared by Viktor Mutt of the Karolinska Institute

in Stockholm, Sweden. The injections elicited a dose-related decrease of liquid food intake in food-deprived rats, but the injections did not decrease water intake in water-deprived rats and did not elicit a conditioned taste aversion. Synthetic CCK-8, the carboxyl-terminal octapeptide of CCK, produced a similar behaviorally selective inhibition of eating. Neither desulfated CCK-8 nor gastrin, which is structurally similar to CCK, affected eating, in agreement with the structure-activity profiles of CCK's visceral effects. Finally, the investigators modified Pavlov's classical sham feeding paradigm to demonstrate that food-deprived rats with open gastric cannulas sham feed essentially indefinitely and that CCK is sufficient to elicit satiation in these animals (Fig. 2). Note that the sham feeding results can be considered analogous to the traditional gland removal technique because the ingested food does not reach the small

intestine to stimulate CCK release. Taken together, these data indicated that exogenous CCK could selectively elicit satiation. This has been confirmed in numerous animal species and in normal-weight and obese humans. In humans, intravenous infusions mimicking normal prandial increases are sufficient.

Endogenous CCK and Satiation

The development of potent and selective CCK receptor antagonists during the 1980s made it possible to test whether endogenous CCK is normally part of the mechanisms by which food ingestion terminates meals. It is. In both animals and humans, premeal treatment with antagonists of the CCK-1 receptor (formerly called the CCK-A receptor) blocks the satiating action of exogenous CCK and, when injected alone, increases meal size. For example, intravenous

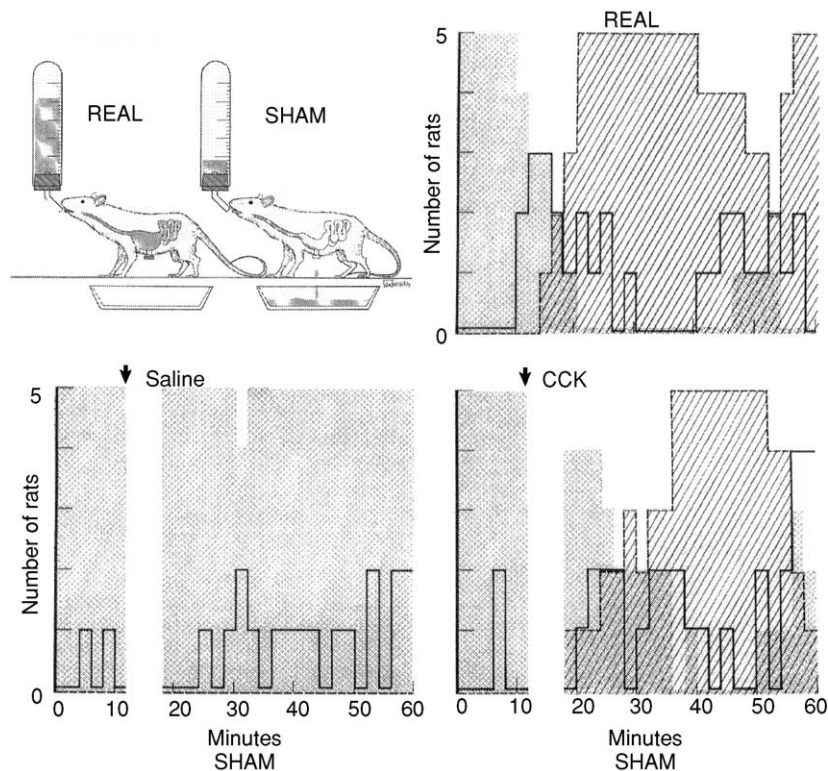

Figure 2 CCK eliciting the behavioral sequence of satiation in sham-feeding rats. Meals of liquid diet were observed in 5 rats with surgically implanted gastric cannulas. The rats either “real” fed, with the cannulas closed, or “sham” fed, with the cannulas open so that the food drained without accumulating in the stomach or entering the intestines. Data are the numbers of rats during successive 2-min blocks that were feeding (gray bars), locomoting or grooming (solid lines), or resting (diagonally lined bars). In the real condition, rats fed for 10 to 20 min, locomoted and groomed for a few minutes, and finally rested. This is the behavioral sequence of satiation. In the sham condition, either saline or CCK was injected (arrows; observations were interrupted for 6 min following injections). Saline-injected sham-feeding rats did not satiate but fed almost continuously during the 60-min test. CCK-injected rats stopped feeding, groomed and locomoted, and rested just as did real-feeding rats. Modified with permission from Antin, J., Gibbs, J., Holt, J., Young, R. C., and Smith, G. P. (1975). Cholecystokinin elicits the complete behavioral sequence of satiety in rats. *J. Comp. Physiol. Psychol.* 89, 784-790.

infusion of a CCK-1 receptor antagonist that was begun just before volunteers began a lunch buffet consisting of a wide variety of appetizing foods significantly increased meal size (expressed as total energy content of the various foods) without affecting the volunteers' enjoyment of their meals or their subjective sense of normal satiation. These data establish CCK as a part of the normal physiological process of satiation in humans as well as in animals.

Mechanism of CCK Satiation

Local infusion experiments reveal that the receptors initiating CCK's satiating action are located in the proximal small intestine. Their activation increases neural activity in the vagal afferent terminals at this site. This neural message is relayed to the nucleus tractus solitarius (NTS) in the caudal brainstem. From the NTS, it is relayed into local brainstem neural networks and into widespread forebrain neural networks. The CCK-1 receptor has both low- and high-affinity states; receptors in the low-affinity state mediate CCK's satiating action. Interestingly, in rats, intraperitoneal injections of CCK are more satiating than intravenous infusions of CCK, indicating that CCK's satiating action in the rat is via a paracrine mode of action rather than an endocrine one. CCK probably has an endocrine mode of action in humans and monkeys given that plasma CCK does increase during meals and intravenous infusions within the range of postprandial increases are effective. Another species difference is that CCK's actions on exocrine pancreas function are mediated by CCK-1 receptors in rats but are mediated by CCK-2 receptors in humans. This may facilitate development of a CCK agonist for therapeutic use in overeating.

Disorders of CCK Satiation

Spontaneous mutations have been identified in the CCK-1 receptor. Rats without CCK-1 receptors overeat at every meal, gain weight, and become diabetic (Fig. 3). Humans without CCK-1 receptors apparently do the same. This syndrome indicates not only that CCK is an important part of the natural process of satiation but also that the physiological system controlling food intake, however complicated, is not completely redundant. Rather, the lack of a single basic control of meal size can produce uncompensated hyperphagia and obesity.

Disorders in CCK satiation occur in eating disorders. Patients with bulimia nervosa display reduced prandial CCK secretion and reduced subjective experience of satiation during meals. Although these

abnormalities improve together with improvement in binge eating, it is possible that they both facilitate the onset of the disorder and retard recovery from it.

Other Gut Peptides in Satiation and Postprandial Satiety

CCK research has been paradigmatic for analyzing the effects of several other peptides that are released by the action of food in the gut and, at least under some circumstances, may control eating.

Pancreatic Glucagon

Glucagon is released from the pancreas during meals, apparently via a cephalic phase reflex, which is a

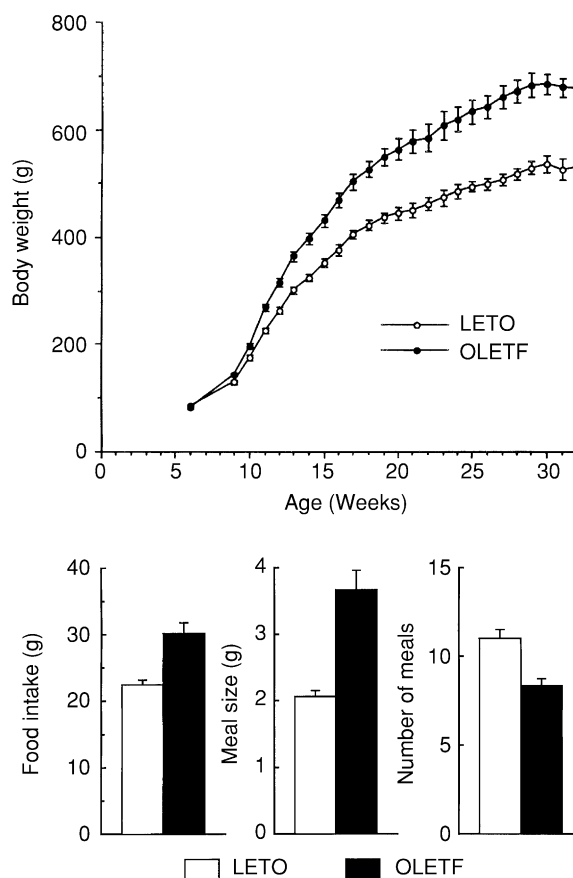

Figure 3 Null mutation of the CCK-1 receptor leading to increased meal size and obesity. Top graph shows weights of normal male rats (LETO strain) and the same rats lacking the CCK-1 receptor (OLETF). Lower graphs show daily food intakes and spontaneous meal sizes and meal frequencies (means \pm SEMs) in the same rats at approximately 30 weeks of age. Modified with permission from Moran, T. H., Katz, L. F., Plata-Salaman, C. R., and Schwartz, G. J. (1998). Disordered food intake and obesity in rats lacking cholecystokinin A receptors. *Am. J. Physiol.* 274, R618–R625.

neuroendocrine reflex whose afferent receptors are olfactory, gustatory, or other receptors in the head. Glucagon administration elicits a behaviorally specific, dose-related reduction in meal size under several conditions, including tests of spontaneous feeding in rats. Glucagon's satiating action appears to be a physiological function, at least in rats, because antagonism of endogenous glucagon by prandial administration of specific antibodies increases meal size. Infusion of glucagon during meals also produces a selective satiating effect in humans. Glucagon satiation originates in the liver because hepatic portal vein glucagon infusions are more effective than vena cava infusions. Vagal afferents transmit a neural satiation signal from the liver to the brain. Whether glucagon's potent hepatic metabolic effects are the cause of this neural signal remains unclear.

Insulin

Insulin secretion increases rapidly with eating as a result of cephalic and intestinal phase reflexes (the latter arise from excitation of intestinal receptors by preabsorptive food stimuli) and of direct substrate actions on the pancreatic beta cells. Acute insulin administration has been demonstrated to decrease meal size under some test conditions in rats, but it has been difficult to establish a reliable dose-response relationship and no satiating effect has been found in humans. Nevertheless, prandial antagonism of endogenous insulin by infusion of specific antibodies increases meal size in rats, suggesting that insulin has at least a permissive effect in normal satiation.

Amylin

Amylin, or islet amyloid polypeptide, is synthesized by the pancreatic beta cells and is sequestered and released together with insulin. Amylin fulfills the criteria for a satiation signal in rats because prandial amylin administration selectively decreases meal size, whereas prandial antagonism of endogenous amylin with receptor antagonists increases meal size. Amylin's satiating action has not been tested in humans. Amylin's satiating action appears to originate through activation of receptors in the area postrema (AP), a structure just dorsal to the NTS with a permeable blood-brain barrier.

Gastrin-Releasing Peptide

Gastrin-releasing peptide (GRP) is synthesized, stored, and secreted by enteric neurons in the stomach and intestines and acts locally via a neurocrine mode. Administration of GRP, or of GRP agonists such as bombesin, selectively reduces meal size in animals and

humans. Local administration studies suggest that the critical site of secretion and action is the stomach. Thus, GRP may mediate some of the satiating effect of the mechanical stimuli produced when ingested food fills the stomach. This peripheral action of GRP is transmitted to the brain via both vagal and spinal visceral afferents (which project indirectly to the NTS).

Peptide YY(3-36)

Peptide YY(3-36) is a gut peptide released mainly from the ileum and colon. It has recently been reported that PYY(3-36) administration produces a dose-related inhibition of eating in rodents and humans. PYY(3-36)'s relatively slow postprandial release and the long-lasting inhibition of eating produced by PYY(3-36) administration suggest that this hormone may signal postprandial satiety rather than satiation. The physiological status of this effect has not yet been proven with antagonist experiments. PYY(3-36) may act centrally in the arcuate nucleus of the hypothalamus, where it is an agonist for the NPY Y2 receptor, an inhibitory presynaptic receptor on NPY neurons that stimulate eating. Thus, it may enter the same neural network as do leptin and insulin.

HUNGER

Ghrelin, discovered in 1999, is the first candidate endocrine signal for hunger. It is the only hormone known whose infusion increases eating in animals or humans. Ghrelin is synthesized and released primarily by endocrine cells in the stomach and small intestine. Although the specific stimuli for ghrelin secretion are unknown, the pattern of plasma ghrelin levels is consistent with a hunger-inducing action. Ghrelin levels increase before meals and decrease after eating (in humans, ghrelin levels also decrease during the hours after midnight but increase again before breakfast). Food deprivation also increases ghrelin levels. It is not yet known whether infusion doses of ghrelin that mimic the premeal level are sufficient to increase eating or whether antagonism of endogenous ghrelin can decrease meal size.

ADIPOSIITY SIGNALS

Body weight, which is influenced by food intake in an important way, feeds back onto the control of meal size via several hormones. One of these, leptin, is a secretory product of the adipose tissue. Three others,

insulin, amylin, and ghrelin, are gut peptides whose secretion is linked to adipose tissue mass as well as to preabsorptive, meal-to-meal changes in the gut.

Leptin

The search for a humoral signal that linked eating and adiposity was stimulated by early analyses of several spontaneous single-gene mutations that produced dramatic phenotypes in mice, especially the obese (*ob*) and diabetes (*db*) genes (Fig. 4). Obese (*ob/ob*) and diabetic (*db/db*) mice display identical syndromes of increased meal size, hyperphagia, obesity, and diabetes. These syndromes are now known to arise from disruptions of the leptin signaling pathway. The wild-type *ob* gene, *lep*, encodes the peptide leptin that is secreted by adipose (and other) cells, and the wild-type *db* gene, *lep-r*, encodes the leptin receptor. The leptin system appears to operate as a negative-feedback control of body fat because plasma leptin levels are closely correlated with body fat mass and because leptin administration decreases meal size, presumably by increasing satiation (Fig. 5). Leptin acts in the brain to reduce meal size; there are leptin receptors in several brain loci, leptin is transported across the blood–brain barrier by a specific transport mechanism, and leptin administration directly into the cerebral ventricles, the hypothalamus, or the NTS area of the caudal brainstem inhibits eating. Furthermore, at least in the short term, central administration of leptin antagonists stimulates feeding. Leptin also appears to have other functions related to nutritional status, including reducing the neuroendocrine responses to food deprivation and regulating the onset of puberty.

Leptin's actions in the hypothalamus have received particular attention. Leptin receptors in the arcuate nucleus of the hypothalamus are on neurons that express various interneuronal signaling molecules that have been linked to the control of feeding, including NPY, α -MSH, and agouti-related peptide, and a great deal of neuroanatomical, neuropharmacological, and neurophysiological information has been amassed about the operation of the neural networks in which these neurons function. This information has not yet shown exactly how leptin reduces meal size. Leptin may do so by influencing the neural networks that determine the satiating potencies of CCK and perhaps of other gut peptides discussed previously.

A challenge for the hypothesis that leptin operates as a negative-feedback regulator of body weight is that animals and humans with apparently normal leptin systems can easily be induced to become obese, for example, by the easy availability of palatable,

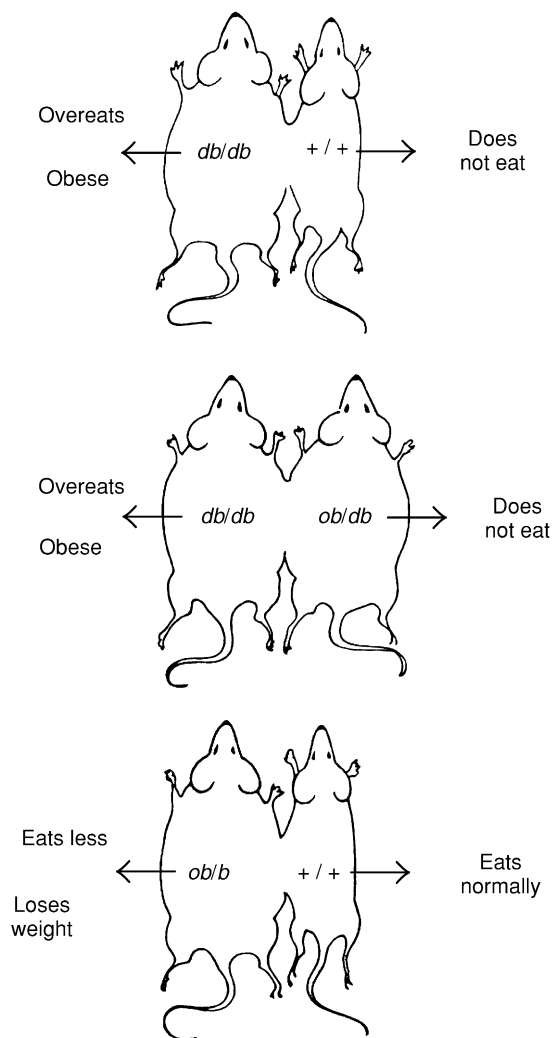

Figure 4 Effects of parabiosis of normal mice and mice with mutations of the leptin signaling system. Parabiotic mice are surgically joined so that blood contents are shared. Each mouse continues to eat independently, and parabiosis of like-genotype mice has no effect on feeding and weight gain. Hyperphagic, obese *db/db* mice continue to overeat when joined with wild type (*+/+*) mice or *ob/ob* mice, but their *+/+* and *ob/ob* partners stop eating and starve. In contrast, when *ob/ob* mice are joined with *+/+* mice, their feeding normalizes and they lose weight. These results suggest that *ob/ob* mice lack a hormone controlling eating and that *db/db* mice lack the hormone's receptor. This hormone was subsequently shown to be leptin. Modified with permission from Coleman, D. L. (1978). Obese and diabetes: Two mutant genes causing diabetes–obesity syndromes in mice. *Diabetologia* **14**, 141–148.

energy-rich foods. Furthermore, obese hyperleptinemic animals are less responsive to exogenous leptin, perhaps because leptin transport into the brain is reduced. Thus, leptin (as well as other adiposity signals controlling eating) may be a relatively ineffective

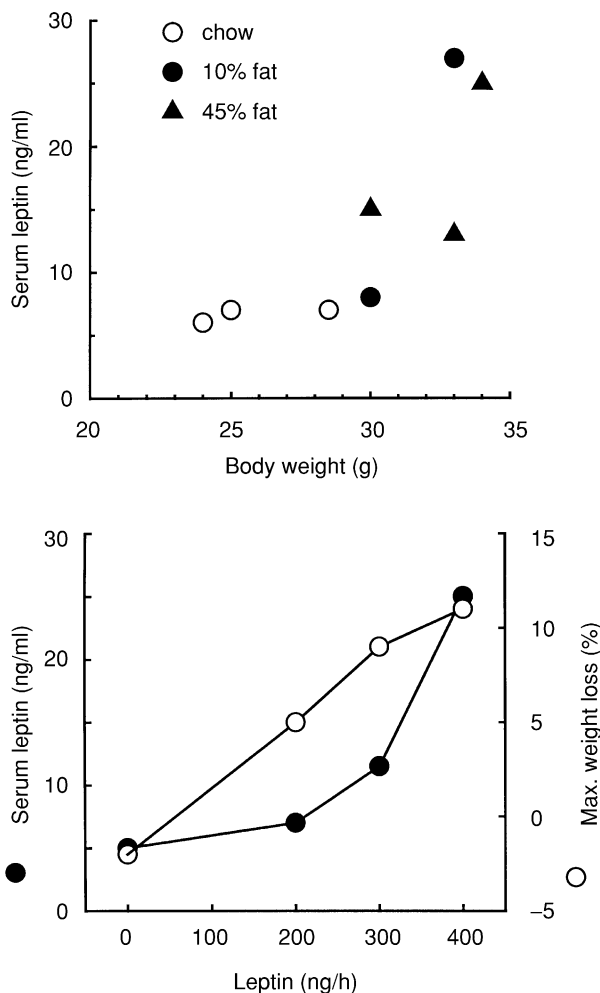

Figure 5 The physiology of the leptin system. As shown in the upper graph, circulating leptin level increases with increased body weight, brought about by feeding mice regular chow or chow enriched with 10 or 45% fat, which they overeat. As shown in the lower graph, continuous subcutaneous leptin infusion in doses that produce leptin levels in the physiological range decrease body weight, which in similar tests was shown to result mainly from decreased food intake. Such data indicate that endogenous leptin is a physiological control of eating. However, note that this control is insufficient to reverse the increased adiposity produced by high-fat feeding. Modified with permission from Van Heek, M., Compton, D. S., France, C. F., Tedesco, R. P., Fawzi, A. B., Graziano, M. P., Sybertz, E. J., Strader, C. D., and Davis, H. J., Jr. (1997). Diet-induced obese mice develop peripheral, but not central, resistance to leptin. *J. Clin. Invest.* 99, 385–390 (upper graph); and Halaas, J. L., Boozer, C., Blair-West, J., Fidathusein, N., Denton, D. A., and Friedman, J. M. (1997). Physiological response to long-term peripheral and central leptin infusion in lean and obese mice. *Proc. Natl. Acad. Sci. USA* 94, 8878–8883 (lower graph).

controller of body weight whose potency can be overwhelmed by stimuli that increase feeding. A few humans with homozygous mutations of the leptin or leptin receptor gene have been identified; not

surprisingly, these individuals display dramatic syndromes such as *ob/ob* and *db/db* mice. Whether less complete defects in the leptin system occur commonly in human obesity and whether manipulation of the leptin system might be therapeutically useful have not yet been determined.

Insulin

Insulin appears to be another endocrine signal linking eating and adiposity. Basal plasma insulin levels vary in proportion to body adiposity, an active transport mechanism carries peripheral insulin through the blood–brain barrier, there are insulin receptors in the arcuate nucleus of the hypothalamus and other brain areas, local administration of insulin into the hypothalamus decreases eating and body weight in several species (including nonhuman primates), and intracerebral administration of insulin antagonists increases food intake in rats and sheep. It is also noteworthy that centrally administered insulin can inhibit feeding without eliciting the hormone's potent anabolic effects in peripheral tissues. Whether selective defects in the brain insulin-signaling pathway can lead to overeating and obesity is unknown. Because adipocytes require insulin to deposit fat, weight gain cannot occur during peripheral insulin insufficiency, even if food intake increases, as occurs in uncontrolled diabetes mellitus.

In general, basal insulin appears to act like leptin in the control of appetite. Like leptin, its main effect is on meal size and it appears to increase CCK's satiating potency. Also similar to leptin, it appears that insulin is a less potent inhibitory influence on appetite than the stimulatory influences that so easily induce obesity and that obesity-related hyperinsulinemia produces insulin tolerance. One important functional difference between the two hormones' actions on feeding has emerged, at least in rodents. Insulin apparently acts more potently than leptin on eating in male animals, whereas leptin acts more potently than insulin on eating in female animals.

Amylin

Amylin is cosecreted with insulin, and basal amylin levels also increase when body adiposity increases. Recent evidence indicates that basal amylin provides another negative-feedback adiposity signal to the brain. Chronic intracerebral infusion of amylin decreased food intake and body adiposity in rats, and similar infusion of an amylin antagonist had the opposite effects. Interestingly, this action of amylin

may be related to decreases in meal number rather than to decreases in meal size, as produced by leptin and insulin.

HYPOTHALAMIC–PITUITARY–GONADAL AXIS

Estradiol and Increased Satiation

Hormones of the hypothalamic–pituitary–gonadal (HPG) axis, in addition to controlling the physiological operation of the reproductive system, act on the brain to affect behavior. For example, female rats and mice are sexually receptive and mate only during the brief periovulatory period (estrus) of the cycle, and this responsiveness is controlled by estradiol and progesterone. Estradiol, but not progesterone, also controls eating. Cycling female rats' food intake is less during estrus than during other days of the cycle, food intake following ovariectomy is tonically increased (producing increases in body adiposity), and a physiological pattern of estradiol replacement normalizes both eating effects and body weight. Estradiol's effects on eating are expressed as changes in meal size; meal frequency changes tend to compensate for the meal size effect. Furthermore, at least in rats, estradiol's effects are not due to decreases in the palatability of sweet or fat foods. Thus, estradiol increases satiation.

Food intake is also decreased during the periovulatory phase of nonhuman primates and women. In women, this amounts to a decrease of a few hundred calories per day. In some studies, this decrease appears to occur throughout the follicular phase of the cycle (i.e., 10 days or more) and so could have body weight implications. Because estradiol increases throughout the follicular phase until ovulation, it is likely that the follicular and periovulatory decreases in eating are due to estradiol, but this has not been proven.

The ovarian cycles of rats and mice end within hours of ovulation, without the prolonged luteal phase that occurs in the ovarian (menstrual) cycles of primates. Some data indicate that food intake may increase during the luteal phase in nonhuman primates and women. It has been suggested that this increase is due to the luteal increase in progesterone. Pharmacological doses of progesterone have some stimulatory effect on eating in rodents, but no feeding effect of a physiological dose of this hormone has ever been documented.

It is unclear whether there is any human parallel to the dramatic increase in eating produced by ovariectomy (oophorectomy) in animals. Women do

increase body fat content by 1 to 2 kg (and lose nearly as much lean body tissue) across the menopausal transition, but changes in eating have not been documented. Estradiol and other HPG hormones have metabolic effects that contribute to the weight gain effects of ovariectomy in animals and may account for the changes in body composition in postmenopausal women.

Food selection may also be influenced by ovarian hormones in women, especially in women with the syndrome of premenstrual (luteal) dysphoria. Such effects appear to represent individuated brain responses to normal steroidal hormone signals that are unlike the normal responses to varying hormone signals that produce estradiol's effects on meal size.

Mechanism of Estradiol's Satiating Effect

In rats, estradiol increases the satiating potency of CCK and glucagon. Thus, like leptin and insulin, estradiol may affect feeding by an effect on the central neural processing of gut hormone satiation signals, perhaps in the NTS.

Estradiol interacts with the classic estradiol receptor, ER α , to inhibit feeding. ER α is widespread in the brain, and which population(s) initiates its feeding effects is unknown, although it is clear that it is not the ventromedial hypothalamus, where estradiol acts to stimulate sexual receptivity.

Pathophysiology

Eating disorders, including anorexia nervosa, bulimia nervosa, and binge eating disorder, occur much more often in women than in men. They are also associated with disorders in the subjective experiences of hunger and satiation as well as disordered eating during meals. In addition, they are associated with disorders in endocrine processes underlying satiation such as CCK secretion. Because these same endocrine processes mediate some or all of estradiol's satiating effects, it is possible that disorders of these mechanisms may be part of the pathophysiology of eating disorders and part of the reason for women's increased vulnerability to eating disorders.

HYPOTHALAMIC–PITUITARY–ADRENAL AXIS

Stress Anorexia

The classical hypothalamic–pituitary–adrenal (HPA) axis stress response consists of release of corticotropin-releasing hormone (CRH) from the

hypothalamus into the hypophyseal portal system, leading to adrenocorticotrophic hormone (ACTH) release from the anterior pituitary, and then glucocorticoid release from the adrenal cortex (the primary glucocorticoid in humans is cortisol and in most rodents is corticosterone). Stress also stimulates the sympathetic nervous system, leading to release of epinephrine from the adrenal medulla. The possibility that the decreases in eating associated with stress (including normal stresses such as exercise) are caused by these hormones has been investigated extensively. Although administration of each of these hormones has inhibited eating in some animal models, a clear picture of the endocrine control of “stress anorexia” has yet to emerge. Undoubtedly, both the farrago of experimental treatments and natural situations that are subsumed under the rubric of “stress” and the highly interactive actions of the HPA axis with the autonomic nervous system, metabolic regulation, and immune system contribute to this situation.

CRH

CRH is secreted into the hypophyseal portal system by neurons with cell bodies in the parvocellular paraventricular nucleus (PVN). CRH-containing neurons, however, also project to other brain sites, including other hypothalamic areas and the NTS, and local administration of CRH into the brain has been shown to inhibit eating. Such inhibition can occur independent of HPA axis activation, suggesting that CRH may control eating in situations not involving stress. These actions of CRH apparently represent neurotransmitter functions rather than endocrine functions.

The recent discovery of another endogenous ligand for CRH receptors, urocortin (UCN), has led to the hypothesis that UCN mediates some or all of these neural actions of CRH. In some studies, UCN has affected eating more potently than has CRH, whereas CRH has affected other stress-related responses more potently than has UCN. Such functional selectivity may occur at the receptor level. CRH-2 receptors have a higher affinity for UCN than does CRH, and CRH-1 receptors have a higher affinity for CRH than does UCN.

Glucagon-like Peptide-1

Glucagon-like peptide-1 (GLP-1) is another molecule with both peripheral hormonal and central neurotransmitter effects. Hormonal GLP-1 is synthesized and released from gut endocrine cells and appears to

act as an incretin (a hormone acting to increase insulin secretion). Neuronal GLP-1 is synthesized by a small cluster of neurons in the caudal brainstem that project to the hypothalamus. This GLP-1 appears to be a key neurotransmitter in the neural network, mediating the anorexia produced by many “stressful” treatments.

Oxytocin and Arginine Vasopressin

The posterior pituitary hormones arginine vasopressin and oxytocin are increased by various stress treatments, and both can produce anorexia. Because both hormones also affect ACTH secretion, their anorectic actions may be related to HPA axis function. But both molecules also occur in neurons. Oxytocinergic neurons project from the PVN to the brainstem, where they appear to produce anorexia by activating the neuronal GLP-1 system described previously.

Glucocorticoids and Obesity

Cushing's Syndrome

Glucocorticoids play a crucial role in a number of obesity syndromes. The hyperphagia and obesity of all gene mutation models, including the *ob/ob* and *db/db* mice discussed previously, are reversed by adrenalectomy and are reinstated by corticosteroid treatment. Cushing's syndrome, which includes insulin resistance, decreased glucose tolerance, hyperlipidemia, and central (visceral) obesity, results from increases in glucocorticoid secretion. Such increases are usually secondary to increased CRH or ACTH secretion, for example, as can be caused by pituitary tumors. Cushing's syndrome can also result from an aberrant glucocorticoid response to gastric inhibitory peptide secreted during meals, suggesting that overeating alone may also contribute to it.

Metabolic Syndrome

Central obesity, insulin resistance, decreased glucose tolerance, and hyperlipidemia most often occur in the absence of elevated plasma glucocorticoids. This has been called the metabolic syndrome. Recent work indicates that obesity and metabolic syndrome can be produced by disordered intracellular metabolism of glucocorticoids. The enzyme 11 β -hydroxysteroid dehydrogenase type 1 regulates the amount of glucocorticoid reaching its intracellular receptors by controlling the interconversion of active glucocorticoids and their inactivated forms. Transgenic mice that overexpress this enzyme only in white adipose tissue developed central obesity, metabolic syndrome, and increased plasma leptin and insulin but maintained

normal plasma glucocorticoid levels. Thus, hepatic glucocorticoid metabolism may be a factor in human obesity in the absence of any sign of endocrine dysfunction. The transgenic mice also overate, perhaps in response to decreased circulating metabolic fuels secondary to increased lipogenesis.

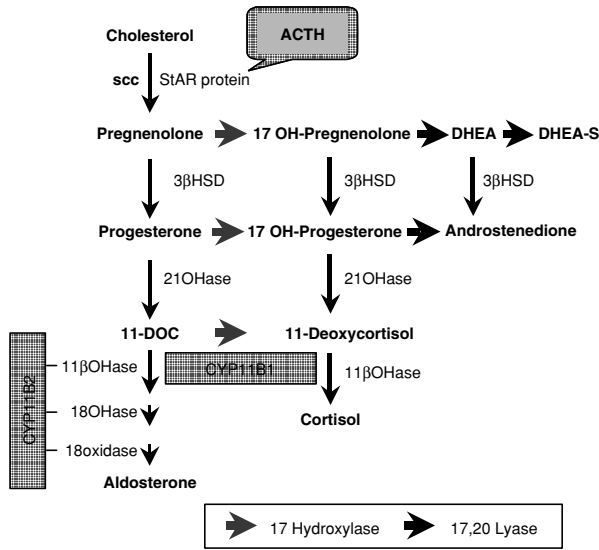

Figure 1 CYP11B1 and CYP11B2 deficiencies and their relations to steroid biosynthesis. SCC, side chain cleavage enzyme; StAR, steroidogenic acute regulatory protein; 3 β HSD, 3 β -hydroxysteroid dehydrogenase; 21-OHase, 21-hydroxylase; 11 β OHase, 11 β -hydroxylase; 18-OHase, 18-hydroxylase.

nonclassical form. The renin-angiotensin pathway is the main route by which CYP11B2 is activated. Therefore, since the excess DOC suppresses plasma renin activity, serum aldosterone levels are low, despite completely normal CYP11B2 enzyme activity.

As mentioned previously, CYP11B2 catalyzes three reactions in the zona glomerulosa of the adrenal gland: 11 β -hydroxylase, corticosterone methyl-oxidase I (CMO-I) (i.e., 18-hydroxylase), and corticosterone methyl-oxidase II (CMO-II) (i.e., 18-oxidase).

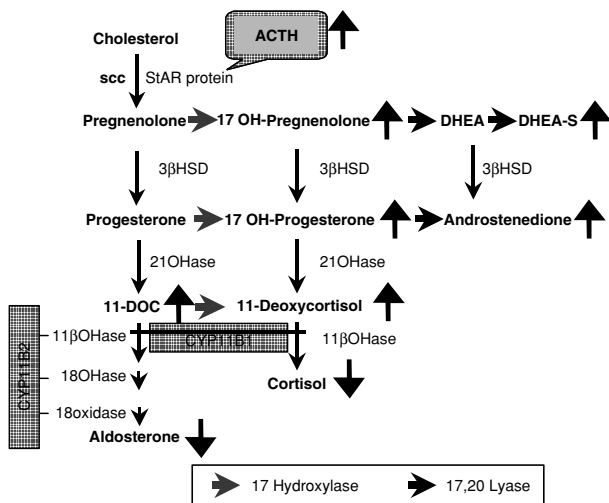

Figure 2 Alterations in steroid biosynthesis caused by CYP11B1 deficiency. Vertical bold arrows indicate increase or decrease in serum concentration. Abbreviations are as in Fig. 1.

Deficiencies of both CMO-I and CMO-II cause salt wasting without virilization. Since the genetics and clinical syndromes are entirely different for CYP11B1 and CYP11B2 deficiencies, these aspects are discussed separately.

CYP11B1 DEFICIENCY: MOLECULAR GENETICS

The CYP11B1 and CYP11B2 enzymes are encoded for by genes on chromosome 8, with each containing nine exons encompassing approximately seven kilobase pairs of DNA. They are relatively close to each other (40 kb apart) and are 95% homologous. CYP11B1 is regulated by the action of ACTH on the surface of cells in the adrenal cortex. The ACTH receptor is a typical seven-transmembrane G protein-coupled receptor. G stimulatory protein activation increases the activity of adenylate cyclase, with a subsequent increase in cyclic AMP. Cyclic AMP then binds to the appropriate response elements in the CYP11B1 promoter, thus activating mRNA expression and protein translation.

The mutations in CYP11B1 mainly cluster in exons 2 and 6–8 (Table I). The majority cause classical CAH due to a completely nonfunctional 11 β -hydroxylase protein. A large group of patients of Moroccan Jewish descent bare a unique common point mutation that causes a change in amino acid 448 from arginine to histidine (R448H). In offspring of Moroccan Jews living in Israel, the incidence of this disorder is 1 in 5000–7000, with an allele frequency of 1 in 70–84 and a carrier frequency of 1 in 35–42. Considering this ethnic group’s isolated existence in the Atlas Mountains of Morocco, with a high rate of inbreeding for approximately two millennia, this common mutation is probably caused by a founder effect. The same mutation has also been identified in other populations, and a different mutation at the same amino acid residue has been identified (R448C), thus making amino acid 448 a hot spot. Other described defects are mostly in regions of the gene important for enzyme function—substrate binding, heme iron binding, binding of oxygen molecules, and proton transfer to the bound oxygen. Like other cytochrome P450 adrenal enzymes, both forms of the 11 β -hydroxylase enzymes depend on electrons transported from NADPH for their hydroxylation activity. These electrons are transferred to adrenodoxin reductase and then to adrenodoxin and finally to the enzyme. Gene mutations in regions important for adrenodoxin binding result in total inactivation of the enzyme.

Table 1 Mutations in CYP11B1 and Their Effects^a

| Exon | Mutations causing classic CAH | Nonclassic mutations |
|----------|---|----------------------|
| 1 | P32del1nt | P42S |
| 2 | L105del28nt, W116X, Q121ins5nt, V129M | None reported |
| 3 | K174X | N133H |
| 4 | W247X | None reported |
| 5 | T318M | None reported |
| 6 | A331V, Q338X, Q356X, E371G, R374Q | T319M |
| 7 | R384Q, R384G, N394ins2nt | None reported |
| 8 | Y423X, L464ins3nt, V441G, R448H (Moroccan Jewish), R448C | None reported |
| 9 | None reported | None reported |
| Multiple | Hybrid gene; promoter and exons 1–6 of CYP11B2 and exons 7–9 of CYP11B1 | |

^aAbbreviations used: del, deletion; ins, insertion; nt, nucleotides. Amino acid mutations: A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine; X, stop codon.

In a particularly interesting mutation, a hybrid gene is formed that includes the promoter and exons 1–6 of CYP11B2 and exons 7–9 of CYP11B1. The resulting enzyme has *in vitro* activity of both CYP11B1 and CYP11B2 but is not expressed in the zona fasciculata since the promoter and regulatory elements of CYP11B1 are replaced by those of CYP11B2.

An interesting phenomenon reported by our group is secondary 11 β -hydroxylase deficiency. This occurs together with 21-hydroxylase deficiency and is probably caused by a local inhibitory effect of the excess androgen caused by the primary 21-hydroxylase defect.

CLINICAL PRESENTATION: CLASSICAL 11 β -HYDROXYLASE CAH

Diagnosis

Most females with the severe or classical form of CAH are diagnosed in the neonatal period after presenting with ambiguous genitalia at birth or in early childhood. Occasionally, females are so severely virilized at birth that their external genitalia are male looking, with a penile urethra and fused labioscrotal folds. This leads to errors in gender assignment. Males, on the other hand, have normal genitalia at birth, but

marked virilization becomes evident (with or without associated hypertension) in childhood. The evaluation of ambiguous genitalia includes verification of the karyotype. A rapid fluorescent *in situ* hybridization for Y chromosome sequences can be obtained in many clinical laboratories within 24–48 h. Negative findings on this test suggest that the patient's genome lacks the Y chromosome, and this must be confirmed by a complete karyotype assessment. At the same time that blood is drawn for genetic studies, biochemical testing is also done. One should determine cortisol, 11-deoxycortisol, 17-hydroxyprogesterone, DOC, aldosterone, DHEA-S, androstenedione, and testosterone concentrations as well as plasma renin and aldosterone, which are particularly useful when hypertension is suspected. Biochemical diagnosis of 11-hydroxylase deficiency is made when the relative values of 11-deoxycortisol/cortisol and DOC/aldosterone are more than three standard deviations higher than the average before or 1 h after intravenous stimulation with 250 $\mu\text{g}/\text{m}^2$ aqueous ACTH.

As previously noted, there is a good association between baseline and stimulated steroid levels. In our experience, baseline levels of the appropriate steroid metabolites are usually sufficiently elevated to allow for a correct diagnosis to be made in classical CAH.

Male patients are not usually diagnosed early in childhood unless either a previous index female case has occurred in the family or hypertension is noted. Rarely, a neonatal salt-wasting crisis can occur. In most cases, male children present with rapid somatic growth, penile but not testicular enlargement, and growth of pubic hair. X-ray of the left hand and wrist will confirm advanced bone age. Biochemical testing in such cases should be performed as for female patients.

Treatment

After biochemical testing has been performed, treatment should be initiated, even prior to receipt of the results, with 15–25 mg/m^2 of hydrocortisone in order to affect replacement of glucocorticoids and to suppress excess androgen formation. We often recommend starting treatment in the neonate with 0.2 mg/day of 9-fludrocortisone in order to prevent salt wasting and because 21-hydroxylase deficiency often cannot be ruled out initially. If the diagnosis of 11 β -hydroxylase deficiency is confirmed, mineralocorticoid treatment can be gradually withdrawn over the first few months of life. In addition to the medical treatment described, surgical correction of the genitalia (i.e., clitoral reduction and vaginoplasty) is

performed preferably during the first year of life. Therefore, a pediatric surgeon or urologist experienced in this type of delicate surgery should be part of the team. It is also recommended that the parents be involved in the early stages of the diagnostic workup so that they become as comfortable as possible with the diagnosis and understand the treatment in which they will have to take part.

Some children are born with such severe virilization that the genitalia appear completely male and the lack of testes in the "scrotum" is overlooked. Indeed, in our series, approximately half of the female children were mistakenly reared as boys, and other series have also included many such cases. Since these "males" have ovaries and do not have testes, the Müllerian system, including the fallopian tubes, uterus, and the upper two-thirds of the vagina, develops normally. In these cases, it is a dilemma whether to change the gender because of possible female fertility or to remove the female organs and continue to rear the child as a male. The decision depends on the age at diagnosis and the cultural context.

Follow-up evaluation and maintenance therapy are ideally performed in a coordinated manner by a team including endocrine, urological, psychological, and genetics expertise. The endocrinologist should monitor compliance with hydrocortisone by regularly measuring ACTH, plasma renin activity, and 11-deoxycortisol and androgen levels and by following growth, bone age, and pubertal development. One should be aware that excess androgens may trigger the onset of early central puberty and should appropriately monitor the patient for signs of such occurrence by regular physical examination and, if necessary, testing for elevated gonadotropin levels. The urologist or surgeon performing vaginoplasty and clitoral reduction will also be required to follow the female patient to ensure adequate genitalia for intercourse. This may require dilatation of the vaginal opening during adolescence and, occasionally, additional surgery. Psychological expertise is required early in life to help the parents come to terms with gender assignment and later to help the adolescent with concerns associated with sexual activity. Genetic counseling should be considered part of the initial therapy, and the possibility of early diagnosis and prenatal treatment should be discussed with the endocrinologist.

Treatment during Acute Illness

Patients with 11 β -hydroxylase deficiency cannot mount a sufficient stress response and should receive

appropriate stress doses of glucocorticoids as for other patients with adrenal insufficiency.

PROGNOSIS

If treated appropriately, patients presenting with the classical form of 11 β -hydroxylase deficiency should theoretically achieve a final height near their genetic potential. Several studies of 21-hydroxylase-deficient patients have documented that many patients do not achieve this final height, probably as a result of undertreatment or overtreatment at various stages of life. A significant loss of final height has been attributed to delayed diagnosis; therefore, the final height of patients with salt-wasting 21-hydroxylase deficiency (who are diagnosed at an early age because of the dramatic presentation) has been reported to be better than that of the simple virilizing form. Similarly, it is understandable that 11 β -hydroxylase-deficient patients tend to be more severely height compromised, although few studies have dealt with this issue.

Prenatal Diagnosis

Although population screening has not been set up for this form of CAH, prenatal diagnosis may be done when a previous sibling has been affected by searching for one of the known mutations. If the mutation is unknown, levels of tetrahydro-11-deoxycortisol and 11-deoxycortisol can be determined in the amniotic fluid and maternal urine, as reported by our group; however, to facilitate this, prenatal treatment must be temporarily halted.

Prenatal Treatment

In utero virilization of female genitalia occurs in CAH because of the accumulation prior to the blocked enzyme of steroid precursors, which are then converted to potent androgens. Early prenatal treatment of the mother with dexamethasone can prevent virilization of female genitalia. Dexamethasone crosses the placenta and suppresses the fetal hypothalamic-pituitary-adrenal axis. Although this treatment is successful if initiated early, it must be initiated prior to diagnosis and can be terminated only after chorionic villous sample (CVS) confirms that the fetus is unaffected, heterozygous, or male. A prerequisite for this is knowledge of the mutation in an index case in the same family so that the CVS can be amplified by polymerase chain reaction and examined rapidly for the mutation. Treatment is controversial because in a

large number of pregnancies the mother is inevitably treated unnecessarily with a drug that may cause her harm (at least seven of eight pregnancies; i.e., all males, four of eight pregnancies; female carriers, two of eight pregnancies; and females without the mutation, one of eight pregnancies). Also, the long-term effects of dexamethasone therapy on the fetus throughout gestation are unknown. Most of the reported experience regards 21-hydroxylase deficiency, and the major side effects are those of transient iatrogenic Cushing's syndrome in the mother. Only two female children homozygotes for 11 β -hydroxylase deficiency have been reported as treated prenatally: One was born virilized and the other had normal female genitalia. Before treatment is contemplated, the parents must be made aware of the risks and benefits involved.

NONCLASSICAL 11 β -HYDROXYLASE DEFICIENCY CAH

Patients with this form of the disease present with clinical signs of hyperandrogenism (i.e., hirsutism, acne, male-type balding, and menstrual irregularities). Several mutations causing nonclassical CAH have been described (Table I), including missense mutations (N133H and T319M) and a nonsense mutation (Y423X). Significantly elevated stimulated levels of the appropriate metabolites define biochemical enzyme deficiency. However, this does not correlate with mutations in the CYPB1 gene. Indeed, in one report, only two of five women with ACTH-stimulated 11-deoxycortisol levels more than three times higher than the 95th percentile had mutations in the gene. Secondary deficiency of 11 β -hydroxylase activity has been reported in patients with late-onset 21-hydroxylase deficiency, probably due to the effects of elevated circulating androgens on the CYP11B1 enzyme.

Patients with nonclassical CAH are diagnosed during evaluation of hyperandrogenism presenting during adolescence or late childhood, and treatment is not dependent on the genetic status. Suppressive therapy with hydrocortisone in childhood or dexamethasone after growth is complete will prevent hyperandrogenism and its effects and therefore is indicated.

Special Considerations

11 β -Hydroxylase deficiency was initially defined as the hypertensive form of CAH. However, our experience, and that of a Saudi Arabian group, includes several

patients in whom neonatal salt wasting occurred. The renal distal tubule is comparatively mineralocorticoid resistant in the neonatal period, and this gives rise to normally elevated levels of renin and aldosterone. It appears that the mineralocorticoid effect of the accumulated precursors is, in some infants, insufficient to prevent renal salt wasting. Furthermore, some precursors (e.g., 17-hydroxyprogesterone) have an antiminerlocorticoid effect. When one suppresses ACTH with hydrocortisone, previously accumulated weakly mineralocorticoid precursors (e.g., 11-deoxycorticosterone) are reduced, thus increasing the likelihood of a salt-wasting crisis. Therefore, it is prudent to initiate therapy with mineralocorticoids and gradually reduce the dose over the first year of life.

Incidentalomas

Adrenal incidentalomas are tumors discovered when abdominal imaging is performed. In up to 70% of these patients, elevated serum 17-hydroxyprogesterone levels have been noted. Evidence of 11-hydroxylase deficiency has been reported for a group of patients with incidentalomas based on ACTH-stimulated ratios of 11-deoxycortisol:cortisol and 11-deoxycorticosterone:corticosterone compared with controls. It is thought that the preexisting undiagnosed deficiency caused adrenal overstimulation, thus producing these small adrenal tumors.

Heterozygotes for CYP11B1 Mutations

CYP11B1-deficiency CAH is an autosomal recessive condition. Several studies have evaluated whether heterozygotes have any detectable abnormality. This is a controversial issue. Our group and others have presented evidence that they do not, although other groups have contested this.

CYP11B2 DEFICIENCY

P450c11aldo, encoded by the CYP11B2 gene, catalyzes the final steps of aldosterone synthesis in the mineralocorticoid pathway. This enzyme is expressed only in the zona glomerulosa of the adrenal gland. CYP11B2 is regulated by angiotensin II via a G protein-coupled receptor that activates the phospholipase C pathway, culminating in increased intracellular calcium. In turn, calcium is thought to activate a calmodulin-dependent protein kinase that phosphorylates various transcription factors. These factors then increase expression of CYP11B2.

Potassium also has a direct effect on the glomerulosa cells by membrane depolarization. The change in transmembrane voltage causes increased calcium influx via voltage-dependent calcium channels. The rest of the activation pathway is the same as the angiotensin II pathway. ACTH is also thought to increase expression of CYP11B2 but appears to have only a short-term effect.

Deficiency of the aldosterone synthase enzyme complex presents with congenital salt wasting due to isolated mineralocorticoid deficiency. Such patients are not virilized and have normal levels of cortisol and sex steroids. The reduced aldosterone production is due to insufficient enzyme activity in the CYP11B2 complex that includes 11 β -hydroxylase, CMO-I, and CMO-II activities, all of which are encoded by the CYP11B2 gene. As previously mentioned, the largest number of cases (with CMO-II deficiency) have been reported among Jews of Iranian descent. These Jews originated in a highly inbred community from Ispahan, Iran, that may be traced back to approximately 500 B.C. The incidence of this condition in Iranian Jews is estimated to be at least 1:4000. All these patients are homozygous for two mutations in CYP11B2: R181W (on exon 3) and V386A (on exon 7). The R181W mutation completely abolishes both CMO-I and CMO-II activity *in vitro*. The second mutation on exon 7, codon 386, produces only a minimal reduction in CMO-I activity. Interestingly, individuals homozygous for either one of these mutations alone are completely asymptomatic. A similar requirement for double homozygosity has been described for other combinations [i.e., T318M and V386A (exons 5 and 7) and also R181W (exon 3) and C372del1nt (exon 6)]. Double homozygosity for E198D (exon 3) and V386A (exon 7) is associated with CMO-I deficiency. Clinical CMO-I deficiency has been reported with double homozygosity for E198D and V386A. Homozygosity for a single V35del2nt and R384P mutation also causes clinical CMO-I deficiency.

The diagnosis of the two types of CYP11B2 deficiency is made based on dramatically increased levels of 18-hydroxycorticosterone in CMO-II, with a marked increase in the 18-hydroxycorticosterone:aldosterone ratio compared with mildly decreased levels in CMO-I deficiency. Serum aldosterone is undetectable in type I deficiency but usually within normal limits in type II.

Both forms of aldosterone synthase deficiency present clinically in the same way. A salt-wasting syndrome with hypovolemia occurs at a few days to a few weeks of age (usually after the first week of life due to the protective effect of maternal steroids). Such

patients are initially stabilized with intravenous saline infusion. Once stable, oral salt supplementation at a dose of 1 or 2 g/day and oral 9-fluorocortisone at a dose of 0.1–0.3 mg/day usually suffice. During childhood, patients can be weaned from therapy, and adults usually do not require treatment. This phenomenon is explained by the ability of these patients to form 11-deoxycorticosterone, a weak mineralocorticoid that is sufficient to prevent salt loss in the mature distal nephron but insufficient in the infant. As a result, although the 18-hydroxycorticosterone:aldosterone ratio is persistently elevated into adulthood, the plasma renin normalizes with age.

Some patients present in a milder fashion and are not diagnosed in infancy but are diagnosed when severe hyponatremia and hyperkalemia occur during gastroenteritis. Otherwise, they may be diagnosed asymptotically upon screening of a family after another infant sibling presents with salt wasting. These mild cases probably do not require treatment except in conditions of severe sodium loss, when they might not be able to mount a sufficient mineralocorticoid response.

Figure 1 Schematic representation of steroid hormone synthesis with 21-hydroxylase enzyme block resulting in accumulation of precursors and synthesis of excess sex hormones. Enzymes: 17 α -OH, 17 α -hydroxylase; 3 β -HSD, 3 β -hydroxysteroid dehydrogenase; 21-OH, 21-hydroxylase; 11 β -OH, 11 β -hydroxylase; 18-OH, 18-hydroxylase; 18-HSD, 18-hydroxysteroid dehydrogenase; 17 β -HSD, 17 β -hydroxysteroid dehydrogenase. Intermediate products: 11-DOC, 11-deoxycorticosterone; DHEA, dehydroepiandrosterone.

CLINICAL FEATURES

The phenotypic spectrum of classical 21-hydroxylase deficiency depends mainly on the genetic sex and residual enzyme activity, if any. Two distinct phenotypes, the salt-wasting and simple virilizing forms, are commonly recognized, although intermediate forms are also known to occur. Patients with nonclassical congenital adrenal hyperplasia do not present at birth, and often female patients present around puberty or later with hyperandrogenic features such as premature pubarche, hirsutism, acne, and menstrual disturbances.

Salt-Wasting Form

Approximately 75% of patients with classical 21-hydroxylase deficiency have severely impaired hydroxylation at C21 and so cannot synthesize adequate amounts of either cortisol or aldosterone. Inadequate aldosterone reserve leads to excessive sodium loss through the kidney, colon, and sweat glands. Concomitant severe cortisol deficiency exacerbates the systemic effects of aldosterone deficiency and results in severe hyponatremic dehydration with vomiting, hypotension, and shock (adrenal crisis). This is often the presenting symptom and occurs 1 to 4 weeks after birth in undiagnosed patients. These adrenal crises are fatal if untreated, and they remain

an important cause of mortality, especially in untreated patients and those under 5 years of age. In addition to salt wasting, these patients have virilization because accumulated precursor 17-hydroxyprogesterone is diverted to produce excess adrenal androgens, which are further converted peripherally to more potent androgens such as testosterone. Genetically female infants with classical 21-hydroxylase deficiency are virilized to a variable degree *in utero* and are born with ambiguous genitalia. The skin of the labia majora is thickened and wrinkled like scrotal skin and is fused to a variable extent, concealing the vaginal orifice. The urethra and vagina open into a common urogenital sinus, and there is invariably a degree of clitoromegaly. In severe cases, the clitoris may resemble a penis and the labia may be partially fused, so that a mistaken diagnosis of hypospadias with cryptorchidism can be made. In extreme cases, complete labial fusion, a phallic urethra, and an external meatus at the penile tip can occur, mimicking a complete male external phenotype with bilateral cryptorchidism. However, these children have normal female organs internally (fallopian tubes, uterus, and upper vagina), and the ovaries are normally situated. In genetic males, sexual differentiation is normal, and there is usually only minimal enlargement, if any, of the penis.

Simple Virilizing Form

Some 25% patients with classical 21-hydroxylase deficiency have 1 to 2% residual enzyme activity, such that the adrenal cortex secretes adequate aldosterone to maintain normal serum electrolytes but cortisol production is low enough to stimulate ACTH and, hence, androgen hypersecretion (Fig. 2). These patients do not have salt wasting but have virilization. In

Figure 2 Gingival hyperpigmentation due to increased secretion of ACTH.

genetic females, this results in ambiguous genitalia. Genetic male newborns escape detection at birth and are often not diagnosed until a few years later when they present with premature sexual development.

Untreated or Late Presentations

Often, classical 21-hydroxylase deficiency might not be diagnosed at birth for a variety of reasons and so might not be treated. The severe salt-wasting form is fatal if unrecognized and untreated during the first few weeks of life. An affected male infant who dies after several weeks of persistent vomiting may be thought to have died of other causes (e.g., pyloric stenosis, infection, gastroenteritis). However, patients with simple virilizing forms survive with progressive postnatal virilization, rapid somatic growth, and precocious puberty. These children will have compromised adult height due to premature fusion of epiphyses. Some 46,XX patients in developing countries may be raised as males.

DIAGNOSIS

Classical 21-hydroxylase deficiency should be clinically considered as a possible diagnosis in all children with genital ambiguity (see Fig. 5). Salt loss might not commence at birth, and electrolytes usually remain normal for the first week of life. Hyponatremic dehydration with shock during the first few weeks of life, especially in boys or in infants with ambiguous genitalia, is a strong clinical indicator of the severe salt-wasting form of congenital adrenal hyperplasia. Hypoglycemia may also be a feature in the very young. Less severe forms can present with lethargy, poor feeding, and poor weight gain. Precocious puberty and virilization in older boys and girls can be a clinical indicator for the untreated simple virilizing form of congenital adrenal hyperplasia. Very high levels of 17-hydroxyprogesterone, the main substrate for the enzyme 21-hydroxylase, are found and are diagnostic. Salt wasters tend to have higher levels than do non-salt wasters. However, some 10% of severely affected infants may have falsely low initial values on day 1 of life. In addition, most sick premature babies have elevated levels without an enzyme defect. This is partly because the fetal zone of the adrenal cortex is still active and secretes a range of steroids that can cross-react with 17-hydroxyprogesterone in an immunoassay. False-positive 17-hydroxyprogesterone results in samples from newborn infants may occur if the laboratory does not include an

additional step to reduce the amount of cross-reacting steroids. The measurement of urinary pregnanetriol (a metabolite of 17-hydroxyprogesterone) can also be of diagnostic value. An ACTH stimulation test can accurately differentiate among various enzyme defects in steroidogenesis by comparing precursor-to-product ratios after stimulation, but this usually is not necessary for the diagnosis of classical 21-hydroxylase deficiency because basal values are diagnostic.

CYP21 genotyping and mutation analysis does not help in making treatment decisions but is helpful in prenatal diagnosis when there is a known proband in the family. There is good correlation between genotype and phenotype, allowing DNA analysis to predict, with certain reliability, the residual enzyme activity and consequent clinical expression.

PATIENT MANAGEMENT

Conventional Hormone Replacement Therapy

The aims of treatment are to replace the missing hormones while at the same time suppressing the excess production and accumulation of precursors. It appears that supraphysiological doses of hydrocortisone are required to inhibit ACTH secretion adequately and to suppress excess androgen production. However, finding the appropriate dose for each patient is a fine balancing act because inadequate treatment will not suppress ACTH adequately and overtreatment results in unwanted side effects of steroids, principally growth retardation and Cushing's syndrome.

Salt-Wasting Form

Hydrocortisone (10–20 mg/m²/day in two or three divided doses) and fludrocortisone (0.1–0.2 mg/day) are usually preferred for replacing cortisol and aldosterone, respectively, in these patients, and lifelong treatment is required. Salt supplements and higher doses of fludrocortisone may be necessary during infancy. Salt wasting generally seems to get better with age, and older children and adults often have lower fludrocortisone dose requirements without salt supplementation.

Simple Virilizing Form

Adequate hydrocortisone replacement alone is enough to normalize growth and stop progressive virilization in these patients, but hydrocortisone treatment is often unable to reverse the virilization that has already occurred (Fig. 3). In some patients who are

Figure 3 2½-year-old boy showing signs of hyperandrogenism with facial acne, pubic hair, and increased penile size. Also note height above 98th centile.

diagnosed very late, the elevated adrenal androgen levels suppress gonadotropin secretion. When treatment with cortisol suppresses these androgens, follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are secreted, resulting in true or central precocious puberty. This should be treated with long-acting luteinizing hormone-releasing hormone (LHRH) analogues because there is a strong risk of reduced final adult height due to early and premature fusion of epiphyses. Compliance is another major problem in adolescent boys because they have few clinical symptoms on a daily basis.

Adrenal Crisis

Patients with classical 21-hydroxylase deficiency are unable to mount an adequate cortisol response during periods of stress, such as infection and surgery, and require additional pharmacological doses of

hydrocortisone. Steroid cover for stress should provide 30 to 60 mg of hydrocortisone/m²/day in divided doses. If children are vomiting or have diarrhea, the hydrocortisone should be injected subcutaneously or intramuscularly. Care should also be taken to recognize and treat hypoglycemia in young children with an adrenal crisis. Untreated and unrecognized stress can be fatal and remains one of the potential causes of mortality in young children.

Ambiguous Genitalia

Gender Assignment at Birth

The established practice is to minimize the period of gender uncertainty by definitive diagnosis and treatment as early as possible. The female sex of rearing is appropriate for most 46,XX patients because it maximizes the chance of fertility. Feminizing genital surgery (clitoral reduction and vaginoplasty) helps psychological adjustment of the parents and reduces the risk of the patient becoming stigmatized. However, the practice of early genital surgery has been questioned during recent years by certain patient advocacy groups, which have urged physicians to assist patients' families, and later patients themselves, in participating in informed decision making regarding the genital surgery. In our opinion, this does not apply to girls with congenital adrenal hyperplasia. A medical benefit from early vaginoplasty is a reduced risk of recurrent urinary tract infection.

Gender Reassignment during Childhood

Some 46,XX patients with markedly masculinized genitalia at birth are inadvertently assigned to the male gender (Figs. 4 and 5). In developing countries, some untreated patients survive and postnatal virilization is progressive. When the correct diagnosis is made later on but still during infancy or early childhood, many physicians recommend sex reassignment to female, taking into account the behavior (masculine or feminine) of the child. Again, female gender rearing is usually considered best for most 46,XX patients. Some 46,XX patients have been reared in the male gender until late childhood or early adolescence, and these are best to remain as boys unless they themselves feel otherwise. A small proportion of patients may self-initiate gender reassignment (female to male) around puberty or later. Such patients have usually been exposed to excessive androgen levels during childhood due to poor compliance with medical therapy.

Figure 4 Phenotypically male genitalia with complete labial fusion, labial scrotalization, clitoromegaly resembling a penis with urethral opening at the tip, and bilateral cryptorchidism (Prader stage 5) in a 46,XX infant with 21-hydroxylase deficiency.

Genital Surgery

Genital reconstructive surgery is performed to make the appearance of the external genitalia concordant with the sex of rearing. The mainstays of surgery in a virilized 46,XX patient assigned a female sex are clitoral reduction and vaginoplasty. With increasing masculinization of the infant, the repair becomes technically more demanding. Some surgeons believe that the repair is more difficult with increasing age because the urogenital sinus lengthens with age and greater degrees of vaginal mobilization are then required. The surgical treatment for 46,XX patients raised as males or those self-initiating gender reassignment include removal of ovaries and uterus, staged hypospadias repair, and insertion of testicular prostheses. These patients would also require testosterone replacement therapy for life.

Figure 5 Ambiguous genitalia in a 46,XX newborn showing labial scrotalization and hyperpigmentation, labial fusion, clitoromegaly mimicking a penis, and bilateral cryptorchidism.

Adult Issues

Short Stature

Most patients with classical 21-hydroxylase deficiency, both men and women and regardless of the age at diagnosis or the quality of endocrine treatment, achieve a final height that is shorter than that of the population in general and the mid-parental height. This loss of height potential can be due to iatrogenic hypercortisolism, adrenal hyperandrogenism, or a combination of both. In general, if the hydrocortisone dose is sufficient to suppress 17-hydroxyprogesterone to less than 20 nmol/L, adrenal androgens are more completely suppressed. Therefore, women with classical 21-hydroxylase deficiency may be androgen deficient. Inadequate dose results in hyperandrogenism, which accelerates linear growth and epiphyseal maturation. Unfortunately an excessive hydrocortisone dose also suppresses growth, so correct treatment involves careful clinical and biochemical monitoring to find the fine line between inadequate and excessive doses of hydrocortisone.

Continuing Hyperandrogenism

Adult females with untreated or undertreated classical 21-hydroxylase deficiency continue to have problems of hyperandrogenism such as hirsutism, menstrual disturbances, and decreased fertility. Increased body hair and acne appear during adolescence and persist into adulthood. Noncompliance with treatment or failure to monitor therapy closely is associated with a higher proportion of these problems. Girls may have delayed menarche and ovarian dysfunction, similar to polycystic ovarian syndrome, which can result in later reduced fertility.

Fertility Issues in Females

Female patients with classical 21-hydroxylase deficiency, particularly the salt wasters, have reduced fertility. They tend to have anovulatory cycles in addition to menstrual disturbances during times of hyperandrogenism. Increased levels of progesterone exert an independent contraceptive effect (“mini-pill effect”) with prevention of conception even in the presence of ovulation. Masculinization of the external genitalia, an inadequate introitus, and other structural factors related to genital reconstructive surgery (e.g., vaginal stenosis, clitoral dysfunction, poor surgical repair) play an important part in reducing heterosexual activity.

Despite these factors, studies show an apparent improvement in fertility due to good compliance, surgical advances in genital reconstruction, careful monitoring before and during pregnancy, and use of ovulation induction agents and other assisted reproductive techniques such as *in vitro* fertilization. In general, most pregnancies have been carried to term successfully with healthy outcomes. Excessive maternal androgens could virilize the genitalia of an unaffected female fetus; therefore, a mother with classical 21-hydroxylase deficiency needs preconception counseling and careful monitoring during pregnancy.

Fertility Issues in Males

Men have impaired gonadal function less frequently than do women. Testicular integrity is normal even during periods of noncompliance. Reduced sperm counts found in men with poorly controlled classical 21-hydroxylase deficiency do not usually preclude fertility. However, a more potent cause of infertility is obstruction of the hilum of the testis by hyperplastic adrenal rests. In most cases, these cause severe oligospermia or even complete azoospermia.

Adrenal Hyperplasia and Adrenal Rest Tumors

The incidence of adrenal “incidentalomas” increases with age and is higher in patients with classical 21-hydroxylase deficiency and heterozygotes than in the general population. The incidence is highest in untreated or inadequately treated classical 21-hydroxylase deficiency patients, especially those with the salt-wasting variant. These adrenal masses are nearly always benign. Occasionally, the adrenal “tumor” is the presenting sign in a previously undiagnosed adult patient. Ectopic adrenal masses or rest tumors are common in the testes of inadequately treated or noncompliant patients, but they may also develop at other sites along the line of testicular descent. These benign masses often have a rock-hard

consistency mimicking testicular malignancies, and the patient is at risk for having one or both testes removed if the correct diagnosis is not made in time. The ultrasound appearance of adrenal rests in the testes is said to be diagnostic.

Gender Identity

Pre- and perinatal exposure of the female to high levels of adrenal androgens may influence gender identity and gender-related behavior during childhood and adult life. Most 46,XX patients with varying degrees of genital ambiguity who have been assigned or reassigned to the female gender during early childhood have remained females lifelong, although their behavior may be somewhat masculine. Nearly all 46,XX patients who have been reared as males until late childhood or adolescence elect to remain boys. A small number of patients have requested surgical gender reassignment around puberty or later. In general, 46,XX patients with classical 21-hydroxylase deficiency have a stable female gender identity. As such, they differ from patients with mixed gonadal dysgenesis and partial androgen insensitivity, who are more likely to identify as males (Figs. 5 and 6).

Sexual Orientation and Sexual Activity

Women with classical 21-hydroxylase deficiency have been found in some (but not all) studies to have an increased rate of bisexual or homosexual orientation, which again is attributed to varying degrees of brain androgenization during the pre- and perinatal periods. This bisexual or homosexual orientation is demonstrated in sexual imagery, fantasies, and attractions, but only few of these women consider themselves to be lesbians or have overt homosexual involvement. More strikingly, women with classical 21-hydroxylase deficiency show greater avoidance of all forms of sexual activity than do other women. Whether this is due to psychological differences or to physical problems, such as an insensitive (or absent) clitoris, vaginismus, failure to lubricate, or a tight introitus, is unclear. Reduced sexual activity undoubtedly contributes greatly to infertility.

FAMILY MANAGEMENT**Genetic Counseling for the Family**

The identification of a genetic abnormality in any member has wide-ranging implications for the whole family. It is appropriate to consider all family members when planning diagnosis and treatment. Parents should be counseled about risks of the problem in

Figure 6 Urogenital sinogram showing urethra, vagina, and cervical indentation (same patient as in Fig. 4).

their other children and future pregnancies. All siblings of the index case have a 25% risk of having 21-hydroxylase deficiency and, hence, should be screened.

Prenatal Diagnosis and Treatment

Preconception counseling should be provided to carrier parents given that there is a 25% risk of an affected fetus in all of their pregnancies. Both parents and the index case should be genotyped if prenatal diagnosis is desired. There are two alternative approaches to prenatal diagnosis. One is to establish the HLA haplotypes for the index case and both parents and then compare them with the haplotype of the fetus. The other is to identify the CYP21 mutation in the index case and screen the fetus for the same mutation. Prenatal treatment with dexamethasone is started as early as the fifth week in the pregnancy. The sex of the fetus is established first by

chorionic villus sampling and a fluorescence *in situ* hybridization (FISH) test using Y-sequence probes. If the fetus is female, further testing is carried out to determine whether classical 21-hydroxylase deficiency is present. The dexamethasone treatment is continued to term only if the fetus is an affected female and is discontinued in other pregnancies with a male or an unaffected female fetus. There are no significant side effects of dexamethasone treatment prior to diagnosis at 9 to 11 weeks in the unaffected fetus or pregnant mother. However, the sudden cessation of dexamethasone may cause steroid withdrawal symptoms (e.g., peeling skin, malaise, hypotension). When dexamethasone treatment is continued to term, the mother tends to gain more weight and is also at risk for high blood pressure, emotional disturbances, loss of bone mineral density, and glucose intolerance. Prenatal treatment has been shown to be effective in reducing genital virilization, and in two-thirds of cases, the genitalia of the infant are either normal or so minimally virilized that surgery is not required. Follow-up studies are not yet available to show whether the treated children are less masculine in their behavior or less prone to confusion about their gender identity.

PUBLIC HEALTH ISSUES

Classical 21-hydroxylase deficiency is a condition that fulfills all of the recommended criteria for newborn screening. The incidence of the disorder in the general population is relatively high, the condition can result in high morbidity and mortality if left undetected, effective treatment is available, and (most important) the means exist for reliable and efficient newborn screening. In general, a blood sample collected and dried on filter paper on day 2 or 3 of life is analyzed for 17-hydroxyprogesterone. Neonatal screening detects cases of CAH that are not suspected clinically. Lives are saved and incorrect gender assignments are prevented. In addition, the early diagnosis of non-salt-losing classical 21-hydroxylase deficiency permits early treatment, and this prevents progressive virilization and loss of adult potential.

FUTURE RESEARCH ISSUES

Most of the adverse outcomes in children treated for classical 21-hydroxylase deficiency are attributable to the side effects of the supraphysiological doses of glucocorticoids that are prescribed in an attempt to lower elevated levels of adrenal androgens. Some alternative therapies are being evaluated.

Peripheral Blockade of Androgen Action

The basis of this alternative approach lies in using a reduced dose of steroids in combination with drugs that block androgen action. An androgen antagonist such as flutamide is used, and an aromatase inhibitor is used to block the conversion of androgen to estrogen. Estrogen blockade is essential because estrogens can advance skeletal maturity and induce premature epiphyseal fusion. Preliminary results from this trial have shown promising results in the short term, with normalized growth rates and bone maturation. Treatment of a pregnant woman with androgen blockers can interfere with normal sex differentiation in a male fetus, and sexually active women should be cautioned to use contraception.

Intra-adrenal Blockade of Androgen Production

This approach takes an additional step in preventing the excess androgen production at the adrenal level without resorting to high doses of hydrocortisone. Ketoconazole blocks adrenal steroid production at several enzymatic steps and can potentially reduce androgen production at the adrenal level. In the future, ongoing pharmaceutical research may provide a specific 17,20-lyase inhibitor capable of blocking the conversion of 17-hydroxyprogesterone to androstenedione.

CRH/ACTH Antagonists

The tropic hormone ACTH primarily drives adrenal hypersecretion of androgens, and if ACTH antagonists were to become available, they would represent a potential new approach to the treatment of classical 21-hydroxylase deficiency. The genes controlling the melanocortin receptor superfamily (of which the ACTH receptor is one member) have been cloned.

Corticotropin-releasing hormone (CRH) antagonists can also be used to inhibit ACTH release and break the negative feedback loop. The administration of a CRH antagonist, antalarmin, to rats decreases ACTH and cortisol secretion without causing overt adrenal insufficiency.

Adrenalectomy

Adrenalectomy is advocated as a treatment for classical 21-hydroxylase deficiency by some endocrinologists. Although still a controversial matter, it is

gaining credibility and acceptance. The benefit of this approach is that lower steroid doses can be used, with fewer side effects, because there is no longer the need to suppress adrenal androgens. Adrenalectomy can be done using a laparoscopic approach, which is safer and more convenient than open surgery. Suitable candidates for adrenalectomy are patients with a null mutation in CYP21 because their adrenal glands are performing no useful function. Lifelong glucocorticoid and mineralocorticoid replacement therapy is essential following adrenalectomy.

Gene Therapy

The 21-hydroxylase gene is exclusively localized in the adrenal cortex, making it a suitable candidate for tissue-targeted gene therapy. Precise regulation is not absolutely essential given that modestly increased gene expression is not harmful and, moreover, the cortisol pathway is tightly regulated by a negative feedback mechanism. An animal model of classical 21-hydroxylase deficiency, the 21-hydroxylase-deficient mouse, has been used to test gene therapy. The experiments involved adenoviral transfection of the adrenals with the normal human CYP21 gene. The results were promising. Provided that metabolic regulation can be obtained, gene therapy may become an ideal treatment for the future.

LHRH Agonist/GH Therapy

LHRH analogues are useful to control rapid progression of central precocious puberty and to optimize growth in a child. Growth hormone (GH) administration is shown to increase adult height in children with idiopathic short stature or Turner syndrome. LHRH analogue treatment for precocious puberty in children with classical 21-hydroxylase deficiency has been shown to improve final adult height, with or without GH therapy.

Deferment of Genital Surgery

The ethics of carrying out feminizing genital surgery in an infant or a child too young to give consent has been questioned. Certain patient advocacy groups recommend that cosmetic genital surgery be deferred until the patient is old enough to give informed consent and to indicate his or her preferences. In our opinion, this is not an approach applicable to genetic females with classical 21-hydroxylase deficiency

because they are fertile and because nearly all of them grow up identifying as female.

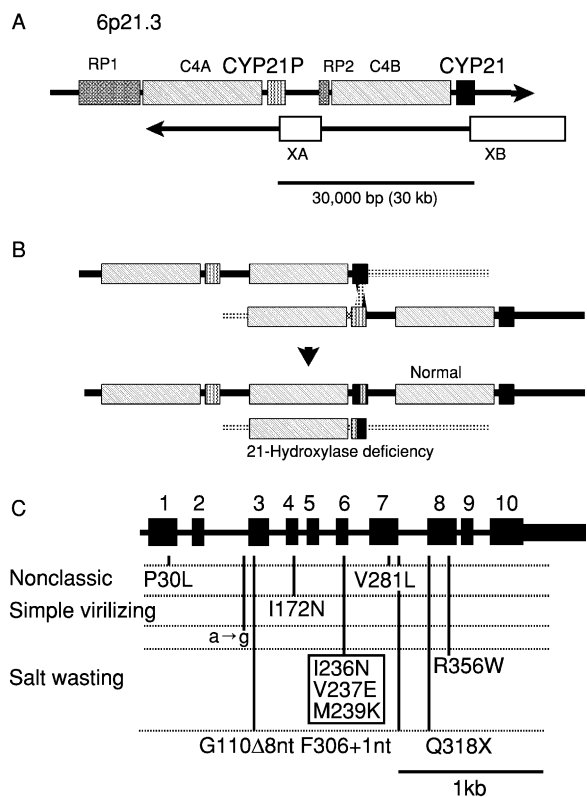

Figure 1 Genetics of steroid 21-hydroxylase deficiency. (A) Map of the genetic region around the 21-hydroxylase (*CYP21*) gene. Arrows denote the direction of transcription. *CYP21P*, 21-hydroxylase pseudogene; *C4A* and *C4B*, genes encoding the fourth component of serum complement; *RP1*, gene encoding a putative nuclear protein of unknown function; *RP2*, truncated copy of this gene. *XB*, tenascin-X gene (not shown full length). and *XA*, a truncated copy of this gene, are on the opposite chromosomal strand. (B) An unequal crossover generating a *CYP21* deletion. For clarity, only the two *C4* and two *CYP21* genes are shown on each chromosome. When these are misaligned during meiosis, a crossover can generate two daughter chromosomes—one with three copies of the *C4*–*CYP21* tandem and the other with one copy. The latter is often a 21-hydroxylase deficiency allele. (C) Diagram of a *CYP21P* gene. Exons are numbered. *CYP21P* has nine mutations that may be transferred into *CYP21* by gene conversion, causing 21-hydroxylase deficiency. These are arranged in the diagram so that those causing increasing enzymatic compromise are arrayed from top to bottom. Dotted lines divide mutants into groups with similar activities. The mutations at the bottom are nonsense mutations or frameshifts that are predicted to completely prevent protein synthesis. The mutations are associated with different forms of 21-hydroxylase deficiency as marked. As an example of mutation terminology, P30L is proline-30 to leucine. a→g is a mutation at nucleotide (nt) 656 in intron 2. The three mutations in the box are invariably inherited together. There are several dozen additional rare mutations that collectively account for 5% of all 21-hydroxylase deficiency alleles (not shown). Δ, deletion; +, insertion. Other single-letter amino acid codes: A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine.

overlaps a truncated copy of this gene (*TNXA*) that does not encode a functional protein.

CYP21 is located approximately 600 kb centromeric of HLA-B and 400 kb telomeric of HLA-DR. It is transcribed in the telomeric to centromeric direction.

CYP21 and *CYP21P* each contain 10 exons spaced over 3.1 kb. Their nucleotide sequences are 98% identical in exons and approximately 96% identical in introns. *CYP21P* contains several mutations preventing synthesis of a functional protein, including an A→G substitution 13 nucleotides (nt) before the end of intron 2 that results in aberrant splicing of pre-mRNA; an 8-nt deletion in exon 3 and a 1-nt insertion in exon 7, each of which shifts the reading frame of translation; and a nonsense mutation in codon 318 of exon 8. There are also eight missense mutations.

HLA LINKAGE

Congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency is inherited as a monogenic autosomal recessive trait closely linked to the HLA complex, meaning that siblings who have 21-hydroxylase deficiency are almost invariably HLA identical. Before cloning of *CYP21*, HLA typing was the main way to perform prenatal diagnosis. In addition, particular forms of 21-hydroxylase deficiency are associated with particular combinations of HLA antigens or haplotypes; this phenomenon is referred to as genetic linkage disequilibrium. An association between the salt-wasting form of the disease and HLA-A3;Bw47;DR7 is most characteristically seen in northern European populations. In addition to 21-hydroxylase deficiency, this haplotype usually carries a null allele at one of the two *C4* loci encoding the fourth component of serum complement. This represents a contiguous gene syndrome due to a single deletion of *C4B* and *CYP21* genes. The nonclassic form of 21-hydroxylase deficiency is often associated with HLA-B14;DR1, particularly in eastern European Jewish populations. This haplotype is associated with the V281L mutation in *CYP21* and with a duplication of complement *C4A* and the *CYP21P* pseudogene. Finally, HLA-A1;B8;DR3 is negatively associated with 21-hydroxylase deficiency. This haplotype has a *C4A* null allele and is associated with deletion of the *C4A* and *CYP21P* genes. Thus, even before the genes were sequenced, comparison of a very few individuals homozygous for HLA-A3;Bw47;DR7 or A1;B8;DR3 strongly suggested that the *CYP21* gene was an active gene, whereas *CYP21P* was a pseudogene.

MUTATIONS CAUSING 21-HYDROXYLASE DEFICIENCY

Approximately 95% of mutations causing 21-hydroxylase deficiency are apparently the result of either of two types of recombinations between *CYP21*, the normally active gene, and the *CYP21P* pseudogene. These two mechanisms are unequal crossing-over during meiosis, resulting in a complete deletion of *C4B* and a net deletion of *CYP21*, or apparent gene conversion events that transfer deleterious mutations normally present in *CYP21P* to *CYP21*.

Because particular mutations occur in many unrelated kindreds, each mutation, and the degree of enzymatic compromise it causes, may be correlated with the different clinical forms of 21-hydroxylase deficiency (i.e., salt wasting, simple virilizing, and nonclassic disease). In addition, the functional effects of missense mutations have been assessed *in vitro* by recreating them in *CYP21* cDNA and expressing the mutant cDNA in cultured mammalian cells or yeast.

Deletions and Large Gene Conversions

Large deletions involving *C4B* and *CYP21* comprise approximately 20% of alleles in patients with classic 21-hydroxylase deficiency in most populations but are rarer in some Latin American countries. Deletions usually extend approximately 30 kb from somewhere between exons 3 and 8 of *CYP21P* through *C4B* to the corresponding point in *CYP21*, yielding a single remaining *CYP21* gene in which the 5'-end corresponds to *CYP21P* and the 3'-end to *CYP21*. Deleterious mutations within the *CYP21P* portion render such a gene incapable of encoding an active enzyme. All patients who carry homozygous deletions suffer from the salt-wasting form of the disorder.

Unequal crossovers may occur anywhere within the duplicated 30-kb region, including the *RP*, *C4*, and *TNX* genes, but only crossover breakpoints within or 3' of the *CYP21* genes cause 21-hydroxylase deficiency. There is apparently no strong selection against chromosomes with one or three copies of the 30-kb region as long as *CYP21* remains intact, and such rearrangements are seen on 16 and 12% of chromosomes 6, respectively.

One kindred has been described that carries an unusual deletion extending into the *TNXB* gene. The patients in this kindred have a contiguous gene syndrome including 21-hydroxylase deficiency and a form of Ehlers-Danlos syndrome due to loss of function of tenascin-X.

In most studies, deletions have been detected by genomic blot hybridization as an absence (or diminished intensity in heterozygotes) of gene-specific fragments produced by digestion with several restriction enzymes. Large gene conversions, in which multiple mutations are transferred from *CYP21P* to *CYP21*, are also detected by this approach when gene-specific restriction endonuclease sites are affected. Large conversions account for approximately 10% of alleles in classic 21-hydroxylase deficiency.

Reliable differentiation of deletions and large gene conversions requires analysis of several different restriction digests in which the sites used to distinguish *CYP21P* and *CYP21* are widely spaced. This is required because the remaining *CYP21*-like gene on a chromosome with a deletion consists of the 3'-end of *CYP21* "spliced" onto the 5'-end of *CYP21P* so that the missing fragment in each restriction digest does not necessarily correspond in size to the *CYP21*-specific fragment in normal chromosomes. In practice, genomic blot hybridizations are no longer routinely used for molecular diagnosis because they are more laborious and less informative than polymerase chain reaction (PCR)-based techniques. However, PCR cannot distinguish deletions from large gene conversions.

Nonsense and Frameshift Mutations

Two other mutations normally found in *CYP21P* completely prevent synthesis of an intact enzyme and cause salt-wasting 21-hydroxylase deficiency if they occur in *CYP21*: the nonsense mutation in codon 318 (Q318X) and the 8-nt deletion in exon 3. The 1-nt insertion in exon 7 of *CYP21P* has generally not been identified as an independent mutation in patients with 21-hydroxylase deficiency.

Mutations Affecting Pre-mRNA Splicing

The nucleotide 13 bp before the end of intron 2 (nt656) is A or C in normal individuals. Mutation to G constitutes the single most frequent allele causing classic 21-hydroxylase deficiency.

This mutation causes aberrant splicing of intron 2 with retention of 19 nucleotides normally spliced out of mRNA, resulting in a shift in the translational reading frame. Almost all of the mRNA is aberrantly spliced, but in cultured cells a small amount of normally spliced mRNA is detected. If no other mutations were present, a small amount of normal enzyme might thus be synthesized.

It is not known what proportion of mRNA is normally spliced in the adrenal glands of patients with this mutation. Most (but not all) patients who are homozygous or hemizygous for this mutation have the salt-wasting form of the disorder, indicating that they have insufficient enzymatic activity to permit adequate aldosterone synthesis. Occasionally, presentation of salt-wasting signs is delayed until several months of age in patients carrying this mutation. Putative asymptomatic nt656g homozygotes have been reported but in fact represent PCR typing artifacts.

Missense Mutations

The missense mutations found in *CYP21P* have varying effects on enzymatic activity when transferred into *CYP21* as gene conversions; they are discussed in ascending order of severity.

Two mutations with relatively mild effects on activity are found most frequently in patients with nonclassic 21-hydroxylase deficiency. V281L occurs in all or nearly all such patients who carry the HLA haplotype B14;DR1, an association that is presumably due to a founder effect. In certain populations (such as Jews of eastern European origin), this is a very common genetic polymorphism, with a gene frequency of more than 10%. In contrast, direct molecular screening of normal newborns in New Zealand yielded a carrier frequency of 2%. Overall, approximately 70% of all nonclassic alleles carry the V281L mutation. This mutation results in an enzyme with 50% of normal activity when 17-hydroxyprogesterone is the substrate but only 20% of normal activity for progesterone. One study suggested that the mutant enzyme is not normally localized in the endoplasmic reticulum, whereas another proposed that heme binding was affected.

The P30L mutation also yields an enzyme with 30–50% of normal activity when expressed in cultured cells. However, enzymatic activity is rapidly lost when the cells are lysed, suggesting that the enzyme is relatively unstable. Patients carrying this mutation tend to have more severe signs of androgen excess than patients carrying V281L. P30L is found in approximately one-sixth of alleles in patients with nonclassic disease, but it may comprise a higher percentage of such alleles in Japan.

As is the case with other microsomal P450 enzymes, *CYP21* is targeted and anchored to the membrane of the endoplasmic reticulum mainly by a hydrophobic “tail” at the amino terminus; this tail is required for enzymatic activity and stability. Most

P450 enzymes have one or more proline residues separating this tail from the remainder of the polypeptide. These residues are predicted to create a turn in the polypeptide chain, and P30L may abolish this turn. Based on studies of other P450 enzymes, this may lead to improper folding of the polypeptide and may interfere with localization in the endoplasmic reticulum. Indeed, the P30L mutant of *CYP21* is poorly localized to the endoplasmic reticulum in some but not all studies.

The I172N mutation is the only one specifically associated with the simple virilizing form of the disease. It results in an enzyme with approximately 1% of normal activity. Improper localization to the endoplasmic reticulum has been demonstrated in some but not all studies. The mutation may disrupt an intramolecular hydrophobic interaction, stabilizing the secondary structure of the enzyme. The mutant enzyme is abnormally sensitive to protease digestion and does not incorporate heme properly.

Because aldosterone is normally secreted at a rate 100–1000 times less than that of cortisol, it is apparent that 21-hydroxylase activity would have to decrease to very low levels before it became rate limiting for aldosterone biosynthesis. Apparently, as little as 1% of normal activity allows sufficient aldosterone synthesis to prevent significant salt wasting in most cases. R356W and a cluster of three missense mutations (I235N/V236E/M238K) both abolish enzymatic activity.

Other Mutations

Mutations that are apparently not gene conversions (i.e., they are not usually found in *CYP21P*) account for 5–10% of 21-hydroxylase deficiency alleles in most populations. The most frequent of these is P453S, which occurs in a number of different populations. This suggests that *CYP21P* may carry P453S as an occasional polymorphism and that this mutation is transferred to *CYP21* in the same way as the other mutations frequently causing 21-hydroxylase deficiency.

Novel mutations are easy to detect using automated sequencing technologies in centers with well-developed prenatal or neonatal screening programs and thus have been reported at an increased rate during the past few years; most are unique. However, several codons, including W22, P30, G291, R356, and R483, have undergone several independent mutations; thus, these areas may be hot spots for such events.

Normal Polymorphisms

Several normal polymorphisms have been detected in *CYP21* in the course of initial sequencing of cloned genes by several groups. An extra leucine near the N terminus (this has confused numbering of other mutations in some reports) and D183E also occur in *CYP21P* and presumably represent gene conversions that do not affect activity. K102R, S268T, and N493S do not represent gene conversions.

DE NOVO RECOMBINATIONS

CAH is unusual among genetic diseases in the high proportion of mutant alleles generated by intergenic recombination. Both *de novo* deletions and *de novo* gene conversions have been documented; the latter usually involve the intron 2 nt656g mutation and comprise approximately 1% of 21-hydroxylase deficiency alleles.

De novo recombinations involving *CYP21* have also been documented by PCR in normal sperm and leukocytes. Unequal crossing over is detected only in sperm, confirming that this process takes place only during meiosis. Gene conversions, however, take place at equal frequencies in somatic cells and gametes, suggesting that gene conversions occur mainly in mitosis and that meiotic recombination (i.e., double crossing over) contributes little, if at all, to this process.

The high rate of recombinations involving the *CYP21* genes may reflect their location in the major histocompatibility complex, in which a high recombination rate between genes encoding transplantation antigens may increase the diversity of the immune response and be evolutionarily favored. The mechanism by which recombination rates might be increased is not known.

In addition, both *CYP21* and *CYP21P* have high rates of single nucleotide polymorphisms, particularly in intron 2. The significance of this is uncertain, but it may mean that additional mechanisms besides intergenic recombination generate sequence diversity within the major histocompatibility complex.

CORRELATIONS BETWEEN GENOTYPE AND PHENOTYPE

The classification of 21-hydroxylase deficiency into salt wasting, simple virilizing, and nonclassic types is a useful way to roughly grade the severity of the disease and to predict the therapeutic interventions

that will likely be required. If molecular diagnosis could predict this classification, it would increase the utility of prenatal diagnosis and neonatal screening and it might serve as a useful diagnostic adjunct to ACTH stimulation tests.

The simplest way to correlate genotype and phenotype is to determine which mutations are characteristically found in each type of 21-hydroxylase deficiency. This is most informative for frequently occurring mutations. As mentioned previously, deletions and large conversions are most often found in salt-wasting patients, the intron 2 nt656g mutation is found in both salt-wasting and simple virilizing patients, I172N is characteristically seen in simple virilizing patients, and V281L and P30L are found in nonclassic patients. This distribution is consistent with the compromise in enzymatic activity conferred by each mutation.

However, patients are usually compound heterozygotes for different mutations, and so this approach has little predictive value in itself. A useful analytic strategy is to consider that 21-hydroxylase deficiency is a recessive disease, and thus the phenotype of each patient is likely to reflect his or her less severely impaired allele. If mutations are provisionally classified by the degree of enzymatic compromise—severe (also termed type A), moderate (type B), or mild (type C)—then one might hypothesize that salt-wasting patients would have severe/severe genotypes; simple virilizing patients would have severe/moderate or moderate/moderate genotypes; and nonclassic patients would have severe/mild, moderate/mild, or mild/mild genotypes. Approximately 90% of patients can be correctly classified in this manner.

The salt wasting, simple virilizing, and nonclassic categories are qualitative in nature, and the distinction between simple virilizing and nonclassic disease is necessarily difficult in males in whom signs of androgen excess cannot be detected at birth. Therefore, attempts have been made to correlate genotype with quantitative measures of disease severity, such as basal and ACTH-stimulated 17-hydroxyprogesterone levels, plasma renin:urinary aldosterone ratios, and Prader genital virilization scores. In general, these are no better correlated with genotype than are the broader clinical categories. There is excellent discrimination between severe and mild genotypes but a high degree of overlap between moderate genotypes and those either more and less affected.

Several explanations for the less than complete correspondence between genotype and phenotype are possible. The most obvious is that the severity of the disease falls on a continuum and patients with

disease severity near the “borders” of the various classifications may easily fall on either side of these borders. Several mutations and genotypes seem to be particularly associated with this problem. First, although the intron 2 nt656g mutation is classified as severe, it is clearly “leaky” and may yield enough normally spliced mRNA to ameliorate the enzymatic deficiency in some patients. Second, the I172N mutant has marginal enzymatic function (1% of normal), and this apparently is not always sufficient to prevent salt wasting. Third, many patients who are “discordant” for genotype and phenotype are compound heterozygotes for mutations with different effects on enzymatic activity; thus, some of these patients may have *in vivo* enzymatic activities intermediate between those seen in patients who are homozygous for each mutation. Consistent with this idea, presumed compound heterozygotes for a classic and nonclassic allele as a group have higher stimulated 17-OHP levels than presumed homozygotes for nonclassic alleles. Fourth, in studies relying on detection of known mutations, additional novel mutations within *CYP21* might not be detected and might adversely affect activity.

Finally, genetic or environmental factors other than 21-hydroxylase activity may influence phenotype. For example, genetically based variations in androgen biosynthesis or sensitivity to androgens would be expected to influence the expression of signs of androgen excess.

MOLECULAR DIAGNOSTICS

One of the most troubling signs of classic 21-hydroxylase deficiency is genital ambiguity in affected females caused by excessive exposure to adrenal androgens *in utero*. This may be at least partially prevented by administration of dexamethasone to the mother starting as early as possible in each pregnancy. Unnecessary treatment of males and unaffected females may be minimized by prenatal diagnosis using chorionic villus sampling and direct detection of *CYP21* mutations after amplification of the gene using PCR. This approach detects mutations on 95% of chromosomes. The same technology can be used as

an adjunct to hormonally based newborn screening for 21-hydroxylase deficiency, although it has not been widely implemented.

A number of sources of confusion should be kept in mind in carrying out molecular diagnosis of this disorder. First, gene conversions may transfer several adjacent mutations to *CYP21* so that more than one mutation may be observed on a single chromosome. Second, if PCR is used to specifically amplify *CYP21*, gene conversions involving the sites used for the primers may prevent one or both chromosomes from being amplified, leading to inaccurate genotyping. This problem is detected by performing PCRs in several overlapping segments. Third, a small percentage of alleles are *de novo* mutations. Fourth, particular mutant alleles may be preferentially amplified in PCR, causing heterozygotes to be typed as homozygous affected.

These problems are addressed by examining parents to determine segregation of each mutation and thus ensure that mutations have been identified on both chromosomes in the proband. Use of highly polymorphic microsatellite markers linked to *CYP21* can help identify affected chromosomes when a proband is available.

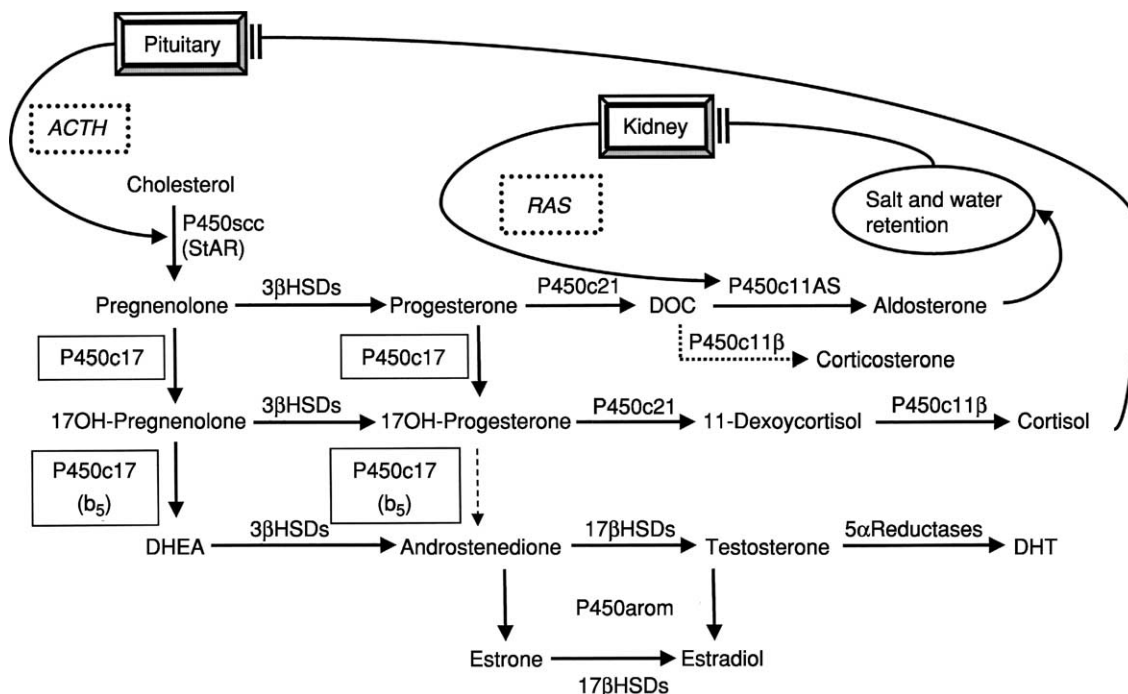

Figure 1 Major human steroidogenic pathways, highlighting the roles of P450c17. Aldosterone synthesis does not use P450c17; in contrast, cortisol production requires 17 α -hydroxylase activity, and sex steroid biosynthesis requires 17,20-lyase activity as well. The synthesis of cortisol is regulated by ACTH, and cortisol feeds back to attenuate ACTH secretion. Aldosterone production is mainly controlled by the renin-angiotensin system (RAS).

to the appearance of a “17,20-lyase enzyme” in the adrenal glands, but when P450c17, which is present in the adrenal glands from birth, was shown to possess both 17 α -hydroxylase and 17,20-lyase activities, alternate explanations for the acquisition of adrenal DHEA synthesis were sought. Thus, 17,20-lyase activity is not only controlled in a tissue-specific manner but also, in the adrenal glands, it is regionally and temporally or developmentally regulated. These phenomena are partially explained by the biochemistry of P450c17.

Biochemistry

P450c17 is a 57-kDa “microsomal” cytochrome P450 located in the smooth endoplasmic reticulum. P450c17 receives two electrons from NADPH via the flavoprotein P450 oxidoreductase (CPR) in two discrete one-electron steps, with substrate and molecular oxygen binding between these transfers of electrons. Although the catalytic cycle of P450c17 uses the same initial steps whether pregnenolone, progesterone, or their 17 α -hydroxylated derivatives are substrates, P450c17 catalyzes at least three fundamentally distinct chemical transformations. First, the

17 α -hydroxylase reaction is a typical P450-mediated hydroxylation, in which an oxygen atom derived from molecular oxygen is inserted into a C–H bond. Human P450c17 also 16 α -hydroxylates at least progesterone and DHEA, presumably by the same mechanism. Second, human P450c17 converts 17 α -hydroxysteroids to C₁₉ steroids via the 17,20-lyase reaction, in which a carbon–carbon bond is oxidatively cleaved to yield the 17-ketosteroid and acetic acid. Unlike the 17 α -hydroxylase reaction, which is approximately equally efficient for both Δ^5 and Δ^4 steroids, the human 17,20-lyase reaction is approximately two orders of magnitude more efficient with the Δ^5 steroid 17 α -hydroxypregnenolone than with its Δ^4 analog, 17 α -hydroxyprogesterone. This discrepancy results from the combination of a 10-fold higher K_m and a 10-fold slower V_{max} for 17 α -hydroxyprogesterone compared to 17 α -hydroxypregnenolone. Kinetic constants obtained for the four principal reactions using his-tagged modified P450c17 purified from *Escherichia coli* and native microsomal P450c17 expressed in yeast are remarkably consistent, confirming differences in both affinity and steady-state turnover rates for the 17,20-lyase substrates.

Third, in the presence of cytochrome b₅, an alternate pathway of pregnenolone metabolism forms androst-5,16-diene-3 β -ol via a different carbon-carbon bond cleavage reaction. In pigs, this pathway forms pheromones, but the roles of these $\Delta^{5,16}$ -dienes in humans are not known.

The electron transfer proteins CPR and cytochrome b₅, collectively referred to as redox partners, profoundly influence both the rate of P450c17 catalysis and the ratio of the 17 α -hydroxylase and 17,20-lyase activities. Increased abundance of CPR favors the 17,20-lyase reaction, which ordinarily occurs at a rate only 1–10% as fast as the 17 α -hydroxylations. More dramatically, the addition of cytochrome b₅ to either purified, modified human P450c17 in reconstituted assay systems or yeast microsomes containing P450c17 and CPR increases 17,20-lyase activity more than 10-fold. At least equimolar amounts of cytochrome b₅ relative to P450c17 are required to augment 17,20-lyase activity, but very high molar ratios inhibit catalytic activity, probably by competing with P450c17 for electrons from CPR. Furthermore, apob₅, which lacks a heme and therefore cannot participate in electron transfer reactions, stimulates 17,20-lyase activity just as well as does holob₅ but does not inhibit it at higher molar ratios. These data indicate that cytochrome b₅ does not act as an electron donor to P450c17 but acts as an allosteric facilitator of the P450c17–CPR catalytic complex. Although the mechanisms whereby CPR and cytochrome b₅ regulate P450c17 activities are not fully elucidated, it is clear that these proteins can profoundly modulate the 17,20-lyase activity of P450c17.

Also influencing 17,20-lyase activity is serine phosphorylation of P450c17. When P450c17 is dephosphorylated *in vitro*, it loses nearly all of its 17,20-lyase activity, but 17 α -hydroxylase activity is not affected. The specific serine residues involved and the responsible kinase have not been identified, so the mechanism by which phosphorylation increases 17,20-lyase activity is unknown but may also be involved in fostering the interaction of P450c17 with its redox partners.

CLINICAL MANIFESTATIONS

Combined 17 α -Hydroxylase/ 17,20-Lyase Deficiency

Although rodents survive admirably without adrenal P450c17, mutations in the *CYP17* gene do cause human disease. Patients with combined 17 α -hydroxylase/

17,20-lyase deficiency (17-OHD) cannot make cortisol, but they do make corticosterone. The lower glucocorticoid potency of corticosterone compared to cortisol results in increased production of cortisol precursors when adrenal 17 α -hydroxylase activity is absent. Consequently, the zona fasciculata produces increased amounts of corticosterone and 11-deoxycorticosterone (DOC) in 17-OHD, and the potent mineralocorticoid activity of DOC causes hypertension and hypokalemia while suppressing plasma renin activity and the secretion of aldosterone from the zona glomerulosa (Fig. 2). Hypertension can begin at any age from infancy to late adulthood and can become fixed if not treated for several years.

Mutations that are completely devoid of enzyme activity cause sexual infantilism and failure to progress into puberty (and adrenarche). Genetically female patients can have substantial breast development and cyclical menses if only a small percentage of activity is retained. Genetically male patients with complete deficiencies also have female external genitalia and remain prepubertal. In contrast, partial 17-OHD leads to undervirilization and sexual ambiguity in 46,XY individuals. The potential for further virilization at puberty with appropriate hormonal replacement therapy must be considered when assigning a sex of rearing and developing a management strategy for these patients.

Isolated 17,20-Lyase Deficiency

Cases of isolated 17,20-lyase deficiency (ILD) were described in the early 1970s, when it was believed that 17 α -hydroxylase and 17,20-lyase were distinct enzymes. Subsequent clinical studies and genetic analyses of the *CYP17* genes from some of these early cases proved that they were actually examples of partial 17-OHD, demonstrating that ILD is not only difficult to diagnose, especially in the newborn, but also either extremely rare or did not exist. By definition, P450c17 mutations in patients with ILD must retain most 17 α -hydroxylase activity; therefore, these patients do not suffer any consequences attributable to adrenal 17 α -hydroxylase deficiency. However, ILD patients have varying degrees of impaired sexual development and intersex features depending on the genetic sex and the severity of the mutation. The few cases studied are 46,XY individuals with sexual ambiguity, but this male predominance probably represents an ascertainment bias because genetic females with ILD might not come to medical attention unless the deficiency was severe enough to cause amenorrhea or pubertal failure.

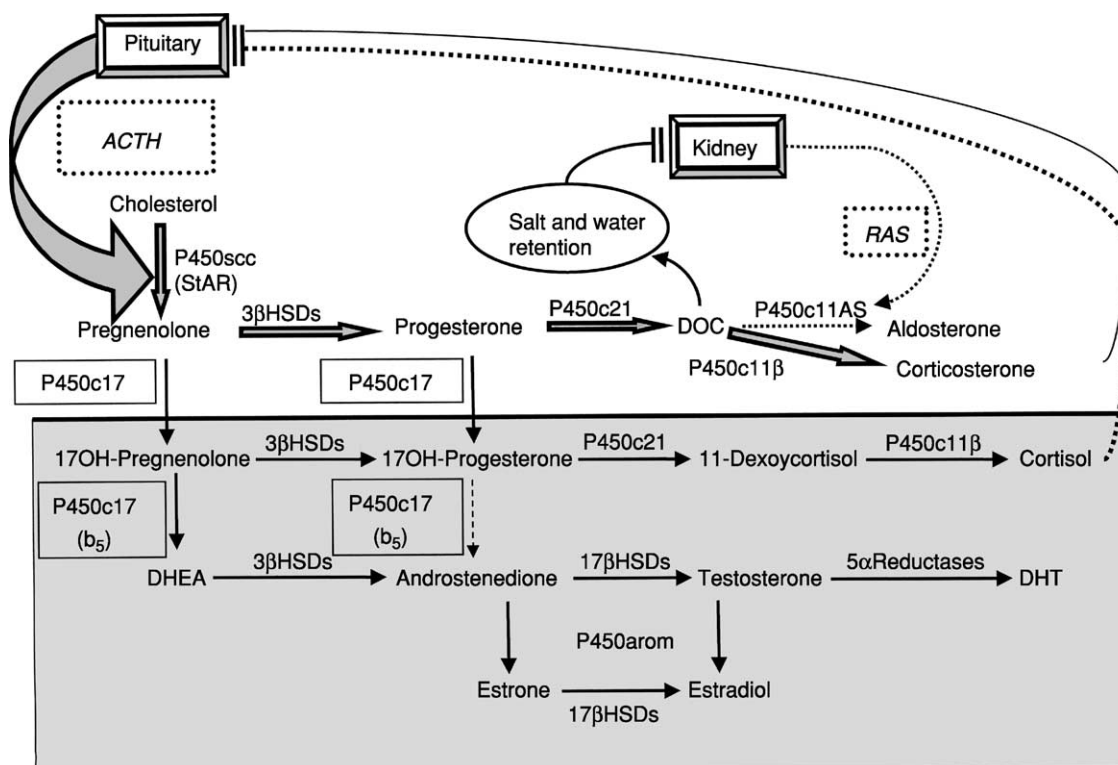

Figure 2 Deranged pathways in 17-OHD. The absence of P450c17 activities abrogates cortisol and sex steroid production (shaded region). Lack of cortisol relieves the negative feedback at the pituitary, and ACTH production increases. Abundant production of corticosterone, a weak glucocorticoid, compensates for the lack of cortisol, but the potent mineralocorticoid 11-deoxycorticosterone (DOC) accumulates and causes salt and water retention, hypertension, and suppression of renin and aldosterone.

MOLECULAR GENETICS

Combined 17 α -Hydroxylase/ 17,20-Lyase Deficiency

Deletions, Truncations, Frameshifts, and Splicing Errors

Although no complete deletions of the *CYP17* gene have been reported, the substitution of 518 base pairs (bps) (comprising most of exon 2 and part of exon 3) with 469 bps of unknown DNA has been found to cause 17-OHD (Table I). The first reported P450c17 mutation was the duplication of a CATC following Ile479. This 4-bp duplication was originally observed in Canadian Menonites but has subsequently been found in at least six Dutch Frieslander families. This mutation leaves 95% of the protein unaffected and creates a mutant enzyme in which only the last 25 residues are altered, but the encoded protein is wholly devoid of enzymatic activity. The crucial nature of the carboxy terminus of P450c17 is also indicated by the complete absence of activity when 9 bps are deleted in-frame, removing residues Asp487, Ser488, and Phe489 within the last 17 residues of the protein.

Computer modeling suggests that the P450c17 polypeptide chain forms two sets of strands for two β -sheet units before terminating at the protein surface. In forming these β -sheets, the last 45 residues fold down from the protein surface into the protein core to a point above the heme, forming the top of the substrate-binding pocket and probably contributing structural elements required for catalysis. Thus, the mutation altering the reading frame after Ile479, the mutation deleting residues 487–489, and the mutation Gln461→stop all disrupt or lack this critical stretch of residues and hence are inactive despite retaining the heme binding site.

Several other truncations, frameshifts, and splicing mutations have been described as early as codons 1 and 17 and as late as codon 438. All these errors delete Cys442, which forms the axial sulfhydryl ligand to the heme iron and is thus essential for enzyme activity.

Missense Mutations/Single Amino Acid Changes

Amino acid substitution mutations in P450c17 can be grouped into mutations in or near the

Table I Mutations Causing 17-OHD: Insertions, Deletions, Frameshifts, and Truncations

^bND, not determined.

substrate-binding pocket, mutations in or near the heme-binding region, and mutations elsewhere in the protein. Mutations Gly90Asp, Arg96Trp, Ser106Pro, and insIle112 map to the β -sheet-rich amino terminus, in or close to regions predicted to form the substrate-binding pocket, and all of these mutations are devoid of activity. The sensitivity of P450c17 to minor changes in this region of the protein is further demonstrated by the finding that the conservative replacement of Ser106 with Thr, the corresponding residue found in rainbow trout P450c17, also abolishes most enzymatic activity.

The best example of a mutation that disrupts heme binding is Arg440His, located two residues away from the heme-liganding Cys442. By comparison with bacterial P450 enzymes of known structure, the positive guanidinium group on Arg440 is predicted to pair with the negative charge on one of the two propionic acid side chains of the heme protoporphyrin ring. Analogous mutations of other P450 enzymes, such as Arg435Cys in P450arom, also cause complete loss of enzyme activity. In the “meander” region, located just prior to the heme-binding domain in the linear sequence of all P450s, two P450c17 mutations have been identified. Both Phe417Cys and the adjacent mutation, Pro409Arg, completely destroy enzyme activity, probably due to impaired heme incorporation (Table II).

Mutation His373Leu yields a protein that fails to incorporate heme, but the large distance of His373 from the heme, both in linear sequence and in

predicted three-dimensional structure, suggests that this mutation causes more global structural alterations that secondarily impair heme binding. Mutation Pro342Thr retains approximately 20% residual activity, and mutations Δ Phe53/54 and Tyr64Ser retain 5–15% of wild-type 17 α -hydroxylase and 17,20-lyase activities. These proteins must incorporate heme to have activity, so the effects of these mutations, which are not directly located in crucial regions for enzyme function, must be more subtle than in the completely inactive mutations.

Isolated 17,20-Lyase Deficiency

The first published cases of ILD that were proven by molecular genetics and biochemical analyses are two 46,XY patients from rural Bahia, Brazil. These patients, from two unrelated but consanguineous families, had ambiguous genitalia and normal 17-hydroxysteroid excretion rates but markedly reduced C₁₉ steroid production. Each patient was homozygous for an arginine substitution, either Arg347His or Arg358Gln (Table II). These mutations retained the capacity to hydroxylate pregnenolone and progesterone when expressed in transfected cells or yeast microsomes. However, these mutations converted only trace amounts of 17 α -hydroxypregnenolone to DHEA when conditions were optimized by using an excess of both CPR and cytochrome b₅. Surprisingly, competition experiments using [³H]pregnenolone demonstrated that 17 α -hydroxypregnenolone binds

^cIsolated 17,20-lyase deficiency.

to the mutant enzymes with an affinity equivalent to that of the wild-type enzyme, proving that these mutations did not affect substrate access or binding.

To understand the biochemistry of these extraordinary mutations, we turned to computational chemistry for insight. Arginines 347 and 358 are located in the J' and K helices, beneath the heme ring on the distal surface of P450c17 that interacts with redox partners and on the opposite side of the heme ring from the substrate-binding pocket. The mutations Arg347His and Arg358Gln neutralize some of the positive charges predicted to lie on this surface and to interact with the negative charges in the FMN-binding domain of CPR. The neutralization of two other positive charges on this surface (lysine 89 and arginine 449) by site-directed mutagenesis also resulted in preferential loss of 17,20-lyase activity. Furthermore, the neutralization of the corresponding arginines of rat P450c17 by mutagenesis (mutation Arg346Ala in particular) also preferentially disrupted 17,20-lyase activity. The consistent loss of 17,20-lyase

activity in these mutations, despite their wide distribution in the linear sequence of P450c17, makes a compelling argument that residues 89, 347, 358, and 449 congregate in the redox partner binding site and are critical for 17,20-lyase activity. This observation is similar to those of earlier biochemical studies that highlighted the importance of CPR and cytochrome b₅ abundance for optimal 17,20-lyase reaction. Both the Arg347His mutation and a closely related Arg347Cys mutation have recently been found in Dutch patients with well-characterized ILD.

The mutation Phe417Cys was formerly implicated as a cause of ILD. Although the residue Phe417 is not predicted to lie within the redox partner binding surface, the aromatic side chain may participate in forming one edge of this surface. However, more careful study demonstrated that this mutation was completely devoid of both 17 α -hydroxylase and 17,20-lyase activities. This example illustrates the complexity of distinguishing ILD from partial 17-OHD and emphasizes the need for detailed

biochemical analyses to prove that a P450c17 mutation causes ILD. It is possible that mutations elsewhere in P450c17, such as in the active site, may cause ILD, but as of mid-2003, the only mutations proven to cause ILD all neutralize positive charges in the redox partner binding site.

Finally, one male pseudohermaphrodite with congenital methemoglobinemia due to a mutation in the gene for cytochrome b₅ has been reported. It is possible that undervirilization of this patient resulted from fetal testosterone deficiency due not to a mutation in the *CYP17* gene but, rather, the loss of the stimulatory influence of cytochrome b₅ on 17,20-lyase activity. Unfortunately, a detailed endocrine evaluation of this patient was not included with the report, but this case indicates the physiologic importance of b₅ in P450c17 physiology and androgen biosynthesis.

CONCLUSION

Human deficiencies in P450c17 can manifest clinically in a variety of forms depending on the specific enzymatic properties of the mutation. The variable clinical expression is due in part to the multiple activities and functions of P450c17 in human physiology. ILD can exist when mutations in the redox partner binding site selectively impair 17,20-lyase activity, but this disease is difficult to distinguish from partial 17-OHD. Careful clinical, genetic, and biochemical studies are necessary to precisely define diseases other than complete, classical 17-OHD.

Figure 1 Simplified scheme for steroidogenesis.

LABORATORY FINDINGS OF 3 β -HSD DEFICIENCY

An elevated ratio of Δ^5 to Δ^4 steroids is considered the best biological finding for the diagnosis of 3 β -HSD deficiency. However, it is well-known that levels of 17-hydroxyprogesterone and Δ^4 -androstenedione and other Δ^4 steroids in plasma are frequently elevated in 3 β -HSD-deficient patients. Such observations suggest functional 3 β -HSD that is expressed in peripheral tissues and responsible for extra-adrenal and extragonadal conversion of 5-ene-hydroxysteroid precursors into corresponding Δ^4 -3-ketosteroids.

The ACTH-stimulated hormonal profiles in reported non-salt-losing 3 β -HSD-deficiency children with *HSD3B2* gene mutation and in children with precocious puberty without *HSD3B2* gene mutation were unequivocally distinguished by the hormonal parameter in the C₂₁ glucocorticoid pathway. Hormonal criteria to identify inherited 3 β -HSD deficiency have been proposed based on hormonal findings in patients with genotype-proven 3 β -HSD deficiency and in those with a normal genotype (Table I).

MOLECULAR BASIS OF 3 β -HSD DEFICIENCY

The structure of the 3 β -HSD gene family has been characterized in humans and several other vertebrate species. The *HSD3B1* gene encodes a 372-amino acid protein and is mainly expressed in the placenta and peripheral tissues, such as skin and mammary glands.

In contrast, the *HSD3B2* gene encodes a 371-amino acid protein that shares 93.5% identity with *HSD3B1*, and it is expressed in the adrenal and gonads. The structures of *HSD3B1* and *HSD3B2* genes consist of four exons within a DNA fragment of 7.8 kb and have been assigned to the chromosome 1p13.1 region at 1 or 2 cM of the centromeric marker D1Z5.

Salt-Losing Form of Classic 3 β -HSD Deficiency

Nineteen different mutations have been detected in the *HSD3B2* gene in 21 patients suffering from the salt-losing form. No mutations have been detected in the *HSD3B1* gene (Table II; Fig. 2).

It is believed that no functional type II 3 β -HSD isoenzyme is expressed in adrenals and gonads of patients bearing mutations leading to a putative truncated protein (W171X, 558/insC/559, n687delC, R249X, n867delG, and Y308X), which is consistent with the severity of disease. Furthermore, A10E, E142K, Y253N, A10E, L205P, P222Q, P222T, T259M, T259R, and 687del27 mutants show no detectable activity. Therefore, in compound heterozygous patients with E142K:W171X or 186/ins/187:Y253N, it is believed that no functional type II 3 β -HSD isoenzyme is expressed. G15D mutation not only decreases the apparent affinity for both substrate and cofactor but also alters the proper intracellular localization or its association with intact membranes *in vivo*, which may exert some strain, preventing adoption of its final maximally efficient conformation. Interestingly, in the case of L108W and P186L

Figure 2 Mutations in the type II 3 β -HSD gene in patients with 3 β -HSD deficiency. Asterisks indicate homozygous mutations.

mutations, low but detectable isoenzyme activities have been detected in intact transfected cells. The L108W and P186L mutant proteins possess a marked reduced affinity for substrate and the cofactor. The *in vitro* overall efficiency was ~0.1–0.3%. Such a low level of activity is clearly inadequate for the formation of a sufficient number of mineralocorticoids to avoid severe salt losing. These findings suggest that the absence of functional type II 3 β HSD due to *HSD3B2* mutation causes the severe salt-losing form of 3 β -HSD deficiency.

Non-Salt-Losing Form of Classic 3 β -HSD Deficiency

Sixteen different point mutations have been detected in the *HSD3B2* gene in 19 families. In general, the presence of mutant 3 β -HSD in patients with non-salt-wasting 3 β -HSD deficiency corresponds closely with the severity of the disease state. L6F, A245P, L173R, G129R, A82T, A10V, and G294V mutations found as homozygous mutations showed decreased but detectable enzyme activity in transfection studies. In contrast, P155L, P222H, and Y254D mutant proteins found as compound heterozygous mutations showed no enzyme activity. Patients with N100S mutation demonstrated a poor male differentiation without severe salt losing. The overall efficiency of the N100S protein is similar to that of L108W and P186L. These findings suggest that the weak residual activity of N100S is sufficient to prevent salt loss at high renin levels, although it is insufficient for preserving normal male differentiation. Homozygous mutation T259M detected in two patients with non-salt-losing

3 β -HSD deficiency showed no 3 β -HSD activity and the instability of the mutant protein.

Interestingly, amino acids Gly15, Ala82, Asn100, Leu108, Gly129, Glu142, Leu173, Tyr253, Tyr254, and Thr259, which are the sites of the missense mutations, are conserved among all members of the vertebrate 3 β -HSD family. Therefore, characterization of the molecular basis of classical 3 β -HSD deficiency provides an understanding of the structure–function relationship of the 3 β -HSD family.

Nonclassic 3 β -HSD Deficiency

3 β -HSD deficiency in older females is called nonclassic or late-onset 3 β -HSD deficiency. However, no mutations have been detected in the coding regions, exon–intron junctions, or the 3' noncoding region, including the polyadenylation site of both *HSD3B1* and *HSD3B2* genes. The fact that no mutations have been detected in patients suffering from nonclassic 3 β -HSD deficiency suggests that this disorder does not result from a mutant type II 3 β -HSD isoenzyme.

at the level of hair follicles and derivatives of the urogenital sinus and urogenital tubercle.

The human ovary produces all three classes of steroid sex hormones: progestins (C-21 compounds), androgens (C-19 compounds), and estrogens (C-18 compounds). It differs from the adrenal gland in that it is deficient in 21-hydroxylase and 11 β -hydroxylase reactions; therefore, glucocorticoids and mineralcorticoids are not produced in ovarian tissue. The adrenal sex steroids are intermediate compounds in the production of glucocorticoids and mineralcorticoids; thus, 21-hydroxylase deficiency at the adrenal level or androgen-producing tumor cells will lead to androgen accumulation and hyperandrogenemia.

Blood Transport

Androgens are present in the bloodstream in bound and unbound forms. The androgenic activity is mediated by free unbound androgens, hence the primary importance of the free portion of androgens. One or 2% of free circulating testosterone is accepted as normal for females. The rest is bound to albumin and sex hormone-binding globulin (SHBG). This globulin is produced in the liver, and its serum levels are a sensitive marker of free testosterone and, hence, androgenic

activity. Normal-high levels of SHBG are maintained during pregnancy, hyperthyroidism, or estrogen administration. SHBG is reduced in overweight patients, those with hyperandrogenemia, or during treatment with corticoids, progestins, and growth hormones. Hyperinsulinemia, related to insulin resistance that characterizes PCOS, is marked by low SHBG levels.

ANDROGEN SOURCES

Research suggests that the main androgen production occurs in the ovaries, adrenals, and peripheral conversion sites, such as the liver, skin, and adipose tissue. In normal women, the production rate of androstenedione is 3 mg/day and that of testosterone is 0.2–0.3 mg/day, of which approximately 50% is derived from peripheral conversion of androstenedione. The remaining 50% of testosterone is produced in approximately equal amounts by the ovaries and the adrenals. In women with signs of hyperandrogenism, such as hirsutism and acne, ovarian and adrenal testosterone production may increase, accounting for up to 75% of total testosterone. Although androstenedione has the highest production rate, testosterone is the major circulating androgen and its free portion is correlated with hyperandrogenism. The testosterone

target organs are the Wolffian duct structures, such as the epididymis, the vas deferens, and the seminal vesicle. At the androgen receptor level, DHT is most important in many sensitive tissues, including hair follicles, male external genitalia, urethra, and prostate. In males, DHT is a product of intracellular testosterone conversion mediated by 5 α -reductase, whereas in females DHT is in part derived from androstenedione and DHEA. Other important androgens, particularly DHEAS, are products of the adrenals.

HYPOTHESIS UNDERLYING FUNCTIONAL HYPERANDROGENISM

Functional hyperandrogenism is not a very well-defined entity. It comes to the clinician's attention when it causes functional or esthetic inconvenience. Many authors have reported normal androgen levels in hirsute women, suggesting the presence of an idiopathic form as the most frequent cause of this problem. On the other hand, a study by Rossi *et al.* on this group of patients using two stimulation tests, gonadotropin-releasing hormone analogue triptoreline and adrenocorticotropin hormone, found mild to moderate ovarian and adrenal abnormalities in the steroidogenesis of 35.4% of these patients.

As shown in Table I, a variety of causes of functional hyperandrogenism have been noted in the literature based on ovarian, adrenal, or skin level abnormalities. Increased cutaneous 5 α -reductase with overproduction of DHT in hirsute women compared with nonhirsute causes hyperactivity of existing hair follicles and pilosebaceous glands. PCOS patients with insulin resistance and hyperinsulinemia have a

Table I Possible Causes of Functional Hyperandrogenism^a

| Skin-level abnormalities | | |
|--|---|--------------------------------|
| Increased cutaneous 5 α -reductase | → | overproduction of DHT |
| Ovarian-level abnormalities | | |
| PCOS (thickened ovarian stroma) | → | overproduction of testosterone |
| Reduced aromatization of androgens into estrogens | → | accumulation of testosterone |
| Dysregulation of the 17 α -hydroxylase/17,20-lyase enzyme complex | → | increase in testosterone |
| Adrenal-level abnormalities | | |
| Dysregulation of the 17 α -hydroxylase/17,20-lyase enzyme complex | → | increase in testosterone |

^aAbnormalities at various tissue levels will result in an increase in androgen precursors/active androgens.

thickened ovarian stroma that is capable of excessive androgen production. Reduced aromatization of androgens into estrogens at the level of granulosa cells in the ovaries of hyperandrogenic-anovulatory women results in androgen accumulation. Dysregulation of the 17 α -hydroxylase/17,20-lyase enzyme complex causes both ovarian and adrenal hyperandrogenism through accumulation of androgens due to overactivity of this enzyme complex.

SIGNS, SYMPTOMS, AND DIAGNOSIS OF HYPERANDROGENISM

Signs and Symptoms

As described in Table II, functional hyperandrogenism is usually discovered as a result of undesirable signs and symptoms. Hirsutism, defined as excess facial and body hair in women, and acne are probably the main complaints of women with hyperandrogenism. Other physical signs and symptoms include menstrual disturbances, irregular ovulation, muscle development, obesity, clitoral hypertrophy, male pattern baldness, voice deepening, and changes in libido.

Diagnosis

Diagnosis of hyperandrogenism is based on medical history, physical examination, and laboratory testing. The main purpose of these is to rule out serious underlying disorders, such as virilizing ovarian or adrenal tumors, congenital adrenal hyperplasia (CAH), or Cushing's syndrome. The most frequent causes of hyperandrogenism are PCOS and severe insulin resistance.

Medical history should take into account regular drug intake (diazoxide, glucocorticoids, cyclosporine, and phenytoin) as well as complaints, such as the

Table II Symptoms and Signs of Hyperandrogenism

| |
|------------------------|
| Hirsutism |
| Acne |
| Menstrual disturbances |
| Irregular ovulation |
| Muscle development |
| Obesity |
| Clitoral hypertrophy |
| Male pattern baldness |
| Voice deepening |
| Changes in libido |

presence and progression of hirsutism and acne, baldness, and deepening in the voice. Hyperandrogenic women often suffer menstrual irregularities with oligomenorrhea and breakthrough bleeding because of anovulation and unopposed estrogen action on the endometrium.

Physical examination will determine the amount and distribution of facial and body hair. It can be scored on a scale of 1 to 4 for 11 different body areas according to the Ferriman and Gallwey method.

Laboratory findings can be based on total and free testosterone levels, SHBG, and androstenedione as markers of ovarian androgen overproduction. On laboratory examination performed during the first days of the menstrual cycle, PCOS patients may be characterized by high luteinizing hormone levels in presence of normal follicle-stimulating hormone levels. High 17-hydroxyprogesterone levels are used to detect CAH, while high DHEAS levels may be a marker of an adrenal androgen-producing tumor.

TREATMENT

Treatment of hyperandrogenism should be directed toward the individual problem. A noteworthy feature of hirsutism is the slow response to treatment because the change in the hair growth cycle is time-consuming.

Hirsute anovulatory women wishing to conceive may be treated by ovulation induction using clomiphene citrate or gonadotropins. Azziz *et al.* performed a multicenter, double-blind, placebo-controlled trial of PCOS women treated with troglitazone, an insulin-sensitizing agent of the thiazolidinedione class. Troglitazone administration improved the ovulatory dysfunction, hirsutism, hyperandrogenemia, and insulin resistance of PCOS patients in a dose-related fashion.

If a patient is interested in a contraceptive method, an oral contraceptive is a good treatment option, particularly one that contains an antiandrogenic progestin such as cyproterone acetate, which is capable of binding to the androgen receptor.

Ovarian androgen secretion may be decreased by gonadotropin-releasing hormone analogs, which suppress pituitary follicle-stimulating hormone and

luteinizing hormone secretion. This blocks the pituitary-ovarian axis and prevents cyclic ovarian follicle development and hormonal production.

Other treatment options include spironolactone, an aldosterone antagonist diuretic, and flutamide, a nonsteroidal antiandrogen. Both act at the androgen receptor level and compete with testosterone and DHT.

The 5α -reductase activity inhibitor finasteride blocks conversion of testosterone into DHT. It is used to treat prostate cancer and can be used to treat hirsutism. Patients treated with finasteride should have an effective method of contraception because DHT is essential for the development of the urogenital sinus and urogenital tubercle into the male external genitalia, urethra, and prostate.

testosterone concentrations are approximately three or four times higher than umbilical cord concentrations (100–140 compared to 33.5 ng/dl).

Protective Mechanisms against Maternal and Fetal Virilization

Most pregnant women and their infants are not virilized despite increases in serum total and free androgen concentrations during pregnancy. Mechanisms postulated to account for this lack of virilization are discussed in the following sections.

Increased Serum SHBG Concentrations

Much of the increase in serum androgen concentrations consists of SHBG-bound androgens, with relatively little increase in free androgens. Therefore, much of the increase in circulating androgens may not be available for action at the target tissues.

Progesterone Competition for Androgen Receptor Binding

Progesterone production increases dramatically (approximately 10-fold) during pregnancy and approaches 250 mg per day at term. Despite the low affinity of androgen receptors for progesterone, the increased progesterone production is so great that there may be inhibition of testosterone binding to the androgen receptor.

Progesterone Competition for Androgen Activation at Target Tissues

Testosterone is converted in target tissues with the aid of 5 α -reductase to the more biologically active dihydrotestosterone. Progesterone also has weak affinity for 5 α -reductase, but due to its excess amount, it may inhibit conversion of testosterone to dihydrotestosterone.

Placental Androgen Aromatization

The placenta has a massive capacity to convert androgens to estrogens. Therefore, it is highly likely that most of the increased androgen production occurring during pregnancy is metabolized by the placenta, thereby affording protection from virilization to both the mother and the female fetus. In one report, a pregnant woman had a serum testosterone concentration of 15,000 ng/dl but the cord serum concentration was only 252 ng/dl. Interestingly, the cord serum concentration of estradiol was elevated compared to that of the mother, suggesting conversion of testosterone to estradiol and indicating a protective mechanism against the passage of testosterone from mother to fetus. In addition, female infants in pregnancies

complicated with placenta aromatase deficiency are virilized. These findings suggest that fetal androgen exposure may be diminished by placenta aromatization of androgen, but aromatization does not fully explain the lack of fetal virilization. In the case mentioned previously, the cord serum concentration of 252 ng/dl would normally be sufficient for virilization, but the female infant was not virilized. This finding and others suggest that decreased androgen action may also protect the female fetus against virilization in normal pregnancies.

CAUSES OF GESTATIONAL HYPERANDROGENISM

Hyperandrogenism in pregnancy is nearly always the result of conditions arising during pregnancy; hyperandrogenism in a nonpregnant woman often results in anovulation and infertility. The incidence of hyperandrogenism during pregnancy is low, with the two most common causes being gestational luteomas and hyperreactio luteinalis (theca lutein cysts of the ovary). It is important for the clinician to appreciate that an increase in androgen production in a pregnant woman can cause hirsutism and virilization in the mother and virilization of the female fetus. The extent of fetal virilization or risk to the fetus are variable, depending on the time of onset of the increased maternal androgen production, its severity, and other unknown factors.

Luteomas

Luteomas are benign, solid ovarian tumors composed of hyperplastic masses of large lutein cells. Luteomas regress and disappear after delivery; therefore, the incidence of these lesions is probably greater than reported because most are unnoticed because they secrete little androgen or have minimal hormonal effects. These subclinical luteomas may be discovered incidentally at the time of cesarean section or other surgery for unrelated reasons. There is evidence that the incidence is increased in the African American population. Pregnant women with luteomas may have increased serum concentrations of testosterone, dihydrotestosterone, and androstenedione. Maternal hirsutism or virilization are seen in approximately 30–35% of women with pregnancy-related luteomas, suggesting that either serum androgen concentrations are often not elevated significantly or androgen action is blunted. Such blunting could occur because of the increased availability of SHBG during pregnancy so that less testosterone is available to peripheral tissues

or because the tissue effects of testosterone are blunted by the actions of estrogens. There are cases suggesting resistance to androgen in which women with luteomas of pregnancy had marked elevations in serum testosterone concentrations (>2500 ng/dl) and were not virilized even though normal gestational concentrations are 50–120 ng/dl.

There is an approximately 80% chance that a female infant born to a virilized mother with a gestational luteoma will be virilized. If the mother is not virilized, neither is the infant. In order to estimate the risk of virilization to a fetus *in utero*, one must consider the sex of the fetus, the duration of exposure to the androgens, and, most importantly, the stage of pregnancy during which the exposure occurred. Cord serum androgen concentrations have been measured in only a few infants born to mothers with marked hyperandrogenism due to luteomas of pregnancy. Two cases had normal cord androgen concentrations and the infants were a normal male and a nonvirilized female. Two other infants had a two- to eightfold elevation in cord serum testosterone concentrations: One was a premature nonvirilized male and the other a virilized female. Based on these very limited data, it appears that the risk of virilization to a female infant may be related to cord serum testosterone concentrations but not maternal concentrations. Maternal hyperandrogenism is therefore necessary but not sufficient to cause virilization of the female infant, implying that some of the previously mentioned protective mechanisms may be in play.

Hyperreactio Luteinalis

The incidence of hyperreactio luteinalis or theca lutein cysts is increased in women with multiple or isoimmunized gestations, underlying diabetes, molar pregnancies, or choriocarcinomas (trophoblastic disease), where the incidence is highest at 10–22%. The size of ovaries containing theca lutein cysts in pregnant women ranges from normal to 10–15 cm each. Approximately 30% of pregnant women with hyperreactio luteinalis are virilized and many, if not all, virilized women have high serum testosterone and androstenedione concentrations. Cord serum testosterone concentrations in infants of virilized mothers are either normal or increased. Despite the presence of maternal virilization and, in some cases, elevated cord testosterone concentrations, none of the reported female infants have been virilized. Therefore, maternal virilization and even fetal hyperandrogenemia seem to have no relationship to fetal virilization in this disorder.

Administration of Progestins and Androgens

The administration of progestin, androgen, and even diethylstilbestrol to pregnant women has been linked to signs of androgen excess in women and masculinization of female fetuses. A similar effect can be seen with placental aromatase deficiency in which the conversion of androgen to estrogen is decreased, leading to androgen accumulation. Female external genital development occurs between 7 and 12 weeks of gestation; therefore, exposure to androgens at this time may result in partial or complete labial fusion and clitoral hypertrophy. After week 12 of gestation, labial fusion does not occur but clitoral hypertrophy remains a risk. Male fetuses do not appear to be affected.

Other Ovarian Tumors

Numerous other ovarian tumors have been associated with hyperandrogenism in pregnancy, including Sertoli–Leydig cell tumors, Krukenberg tumors, lipoid cell tumors of the ovary, Brenner cell tumors, and sclerosing stromal cell tumors. Sertoli–Leydig cell tumors (arrhenoblastomas) have been reported in 18 pregnant women; the rarity is a reflection of the effects of hyperandrogenism and its association with anovulation. However, there have been a few cases in which the tumor was thought to be present at the time of conception. The risk of malignancy in Sertoli–Leydig cell tumors is higher in the pregnant state (40–50 vs 12–22% in the nonpregnant state). Pregnant women are virilized at a rate similar to that of nonpregnant women (approximately 69–87%). Krukenberg tumors, which are ovarian metastasis of primary tumors of the gastrointestinal tract, are solid and bilateral in approximately 80% of cases. In a few cases reported during pregnancy, most of the women had hirsutism or virilization and half delivered virilized female infants. Polycystic ovary syndrome (PCOS) with no associated ovarian tumor has been associated with increased virilization in pregnancy, although very few cases have been described despite the relatively common occurrence of PCOS. One case reported associated fetal virilization but the PCOS was not confirmed histologically.

Role of Human Chorionic Gonadotropin

It has been postulated that human chorionic gonadotropin (hCG) can contribute to the pathogenesis of and hormone secretion by luteomas and theca lutein cysts. In the case of luteoma, this concept is supported by the regression of the tumor mass and prompt

decline in androgen levels after delivery. However, most luteomas are diagnosed late in pregnancy, well after the time of peak hCG production. Also, theca lutein cysts, not luteomas, are the characteristic ovarian lesions among women who produce excess amounts of hCG, such as those with trophoblastic disease. Therefore, hCG may be necessary for hormone production by luteomas, but there may be other factors causing growth and androgen production in late gestation.

Women with theca lutein cysts tend to have increased hCG production. However, administration of hCG alone does not cause these cysts, and not all women with massive elevations in serum hCG concentrations have them. Furthermore, the cysts may persist for several months after the evacuation of molar pregnancies, which is followed by a rapid decline in serum hCG concentrations. Therefore, as with luteoma, hCG is not the only factor involved in the pathogenesis of this condition.

DIAGNOSIS AND MANAGEMENT

Gestational-related hyperandrogenism may cause hirsutism and virilization of the mother and virilization of the female fetus (Fig. 1). The major causes of

pregnancy-related hyperandrogenism are shown in Table I.

Signs and Symptoms

Consideration of androgen excess in pregnancy usually occurs when a pregnant woman presents with a rapid onset of masculinization. Signs and symptoms include hirsutism, temporal balding, acne, clitoromegaly, and deepening of the voice. There may be palpable pelvic or abdominal masses due to tumors or cysts, which could include luteomas, hyperreactio luteinalis, other ovarian tumors, and adrenal tumors. Exogenous hormones or placental aromatase deficiency are not expected to be associated with masses. Sometimes, the first suspicion of gestational hyperandrogenism occurs at the time of delivery of a virilized female infant. It is important to remember that luteomas and theca lutein cysts undergo spontaneous regression in the postpartum period.

Diagnostic Approach

A thorough evaluation is warranted when evaluating a woman with gestational hyperandrogenism because of the possibility that the masculinizing lesion may be malignant. Sertoli–Leydig cell tumors, granulosa

theca cell tumors, ovarian mucinous cystadenocarcinomas, Krukenberg tumors, and adrenocortical carcinomas are examples of malignant tumors. Cushing's syndrome, although rare during pregnancy, should also be considered.

Information should be gathered regarding the time of onset of hirsutism and virilization. Exposure to elevated levels of androgens during early pregnancy may cause labiascrotal fusion and clitoromegaly, which may be irreversible, whereas exposure after 12 weeks of gestation causes only clitoral hypertrophy. If the mother has a history of chronic hirsutism, theca lutein cysts are more likely, although recurrence of virilizing tumors has been reported. In early pregnancy, one should consider trophoblastic disease.

Ultrasonography may be helpful in distinguishing solid and cystic ovarian tumors, uteralateral from bilateral ovarian disease, and ovarian from adrenal tumors. Theca lutein cysts are almost always bilateral, whereas most malignant tumors are unilateral, with the exception of Krukenberg tumors.

Table II lists characteristics of the major causes of gestational hyperandrogenism. Ultrasonography cannot reliably predict fetal sex until midgestation. As a result, its use for evaluation of fetal virilization is limited. There is very little information on the use of laparoscopy in diagnosis, but it could potentially be helpful in the first trimester.

Maternal serum hormone determinations are of questionable benefit because there are elevations of androgens in normal pregnancy, and even extremely elevated levels are not always associated with fetal virilization.

Percutaneous umbilical blood sampling for karyotyping and measurement of circulating fetal androgen levels could potentially provide helpful prognostic information if it could be done early enough in gestation. However, the procedure cannot be performed prior to differentiation of the fetal gonads and,

therefore, cannot be performed early enough to allow preventative intervention.

Prognosis and Therapy

Luteomas should be suspected in women with bilateral solid lesions, but Krukenberg tumors are still possible. Luteomas should regress and disappear after delivery. The risk of maternal hirsutism or virilization is approximately 35% in women with pregnancy-related luteoma and approximately 80% of female fetuses of effected mothers have been virilized. If the mother has no clinical manifestations of androgen excess, fetal virilization is rare. The fetus does not appear to be at risk for virilization in the woman with hyperreactio luteinalis even when maternal serum androgen concentrations are elevated. These cysts also regress after delivery and should not require surgical therapy.

Approximately 7% of ovarian tumors in pregnancy are malignant, but if the pregnant woman is virilized and has a unilateral solid ovarian mass, the risk of malignancy is approximately 50%. The risk of maternal and fetal virilization due to exogenous hormone exposure is poorly studied. The effects are expected to vary according to when the fetus was exposed. There is no evidence that cord blood measurements of androgens or other hormones are helpful in determining the risk of fetal virilization in these cases.

Management

It is important to remember that male infants are not thought to be at risk and that exposure of a female fetus to high androgen concentrations in early pregnancy may be associated with irreversible virilization.

Elevated cord serum concentrations of testosterone and androstenedione (based on four cases) appear to be necessary for virilization of a female infant. Therefore, if cord levels are low, virilization is not expected. Surgery is not generally indicated for women with luteomas or theca lutein cysts because both lesions regress in the postpartum period.

Antepartum treatment remains generally unavailable despite our ability to recognize the clinical manifestations and the ability to evaluate fetal androgen exposure.

FUTURE DIRECTIONS

Given the limitations in antepartum therapy, future efforts may be aimed at determining which patients are at risk and at developing screening tests to identify gestational hyperandrogenism earlier in pregnancy. With earlier diagnosis, it may be possible to implement therapies that decrease androgen exposure, thereby limiting fetal exposure to androgens during the critical period of sex determination.

active hormone. Several end organs have androgen receptors whose sensitivity to the hormone varies greatly, including total insensitivity seen in feminizing syndromes. In the skin, conversion to potent DHT by 5α reductase enzymes determines the response of the pilosebaceous unit, which controls hair growth and sebaceous gland secretion.

ETIOLOGY AND CLINICAL MANIFESTATIONS OF HYPERANDROGENISM

Hyperandrogenism etiology varies; it is principally ovarian, mainly involving the polycystic ovary, and rarely due to an enzymatic defect or neoplasia. In the adrenal, it is caused by an enzymatic defect in congenital adrenal hyperplasia, usually partial 21 -hydroxylase deficiency and rarely Cushing's disease and neoplasia. The clinical response to excess androgens varies and is genetically and race dependent. Caucasians are most sensitive and Asians are least sensitive. Oily skin, acne, and excess coarse facial, chest/breast, back, and genital area hair may be found. In more severe cases, signs of virilization (clitoromegaly and voice changes) may be present. The ovary frequently contains small cysts and there is thecal thickening and stromal hypertrophy. The endometrial lining may cause hyperplasia. Menstrual dysfunction ranges from minimal to anovulation and amenorrhea, frequently leading to infertility.

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS) is a multifaceted syndrome with a range of clinicopathological manifestations associated with altered androgen metabolism and frequently combined with altered glucose and lipid metabolism. The initiating defect is unclear, but central to it is increased ovarian androgen production due to LH-induced up-regulation of theca cells. Local inhibin B may be involved by stimulating androgen production. In the ovary, insulin acts through the insulin-like growth factor-1 receptor, but at high levels it may act through its own receptor. Insulin abnormalities are variable, and circulating levels in PCOS are modestly elevated. Any insulin abnormality, including altered receptor function, may lead to PCOS. Consequently, in addition to reproductive dysfunction, patients are at risk for a number of serious medical conditions, including diabetes and cardiovascular disease.

PCOS generally begins at menarche and is progressive. By the fourth decade, 40–50% of

women with PCOS develop diabetes mellitus. Insulin abnormalities are not fully characterized since the increase in liver glucose production is beyond the control of insulin. Measurable levels of testosterone, preferably the free form, and DHEAS are the hallmark for laboratory diagnosis. Very high levels are due to tumors, whereas lower levels may be due to PCOS. The androgen source is determined by administering oral contraceptives (estrogen/progestin) that suppress mostly androgens of ovarian origin. Dexamethasone administration (which blocks ACTH), on the other hand, will lower adrenal production of androgens. Management is cosmetic and dermatologic for skin disorders, and oral contraceptives with a weak androgenic component (norgestimate) are effective in lowering both ovarian and adrenal sources of androgen production. If the adrenal component is significant, low doses of prednisone may be administered. Less common is the use of spironolactone or ketoconazole. The addition of oral hypoglycemics, such as troglitazone, has been shown to significantly affect the insulin response to glucose challenge and to improve the response to clomiphene citrate in ovulation-induction regimens.

IMPLICATIONS OF SYNDROME X

The central defect is insulin resistance, which is compensated by increased insulin secretion. However, the precise definition of what constitutes resistance is vague; based on standard criteria, patients are not diabetic. The associated defects are variable but may be severe, and the etiology may be partially genetic and partially environmental (obesity and lack of physical exercise). Insulin resistance is manifested in the muscle and fat cells. Defects include abnormalities in glucose secretion and a mild increase in uric acid levels due to decreased renal clearance. The lipid abnormalities are increased triglycerides, secretion of very low-density lipoprotein, and decreased high-density lipoprotein secretion by the liver due to chronic hyperinsulinemia. Syndrome X is associated with increased heart rate, sodium retention, and hypertension. Changes in the coagulation profile as reflected by increased plasminogen activator inhibitor-1 levels are present. The result of these abnormalities is an increased risk for coronary heart disease.

infants and increasing to 1500 mg/day during adolescence and adulthood. At supplementary doses of 1500 mg/day, there appear to be no hazards to calcium administration. Increasing calcium intake to more than 4 g/day can overwhelm the homeostatic mechanisms designed to protect against hypercalcemia, particularly in patients with increased $1,25(\text{OH})_2\text{D}_3$ levels such as hyperparathyroidism (HPT), sarcoidosis, and exogenous vitamin D administration.

CALCIUM HOMEOSTASIS

Regulation of Extracellular Calcium Concentration

Compared with the large changes in cytosolic calcium concentration, variation in extracellular calcium concentration, as measured by the ionized calcium levels in blood, is quite small. Normal extracellular calcium concentration is regulated by three calciotropic hormones: parathyroid hormone (PTH), calcitonin, and vitamin D. These hormones act on three target organs—kidney, bone, and intestine—to maintain serum calcium within a very narrow range. The most critical of these hormones on a minute-to-minute basis is PTH. Acutely, slight changes (1–2% decrease) in extracellular calcium concentration result in a prompt increase in PTH secretion, restoration of extracellular fluid (ECF) calcium to normal, and inhibition of further PTH secretion (Fig. 1). This stability is maintained by exquisitely sensitive calcium ion receptors (CaR) that influence the distribution of calcium in different physiological compartments. The CaR, first identified on parathyroid cells, belongs to family C of the superfamily of G protein-coupled receptors (GPCRs).

Increases in $[\text{Ca}]_e$ within the millimolar range result in CaR-initiated G protein-dependent activation of diverse intracellular signaling pathways that ultimately inhibit PTH secretion. Figure 1 depicts the major sites of PTH action in calcium homeostasis.

In the kidney, PTH stimulates the renal tubular reabsorption of calcium and excretion of phosphorus and increases synthesis of the active form of vitamin D, $1,25(\text{OH})_2\text{D}_3$, from its precursor, $25(\text{OH})\text{D}_3$. The kidney filters approximately 10,000 mg/day of calcium, reabsorbs 98%, and excretes 2% of the filtered load. A variety of factors influence renal calcium handling. Total urinary calcium excretion increases with increased dietary calcium. Calcium excretion is facilitated by increased sodium chloride intake due to inhibition of proximal tubular calcium reabsorption as

a result of volume expansion. This relationship is exploited clinically in the use of sodium chloride loading in the treatment of severe hypercalcemia. Calcium excretion is also increased by administration of loop diuretics such as furosemide. PTH blocks sodium-dependent phosphate cotransport in the proximal and distal tubules, resulting in increased phosphate excretion. PTH decreases calcium reabsorption in the proximal tubule but stimulates calcium absorption in the distal tubule, with the overall effect being net calcium absorption. In proximal tubular cells, PTH activates the $25(\text{OH})\text{D}_3$ 1α hydroxylase, which catalyzes the synthesis of the most active metabolite of vitamin D, $1,25(\text{OH})_2\text{D}_3$. Increased levels of $1,25(\text{OH})_2\text{D}_3$ directly stimulate intestinal absorption of calcium and phosphate as well as mobilization of calcium and phosphate from bone. In a negative-feedback loop, $1,25(\text{OH})_2\text{D}_3$ acts via the vitamin D receptor (VDR) to inhibit PTH gene transcription, PTH secretion, and parathyroid cell proliferation. Conversely, reduced levels of $1,25(\text{OH})_2\text{D}_3$ are seen in patients with uremia and are associated with parathyroid hyperplasia.

Figure 1 The calcium homeostatic system. A small decrease in serum-free calcium concentration results in prompt release of PTH by the parathyroid cells. PTH acts on the kidney to increase calcium reabsorption and phosphate excretion. PTH also stimulates the synthesis of $1,25(\text{OH})_2\text{D}_3$, which facilitates active absorption of calcium and phosphate from the intestine. In addition, PTH acts on bone to mobilize calcium and phosphate. All of these effects result in a return of extracellular calcium to the normal range. Calcium activation of the calcium sensor inhibits PTH secretion in a classic negative feedback loop.

The Skeleton as a Calcium Reservoir: Osteoclastic Activity and Hypercalcemia

During development and growth, the skeleton is sculpted or “modeled” into its adult form by removal of bone at one site and deposition at another. At maturity, periodic replacement of old bone by new bone at the same site (remodeling) is carried out such that the entire adult skeleton is regenerated every 10 years or so. Osteoclastic bone resorption and osteoblastic new bone formation are tightly linked under normal conditions by local (autocrine and paracrine) and systemic endocrine factors. Excessive osteoclastic activity is an important mechanism in the development of hypercalcemia, and many treatments are based on modifying osteoclastic regulation. Osteoclasts, the agents of bone resorption, are multinucleated cells of the monocyte/macrophage family (Fig. 2). Their development requires the presence of osteoblast precursors, which express macrophage colony-stimulating factor (M-CSF) and receptor for activation of nuclear factor kappa B (NF- κ B) (RANK) ligand (RANKL). PTH and other osteoclastogenic agents act on osteoblasts or stromal precursors to increase the production of RANKL and other local factors, such as interleukin-1 (IL-1) and TNF α , which stimulate the release of soluble factors from osteoblasts and lead to further recruitment, differentiation, and activation of osteoclasts. Malignant and inflammatory cells can overexpress a number of products that stimulate osteoclastogenesis and the osteolytic cascade, including PTHrP, 1,25-vitamin D, prostaglandins, interferons, growth factors, and RANKL. Several factors are responsible for the inhibition of osteoclastic bone resorption. Osteoblasts also secrete osteoprotegerin (OPG), which competes with RANKL for RANK and inhibits osteoclastogenesis. Estrogen directly or indirectly suppresses or regulates the production of many stimuli of osteoclastogenesis. Interaction of calcitonin with its receptors on the mature osteoclast results in potent inhibition of bone resorption.

Osteoclasts secrete protons, collagenase, hyaluronidase, and other matrix-degrading enzymes into the space between their ruffled border and the bone surface (Fig. 2). This leads to the resorption and removal of both the mineral and matrix phases of bone. Subsequently, increased local concentration of a variety of factors, including calcium, leads to decreased osteoclast numbers (apoptosis or programmed cell death) and activity and also sets the stage for osteoblast recruitment, osteoblast activation, and new bone formation.

Figure 2 Therapeutic targets for modulation of osteoclast activity. Current therapies include estrogen and selective estrogen receptor modulators (SERMs) for suppressing osteoclast formation and include bisphosphonates and calcitonin for inhibiting osteoclast activity. Some potential new targets include blocking the action and signaling of the OPG/RANKL/RANK pathway (1–4), blocking acidification of the resorption lacuna by inhibiting the activity of carbonic anhydrase or H⁺-ATPase (5,6), blocking enzymatic degradation of collagen and matrix proteins (7), developing more robust calcitonin receptor ligands (8), blocking α v β ₃ integrin-mediated cytoskeletal signaling (9), and selectively stimulating osteoclast apoptosis (10). DIFFERENTIAL DIAGNOSIS OF HYPERCALCEMIA

As is evident in Table I, the etiology of hypercalcemia is multifactorial. The symptoms of hypercalcemia (Table II) reflect the critical physiological role of calcium in all tissues. The construction of a working differential diagnosis of hypercalcemia in an individual patient begins by obtaining a good clinical history.

Exogenous Factors

A variety of common medications influence calcium metabolism. Thiazide diuretics inhibit urinary calcium excretion, resulting in a mild rise in serum

calcium concentration sufficient to render patients with previously unrecognized HPT frankly hypercalcemic.

There appears to be a duration-dependent relationship between lithium use and the development of HPT. In addition, some HPT patients on chronic

lithium therapy might not revert to a normocalcemic state with drug withdrawal and tend to have multiple gland disease at surgery. Short-term therapy may also unmask mild preexisting HPT, as do the thiazide diuretics.

The milk-alkali syndrome, defined as hypercalcemia and metabolic alkalosis occurring with a history of consumption of large quantities of calcium and absorbable alkali in the absence of other explanations for the metabolic abnormalities, was initially described as a complication of treatment for peptic ulcer disease. Such patients can be identified by an appropriately suppressed PTH level in the face of hypercalcemia and can be easily treated by limiting calcium intake.

Vitamin D and its metabolites are used to treat a variety of metabolic bone diseases and to retard the development of secondary HPT in patients with chronic renal failure. However, vitamin D can cause hypercalcemia when given in high doses, and severe illness, including renal impairment and death, have been reported. Hypervitaminosis is diagnosed by elevated levels of serum 25(OH)D₃ and hypercalcemia or hypercalciuria (or both) and by a history of vitamin D intake. Although the half-life of vitamin D metabolites is short, the half-life of vitamin D is weeks to months. Treatment of vitamin D intoxication includes, in addition to drug withdrawal, hydration, calciuresis, and perhaps glucocorticoids.

Hypercalcemia can also occur as a consequence of administration of vitamin A and its analogues (*cis*-retinoic acid), probably due to increased osteoclast-mediated bone resorption.

Malignancy-Associated Hypercalcemia

Hypercalcemia resulting from cancer is the most common form of hypercalcemia among hospitalized patients and is second in frequency only to primary HPT as a cause of hypercalcemia among outpatients. Approximately 10 to 25% of patients with squamous carcinoma, ovarian carcinoma, multiple myeloma or lymphoma, renal adenocarcinoma, or carcinoma of the breast will develop hypercalcemia during the course of their disease, and in a substantial portion of these, hypercalcemia will produce clinical signs and symptoms (e.g., polyuria, polydipsia, confusion, obtundation, renal failure) that directly contribute to the demise of the affected patient. Hypercalcemia generally occurs late in the course of the patient's disease. In a minority of patients, malignancy-associated hypercalcemia is due to direct tumor involvement with the

skeleton, a syndrome that is called “local osteolytic hypercalcemia” (LOH). This syndrome is most commonly encountered in patients with breast cancer, multiple myeloma, lymphoma, or leukemia. In these cases, hypercalcemia is due to extensive malignant skeletal involvement. Bone scans, bone biopsies, and autopsies reveal large skeletal tumor burdens. In addition, malignant cells within the marrow space secrete cytokines, which lead to the recruitment and activation of osteoclasts, as shown in Fig. 2. The local activation of osteoclastic bone resorption leads to hypercalcemia, suppression of PTH secretion, hyperphosphatemia, hypercalciuria, suppression of nephrogenous cyclic AMP (cAMP) excretion, and suppression of circulating $1,25(\text{OH})_2\text{D}_3$. These findings are summarized in Table III. The diagnosis of LOH is usually straightforward, requiring only the clinical history; extensive biochemical testing is rarely necessary.

A more common type of malignancy-associated hypercalcemia occurs in patients with squamous carcinomas (head and neck, lung, cervix, vulva, esophagus, skin, and other sites), renal carcinomas, ovarian carcinomas, and transitional carcinomas of the bladder. Recently, it has been reported to occur in patients with HTLV-1 lymphoma/leukemia and is being observed increasingly in women with breast cancer in the absence of bone metastases. This “humoral hypercalcemia of malignancy” (HHM) accounts for 80% of patients with malignancy-associated hypercalcemia. Affected patients have minimal skeletal metastatic disease, and hypercalcemia subsides with tumor removal.

The agent responsible for hypercalcemia in these cases, PTHrP, was discovered in 1987. PTHrP, a product of many normal cells, has significant homology with PTH at the amino terminal end of the

molecule and interacts with the PTH/PTHrP shared receptor. Thus, when PTHrP is overexpressed systemically by tumor cells, it can produce most of the physiological effects of PTH, including hypercalcemia, activation of bone resorption, inhibition of renal phosphorus reabsorption, and hypophosphatemia (Table III). PTHrP may also stimulate renal reabsorption of filtered calcium, mimicking the anticalciuric effect of PTH and further exacerbating hypercalcemia. Hypercalcemia leads to suppression of PTH, but nephrogenous cAMP excretion is elevated as a result of the effects of PTHrP on the renal proximal tubular PTH receptor. For reasons that are still unclear, plasma $1,25(\text{OH})_2\text{D}_3$ concentrations are reduced in HHM. Bone biopsy shows striking activation of osteoclastic bone resorption in the absence of osteoblastic bone formation. The reasons for this uncoupling of bone formation from bone resorption also remain unclear despite having been described two decades ago. These findings are contrasted with those observed in patients with LOH and with primary HPT in Table III.

Rarely, the ectopic secretion of authentic PTH may be responsible for humoral hypercalcemia of malignancy. These patients are usually identified following an unsuccessful attempt at parathyroidectomy.

Another unusual form of malignancy-associated hypercalcemia occurs in patients with lymphomas, which overproduce $1,25(\text{OH})_2\text{D}_3$. In this setting, $1,25(\text{OH})_2\text{D}_3$ stimulation of intestinal calcium absorption and osteoclastic bone resorption results in the development of hypercalcemia. Such patients display hypercalcemia, suppressed PTH values in the setting of high-normal or elevated plasma $1,25(\text{OH})_2\text{D}_3$ concentrations, and suppressed nephrogenous cAMP excretion.

It is important to recognize that the differential diagnosis of hypercalcemia occurring in a patient with cancer includes the entire differential diagnosis of hypercalcemia. For example, both breast cancer and primary HPT are common conditions and may coexist in a given patient. Because the clinical outcome of a patient whose hypercalcemia is due to cancer is generally poor, identification of a nonmalignant cause of the hypercalcemia may permit its effective treatment and may dramatically change the patient’s prognostic category.

Besides the tumors mentioned previously, nearly any type of cancer can cause hypercalcemia. In addition, benign neoplasms (pheochromocytomas and giant mammary fibro-adenomas) have occasionally been associated with hypercalcemia due to overproduction of PTHrP.

Table III Biochemical Comparison of Local Osteolytic Hypercalcemia, Humoral Hypercalcemia of Malignancy, and Hyperparathyroidism

| | Hyperparathyroidism | Humoral hypercalcemia of malignancy | Local osteolytic hypercalcemia |
|-------------------------------|---------------------|-------------------------------------|--------------------------------|
| Serum calcium | Increased | Increased | Increased |
| Renal phosphorus threshold | Decreased | Decreased | — |
| Parathyroid hormone | Increased | Decreased | Decreased |
| PTHrP | Decreased | Increased | Decreased |
| NcAMP | Increased | Increased | Decreased |
| $1,25(\text{OH})_2\text{D}_3$ | Increased | Decreased | Decreased |

In summary, the diagnosis of malignancy-associated hypercalcemia is generally straightforward because the tumor burden in such patients is virtually always large. Thus, a thorough history, a careful physical exam, a chest X ray, urinalysis, routine chemistries, and a complete blood count will almost always point to the responsible tumor or to an alternate cause of hypercalcemia. Extensive biochemical testing (e.g., PTH, PTHrP, plasma $1,25(\text{OH})_2\text{D}_3$, nephrogenous cAMP) is most appropriate in more difficult cases.

Other Endocrinopathies

Addison's Disease

The etiology of hypercalcemia in adrenal insufficiency is probably multifactorial. Hypovolemia and decreased glomerular filtration rate lead to a reduction in filtered calcium and an increase in proximal tubular reabsorption of sodium and calcium. Some of the proximal tubular calcium abnormalities may be related to glucocorticoid insufficiency given that they are not corrected by volume resuscitation alone but return to normal with hormone replacement. In Addison's disease, there is also an increase in calcium mobilization from bone, perhaps due to physiological effects of thyroid hormone unopposed by glucocorticoids or to other effects on osteoclast-mediated bone resorption. In any case, hypercalcemia can be an important sign of an impending Addisonian crisis. The treatment is prompt fluid resuscitation with normal saline and glucocorticoid replacement.

Thyrotoxicosis and Pheochromocytoma

Mild hypercalcemia frequently occurs in thyrotoxicosis, probably due to thyroid hormone-induced osteoclastic bone resorption. Hypercalcemia resolves after treatment of the hyperthyroid state. Significant hypercalcemia can be seen in some patients with pheochromocytoma. In some cases, this is caused by concomitant HPT, as in MEN2A syndrome. In other instances, the pheochromocytoma may be producing a substance that increases bone resorption such as PTHrP.

Miscellaneous

Granulomatous Diseases

Hypercalcemia is a common occurrence in sarcoidosis, with probably 10% of patients developing hypercalcemia and 20% developing hypercalciuria at some time during the course of their disease. The hypercalcemia, hypercalciuria, and accelerated bone loss have

been shown to be due to increased production of $1,25(\text{OH})_2\text{D}_3$ by disease-associated macrophages. Unlike the hydroxylation reaction in the renal tubular cell, the macrophage reaction is not stimulated by PTH or inhibited by $1,25(\text{OH})_2\text{D}_3$. Instead, it is inhibited by glucocorticoids, which form the basis for treatment. In addition, patients with hypercalcemia due to sarcoidosis should have limited dietary intake of calcium and vitamin D and should avoid sunlight exposure. Other granulomatous diseases, such as tuberculosis, silicon-induced granulomatosis, disseminated candidiasis, and leprosy, have also been associated with the development of hypercalcemia. In some cases, hypercalcemia may be due to macrophage production of PTHrP, which stimulates vitamin D activation, and RANKL production, with resultant osteoclast activation.

Immobilization

Prolonged weightlessness or immobilization results in increased bone resorption and hypercalcemia, especially in those patients whose underlying rates of bone turnover are high. Thus, children and young adults, as well as patients with HPT, Paget's disease, or malignancy-associated hypercalcemia, are at special risk. Hypercalcemia begins within days to weeks of bed rest and can result in nephrolithiasis as well as osteopenia in the long term. The actual cause of the observed increase in osteoclastic activity and the observed decrease in osteoblastic function is unknown. PTH and $1,25(\text{OH})_2\text{D}_3$ levels are appropriately suppressed in these hypercalcemic patients. Although administration of bisphosphonates may have some benefit, the most effective treatment is weight-bearing exercise.

Primary Hyperparathyroidism

Primary HPT is the most common cause of hypercalcemia in the outpatient population. The diagnosis of HPT is made by demonstrating an inappropriately elevated PTH level for the simultaneously measured serum calcium.

Primary HPT is caused by inappropriate (for the ambient calcium concentration) PTH secretion by a parathyroid adenoma(s), hyperplasia, or carcinoma. In HPT, there is both increased cell proliferative activity (enlarged glands) and decreased sensitivity of the cells to secretory inhibition by calcium (altered set point). Sporadic primary HPT is the most common cause of hypercalcemia in an outpatient setting, with a prevalence of 1 in 500 women and 1 in 2000 men over 40 years of age.

Genetic Aspects of Hyperparathyroidism

Investigation into the genetics of familial HPT, as seen in MEN1 and MEN2, familial hypocalciuric hypercalcemia (FHH), hyperparathyroidism–jaw–tumor syndrome (HPT-JT/HRPT2), and familial isolated hyperparathyroidism (FIHP) syndromes, has illuminated many aspects of normal and abnormal parathyroid cell function. The genetic abnormalities described in HPT are shown in Table IV.

MEN1

Primary HPT is the most common feature of the MEN1 syndrome, present in 87 to 97% of patients. The syndrome was mapped to chromosome 11q13 and the MEN1 gene encoding a 610-amino acid protein, MENIN, whose function is consistent with that of a tumor suppressor gene. Interestingly, allelic loss on chromosome 11 has also been seen in patients with tertiary HPT. The clinical features of HPT in the MEN1 syndrome recapitulate those seen in sporadic

HPT. However, the average age of onset of HPT in MEN1 is 25 years, substantially younger than that of primary HPT due to sporadic adenoma, and instances of hypercalcemia in individuals as young as 4 years of age have been reported. By 50 years of age, essentially 100% of affected family members will demonstrate HPT. Also unlike sporadic HPT, in MEN1 there is a similar prevalence between males and females. At surgery, multiple-gland involvement is the rule, although this may be quite asymmetric. Single adenomas and parathyroid cancer have also been described in the setting of MEN1.

MEN2

HPT also occurs as part of the MEN2A syndrome, although its incidence is low (5–20%) compared with MEN1. MEN2A, MEN2B, and familial medullary carcinoma of the thyroid result from a mutation in the RET protooncogene. RET encodes a putative tyrosine kinase receptor, and mutations appear to result in activation of the RET oncogene rather than in loss or inactivation of a tumor suppressor. Unlike the MEN1 gene, mutations of the RET protooncogene apparently are not found in sporadic parathyroid adenomas. The occurrence of HPT, as well as the age at onset, appears to be specific to the kindred in which it occurs. The clinical spectrum of HPT in patients with MEN2A resembles that seen in sporadic disease, with hypercalcemia and nephrolithiasis being the most common features. At surgery, multiple-gland enlargement or an adenoma may be found. Interestingly, HPT is not a feature of MEN2B.

Hyperparathyroidism–Jaw–Tumor Syndrome

In the hereditary HPT–JT syndrome, affected patients present with aggressive HPT (adenoma or carcinoma), and fibro-osseous tumors of the mandible or maxilla. Associated lesions include a variety of renal lesions (both benign and malignant). The HPT–JT gene, denoted HRPT/2, maps to chromosome 1q21–31 in the region of the susceptibility gene for hereditary prostate cancer (HPC1).

Familial Isolated Hyperparathyroidism

A number of families have been reported with FIHP without other associated clinical manifestations of the MEN or HPT–JT syndromes. In many of these cases, clinical follow-up will disclose the development of syndromic disease. Undoubtedly, linkage to other known syndromes or isolated genetic causes of HPT will be discovered. Clinical and genetic screening should be undertaken in patients whose family history suggests familial disease so as to facilitate treatment

Table IV Genetic Findings in Hyperparathyroidism

| Gene | Chromosome | Product | Clinical phenotype |
|-------------------|-------------------------|--------------------|--|
| MEN1 | 11q13 | MENIN | MEN1 20–40% sporadic adenomas Familial isolated HPT |
| RET | 10q21 | RET | MEN2A |
| CASR | 3q13–21 | CaR | FHH (heterozygotes) NSHPT (homozygotes) ADMH |
| HPC1/ HRPT2 | 1q24–31 1q21–31 | Unknown | Hereditary prostate CA HPT–JT syndrome Familial isolated HPT |
| RB | 13q | Tumor suppressor | Parathyroid CA |
| p53 | 17p13 | Tumor suppressor | Parathyroid CA |
| PRAD1 | 11q13 11p15 | Cyclin D1 | Sporadic adenoma |
| VDR | 12q | Vitamin D receptor | Primary HPT |
| Tumor suppressors | 1p, 6q, 9p, 15q, 22q | Tumor suppressors | Sporadic HPT |
| Oncogenes | 16p, 19p | | Sporadic HPT |

planning and follow-up for both the patients and their family members. Patients with FIHP without the MEN1 syndrome have multiple-gland disease and more profound hypercalcemia and higher rates of persistent and recurrent HPT than do those with either MEN1 disease or sporadic HPT. Patients with this condition may be at increased risk for parathyroid carcinoma.

Familial Hypocalciuric Hypercalcemia

FHH is a usually benign and asymptomatic disorder inherited as an autosomal dominant trait with essentially 100% penetrance. Patients with FHH have hypercalcemia with inappropriately elevated PTH levels. Despite their hypercalcemia, affected individuals exhibit none of the morbidity seen in hypercalcemic patients with HPT, and surgical treatment should not be undertaken. Neonatal severe HPT is a rare disease characterized by extreme hypercalcemia (commonly more than 20 mg/dl), skeletal demineralization, respiratory distress, parathyroid hyperplasia, and hypotonia. Without urgent parathyroidectomy, the disease is usually fatal. FHH and neonatal severe HPT have been shown to be the heterozygous and homozygous, respectively, phenotypic consequences of mutations in the calcium receptor (CaR) gene.

Molecular Mechanisms in Sporadic Disease

Using molecular tools developed to study familial disease, various workers have investigated sporadic parathyroid tumors, which in most cases have been shown to be clonal in origin. Evidence for both oncogene activation and suppressor gene inactivation (Table IV) has been reported.

Vitamin D Receptor Polymorphisms

Genetic variation in vitamin D metabolism has been found to be associated with some HPT states, particularly in the postmenopausal setting.

Radiation-Associated Hyperparathyroidism

HPT also occurs with increased frequency after radiation to the head and neck. HPT has also been described to have increased frequency after ¹³¹I treatment for Graves' disease, although not after radioiodine treatment for malignant thyroid disease. Genetic analyses of radiation-associated parathyroid tumors have disclosed multiple alterations per tumor, most commonly involving losses in 11q and 1p. Such profiles are similar to those seen in adenomas exhibiting MEN1 gene abnormalities and suggest that this gene may be vulnerable to irradiation. These data argue for long-term monitoring of patients for both

parathyroid and thyroid disease after radiation exposure as well as for careful intraoperative assessment of both thyroid and parathyroid glands during surgery for either condition.

Secondary Hyperparathyroidism

The most common cause of secondary HPT (and of tertiary or refractory HPT) is chronic renal failure. Hyperplasia of the parathyroid glands and increased serum PTH levels occur early in the development of renal dysfunction. The primary factors responsible for the development of HPT in renal failure are phosphorus retention, decreased levels of calcitriol, hypocalcemia, and skeletal resistance to the calcemic action of PTH.

The increase in serum phosphorus seen as a result of decreasing renal function results in a reduction in the level of ionized calcium in the blood and stimulates PTH secretion. PTH reduces the tubular reabsorption of phosphorus, promoting phosphate excretion and leading to a return of both calcium and phosphorus toward normal levels at the expense of the "trade-off" of a higher circulating PTH level. In uncomplicated secondary HPT, patients are usually normocalcemic.

In advanced secondary HPT, autonomous function of hyperplastic parathyroid tissue may lead to hypercalcemia. Similarly, persistence of hyperfunction after successful renal transplantation is termed "tertiary hyperparathyroidism." The incidence and clinical significance of persistent posttransplant abnormalities in parathyroid function are still a matter of debate. As many as one-third of patients may develop hypercalcemia after transplantation, and the majority will resolve over 1 to 3 years following surgery. A minority of patients will continue to exhibit abnormalities of calcium metabolism, and perhaps 5% will require a parathyroidectomy. Indications for surgery are usually a decrease in renal function and evidence of ongoing bone disease.

Parathyroid Carcinoma

Parathyroid carcinoma is an uncommon cause of hypercalcemia, present in less than 1% of patients with primary HPT. Parathyroid carcinoma has been reported to arise within the context of adenomatous or hyperplastic parathyroid disorders, but no clear evidence exists to suggest that malignant transformation of what was originally benign parathyroid tissue occurs. Parathyroid carcinoma has also been reported after head and neck irradiation and in familial HPT. Clinically, parathyroid carcinoma is typically characterized by severe manifestations of HPT. Patients with parathyroid carcinoma usually have markedly elevated

serum calcium levels, on the order of 14 mg/dl or higher, and concomitant PTH levels that are 3 to 10 times the upper level of normal. Compared with typical patients with HPT, those with carcinoma are almost invariably symptomatic. Patients may exhibit features of bone disease and nephrolithiasis, a combination that is very unusual in patients with primary HPT of benign etiology. Physical signs in parathyroid carcinoma may include a neck mass or hoarseness due to recurrent laryngeal nerve paralysis, both of which are unlikely to occur in patients with benign disease.

In addition to clinical parameters, several intraoperative findings may suggest a diagnosis of parathyroid carcinoma. Parathyroid carcinoma is usually a fibrotic, poorly circumscribed mass that is often adherent to surrounding structures, especially the thyroid gland. Regional lymph nodes may be sites of metastatic spread. The presence of metastatic deposits in regional nodes, clear invasion of contiguous structures, and/or evidence of distant metastases to lung, liver, or bone are the most reliable diagnostic criteria for parathyroid carcinoma. Histological criteria for malignancy are nonspecific but include the presence of fibrous trabeculae traversing the tumor, capsular or vascular invasion, and frequent mitoses.

TREATMENT OF HYPERCALCEMIA

Treatment of hypercalcemia ideally is directed toward correcting its cause. Successful therapy of malignancy-associated hypercalcemia requires an effective long-term surgical, radiotherapeutic, or chemotherapeutic treatment strategy. Without such a strategy, the overall prognosis is very poor. As a corollary, antihypercalcemic therapy should best be viewed as a temporizing measure that is used to buy time while an effective therapeutic plan aimed at treating the tumor is undertaken. If no effective antitumor treatment is available in a given case, it may be most rational to withhold antihypercalcemic therapy given that death due to hypercalcemia may be preferable to other options.

Medical Treatment of Hypercalcemia

Regardless of etiology, hypercalcemic crisis or severe hypercalcemia is a life-threatening emergency, and although it is more commonly seen in malignancy, it can complicate primary HPT. Although strict diagnostic criteria are lacking, hypercalcemic crisis can be defined as a calcium level greater than 14 mg/dl associated with acute signs and symptoms attributable

to the elevated calcium such as volume depletion, neurological findings, and cardiac arrhythmias. Treatment of hypercalcemic crisis, whether due to HPT or to malignancy, is two-pronged: promotion of calcium excretion by the kidney and inhibition of bone resorption.

Initially, treatment is directed toward volume restoration with isotonic or half-normal saline. This also provides an obligatory calcium diuresis due to the sodium excretion. Because the volume required may be in the range of 2 to 4 L/day, patients must be carefully observed for signs of fluid overload. Thiazide diuretics must not be used because they increase renal tubular calcium reabsorption. Loop diuretics facilitate calcium excretion but may also result in dehydration and exacerbate the hypercalcemia. They may be required, however, to prevent fluid overload in older patients. Resultant hypokalemia and hypomagnesemia must be corrected. Volume expansion with improvement in glomerular filtration rate and calcium excretion may be expected to lower the serum calcium level by 1.5 to 2.0 mg/dl in 24 to 48 h.

As volume expansion measures are initiated, anti-resorptive therapy should be undertaken. Calcitonin, a potent inhibitor of osteoclastic bone resorption, should be given early and at maximal doses (up to 8 IU/kg by subcutaneous or intramuscular injection every 6 h). A decrease in serum calcium concentration of 2 to 3 mg/dl may be seen within a few hours, with a nadir expected at about 24 h. However, resistance to the hypocalcemic effect of calcitonin is commonly seen within several days of treatment, so it is most useful as part of initial therapy.

Because bone resorption is influenced by the calcium-phosphate ion product, phosphorus has been used both orally and parenterally in the past to lower serum calcium and inhibit osteoclastic activity. Because of the risk of extraskelatal calcification and the availability of safer agents, phosphate administration has little role in the management of hypercalcemia today. Oral phosphorus supplementation, in the form of neutral phosphate (250 mg orally four times per day), should be given only to patients with normal renal function whose phosphorus concentrations are below 2 mg/dl, that is, where complications of hypophosphatemia are of concern. Bisphosphonates ameliorate hypercalcemia by blocking osteoclasts and acting as bone crystal substitutes. They are highly effective at lowering serum calcium within several days and are essentially nontoxic. The preferred drug in the United States is pamidronate, generally given in a dose of 60 to

90 mg intravenously in 500 ml of saline over 4 to 24 h. Response begins within 1 to 2 days and is maximal after 4 to 5 days, with the majority of patients so treated returning to normal serum calcium values. Other effective bisphosphonates include risendronate, zoledronate, and ibandronate.

Glucocorticoids, once widely used in treating hypercalcemia, today have most utility in those cases where a glucocorticoid responsive etiology is the cause of the hypercalcemia. Patients with vitamin D intoxication or granulomatous diseases would be candidates for glucocorticoid therapy. Other malignancies such as myelomas, lymphomas, lymphocytic leukemias, and some breast cancers may be responsive to glucocorticoids.

Recently, several "calcimimetic" organic compounds of the phenylalkylamine family have been shown to allosterically modify the CaR and increase its sensitivity to activation by extracellular calcium. In short-term, placebo-controlled clinical trials, one of these agents, NPS R-568, has been shown to lower PTH and serum calcium levels in patients with both primary and secondary HPT. In animal models of secondary HPT, both continuous and cyclic administration of calcimimetics have decreased parathyroid cell growth.

Finally, dialysis may be indicated in patients with impaired renal function or in extreme emergencies. Weight-bearing mobilization of bedridden patients is important when possible.

Surgical Treatment of Hypercalcemia Due to Hyperparathyroidism

Indications for Surgery

In HPT, surgical therapy has a success rate of close to 100% with minimal morbidity and negligible mortality. Patients with symptoms directly attributable to HPT, such as nephrolithiasis and nephrocalcinosis, and those with overt bone disease should be offered surgical treatment.

Currently, many patients with HPT identified as hypercalcemic by automated multiphasic serum chemistry screening do not exhibit the classic signs and symptoms of HPT. Such patients are often referred to as "asymptomatic," although many have subtle findings that are often attributed to other conditions and that are alleviated by parathyroidectomy. Nonetheless, several studies have shown that most patients with asymptomatic HPT can be followed for long periods of time without significant clinical progression of their disease. The National Institutes of

Health recently reported on the results of a second Consensus Conference on indications for surgical intervention in primary HPT. The recommendations are summarized as follows:

1. Serum calcium greater than 1 mg/dl above the upper limits of normal
2. Creatinine clearance reduced by more than 30% compared with age-matched controls
3. 24-h urinary calcium excretion greater than 400 mg/dl
4. Bone density at the lumbar spine, hip, or distal radius that is more than 2.5 *SD* below peak bone mass (T score < 2.5)
5. Patients for whom medical surveillance is either not desirable or not possible
6. Young patients (under 50 years of age)

The role of parathyroidectomy in pregnancy is a matter of some debate. HPT increases the risk of spontaneous abortion, stillbirth, and fetal demise, but some patients with very mild disease may be appropriate for nonoperative management. After delivery, neonates must be watched for signs of hypocalcemia until their suppressed parathyroids regain function. In any case, the development of unexpected complications in the pregnant patient, such as renal calculi, pancreatitis, and peptic ulcer disease, should raise the question of the presence of HPT. Patients with severe or complicated HPT should be referred for surgery.

Aspects of Surgical Treatment

Successful parathyroid surgery requires an appreciation for the normal anatomical relationships of the thyroid and parathyroid glands, the recurrent and superior laryngeal nerves, and the inferior thyroid arteries as well as their common embryological variations. Although the availability of better imaging techniques and the use of intraoperative PTH determination may permit a less invasive surgical approach in some patients with HPT, the standard of care is still the traditional bilateral dissection with visual assessment of all four glands.

Role of Imaging Studies

Until recently, the contribution of imaging studies to the management of patients with HPT has been limited by the accuracy of the available modalities. Currently, nuclear imaging with technetium sestamibi is the method of choice for preoperative localization of parathyroid adenomas. Technetium sestamibi exhibits preferential uptake and retention in abnormal parathyroid glands. The addition of single positron

emission computerized tomography (SPECT) analysis to the sestamibi scan provides three-dimensional information about the location of the imaged gland. Ultrasound can also provide three-dimensional information and provides assessment of coexisting thyroid disease that may require evaluation or treatment at the time of parathyroid surgery. In recent reports, the combined application of sestamibi and ultrasound resulted in successful visualization of an adenoma in 96% of cases.

In reoperative situations, all imaging modalities are used, beginning with the least to the most invasive procedures.

If sestamibi and U.S. studies are negative, other anatomical studies, such as computerized tomography (CT) and magnetic resonance imaging (MRI), may be useful. Angiography and selective venous sampling may be required in some cases. Angiography has been reported to localize parathyroid tumors in 60% of cases and may permit angiographic ablation of mediastinal adenomas. Selective venous sampling may provide regional localization data but requires a high level of expertise that is not available in most institutions. Where it is available, analysis of venous samples can be carried out in "real time" in the radiology suite using the "quick" intact PTH assay.

Imaging modalities may contribute to intraoperative management as well. The combination of sestamibi SPECT imaging with three-dimensional reconstruction and probe-directed intraoperative radionuclide detection may allow for a more limited dissection, as may the use of high-resolution intraoperative ultrasound.

In summary, current data do not support the use of routine preoperative imaging in the treatment of HPT unless the intent is to perform a unilateral or minimally invasive exploration, although it appears that accurate localization does shorten the procedure. Preoperative identification of an apparently solitary enlarged parathyroid gland also does not guarantee that it is the only abnormal gland. The role of imaging is, however, critical in the reoperative circumstance.

Approaches to Parathyroidectomy

Critical to the success of the operation is the maintenance of meticulous homeostasis throughout. In the majority of cases, an adenoma will be present and the initial goal is the identification of an enlarged and a normal-appearing gland on the affected side. If imaging data are available, the suspected side is explored first. If an adenoma is identified grossly and three other apparently normal glands are visualized, one may be biopsied to confirm the presence of

parathyroid tissue. In general, there are no histological criteria that can reliably differentiate among normal, hyperplastic, and adenomatous parathyroid tissue. The adenoma is resected and the procedure is completed. If it is available, demonstration by the quick intraoperative assay that PTH levels have dropped by 50 to 65% of baseline after resection of a presumed adenoma has reliably confirmed that all abnormal tissue has been resected. The most common cause of unsuccessful parathyroid surgery is failure to find an adenoma, and in most cases the adenoma is ultimately found in one of the common sites of embryological derivation.

Given the preponderance of a single adenoma in patients with primary HPT, a unilateral approach in patients whose disease has been localized has long been attractive. Early limited experience suggested that good results could be obtained with a unilateral exploration when an enlarged gland and a normal gland are found on one side. More recently, the availability of convincing preoperative localization studies and quick intraoperative PTH assays has permitted focused dissection with either general or local anesthesia in many patients. It should be recognized that the intent to perform a unilateral exploration is just that. In 50% of cases, a bilateral dissection is ultimately required, either because the adenoma is not found on the initial side or because the patient is found to have more than one abnormal gland or other (usually thyroid) pathology requiring treatment.

The laparoscopic era has produced several endoscopic approaches to diseases of the thyroid and parathyroid glands. These include both totally endoscopic and video-assisted techniques. In a recent multi-institutional study, video-assisted parathyroidectomy could be carried out in 89% of 123 qualified patients. Patients were excluded as candidates for an endoscopic approach if they had negative imaging studies, suspected multiglandular or concomitant thyroid disease, and/or prior neck surgery or irradiation. Disadvantages of this procedure over a conventional approach included the need for general anesthesia and longer operating times. These approaches may find the greatest utility in patients with deeply situated, typically superior adenomas for which a conventional approach would require a more extensive dissection.

Intraoperative Decision Making: Multiple-Gland Disease

If multiple abnormal glands are encountered, the decision must be made as to how much tissue is to be removed. Double adenomas are estimated to occur in 2 to 5% of the general population and in perhaps 9% of older patients. The presence of more than one

enlarged gland more often implies a diagnosis of hyperplasia; this may be quite asymmetric in nature, and a complete evaluation of all glands is mandatory. Clarification of the status and location of all parathyroids should be carried out before any gland is resected. The role of the quick intraoperative PTH assay in directing the extent of resection is undergoing investigation in several centers.

If all four glands are enlarged, subtotal parathyroidectomy—the resection of three to three and one-half glands—is a reliable treatment. Intraoperative PTH determination may help to guide the extent of resection in many cases. In patients with secondary hyperparathyroidism and MEN1 syndrome, even when four glands have been identified, the cervical thymus should be resected because the incidence of supernumerary glands is significant in these conditions.

A second approach to four-gland hyperplasia is total parathyroidectomy and autotransplantation. After total parathyroidectomy, minced fragments of parathyroid tissue are placed in separate sites of the brachioradialis muscle in the forearm and are secured with nonabsorbable suture material. The theoretical advantage of this approach is that if recurrent (graft-dependent) HPT occurs, treatment requires only removal of some of the grafts under local anesthesia rather than a neck reexploration. Of course, successful application of the technique depends on identification and removal of all parathyroid tissue from the neck (including supernumerary glands).

Besides patients with secondary HPT, other individuals at risk for recurrent HPT who may be candidates for these procedures include patients with familial hyperplasia, particularly those with MEN1.

In summary, the choice of whether to perform a total parathyroidectomy and autotransplant or to perform a subtotal resection in the case of secondary HPT or MEN1 is a matter of personal preference; both are reliable techniques when performed by experienced surgeons.

Parathyroid Carcinoma

The most effective management of parathyroid carcinoma is complete resection of the tumor at the time of initial exploration. Half of patients so treated may be cured. Where possible, an *en bloc* resection should be carried out, removing the mass with the contiguous thyroid lobe and nodes in the central (paratracheal) compartment. The other parathyroids must be identified because carcinoma and hyperplasia may exist concurrently. Parathyroid carcinoma is usually an indolent malignancy, with local recurrence and distant

metastases to lung and bone occurring over many years. Because the major physiological effects of parathyroid carcinoma are related to unregulated PTH secretion and hypercalcemia rather than to tumor burden, resection of metastatic disease plays an important role in patient management. For similar reasons, reoperation for locally recurrent parathyroid carcinoma is appropriate.

Outcome of Surgical Treatment for Hypercalcemia Due to HPT

In experienced hands, parathyroidectomy is effective at returning the serum calcium and PTH levels to normal in 95 to 99% of cases of primary HPT. The ability of serum calcium to suppress PTH secretion also promptly returns to normal after resection of parathyroid adenomas, reflecting the normal “set point” of the remaining glands. There are also abundant data documenting the effects of successful parathyroidectomy on associated conditions such as renal function, urolithiasis, and bone disease.

The effect of surgery on the clinical course of other conditions associated with HPT is less clear. Hypertension is more prevalent in HPT patients than in control populations, and some studies have shown an improvement in blood pressure after parathyroidectomy. Likewise, some data indicate improvement in left ventricular hypertrophy and endothelial function after parathyroidectomy. Because correction of HPT results in lowering of IL-6 levels and other acute phase reactants related to cardiovascular risk, it is possible that longitudinal follow-up studies currently in progress may show a beneficial effect on cardiovascular parameters in surgically treated patients.

Several health assessment studies have documented improvement after successful parathyroid surgery in a variety of the neuropsychiatric and musculoskeletal complaints common to the hypercalcemic state. A controlled clinical trial to compare the outcomes of surgical and medical treatment of HPT (including use of calcimimetics as they become available) with respect to these issues will be important in defining the appropriate criteria for surgical treatment of mild or asymptomatic primary HPT.

CONCLUSIONS

Hypercalcemia is a common and, when severe, potentially life-threatening condition. Understanding the basic mechanisms of calcium homeostasis and the abnormalities that occur in various diseases is critical

to safe, successful, and cost-effective patient management. Current research has begun to define many of the molecular mechanisms that underlie the common causes of hypercalcemia. Malignancy-associated hypercalcemia and HPT together account for the vast majority of cases of hypercalcemia. New diagnostic and medical and surgical approaches to these diseases continue to refine treatment and improve patient outcome.

Factors that influence renal tubular calcium reabsorption can be divided into two categories: (1) those that decrease calcium reabsorption, increasing calcium excretion such as hypercalcemia, loop diuretics, extracellular fluid volume expansion, NaCl, protein or glucose intake, phosphate or potassium depletion, and metabolic acidosis; and (2) those that increase calcium reabsorption, thereby reducing urinary calcium, such as PTH, PTH-related protein, thiazide diuretics, metabolic alkalosis, phosphate or potassium administration, hypocalcemia, and extracellular fluid volume depletion.

Urinary calcium should not exceed 300 mg (7.5 mmol)/day, considering the adequate intake of 1000 mg/day as recommended for 30- to 50-year-old adults as part of the Dietary Reference Intake (DRI) or even if the intake goes up to 2000 mg/day. Among normal individuals, urinary calcium increases only about 8% as dietary calcium intake increases. Conversely, patients with IH may exhibit a twofold higher calcium excretion across a similar range of calcium intake. Therefore, compared with people without stones, IH patients show a marked increase in the fraction of diet calcium absorbed and lost in urine as well as in bone mineral lability. Hypercalciuria is consequent to a dysregulation of calcium transport in the gut, kidney, or bone, thereby representing a systemic abnormality in calcium homeostasis. The continued excessive urine calcium excretion may result in bone demineralization.

To establish the diagnosis of normocalcemic IH in stone formers, the serum calcium level should be measured to rule out hypercalcemic disorders. Among hypercalcemic hypercalciuric conditions that may alter urinary calcium in CSF patients, primary hyperparathyroidism (PHP), characterized by the presence of elevated serum calcium with nonsuppressed serum PTH values, is the most common, accounting for more than 50% of cases. On the other hand, PHP affects only 0.5 to 5% of all CSF patients. Other causes of hypercalcemic hypercalciuric states include granulomatous diseases such as sarcoidosis and tuberculosis due to the extrarenal conversion of $25(\text{OH})\text{D}_3$ to $1,25(\text{OH})_2\text{D}_3$ in the granulomatous tissue, leading to increased intestinal calcium absorption. Prolonged immobilization, hyperthyroidism, and acromegaly may also be associated with hypercalcemic hypercalciuria. In previous evaluations by our group, the incidence of stones in hyperthyroidism patients had been only 1.6% despite the presence of hypercalciuria in 9% of the patients, whereas the frequency of renal stones and hypercalciuria in acromegalic patients were 9.5 and 36%, respectively. Most likely, those

findings may be ascribed to the earlier control of the hyperthyroid state, resulting in a shorter period of hypercalciuria, in contrast with acromegaly, in which late diagnosis may be associated with long-lasting hypercalciuria. Hypercalcemia associated with malignancy also does not ordinarily result in stone formation because patients do not live long enough to form stones. Milk-alkali syndrome as a cause of hypercalcemic hypercalciuria is unusual since the advent of H_2 acid-blocking drugs has replaced the need for calcium-containing nonabsorbable antacids. Familial hypocalciuric hypercalcemia patients are not at increased risk for making stones because they do not present with hypercalciuria.

PATHOGENESIS OF HYPERCALCIURIA

Mechanisms

IH may result from disordered regulation of calcium fluxes in the intestine, kidney, and/or bone. The first underlying mechanism seems to be an increased intestinal calcium absorption either occurring directly or mediated by the excess of $1,25(\text{OH})_2\text{D}_3$, which would result in hypercalcemia and suppression of PTH, leading to an increased filtered load of calcium. Hypercalciuria would then be ascribed to the combination of increased filtered load of calcium and suppression of PTH. The increased calcium excretion then corrects the hypercalcemia, and serum calcium returns to normal levels. The second alternative mechanism is the reduction on renal tubular reabsorption of calcium, leading to a subsequent decrease in serum calcium level, which in turn stimulates PTH secretion, with subsequent increased $1,25(\text{OH})_2\text{D}_3$ levels resulting in a secondary increased intestinal calcium absorption. The increased urinary calcium excretion in this condition should persist after an overnight fast. In some patients, the cause of the hyperabsorption would be a defect in renal tubular phosphorus reabsorption, causing hypophosphatemia, high $1,25(\text{OH})_2\text{D}_3$ levels, and secondary intestinal hyperabsorption of calcium, resulting in hypercalciuria. Finally, the third proposed mechanism is an enhanced bone demineralization as a primary process (not caused by hyperparathyroidism), leading to an increased serum calcium concentration, a decreased level of PTH, and an increased filtered load of calcium, resulting in hypercalciuria. Those patients should also present with higher calcium excretion after an overnight fast, similarly to those with defective renal tubular calcium reabsorption. In summary, in pure intestinal calcium hyperabsorption, namely

“absorptive hypercalciuria,” the levels of serum PTH or urinary cAMP should be low or normal and the overnight fasting should abolish the hypercalciuria. Conversely, the other subtype of hypercalciuria caused by a defect in calcium tubular reabsorption or “renal leak,” defined initially as renal hypercalciuria, would present with an opposite profile, one with high serum PTH and urine cAMP together with high fasting urine calcium.

This pathophysiological classification seemed to be very appealing because of its simplicity, disclosed by Pak and associates in 1975 through the development of a simple acute oral calcium load test that could clearly distinguish between absorptive and renal hypercalciuria subtypes. One of the parameters that helped to distinguish between renal and absorptive hypercalciuric patients using this test was the measurement of the overnight fasting urinary calcium corrected for creatinine excretion (urinary calcium/creatinine ratio), with a cutoff value of 0.11. Absorptive hypercalciuria subtype exhibited a urinary calcium/creatinine ratio lower than 0.11 and an exaggerated response of urinary calcium/creatinine after the oral calcium load, whereas the renal subtype presented a fasting urinary calcium/creatinine higher than 0.11 in addition to high levels of serum PTH. Practical therapeutic implications derived from this test included the recommendation of a low-calcium diet for absorptive-type hypercalciuria and that of thiazide agents for renal or fasting hypercalciuria. In a previous study by our group in 1996, we collected a 24-h urine sample for calcium determination, under conditions of a mean usual calcium intake of 540 mg/day, from CSF patients who previously presented with an “absorptive” or “renal” type of response to the oral calcium load test. We observed that the majority of these patients (63 and 78% of each group, respectively) presented with normocalciuria rather than hypercalciuria. Because this apparently normal calcium excretion might have resulted from a combination of high calcium absorption and low calcium intake, these patients were then challenged with a higher calcium intake of 1500 mg/day given as a supplement for 1 week. Regardless of whether there was a former absorptive or renal type of response to the acute calcium load test, the higher calcium intake disclosed the presence of subpopulations sensitive to calcium intake in previously normocalciuric patients (dietary calcium dependent). Conversely, most of the hypercalciuric patients, when challenged with a higher calcium intake, did not present a further increase in their urinary calcium. This showed that

under conditions of low calcium intake, as was the case for these patients as part of their dietary habit, they were already excreting calcium in excess of their intake, hence being considered as dietary calcium independent. In addition, because the morning urinary fasting calcium/creatinine ratio seemed to be the single parameter that would distinguish between renal and absorptive hypercalciuric patients with a cutoff value of 0.11, this determination was repeated in 31 patients. Fully 87% of them changed their results from values higher than 0.11 to values lower than 0.11. Other investigators also detected renal and absorptive hypercalciuria in the same patients when examined at different points of time. This discrepancy between different determinations of urinary fasting calcium/creatinine may also be ascribed to an incomplete intestinal calcium clearance, a previous higher sodium or protein intake inducing mild acidosis, a higher bone resorption, or even a state of chronic suppression of PTH. Therefore, elevated fasting hypercalciuria might not always reflect the presence of a renal leak, and the single determination of this urinary parameter might not be a specific criterion for patient classification.

Neither cAMP nor serum vitamin D helped to distinguish between absorptive and renal hypercalciuria. Taken together, these data suggested that absorptive and renal hypercalciuria should be considered the same rather than two distinct entities, a hypothesis raised previously by Coe and co-workers in 1982. These investigators observed that feeding IH patients a very low-calcium diet, approximately 140 mg/day for 9 days, all but a few lost more calcium in the urine than they ate, and their urine losses formed a smooth continuum from overlap with the top of the normal values to much higher, without evidence of a break or division point along the obtained curve. The values of PTH were generally low despite calcium losses and did not rise when the normal diet was replaced with the low-calcium diet. Serum calcitriol values ranged from normal to high. On the other hand, some authors have recommended that, for a clear-cut distinction between these subtypes, patients must be evaluated under a more prolonged dietary calcium restriction for at least 4 weeks to disclose some difference.

It seems that IH patients most likely would fit better into two extremes of a continuum and broad behavior, representing a single process for pathogenesis, that varies in severity (some tend to hyperabsorb calcium more than do others) and probably results from abnormal regulation of $1,25(\text{OH})_2\text{D}_3$.

The Role of PTH

Theoretically, the negative calcium balance found among patients with renal hypercalciuria or renal leak could conceivably lead to secondary hyperparathyroidism. Early studies by Coe in 1973 and Pak in 1975 demonstrated that patients with renal hypercalciuria exhibited a higher serum PTH or fasting urinary cAMP. Shortly thereafter, it was shown that high PTH levels were scarce, so that the term “renal hypercalciuria” should instead be “fasting hypercalciuria” whenever one found elevated fasting urinary calcium in the absence of elevated serum PTH. In 1982, Coe observed normal or low values of PTH despite calcium losses in another series of patients. Subsequently, several investigators reported normal parathyroid function in IH either through urinary cAMP determination or by using newer serum PTH assays. In summary, there is no agreement on the existence of secondary hyperparathyroidism in hypercalciuria. However, considering the lack of secondary hyperparathyroidism in most of the recent series, and considering the evidence for high levels or disordered control of $1,25(\text{OH})_2\text{D}_3$, it seems reasonable to assume that in this condition, calcitriol may suppress the secretion of PTH, explaining why most IH patients do not exhibit high PTH levels.

The Role of $1,25(\text{OH})_2\text{D}_3$

Early studies by Broadus, Insogna, and colleagues in 1984 found plasma levels of $1,25(\text{OH})_2\text{D}_3$ to be in the upper normal range or elevated in the majority of patients with absorptive hypercalciuria when compared with nonhypercalciuric stone formers, probably due to a higher renal synthesis of this hormone. However, normal serum calcitriol levels have also been detected among patients with high rates of calcium absorption. In 1991, Lemann and colleagues speculated that even small elevations of serum $1,25(\text{OH})_2\text{D}_3$ seem to be sufficient to increase bone resorption when dietary calcium intake is low, indicating that $1,25(\text{OH})_2\text{D}_3$ may up-regulate its own receptor and so amplify its effect. Therefore, rates of calcium transport by enterocytes that are high in relation to the effects of calcitriol, or possibly abnormal levels of the vitamin D receptor (VDR) amplifying the effect of circulating $1,25(\text{OH})_2\text{D}_3$, could explain the occurrence of calcium hyperabsorption and also the mobilization of bone mineral induced by a low-calcium diet despite the presence of normal calcitriol levels among patients with IH. Approximately two decades ago, David A. Bushinsky and his group started

to develop a model of hypercalciuria in rats that were successively inbred for more than 50 generations until they produced a strain of a genetic hypercalciuric (GHS) rat. In this experimental model, Bushinsky was able to show that the increased calcium absorption is mediated by an increase in the number of VDR in the intestine (duodenum), kidney cortex, and bone. Not only are there more receptors, but they are hyperresponsive to $1,25(\text{OH})_2\text{D}_3$, as evidenced by a higher calcium efflux from GHS rats' calvariae when exposed to increasing amounts of $1,25(\text{OH})_2\text{D}_3$ relative to control animals. The increased number of intestinal VDR, even if levels of circulating $1,25(\text{OH})_2\text{D}_3$ are normal, may result in increased functional VDR- $1,25(\text{OH})_2\text{D}_3$ complexes that exert biological actions in enterocytes to increase intestinal calcium transport. The defective tubular calcium reabsorption in this model is further evidenced by a threefold calcium excretion when compared with normal rats at similar glomerular filtration rates and ultrafiltrable calcium concentration, resulting in similar filtered loads of calcium. Because the renal tubular defect would necessitate bone resorption to maintain normal serum calcium levels, the renal and bone defects have been shown to be independent of each other. The use of a bisphosphonate, a bone resorption blocker agent (alendronate), induced a decrease in urinary calcium excretion in GHS rats, confirming the hypothesis that bone contributes to hypercalciuria.

The Role of Bone

Decreased bone mineral density (BMD) has been consistently reported in several series of hypercalciuric CSF patients, owing to the important contribution of hypercalciuria to bone demineralization. A histomorphometric study undertaken by our group in 1994 confirmed a low bone volume, a tendency of low bone formation coupled with increased bone resorption and delayed bone mineralization, in male hypercalciuric CSF patients. Further studies showed conflicting data regarding bone resorption, but all suggested a severe mineralization defect among hypercalciuric patients. The reason for such a defect remains unknown considering the adequate levels of serum calcium, phosphorus, and vitamin D. A population-based cohort study by L. Joseph Melton, III, and colleagues in 1998 showed a fourfold increase in vertebral fracture risk among urolithiasis patients. In a large cross-sectional study conducted by Diane S. Lauderdale, Murray J. Favus, and other investigators in 2001

using the Third National Health and Nutrition Examination Survey (NHANES III), a history of kidney stones was found to be associated with lower femoral neck BMD and more prevalent wrist and spine fractures in men after adjustments for age and body mass index. For the men (but not the women) who formed kidney stones, there was a correlation between low milk consumption and low neck BMD. It is interesting that most of the reports on low BMD among hypercalciuric CSF patients in the literature show a higher prevalence in men than in premenopausal women for some unknown reason. However, postmenopausal women with a previous history of renal stones still present a higher frequency of osteopenia than do normal postmenopausal women. Experimental studies in GHS rats highlight the contribution of bone demineralization, as noted previously.

In 1991, Pacifici and co-workers demonstrated that monocytes from patients with fasting hypercalciuria overproduced interleukin-1 (IL-1), a potent *in vitro* and *in vivo* stimulator of bone resorption. Subsequently, in 1996, Weisinger and his associates found increased IL-1 α mRNA in unstimulated monocytes from IH patients as well as higher lipopolysaccharide-induced production of IL-6 and TNF α . Based on these findings, which were corroborated in several other reports, it has been suggested that bone resorption induced by elevated cytokines could represent the primary mechanism leading to hypercalciuria. It still remains to be clarified whether the hypercalciuria is a "bone disease," resulting from elevated bone resorption (primary mechanism), or a "renal tubular disease," in which the renal tubular defect leads to hypercalciuria and the resultant negative calcium balance then stimulates bone resorption (secondary mechanism). The reduction of hypercalciuria by a bone resorption blocker agent, such as alendronate, favors the first mechanism, whereas the improvement of bone mass by a drug that reduces calcium losses by acting on the renal tubules favors the second mechanism.

The Role of Diet

In the past, calcium restriction became a very popular recommendation, based on the contribution of calcium intake and intestinal calcium hyperabsorption to hypercalciuria, augmenting the risk of stone formation. However, there has been no evidence that a reduction in dietary calcium intake prevents stone recurrence. In addition, in a large prospective epidemiological study conducted by Curhan and his group in 1983, healthy men with different levels of calcium

intake were followed up for 8 years; surprisingly, it was observed that the lower the calcium intake, the higher the incidence of stone formation. A hypothesis to explain such an unexpected effect was a secondary increase in urinary oxalate due to a decreased binding of oxalate to calcium in the gastrointestinal tract. Thus, dietary calcium binds intestinal oxalate, preventing its absorption and subsequent excretion. Nevertheless, one has to consider that the benefits of a high-calcium supply do not apply to calcium supplements, which usually are not taken with meals, thereby losing their oxalate-chelating properties. It is very well established that calcium excretion is not solely affected by the intake of calcium but that other nutrients, such as animal protein, sodium, oxalate, and potassium intake, might influence calcium excretion as well. Finally, focusing on the bone issue, many investigators have addressed the loss of bone mass in hypercalciuric patients, not only suggesting the contribution of a low-calcium diet in such loss but also stressing the deleterious effects of high animal protein and sodium intake on bone. In summary, there are many reasons why calcium restriction should be avoided in hypercalciuric patients. First, there is no clear distinction between absorptive and renal hypercalciuria. Second, no prospective studies have supported the belief that calcium restriction leads to a reduction in stone recurrence. Third, calcium restriction induces secondary hyperoxaluria. Fourth, calcium restriction predisposes to bone loss due to a negative calcium balance. Fifth, chronic calcium restriction might up-regulate VDRs, allowing 1,25-vitamin D to stimulate both intestinal calcium absorption and bone resorption. Sixth, other nutrients, such as protein, sodium, oxalate, and potassium, may affect calcium excretion as well. Animal protein-induced hypercalciuria may be caused by a higher bone resorption and lower tubular calcium reabsorption to buffer the acid load, and it may also be caused by the elevated filtered load of calcium and the presence of non-reabsorbable calcium sulfate in the tubular lumen. The effect of NaCl intake on increasing calcium excretion is well established. Every 100-mmol increase in dietary sodium results in an approximately 25- to 40-mg rise in urinary calcium per day. The adverse effects of a high-NaCl intake and the resultant higher calcium excretion have been reported extensively by many investigators. In a previous study by our group in 2000, Martini and colleagues showed that a high-NaCl consumption (higher than 16 g/day) is associated with low BMD in hypercalciuric stone formers. A carefully controlled long-term study by Loris Borghi in 2002 showed that for men with IH, a diet with a normal amount of calcium (1200 mg/day) but

reduced amounts of animal protein (52 g/day) and salt (50 mmol/day) for 5 years is superior to a low-calcium diet (400 mg/day) in preventing recurrent stones.

DRUG TREATMENT

Thiazide diuretics are the first-choice drugs for hypercalciuria. Indapamide, a thiazide-like agent, has also been employed. Thiazides increase renal tubular calcium reabsorption, lowering urine calcium and leading to a consequent fall in calcium oxalate and phosphate supersaturation. Two double-blind, randomized, prospective, and placebo-controlled trials using either hydrochlorothiazide or chlorthalidone, in doses of 25 to 50 mg/day, showed a significantly lower rate of recurrent stone formation only after 3 years (up to 25%) compared with placebo (up to 55%). Surprisingly, these studies were performed in patients not categorized according to urinary derangement, and response to therapy was independent of baseline level of urinary calcium. As for the effects on bone, small studies conducted by our group and others suggested additional benefits of thiazides on BMD, as one would expect. On the other hand, thiazides' adverse effects, which are often dose related (e.g., sexual impotence, potassium wasting, raised serum cholesterol, glucose tolerance) are common; thus, intolerance should be kept in mind.

GENETICS OF HYPERCALCIURIA

In the majority of the family-based studies, increased calcium excretion is the most common phenotype associated with kidney stone formation. According to a study by Scheinman in 1999, approximately 40% of patients with IH have a family history of nephrolithiasis. The X-linked recessive nephrolithiasis (Dent's disease) is a rare monogenic kidney stone disease affecting males for which a responsible gene has already been identified, a mutated *CLCN-5* chloride channel that determines hypercalciuria, hematuria, low-molecular-weight proteinuria, nephrocalcinosis, and nephrolithiasis with eventual renal failure. *CLCN-5* is a member of the family of voltage-gated chloride channels that also includes *CLC-Kb*, which is disrupted in the largest group of patients with Bartter syndrome, another hypercalciuric condition. Nevertheless, mutation analysis of the *CLCN-5* gene was normal among patients with IH, and *CLCN-5* sequence was shown to be normal in the GHS rat.

Although several authors have reported families in which IH appears to be inherited as a single

autosomal dominant genetic disorder, there are many reasons to conclude that IH should instead be attributed to a complex polygenic trait. The distribution curve of calcium excretion in stone formers is similar in shape to that in controls, albeit shifted toward higher rates of excretion, probably resulting from the influence of several factors. Failure in attempts to categorize IH patients under distinct subtypes probably illustrates that different mechanisms participate in producing hypercalciuria in different patients. Some candidate genes for IH have been suggested by their known physiology, including those encoding the adenosine triphosphatase (ATPase), calbindin (28 kDa), osteocalcin, IL-1 α , IL-1 β , renal sodium-dependent phosphate transporter, chloride channels, VDR, calcium-sensing receptor, and 1 α -hydroxylase of vitamin D. The multifaceted physiology of IH may reflect the combined effects of polymorphisms in several genes. Thus, in some patients presenting features of absorptive hypercalciuria, overexpression of VDR and/or overactivity of the renal 1 α -hydroxylase could underlie the excessive intestinal calcium absorption. In a 1998 study, Alain Bonnardeaux and co-workers found no linkage between the putative 1 α -hydroxylase of vitamin D locus and quantitative traits associated with IH. Shortly thereafter, the same authors suggested evidence for a susceptibility gene near the VDR locus in idiopathic calcium stone formation, and quantitative trait linkage (QTL) analysis of urinary calcium yielded linkage to some, but not all, of the markers. In a recent evaluation by our group, BsmI VDR polymorphism was not associated with bone loss in hypercalciuric CSF patients. Genetic variants of the calcium-sensing receptor gene were not linked to biochemical markers of IH. In a 1999 study, Berenice Reed and colleagues found linkage to chromosome 1q23–24 in three families with absorptive hypercalciuria. In more recent work, the same group reported the occurrence of base-pair substitutions in the soluble adenylate cyclase gene that segregate with the disease in the same three kindreds and also reported that these changes were associated with absorptive hypercalciuria and low spinal bone density in a population of patients. However, there is still no evidence that substitutions or mutations in this gene cause absorptive hypercalciuria. It is likely that different genetic mechanisms may predominate in different patient populations. Technical advances will shed light on our understanding of the role of genetics in hypercalciuria.

As is evident from the current knowledge, the pathophysiology of hypercalciuria cannot be explained by a single mechanism or theory. [Figure 1](#) presents a

Figure 1 Hypothetical mechanisms for idiopathic hypercalciuria. Increased intestinal calcium absorption (mediated or not by $1,25(\text{OH})_2\text{D}_3$), decreased renal tubular calcium reabsorption, and enhanced bone resorption are potential mechanisms representing a systemic abnormality in calcium homeostasis. Experimental and genetic data point to a possible pivotal involvement of vitamin D receptor (VDR) and/or $1,25(\text{OH})_2\text{D}_3$ under the influence of diet as well. The role of cytokines is crucial in bone demineralization. Disordered control of $1,25(\text{OH})_2\text{D}_3$ may further suppress parathyroid hormone (PTH). There is a complex interrelationship among all of these factors, and genetic influence seems unequivocal. IL- 1α , interleukin-1; IL-6, interleukin-6; TNF, tumor necrosis factor; GM-CSF, granulocyte macrophage-colony-stimulating factor.

hypothetical view of the pathophysiological events leading to idiopathic hypercalciuria in CSF patients.

every 700 people in several Caucasian populations in North America and Europe, FDB is one of the most common single-gene defects known to cause an inherited abnormality. The genetic disorder FDB is caused by a single base substitution (G to A) at nucleotide 10708 in exon 26 of the apoB100 gene (2p23.24), creating an arginine to glutamine substitution in the codon for amino acid 3500. Nearly everyone with FDB is of European descent; in most cases, the CGG-to-CAG mutation in the codon for amino acid 3500 in apoB is on a chromosome with a rare haplotype at the apoB locus, suggesting that most probands descended from a common ancestor who lived in Europe about 6750 years ago.

Except for a few cases in which tryptophan substitutes for arginine-3500, cysteine for arginine-3531, or tryptophan for arginine-3480, extensive searches have not revealed any other apoB100 mutations that cause defective receptor binding of LDL. All mutations are located within a stretch of 51 amino acids and result in the loss of an arginine. However, none of these mutated residues appears to be directly involved in binding to the LDLR given that site-directed mutagenesis has indicated that residues 3359 to 3369 in apoB100 are responsible for LDL-receptor interaction.

How do these mutations give rise to the defective LDLR binding? Immunoelectron microscopy studies have shown that the first 89% of apoB100 enwraps the LDL particle like a belt and that the carboxyl-terminal 11% constitutes a bow that crosses over the belt, bringing the carboxyl-terminal portion of apoB100 close to amino acid 3500 (Fig. 1). Recent data indicate that the bow is stabilized by an interaction between arginine-3500 and tryptophan-4369. It has also been proposed that arginine-tryptophan interactions are crucial during the conversion of VLDL to LDL for positioning apoB100's carboxyl

Figure 1 The first 89% of apoB100 enwrapping the LDL particle like a belt, with the carboxyl-terminal 11% constituting a "bow" that crosses over the belt. The bow is stabilized by an interaction between arginine-3500 (R3500) and tryptophan-4369 (W4369). Site B (residues 3359–3369) is the LDL receptor-binding site.

tail to permit apoB100 on LDL to bind normally to the receptor. A disturbed refolding process gives rise to the two characteristics of FDB: a defective conformation of apoB100, as demonstrated by binding studies with monoclonal antibodies and C nuclear magnetic resonance analysis, and hypercholesterolemia due to ligand-binding-defective apoB100.

CLINIC

The first disorder, familial hypercholesterolemia, is well studied. LDL cholesterol is elevated to about twice its normal levels in heterozygous FH. In the latter, familial defective apolipoprotein B, LDL is also elevated, but not to the same degree. Furthermore, the clinical consequences of heterozygous FH tend to be more severe than those of FDB. However, as they are presented in the clinic, the patients with FDB and FH are very similar. The first clinical evidence of the disease often is tendon xanthoma, that is, a tough, noncancerous, yellow-colored deposit of fat that develops beneath the skin. Xanthomas can occur anywhere on the body but are commonly found on the knees, elbows, hands, feet, buttocks, joints, and tendons. The tendency to develop xanthoma is quite variable; xanthomas may appear during adolescence or young adulthood, and some patients do not develop xanthomas even during their later years.

The main clinical complication is early manifestations of coronary heart disease (CHD). In patients with heterozygous disease, the risk of CHD at 30 years of age has been estimated at 5%; this risk rises to an estimated 50% by 50 years of age. Women develop CHD about 10 years later than do men, and as in the general population, other risk factors, such as tobacco smoking and hypertension, further increase the risk of CHD. Without proper treatment, only about 15% of males with heterozygous FH reach 65 years of age without an ischemic coronary event. With modern treatment, these risks seem to be substantially reduced. The severity of the CHD is determined by the presence of other risk factors, but there also seems to be a variation between families and between patients with different mutations of the receptor.

In patients with homozygous disease, the clinical course is more malignant. Xanthomas often develop during early childhood, and at least half of these patients have CHD at 20 years of age. The diagnosis of heterozygous FH can be detected already in cord blood or during childhood, when patients have elevated plasma cholesterol in relation to age and

gender. Beyond 20 years of age, plasma cholesterol usually is in the range of 8 to 12 mmol/L. Plasma cholesterol in homozygotes ranges between 15 and 25 mmol/L.

Heterozygous FH and FDB can, in most cases, be treated effectively with lipid-lowering drugs. The most potent cholesterol synthesis inhibitors, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins), may reduce plasma cholesterol levels by as much as 50 to 60%. When therapeutic goals are not reached, statins may be combined with other drugs such as bile acid binding resins, nicotinic acid, and inhibitors of dietary cholesterol absorption.

weakness, and osteoporosis. Thromboembolic phenomena, including deep venous thrombosis and pulmonary embolism, may occur and can be part of the initial presentation of Cushing's syndrome.

ETIOLOGY

Exogenous administration of glucocorticoids, mostly iatrogenic or (rarely) factitious (self-induced), accounts for the majority of cases of ACTH-independent Cushing's syndrome. Prednisone often causes Cushing's syndrome when it is used as an immunosuppressive and anti-inflammatory agent for a myriad of nonendocrine diseases. Cushing's syndrome can also be caused by other oral, injected, topical, and inhaled glucocorticoids as well as by medroxyprogesterone acetate. Surreptitious or factitious intake of a glucocorticoid can occur and should be considered during the early stages of the diagnostic process. The detection of synthetic glucocorticoids in the plasma or urine by high-pressure liquid chromatography (HPLC) is effective in excluding this disorder.

If exogenous glucocorticoid administration is excluded, the diagnosis of endogenous Cushing's syndrome is confirmed by demonstrating the presence of cortisol hypersecretion. Endogenous Cushing's syndrome is more common in women than in men, with an incidence of approximately 2 to 4 new cases per 1 million population per year in women. It can result from autonomous cortisol hypersecretion by cortisol-secreting adrenal tumors, adrenal hyperplasia (macro- and micronodular), or excess ACTH or (rarely) corticotropin-releasing hormone (CRH) secretion.

Once the diagnosis of endogenous Cushing's syndrome is made, the clinician must determine whether the patient has primary adrenal disease or an ACTH-secreting tumor (ACTH dependent or ACTH independent) (Table I). ACTH-dependent Cushing's syndrome accounts for approximately 85% of endogenous cases. In the great majority of these cases (80%), the cause is autonomous pituitary ACTH secretion and is referred to as Cushing's disease. In the remaining 20%, the source of ACTH or (rarely) CRH secretion is ectopic. The molecular pathophysiology of ACTH-secreting tumors remains elusive. Unlike the case of growth hormone-secreting adenomas, abnormalities of the G proteins are not frequent in corticotropinomas. Nonetheless, approximately 50% of these tumors overexpress the cytoplasmic form of the p53 tumor suppressor gene.

ACTH-independent Cushing's syndrome accounts for approximately 15% of endogenous cases and is

more often caused by benign cortisol-secreting adrenal adenomas, adrenocortical carcinomas, or (rarely) ectopic (extra-adrenal) adrenocortical tumors. Cortisol-secreting adrenal tumors are monoclonal in origin, but their pathogenesis remains largely unknown. Abnormalities of the p53 tumor suppressor gene or of the inhibitory subunit of G proteins and overexpression of insulin-like growth factor-2 (IGF-2) were identified in a subset of these neoplasms and might be implicated in their pathogenesis. It is noteworthy that, unlike the case of the thyroid-stimulating hormone (TSH) receptor in hyperfunctioning thyroid adenomas, the ACTH receptor, which also couples to G proteins and adenylyl cyclase, does not appear to be oncogenic.

Several genetic syndromes have been associated with adrenocortical tumors. These include the Li-Fraumeni syndrome (due to p53 mutations), the multiple endocrine neoplasia type 1 syndrome (due to mutations of the *menin* gene), the Beckwith-Wiedemann syndrome, and Carney's syndrome or complex. The latter is a rare autosomal dominant

disorder characterized by mucocutaneous pigmented lentiginos, blue nevi, and multiple endocrine tumors. Overt Cushing's syndrome caused by bilateral micronodular adrenal hyperplasia occurs in 25% of all patients with Carney's complex, but histological changes in the adrenal cortex are found at autopsy in nearly every patient. Testicular (Sertoli cell), pituitary, and thyroid neoplasms can also occur. Nonendocrine tumors such as cutaneous, mammary, and atrial myxomas, as well as psammomatous melanotic schwannomas, may also be present. Mutations of *PRKAR1A*, an apparent tumor suppressor gene that encodes the protein kinase A regulatory 1 α -subunit, are present in some families with Carney's complex.

INITIAL LABORATORY SCREENING: BIOCHEMICAL DIAGNOSIS

Because signs and symptoms of Cushing's syndrome are not specific, appropriate documentation and verification of sustained endogenous hypercortisolemia is the cornerstone for the detection and diagnosis of this syndrome.

Determination of 24-h urinary-free cortisol (UFC) excretion with immunometric techniques or HPLC, gas chromatography coupled with mass spectrometry, or tandem mass spectrometry is often used as a screening test. Because one of four measurements may be normal in as many as 15% of patients with Cushing's syndrome, two or three 24-h samples should be obtained. The sensitivity of UFC in the evaluation of Cushing's syndrome is 95 to 100%, and its specificity is 94 to 98%. UFC corrected for body surface area is not altered by age, sex, body mass index (not exceeding 35–40 kg/m²), moderate alcohol intake, or smoking. Values consistently in excess of 300 μ g/day are highly suggestive of Cushing's syndrome. When assays for UFC excretion are not available, measurement of urinary 24-h 17-hydroxysteroids can be of help. These compounds include all cortisol metabolites with a 17-dihydroxyacetone side chain; thus, they give an indirect measure of the rate of cortisol secretion. Appropriate urine collection and determination of the creatinine excretion rate are essential for the interpretation of this test. In addition, UFC may be higher than the normal limits in up to 40% of patients with depression, anxiety disorder, obsessive-compulsive disorder, sleep apnea, morbid obesity, polycystic ovary syndrome, poorly controlled diabetes mellitus, familial resistance to glucocorticoids, hyperthyroidism, and alcoholism. Urinary cortisol excretion may be falsely elevated in those patients treated with

cortisone or hydrocortisone (topical or oral) and in women treated with vulvovaginal applications of hydrocortisone.

The 1-mg overnight dexamethasone suppression test (DST) is a simple screening tool for Cushing's syndrome, with reported sensitivity of 95 to 98% and specificity of 87%. During this procedure, a plasma cortisol measurement at 0900 h, following a single dose of 1 mg dexamethasone taken at midnight, is obtained. In children, the dose of dexamethasone that should be employed is 15 mg/kg body weight. An alternative screening method involves the determination of a single plasma or serum cortisol level following 48 h of dexamethasone (0.5 mg) every 6 h. Overall, the 2-day test and the overnight 1-mg DST can be done in outpatients and appear to have comparable sensitivities. Patients with obsessive-compulsive disorder, those with Alzheimer's dementia, and alcoholics experiencing acute alcohol withdrawal may show nonsuppressed (false-positive) overnight DST. Moreover, false-positive DSTs have been reported following weight loss and after sleep deprivation. Patients who are treated with medications that enhance the hepatic metabolism of dexamethasone, such as phenytoin, barbiturates, rifampicin, and carbamazepine, may also have false-positive results.

Patients with Cushing's syndrome have elevated nocturnal cortisol levels as compared with normal controls. The disruption of normal diurnal variation in serum cortisol secretion makes its measurement at midnight a simple screening tool for Cushing's syndrome. A measurement of plasma cortisol between 11 PM and midnight (late evening serum cortisol) reliably documents the loss of the normal circadian rhythm of cortisol secretion in patients with Cushing's syndrome. The sensitivity and specificity of this test in distinguishing patients with pseudo-Cushing's states from patients with Cushing's syndrome vary from 89 to 95% and from 97 to 100%, respectively. Normal individuals who have irregular sleeping patterns or who have recently crossed many time zones may have abnormal results. An alternative to the serum midnight cortisol test is the bedtime salivary cortisol test (which measures the free hormone fraction), which has a sensitivity of approximately 93% and a specificity of approximately 100% as well as the advantage of being an outpatient procedure.

Distinguishing Mild Cushing's Syndrome from Pseudo-Cushing's States

The diagnosis of Cushing's syndrome may be difficult given that hypercortisolism can occur in several

disorders other than Cushing's syndrome (Table I). Patients with severe isolated obesity or obesity associated with the polycystic ovary syndrome can have increased cortisol secretion. As many as 80% of patients with major depressive disorders have increased cortisol secretion. The abnormal cortisol secretion possibly results from HPA axis hyperactivity and disappears after remission of depression. Chronic alcoholism is an uncommon cause of pseudo-Cushing's syndrome. Alcohol abstinence results in normalization of the hormonal abnormalities. Critically ill patients who are stressed may have increased cortisol secretion.

The dexamethasone-CRH stimulation test distinguishes patients with pseudo-Cushing's syndrome from those with Cushing's syndrome. Thus, most patients with Cushing's syndrome (80-90%) show inadequate suppression to low-dose dexamethasone (0.5 mg every 6 h for 2 days), in contrast to the normal responses of pseudo-Cushing's patients. In addition, patients with Cushing's disease (85%) have a "normal" or exaggerated ACTH response to CRH. When these tests are considered individually, their diagnostic accuracy in the differential diagnosis of mild hypercortisolism does not exceed 80%. However, when they are used sequentially, dexamethasone suppression (0.5 mg every 6 h for 2 days) and the ovine CRH (Dex-CRH) stimulation test can distinguish Cushing's disease from pseudo-Cushing's state. In the former, the pituitary corticotrope is appropriately restrained by glucocorticoid feedback and does not respond to CRH; in the latter, the corticotrophic tumor is generally resistant to this dose of dexamethasone and responds to CRH. The criterion used for the diagnosis of Cushing's disease is a 15-min cortisol level greater than 38 nmol per liter after the CRH injection. In a limited number of patients with Cushing's syndrome, sensitivity and specificity for the dexamethasone-CRH test were found to be 100%. However, the sensitivity was lower (90%) when comparing normal individuals to patients with Cushing's syndrome. Moreover, the accuracy of the dexamethasone-CRH test in patients with episodic hormonogenesis has not been tested. Therefore, this test should be reserved for those patients with

mild hypercortisolemia who fail to respond to 1 mg of overnight dexamethasone.

Interpretation of Screening Tests

Cushing's syndrome is generally excluded if the response to the single-dose dexamethasone suppression test and the appropriately collected 24-h UFC measurements are normal. However, one should bear in mind that cortisol hypersecretion may be intermittent and periodic in 5 to 10% of patients with Cushing's syndrome of any etiology. Documenting loss of diurnal variation of plasma cortisol would support the diagnosis of Cushing's syndrome and vice versa. Obtaining more than single morning and evening blood draws increases the diagnostic value of the test because a significant variability of cortisol levels may be present. Another strategy involves close monitoring of the patient over the course of a few months. Although true hypercortisolism will persist and possibly produce further symptomatology, the hypercortisolism of pseudo-Cushing's states will be corrected spontaneously (Table II).

DIFFERENTIAL DIAGNOSIS OF CUSHING'S SYNDROME: ACTH DEPENDENT VERSUS ACTH INDEPENDENT

Once the diagnosis of endogenous Cushing's syndrome has been made, the source of excess cortisol should be found. A stepwise sequential diagnostic approach is essential to successfully differentiate ACTH-dependent from ACTH-independent Cushing's syndrome and its subtypes. Such an approach involves the determination of serum ACTH levels, the response of the HPA axis to dynamic endocrine testing, and the performance of adequate imaging studies. The serum ACTH level distinguishes ACTH-dependent from ACTH-independent Cushing's syndrome, whereas the high-dose dexamethasone suppression test (8 mg overnight), the CRH stimulation test, and bilateral inferior petrosal sinus sampling (BIPSS) are used to

Table II Differential Diagnosis of Hypercortisolism

| | UFC | 1-mg DST test | Dex/CRH test | Clinical features (Cushingoid appearance) | Natural history |
|-------------------------|-------------------------------|---------------|-------------------------|---|-----------------|
| Pseudo-Cushing's | Mild elevation (< 3 × normal) | Variable | Cortisol suppressed | None or mild | Remission |
| Cushing's | Mild to severe (>3 × normal) | Variable | Cortisol not suppressed | Mild to severe | Progression |

distinguish Cushing's syndrome due to ectopic ACTH secretion from Cushing's disease. Because they may compromise the diagnostic accuracy of the tests, all adrenal-blocking agents should be discontinued for at least 6 weeks prior to testing.

Early-morning measurement of blood ACTH and cortisol concentration distinguishes ACTH-dependent from ACTH-independent Cushing's syndrome. Circulating ACTH is typically suppressed in adrenal cortisol-secreting tumors, micronodular adrenal disease, and autonomously functioning macronodular adrenals. In contrast, plasma ACTH concentrations are normal or elevated in Cushing's disease and in those patients with ectopic ACTH and CRH secretion. Serum CRH levels should be measured if ectopic CRH secretion is suspected. Although the determination of plasma ACTH levels is often helpful, normal ACTH levels can be found in a subset of patients with Cushing's disease, those with ectopic ACTH secretion, and those with adrenal tumors. Similar overlap of baseline ACTH levels may also be seen in children and adolescents with Cushing's syndrome. The discrepancies in the diagnostic value of serum ACTH in the differential diagnosis of Cushing's syndrome are probably a reflection of different assay techniques.

DIFFERENTIAL DIAGNOSIS OF ACTH-DEPENDENT CUSHING'S SYNDROME: PITUITARY VERSUS ECTOPIC

Approximately 80% of Cushing's syndrome cases are caused by an ACTH-secreting pituitary neoplasm and less often from an ectopic site, usually a thoracic or abdominal tumor. Ectopic ACTH secretion is a rare cause of Cushing's syndrome. Because of its low prevalence, the pretest probability of ectopic ACTH secretion is low. Therefore, one must consider confirming the diagnosis with at least two biochemical tests prior to proceeding with imaging studies intended to localize the tumor. The strategies used to differentiate the subtypes of ACTH-dependent Cushing's syndrome include biochemical tests (CRH stimulation test and high-dose dexamethasone suppression test), imaging tests (magnetic resonance imaging [MRI], computed tomography [CT], radio-nuclide scans), and venous angiography with sampling of the inferior petrosal sinuses for ACTH before and after CRH administration.

CRH Stimulation Test

Most patients with Cushing's disease respond to CRH with increases in plasma ACTH and cortisol, whereas

patients with ectopic ACTH production do not. A mean cortisol increase at 30 and 45 min of greater than 20% following a bolus infusion of ovine CRH (1 $\mu\text{g}/\text{kg}$ intravenously) has a sensitivity of 91% and a specificity of 88%. Similarly, an increase of mean ACTH concentrations at 15 and 30 min after CRH by at least 35% above the mean basal values achieves a sensitivity of 91% and a specificity of nearly 100%. The CRH test is rapidly substituting the classic tests of dexamethasone suppression and metyrapone stimulation because it is simple, brief, reliable, and more economical.

High-Dose Dexamethasone Suppression Test (Liddle's Test)

This test has been used extensively in the differential diagnosis of ACTH-dependent Cushing's syndrome. Patients with Cushing's disease are sensitive to glucocorticoid inhibition only at high doses of dexamethasone (2.0 mg every 6 h for 2 days). In contrast, patients with ectopic ACTH syndrome or cortisol-secreting adrenal tumors fail to respond to the same dose. The classic Liddle's criterion for a positive response consistent with Cushing's disease is a greater than 50% drop in 17-hydroxysteroid excretion on day 2 of high-dose dexamethasone (80% diagnostic accuracy). However, the diagnostic accuracy of the test increases to 86% by measuring both UFC and 17-hydroxysteroid excretion and by requiring greater suppression of both steroids (> 64 and 90%, respectively, for 100% specificity).

Overnight 8-mg Dexamethasone Suppression Test

A simple, reliable, and inexpensive alternative to Liddle's dexamethasone suppression test is the overnight 8-mg dexamethasone suppression test. The advantages are its outpatient administration and the avoidance of errors due to incomplete urine collection. The diagnostic accuracy of this overnight test may be similar to that of the standard Liddle's dexamethasone suppression test.

Imaging Evaluation

Imaging techniques can help to clarify the etiology of hypercortisolism. These usually include MRI of the pituitary and CT scanning of the adrenal glands. CT and MRI scans of the chest and abdomen and isotope scans are also employed when tumors secreting ectopic ACTH are sought.

CT is the preferred diagnostic method in the detection of adrenal tumors. Most adrenal adenomas causing hypercortisolism are larger than 2 cm in diameter. Tumors with diameters greater than 6 cm, those containing areas of necrosis, and those with local spread should raise the suspicion of malignancy.

MRI is as sensitive as CT for the visualization of both normal and enlarged adrenal glands. T2-weighted MRIs may prove to be helpful in differentiating between malignant and benign adrenocortical neoplasms. Bilateral enlargement of the adrenal gland with preservation of a relatively normal overall glandular configuration is observed in both Cushing's disease and ectopic ACTH production. Approximately 10 to 15% of patients with ACTH-dependent Cushing's syndrome demonstrate bilateral nodules (macronodular hyperplasia).

CT and MRI scans have largely superseded the need for iodocholesterol scans in the evaluation of patients with Cushing's syndrome. However, the iodocholesterol scan can occasionally be useful in distinguishing between ACTH-dependent (bilateral uptake) and ACTH-independent (unilateral uptake) macronodular adrenals or in localizing ectopic adrenal tissue (adrenal rest) or an adrenal remnant causing recurrent hypercortisolism after bilateral adrenalectomy.

MRI scanning is the imaging procedure of choice to visualize pituitary adenomas. The large majority of pituitary ACTH-secreting tumors are microadenomas with diameters less than 10 mm. The ACTH-secreting adenomas are best demonstrated on coronal T1-weighted images as foci of reduced signal intensity within the pituitary gland. However, on unenhanced scans, ACTH-producing adenomas are detected in only 40% of patients with Cushing's disease. An additional 15 to 20% of microadenomas are visualized with injection of contrast material (gadolinium-DTPA) and repeat T1-weighted coronal scan immediately after the injection (combined MRI sensitivity of 55–60%). Although still experimental, it appears that spoiled gradient recalled acquisition MRI might be superior to conventional postcontrast spin echo MRI for detection of adrenocorticotropin-secreting pituitary tumors. CT scanning with infusion of contrast demonstrates pituitary microadenomas in less than 20% of patients with bona fide lesions on subsequent surgery. Thus, pituitary CT should be performed if necessary only to demonstrate bony anatomy prior to transsphenoidal surgery.

If suppression and/or stimulation tests are suggestive of ectopic ACTH production, radiological imaging of the chest and abdomen should be undertaken.

ACTH-producing thymic carcinoids and pheochromocytomas are generally apparent by CT at the initial presentation. Patients with a negative CT should undergo MRI of the chest and abdomen using T2-weighted images. A body scan following the injection of the radiolabeled somatostatin analogue octreotide might be helpful and disclose the tumor site, which can be reexamined by CT or MRI. However, a significant number of small ectopic tumors may remain elusive. In these cases, reassessments of the chest with MRI every 3 to 6 months are indicated.

Distinguishing Cushing's disease from the ectopic ACTH syndrome frequently presents a major diagnostic challenge. Both pituitary microadenomas and ectopic ACTH-secreting tumors may be radiologically occult and may have similar clinical and laboratory features. Bilateral inferior petrosal venous sinus and peripheral vein catheterization with simultaneous collection of samples for measurement of ACTH before and after CRH administration is one of the most specific tests available to localize the source of ACTH production.

Venous blood from the anterior pituitary drains into the cavernous sinus and subsequently into the superior and inferior petrosal sinuses. Catheters are led into each inferior petrosal sinus via the ipsilateral femoral vein. Samples for measurement of plasma ACTH are collected from each inferior petrosal sinus and a peripheral vein both before and after injection of 1 µg/kg body weight of ovine or human CRH. Patients with ectopic ACTH syndrome have no ACTH concentration gradient between either inferior petrosal sinus and the peripheral sample. A ratio greater than or equal to 2.0 in basal ACTH samples between either or both of the inferior petrosal sinuses and a peripheral vein is highly suggestive of Cushing's disease (95% sensitivity and 100% specificity). Stimulation with CRH during the procedure, with the resulting outpouring of ACTH, increases the sensitivity of BIPSS for detecting corticotropin adenomas to 100% when the peak ACTH central-to-peripheral ratio is greater than or equal to 3.0. Petrosal sinus sampling must be performed bilaterally and simultaneously because the sensitivity of the test falls to less than 70% with unilateral catheterization.

BIPSS is technically difficult and, like all invasive procedures, can never be risk free even in the most experienced hands. It should be reserved only for patients with a clear diagnosis of hypercortisolism and a negative or equivocal MRI of the pituitary or for those patients with a positive pituitary MRI but equivocal dynamic endocrine testing.

UNUSUAL FORMS OF HYPERCORTISOLISM

Periodic Cushing's Syndrome

Occasionally, cortisol production in Cushing's syndrome might not be constantly increased but instead may fluctuate in a "periodic" infradian pattern, ranging in length from days to months. This relatively rare phenomenon of periodic, cyclic, or episodic hormonogenesis has been described in patients with Cushing's disease, ectopic ACTH-secreting tumors, cortisol-secreting adrenal tumors, and micronodular adrenal disease.

Patients with periodic hormonogenesis may have consistently normal 24-h UFC and paradoxically "normal" responses to dexamethasone in the presence of clinical stigmata of Cushing's syndrome. To establish the diagnosis in such patients, several weekly 24-h UFC determinations for a period of 3 to 6 months may be necessary.

Occult Ectopic ACTH Syndrome

Occult ectopic ACTH syndrome can mimic the clinical and biochemical behavior of Cushing's disease. In some circumstances, despite extensive localization studies, the source of ACTH secretion remains elusive. In such cases, the absence of a central-to-peripheral ACTH gradient before and after administration of ovine CRH in BIPSS rules out Cushing's disease. After excluding an ACTH-secreting pituitary adenoma, imaging studies with special emphasis on the lungs, thymus, pancreas, adrenal medulla, and thyroid should be obtained given that most described ectopic ACTH-secreting tumors have been found in these organs. Thymic vein sampling for measurement of ACTH concentrations can be of help in localizing the tumor to the thorax but not necessarily to the thymus.

Cushing's Syndrome during Pregnancy

The physiological changes that occur during pregnancy may make the diagnosis of Cushing's syndrome more complicated. During normal pregnancy, human placental CRH mRNA transcription and CRH plasma levels increase significantly during the third trimester of pregnancy. A small progressive rise in plasma ACTH and a two- to threefold increase in plasma total and free cortisol also occur. UFC is also elevated during pregnancy, especially between the 34th and 40th weeks of gestation, and the suppression of cortisol by dexamethasone may be blunted.

Nonetheless, the diurnal rhythm in serum cortisol is maintained.

Nonhypercortisolemic Cushing's Syndrome (Glucocorticoid Hypersensitivity Syndrome)

Increased tissue sensitivity to cortisol has been reported in two patients with signs of Cushing's syndrome, with normal or low cortisol secretion, in whom iatrogenic corticosteroid administration was excluded. However, the molecular mechanisms underlying this entity remain elusive because mutational analysis of the glucocorticoid receptor did not reveal any abnormalities.

Primary or Sporadic Cortisol Resistance Syndrome

Glucocorticoid resistance is a rare familial or sporadic condition caused by mutations of the glucocorticoid receptor that results in generalized or partial end organ insensitivity to physiological glucocorticoid concentrations. The diagnosis should be considered in patients with elevated urine and plasma cortisol and ACTH levels that are not suppressed by dexamethasone. Plasma cortisol has a circadian rhythm similar to that of normal individuals, albeit at elevated concentrations, and responds normally to stress tests such as insulin-induced hypoglycemia. In addition, these patients frequently have elevated plasma and urinary adrenal androgens and mineralocorticoids, resulting in hyperandrogenism and hypertension.

TREATMENT

Cushing's Disease

The treatment of choice for Cushing's disease is selective transsphenoidal microadenectomy, a procedure with a cure rate approaching 95% on the first exploration by expert pituitary neurosurgeons. Failure of surgery at the first exploration may be followed by a repeat procedure with a 50% chance of cure. Success is defined as a drop of serum cortisol and UFC to an undetectable level during the immediate postoperative period. A successful outcome can also be predicted by lack of cortisol response to ovine CRH when the test is performed 7 to 10 days after surgery.

For patients who are not cured by transsphenoidal resection or in those where a tumor is not found, pituitary irradiation is the next treatment option. Although data on long-term follow-up are still scant,

stereotactic radiotherapy provides less irradiation to neuronal tissues and may offer similar or superior results when compared with conventional radiotherapy. Conventional linear accelerator with 4500 to 5000 rad delivered over a period of 6 weeks will correct the hypercortisolism in approximately 45% of adults and 85% of children, usually within 3 to 12 months of administration. Addition of the adrenolytic agent mitotane improves the correction of hypercortisolism produced by pituitary radiotherapy. Pituitary irradiation also decreases the occurrence of Nelson's syndrome in patients not cured by irradiation who require bilateral adrenalectomy. If irradiation fails to normalize cortisol secretion, adrenal enzyme inhibitors (medical adrenalectomy) can be used to ameliorate the hypercortisolism. Surgical bilateral total adrenalectomy with lifelong daily glucocorticoid and mineralocorticoid replacement therapy is the final definitive cure.

Ectopic ACTH

Once the source of ectopic ACTH is identified, surgery is warranted. If surgery is contraindicated, medical therapy with adrenal enzyme inhibitor is the treatment of choice. Ketoconazole blocks adrenal steroidogenesis at several levels by inhibiting the C17–20 lyase, 11 β -hydroxylase, 17-hydroxylase, and 18-hydroxylase. Reversible side effects, including elevations of hepatic transaminases and gastrointestinal irritation, may occur and may be dose limiting. In this case, metyrapone can be added to achieve normocortisolemia. Hypercortisolism is usually easily controlled within a few days with 200 to 400 mg of ketoconazole per day and/or 250 to 750 mg of metyrapone three times per day. Other blocking agents that may be used alone or in combination with ketoconazole and/or metyrapone include aminoglutethamide and mitotane. Etomidate, a hypnotic imidazole derivative, may also be used safely as a parenteral agent.

If the source of ACTH secretion is not localized, repeat searches for the tumor should be undertaken every 6 to 12 months. If by 2 years the tumor has escaped detection, bilateral adrenalectomy could be considered. This may have to be done earlier in developing children in whom ketoconazole and the other medications may interfere with growth and pubertal progression.

Adrenal Tumors

Unilateral or bilateral benign tumors of the adrenals should be surgically resected. Laparoscopic adrena-

lectomy is the procedure of choice nowadays. Aggressive and repetitive open surgery provides the only chance for cure or prolonged survival in adrenal carcinomas. An anterior transabdominal approach with careful examination of the liver and pararenal structures should be performed. Mitotane may be added to maximally tolerated levels or toxicity when complete resection of the tumor is unsuccessful.

Corticosteroid Replacement

Glucocorticoid replacement should be started after a successful pituitary adenomectomy or a complete resection of an ACTH-secreting ectopic or unilateral cortisol-producing adrenal tumor. Hydrocortisone should be replaced at a rate of 10 to 12 mg/m²/day by mouth, with appropriate increases in minor stress (2-fold) and major stress (10-fold) for appropriate lengths of time. The recovery of the suppressed HPA axis can be monitored with a short ACTH test every 3 months. When the 30-min plasma cortisol exceeds 18 μ g/dl, hydrocortisone can be discontinued. After a bilateral adrenalectomy, corticosteroid replacement will be necessary for life and includes both glucocorticoids and mineralocorticoids.

CONCLUSIONS

The diagnosis of Cushing's syndrome is suspected on a clinical basis and requires the demonstration of pathological hypercortisolism. Screening tests include the determination of 24-h urine cortisol excretion, the 1-mg dexamethasone suppression test, and the measurement of late-night serum cortisol levels. In mild cases, distinction from the hypercortisolism of pseudo-Cushing's states may prove to be difficult. A dexamethasone-CRH test or close monitoring of the patient may be helpful. Excess endogenous glucocorticoid production can be ACTH dependent or ACTH independent. Distinction between ACTH-dependent and ACTH-independent hypercortisolism is made on the basis of basal and CRH-stimulated plasma ACTH determinations and adrenal CT. Most cases of primary adrenal Cushing's syndrome can be ruled out on the basis of undetectable basal and/or CRH-stimulated plasma ACTH and the absence of an identifiable lesion on imaging studies. ACTH-dependent Cushing's syndrome can then be differentiated on the basis of CRH testing and imaging studies. A discrete pituitary lesion on imaging and a standard CRH test with results consistent with such lesions are sufficient to proceed with transsphenoidal surgery. If

no visible pituitary lesion is present or if the CRH test is equivocal, simultaneous BIPSS with CRH administration is necessary to distinguish between a pituitary source and an ectopic source. Surgery is the treatment of choice for all types of Cushing's syndrome. Radiation therapy, radiosurgery, and medical adrenalectomy with adrenolytics and adrenal enzyme inhibitors are effective adjuvant treatments. Bilateral adrenalectomy is reserved for those patients who have failed all other forms of treatments.

tertiary centers is estimated to be 1.5%. The majority of men with Klinefelter's syndrome are undiagnosed. When suspected, the diagnosis may be confirmed by the presence of the chromosomal aberration in a karyotype analysis of peripheral blood lymphocytes. Buccal smears, which are examined for the presence of Barr bodies, can be used as a screening test.

Klinefelter's syndrome is characterized by small firm testes with absent spermatogenesis. Additional clinical manifestations, which are more variably present, are gynecomastia, eunuchoid body habitus, micropenis, and sparse body hair. XXY males have above average height from 5 years of age onward, with grown males tending to be tall. In addition, they have eunuchoidal skeletons, characterized by an arm span that exceeds height, narrow shoulders, and an elevated ratio of lower to upper body length. The increased length of the lower body is present before puberty; therefore, it is secondary to the karyotype itself rather than to hormonal levels. Gynecomastia results from a decreased ratio of testosterone to estrogen. The hips of these males tend to be wide from a more feminine fat distribution.

Boys with Klinefelter's syndrome enter normal puberty and tend to have low testosterone levels during late adolescence and adulthood. Classically, gonadotropins become elevated by 12 to 14 years of age, with a plateau of testosterone concentrations in the subnormal range by 16 years of age. Testicular biopsy reveals hyalinization and fibrosis of the seminiferous tubules with a reduced number of germ cells. Loss of seminiferous tubular function and Sertoli cells prevents feedback inhibition and leads to an increase in FSH secretion. Klinefelter's patients have impairment in Leydig cell function, leading to elevations in LH. Virtually all men with Klinefelter's syndrome are infertile; however, there are isolated reports of confirmed paternity. In 1998, assisted reproductive technology, involving testicular extraction and intracytoplasmic sperm injection from two 47,XXY Klinefelter's males, resulted in the delivery of healthy infants.

The mean intelligence level of 46,XXY males is slightly below that of controls, although there is a wide range of intelligence quotients (IQs). Verbal IQ is usually lower than performance IQ. For every additional X chromosome, there is an approximate 10- to 15-point drop in the IQ. Language deficits may be the cause of the academic difficulties and social withdrawal that occurs during the school years in some affected males. None of the chromosomal variants manifests any shortening of life expectancy.

Klinefelter's syndrome is associated with other medical conditions. XXY males have a rate of breast cancer that is 20 times higher than that of the general male population. They have higher rates of germ cell tumors and of autoimmune diseases such as systemic lupus erythematosus, rheumatoid arthritis, and Sjogren's syndrome. They also have higher rates of diabetes mellitus and hypothyroidism. They are prone to venous stasis, varicose veins, deep venous thromboses, and pulmonary emboli. Hypogonadism makes them susceptible to osteoporosis. There is a high incidence of taurodontism, characterized by an enlarged pulp chamber and thinning of the tooth surface, thereby making teeth prone to early decay.

Testosterone replacement enhances the development of secondary sex characteristics, causes a more masculine fat distribution, has beneficial effects on the libido, and promotes behavioral and work performance. Testosterone therapy does not affect testicular size, spermatogenesis, and fertility. It usually does not reverse gynecomastia, which can be corrected with surgical reduction.

XX Males

The XX male syndrome occurs in 1 in 20,000 to 24,000 births. XX males are phenotypically similar to Klinefelter's males. They have small firm testes, azoospermia, infertility, and seminiferous tubule hyalinization. Gynecomastia is present in about one-third of the cases. These patients have elevated LH and FSH levels, whereas testosterone levels are low. However, men with this disorder differ phenotypically from Klinefelter's males in that they have below average height, they do not have intellectual impairment, and they have hypospadias more commonly. XX males occasionally have severe genital ambiguity.

Frequently, XX males have a genetic translocation involving the testis-determining gene, SRY. SRY, which encodes a DNA-binding protein, is normally located near the pseudo-autosomal region of the short arm of the Y chromosome. In most XX males, SRY has been incorporated into the X chromosome or another autosome. This is thought to result from aberrant recombination between the X and Y chromosomes. Two-thirds of XX males have detectable Y chromosomal sequences in the distal region of the X chromosome. Some XX males have a mosaic pattern of expression, with a few cell lines expressing 46,XY and the rest expressing 46,XX. Interestingly, all known XX males with hypospadias and genital ambiguity have been found to lack the SRY gene. Hence, the disorder is heterogeneous, and some cases remain

unexplained. Although most cases are sporadic, there are familial cases of 46,XX males, with all familial cases having genital ambiguity.

Myotonic Dystrophy

Testicular atrophy occurs in 75% of men with myotonic dystrophy, an autosomal dominant disorder. Pathological examination of the testes reveals seminiferous tubule degeneration with Leydig cell preservation, although Leydig cell function is obviously impaired. As a result, patients usually have high LH and FSH levels along with low levels of testosterone.

Inherited Disorders of LH and FSH

Mutations in the α -chains of the gonadotropins have not been described in humans. Mutations in the β -chains of LH and FSH have been described. The hormonal profile in disorders caused by these mutations can often be suggestive of hypergonadotropic hypogonadism, with low levels of testosterone accompanied by high levels of one or both gonadotropins.

One LH β -mutation has been reported, with the affected male having delayed puberty, low testosterone, and arrested spermatogenesis. This patient harbored a missense mutation in the LH beta gene. The mutation permitted hormone synthesis and immunoreactivity; however, it prevented binding of the hormone to its receptor. Consequently, the patient's LH level was elevated by radioimmunoassay and his FSH level was normal. Treatment with human chorionic gonadotropin (hCG) caused increased testosterone levels, testicular enlargement, virilization, and an improved sperm count; however, the patient remained infertile. At 44 years of age, his gonadotropin levels were uniformly elevated.

In 1998, the first two men harboring homozygous mutations in the FSH beta gene were described. One of the men, who was found to have a two-base pair deletion in FSH beta, presented with delayed puberty, small testes, and azoospermia. He had undetectable serum FSH levels by radioimmunoassay, high serum LH levels, and low serum testosterone. Although the other man had undergone normal puberty, he had azoospermia. He was found to have a missense mutation in the FSH beta gene. This individual had absent FSH along with normal LH and testosterone.

LH and FSH Resistance

The LH and FSH receptors belong to the G protein-coupled class of receptors that have

seven-transmembrane domains. Mutations of the LH and FSH receptors may result in a failure of the receptor to bind ligand or in a failure of the receptor activation cascade, which is mediated by cyclic AMP (cAMP).

LH resistance, caused by inactivating mutations of the LH receptor, is a rare cause of hypergonadotropic hypogonadism. Missense mutations, nonsense mutations, insertions, and deletions have been reported. These loss-of-function mutations lead to an entity known as Leydig cell hypoplasia, characterized by the complete or relative absence of Leydig cells. Patients who are homozygous for LH receptor mutations have an impaired or absent response to hCG or LH, the natural ligands for the LH receptor.

The clinical manifestations of LH receptor mutations are variable. In milder forms, patients may have varied phenotypes such as micropenis, severe hypospadias, hypogonadism without sexual ambiguity, and isolated infertility. In its most severe form, the syndrome is characterized by male pseudohermaphroditism, with female or ambiguous genitalia, low testosterone levels, high LH levels, absence of male secondary sexual characteristics, and a lack of response to hCG or LH challenge.

Only one complete loss-of-function mutation in the FSH receptor has been described; this mutation impairs receptor function by causing a marked reduction in ligand binding and a complete inhibition of signal transduction. Five men homozygous for the FSH mutation were identified in the Finnish population. All had normal testosterone levels, normal or slightly elevated LH levels, moderately elevated FSH levels, and slightly to markedly reduced testicular volume. Two of the men had successfully fathered two children each. However, all five men had abnormal semen parameters, including oligospermia, low sperm volume, and teratozoospermia. Partial functional impairment of the FSH receptor has been described in women but not in men.

DEVELOPMENTAL CAUSES

Cryptorchidism or Anorchia

Males with cryptorchidism or anorchia often have hypergonadotropic hypogonadism. Cryptorchidism is caused by a disruption of normal testicular descent. The most common sites for cryptorchid testes are the neck of the scrotum or just outside the external inguinal ring. Although the etiology of cryptorchidism is multifactorial, it is believed to be a defect in prenatal androgen secretion from either decreased

pituitary gonadotropin stimulation or impaired placental production of gonadotropins. Hormonal levels are usually normal at birth, and only later during infancy is the production of androgens impaired. Deficient androgen production with elevated gonadotropins may be caused by elevated intra-abdominal temperature or by an intrinsic testicular defect.

Cryptorchidism occurs in 4 to 5% of males at birth, although more than half of the cases resolve by 6 to 12 months of age. Men with a past history of cryptorchidism have a higher risk of infertility. In addition, these men have an approximately 5- to 10-fold risk of malignant testicular tumors compared with the general male population. Of note, there is an increased risk of malignancy in the contralateral testis in unilaterally cryptorchid men. Treatment of cryptorchidism with hCG or luteinizing hormone-releasing hormone (LHRH) has a success rate of 10 to 20%. However, surgical treatment is more effective in treating cryptorchidism and prevents testicular germ cell degeneration. Testosterone synthesis becomes impaired within a few months of birth; therefore, early correction is imperative. In infants, surgery is usually recommended between 1 and 2 years of age. Electron microscopic studies showing evidence of germ cell degeneration in humans at 6 to 12 months of age suggest that orchiopexy should be performed even earlier.

There is an association between low birthweight and cryptorchidism as well as between complex genital malformations and cryptorchidism. Cryptorchidism is the most common cause of azoospermia. Fully 89% of untreated cryptorchid patients develop azoospermia. The incidence of azoospermia in unilaterally cryptorchid patients is 13% regardless of whether they are treated. There is a correlation between maldescent of one testis and poor spermatogenesis in the contralateral testis.

Patients without palpable or visible testes may have either cryptorchidism or complete anorchia. To distinguish between the two, hCG may be administered intramuscularly. In cryptorchid males, a rise in plasma testosterone should ensue. In anorchid males, there will be no rise in testosterone levels. In addition, anorchid males have undetectable levels of anti-Müllerian factor during childhood. Therefore, in prepubertal males, measurable levels of anti-Müllerian factor indicate the presence of testicular tissue. However, during puberty, anti-Müllerian factor becomes undetectable in all males; therefore, this assay is not useful in peri- or postpubertal males. Whereas some cryptorchid males might not have elevated basal levels of gonadotropins, in anorchid males

basal gonadotropin levels are uniformly high. Anorchid males have otherwise normal male genital development. They are thought to have had testes during early fetal life that underwent degeneration during the 13th week of gestation, allowing normal genital development.

ACQUIRED CAUSES

Chemotherapy

Testicular damage in response to cytotoxic drugs was first described in 1948. Of 30 men studied at autopsy after being treated with nitrogen mustard, 27 were found to have azoospermia. The testes are more sensitive to damage from chemotherapy or radiation than are the ovaries. The germinal epithelium is more sensitive to the damaging effects of chemotherapy than are Leydig cells. Gonadal dysfunction from chemotherapeutic agents is variable. Patients may have any or all of the following: elevated LH and FSH levels, azoospermia, and evidence of testicular damage on pathology specimens. Testosterone is usually in the normal range. Testicular damage as a result of chemotherapeutic agents is usually dose dependent. The drugs known to be gonadotoxic are listed in [Table I](#).

Radiotherapy

The testis is one of the most radiosensitive organs. The more immature a testicular cell, the more sensitive it is to radiation damage. Thresholds have been established for the amount of radiation that will cause specific testicular cell damage. Recovery of spermatogenesis depends on the presence of intact type A spermatogonia and, therefore, on the dose of radiation received. The Leydig cells are more resistant to

Table I Gonadotoxic Drugs

| | |
|-------------------|------------------|

Adapted from Howell and Shalet (1998).

radiation damage than is the germinal epithelium, although Leydig cell damage can occur with high radiation doses that are sometimes used in the treatment of testicular cancer.

Mumps and Viral Orchitis

Mumps is the most common cause of viral orchitis, followed by echovirus, lymphocytic choriomeningitis virus, and group B arbovirus. The incidence of mumps orchitis has declined dramatically since the introduction of the mumps vaccination. It is rare in prepubertal boys; however, it develops in 15 to 35% of adolescent boys and men infected with the mumps virus. It usually presents with marked scrotal swelling and fever. Most patients have typical mumps parotitis preceding the scrotal manifestations. Orchitis results from direct invasion of the testes by the virus. Acutely, patients have elevated plasma FSH and LH along with decreased testosterone levels. After testicular swelling has resolved, gonadal function and the hormonal profile may return to normal. However, in one-third of men with orchitis, the affected testis may atrophy, causing persistently increased gonadotropins and low testosterone as well as azoospermia. In one-tenth of patients, both testes are affected. In some cases of unilateral involvement, atrophic changes may be observed in the contralateral and seemingly unaffected testis.

Atrophy is a result of destruction by the virus and ischemia from edema. On pathological examination, atrophic testes show progressive tubular sclerosis and hyalinization. Atrophy is usually present within 1 to 6 months after inflammation subsides. Approximately 50% of patients with unilateral orchitis have azoospermia. However, within 1 to 2 years, the sperm count returns to normal in three-quarters of those individuals. On the other hand, sperm counts in patients with bilateral orchitis return to normal in only one-third of patients.

Aging

The effect of aging on the hypothalamic–pituitary–gonadal axis appears to be primarily at the level of the testicle. Necropsy studies have revealed an age-related decrease in the number of sperm as well as increased morphological sperm abnormalities. Normal aging in men is accompanied by a slow but statistically significant decline in androgens, particularly in free testosterone levels. There is estimated to be a 1 to 2% annual decline in levels of testosterone beginning during the fourth decade of life. This decline is not

present in every individual, and it varies considerably among individuals. Of note, the drop in testosterone levels in aging males is so gradual that the majority of elderly men still have testosterone levels within the normal range. The hormonal profile found in hypogonadal aging men is typical of hypergonadotropic hypogonadism. FSH tends to increase at a more rapid rate than does LH. Aging is also associated with increased testosterone binding to sex hormone-binding globulin (SHBG), which lowers the levels of free, or biologically active, testosterone.

Older men commonly report symptoms of depression, impaired memory, irritability, poor concentration, and decline in sexual interest and function. As men age, they experience decreasing muscle mass, increasing central adiposity, and increasing incidence of osteoporosis and bone fractures. Although these clinical signs and symptoms are typically present in young hypogonadal men, they are not clearly attributable to hypogonadism in older men. Hypogonadal young men respond well to testosterone replacement, with resolution or amelioration of their symptoms. In aging men with normal or low-normal levels of testosterone, the benefit of replacement therapy is much less obvious.

Fewer than 5% of men over 60 years of age are strictly hypogonadal. However, if one defines hypogonadism as a subnormal level of non-SHBG-bound testosterone, the percentage of men over 60 years of age who are hypogonadal may be as high as 50%. The goals of testosterone replacement in aging men include improved libido and erectile function, improved psychological well-being, increased lean body mass and muscle strength, preserved bone mass, and increased stamina. Although it is effective in restoring libido, testosterone supplementation in older men rarely reverses erectile dysfunction. In some studies, testosterone replacement has been shown to improve parameters of bone formation and resorption in aging men. However, other studies have shown no effect. Although testosterone therapy dramatically improves lean body mass in young hypogonadal men by 9 to 19%, it has a more modest effect in healthy older men with low to low-normal testosterone levels.

There is general concern regarding the effects of supplemental testosterone on disorders of the cardiovascular system and the prostate. Testosterone can adversely affect the cholesterol profile as well as other cardiovascular risk factors. Nonaromatizable testosterone preparations, including the oral agents oxandrolone and methyltestosterone, decrease high-density lipoprotein (HDL) cholesterol levels, increase low-density lipoprotein (LDL) cholesterol levels, and

have even been reported to lead to myocardial infarction and stroke in young men. Testosterone may increase cardiovascular risk by causing a propensity for vascular constriction via endothelin. It also promotes platelet aggregation and thrombus formation. On the other hand, most epidemiological studies indicate that higher testosterone levels in men correlate with a lower cardiovascular risk. This may be due to a secondary effect from comorbidities in elderly men with cardiovascular disease such as diabetes mellitus, cirrhosis, and renal failure, all of which are associated with hypogonadism. Studies of men treated with aromatizable testosterone agents have shown lowering of LDL cholesterol and no effect on HDL cholesterol. Furthermore, by decreasing visceral fat accumulation, testosterone may be a cardioprotective agent. The resultant cardiovascular effect in a given individual treated with testosterone replacement is unknown.

Testosterone, via conversion to dihydrotestosterone by the enzyme 5- α -reductase, has also been implicated as a growth stimulant for both normal and neoplastic prostatic tissue. There is widespread concern that testosterone replacement may exacerbate benign prostatic hypertrophy (BPH) and accelerate the growth of prostate cancer. However, although no causal link between testosterone administration and either prostate cancer or BPH has been demonstrated, caution is advised. Testosterone has been implicated in exacerbating cases of sleep apnea. It also stimulates erythropoietin production, thereby elevating hematocrit, hemoglobin, and red cell mass.

Chronic Illness

Chronic illnesses are frequently associated with testicular dysfunction that mimics primary testicular failure. There have been reported cases of primary gonadal failure with hemochromatosis. Primary hypogonadism is seen in sickle cell disease and is thought

to result from direct testicular damage related to vascular trauma from sickling with its consequent impairment of blood flow. Chronic renal failure can cause primary testicular failure. Finally, AIDS may cause features of both primary and secondary hypogonadism. The mechanism for the association of poor testicular function with chronic disease has not been elucidated, but it may represent a nonspecific response of the testes.

PRECIPITATING FACTORS

Respiratory and urinary tract infections are common precipitants; others include myocardial infarction, pulmonary embolism, and acute pancreatitis. Certain antihypertensive drugs, including high-dose diuretics and beta-blockers, have been implicated; diuretics may exacerbate dehydration and potassium depletion. Other drugs include phenytoin, cimetidine, and chlorpromazine. High-dose corticosteroids have potent effects on carbohydrate and lipid metabolism, readily precipitating metabolic decompensation in predisposed individuals.

DIAGNOSIS

Urinalysis reveals marked glycosuria with a “negative” or “trace” ketone reaction using semiquantitative nitroprusside-based test strips. Blood glucose concentration is markedly elevated, i.e., >500 mg/dl. Blood urea nitrogen is elevated and hematocrit is raised. Serum osmolality can be measured directly in the laboratory (by freezing-point depression), or the effective osmolality can be estimated from the formula

$$\text{Sodium(mEq/L)} + \frac{\text{Glucose(mg/dl)}}{18} = \text{mOsm/kg H}_2\text{O}$$

Table I Guide to Initial Treatment of Hyperosmolar Nonketotic Hyperglycemia in Adults

Fluids and electrolytes

Volumes

- 1 liter per hour \times 2–3, thereafter adjusted according to the degree of hydration and taking continuing polyuria into account. N.B. Use caution in patients with known renal disease or cardiovascular insufficiency; consider central venous pressure monitoring.

Fluids

- Isotonic saline (0.9%, 150 mEq/liter sodium chloride) initially.
- Hypotonic saline (0.45%, 75 mEq/liter sodium chloride) if serum sodium exceeds 150 mEq/liter (restrict to 1–2 liters in total and consider use of 5% dextrose with increased insulin if marked or worsening hyponatremia).
- 5% Dextrose at 1 liter every 4–6 h replaces saline when blood glucose has fallen to 250 mg/dl until patient is eating and drinking again.

Potassium replacement

- No potassium chloride added to the first liter of fluid, unless initial plasma potassium <3.5 mEq/liter.
- Measure serum potassium every 2 h initially (see below: Other Measures)
- Thereafter, add dosages below to each liter of fluid:
 - If plasma K^+ :
 - <3.5 mEq/liter, add 40 mEq potassium chloride (severe hypokalemia may require more aggressive replacement with careful monitoring of serum potassium concentration).
 - 3.5–5.5 mEq/liter, add 20 mEq potassium chloride.
 - >5.5 mEq/liter, add no potassium chloride to the infusion.

Insulin

- 5–10 U/h (average 6 U/h in adults) by continuous intravenous infusion initially until blood glucose has fallen to 250 mg/dl. Thereafter, adjust rate (usually 1–4 U/h required in the absence of severe infection) together with dextrose infusion to maintain serum glucose between 100 and 200 mg/dl until patient is eating and drinking again.
- Thereafter, change to an appropriate subcutaneous insulin regimen.
- Review continuing need for insulin therapy 2–3 months after full recovery.

Other measures

- Search for and treat precipitating cause (e.g., infection, myocardial infarction).
- Systemic hypotension usually responds to adequate fluid replacement with crystalloids.
- Pass bladder catheter if level of consciousness is impaired or no urine is passed within 2 h of the start of therapy.
- Continuous electrocardiographic monitoring may warn of hyperkalemia or hypokalemia (serum potassium should be measured hourly if <3.5 or >5.5 mEq/liter).
- Consider cranial computed tomography imaging to exclude other pathology (e.g., cerebral hemorrhage, venous sinus thrombosis) if the level of consciousness remains impaired following correction of hyperosmolar state.
- Treat acute thrombo-embolic complications with anticoagulant doses of heparin.
- Update clinical and biochemical progress using a purpose-designed flowchart.

Total body sodium is reduced, yet blood sodium concentration at presentation can be low, normal, or high, depending on the concomitant water deficit. Hyperglycemia may depress sodium concentration (correction factor: add 1.6 mEq sodium per 100 mg plasma glucose >100 mg/dl to the measured serum sodium concentration). Hypertriglyceridemia may result in pseudo-hyponatremia; plasma should be examined for turbidity. Dehydration is usually severe, with an average deficit in adults of approximately 8–10 liters. Arterial plasma pH is >7.30 and bicarbonate is >15 mEq/liter. However, a degree of acidosis may result from impaired renal excretion of H⁺ ions allied to tissue hypoperfusion. Urinary losses of potassium are approximately 400–700 mEq in adults.

TREATMENT AND COMPLICATIONS

Initial Emergency Treatment

Successful management depends on early recognition of the diagnosis, general intensive care of the unconscious patient, and prompt treatment of underlying causes. The principal elements of initial treatment include the following: (1) intravenous rehydration, with saline; (2) insulin therapy, by continuous intravenous infusion; and (3) replacement of electrolytes, especially potassium (Table I).

Longer-Term Management

Following recovery, in the medium to long term, oral anti-diabetic agents may control type 2 diabetes, thereby permitting safe withdrawal of insulin treatment. The need for insulin therapy should be reviewed 2–3 months after recovery. Steps should be taken to avoid recurrences wherever possible.

Complications and Outcomes

Nontraumatic rhabdomyolysis in patients with greater degrees of hyperosmolarity may precipitate acute renal failure. There is a high frequency of thrombo-embolic complications. The average mortality rate is approximately 15%, higher than for patients with diabetic ketoacidosis. The acute outcome tends to be worse for individuals of advanced age or with serious comorbidity.

| Familial isolated hyperparathyroidism (FIHP) |
| Malignant tumors |
| Parathyroid carcinoma |
| Chemical induced |
| Lithium |

which (>99%) are benign. The only environmental factor associated with PHPT (benign adenomas) is childhood exposure of the neck or upper chest to ionizing radiation (e.g., a common treatment for facial acne prior to 1950). The only medication known to cause PHPT is lithium. Chronic administration of lithium is associated with PHPT in at least 6% of patients who are treated with lithium for 15 years or more. Prospective studies have shown that during the first few years of lithium therapy, parathyroid hormone (PTH) levels rise, urinary calcium excretion falls, and serum calcium levels remain normal. Over time, true PHPT can develop, and the subsequent discontinuation of lithium does not reverse the hyperparathyroidism. In small surgical series, half of patients with lithium-associated PHPT have had single parathyroid adenomas and half of patients have had multigland disease.

Single Adenomas

In most patients (80–90%), PHPT is the result of a solitary parathyroid adenoma. Parathyroid adenomas are benign monoclonal tumors. Most parathyroid adenomas are in the neck, but in some cases an abnormal gland may descend to an ectopic location (i.e., pseudoectopia), particularly when hyperparathyroidism is due to superior gland disease. Approximately 15% of all inferior parathyroid adenomas will be found within thymic tissue, and in rare cases (1–5%) an adenoma will be located ectopically in the thyroid, the mediastinum, or the angle of the jaw (undescended gland).

Double Adenomas

Occasional patients have double adenomas, which can be asynchronous or parathyroid cysts.

Multigland Disease

Approximately 5 to 15% of patients with PHPT have multigland disease, previously termed parathyroid hyperplasia, in which all four parathyroid glands (or more in cases where an extra gland is present) are abnormal. Parathyroid enlargement in multigland disease can be asymmetrical, and some abnormal glands may appear to be normal in size (up to 10:1 size ratios can be seen). Multigland disease occurs most commonly in patients with familial forms of PHPT that are inherited as distinct autosomal dominant traits. The age at diagnosis in hereditary PHPT is typically 20 to 35 years, three decades younger than seen in sporadic single-parathyroid adenoma patients. Five familial syndromes that are associated with PHPT have been described.

First, multiple endocrine neoplasia, type I syndrome (MEN1, MIM131100), is associated with tumors of at least 20 different tissues, most frequently of the parathyroids, pituitary, and pancreas. The parathyroid tumors are almost always benign, but tumors of the pancreas and gut (foregut carcinoid) are often malignant. The MEN1 gene located on chromosome 11 encodes menin, a nuclear factor that appears to function as a tumor suppressor. Nearly all patients (95%) with MEN1 will develop PHPT by 40 years of age. The average age at onset is 25 to 30 years, although patients as young as 8 years old have been reported. Genetic mutation analysis for the MEN1 gene located at 11q13 is available, but measuring the serum calcium level remains an effective, albeit late, approach to screening at-risk members of known kindreds.

Second, multiple endocrine neoplasia, type II (also termed MEN2A) syndrome (MIM 171400), is a tumor syndrome that includes medullary thyroid cancer, pheochromocytoma, and PHPT. The parathyroid tumors are almost always benign, with a mean age of diagnosis of 34 years. PHPT occurs in only 30 to 50% of patients with MEN2A but may be recognized prior to discovery of medullary thyroid cancer. MEN2A is caused by heterozygous-activating mutations in the RET protooncogene (MIM 164761) located at 10q11.2.

Third, familial hypocalciuric hypercalcemia (MIM 145980; also termed familial benign hypocalciuric hypercalcemia [FHH]) is an atypical form of PHPT in which adverse effects of hypercalcemia are rare and no specific treatment is required. Patients with FHH have hypercalcemia from birth, and in some cases affected newborns manifest life-threatening hypercalcemia, a variant previously termed “neonatal severe primary hyperparathyroidism.” Unlike other forms of

PHPT, urinary calcium excretion is low and so the risk of calcium kidney stones is not increased. In most cases (> 90%), FHH is caused by a heterozygous loss-of-function mutation in the gene encoding the calcium-sensing receptor located at 3q13.3–q21. This form of FHH has been designated as FHH1 (or FBH1) to distinguish it from much less common variants that have been mapped to 19p13.3 (termed FBH2) or linked to loci on 19q (FBH3). The 50% reduction in calcium-sensing receptors on the surface of parathyroid cells leads to secretion of PTH at higher ambient serum levels of calcium than normal, and serum levels of PTH are generally normal or only slightly elevated. A similar reduction in calcium-sensing receptors in the kidney results in increased renal reabsorption of calcium and accounts for the very low urinary calcium clearance (i.e., less than 0.01) that can be used to distinguish FHH from other forms of PHPT. In nearly all cases, patients with FHH do not develop adverse effects from either elevated levels of serum calcium or PTH. It is important to recognize when PHPT is due to FHH so that unnecessary and inappropriate surgery can be avoided.

Fourth, hyperparathyroidism–jaw tumor syndrome (HPT-JT, MIM 607393) is a rare syndrome of PHPT and ossifying jaw tumors (seen in dental radiographs). Unlike other hereditary forms of PHPT, as many as 15% of parathyroid tumors in HPT–JT are malignant. HPT–JT syndrome is caused by inactivating germline mutations in the *HPRT2* gene. Similar somatic mutations have been identified in approximately 5% of sporadic parathyroid adenomas with cystic features. This gene, which is located at 1q25–31, encodes a putative tumor suppressor protein that has been termed parafibromin.

Fifth, familial isolated hyperparathyroidism (FIHP) is another rare syndrome. Affected individuals do not have additional endocrine tumors or other syndromic features. Germline mutation of *HPRT2*, the gene responsible for the HPT–JT syndrome, has been identified in some cases of FIHP.

Parathyroid Cancer

Malignant parathyroid tumors comprise less than 1% of cases of PHPT. These patients tend to be younger than patients with benign tumors and present with severe symptomatic hypercalcemia. Patients with parathyroid carcinoma often will have both skeletal and renal complications of PHPT, and many (50%) will have a palpable neck mass.

CLINICAL PRESENTATION OF PHPT

In the United States and other developed nations, PHPT is most commonly diagnosed after the incidental discovery of symptomatic hypercalcemia on a multichannel chemistry panel. Therefore, at the time of diagnosis, few patients will manifest the specific clinical signs and symptoms that have been classically ascribed to PHPT and that are still common in patients who live in regions of the world where periodic measurement of the serum calcium level is not routine. These clinical features may be recalled through the following mantra: stones (nephrolithiasis), bones, (osteoporosis), abdominal groans (pancreatitis, peptic ulcer disease, constipation), and psychic overtones (depression, lethargy, poor concentration). Muscle weakness resulting from a neuropathic myopathy or arthritis resulting from pseudogout can also occur.

Nephrolithiasis and Nephrocalcinosis

The incidence of kidney stones (nephrolithiasis) in PHPT has declined over the past 25 years and is now considered to be 15 to 20%. PHPT is an uncommon cause of kidney stones in general, and only about 5% of unselected patients with a renal stone will be found to have PHPT. Kidney stones in patients with PHPT are similar in composition to calculi from nonhyperparathyroid patients and may contain pure calcium oxalate, pure calcium phosphate, or a mixture of calcium phosphate and calcium oxalate. Most studies show, however, that calcium phosphate stones are more common in patients with PHPT than in the general stone-forming population. The factors contributing to stone formation include increased urinary excretion of calcium and phosphate, reduced urinary excretion of crystallization inhibitors (e.g., pyrophosphate, citrate, magnesium), hyperuricosuria, and alkaline urine due to mild renal tubular acidosis. Successful parathyroid surgery reduces the risk of recurrent kidney stones in approximately 90% of patients; persistent postoperative hypercalciuria is typically found in those patients who continue to form stones after surgery. Calcium phosphate crystals may form throughout the renal parenchyma, a process termed nephrocalcinosis. Nephrocalcinosis is less common than nephrolithiasis (e.g., 5%) and might not be associated with formation of stones or development of renal insufficiency. Nephrocalcinosis does not resolve after correction of PHPT.

Bones

Excessive PTH action activates osteoclastic bone resorption, which when severe results in radiological manifestations that collectively are termed osteitis fibrosa cystica: subperiosteal resorption of the distal digits (particularly along the radial side of the middle phalanges), erosion of the distal one-third of the clavicles, salt-and-pepper skull, and bone cysts or brown tumors. Osteitis fibrosa cystica can cause pathological fractures and pain but is distinctly uncommon today. A characteristic pattern of skeletal demineralization, in which significant reductions in cortical bone density are seen regularly with relative preservation of cancellous bone density, is more common in patients with PHPT today. This results in a pattern of bone loss that contrasts sharply with that of postmenopausal osteoporosis, specifically a more significant loss of bone density at cortical sites (e.g., distal one-third site of the forearm) than at cancellous sites (e.g., spine). The hip (composed of cancellous and cortical bone) shows less consistent reductions in bone mass. The risk of fracture is increased in PHPT and overall is about 1.8-fold. Studies of PHPT have consistently found an increased risk of forearm fractures, but the risk of hip and spine fractures appears to be more variable. After surgical correction of PHPT, bone mass increases dramatically at all sites.

LABORATORY EVALUATION

Serum Calcium

Hypercalcemia is the primary biochemical hallmark of PHPT and is an essential diagnostic criterion. Several determinations of serum calcium may be required to confirm hypercalcemia because it may occur only intermittently. Routine determination of the serum calcium value measures the concentration of total serum calcium, which can sometimes provide misleading information. For example, hypercalcemia may result from elevated or abnormal circulating proteins or from hemoconcentration induced by prolonged application of the tourniquet. By contrast, total serum calcium can be normal in patients with PHPT who have abnormally low concentrations of serum albumin. Several algorithms have been proposed to correct the measured total serum calcium for a low level of serum albumin (e.g., $[(4.0 - \text{measured albumin in mg/dl}) \times 0.8]$), but none is entirely satisfactory. Under conditions where abnormal circulating proteins may reduce the reliability of determining the total serum calcium concentration, it is advisable to measure

the ionized serum calcium concentration directly. If both the total and ionized serum calcium concentrations are normal, it is difficult to make a definitive diagnosis of PHPT. Rare patients with PHPT and coexisting vitamin D deficiency (typically with 25-hydroxy-vitamin D levels < 20 ng/ml) may have serum calcium levels that are consistently normal. In these patients, a diagnosis of PHPT might not be obvious until correction of vitamin D deficiency permits development of hypercalcemia.

Parathyroid Hormone

The immunometric and chemiluminescent assays for intact PTH are currently the preferred formats for measuring circulating concentrations of biologically active PTH. These assays are highly sensitive and have replaced older immunoassays that were directed against midmolecule or carboxy-terminal epitopes of PTH. Assays for intact PTH provide outstanding diagnostic accuracy for PHPT, even in patients with renal insufficiency. Serum levels of intact PTH are elevated or high normal in nearly 90% of patients with PHPT. Although the upper limit of normal for intact PTH is considered to be 65 pg/ml, in individuals under 45 years of age the upper limit of normal has been determined to be closer to 45 pg/ml given that levels of PTH normally rise with age. Although assays for intact PTH had been considered specific for the full-length PTH 1–84 molecule, recent studies have determined that intact PTH assays also detect circulating PTH fragments that consist of the 7–84 sequence. These truncated fragments possess inhibitory activity and can comprise as much as 35% of circulating “intact” PTH immunoreactivity. Newer assays that appear to be specific for only PTH 1–84 (“whole” PTH assay) have been developed and may provide improved diagnostic discrimination. Intact (or whole) PTH is elevated or normal in PHPT and is suppressed or undetectable in other causes of hypercalcemia (e.g., malignancy, granulomatous disease, vitamin D intoxication). Importantly, currently available assays for PTH do not cross-react with parathyroid hormone-related protein (PTHrP), the cause of hypercalcemia in most cases of malignancy-associated hypercalcemia in solid tumors.

Serum Phosphate, Chloride, Vitamin D, and Bone Turnover Markers

The serum phosphate level is usually in the low or low-normal range because of reduced renal tubular

reabsorption of phosphorus. This change in renal handling of phosphorus can be calculated as the tubular reabsorption of phosphorus (TRP) or as the renal tubular maximum reabsorption of phosphate per liter of glomerular filtration rate (TmP/GFR) from plasma and urine creatinine and phosphate measurements. A mild hyperchloremic metabolic acidosis (Cl >103 mEq/L) is common. Serum levels of 25-hydroxy-vitamin D are usually normal or low normal, whereas serum levels of calcitriol (1,25-dihydroxy-vitamin D) are at the upper limit of normal in most patients with PHPT, with levels that are frankly elevated in one-third of patients. Most patients with PHPT have an elevated rate of bone turnover. This can be documented by measuring markers of bone resorption, such as serum C-telopeptide or N-telopeptide (best measured on fasting blood specimens) or urinary N-telopeptide (best measured using a first- or second-morning urine sample), which reflect the breakdown products of type I collagen. Markers of bone formation, such as the bone-specific alkaline phosphatase isoenzyme, type I procollagen peptide, and serum osteocalcin, are also elevated in many patients with PHPT. These markers can be elevated in patients with even mild PHPT who have normal serum levels of total alkaline phosphatase.

Urinary Excretion of Calcium and Magnesium

A 24-h urine collection should be obtained for determination of calcium, creatinine, and sodium (Table II). Hypercalciuria is present in 40% of patients with PHPT and likely reflects increased gastrointestinal absorption of calcium as well as increased bone resorption. The renal tubular handling of calcium and sodium is related such that factors that promote natriuresis also

increase urinary calcium excretion. Therefore, patients with an elevated dietary intake of salt are at increased risk for hypercalciuria. If the urine calcium and sodium both are high, repeating the collection on a reduced sodium intake (i.e., less than 100 mmol sodium) may be useful. Patients with PHPT also have an increased renal clearance of magnesium. In contrast, patients with FHH have unexpectedly normal or low urinary calcium excretion (generally less than 100 mg/24 h) with a fractional excretion of calcium (i.e., renal calcium-to-creatinine clearance ratio) that is typically less than 0.01 and relative hypomagnesuria. Vitamin D deficiency is also associated with low urine calcium levels (e.g., <100 mg/24 h), and coexistence of vitamin D deficiency with PHPT can cause a low enough urinary calcium level to suggest FHH. In this case, repletion with vitamin D and repeating serum and 24-h urine calcium measurement can clarify the correct diagnosis.

IMAGING STUDIES

Skeletal Evaluation

Skeletal radiographs to search for signs of osteitis fibrosa cystica are not recommended except in patients with symptomatic bone pain or pathological fractures. Subperiosteal bone resorption is most readily detected in the distal phalanges using high-sensitivity X-ray film; in advanced cases, evidence of excessive bone resorption may also be present in the skull or distal clavicles. In most patients with PHPT, bone resorption is more subtle and evaluation of bone density in the hip, spine, and radius by dual-energy X-ray absorptiometry (DEXA or DXA) will be necessary to appreciate skeletal demineralization. PHPT causes a preferential loss of bone density at sites that are enriched in cortical bone (distal radius). DXA should be repeated annually in patients who are not referred for surgery.

Urological System

In selected cases, a single abdominal radiograph or an ultrasound study can be useful in assessing the presence of nephrolithiasis or nephrocalcinosis. Although computed tomography (CT) is more sensitive for detecting small stones and nephrocalcinosis, the higher levels of radiation associated with CT compared with other techniques make its routine use imprudent.

Parathyroid Imaging

Technetium-99m (Tc-99m) sestamibi with or without single photon emission computed tomography

Table II Differential Diagnosis of Elevated Parathyroid Hormone

| Diagnosis | Serum calcium | Intact parathyroid hormone | Urine calcium |
|--------------------------------------|---------------|----------------------------|---------------|
| Primary hyperparathyroidism | H | H or N | H or N |
| Familial hypocalciuric hypercalcemia | H | H or N | L |
| Secondary hyperparathyroidism | N or L | H | H, N, or L |

Note. H, high; N, normal; L, low.

(SPECT), ultrasound (US), CT, and magnetic resonance imaging (MRI) all are noninvasive techniques that can detect enlarged or abnormally functioning parathyroid tissue. Tc-99m sestamibi appears to be the most sensitive and specific of these techniques and is commonly used to identify a parathyroid lesion in patients who are candidates for minimally invasive parathyroid surgery. In contrast, parathyroid imaging does not appear to improve the outcome of a standard bilateral neck exploration when it is performed by an experienced operator on a patient who has not had previous parathyroid surgery. Tc-99m sestamibi imaging is typically performed using early and delayed images to take advantage of the fact that the thyroid gland discharges the radionuclide more rapidly than does the abnormal parathyroid gland. Alternatively, Tc-99m sestamibi can be combined with a second imaging agent, such as ^{123}I , so that the thyroid gland image can be “subtracted” from the image obtained with Tc-99m sestamibi. Imaging with Tc-99m sestamibi can identify a pathological parathyroid gland in 70 to 80% of patients with PHPT.

DIAGNOSIS

Elevated serum calcium and elevated or normal PTH are required for the diagnosis of PHPT (Table II). The intact PTH (iPTH), the most sensitive assay, but can be normal in up to 10 to 15% of patients with surgically proven PHPT. In these cases, a normal serum iPTH value in the presence of hypercalcemia indicates nonsuppressible or autonomous parathyroid tissue (e.g., adenoma). However, a serum iPTH level that is below 35 pg/ml is strong evidence that hypercalcemia is due to a nonparathyroid etiology (e.g., malignancy, granulomatous disease, vitamin D intoxication). The 24-h urine excretion of calcium may be elevated or normal in PHPT, but a calcium/creatinine clearance ratio that is less than 0.01 should raise suspicion of possible FHH.

TREATMENT: WHEN TO REFER TO SURGERY

Surgical removal of hyperfunctioning parathyroid tissue remains the only definitive treatment of PHPT. However, patients with neither signs nor symptoms of PHPT, defined as asymptomatic PHPT, might not require surgery. The management of asymptomatic PHPT was addressed by participants

of a National Institutes of Health (NIH) Consensus Conference in 1990 and was subsequently updated in 2002. The NIH Consensus Conference produced a set of guidelines to help clinicians decide which patients should be referred for surgery and which patients could be placed under medical surveillance. The 2002 workshop led to a new set of guidelines for managing patients with PHPT:

- Serum calcium ≥ 1 mg/dl above normal
- Kidney stone or extreme hypercalciuria (24-h urine calcium > 400 mg/day)
- Creatinine clearance reduced by 30% compared with age-matched normal individuals
- Reduced bone density compared with young normals at peak bone mass (T score < -2.5) at hip, lumbar spine, or distal radius
- Patient age less than 50 years
- Patients for whom medical surveillance is neither desirable nor possible (e.g., patients for whom serial monitoring is impractical or unacceptable)

Other factors to consider when deciding whether to recommend surgical intervention include neuropsychological abnormalities (e.g., weakness, depression) and onset of menopause (when accelerated bone loss is anticipated). Using these guidelines, approximately half of patients with PHPT have one or more indications for surgery. In addition, surgery is always an acceptable choice for patients who prefer surgery to conservative follow-up after a definitive diagnosis of PHPT is made.

Minimally invasive parathyroid surgery under local or regional anesthesia has become a popular alternative to conventional surgery for many patients with PHPT, particularly those who are poor candidates for general anesthesia. The success of a minimally invasive surgical procedure is dependent on positive preoperative localization of a parathyroid lesion using a noninvasive imaging technique (e.g., Tc-99m sestamibi imaging). Intraoperative monitoring of serum PTH levels with a modified rapid iPTH assay is now performed at many centers and is considered by many as a useful adjunct to both minimally invasive and classical parathyroid surgery. A fall of at least 50% from baseline within 15 min of removal of hyperfunctioning parathyroid tissue is indicative of resolution of clinical signs in 95% of cases. In the case of solitary adenoma, iPTH is not only a biochemical substitute for histological examination but also a predictive test of normocalcemia.

NONSURGICAL MANAGEMENT

Chronic Medical Management

General Measures

Conservative management consisting of medical surveillance is appropriate for patients who are asymptomatic and have no surgical indications. Patients should be advised that dehydration could worsen hypercalcemia and so they should drink at least 2 L of water per day. Diuretics should be used with caution. Thiazide diuretics are particularly troublesome because they reduce renal calcium excretion through a direct effect on the distal renal tubule and can also cause dehydration. Although loop diuretics (e.g., furosemide) can induce calciuria at high doses, at typical oral doses their primary effect is to reduce extracellular volume. A reduction in extracellular volume can decrease the glomerular filtration rate and thereby reduce renal calcium excretion, further increasing the serum calcium level. The dietary calcium intake should not be restricted but should be limited to a moderate intake of 1000 mg/day. Patients should avoid very low-calcium diets that can worsen a negative calcium balance and that may further increase PTH secretion. Vitamin D supplementation of 400 IU/day can help to prevent bone loss and does not exacerbate hypercalcemia unless there is an underlying vitamin D deficiency; higher doses and other forms of vitamin D (e.g., calcitriol) should be avoided. Because immobilization can increase bone resorption and result in hypercalciuria or hypercalcemia, patients should be instructed to avoid protracted bed rest and to maintain (or increase if possible) their general level of activity.

Bisphosphonates

Bisphosphonates are analogues of inorganic pyrophosphate that adsorb to the hydroxyapatite matrix of bone and inhibit osteoclast-mediated bone resorption. Bisphosphonate compounds can be divided into two distinct pharmacological classes with different mechanisms of action depending on whether they contain a nitrogen atom(s) in their side chains. Non-nitrogen-containing bisphosphonates, including etidronate, clodronate, and tiludronate, are metabolized intracellularly to cytotoxic, nonhydrolyzable analogues of adenosine triphosphate (ATP). Nitrogen-containing bisphosphonates, including alendronate, ibandronate, pamidronate disodium, risedronate, and zoledronic acid, inhibit protein prenylation and are more potent inhibitors of osteoclast-mediated bone resorption. Zoledronic acid is a

new-generation, heterocyclic, nitrogen-containing bisphosphonate and is the most potent inhibitor of bone resorption identified to date. The more powerful oral and parenteral bisphosphonates can acutely lower serum and urinary calcium values and can increase PTH in patients with PHPT. Short-term use of oral bisphosphonates lowers serum calcium levels, but during chronic use the serum and urinary calcium levels tend to increase over time and generally return to their pretreatment elevations; PTH levels may remain higher than at pretreatment. Despite a lack of persistent beneficial effect on serum levels of calcium and PTH in PHPT, the newer, more potent oral bisphosphonates (e.g., alendronate, risedronate) demonstrate sustained efficacy in reducing bone resorption that can result in moderate increases in bone mass (3–8% over 2 years). The ability to prevent (or reverse) bone loss makes bisphosphonates useful adjuncts in the medical management of patients with PHPT who are not candidates for surgery.

Estrogens, SERMs, and Progesterone

Estrogen reduces bone turnover in both normal postmenopausal women and those with PHPT. Estrogen therapy can reduce serum calcium levels in patients with PHPT without increasing PTH secretion; this is in contrast to bisphosphonates, which increase PTH levels. In addition, therapy with estrogen can increase bone mineral density, with significant increases after 2 years of treatment in both the lumbar spine (4–5%) and femoral neck (3–4%). Estrogen therapy appears to be most useful in asymptomatic postmenopausal women with PHPT and mild osteopenia but with no other indications for surgery. However, the increased risks of stroke, myocardial infarction, thromboembolic disease, and breast cancer must be carefully considered before recommending long-term use of estrogen therapy. These concerns have raised interest in the potential use of selective estrogen receptor modulators (SERMs) as an alternative to estrogen in women with PHPT. Preliminary studies performed in small numbers of women with mild PHPT who had refused either surgery or estrogen have produced encouraging results. Treatment with raloxifene (60 or 120 mg/day for 12 months) increased bone mineral density by 3.4% at lumbar spine and by 2.5% at femur neck. Although total calcium levels decreased modestly in all patients after 12 months of treatment, serum levels of ionized calcium and iPTH returned close to baseline values after 12 months. Markers of bone resorption showed sustained reductions over the 12 months of treatment.

Progestins vary in their effect on bone metabolism in PHPT. Norethindrone, a progestin with relatively high androgenic activity, has effects that are similar to but less potent than those of estrogen, but less androgenic progestins (e.g., medroxyprogesterone acetate) have no effect on bone metabolism in PHPT.

Calcimimetic Agents

Calcimimetic drugs are in development as a therapy for primary and secondary hyperparathyroidism. These agents directly reduce PTH secretion through their effect on the calcium-sensing receptor on the parathyroid cell. The calcimimetics increase the sensitivity of the calcium-sensing receptor to ambient concentrations of extracellular calcium, thereby increasing the suppressive effect of hypercalcemia on PTH secretion. Clinical trials of NPS568, a first-generation calcimimetic, and AMG073, a longer acting and more potent second-generation agent, have yielded very promising results as potential medical treatments for PHPT. These agents can decrease both serum calcium and PTH levels in a dose-dependent manner and, when used over long periods of time, can also reduce parathyroid size. Although calcimimetics are not yet generally available, they can be obtained on a compassionate need basis for patients with severe PHPT due to parathyroid cancer.

Phosphate

In the past, oral phosphate was a common treatment for patients with PHPT who required medical therapy, particularly when there was a risk of recurrent nephrolithiasis. Phosphate reduces serum and urine calcium levels via suppression of 1,25-dihydroxyvitamin D, which in turn reduces calcium absorption from the gut. However, phosphate also increases PTH secretion, which is undesirable in patients with PHPT. Phosphate is contraindicated in patients with renal insufficiency and its dose is limited by the side effect of diarrhea. The frequent occurrence of gastrointestinal intolerance and the concern that patients who develop an elevated calcium-phosphate product will develop soft tissue (metastatic) calcification have reduced enthusiasm for long-term phosphate therapy, and the introduction of powerful oral and intravenous bisphosphonates has largely replaced phosphate as a therapy for PHPT. Phosphate is no longer recommended for long-term use, but in selected cases of PHPT, short-term phosphate

treatment (1–2 g/day in three or four divided doses) can be beneficial.

Urgent Management for Severe PHPT or Hypercalcemic Crisis

Patients who have marked hypercalcemia (i.e., serum calcium level > 13 mg/dl) or milder hypercalcemia (i.e., serum calcium level > 12 mg/dl) with symptoms (e.g., altered mental status) or a shortened QT interval on EKG should be treated promptly. Intravenous infusion of 0.9% saline should be administered immediately at 200 to 800 ml/h, depending on the severity of symptoms and cardio-renal status, to maintain a normal to expanded state of hydration and to induce calciuresis. Hydration in conjunction with a loop diuretic requires careful monitoring to avoid dehydration. This treatment will be sufficient in many cases of mild to moderate hypercalcemia, but patients with severe hypercalcemia will require an additional intervention to inhibit bone resorption so as to eliminate the primary source of excess serum calcium. A wide variety of agents have been used to reduce bone resorption, including phosphate, mithramycin, calcitonin, gallium nitrate, and bisphosphonates. Administration of an intravenous bisphosphonate (e.g., pamidronate, zoledronic acid), coupled with adequate hydration, effectively normalizes serum calcium in the majority of patients with severe hypercalcemia. Pamidronate is given as a single infusion of 60 to 90 mg over 12 to 24 h in 500 ml of 0.9% saline. Zoledronic acid is more potent than pamidronate, and comparison studies between these two agents in hypercalcemia of malignancy show that patients treated with zoledronic acid had a more rapid normalization of serum calcium levels than did those in the pamidronate disodium group. Mean serum calcium levels at days 4, 7, and 10 were significantly lower in patients treated with 4 or 8 mg of zoledronic acid than in patients treated with pamidronate disodium, and the median time to relapse, median duration of response, and time to relapse all were longer in the zoledronic acid group than in the pamidronate disodium group. Zoledronic acid (4–8 mg) is infused over 5 to 15 min. Restoration of eucalcemia occurs within days and may last from 1 week to several weeks. Treatment may be repeated as needed. The most common adverse events are transient fever and hypophosphatemia, with these events typically being associated with bisphosphonate therapy. Neck surgery should be undertaken as soon as an elevated or

inappropriately normal iPTH is confirmed and the patient is stable.

Because the dietary intake of phosphate is variable, the kidney plays an important role in maintaining phosphate balance by adjusting excretion to match dietary intake. Approximately 80 to 90% of plasma phosphate is unbound and freely filtered by the glomerulus. Under conditions of a normal phosphate diet, approximately 80% of the filtered phosphate is reabsorbed and 20% is excreted in the urine. Virtually all of the reabsorption occurs in the proximal tubule, consistent with the exclusive localization of the phosphate transporter to this segment of the nephron.

A number of hormones and other factors have been shown to regulate the renal excretion of phosphate. However, the major factors appear to be the level of intake of phosphate and PTH. Dietary phosphate has a major influence on the urinary excretion of phosphate. Thus, an increase in phosphate intake decreases reabsorption, resulting in increased excretion of the anion. Conversely, low-phosphate diets increase renal reabsorption of phosphate such that urinary excretion may fall to zero. These adaptations in the reabsorption of phosphate can occur in the absence of measurable changes in plasma phosphate and in the absence of PTH. The factor(s) responsible for this remarkable adaptive change in the kidney to dietary phosphate intake is unknown.

In addition to diet, PTH plays a major role in the regulation of phosphate excretion. PTH has a direct effect on the proximal tubule to decrease phosphate reabsorption. Thus, parathyroidectomy decreases phosphate excretion, whereas administration of PTH increases phosphate excretion. Plasma phosphate levels, in turn, can regulate PTH secretion. Elevation of plasma phosphate increases PTH synthesis/secretion by two mechanisms. Phosphate can complex with calcium, resulting in a reduction of plasma calcium. The resulting fall in plasma calcium is a major stimulus for PTH secretion from the parathyroid glands. In addition, recent studies have shown that high plasma phosphate per se can increase PTH synthesis by the parathyroid gland. This feedback mechanism, which under normal physiological conditions functions to maintain plasma phosphate levels, plays a major role in the hyperphosphatemia of chronic renal failure.

CAUSES OF HYPERPHOSPHATEMIA

There are a number of causes of hyperphosphatemia. For example, hereditary or acquired hypoparathyroidism, in which circulating levels of PTH are low or absent, results in the development of hyperphosphatemia, most likely due to increased renal reabsorption

of phosphate. Elevated levels of growth hormone, as seen in acromegaly, are also associated with elevated plasma phosphate levels due to increased renal absorption. Other causes of hyperphosphatemia include the release of phosphate from the large intracellular pool as a result of cell injury or cell death as occurs in tumor lysis syndrome or rhabdomyolysis.

However, perhaps the most common cause of chronic hyperphosphatemia, and the one with the most dire consequences for the patient, is that associated with chronic renal disease. When renal function is compromised either experimentally or by disease, there is a compensatory enlargement of the remaining nephrons and an increased rate of filtration per nephron. To remain in balance, the phosphate excretion per nephron must also increase. Increased levels of PTH appear to mediate the increased excretion of phosphate per nephron in early renal disease. Thus, normal plasma phosphate levels are maintained, but at the expense of elevated PTH levels. As renal function progressively declines, increasingly higher levels of PTH are needed to maintain phosphate homeostasis. In advanced stages of renal disease in which the kidney's excretory function is markedly reduced, the elevated levels of PTH are unable to maintain normal phosphate levels and hyperphosphatemia becomes evident. The consequences of hyperphosphatemia are numerous, with the most important being the development of secondary hyperparathyroidism, uremic bone disease, and the promotion of vascular and visceral calcifications (Fig. 1).

Secondary hyperparathyroidism is a common complication in renal failure patients. Hyperphosphatemia contributes to elevated levels of PTH by at least three mechanisms. First, phosphate by itself appears to increase PTH synthesis by the parathyroid gland by

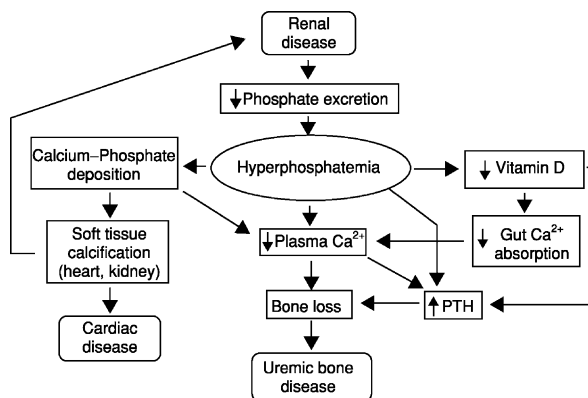

Figure 1 Development and consequences of hyperphosphatemia in chronic renal disease.

posttranslational mechanisms. Second, high levels of plasma phosphate can lead to the precipitation of calcium phosphate in soft tissues, resulting in a decrease in plasma calcium, which is a major signal for PTH release. Finally, vitamin D₃ is a major inhibitor of PTH gene transcription and also promotes intestinal calcium absorption. The kidney is the major source of the enzyme 1 α -hydroxylase, which is responsible for converting 25(OH)-vitamin D to the active form, 1,25(OH)₂-vitamin D₃. Not only is 1 α -hydroxylase activity decreased in renal disease because of the reduction in renal mass, but high levels of phosphate can also inhibit the enzyme activity. Therefore, hyperphosphatemia, either directly or indirectly, can attenuate major negative feedback mechanisms aimed at reducing circulating PTH. Furthermore, with low levels of vitamin D₃, intestinal calcium absorption is impaired, and this can also contribute to the hypocalcemia. All of these abnormalities related to phosphate, calcium, PTH, and vitamin D₃ metabolism in chronic renal disease patients result in nearly all such patients having some degree of abnormal bone metabolism, generally known as uremic bone disease or renal osteodystrophy.

As mentioned previously, high levels of plasma phosphate can complex with calcium, resulting in the deposition of calcium-phosphate crystals in soft tissues. Recent attention has been directed toward the consequences of soft tissue calcification. It is now clear that hyperphosphatemia and an elevated calcium-phosphorus product (Ca \times P) can promote visceral and vascular calcification and are linked to increased cardiovascular mortality. Cardiovascular disease accounts for nearly 50% of all deaths in dialysis patients, a percentage that is markedly higher than that in the general population. A recent analysis of dialysis patients revealed that the relative risk of death increased in proportion to elevations in the Ca \times P product. In another study of dialysis patients, the prevalences of mitral and aortic valve calcification were markedly higher (44.5 and 54.0%, respectively) than those in the control populations (10.0 and 4.3%, respectively). There is also evidence that elevated PTH levels may contribute to cardiovascular morbidity and mortality through their effects on arteriolar wall thickening and myocardial interstitial fibrosis. All of these recent findings have led to recommendations for the tighter control of plasma phosphate, calcium, and PTH levels in patients with chronic renal disease, especially in the dialysis population.

TREATMENT OF HYPERPHOSPHATEMIA

The preceding studies point to the importance of dietary phosphate intake and plasma phosphate in renal disease progression as well as the complex interaction among phosphate, PTH, calcium, and vitamin D in the development of secondary hyperparathyroidism and uremic bone diseases. Nonpharmacological approaches to the treatment of secondary hyperparathyroidism include surgical parathyroidectomy. In end stage renal failure patients, phosphate removal by dialysis is limited due to complex elimination kinetics; therefore, additional pharmacological means are needed to control plasma phosphate. Current and potential pharmacological approaches to the management of hyperphosphatemia and its consequences can be grouped into three categories: (1) modification or inhibition of dietary phosphate intake, (2) suppression of elevated PTH levels, and (3) vitamin D₃ analogues.

Modification of Dietary Phosphate Intake

Long-term restriction of phosphate intake by dietary means is limited by the difficulty of maintaining adequate nutrition on such a diet in patients with chronic renal disease and by poor patient compliance. Accordingly, phosphate binders, which are compounds that bind ingested phosphate and so prevent its intestinal absorption, are required in the majority of patients for adequate control of plasma phosphate. Aluminum-containing phosphate binders (e.g., aluminum hydroxide) are effective at inhibiting intestinal phosphate absorption but are little used due to the accumulation of aluminum in the brain and bone as well as the resulting side effects of osteomalacia, dementia, and myopathy. Calcium-based binders (e.g., calcium carbonate, calcium acetate) have largely replaced the aluminum-based binders; they effectively bind intestinal phosphate and help to control plasma phosphate. However, the large amounts of calcium ingested with calcium-based binders can lead to hypercalcemia, especially in patients on concurrent vitamin D therapy, and may worsen soft tissue calcification.

Newer calcium- and aluminum-free phosphate binders that effectively control plasma phosphate without the side effects associated with calcium- and aluminum-containing binders have been developed. Sevelamer hydrochloride is a cross-linked polyallylamine approved by the Food and Drug Administration as a phosphate binder. In clinical

studies on hemodialysis patients, sevelamer hydrochloride reduced plasma phosphate and the $\text{Ca} \times \text{P}$ product with a potency similar to that seen with calcium-containing binders. Sevelamer also significantly reduced plasma PTH and cholesterol levels. Additional phosphate binders based on ferric-containing compounds are under investigation.

Inhibition of Phosphate Transport

A little-discussed but potential therapeutic target to control hyperphosphatemia is the development of compounds that inhibit the renal and/or intestinal phosphate transporters in a way similar to the inhibition of the Na-K-Cl transporter by furosemide. Theoretically, such compounds should both decrease intestinal phosphate absorption and increase renal phosphate excretion during the early phases of renal failure. When little functional renal mass is present in severe renal failure or end stage renal disease, compounds selective for the intestinal phosphate transporter would function in a way similar to that of phosphate binders. Little has been published in this area except for studies on nickeritrol and various monophosphonates. Nickeritrol is a pro-drug of nicotinic acid, which is used to improve peripheral circulation and plasma lipid profiles. Experiments in animals and hemodialysis patients have shown that nickeritrol reduced plasma phosphate levels by inhibiting intestinal phosphate absorption. The monophosphonate phosphonoformic acid (foscarnet), which was originally developed as an antiviral agent, has been shown to be a relatively weak but selective inhibitor of Na^+ -dependent phosphate transport across renal and intestinal brush border membranes. Furthermore, fosfarnet is phosphaturic in rats when administered parenterally or orally. In a rat model of chronic renal failure, oral administration of fosfarnet for 48 h resulted in an increase in phosphate excretion and in a small but significant decrease in plasma phosphate. Longer term treatment with fosfarnet (8 weeks) in this animal model also increased phosphate excretion, but no consistent effects on plasma phosphate or on the rate of decline in renal function were observed. Although fosfarnet did not alter the course of renal failure in these studies and is nephrotoxic at high doses, the results are encouraging and suggest that inhibiting renal and especially intestinal phosphate transporters may be a viable therapeutic target to control hyperphosphatemia. However, longer term

studies with these compounds are needed to address issues of side effects and tolerability.

PTH Suppression

The discovery and cloning of the extracellular calcium-sensing receptor (CaR) and elucidation of its role in divalent cation metabolism has opened up new therapeutic areas for the treatment of hyperparathyroidism and other mineral metabolism disorders. The CaR is a low-affinity G protein-coupled receptor present on parathyroid cells, renal cells, and elsewhere in the body. In the parathyroid gland, activation of the CaR by small increases in extracellular calcium results in a decrease in PTH secretion. Calcimimetics, compounds that enhance the affinity of the CaR for calcium, have been synthesized and are undergoing evaluation for the treatment of primary and secondary hyperparathyroidism. One of these compounds, NPS 568, has been shown to halt the progression of secondary hyperparathyroidism in uremic rats and to lower PTH levels in hemodialysis patients with mild or severe secondary hyperparathyroidism. Another compound of this class, AMG 073, has been shown to reduce plasma PTH, calcium, phosphate, and the $\text{Ca} \times \text{P}$ product in hemodialysis patients with secondary hyperparathyroidism. Although further clinical assessment is necessary, these compounds may provide an additional option for the treatment of secondary hyperparathyroidism in chronic renal disease.

Vitamin D Analogues

Treatment with vitamin D_3 and vitamin D analogues has long been used for controlling various aspects of uremic bone disease. The most active metabolite of vitamin D, calcitriol ($1,25(\text{OH})_2\text{D}_3$), has been used in the treatment of secondary hyperparathyroidism. Intravenous calcitriol effectively suppresses PTH levels in patients with secondary hyperparathyroidism. However, calcitriol also has potent effects to increase intestinal calcium and phosphate absorption and calcium mobilization from bone. Therefore, therapeutic doses of calcitriol often result in hypercalcemia and a worsening of hyperphosphatemia, especially in patients taking calcium-containing phosphate binders. Accordingly, newer analogues of vitamin D that retain the therapeutic effects on PTH levels with less calcemic and phosphatemic activity are

under investigation. Paricalcitol (19-nor-1,25-dihydroxy-vitamin D₂) is a recently approved injectable calcitriol analogue that decreased PTH levels by approximately 60% in hemodialysis patients, with only a few incidences of hypercalcemia that occurred in patients whose PTH levels decreased to very low levels. Oral 1 α -hydroxy-vitamin D₂, which has also been recently approved, decreased PTH levels with a low incidence of hypercalcemia or hyperphosphatemia. Finally, 22-oxacalcitriol, which is still under investigation, was as effective as calcitriol at reducing PTH levels in mice and rats but was less calcemic.

SUMMARY

A major cause of chronic hyperphosphatemia is progressive renal disease. In end stage renal failure patients, appropriate levels of plasma phosphate cannot be achieved by dialysis without the aggressive use of phosphate binders and vitamin D analogues. With the growing awareness that abnormal phosphate metabolism and secondary hyperparathyroidism play a key role in the morbidity and mortality of these patients, new therapeutic approaches are needed. The recent introduction of noncalcemic phosphate binders and vitamin D analogues partially addresses this issue. Initial results with novel agents, such as calcimimetics, to reduce PTH levels are promising and await full

clinical testing. Other approaches that could prove to be fruitful include inhibition of intestinal and renal inorganic phosphate transporters and the development of PTH receptor antagonists.

diuretics, ACE inhibitors, angiotensin receptor antagonists, and vasodilators and is decreased by beta-blockers and centrally acting agents. Treatment with these drugs should be interrupted before renin levels are assessed, although this may be difficult in patients with severe hypertension. In such cases, alpha-blockers and calcium antagonists may be continued because they have little effect on renin release.

Acute Renin-Suppression Tests

Acute renin-suppression tests interrupt the renin-angiotensin system, showing that this system is involved in the control of hypertension. The ACE inhibitor captopril is generally administered orally due to its rapid onset of action (20 min) and maximum length of action (1–3 h). BP should consistently decrease in patients with renin-dependent hypertension.

When Is It Useful to Measure Renin?

In patients with essential hypertension, renin determination may help doctors to select the most effective first-line treatment. Patients in the highest renin index quartile show the greatest response to beta-blockers and those in the lowest quartile respond better to diuretics. However, considering the fluctuations in renin levels in individual patients and the relatively high cost, the therapeutic value of measuring plasma renin during routine investigation of mild to moderate essential hypertension is limited (see [Table I](#)). Renin should be measured in patients prone to secondary hypertension. Such patients can be identified by their medical history, signs, and symptoms, or the presence of hypokalemia, hyperazotemia, or asymmetrical kidneys (see [Table III](#)). Renin should also be measured in the small proportion of patients with severe untreated hypertension or those in whom hypertension is resistant to conventional treatment. In such cases, an unsuspected form of secondary hypertension or a pronounced drug-induced stimulation of the renin-angiotensin system may be found. Such findings may indicate that additional etiologic evaluation is required or that an ACE inhibitor, an angiotensin receptor antagonist, or a beta-blocker should be added to the treatment regimen.

RENIN-DEPENDENT FORMS OF HYPERTENSION

Primary Hypertension

High renin levels are found in approximately one in six patients with benign essential hypertension

(see [Table II](#)). The purpose and efficiency of screening for high renin hypertension in this setting is discussed above. Most patients with malignant hypertension have high renin levels. The renin concentration is very high in patients with hyponatremic hypertensive syndrome, leading to hyperangiotensinemia with thirst, polyuria, and hyponatremia and secondary aldosteronism with potassium wasting and hypokalemia. Malignant hypertension may be primary or, as in 45% of cases, the consequence of an underlying renal or adrenal disease.

Renal Artery Stenosis

Renal ischemia associated with renal artery stenosis (RAS) is the most frequent condition occurring with renin-dependent hypertension. Uni- or bilateral RAS can cause renovascular hypertension, a form of hypertension that can be reversed by nephrectomy or renal revascularization. Approximately two-thirds of stenoses are due to atherosclerosis, usually in patients over the age of 50 years. One-third are due to fibromuscular dysplasia, mostly in young female patients. The standard procedure for diagnosing RAS is catheter angiography. For screening purposes, this invasive procedure can be replaced by computed tomography (CT) angiography, magnetic resonance angiography, or duplex Doppler sonography. These techniques estimate the frequency of RAS at 1% in unselected patients with hypertension and at 10 to 30% in patients with drug-resistant hypertension or with atherosclerosis elsewhere. The standard for defining renovascular hypertension is a favorable BP outcome following revascularization. This definition is retrospective and the actual frequency of the condition is unknown because hypertension reversal is dependent on several parameters, such as the patient's age, hypertension duration, stenosis etiology and grade, parenchymal consequences of hypertension, the feasibility of revascularization, and the risk of restenosis.

Considering the risks associated with renal artery surgery or percutaneous angioplasty, attempts have been made to design tests to select RAS patients who have truly renin-dependent hypertension. In such patients, the captopril test is expected to induce a sharp decrease in BP. The captopril test, with concurrent determination of plasma renin levels, is predicted to induce a homeostatic increase in renin secretion from the stenotic kidney. Although the captopril test has been analyzed in numerous patients at risk of having renovascular hypertension, a complete analysis is not possible because of multiple inconsistencies in patient selection, standards, test procedures, and cutoff points.

Table I When to Measure Renin?

| Setting | Aim | Comments |
|--|---|--|
| Mild or moderate untreated hypertension | Determination of renin subgroup for prognostic or therapeutic purposes | Classification of individual patients into low- or high-renin subgroups probably not cost-effective in this setting |
| Severe untreated hypertension (diastolic BP consistently >110 mm Hg) and/or hypokalemic hypertension | Guidance for subsequent etiologic investigations | High renin levels suggest that CT angiography, magnetic resonance angiography, or duplex Doppler sonography should be performed, whereas low renin levels suggest adrenal investigations |
| Drug-resistant hypertension | Guidance for antihypertensive treatment adaptation | Discontinue current treatment (calcium channel antagonists and alpha-blockers may be continued) and determine plasma renin levels; high renin levels suggest that a beta-blocker, an ACE inhibitor, or an angiotensin II receptor antagonist should be added to the previous treatment regimen |
| Hypertension with renal failure | Guidance for antihypertensive treatment adaptation | Low or normal renin levels suggest that the daily dose of loop diuretic should be increased; high renin levels suggest that an ACE inhibitor should be added |
| Hypertension with renal artery stenosis or unilateral small kidney or kidney tumor | Evaluation of asymmetrical renin secretion before nephrectomy or renal artery angioplasty | A RVR ratio ≥ 1.5 is generally associated with a favorable BP outcome following nephrectomy or renal artery angioplasty |

Simultaneous determination of renin in both renal veins has been used to predict BP outcome following revascularization in patients with unilateral RAS. If the renal vein renin (RVR) ratio (i.e., the ratio between the RVR levels on the stenotic and nonstenotic sides) exceeds 1.5, the stenosis is assumed to cause renin-dependent hypertension amenable to surgical or angioplastic cure. The test may be performed after acute oral captopril administration. Postcaptopril renal scintigraphy is a less invasive alternative to RVR determination and is more accurate than the captopril–renin test. Postcaptopril scintigraphy is the most appropriate test in unilateral RAS. RVR determinations should be performed only in complex cases such as branch stenoses or renovascular disease associated with focal renal parenchymal infarction.

Other Conditions with Renal Ischemia

A few conditions characterized by chronic or acute intrarenal ischemia may also induce renin-dependent hypertension. These include systemic diseases such as polyarteritis nodosa and scleroderma, in which BP and renal outcomes are greatly improved by ACE inhibitors, and segmental renal infarction. Segmental renal infarction may result from renal embolism, renal artery thrombosis or dissection, or *in situ* thrombosis in cases with coagulation disorders. It usually presents as an abrupt-onset malignant hypertension with hyponatremic hypertensive syndrome. The condition

may revert spontaneously to normotension because the ischemic renal tissue, which releases large amounts of renin, may subsequently turn into a silent renal scar.

Renal Tumors and Cysts

Primary reninism is a rare, purely renin-dependent form of hypertension. It may be caused by juxtaglomerular cell tumors, malignant kidney tumors (nephroblastoma, adenocarcinoma), or epithelial or soft tissue tumors. Primary reninism is associated with very high plasma renin concentrations and by the absence of RAS and intrarenal ischemia (as determined by renal angiography). A small, hypodense renal cortical tumor (juxtaglomerular cell tumor) or a larger renal or extrarenal tumor is then detected by CT scan. BP usually drops during ACE inhibition and hypertension can be cured by tumor resection, although it may recur if metastases develop in malignant cases. In the 43 reported cases of juxtaglomerular cell tumors, hypertension was severe [median BP (range) 210/114 mm Hg (160–260/115–170 mm Hg)] and associated with hypokalemia [2.9 mmol/liter (2–3.9 mmol/liter)]. PRA or renin concentration was markedly elevated in all cases (medians cannot be provided because renin was reported as PRA or active renin concentration, before or after the conversion of prorenin into renin). CT scanning revealed small renal tumors [diameter 25 mm (8–50 mm)].

Table II Etiology, Presentation, and Key Findings in Renin-Dependent Hypertension

| Underlying disease | Usual presentation | Key tests and findings |
|--------------------------------------|---|---|
| Primary hypertension | | |
| Benign | Nonspecific; 10–15% of patients with primary hypertension belong to the high-renin subgroup | Larger than average response to beta-blockers or ACE inhibitors |
| Accelerated or malignant | Headache, thirst, weight loss, diastolic BP usually >140 mm Hg with hypokalemia, azotemia, proteinuria | Funduscopy: hemorrhages, exudates, papilledema; an underlying renal disease is present in ≈50% of cases |
| Renal ischemia | | |
| Renal artery stenosis | Recent, progressive, and/or severe hypertension; hypertension in young females (fibromuscular dysplasia) or in patients with angina or arteritis (atherosclerosis); hypertension with ACE inhibitor-induced rise in plasma creatinine | Renal angiogram: renovascular (curable) hypertension is probably present if reduction in artery diameter (1) exceeds 75% or is (2) between 50 and 75% with a positive captopril test, a lateralized captopril renography, or a RVR ratio ≥ 1.5 |
| Renal infarction | Hyponatremic hypertensive syndrome: lumbar pain and hematuria followed by acute hypertension, polyuria, hypokalemia, hyponatremia, and very high renin concentrations | Segmental renal infarction is detected by CT scan and its cause is determined by renal angiogram (embolism, thrombosis, renal artery dissection, or occlusion) |
| Polyarteritis nodosa | Systemic necrotizing vasculitis | Widespread microaneurysms on renal angiogram |
| Systemic scleroderma | Skin thickening, Raynaud's phenomenon, progressive hypertension, and azotemia | Clinical presentation; ACE inhibitors greatly improve scleroderma crisis |
| Renal tumors and cysts | | |
| Juxtaglomerular cell tumor | Severe hypokalemic hypertension with very high prorenin and active renin levels | Normal renal angiogram with a small cortical tumor on CT scan |
| Other renal renin-producing tumors | Hypertension with renal cell carcinoma | Primary reninism is present and BP returns to normal following nephrectomy in ≈5% of cases |
| Compressive cysts and tumors | Hypertension with ultrasound scan evidence of a large cyst or tumor | Improvement in BP following cyst drainage or tumor resection may be expected if RVR ratio >1.5 |
| Polycystic kidney | Family history of renal cysts, hypertension, and azotemia | Ultrasound scan evidence of >3 bilateral cysts in a person with a positive family history |
| Unilateral nonvascular small kidneys | Hypertension with asymmetrical kidneys and frequently a history of recurrent urinary tract infection | Pyelographic or ultrasound scan evidence of pyelonephritic scarring, reflux nephropathy, and/or segmental hypoplasia |
| Extrarenal tumors | | |
| Pheochromocytoma | Paroxysmal hypertension with vasomotor symptoms | High urinary catecholamine metabolites, adrenal tumor |
| Ectopic primary reninism | Malignant tumor with hypertension and/or hypokalemia | Rare cases of lung, liver, pancreas, or ovary cancers |

Some large non-renin-secreting cysts and tumors may be found in cases of renin-dependent hypertension as the mechanism of renin stimulation is renal artery compression. In selected cases, with a lateralized RVR ratio, cyst drainage or tumor resection may improve or cure hypertension.

Unilateral Nonvascular Small Kidneys

Pyelonephritic scarring associated with urinary tract infection and vesicoureteric reflux can cause childhood hypertension and progressive degradation of renal function. PRA is often high and has been shown to be the cause of hypertension. High renin concentrations may also occur in cases of renal hypoplasia. In cases with a very small unilateral kidney and a lateralized RVR ratio, unilateral nephrectomy may improve hypertension.

Extrarenal Tumors

The high BP levels associated with pheochromocytoma are caused by high plasma catecholamine concentrations both directly, through stimulation of vascular α -adrenergic receptors, and indirectly, through renin activation mediated by the adrenergic stimulation of juxtaglomerular cells and renal vasoconstriction. Consequently, ACE inhibition may be used to control BP before surgery.

As mentioned above, rare cases of primary reninism may be due to extrarenal tumors.

HYPERRENINEMIA WITH NORMAL BLOOD PRESSURE LEVELS

In most conditions with normal BP levels, hyperreninemia is a homeostatic response to reduced renal perfusion pressure or plasma flow. These conditions include dehydration, hemorrhage, diuretic use or pharmacological vasodilation, cardiac failure, and reduced plasma volume due to hypoproteinemia in patients with nephrotic syndrome or kidney failure. These conditions have numerous signs and symptoms that cannot be listed here and the assessment of the renin-angiotensin system has no added diagnostic

value. Renin levels are related to survival in patients with cardiac failure; high levels are associated with a poor prognosis. The prognostic value of atrial and brain natriuretic peptides, however, is higher than that of renin; thus, renin is rarely used to assess prognosis.

Bartter's syndrome, or inherited hypokalemic metabolic alkalosis, is an autosomal-recessive disorder characterized by salt wasting, insensitivity to the vasoconstrictive effects of angiotensin II, and consequently high renin levels with normal BP, hyperaldosteronism, and hypokalemia. Gitelman's syndrome is a type of Bartter's syndrome in which patients have hypomagnesemia and hypocalciuria. Advances in the field of molecular genetics have demonstrated that this disease is caused by four genetically distinct abnormalities that result from mutations in renal electrolyte transporters and channels.

blockers (ARBs). All of these trials showed impressive reductions of cardiovascular morbidity and mortality or of progression of renal damage by the active drug regimen compared with placebo.

In the Heart Outcomes Prevention Evaluation (HOPE) trial, the 3600 high-risk diabetics achieved as much protection as did the nondiabetics by the addition of the ACEI ramipril. As summarized by Hostetter, three trials have shown renoprotection by ARBs, so these drugs can be added to the list of agents appropriate for those with diabetic nephropathy.

EVIDENCE THAT DRUGS DO NOT DIFFER IN THEIR PROTECTIVE EFFECTS

Nearly 5000 diabetic hypertensives have been included in RCTs that compare one agent against another (Table II). The overall data from these comparative trials of diabetic hypertensives provide no clear proof that one class of drug is better than another, although

CCB-based therapy was associated with fewer events (Table II). However, there is considerable evidence that ACEIs are better than any other class of antihypertensives at protecting against one of the most common and serious complications seen in diabetic hypertensives: progressive renal damage leading to end stage renal disease. The September 2000 consensus report of the National Kidney Foundation authored by Bakris and colleagues states, "Antihypertensive regimens should include an ACE inhibitor in order to provide maximum cardiovascular and renal benefits in this population." This preference for an ACEI, or for an ARB if the patient cannot tolerate the ACEI because of a cough, seems to be unequivocal for renal protection. Whether it extends to all other cardiovascular events remains to be seen.

THE NEED FOR MULTIPLE DRUGS

To achieve the desired reduction in blood pressure to a level of 130/80 mm Hg or lower, most diabetic hypertensives will require two, three, or four

Table II Comparative Trials in Diabetic Hypertensives

| Primary drug | Patients | Total events per 1000 patients | | | |
|------------------------------|----------|--------------------------------|--------------------------|--------|-----------|
| | | Coronary heart disease | Congestive heart failure | Stroke | Mortality |
| Diuretic and/or beta blocker | 1903 | 75 | 27 | 62 | 125 |
| ACEI | 1368 | 84 | 25 | 66 | 120 |
| CCB | 1657 | 69 | 28 | 53 | 82 |

antihypertensive drugs. As noted in the consensus report by Bakris and colleagues,

Data from several major recent trials, including UKPDS and HOT, demonstrate ... that attainment of these lower goal blood pressures is virtually impossible to achieve with monotherapy. The majority of the time addition of multiple antihypertensive medications including a diuretic, CCB, or any similar combination is required to achieve these lower blood pressure goals.

The burden of such multiple drugs, both financial and beyond, can be lessened by intensive attention to lifestyle modifications, including weight reduction, physical activity, and moderation of sodium, protein, and alcohol intake. These maneuvers may also improve control of hyperglycemia and dyslipidemia, which also demand attention. Despite the need for such intensive therapy, the benefits may well exceed the miseries and costs of uncontrolled diabetes and hypertension.

CONCLUSION

The following guidelines seem to be appropriate for the management of hypertension in diabetic patients:

- The target of blood pressure reduction should be lower than 130/80 mm Hg.
- All antihypertensive drugs are beneficial compared with placebo.
- Multiple drugs will usually be needed to achieve the target.
- The choice of drugs should always include an ACEI (or an ARB if the ACEI is not tolerated) and a diuretic. If additional therapy is needed, a CCB, a beta blocker, or an alpha blocker may be used.
- Attention should be given to lifestyle changes (e.g., weight reduction; regular exercise; moderation of sodium, protein, and alcohol) as well as control of hyperglycemia, dyslipidemia, and proteinuria.

As the population grows older and fatter, diabetes and hypertension will become increasingly common.

It is hoped that their serious consequences can be reduced by such an approach.

Table 1 Metabolic and Cardiovascular Risk Factors with Insulin Resistance and/or Visceral Obesity

- Increased systolic and diastolic blood pressure
- Hyperinsulinemia/Insulin resistance
- Endothelial dysfunction
- Low high-density lipoprotein cholesterol levels
- High triglyceride levels
- Increased Apo lipoprotein B levels
- Small, dense low-density lipoprotein levels
- Increased fibrinogen levels
- Increased plasminogen activator inhibitor-1 levels
- Hypercoagulability (increased PAI-1/plasminogen activator ratio)
- Increased blood viscosity
- Increased C-reactive protein and other inflammatory markers
- Microalbuminuria
- Absent nocturnal dipping of blood pressure and heart rate
- Increased uric acid levels
- Increased left ventricular hypertrophy
- Premature atherosclerosis (coronary artery disease and stroke)

The mechanisms for HTN in the metabolic syndrome are multiple and include hyperinsulinemic activation of the sympathetic nervous system (SNS), increased renal sodium retention, overexpression of the rennin-angiotensin-aldosterone system (RAAS), and a decrease in the vasodilatory properties of INS and INS-like growth factor-1 (IGF-1). These peptides have functional and receptor homology in cardiovascular tissue as well as in adipose and skeletal muscle tissue. INS resistance appears to correlate with tissue resistance to IGF-1. Resistance to the actions of these peptides is associated with impairment of vascular nitric oxide (NO) production, which results in decreased vasodilatory response in INS-resistant, obese, and hypertensive persons. Also, a strong relationship exists between the pressor effects of angiotensin II and HTN. Angiotensin II interferes with signaling through the metabolic (PI-3 kinase) pathway (in part responsible for INS/IGF-1 activity) in vascular smooth muscle cells. Overexpression of the RAAS may interfere with INS/IGF-1-induced NO production. Furthermore, angiotensin-converting-enzyme inhibitors (ACEIs) prevent INS-induced HTN and may improve INS resistance, as was suggested by two large trials. Improvement in INS resistance may have played a role in the cardiovascular benefits demonstrated in the HOPE and CAPP trials. ACEIs also increase NO release by increasing bradykinin via reduction of its degradation, thereby adding to their vasodilatory effects.

The increased free-fatty acids (FFAs) in INS-resistant/obese persons may contribute to vascular

resistance to INS and, therefore, to its vasodilatory properties. Aerobic exercise reduces FFAs by increasing type 1 (INS-sensitive) muscle that uses primarily FFAs, leading to decreased truncal obesity, correction of INS resistance, and lowered BP.

DIABETES

The cardiometabolic syndrome, a precursor of diabetes, shares similar pathology and traits. It goes to reason that HTN is more prevalent in diabetics. HTN is twice as frequent in diabetics than in nondiabetics and accounts for 75 % of CVD risk. Plasma INS and BP correlated directly in patients with diabetes. A study of 24 adult hypertensive patients showed that INS resistance, hyperglycemia, and hyperinsulinemia cosegregate. Characteristics of HTN in diabetics include increased sensitivity to salt and volume expansion; accelerated atherosclerosis, causing premature stiffness of larger arteries and resulting in isolated systolic HTN at a relatively younger age; and loss of drop of nocturnal BP and heart rate, associated with excessive CVD risk. All of these characteristics are associated with microalbuminuria in type 2 diabetics (Fig. 1).

The characteristics of diabetes and its sequelae require special consideration in treating associated HTN. The Systolic Hypertension in the Elderly Program (SHEP) demonstrates that HTN in diabetics is less likely to respond to monotherapy. The Joint National Committee (JNC) VI guidelines classify HTN in diabetes as high risk or complicated, and drug therapy and lifestyle changes are recommended at the onset. The American Diabetic Association and the Canadian Hypertension Society have adopted a BP goal of 130/80 or lower and may require two or more drugs. The JNC VII guidelines adopted 130/80 or lower as the goal for diabetics and also reported that two or more drugs may be necessary. For diabetics who excrete at least 1 g of protein in urine, the target BP is 125/75 or lower.

Various classes of antihypertensives compile the armamentarium for treating hypertensive diabetics. ACEIs attenuate albuminuria and progression to renal disease, and they may also improve INS sensitivity. They are recommended as firstline therapy in diabetics with HTN, proteinuria, and/or heart failure. Angiotensin receptor blockers (ARBs) have a lower incidence of cough and angioedema but may be equal to ACEIs for diabetic renal protection. Beta blockers are appropriate therapy in diabetics, particularly in those with ischemic heart disease. In the U.K.

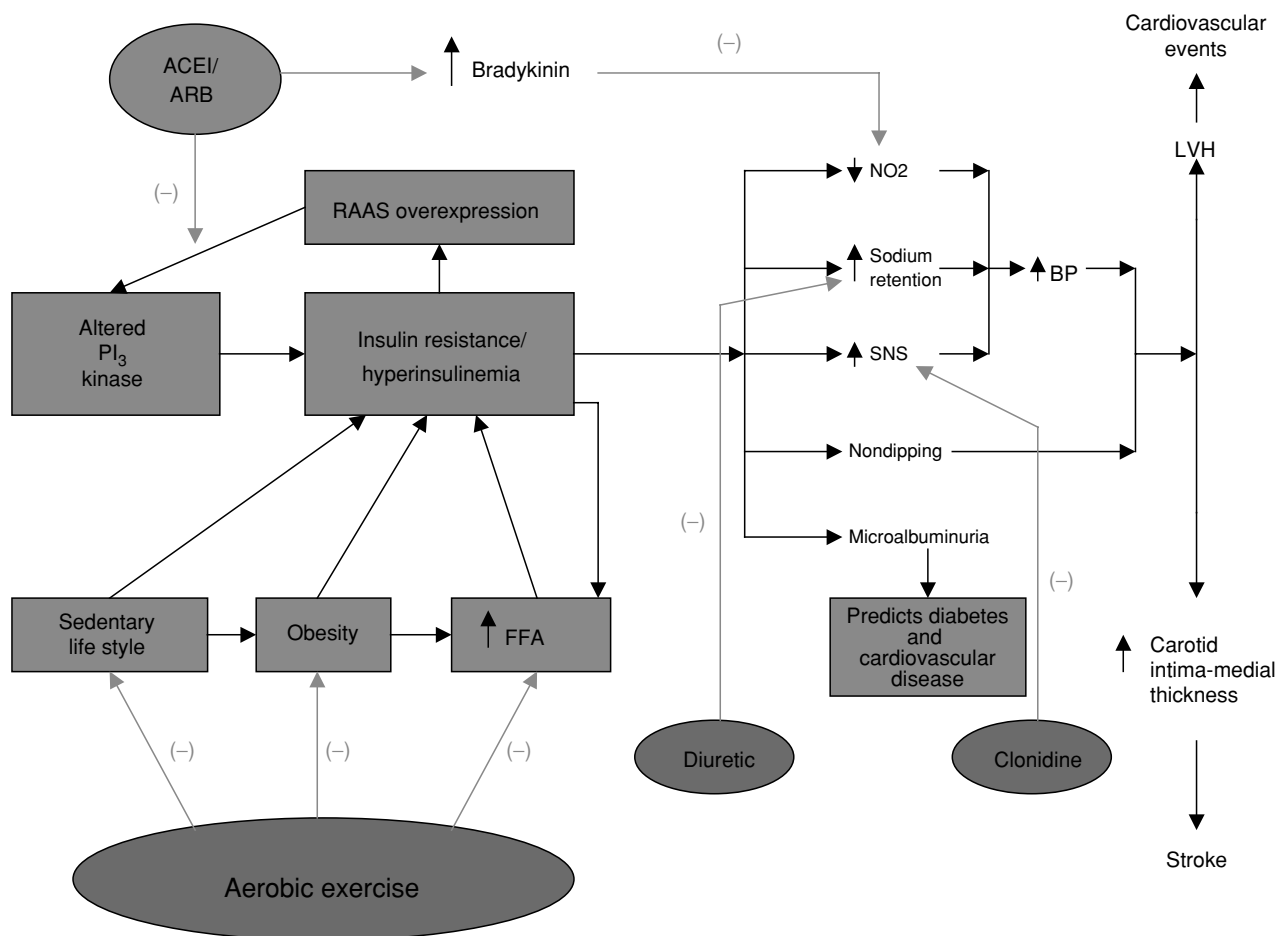

Figure 1 The cardiometabolic syndrome. RAS, renin-angiotensin-aldosterone system; FFA, free fatty acids; BP, blood pressure; SNS, sympathetic nervous system; LVH, left ventricular hypertrophy; ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; NO₂, nitric oxide. Minus sign (-) indicates inhibition of pathological process.

Prospective Diabetes Study, the beta blocker atenolol reduced microvascular complications, strokes, and diabetes-related deaths. It had significant long-term effects on CVD in hypertensive patients with diabetes and is equal in efficacy to captopril in reducing micro- and macrovascular complications of diabetes. In nondiabetic African Americans with nephropathy, dihydropyridine calcium channel blockers (CCBs) adversely affected renal function compared with ACEIs and beta blockers. The nondihydropyridine CCBs may be more beneficial than dihydropyridine channel blockers in reducing proteinuria. However, the addition of an ACEI with a dihydropyridine CCB has been shown to reduce both proteinuria and CVD event rate. Low-dose diuretics are effective in diabetics because of salt sensitivity and its associated volume expansion, especially in African Americans, without adversely affecting lipid or glucose metabolism. For isolated systolic HTN, the JNC VII

guidelines recommend diuretics for their reduced rates of CVD, strokes, and all-cause mortality. Although alpha₁ blockers may improve lipid profile and enhance INS sensitivity, the increased propensity of some diabetics to orthostatic hypotension leads to avoidance of alpha₁ blockers as firstline agents for treatment of HTN associated with diabetes. Furthermore, in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), doxazosin seemed to be more associated with an increased incidence of congestive heart failure (CHF) than did chlorthalidone. Those diabetics with orthostasis and hyperadrenergic symptoms may benefit from low-dose clonidine.

PRIMARY HYPERALDOSTERONISM

The incidence of primary hyperaldosteronism in essential HTN is 10 to 20%. Its diagnostic importance

is derived from the benefits of successful treatment given that reduced morbidity and mortality of heart failure are noted with low-dose spironolactone. Screening for primary hyperaldosteronism (PA) should be considered in all patients with refractory or severe HTN, with spontaneous or provoked (with diuretics) hypokalemia, or requiring excessive potassium supplements. This condition is not necessarily associated with severe HTN, and hypokalemia is a poor screen. Approximately 61 to 70% of all cases have normal potassium. The ratio of aldosterone to plasma-rennin activity (A/R) is a good screen but may be of limited use with low-renin HTN. False-positive results with A/R ratio may occur with renal impairment due to suppression by sodium retention, and aldosterone may be increased by the associated hyperkalemia. Beta blockers, methyldopa, and clonidine may suppress renin and give false-positive results. Drugs that stimulate renin, such as diuretics, ACEIs, and dihydropyridine CCBs, falsely lower the A/R and may be useful given that a failure of renin to increase may be evidence of primary aldosteronism. False-negative results may occur with severe sodium restriction, pregnancy, and malignant HTN due to excessive renin and may also occur in patients with hypokalemia. In patients with PA, ACEIs do not appear to stimulate renin and might not cause false-negative results as was previously thought. This may depend on whether PA is dependent on angiotensin II. Verapamil and hydralazine have little effect, whereas prazosin has no effect on A/R. The sensitivity and specificity of an A/R ratio of at least 35 are increased with postcaptopril testing. The diagnosis may be confirmed by a high 24-h urinary aldosterone on a high-sodium diet, acute saline loading, or fludrocortisone suppression.

Once the diagnosis is confirmed, it is necessary to distinguish between a unilateral adenoma and a bilateral hyperplasia. Computed topography (CT) scanning of the adrenals can help. A solitary tumor greater than 1 cm in a young patient is an indication for surgery. However, in many cases, the CT scans appear to be normal. A nondiagnostic scan or an adrenal mass less than 1 cm requires bilateral adrenal vein sampling to demonstrate and lateralize an adenoma, especially because CT scans miss 50% of adenomas and can incorrectly lateralize the mass. Lateralization based on an elevated aldosterone/cortisol ratio associated with contralateral suppression is more sensitive and specific than imaging and is an indication for unilateral adrenalectomy. For nonlateralization, or if sampling is not available, low-dose spironolactone is the treatment of choice.

Mineralocorticoid excess induces an increase in the number of epithelial sodium channels (ENaCs) that reabsorb sodium in the collecting duct of the kidney. HTN is caused by sodium and water retention by the kidney with expansion of the extracellular fluid compartment. Direct effects of aldosterone on the central nervous system may contribute to HTN. Aldosterone causes cardiac and vascular fibrosis in animals, an action prevented by aldosterone receptor blockade. In the clinical setting, aldosterone antagonists improve endothelial dysfunction and decrease hospitalization, symptoms, and mortality from progressive CHF and other heart-related deaths. Eplerenone, a selective aldosterone blocker, displays similar results.

CONGENITAL ADRENAL HYPERPLASIA

Of the enzyme abnormalities that cause congenital adrenal hyperplasia (CAH), the two that cause HTN are 11 β -hydroxylase (CYP11B1) and 17 β -hydroxylase (CYP17) deficiencies.

11 β -Hydroxylase Deficiency

Approximately 5 to 8% of CAH cases are due to CYP11B1 deficiency. With CYP11B1 deficiency, production of cortisol and corticosterone is inhibited, and enhanced adrenocorticotropin (ACTH) secretion further increases the precursors, deoxycorticosterone (DOC) and 11-deoxycortisol (11DOC), as well as androgens. Although DOC is a weak mineralocorticoid, its normetabolites may be more potent in causing salt and fluid retention with subsequent HTN. Plasma renin activity (PRA) and aldosterone are suppressed. Hypokalemia with muscle weakness and cramping is seen in a minority of patients. The severe homozygous classic form is common in Jews from Morocco, and at least 20 mutations have been identified with varying degrees of severity. Signs of androgen excess are demonstrated in both sexes, and female infants are masculinized. Accelerated skeletal growth and short stature with acne and premature adrenarche are manifested clinically. Those with the severe classic form have mild to moderate HTN appearing during the first few years of life and have a high incidence of left ventricular hypertrophy (LVH) and/or retinopathy. Diagnosis is made by demonstrating an increase in basal and/or ACTH-stimulated serum DOC, 11DOC, and adrenal androgens or elevated levels of urinary metabolites, tetrahydro-DOC and tetrahydro-11DOC, and 17-ketosteroids in a 24-h urine

collection. Steroid replacement suppresses ACTH levels, subsequently lowering both mineralocorticoid and adrenal androgen production and so controlling BP and preventing further virilization. Potassium-sparing diuretics, such as spironolactone and amiloride, may be needed to control HTN of long standing while preventing hypokalemia. Alternatively, a calcium channel blocker may be used.

17 β -Hydroxylase Deficiency

Absence of secondary sexual development differentiates CYP17 deficiency from CYP11B1 deficiency, which might not be apparent until the expected onset of puberty. Prepubertal females appear to be normal but may later fail to develop normal sexual characteristics. Genetic males are phenotypically female, with a blind-ending vagina, inguinal testes, or undescended testes, or they may present with genital ambiguity. Although cortisol is not produced, adrenal insufficiency is not seen because corticosterone, which has glucocorticoid activity, is still produced. DOC is produced in excess, resulting in low-renin HTN and hypokalemia. Overproduction of DOC in the zona fascicula, which results in sodium and fluid retention, suppresses the production of aldosterone in the zona glomerulosa. Treatment with a glucocorticoid will increase aldosterone and PRA and will normalize BP. The increase in aldosterone does not result in HTN, presumably because it is regulated by volume status.

GLUCOCORTICOID-REMEDIAL ALDOSTERONISM

Glucocorticoid-remedial aldosteronism (GRA), also called dexamethasone-suppressible hyperaldosteronism or familial hyperaldosteronism type 1, was first described by Sutherland and colleagues in 1966. Inherited in a Mendelian autosomal dominant fashion, GRA results from a chimeric gene that fuses the 11 β -hydroxylase regulatory gene to the coding gene of aldosterone synthase. It is a mineralocorticoid excess state characterized by low PRA with an A/R ratio greater than 30, HTN, and spontaneous hypokalemia. The BP elevation is typically severe but can masquerade as essential HTN with an increased prevalence of early, and often fatal, cerebrovascular hemorrhage. The full phenotype is seldom seen. One prospective study showed that most patients are normokalemic unless they are given potassium-wasting diuretics.

The diagnosis is supported by improved BP following dexamethasone suppression testing (DST) with a decrease in aldosterone to nearly undetectable levels, demonstrating the ACTH dependency of this condition. A plasma aldosterone of less than 4 ng/dl post-DST is considered sensitive and specific. Suppression can also occur with aldosterone-producing adenomas (APAs) and bilateral adrenal hyperplasia (BAH) but fails to fall to very low levels. Furthermore, elevated 18-hydroxy and 18-oxy cortisol in the urine of patients with GRA will help to distinguish it from APA and BAH. However, sometimes these urinary metabolites are also elevated with APA. Sustained ACTH stimulation may cause an initial rise in aldosterone followed by a decline in normal persons and patients with APA and BAH, whereas in GRA the rise in aldosterone is sustained, similar to that seen with CAH. However, in contrast to CAH, patients with GRA show a normal cortisol and 17-hydroxy urinary corticosteroid response to ACTH. Polymerase chain reaction (PCR) is simple and reliable without the pitfalls of other tests, making genetic testing essential for confirmation.

Although glucocorticoid suppression is the treatment of choice, normalization of BP might not always occur. Linear growth should be monitored in children, and manifestations of Cushing's syndrome should be avoided. Furthermore, hypoaldosteronism may occur with hypotension. Spironolactone is also effective as monotherapy, and amiloride and triamterene may be used as alternatives.

LIDDLE'S SYNDROME

In 1963, G. W. Liddle described a syndrome of HTN, increased potassium excretion, metabolic alkalosis, decreased sodium excretion, and suppressed aldosterone. Hypokalemia is not a universal finding. Spironolactone was ineffective, but triamterene, amiloride, and salt restriction corrected hypokalemia and HTN. Renin is also suppressed by a volume-expanded state with atrophy of the juxtaglomerular apparatus. Later, it was observed that the HTN, hypokalemia, and metabolic alkalosis were ameliorated by renal transplantation with establishment of a renin response to a low-sodium diet, pointing to a disorder of the renal tubule. The absence of edema may be attributed to aldosterone escape due to suppressed sodium reabsorption in other parts of the nephron and to enhanced release of atrial natriuretic peptide in response to volume expansion. Liddle's

syndrome is an autosomal dominant-activating mutation of the renal ENaC located in the collecting ducts. The ENaC is made of three subunits: α , β , and γ . Mutations resulting in truncation of the tail of either the α - or β -subunit is responsible for functional gain of the ENaC in Liddle's syndrome. Thus, this is a salt-retaining, volume-expanded, genetic form of HTN.

GORDON'S SYNDROME

In 1970, R. D. Gordon described a congenital renal tubule defect that includes HTN and severe hyperkalemia, in association with suppressed renin and aldosterone, that was completely reversed with dietary sodium restriction. This syndrome, which includes a normal glomerular filtration rate (GFR), can be rapidly reversed with thiazide diuretics. Also, a hyperchloremic acidosis in which bicarbonate wasting exists is the result of hyperkalemia and volume expansion. This condition is also called type 2 pseudohypoaldosteronism (type 1 is associated with sodium wasting and hypotension during infancy) because of the proposed inability to increase urinary potassium excretion with hyperkalemia despite the addition of mineralocorticoids. The pathophysiology of Gordon's syndrome remains undefined.

Gordon proposed that an inability to respond to atrial natriuretic peptide (ANP) or renal natriuretic prostaglandins may be responsible. Lack of response to ANP, which was noted by Klemm and colleagues, also explains the hyperchloremia and decreased levels of renal vasodilatory prostaglandin that is demonstrated in the urine of Gordon's syndrome patients. These result in volume expansion and suppression of renin and aldosterone to dietary salt despite high serum potassium. The low aldosterone level could be responsible for maintaining a high potassium level. Salt restriction or diuresis stimulates renin and aldosterone, thereby lowering potassium to normal.

Renal potassium excretion is not increased by mineralocorticoids or sodium loading but did increase when nonchloride forms of sodium were administered, suggesting another mechanism. Shambelan and colleagues proposed that enhanced chloride reabsorption leads to enhanced sodium, hydrogen ion, and potassium reabsorption. The inability to excrete potassium despite mineralocorticoid administration may also imply an altered clearance of potassium in the distal tubule. Decreasing potassium with sodium polystyrene sulfate corrected the hyperchloremic acidosis, probably by increasing ammoniogenesis by the nephron.

SYNDROME OF APPARENT MINERALOCORTICOID EXCESS

The syndrome of apparent mineralocorticoid excess (AME) is a relatively rare autosomal recessive mutation occurring in consanguineous populations and presenting during childhood with HTN and hypokalemia. The hypokalemia results in hypercalciuria with nephrocalcinosis and nephrogenic diabetes insipidus, and it may also result in rhabdomyolysis. Cardiovascular accidents and death can occur during infancy and adolescence. The enzyme that confers specificity to aldosterone, by degrading other mineralocorticoids at the distal renal tubule, is deficient or absent. Cortisol is converted to its metabolite (cortisone), which has no mineralocorticoid activity, by a reversible kidney enzyme, type 2 11β -hydroxycorticosteroid dehydrogenase (11β -HSD). When 11β -HSD is deficient, cortisol is allowed unrestricted access to the mineralocorticoid receptor. Glycyrrhetic acid from licorice and its semisynthetic analogue carbenoxylone can induce AME by inhibition of the same enzyme. All mineralocorticoids are low, and cortisol acts as a stronger agonist at the aldosterone site than is usually the case. The diagnosis can be made by demonstrating an increased ratio of urinary metabolites of cortisol (tetrahydrocortisol and allo-tetrahydrocortisol) to a low urinary metabolite of cortisone (tetrahydrocortisone).

Treatment with spironolactone corrects the hypokalemia and HTN. Thiazide diuretics have been used successfully to treat nephrocalcinosis and may allow a decreased dose of spironolactone, reducing the likelihood of gynecomastia. Amiloride, beta blockers, and ACEIs can be used alternatively. In one reported case, a patient was successfully treated with an ACEI, a beta blocker, and dexamethasone. Years later; kidney transplant in the same patient normalized potassium, PRA, and BP as a result of the new kidney synthesizing the deficient enzyme. Loop diuretics should be avoided because they can aggravate hypokalemia and alkalosis.

CUSHING'S HYPERTENSION

HTN is seen in 80% of patients with Cushing's syndrome, and cortisol is primarily responsible. Local cortisol excess is responsible for the HTN associated with AME and licorice intoxication. Although cortisol and aldosterone have equal binding affinity, 11β -HSD, by locally changing cortisol, prevents its binding to the mineralocorticoid receptor in the

nephron-collecting tubule. Excess cortisol may overwhelm this enzyme and bind to the receptor. Indeed aldosterone and renin levels are low in Cushing's HTN, suggesting an apparent mineralocorticoid overactivity that causes sodium and volume retention. Despite this, hypokalemia, metabolic alkalosis, and edema are more often associated with ectopic secretion of ACTH, reflecting its very high levels. Elevated levels of corticosterone and deoxycorticosterone associated with ectopic ACTH production may also contribute. Because ANP and decreased sodium reabsorption occur with volume expansion, thereby causing aldosterone (in this case mineralocorticoid) escape, the amount of sodium being exchanged is increased. This may explain the presence of normokalemia and the lack of edema seen with Cushing's syndrome. However, plasma volume is expanded with salt intake, but not to the point of edema, which may occur prior to the escape mechanism.

HTN in Cushing's syndrome may be due to mechanisms other than sodium and fluid retention; with dexamethasone, virtually devoid of mineralocorticoid activity, HTN is not associated with volume expansion. Dexamethasone increases total peripheral resistance but not cardiac output. Although cortisol is associated with an increase in cardiac output, pretreatment with beta blockers will decrease cardiac output but not the BP response to cortisol that is explained by an increase in total peripheral resistance. An increased response to pressor substances is noted in cortisol-treated persons. Furthermore, enhanced binding and response of angiotensin II occur in vascular smooth muscle cells (VSMCs), resulting in augmented renovascular and forearm arterial resistance. The "glucocorticoid" activity of dexamethasone and other steroids could result from increased calcium channel binding and uptake of calcium and inhibited inducible NO synthase in VSMCs and endothelium, respectively (with the former blocked by nifedipine). ACTH-dependent, but not primary adrenal, Cushing's is coupled with increased levels of 19-hydroxy androstenedione, which has pressor activity.

The pathophysiology of HTN in Cushing's syndrome is complex, with a number of possible mechanisms. Treatment of the HTN should be directed at the primary source of excess cortisol: ectopic/pituitary ACTH, adrenal, or exogenous. Calcium channel blockers or drugs that improve endothelial NO production, such as ACEIs and ARBs, may be used until a final diagnosis is reached.

HIGH-RENIN HYPERTENSION

Conditions of secondary aldosteronism can occur in normotensive and hypertensive patients. Secondary hyperaldosteronism may be an appropriate physiological response but may be noncompensatory and detrimental in pathophysiological settings. A high incidence of unsuspected renovascular atherosclerosis is found in patients who undergo cardiac catheterization where age, blood urea nitrogen, and diabetes may predict renal artery stenosis. Other diagnostic modalities include color Doppler ultrasound, magnetic resonance imaging (MRI), magnetic resonance angiography (MRA), computed tomography (CT), computed tomography-angiography, scintigraphy, and captopril-enhanced renography or scintigraphy. Selective use of renal MRA can avoid invasive, potentially nephrotoxic conventional angiography in high-risk patients. Clinical features of renal artery stenosis include abrupt onset or accelerated HTN, acute or chronic azotemia, azotemia induced by ACEIs, asymmetric kidney size, CHF with normal ventricular function, and nonischemic ("flash") pulmonary edema. Elderly patients with generalized atherosclerosis typically have non-renin-dependent HTN, and revascularization rarely cures HTN in atherosclerotic renal artery disease, whereas young or middle-aged women with fibromuscular dysplasia are often renin dependent. Revascularization should be reserved for severe or resistant cases of HTN due to renovascular atherosclerosis. Gill and colleagues reported improved BP in a majority of resistant cases with recovery of renal function. Ischemic nephropathy is best treated before the onset of renal failure. Revascularization with surgery or stenting should be considered with creatinine less than 2 mg/dl, bilateral renal artery stenosis, absence of proteinuria, and/or evidence of end-organ injury.

Severe HTN with secondary hyperaldosteronism can occur in systemic sclerosis due to renal artery vasospasm and subsequent hyperreninemia. Nifedipine has led to normalization of BP, renin, and aldosterone.

Secondary hyperaldosteronism and HTN can result from renin-secreting tumors. Juxtaglomerular cell tumors can cause hyperreninemia, typically in teenagers. Renal vein renin failed to lateralize the tumors in 52% of cases in one study. In that study, 100% of renal masses were demonstrated by CT scan. Sonography can be helpful as well. Surgical treatment results in prompt normalization of BP, and a calcium channel blockade may control BP until surgery. Renal

cell carcinoma rarely causes hyperreninemia or secondary hyperaldosteronism.

PHEOCHROMOCYTOMA

Pheochromocytoma (PCC), a chromafin tumor, can be life threatening, whereas early diagnosis can be life saving. A crisis can be associated with signs and symptoms of myocardial infarction, supraventricular tachycardia, or CHF. Sudden elevations in arterial pressure are common and do not correlate with levels of plasma catecholamines (norepinephrine and epinephrine [sometimes dopamine]). Even in patients with persistent elevations of BP, symptoms may be paroxysmal; the most frequent symptoms include headache, diaphoresis, and palpitations. Other symptoms may include pallor, nausea, tremor, anxiety, abdominal pain, chest pain, dyspnea, and (rarely) flushing. Occasionally, an orthostatic drop in BP is observed. A patient may be normotensive between episodes. Sometimes, paroxysms may be absent, mimicking essential HTN. This is important to recognize in that 76% of patients with PCC in one study were discovered postmortem, and 54% of these had HTN. Approximately 10% are bilateral, extra-adrenal (paragangliomas), familial, multiple (other than bilateral), or malignant. Diagnosing PCC requires a high index of suspicion. One should suspect this disease when any of those features listed in Table II apply (Table II).

The HTN in PCC is the result of increased peripheral resistance. BP elevations do not correlate well with plasma catecholamines. Clonidine, a centrally working agent that works as well for this condition as it does for essential HTN, is effective because of a

functional SNS. This implies an effect of catecholamines at the synaptic junction and not in the plasma. Small tumors release large amounts of catecholamines into the blood, whereas large tumors, which metabolize much of the catecholamines prior to their release, release small amounts. Large tumors produce greater amounts of the urinary metabolites (metanephrines).

A 24-h urinary vanillylmandelic acid (VMA) collection has poor sensitivity with a false-negative rate of 41%, whereas urinary catecholamines have a false-negative rate of 14%. However, the combination of plasma catecholamines of at least 2000 pg/ml and urinary metanephrines of at least 1.8 mg/24 h is 98% accurate with a false-negative rate of 7%. The specificity of any of these is high. Free plasma metanephrines alone have a specificity of 96% and a sensitivity of 97% for the familial form of PCC. Although the sensitivity remains high for the sporadic form, the specificity drops to 82%. Combining plasma metanephrines with urinary metanephrines increases the specificity to 89%. A plasma catecholamine level of at least 2000 pg/ml is diagnostic, and a level of less than 500 pg/ml rules out PCC. Intermediate values require further testing. A provocative test with glucagon (1 mg intravenously) can be used for levels of 500 to 1000 pg/ml and a BP under 170/100. A threefold increase or a level greater than 2000 pg/ml 3 min later is diagnostic. A clonidine suppression test is used for levels of 1000 to 2000 pg/ml and a BP above 160/90. A 50% drop from baseline, or to less than 500 pg/ml, is a negative test. This has a low false-negative rate.

MRI has slightly better sensitivity than CT, approaching 100% but without the need for contrast. A T2-weighted image of a PCC has a characteristically hyperintense image in comparison with that of the liver. Scintigraphy with ¹³¹I-metaiodobenzylguanidine (MIBG) is used when biochemical testing is highly suspicious but MRI and/or CT are negative. It is also useful when multiple tumors are suspected but MRI and/or CT are negative such as in children or those with a family history of MEN/familial PCC or possible malignant spread. Although octreotide scintigraphy is also useful for visualizing chromafin tumors and has good sensitivity for locating head and neck paragangliomas, its sensitivity for detecting intra-abdominal PCCs is limited. However, it has been shown to find tumors not detected by MIBG and may be complementary to MIBG. One case report of a cardiac PCC, which was missed by MIBG and CT scan, was localized by octreotide scintigraphy and confirmed by MRI. Venous sampling should be used only when suspicion is very high and

Table II Features That Are Suspicious for Pheochromocytoma

-
- Symptoms of pheochromocytoma
 - Paradoxical responses to antihypertensive drugs especially beta blockers
 - Signs and symptoms of accelerated or malignant hypertension
 - Hypertensive paroxysms with exercise, intubation, manipulation of the abdominal contents
 - Family members with MEN syndromes or familial pheochromocytoma
 - Coexisting hypertension with neurofibromatosis, von Hippel-Lindau disease, or Cushing's syndrome
 - Orthostasis without antihypertensives
 - Incidental adrenal tumors
-

all imaging studies are negative. Positron emission tomography, a new modality using 6-fluorodopamine, may be superior to other nuclear imaging.

Treatment involves avoidance of hypertensive episodes during surgery and postsurgery. The nonselective alpha blocker phenoxybenzamine allows for volume repletion but is associated with significant reflex tachycardia and orthostasis and may prolong postsurgical hypotension. After volume repletion, selective alpha₁ blockers such as prazosin have a shorter duration of action and do not cause reflex tachycardia. Alpha₁ blockers can still be associated with postoperative hypotension as well as mask the hypotension associated with the removal of the tumor. The latter is used by surgeons as an indication of complete tumor removal. Boutros and colleagues suggested holding alpha blockers and CCBs unless needed. CCBs seldom cause orthostasis or hypotension and are safe to use in normotensive patients. They also prevent catecholamine-induced spasm of the coronary arteries. By decreasing the norepinephrine-induced increases of calcium entry into the VSMCs, CCBs can prevent the hypertensive response in PCC. Beta blockers should be used only after alpha blockade.

A PCC crisis can be treated by sodium nitropruside. A beta₁-selective blocker, to avoid unopposed alpha activity, can control supraventricular or reflex tachycardia. Esmolol is preferred for its rapid onset and short duration.

In MEN 2 and MEN 3, adrenal involvement is usually diffuse nodular hyperplasia, bilateral, and sometimes malignant. Pheochromocytoma can by itself cause hypercalcemia; therefore, it might not be associated with the hyperparathyroidism of MEN 2.

PRIMARY HYPERPARATHYROIDISM

Although primary hyperparathyroidism (HPT) has been associated with HTN, the relationship between these entities is not fully understood. Whereas some studies show a possible causal connection between HPT and HTN, others do not. One study showed that parathyroidectomy (PTX) did not correct HTN, whereas another investigation reported significant BP reductions in 20 of 45 hypertensive patients with HPT following PTX.

Gennari and colleagues showed a greater pressor response to norepinephrine in those hypertensives with HPT, possibly due to the effect of the catecholamine to increase calcium entry into the VSMCs (of a hypercalcemic person). In the same study, PTX cured 8 of 10 persons with HPT of HTN with a

reduction in PRA and aldosterone, suggesting a direct effect of PTH on renin secretion. Furthermore, intracellular calcium is increased in essential HTN as well as in HPT, with the fall in BP being correlated with the decrease in intracellular calcium after PTX. Nifedipine reduced both BP and intercellular calcium in hypertensives with HPT. Parathyroid hypertensive factor (PHF) is found in some persons with essential HTN and is known to be secreted by the parathyroids of spontaneously hypertensive rats. Significantly higher PHF levels were reported in hypertensive persons with HPT than in their normotensive counterparts. In those patients undergoing a PTX, a postoperative fall in BP could be predicted by the level of PHF, suggesting that human parathyroids can secrete PHF. Although BP remained unchanged in some patients with HPT undergoing PTX, endothelium-dependent (flow-mediated) vasodilation improved postsurgery.

ACROMEGALY

Acromegaly is associated with a higher incidence of HTN contributing to increased morbidity and mortality. Hypertensive acromegalics tend to be women, weigh more, and are older than their normotensive counterparts, suggesting risk factors similar to those of the general population. Although there was no correlation with growth hormone (GH), another study showed a direct association of BP with IGF-1 and serum sodium in only those acromegalics with a family history of HTN. Systolic BP was the largest independent risk factor for LVH, followed by GH levels. A subgroup of acromegalics with diabetes had the highest prevalence of LVH and impairment of diastolic and systolic dysfunction. Acromegaly is frequently associated with INS resistance and hyperinsulinemia and may induce HTN by stimulating renal reabsorption of sodium and SNS. The sodium and volume retention may be due, in part, to an ability of either GH or IGF-1 to activate the RAAS and suppression of ANP. Indeed PRA and aldosterone levels increased with administration of GH, and this was blocked by captopril and spironolactone. There is no consensus on the mechanism of HTN with acromegaly.

HYPOTHYROIDISM

Hypothyroidism is associated with HTN that may be resistant to antihypertensive treatment. Treatment with thyroxine may result in a reduction in BP.

Hypothyroidism is also associated with an increase in cholesterol, triglycerides, homocysteine, and total cholesterol/HDL ratio as well as with accelerated atherosclerosis and coronary artery disease. Subclinical hypothyroidism is also associated with HTN (mostly diastolic) and lipid disorders. In one study, treatment of hypothyroidism improved coronary insufficiency, with relapse on therapeutic withdrawal. The increase in BP may be due, in part, to increased vascular resistance and aortic stiffness. A correlation of BP reduction with an associated decrease in aortic stiffness occurred with thyroxine treatment in hypothyroid patients. Stimulation of adrenal function by augmenting PRA, with an increase in aldosterone and cortisol, occurs in hypothyroidism. This also is reduced with thyroxine treatment. Indeed, the use of captopril and spironolactone was effective in treating the associated HTN. An alternative mechanism for high BP is animation of the SNS. Correction of the hypothyroid state can reduce the elevated levels of epinephrine and norepinephrine that exist with hypothyroidism along with a concurrent decline in BP. Furthermore, heart rate variability decreased with therapy, highlighting the importance of the SNS. The HTN of an underactive thyroid is also associated with an elevated total peripheral resistance, possibly due to an overactive SNS.

HYPERTHYROIDISM

A decreased total peripheral resistance occurs in hyperthyroidism. The HTN associated with an overactive thyroid is mainly systolic and is due to increased cardiac output. This may be the result of an increased number of beta receptors in the heart making it more sensitive to catecholamines. Treatment with beta blockers can control many of the symptoms of hyperthyroidism, including elevated BP. Furthermore, treatment of the hyperthyroid state leads to a decrease in or complete control of BP in those who are younger and without essential HTN. An other cardiovascular effect of thyrotoxicosis, as demonstrated in rats, is the development of LVH, which was prevented by valsartan, suggesting that the RAAS plays a role.

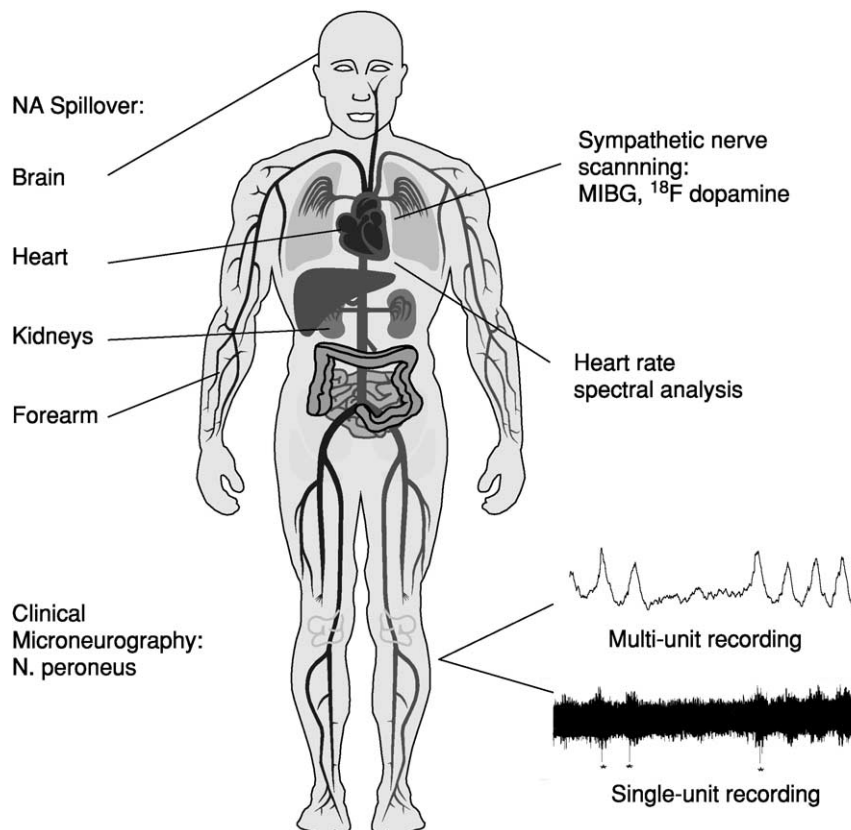

Figure 1 Clinically applicable methods for studying sympathetic activation in various regions in humans. Overflow of noradrenaline (NA) to plasma from internal organs can be measured by isotope dilution methodologies. Rates of nerve firing can be measured from postganglionic sympathetic fibers distributed to the skeletal muscle vasculature using microneurography as either multiunit or single-fiber recordings. Scanning techniques allow visualization of sympathetic nerves in the heart, enabling assessment of cardiac sympathetic nerve density. Heart rate spectral analysis has been applied as a noninvasive method for studying sympathetic function in the heart, although its validity is questioned. MIBG, meta-iodobenzylguanidine; N. peroneus, nervus peroneus.

Plasma Noradrenaline

Although the measurement of noradrenaline (NA) plasma concentration is still widely used, it is a poor marker of overall sympathetic tone given that plasma NA concentrations depend not only on sympathetic tone and NA release but also on rates of removal of the neurotransmitter from plasma and do not provide any information on regional differentiation of sympathetic drive.

Microneurography

Postganglionic muscle sympathetic nerve activity (MSNA) can be measured directly by placing a fine electrode into a superficial peripheral nerve, most commonly the peroneal nerve due to its easy accessibility, and recording its activity. MSNA contributes substantially to the regulation of peripheral vascular

resistance and can be identified by a characteristic spontaneous, intermittent, and pulse-synchronous burst pattern. Microneurography is unique in that it provides direct and continuous assessment of adrenergic activity to the skeletal muscle circulation.

Noradrenaline Spillover Rate Measurement

The application of isotope dilution methodology to measure total rates of NA spillover to plasma from sympathetic nerves, adopting a measurement strategy applied in clinical endocrinology for the measurement of hormone secretion rates, eliminated the confounding effect of variation in NA plasma clearance on plasma NA concentration. The lack of clinical methods for studying human sympathetic nervous outflow in otherwise inaccessible internal organs provided an incentive for the development of

biochemical techniques for studying the rates of overflow of catecholamines from these organs to the circulation. Using radiotracer-derived methods involving the infusion of tritiated NA and regional blood sampling from the coronary sinus and jugular and renal veins, the appearance rate of NA in plasma from the heart, cortical and subcortical brain areas, and kidneys can be measured (Fig. 1).

Heart Rate Power Spectral Analysis

Spectral analysis techniques are commonly applied as an alternative noninvasive method for studying sympathetic function in the heart. With this technique, mathematical partitioning allows identification of individual superimposed rhythms producing cyclical variation in heart rate and arterial pressure. Despite earlier enthusiasm for this approach, it is now clear that the low-frequency spectrum of heart rate variability is not a reliable measure of cardiac sympathetic nervous activity.

FEATURES OF NEUROGENIC HYPERTENSION

There exists a typical pattern of sympathetic nervous activation, particularly in younger individuals (<40 years of age), evident in a high heart rate, elevated cardiac output, elevated renal renin release and plasma renin activity, and (in some patients) isolated systolic hypertension. An increase in muscle sympathetic nerve firing and high rates of spillover of NA from the heart and kidneys are further manifestations of the syndrome of neurogenic hypertension, whereas adrenal medullary secretion of adrenaline is normal. The increased cardiac and renal sympathetic nerve firing provides a plausible mechanism for the development of hypertension through the regulatory influence of the sympathetic nervous system on renin release, glomerular filtration rate, and renal tubular sodium reabsorption as well as on cardiac growth and pump performance.

NEUROGENIC MECHANISMS OF BLOOD PRESSURE ELEVATION

Traditionally, a common view was that increased sympathetic nervous activity could not cause sustained elevation of blood pressure and could not be of importance in the pathogenesis of essential hypertension. The sympathetic nervous system was thought to exert minute-by-minute control over the circulation, with

long-term blood pressure control being exercised principally through control of salt and water balance by the kidneys.

Renal Neural Mechanisms

It is now well established that neural mechanisms are involved in hypertension development through regulatory effects of the renal sympathetic nerves on renin release, glomerular filtration rate, renal tubular reabsorption of sodium, and renal pressure natriuresis. Renal renin release in particular is clearly related to activation of renal sympathetic nerves, the structural basis of which is evident in the rich postganglionic sympathetic innervation of the juxtaglomerular apparatus. Younger essential hypertensive patients with high renal sympathetic activity (manifest in elevated renal NA spillover) have "high renin essential hypertension" with markedly increased renal renin release but without reduction in renal blood flow.

Cardiac and Vascular Neural Mechanisms

An increase in NA release from the heart in essential hypertension is likely to contribute to the hemodynamic profile of early human hypertension. The patient commonly has isolated essential hypertension, to which neural increases in stroke volume and left ventricular (LV) ejection rate, as well as a neurally mediated reduction in arterial compliance, all contribute. Experimental data suggest that NA exerts tropic effects on vascular smooth muscle cells and cardiomyocytes, thereby contributing to LV hypertrophy commonly present in hypertension. In line with these observations, clinical studies have demonstrated that increased sympathetic outflow to the skeletal muscle vasculature and NA spillover from the heart are directly related to human hypertensive LV hypertrophy, which in turn is a strong and independent risk factor for the development of arterial hypertension. Whereas neural mechanisms appear to initiate the increase in blood pressure, NA-induced LV hypertrophy may be one of the factors contributing to sustained blood pressure elevation.

ORIGINS OF HIGH SYMPATHETIC TONE IN ESSENTIAL HYPERTENSION

Genetics

Whether inherited higher levels of sympathetic nervous activity predispose to subsequent development of

hypertension in primary human hypertension has been little studied. In normotensive offspring of hypertensive parents, the MSNA response to mental stress was found to be more pronounced than that in offspring of normotensive parents. Normotensive young men with a family history of hypertension were reported to have higher rates of NA spillover to plasma than were young men with a negative family history of hypertension. The limited search undertaken for single-gene abnormalities involving the sympathetic nervous system in patients with high blood pressure, such as for polymorphisms of the α_2 -adrenergic receptor and NA transporter genes, has not disclosed abnormalities that could account for the consistent increase in spillover of NA or the impaired neuronal NA reuptake.

Lifestyle Influences

Overweight, physical inactivity, and mental stress all have proven stimulatory effects on the sympathetic nervous system, and this might be important in mediating the blood pressure elevation. Patients with primary hypertension are commonly overweight. An excessive dietary energy load is known to stimulate the sympathetic nervous system and elevate arterial pressure. In obese individuals, a selective activation of the sympathetic nerves to the kidneys and skeletal muscle vasculature has been demonstrated, and this could be driven by high plasma levels of leptin. An additional factor contributing to sympathetic nervous overactivity in hypertensive patients, and particularly evident in obese individuals, is a sedentary lifestyle. Regularly performed physical exercise produces long-term lowering of blood pressure that is caused by inhibition of the sympathetic nerves of the kidneys. Exposure to ongoing mental stress has recently been acknowledged as a proven cause of hypertension by an Australian government body. In addition to epidemiological evidence, this body took into account the findings of sympathetic activation, adrenaline cotransmission, and activation of suprabulbar subcortical projections of brainstem noradrenergic neurons that were considered to provide biological evidence of ongoing mental stress.

Central Nervous System Control of Sympathetic Nervous Activity in Hypertension

There is growing evidence of a disturbance in central nervous system (CNS) monoaminergic control of sympathetic outflow, and this may be the common

mediating mechanisms of peripheral sympathetic activation with stress, obesity, and physical inactivity. Catecholaminergic neurons releasing NA are widely distributed in the brain and are located in particular in the medulla and pons. Overflow of NA and its lipophilic metabolites, dihydroxyphenylglycol (DHPG) and 3-methoxy-4-hydroxyphenylglycol (MHPG), from the brain into the internal jugular veins is higher in patients with essential hypertension. Cerebral venous scans indicated that the increased turnover of NA in hypertensive patients is in subcortical brain regions only. In patients shown to have increased CNS NA turnover, peripheral sympathetic activity was increased. These findings suggest a primary importance in pathogenesis of increased neuronal firing in brainstem neurons projecting to forebrain noradrenergic pressor areas.

Sympathetic Nerve Density

Spontaneously hypertensive rats exhibit an increase in the density of sympathetic innervation, probably related to increased neurotropic stimulation due to overexpression of nerve growth factor (NGF). Whether such mechanisms are operational in human hypertension has not yet been delineated. Sympathetic hyperinnervation would be expected to lead to increased interstitial concentration of NA in tissues and increased spillover of NA into the venous drainage of individual organs even at normal rates of nerve firing (Fig. 2). Intraneuronal stores of NA would also be expected to be elevated. However, preliminary data from our laboratory suggest that NA stores, estimated by measuring the specific activity of tritiated DHPG (the intraneuronal metabolite of tritiated NA) produced by the heart, are decreased in essential hypertension. Similarly, the transcatheter venoarterial gradient of NGF appears to be reduced in hypertensive individuals. Whether these findings are indicative of reduced sympathetic innervation as an adaptive response to increased sympathetic tone has been under investigation.

Sympathetic Cotransmission

Adrenaline, the principal hormone of the adrenal medulla, is also present in low concentrations in extra-adrenal tissues largely contained within sympathetic nerves. Adrenaline within sympathetic nerves may be released with NA as a cotransmitter, facilitating the release of the major transmitter through stimulation of presynaptic β_2 -adrenoceptors on sympathetic nerves and increasing the amount of NA released per nerve impulse (Fig. 2). It has been demonstrated that

Figure 2 Schematic illustration of possible mechanisms underlying the increased spillover of noradrenaline (NA) to the circulation in patients with neurogenic essential hypertension. Sympathetic hyperinnervation, if present in patients with essential hypertension, would be expected to lead to increased spillover of NA (1). Increased rates of nerve firing results in enhanced release of NA from vesicles in the sympathetic nerve terminal (2). Impaired neuronal reuptake, possibly due to dysfunction of the noradrenaline transporter (NET), increases the amount of NA in the synaptic cleft and could amplify the neuronal signal (3). Corelease of adrenaline (ADR) and subsequent stimulation of presynaptic β_2 -adrenoceptors could facilitate the release of the main neurotransmitter, NA (4). Angiotensin II (Ang II) may exert excitatory effects on the sympathetic nervous system by facilitating NA release from sympathetic nerve terminals or inhibiting NA reuptake (5).

adrenaline is released from the heart in patients with essential hypertension and that a proportionality exists between the rate of cardiac adrenaline and the rate of NA release. These findings, in conjunction with a previous report of adrenaline release from the renal sympathetic nerves in essential hypertension, provide perhaps the most direct evidence in support of the “adrenaline hypothesis” of essential hypertension, which draws on the concept that stress is a major factor in hypertension pathogenesis, with stress-induced elevations in the plasma concentration of adrenaline enlarging the pool of adrenaline present in sympathetic nerves, leading to release of adrenaline as a cotransmitter, facilitation of NA release, cardiovascular stimulation, and development of arterial hypertension.

Impaired Neuronal Noradrenaline Reuptake

Neuronal NA reuptake may be impaired in essential hypertension, perhaps due to dysfunction of the NA

transporter, and might contribute to the development of essential hypertension (Fig. 2). We have further tested this proposition by applying specific radiotracer methods and using pharmacological blockade of NA transport. The fractional extraction of plasma-tritiated NA in passage through the heart, determined mainly by neuronal NA uptake, was found to be reduced in essential hypertensive patients, as was the cardiac release of the tritiated NA metabolite, tritiated DHGP, produced intraneuronally by monoamine oxidase after uptake of tritiated NA by the transporter. The reduction in NA transport in response to its blockade with the tricyclic antidepressant desipramine was found to be less pronounced in hypertensive patients. These findings strongly suggest that neuronal reuptake of NA is impaired in essential hypertension. By amplifying the neural signal, such a defect could constitute a neurogenic variant of essential hypertension. No mutation in the NA transporter gene that might explain this phenotype has been found.

Angiotensin II Neuromodulation

A body of experimental evidence suggests that angiotensin II exerts excitatory effects on the sympathetic nervous system by stimulating sympathetic outflow, facilitating NA release from sympathetic nerve terminals, amplifying adrenergic receptor responsiveness to various stimuli, and inhibiting NA reuptake (Fig. 2). Despite evidence from animal and human studies to support the hypothesis of a functional cardiac renin-angiotensin system, it remains to be determined whether there is any functional effect on the cardiac sympathetic nerves in humans. The clinical course of heart failure has been associated with a progressive increase in cardiac angiotensin II formation that may contribute to the substantial increase in cardiac sympathetic drive characteristic of that condition. The limited data available in essential hypertensive patients suggest that angiotensin II, at least in the heart, does not contribute substantially to sympathetic augmentation present in essential hypertension.

DIAGNOSTIC PITFALLS

Although a combination of elevated blood pressure and increased heart rate suggests the presence of neurogenic hypertension, sophisticated measures of regional sympathetic nervous activity are needed to confirm the diagnosis. There are several possible sources of confusion. An important example is pheochromocytoma, in which resting heart rate is often elevated. The presence of a catecholamine-producing tumor must be suspected if there is a history of episodic symptoms of palpitations, sweating, headaches, and/or chest or abdominal pain, with hypertension being paroxysmal or sustained, and then must be confirmed biochemically by testing for increased urine or plasma concentrations of catecholamines or their metabolites. These generally are substantially higher

than the concentrations typically seen in neurogenic forms of essential hypertension, in which plasma and urine NA levels are rarely elevated sufficiently to cause diagnostic uncertainty. Patients suffering from panic disorder can also cause diagnostic difficulties. During panic attacks, these patients exhibit a substantial increase in blood pressure, heart rate, sympathetic nerve activity, and epinephrine secretion but exhibit no such features between attacks. Similarly, patients with “white coat hypertension” display an alerting response to medical examination; however, in contrast to patients with neurogenic essential hypertension, these patients have normal blood pressure values on 24-h ambulatory blood pressure monitoring.

(3) total blood volume, and (4) tension generated by the walls of the largest blood vessels (termed conduit arteries) in resisting the pulse of blood ejected into the arteries by the heart.

Vascular Compartments

All multicellular organisms, from the most primitive to humans, have one key requirement for survival: a functional pathway whereby all of the organism's cells may be reached so that nutrients and critical gases (e.g., oxygen) may be distributed and waste products (e.g., carbon dioxide) may be removed. Evolution has matched more complex organisms with comparably complexed circulatory systems. In mammals, blood, containing both cells and dissolved materials, circulates continuously through an extensive closed network of tubes (blood vessels). This vascular system actually consists of three separate but connected sections: arterial (arteries), capillaries, and venous (veins).

The arterial compartment carries blood away from the heart, beginning with the aorta and extending, in an ever-branching manner, to all of the organ systems and tissues. The arterial system is a high-pressure circuit, and the large conduit arteries receive the full pressure and flow of the blood pumped from the left ventricle of the heart. Conduit arteries serve as "feeder vessels" to an increasing number of smaller vessels ultimately connecting with the capillary compartment. Arterial pressure is highest in the aorta and other conduit vessels and declines as the vessels become smaller, becoming lowest (in the arterial circuit) at the junction with the capillary network. Conduit arteries, such as the aorta and carotid, also serve to dampen the large "pressure pulse" generated by contraction of the left ventricle and function to smooth out the pressure wave that spreads from the heart to the smallest blood vessels. One way in which they accomplish this is through the elasticity of the vessel wall, which "captures" some of the energy of the pulse of blood ejected by the heart into the arterial compartment. As the pressure wave progresses away from the heart, the conduit arterial walls relax and return the energy to the blood, supporting the arterial pressure while the heart is not contracting. When conduit arteries lose their elasticity, systolic hypertension, a disorder common in the elderly, may result.

Arterial blood vessels are complex and consist of multiple cell types and several discrete layers. In immediate contact with blood is a single cell-thick lining of endothelial cells with underlying connective tissue protein, a layer termed the intima of the vessel.

Arterial endothelial cells serve many functions, including local release of chemicals that may relax or contract the vessel wall and regulation of hemostasis and clot formation. The intima is the site of atherosclerotic plaques and has assumed increasing importance in studies to identify the causes of primary genetic hypertension. The middle layer of the arterial vessel wall is termed the media and consists primarily of multiple layers of contractile smooth muscle cells. The state of contraction (termed tone) of the smooth muscle cells imparts strength to the wall to resist the blood pressure within the lumen of the blood vessel and, at the terminal ends of the arterial compartment, comprises the "resistance elements" that determine the rate of flow of blood out of the arterial compartment into the capillary network. Systemic arterial resistance is a measure of the average tone (contraction state) of all the resistance elements of the arterial compartment. The outer layer of the artery wall is the adventitia, consisting of connective tissue cells such as fibroblasts, elastic and connective tissue proteins, nerve endings of the sympathetic branch of the autonomic nervous system (ANS), and other cell types that vary according to the size of the vessel and the organ system.

The capillary network includes the smallest blood vessels in all three compartments of the vascular system. These vessels consist of only a single-cell layer of endothelial cells with associated connective tissue proteins and no media or adventitia. This structure permits rapid diffusion of materials, in both directions, between the blood within the vessel and fluids in the adjoining tissue. This vascular compartment is primarily a passive circuit for exchange; however, it has significant importance in maintaining the amount of fluid outside of the vascular compartments and in tissues. An imbalance in fluid exchange, due to altered control of fluid dynamics between the arterial and venous compartments, contributes to tissue fluid retention in individuals with compromised heart function and in uncontrolled hypertension. Although antihypertensive drugs are not designed to work directly on the capillaries, these drugs do affect the capillaries' functioning indirectly through improved fluid dynamics and enhanced elimination of retained fluids through increased urine formation in the kidneys (diuretics).

The third compartment is the network of vessels termed the venous compartment, which collects the output of the capillary compartment. The venous compartment commences at the outflow from the capillary compartment and extends to the right atrium of the heart. There are two functions of this compartment

that directly influence arterial pressure: (1) collecting the blood from the capillary compartment and returning it to the heart (termed venous return) and (2) acting as a reservoir of blood in the body. The venous compartment is a mirror image of the arterial compartment with small veins, highly ramified, joining into successively larger vessels. Veins are complex vessels, just like arteries, and consist of an endothelial cell lining, medial smooth muscle, nerves, and multiple types of cells; however, the venous system is a low-pressure circuit, so the media and adventitia of the vessel wall are thinner than arteries. Large veins are termed capacitance vessels because they have the capacity to expand and hold large amounts of blood. When needed, contraction of the capacitance vessels (through contraction of venous smooth muscle) allows the recruitment of blood back into the arterial and capillary compartments. This is accomplished by the formation and release within the body of chemicals, which contract the smooth muscle, and through the activity of the sympathetic branch of the ANS.

Among other vascular compartments that are unique and are not addressed in this article are the pulmonary and cerebral vascular compartments. Blood vessels connecting the heart and lung constitute a special (pulmonary vascular) compartment. Whereas arteries from the left ventricle of the heart to all of the organ systems (except the lungs) carry highly oxygenated blood and veins returning to the right atrium of the heart carry low-oxygenated blood from the tissues, the converse exists in the pulmonary vascular compartment. The pulmonary artery, from the right ventricle of the heart to the lungs, carries venous blood of low oxygen content, whereas the pulmonary vein, from the lungs to the left atrium of the heart, carries highly oxygenated blood. Pulmonary hypertension is excess blood pressure in the pulmonary artery from the heart to the lung. It is not equivalent to systemic arterial hypertension, the subject of this article, and generally has other causes and treatment. For this reason, this article does not deal with this special form of hypertension. The cerebral vascular compartment is also unique in being both autoregulatory (i.e., it responds to changes of pressure within the compartment so as to maintain blood flow to the brain constant) and generally unresponsive to chemicals and neurohormones in the blood.

Arterial Blood Pressure Gradient

Blood pressure is highest in the large conduit arteries, which leave the left ventricle of the heart, and

decreases steadily through the arterial, capillary, and venous compartments; however, the largest drop in pressure occurs on the arterial side. Maintenance of this decreasing gradient of pressure is essential to ensure adequate blood delivery to all tissues, to optimize fluid and material exchange in the capillary network, and to deliver the blood back to the right side of the heart. A disease process that interferes with any of these three functions will invariably result in a form of hypertension.

Determinants of Levels of Arterial Pressure

Hypertension is a disorder of regulation of systemic arterial pressure, which itself is set and regulated by multiple organ systems.

Arterial pressure derives from the pumping action of the left ventricle of the heart; therefore, the level of arterial pressure at any point in the arterial vascular compartment reflects on the functioning of the left ventricle. During each contraction of the left ventricle, the highest systemic pressure generated within the arteries is termed the systolic pressure. When the heart valve controlling outflow from the left ventricle closes and the left ventricle relaxes (between beats), the arterial pressure drops as the arterial blood rapidly flows out of the arterial compartment into the capillaries. The rate of drop of pressure is controlled by the terminal arterioles and by the energy being returned to the blood with relaxation of the walls of the large conduit arteries, a process termed the windkessel effect and related directly to the elasticity (termed compliance) of the conduit arteries. The windkessel process is very much like the stretched rubber band of a slingshot rebounding and exerting force on the object being propelled. The lowest systemic arterial pressure level is reached just prior to the next contraction and is termed the diastolic pressure. Thus, systolic pressure reflects the action of the heart, resistance to outflow from the arterial compartment, and the windkessel effect, whereas diastolic pressure is set by the rate of outflow (resistance set by the arterioles) and the time between contractions (the “interbeat” interval or heart rate). At constant arteriole resistance, increasing heart rate may increase apparent diastolic pressure. Diastolic pressure also tracks systolic pressure given that an increase in systolic pressure sets a higher starting point from which the arterial pressure may descend between contractions. The pressure difference between systolic and diastolic pressure is termed the pulse pressure.

Pulse pressure is assuming greater research interest as a potential contributor to the development of systemic hypertension and damage to the arterial wall leading to atherosclerosis.

Levels of systolic and diastolic pressure are not constant over time but rather vary continuously, on a beat-by-beat basis, even during rest and sleep. Arterial pressure depends on many factors, including age, gender, body weight, level of physical conditioning, current physical activity, and behaviors of all kinds (e.g., eating, drinking). Of course, arterial pressure is also influenced by many drugs, including prescription drugs, over-the-counter drugs, and drugs of abuse. Human systemic arterial pressure is usually measured with an occlusive device (cuff) placed on one or both arms. When arterial pressure is measured in this manner, both upper and lower values are quoted (e.g., 120 over 80, systolic over diastolic). Rather than systolic and diastolic, we may also speak of mean arterial pressure (MAP), which is the average pressure between systolic and diastolic pressure. MAP, when averaged over time, is defined by the following relationship involving cardiac output (CO) and total systemic vascular resistance (TSVR): $MAP = CO \times TSVR$. TSVR is the sum total resistance to the flow of blood out from the arterial compartment and reflects the action of all terminal arterioles. CO is the amount of blood (in liters) pumped by the left ventricle of the heart over a full minute. This volume of blood is determined by the force of contraction of the left ventricle, the heart rate, and the amount of blood contained in the left ventricle chamber during each contraction. The latter is controlled in part by the amount of blood that returns to the heart from the venous compartment (termed venous return) and by the resistance encountered when the heart pumps the blood into the arterial circuit. Because capacitance veins influence venous return, changes in both blood volume and the degree of constriction of venous smooth muscle influence the low blood pressure in the veins and the amount of blood returned to the heart. Because CO is defined by volume of blood ejected by the left ventricle with each beat (termed stroke volume) and by heart rate, arterial pressure is determined by stroke volume, heart rate, and TSVR.

Within all organisms, arterial pressure is set and regulated by many factors, most of which are integrated through mechanisms of information exchange, both nervous system and chemical. The major system that regulates and sets arterial pressure is the ANS, which works in an integrated fashion with the central nervous system (CNS). Both branches of the ANS,

sympathetic and parasympathetic, work together in an integrated fashion to control arterial pressure. Some studies indicate that the two systems work in opposition, with one stimulating (sympathetic) and the other inhibiting (parasympathetic) to achieve regulation of arterial pressure and heart action. However, a more accurate view is that the two systems work together to achieve the ultimate goal, namely to permit the organism to survive and accomplish whatever it seeks to do. It is important to appreciate this concept to understand the importance of blood pressure dynamics. The sympathetic system is generally considered the stress-responsive branch of the ANS because it alters organ system functions to optimize an organism's response to stress, whether the stress arises externally or internally. The parasympathetic system is considered the "vegetative" branch of the ANS, regulating the most primitive and essential biological actions necessary for survival of the organism and the species. The sympathetic system (1) can increase heart rate and force of contraction; (2) can increase tension (tone) of the smooth muscle in the terminal arterioles, thereby decreasing the rate of outflow of blood from the arterial compartment and increasing systemic vascular resistance; (3) will stimulate release of chemicals from the kidney and adrenal glands that are important for control of blood volume, blood electrolytes, and contraction or relaxation of smooth muscle in the arteries and arterioles; and (4) controls a myriad of additional functions from metabolism, to functioning of eyes, to sexual functions. One of the most important functions of the sympathetic system is shifting the flow of blood between organ systems to meet the needs of the tissues. Each organ system gets a fraction of total CO; however, during some functions of the individual, one organ system might need more. This is accomplished by the CNS through a selective increase in sympathetic nerve activity to particular organ systems that do not need the flow (at that time) and a decrease in nerve activity to organ systems that need more blood. The parasympathetic system controls many organ systems so as to maintain normal homeostasis in the absence of stress. For example, the parasympathetic system slows the heart, increases gastrointestinal activity and secretion to aid digestion, facilitates elimination of waste products from the body, protects the lungs from inhaling toxic chemicals and substances, protects the retina from excessive light, and facilitates vision at short distances. Both the sympathetic and parasympathetic branches of the ANS project from the CNS to the heart; however, only the sympathetic system sends nerve projections to blood vessels.

The ANS originates in the CNS and is intimately linked, through short and long nerves, to the parts of the brain that are important in coordinating cardiovascular and respiratory functions (brainstem) as well as parts that are important for primitive and complex behaviors and even cognition. Each behavior or action of an individual requires an appropriate and selective autonomic response; otherwise, the organism could not perform the desired action. For example, “fear” generally increases sympathetic activity and diminishes parasympathetic activity. Yet, although both fear from an external threat and fear deriving from an “internal” cognitive (perceived) threat may result in activation of a sympathetic response (e.g., increased heart rate), the specific changes in autonomic functioning are not the same. Thus, one cannot generalize and say that all fear responses will have the same effect on the cardiovascular system; some may be more demanding or even more detrimental than others. The relationships between behavior and normal or abnormal cardiovascular functioning are just recently being elucidated, and such studies comprise an area of investigation termed behavioral–autonomic coupling. That such coupling is dictated by genes, and thus becomes controlled partly by inheritance, has been established recently through studies within our laboratory. Could an individual inherit genes that lead to aberrant behavioral–autonomic coupling?

Systemic arterial pressure also exhibits a diurnal rhythm that is generally higher during the awake/day period and lower during the rest/sleep period. When an individual’s arterial pressure decreases from a high during the active period to a low during the rest period, the individual may be classified as a “dipper.” Interestingly, many human hypertensives exhibit a failure to “dip” and are termed “nondippers.”

The endocrine system has direct and indirect effects in determining the levels of systemic arterial pressure. Steroids, both gonadal and adrenal cortical, exert direct influences on all of the cellular components of the arterial compartment (including smooth muscle and endothelial cells), on functioning of the kidneys that relates to retention of sodium and water, on the actions of the heart, and especially on functioning of the CNS. Endocrine systems are linked with control of diurnal (circadian) rhythm and will directly influence the CNS (including cognitive areas). Furthermore, given that every behavior must have an appropriate autonomic and cardiovascular response, it is clear that subtle endocrine-mediated changes in behavior, when exerted over an extended period, may have profound effects on the level of systemic arterial pressure.

HYPERTENSION AS A DISORDER IN HUMANS

Because arterial pressure is determined by the functioning of the heart, the state of resistance to outflow from the arterial compartment, the state of constriction of veins, the total volume of the system, behavioral–autonomic coupling, and the endocrine state, hypertension could be the result of potentially many different factors. However, there are numerous integrated control mechanisms that function to compensate for changes in one or more of these factors so as to keep arterial pressure constant. For example, if TSVR increases and leads to increased arterial pressure, CO is reflexively decreased through homeostatic mechanisms that increase parasympathetic activity to slow heart rate and reduce contractility. This is mediated by a nervous system pathway known as the high-pressure baroreceptor reflex. Likewise, if CO drops (e.g., due to a sudden loss of blood), there is a homeostatic increase in sympathetic activity to blood vessels, resulting in strong constriction of smooth muscle in resistance arterioles and thereby a concomitant increase in TSVR, with maintenance of diastolic pressure. These homeostatic regulatory systems operate continuously and dynamically on a beat-by-beat basis.

Hypertension is considered a disorder of regulation, in part because in hypertension many homeostatic mechanisms appear to continue to operate but “reset” to a higher level of arterial pressure. Therefore, a resetting of the level of homeostasis permits sustained elevated arterial pressure. In all hypertension, the baroreceptor reflex resets to maintain arterial pressure at a higher level; thus, with initial drug therapy for hypertension, the cardiovascular system resists lowering arterial pressure. With chronic elevation of arterial pressure, there is a compensatory thickening of the smooth muscle layer in the media of arteries to resist the increased pressure within the vessel. This thickening causes the lumen of the vessel to become smaller, and this itself raises the resistance to flow (increases TSVR). If it is not reversed in time, this thickened lumen leads to a resetting of the basal state of resistance to flow. Furthermore, over time, there is a decrease in the compliance of the conduit vessels and a failure to dampen out pulse pressure. Changes also take place in the heart, termed hypertrophy, which can progress to heart failure if untreated.

Arterial pressure is termed a quantitative trait because there is not a single value for normal arterial pressure. Rather, arterial pressure is continuously changing depending on what the individual is doing; however, it tends to range about an average, with

transient excursions outside of that range. To define the state of hypertension, researchers have measured large numbers of individuals to obtain a population average as the reference value for normal pressure; however, it must be remembered that many individuals may be higher, and many may be lower, and still be categorized as normal. An individual's arterial pressure must be compared with the population average for comparable individuals. For example, gender is important with differences between age-matched males and females. Furthermore, the average arterial pressures of normally cycling females are generally lower than those of age-matched males or postmenopausal females. Blood pressure is also influenced by body mass or weight and by the extent of physical conditioning. A blood pressure that is considered normal in one individual may be considered abnormal in another individual. The well-known values of 120 mm Hg systolic and 80 mm Hg diastolic entered our vocabulary to imply normal blood pressure; however, these values are, at best, approximations for the population of adults as a whole. Biological variability results in a range of normal arterial pressures; therefore, a complete history and physical examination with appropriate and repeated testing are essential in defining the disorder of hypertension.

There is a consensus among researchers and physicians that diastolic pressures for adults should be below 90 mm Hg and that systolic pressures should not exceed 140 mm Hg. For this reason, these have become the levels for defining a state of clinical hypertension. Critical to this definition is that the pressures be measured several times, over weeks, in both the physician's office and at home (if possible) and that all potentially extenuating circumstances or influences be defined and excluded, to the extent possible. In general, for all but the elderly, diastolic pressure measurements are considered a more important guide for classifying the disorder than are systolic pressure measurements. Why? Although elevated systolic pressures (160 mm Hg or higher) alert to the possibility of hypertension and, in hypertensive patients, provide valuable information on adverse effects to the cardiovascular system, systolic pressure is very sensitive to environmental factors such as stress and anxiety. Recall that systolic pressure is determined in large part by the action of the heart, which can readily respond to states of stress and anxiety. In contrast, diastolic pressure is determined largely by systemic vascular resistance and blood vessel compliance. Therefore, a sustained elevation of diastolic pressure would more likely reflect irreversible changes in the

structure of arterial vessels, heightened vascular resistance, or a significant and chronic alteration in homeostatic regulation. An excessive diastolic pressure also will result in hypertrophy of the left ventricle, an event that could contribute to a compensatory increase in TSVR.

When does an individual become classified as having hypertension? Studies of the adult population have resulted in guidelines, and in 2003 the National Heart Lung and Blood Institute issued the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, the JNC7 Report (www.nhlbi.nih.gov/guidelines/hypertension/jncintro.htm). The JNC7 Report argues that healthy adults should have a target average (awake) systolic/diastolic pressure not exceeding 140/90 mm Hg, whereas that of individuals with diabetes or chronic kidney disease should not exceed 130/80 mm Hg. The JNC7 Report also addresses appropriate therapeutic interventions for individuals with measurements exceeding 140 systolic or 90 diastolic. There is little disagreement that a sustained diastolic pressure exceeding 95 mm Hg or a systolic pressure of 160 mm Hg warrants appropriate therapeutic intervention. But what about the individual whose diastolic falls within the range of 90 to 94 mm Hg, considered as a borderline hypertensive? It is increasingly accepted that such an individual should also be considered as a candidate for therapeutic intervention. However, such an individual should not necessarily be considered for antihypertensive drugs; rather, nondrug interventions may be more appropriate.

How is hypertension identified? Although many people believe that headaches and rapid heartbeat are indicators of hypertension, these symptoms are not most commonly associated with the disorder. In fact, hypertension has been termed the "silent killer" because a patient may be hypertensive for years without any evident symptoms. Within recent years, the importance of hypertension as a major risk factor for atherosclerosis, heart attack, stroke, and kidney failure has raised awareness among all health professionals to identify hypertensive individuals. Ophthalmologists and opticians often discover hypertensive patients while examining the retina (the back inner surface of the eye). The retina is highly vascularized, and chronic untreated hypertension damages the retinal vascular bed (damage that can be readily observed on examination). However, atherosclerosis and diabetes may cause similar changes in the retina, and such conditions must be excluded. Yet given the high frequency of untreated hypertensives who develop

diabetes or atherosclerosis, the possible concurrence of these disorders is more likely the norm rather than the exception.

Identification of hypertension during routine physical examination must be rigorous and thorough. A single finding of elevated diastolic or systolic pressure does not constitute sufficient proof to initiate therapy, whereas dismissal of borderline readings of heightened arterial pressure without follow-up also places the patient at risk for future disease. Accurate measurement of arterial pressure is not trivial. Nearly all methods of measurement employ a form of the sphygmomanometer technique, an indirect method using the cuff occlusion. This involves measurement of the external pressure required to occlude, totally or in part, blood flow in a readily accessible artery such as the brachial artery of the upper arm. The procedure involves wrapping a correctly sized rubber cuff around the upper arm and inflating it to stop the flow of blood through the major artery. The individual taking the reading then listens for the resumption of blood flow as the pressure is lowered; in the absence of flow, no sounds are heard. Two characteristic sounds (termed Korotkoff sounds) are monitored. The first is the start of flow in the vessel as the cuff pressure is lowered and defines systolic (maximal) pressure, whereas the second is when no flow sounds are present and indicates no restriction on flow. This defines the level of diastolic (minimal) pressure. Blood pressures are expressed in terms of millimeters of mercury because the first, and still the most accurate, sphygmomanometers use a column of liquid mercury to determine air pressure. It is essential that the cuff fit the individual; too small a cuff may give an anomalously high value, whereas too large a cuff may give a falsely low value. Arterial pressure is measured while either sitting or standing (termed upright) or when the individual is in a lying-down (termed supine) position. Measurements should be taken in a calming environment to minimize stress and anxiety effects. Although automated cuff arterial pressure measuring devices found in pharmacies and food stores may be quite reliable, they cannot be used to exclude or diagnose hypertension.

A well-described phenomenon termed white coat hypertension is an elevated arterial pressure whenever pressure is measured in a physician's office or clinical setting. This form of apparent hypertension actually reflects an overreactive cardiovascular response to the stress or anxiety associated with the environment. White coat hypertension often disappears when the pressure is taken in a less forbidding environment. The use of 24-h ambulatory monitoring of arterial

pressure is being more widely used to exclude white coat hypertension and to identify extremes of arterial pressure over a typical 24-h activity day.

The most common form of human hypertension, estimated to be responsible for more than 80% of all hypertension worldwide, is of unknown cause and is called primary or essential hypertension. Some investigators believe that essential hypertension reflects a variety of forms of hypertension, each due to a different abnormality of arterial pressure and/or volume regulation. In contrast, others believe that essential hypertension is one syndrome that can arise from a variety of different abnormalities in regulation. Essential hypertension is considered to be a genetic disorder, with a strong sensitivity to environmental factors, and includes individuals who exhibit salt-dependent or obesity-dependent forms of hypertension if no other cause can be ascertained. Genetic hypertension in humans (and rodents) is due to the inheritance of multiple genes that predispose the individual (or organism) to develop the disorder, usually after puberty. Essential hypertension is age dependent in symptom expression; however, studies indicate that elevated arterial pressures may be observed even at very early ages, leading to increased efforts to evaluate arterial pressure in children.

A much smaller percentage of individuals (estimated at 10–25%) have hypertension that is attributable to a known or identifiable cause, most often of endocrine-related origins. This form of hypertension is termed secondary. Renovascular hypertension, believed to be responsible for 5 to 8% of all human hypertension, is caused by a pathophysiological process that affects the kidney and leads to activation of the renin–angiotensin system. Often, renovascular hypertension stems from diminished or restricted arterial flow to one kidney, frequently caused by a tumor that impedes vessel flow. Removal of the tumor may reverse the hypertension provided that the elevated arterial pressure was not of sufficient duration to lead to irreversible changes in the media of arteries. Another potential cause of secondary hypertension is a rare tumor of the adrenal medulla, a pheochromocytoma, which episodically releases large quantities of the neurohormone epinephrine into the bloodstream. Such patients exhibit episodes of very high arterial pressure. Again, removal of the tumor before it metastasizes may reverse the hypertension if irreversible changes in the arteries or kidney have not occurred.

Hypertension may also result from taking drugs that exert their direct actions on the kidney, arterial or venous smooth muscle, or endocrine systems. For example, oral contraceptive-induced hypertension

became widespread shortly after the birth control pill was released for general use. This form of secondary hypertension has been attributed to sex steroid induction of the synthesis by the liver of angiotensinogen, the protein precursor of the angiotensin peptide. Changing the composition of the pill has greatly reduced the incidence of this drug-induced hypertension. The active peptide of angiotensinogen, angiotensin II, is a very potent peptide hormone whose primary functions include salt and water retention and an increase in the state of contraction of arterial smooth muscle. Excessive formation of angiotensin II may result in many actions, including increased synthesis and release of the steroid aldosterone from the adrenal cortex that directly drives salt and water retention, heightened TSVR, and blunting of the high-pressure baroreceptor reflex. Another form of secondary hypertension strikes some women during the second and third trimesters of pregnancy and poses significant risks for both the fetus and the mother. Although the causes of pregnancy-induced hypertension remain controversial, this too is a secondary form of hypertension because it generally reverses following delivery. There is evidence that these latter forms of secondary hypertension are under genetic influence; that is, inheritance of specific genes may predispose the individual to these forms of hypertension. If future genetic studies prove an inheritable tendency, the possibility for prevention should be greatly enhanced.

Malignant hypertension is a term used for patients who show extremely high blood pressure and frequently irreversible hypertension. This term does not imply a cancerous origin to the disorder; rather, patients with malignant hypertension are generally those who have had untreated high blood pressure for long periods of time or who fail to respond to drug therapy. Often, malignant hypertension is associated with severe kidney failure and/or severe changes in the arterial vascular compartment. Such hypertensive patients exhibit very high sustained arterial pressure, both systolic and diastolic, and constitute a medical emergency necessitating bold drug treatment to lower the blood pressure and prevent further organ damage and heart failure.

Today, all physicians and health care professionals are urged to identify potential hypertensive individuals through family histories. Evidence of hypertension or cardiovascular disease and death in the family history should result in annual monitoring for elevations in arterial pressure or other cardiovascular risk factors. This is especially the case for individuals whose ethnic backgrounds show increased expression

of essential or salt-sensitive hypertension or when other risk factors for hypertension (e.g., obesity) are present.

GENETIC PREDISPOSITION TO HYPERTENSION

Essential hypertension has a major hereditary or genetic component; that is, the potential for developing hypertension may be passed from one generation to another within a family. This means that there are hypertensive-prone individuals. However, because there is also a strong effect of environment, it is not clear whether all hypertensive-prone individuals will eventually become hypertensive. In fact, there is increasing evidence that hypertension may be significantly delayed in onset or even prevented by appropriate control of the environment, diet, lifestyle, and exercise/activity. Remember that hypertension develops with age, so changes in lifestyle that delay the development of elevated arterial pressure will like directly prevent its occurrence. Is it possible that earlier generations were hypertensive prone but that their lifestyle prevented the disorder from appearing until they were quite elderly? An interesting study conducted nearly 20 years ago with a strain of rat that spontaneously develops hypertension at 6 to 12 weeks of age (due to inheritance of hypertension genes) showed that if the animals were raised from birth in a stress-free environment under controlled dietary conditions, the rate of development of hypertension was greatly delayed and nearly prevented. Environmental effects also influence the state of the endocrine system, and altered hormonal secretions may be coupled to the rate of onset and progression of arterial hypertension.

POTENTIAL CAUSES OF ESSENTIAL HYPERTENSION

Essential hypertension is a multigene disorder with strong contributions from environmental factors on disease development. Discovering the cause is complicated by the many factors that determine the level of arterial pressure, including disturbances in ANS activity, blood volume, action of the heart as a pump, compliance and elasticity of arterial vessels, behavioral-autonomic coupling, and endocrine regulation of the CNS. A complete discussion of these factors is beyond the scope of this article; however, a brief introduction is warranted because therapy is directed at one or more of these possible causative mechanisms.

There is ample evidence from both animal and human studies indicating that an elevation of activity of the sympathetic branch of the ANS is observed in all forms of hypertension. This system is critical to arterial pressure regulation. For example, if the sympathetic branch is blocked with drugs, individuals show a loss of arterial pressure control in going from a supine position to an upright one (termed postural hypotension). In addition to effects on the heart and blood vessels, the sympathetic system is important in autonomic regulation of glucose and fat metabolism, coupling hypertension with diabetes, atherosclerosis, and obesity. Perhaps most important, the sympathetic branch is a major mechanism for stimulating secretion of the proteolytic enzyme renin into the blood by the kidney. Renin enzymatically attacks angiotensinogen circulating in the blood and releases from angiotensinogen, angiotensin I, the peptide precursor of active angiotensin II. Angiotensin I, which is inactive, is converted to active angiotensin II by the enzyme angiotensin-converting enzyme (ACE) present throughout the vascular system. Thus, the sympathetic system acts directly on the heart and arterioles and indirectly via many other mechanisms, such as angiotensin, to promote salt and water retention. All of these actions can and do result in an elevation of arterial pressure. Interestingly, angiotensin II is also a potent inhibitor of the high-pressure baroreceptor reflex, which would normally reduce sympathetic activity if arterial pressure became too high. Finally, nearly all of the effective antihypertensive drugs in use today interfere, directly or indirectly, with sympathetic activity or its physiological effects.

In addition to autonomic control, regulation of systemic arterial pressure is achieved through electrolyte (e.g., sodium, potassium, chloride) and water homeostasis. Endocrine mechanisms are central to volume control mechanisms and operate both within the CNS and in peripheral organ systems. A very common finding with established essential hypertension and many forms of secondary hypertension is abnormalities in kidney function that lead to abnormal retention of sodium and, with it, water. Here again, angiotensin is a key hormonal system; however, adrenal cortical steroid hormones, such as aldosterone and vasopressin (secreted by the pituitary), are also involved in salt and water homeostasis. Yet aberrant electrolyte regulation may be independent of the angiotensin system given that one form of hypertension is characterized by low plasma renin activity but high sodium retention and elevated (termed expanded) blood volume. This form of hypertension may reflect abnormalities in kidney function or in

endocrine hormones that regulate kidney function and excretion. Restriction of sodium (or salt) intake can lower arterial pressure in most hypertensive patients, yet severe restriction may be counterproductive because too little sodium intake actually activates the renin and angiotensin systems. There is epidemiological evidence that excessive dietary salt intake in Western societies elevates population averages of arterial pressure, and many studies have demonstrated a positive relationship between the amount of salt consumed in the diet and the incidence of hypertension. Yet we now know, from human and rodent genetic studies, that salt intake and the effect of salt on arterial pressure are also genetically controlled. Furthermore, we have evidence that genes, which control salt sensitivity of arterial pressure, are inherited independently of genes for hypertension, at least in the rodent genetic hypertension model. Therefore, salt sensitivity of arterial pressure is an inherited trait; however, coinheritance of genes for salt sensitivity with one or more genes predisposing to hypertension may exacerbate the disorder and likely leads to onset of hypertension at an earlier age.

An attractive but unproven theory is that repeated exposure to stress in everyday life activities may result in abnormal cardiovascular responses in hypertensive-prone individuals. It is possible that repeated stress leads to irreversible changes in arterial blood vessels, resulting in a sustained elevation of peripheral vascular resistance and ultimately to hypertension. Behavioral stressors have been shown to result in adjustments in CO, and repeated changes in blood pressure due to stress may cause a resetting of the baroreceptor reflex associated with hypertension. There is genetic evidence that supports the effects of stress on increases in blood pressure. Individuals with family histories of hypertension exhibit heightened cardiovascular responses to both physiological and psychological stressors compared with those with no family histories of hypertension. Although it may be intuitive to expect that repeated exposure to stressful situations would have some adverse cardiovascular effects, there is no evidence supporting a hypertensive type A personality. The potentially deleterious effects of mental stress on the cardiovascular system may reflect an impaired "coping" mechanism. A failure to habituate to, or cope with, stress appears to pose an inherent risk factor in the development of hypertension; however, it remains uncertain whether it merely exacerbates the hypertension, increases its rate of development, or increases the risk of hypertension-induced organ system damage. Finally, the majority of research suggests that stress-induced increases in

arterial pressure and changes in CO that lead to the development of hypertension, over time, are the result of increased activity of the sympathetic nervous system. One reason why it is difficult to resolve the role of stress in the development of hypertension is the complex interplay of multiple endocrine mechanisms that regulate arterial pressure and blood volume. There is also a complex genetic component in both physiological and psychological coping or adjustment to stress that is in play and has not been resolved.

Not only arterial pressure and heart rate but also metabolic factors, such as blood glucose, insulin, other neurohormones, and endocrine secretions, exhibit inherent diurnal rhythms. Humans and rodents exhibit the property of lowered arterial pressure during rest (sleep) followed by an early-morning “anticipatory” increase in heart rate and arterial pressure (dippers). Many hypertensive individuals (and genetic hypertensive rats) exhibit abnormal arterial pressure and heart rate rhythms (nondippers). This abnormal rhythm is frequently associated with left ventricular hypertrophy, coronary artery disease, and increased damage to organ systems. Nondipper essential hypertensives can exhibit increased circulating norepinephrine and renin levels, decreased sleep patterns (perhaps due to altered melatonin levels), decreased ANS function, increased albumin (protein) excretion in the urine (which may hallmark increased pressure in the kidneys and kidney damage), and increased total and low-density lipoprotein (LDL) cholesterol. However, no differences have been reported in levels of insulin, leptin, or homocysteine between dippers and nondippers. The clinical importance of the absence of dipping is still under investigation; however, our laboratory has demonstrated that, at least in rodents, dipping and nondipping are not directly associated with the inheritance of high blood pressure. Nevertheless, the inability to lower arterial pressure during rest may contribute to long-term detrimental effects of hypertension.

The central biological or circadian clock relevant to cardiovascular control is believed to be located in the suprachiasmatic nucleus (SCN) of the CNS; however, there is increasing evidence of secondary “clocks” outside of the CNS and even in blood vessels and the liver. The SCN regulates bodily functions by sending daily rhythmic messages via neurohormonal signals and by direct neuronal connectivity to all organs of the body. The peptide hormones of the SCN that are crucial to its function appear to be vasopressin, vasoactive intestinal peptide (VIP), and neurotensin. Vasopressin is believed to act on rhythm oscillations, whereas VIP and neurotensin act as “pacemakers.” All three

peptides are decreased to nearly half their levels in the SCN of hypertensive patients compared with those in normotensives. In addition, the SCN has direct influence on autonomic outflow via neuronal connections with the paraventricular nucleus (PVN) of the hypothalamus that itself connects with the nucleus tractus solitarius (NTS) in the brainstem, the primary site that receives sensory information on the level of arterial pressure in the aorta and carotid arteries. Therefore, abnormal functioning of the SCN could lead to interference in the continuous flow of information to and from the NTS and eventual alteration in arterial pressure. However, the “chicken and egg” question remains unanswered: does genetic hypertension cause a pathological functioning of the SCN and effects on circadian rhythms, or is it the reverse? Studies in which SCNs were transplanted from a hypertensive rat to a normotensive rat showed that the transplant caused hypertension in the genetically normotensive animal. This may indicate that the SCN, responding to the environment, has a significant role in genetic hypertension.

THERAPY OF HYPERTENSION

Hypertension is classified according to the level of diastolic pressure with three categories relevant to the discussion: borderline hypertension (diastolic pressures between 90 and 94 mm Hg), mild hypertension (diastolic pressures between 95 and 104 mm Hg), and moderate to severe hypertension (diastolic pressures exceeding 104 mm Hg). These three categories are loosely defined because some patients are at greater risk than others for developing severe cardiovascular complications with any degree of elevated arterial pressure. Furthermore, essential hypertension is a chronic disorder that extends over many years, and patients may progress from mild to severe hypertension in a short time, especially with inadequate treatment. Even with treatment, most patients still progress, over years, to a state necessitating more severe therapeutic approaches. Therefore, the primary goal of all therapy is to reduce the rate of progression or to prevent it entirely.

When to initiate therapy and what types of therapy to use remain controversial. Therapy takes the form of either antihypertensive drugs (i.e., pharmacotherapy) or nonpharmacological approaches such as behavior and lifestyle modification. Drug therapy, along with surgery as needed, is frequently the choice for secondary forms of hypertension; however, with essential hypertension, whether to treat or not depends on the classification of severity and the presence or absence

of other risk factors (e.g., diabetes, atherosclerosis, obesity, heart condition). Borderline hypertension should always be addressed first by behavioral and lifestyle modification before pharmacotherapy. Mild to moderate hypertension warrants both nondrug and drug therapy. The primary goal of all therapeutic approaches must be to lower the diastolic (and systolic) pressure into the normal range or, if that cannot be reached, to as low a pressure as possible. All therapeutic approaches must be individualized to the patient.

Among nonpharmacological approaches are weight reduction, restriction of salt intake, stress reduction, lifestyle changes, exercise, discontinuance of alcohol intake, and cessation of smoking. Depending on ethnic background, other approaches, such as meditation and acupuncture, may be useful. For some individuals, these therapeutic approaches may be all that is needed. For example, it was shown during the 1980s that a relatively small reduction in weight (less than 10%) markedly lowered arterial pressure in essential hypertensives, resulting in a reduction or even total discontinuance of antihypertensive drugs in some patients. Weight reduction achieves two immediate goals: reduction of the workload placed on the heart and reduction in total blood volume. Another nondrug approach is stress relaxation and/or lifestyle modification. Stress reduction could lower sympathetic drive, thereby lowering activation of neurohormones as well as directly decreasing stimulation of the heart. Nondrug therapies such as stress reduction may take several months before evidence of their effectiveness is clear. For this reason, patients are usually placed on limited antihypertensive drug therapy to assist in lowering the blood pressure more quickly. Whether or not this is necessary depends on the individual patient.

The best source of currently recommended drugs is the JNC 7 report, which was discussed earlier and need not be repeated here. Pharmacotherapy of hypertension uses what is termed a stepped care approach: introduce one antihypertensive drug (selected by the severity of the hypertension and other risk factors present), and if reduction of arterial pressure is inappropriate, then complement the first agent with a second or shift to a different class of agents. In the United States, the most common drug initially prescribed (termed first-line therapy) is diuretics, which increase urine production by increasing the loss of sodium and water from the body. However, such agents have many secondary (and sometimes undesirable) actions such as increasing loss of potassium.

Some patients receive a type of diuretic that is potassium sparing; that is, it does not cause a loss of potassium. Excessive loss of potassium may lead to heart rhythm abnormalities. In the absence of a potassium-sparing diuretic agent, potassium supplementation, by drugs or diet, is often necessary. Diuretics may be used alone or in combination with other drugs, often being prescribed with agents that block sympathetic function because the latter tend to promote salt and water retention. An alternate first-line therapy is β -adrenergic receptor blockers (termed beta blockers). These drugs partially block the ability of the sympathetic nervous system to stimulate the heart and release renin from the kidney. Some beta blockers may also work in the brain to reduce sympathetic nervous system activity and the secretion of brain hormones that can raise arterial pressure. A relatively new class of agents, successful both in treating hypertension and in reducing adverse restructuring of the heart, are ACE inhibitors. ACE inhibitors not only block the formation of active angiotensin II, they also increase the lifetime and activity of another peptide, bradykinin, which relaxes vascular smooth muscle, releases vasodilator nitric oxide from endothelial cells, and releases vasodilator polyunsaturated fatty acids known as eicosanoids. If arterial pressure is still uncontrolled with these first-line drugs, calcium channel blockers or drugs that work primarily in the brain to reduce sympathetic activity would be added to one of the three first-line agents. If control is still not achieved, third-line agents, such as α -1 adrenergic receptor blockers, would be tried. However, the latter have significant side effects, such as postural hypotension, and are generally reserved for unresponsive patients or medical emergencies. New agents are being developed continuously, so these categories will likely change with time.

It is generally considered that, with time (years), patients will progress to either combinations of drugs or the stronger third-line agents. However, many investigators believe that there has been inadequate attention to combining nondrug methods with pharmacotherapy. Reliance on pharmacotherapy without strong efforts to promote concurrent nondrug therapies has demonstrated that progression is inevitable.

CONCLUSION

Hypertension is a disorder of regulation of systemic arterial pressure. Essential hypertension and many

forms of secondary hypertension have major genetic elements that dictate predisposition to the disorder. Early recognition of abnormal regulation of arterial pressure is essential if progress is to be arrested. All therapeutic approaches must focus on slowing progression of the disorder and returning, if possible, the arterial pressure to population-defined normative limits. However, what is normal for one individual may still be abnormal for another, or conversely, what is abnormal for one individual may be normal for another. Arterial pressure permits organisms to function and survive. It must be understood that hypertension may be the result of efforts by the body to satisfy the cardiovascular and autonomic requirements of the individual. Reversing hypertension without addressing the origins of the elevated arterial pressure may be therapeutically inadequate and potentially detrimental. Until more is known about the genes that regulate cardiovascular and autonomic coupling, the approach to the treatment of hypertension must be to slow progression of the disorder. Thus, the treatment of hypertension involves an ongoing series of decisions and evaluations by the physician based on the individual patient. Continued interaction and communication among patient, physician, and health professional are essential to the prevention of the damaging effects of hypertension. In the case of hypertension, as with many diseases or disorders, prevention remains the preferred first step in treatment.

first 1301 bp of the 5'-flanking region, a classic silencer element within the first intron (intron A) of the gene, and a strong enhancer located far upstream (bp -5777 to -5552 in humans). There is accumulating evidence that renin expression is regulated according to the "variegation concept," meaning that transcription of a single gene is either switched on or switched off, but not gradually modified. A more or less pronounced expression of renin within a tissue would consequently be the result of more or less "switched-on," renin-transcribing cells.

Additional data show mechanisms for a posttranscriptional control of renin synthesis. These mechanisms seem to involve the stabilization of renin mRNA by the binding of specific proteins, whose expression is stimulated by cyclic AMP.

Molecular genetics studies did not find any evidence of an association between renin gene expression and hypertension.

BIOSYNTHESIS, PROCESSING, AND EXPRESSION OF RENIN

Translation of renin genes yields a precursor molecule, preprorenin, which consists of 340 amino acids. Preprorenin is processed to enzymatically inactive prorenin (MW 57,000). Prorenin can be activated *in vitro* by acidification or prolonged cooling, as well as by exposure to neutral serine proteases (e.g., trypsin, plasmin, kallikrein) or acid proteases (e.g., pepsin, cathepsin D). More than 80% of the total circulating renin is prorenin.

Renin is expressed in a complex tissue-specific and developmentally specific pattern. Early in development, renin is abundant in smooth muscle cells in the intrarenal arteries. During development, however, renin expression is progressively more reduced to the "classical" place of synthesis, the juxtaglomerular apparatus, where it is produced and stored in granules.

Very strong, chronic stimuli, however, are able to reestablish a cell's ability to synthesize renin. In the heart, for example, where renin mRNA is normally absent, conditions known to increase renin synthesis in the kidney (such as sodium depletion for at least a week or chronic ACE inhibition) lead to a massive rise in cardiac renin mRNA expression. The same phenomenon (called "recruitment") was observed in afferent arteriolar cells extending further upstream of the juxtaglomerular apparatus, which usually show no renin mRNA expression.

MECHANISMS CONTROLLING RENIN RELEASE

Renin is synthesized, stored, and secreted into the renal arterial circulation by the granular juxtaglomerular cells that lie in the walls of the afferent arterioles as they enter the glomeruli.

Effective stimuli for renin release and thereby for the induction of the renin-angiotensin-aldosterone cascade are sodium deficiency, hypovolemia, a significant decrease in arterial blood pressure, and an increased sodium concentration in the distal tubule (tubuloglomerular feedback).

The secretion of renin from juxtaglomerular cells is controlled by three pathways, as follows:

The first intrarenal mechanism controlling renin release is called the macula densa pathway. A specialized segment of the early distal tubule, the macula densa segment, comes into direct contact with the afferent and efferent arterioles of its own nephron. A change in NaCl reabsorption by the macula densa results in the transmission of chemical signals to nearby juxtaglomerular cells, which modify the release of renin; the increase in NaCl flux across the macula densa inhibits the release of renin and the decrease stimulates the release of renin. The other chemical signals mediating the macula densa pathway involve adenosine, prostaglandins, and nitric oxide.

The second mechanism controlling renin release is called the intrarenal baroreceptor pathway. In 1934, Goldblatt showed that it was possible to produce persistent hypertension in dogs by constricting the renal arteries. Later, the concept of a "baroreceptor mechanism for renin secretion" was formulated by Skinner. Increases and decreases in blood pressure in the preglomerular vessels inhibit and stimulate renin release, respectively. The underlying mechanism is believed to be a reduction in the tension within the wall of the afferent arteriole.

The third mechanism is called the β -adrenergic receptor pathway. It has long been known that an increase in sympathetic activity influences renin release. The studies of Kirchheim and related investigations have clearly established that an increase in sympathetic tone to the kidney stimulates renin release via the activation of β_1 -adrenergic receptors on juxtaglomerular cells.

RENIN ACTIONS

Renin acts on angiotensinogen, splitting off a decapeptide, angiotensin I, from the N-terminal end of the

Figure 1 Drugs affecting the renin–angiotensin–aldosterone system. ACE, angiotensin-converting enzyme; ANG I, angiotensin I; ANG II, angiotensin II; AT1, angiotensin receptor type 1; AT2, angiotensin receptor type 2.

protein (Fig. 1). ANG I is acted on by a second proteolytic enzyme, ACE, that removes two more amino acids to form the highly active octapeptide, ANG II. The removal of one more amino acids yields the heptapeptide, angiotensin III (ANG III). ANG II and ANG III induce the release of the mineralocorticoid aldosterone, the most important hormone for sodium balance, from the adrenal cortex.

THE SUBSTRATE FOR RENIN: ANGIOTENSINOGEN

Angiotensinogen, an α_2 -globulin, is the precursor molecule for angiotensin II and the substrate for renin. Angiotensinogen is synthesized and secreted mainly by the liver and is found in the α -globulin fraction of plasma. Moreover, it is also found in diverse tissues expressing local RAASs. Its synthesis is stimulated by glucocorticoids, thyroid hormone, estrogens, and ANG II. Increases in angiotensinogen levels are associated with essential hypertension. Moreover, a linkage to essential hypertension was found in regions within or close to the angiotensinogen gene. Transgenic mice expressing the rat angiotensinogen gene are hypertensive and mice lacking the angiotensinogen gene are hypotensive.

ANGIOTENSIN-CONVERTING ENZYME

ACE is the second enzyme (Fig. 1) in the cascade of ANG II synthesis, converting the inactive decapeptide, ANG I, to the potent octapeptide pressure hormone, ANG II. ACE is a nonspecific peptidase that

can cleave C-terminal dipeptides from various peptides (dipeptidyl carboxypeptidase). The enzyme kininase II is identical to ACE and contributes to the inactivation of kinins, such as bradykinin, and other potent vasodilator peptides. ACE is primarily localized on the luminal side of the vascular endothelium. The lung, which has a vast surface area of vascular endothelium, is rich in ACE. Additionally, ACE is present in other organs including kidney, heart, brain, and striated muscle skin, as it is a part of local RAASs.

ANGIOTENSIN II AND ITS RECEPTORS

ANG II, an octapeptide hormone, is the main active component of the RAAS. It contributes to the regulation of blood pressure, plasma volume (via aldosterone-regulated sodium excretion), and sympathetic nervous activity. It is, moreover, involved in such diverse effects as proliferation, differentiation, regeneration, and apoptosis. The multiple actions of ANG II are mediated via specific, highly complex intracellular signaling pathways that are stimulated following an initial binding of the peptide to its cell surface receptors. The major actions of ANG II are mediated by two subtypes of G protein-coupled angiotensin receptors, the angiotensin receptor type 1 (AT1) and the angiotensin receptor type 2 (AT2) receptors, which are seven-transmembrane glycoproteins with only 32–34% sequence homology.

The AT1 Receptor

The AT1 receptor is involved in the classical physiological actions of ANG II: regulation of blood

pressure, electrolyte and water balance, thirst, hormone secretion, and renal function. The AT1 receptor belongs to the G protein-coupled receptor superfamily and typically activates phospholipase C through the heterotrimeric G_q protein.

AT1 receptors are present in the human vasculature, lung, liver, brain, kidney, adrenal gland, skin, and endometrium.

The classical actions of AT1 receptors include the following: generalized vasoconstriction; increased release of noradrenaline from sympathetic nerve terminals, reinforcing vasoconstriction and increasing the rate and force of contraction of the heart; stimulation of proximal tubular reabsorption of sodium ions; secretion of aldosterone from the adrenal cortex; and cell growth in the cardiac left ventricle and in the arterial wall.

ANG II via the AT1 receptor furthermore controls cellular growth, adhesion, migration, and intercellular matrix deposition, influencing chronic adaptive changes in vascular and cardiac growth, remodeling, repair, and atherosclerosis. In vascular smooth muscle cells and in endothelial cells, ANG II via the AT1 receptor stimulates phospholipase A₂ activity, leading to the release of arachidonic acid and eicosanoids, which influence vascular and renal mechanisms important in the regulation of blood pressure and cell growth.

The expression of AT1 receptors is altered by various pathophysiological conditions: renovascular hypertension, myocardial infarction, ventricular hypertrophy, and bilateral nephrectomy. Overexpression of the vascular AT1 receptor can be observed in hypercholesterolemic men. These findings may help to explain why hypercholesterolemia is frequently associated with hypertension and why blockade of the RAAS attenuates the progression of atherosclerosis. The down-regulation of AT1 receptors in sepsis is the main reason for the attenuated responsiveness of blood pressure and of aldosterone formation to ANG II and, therefore, may contribute to the characteristic septic shock.

The AT2 Receptor

The AT2 receptor is widely expressed in fetal tissues, where its expression is dramatically decreased after birth, being restricted to a few organs such as brain, adrenal, heart, kidney, myometrium, skin, and ovary. Although the AT1 receptor is dominant in the adult organism, an increase of AT2 receptor expression has been observed in pathological conditions, such as

vascular injury, myocardial infarction, congestive heart failure, renal failure, brain ischemia, and sciatic or optic nerve transection.

It seems that the AT2 receptor exerts a protective effect against an overstimulation of AT1 receptors by counteracting AT1 receptor-mediated actions; e.g., whereas the AT1 receptor stimulates cell proliferation, the AT2 receptor has an antiproliferative effect and promotes cell differentiation. Moreover, inhibition of AT2 receptors enhances the immediate left ventricular growth response to ANG II.

The signaling mechanisms of the AT2 receptor are diverse and only a few mechanisms have been characterized reasonably well. In some cases, they are coupled to G_i proteins. One pathway in neurons (and perhaps other tissues) involves the activation of the protein serine/threonine phosphatase PP2A, which leads to the activation of the delayed rectifier K⁺ channel, hyperpolarization of plasma membranes, and suppression of cellular activities stimulated by depolarization. Other pathways shown thus far involve the activation of protein phosphotyrosine phosphatases, mitogen-activated protein kinase phosphatase 1, phospholipase A₂, and—very importantly—the release of bradykinin and nitric oxide (NO). The AT2 receptor stimulates the production of NO, which results in an increased formation of the second messenger cyclic GMP (cGMP). cGMP, in turn, mediates many of the biological actions of NO, such as vasodilation, natriuresis, and anti-growth by activating cGMP-dependent protein kinase.

A negative crosstalk between AT1 and AT2 receptors has been proposed not only on a functional level, but also on the level of intracellular signaling.

Further knowledge about the tissue-protective effects of the AT2 receptor might lead to new therapies in the future and should be confirmed by clinical studies.

ALDOSTERONE

The mineralocorticoid aldosterone is produced in the zona glomerulosa of the adrenal medulla. Its main action is the reabsorption of Na⁺ (Cl⁻ and H₂O follow) in exchange for K⁺ in the distal tubules of the kidney. Low plasma sodium or high plasma potassium concentrations affect the zona glomerulosa cells of the adrenal directly, stimulating aldosterone release. Aldosterone secretion is also controlled indirectly by the juxtaglomerular apparatus, which is sensitive to the composition of the fluid in the distal tubule. A decrease in the sodium chloride

concentration of the filtrate is sensed by macula densa cells, which stimulate renin release. This leads—as illustrated above—to the formation of ANG II, which in turn, via AT1 receptors, stimulates the synthesis and release of aldosterone by the adrenal cortex. Moreover, in the process of aldosterone synthesis, angiotensins (ANG II and ANG III) regulate the corticosterone methyl oxidase I and II enzymes, which catalyze the hydroxylation and aldehyde formation at C-18 of corticosterone.

In the kidneys, in the late distal tubule and collecting duct, aldosterone binds to cytoplasmic receptors, which migrate to the nucleus and initiate DNA transcription, translation, and production of proteins, which activate Na^+ and K^+ channels and increase the synthesis of Na^+/K^+ ATPase and production of ATP. As a result, the reabsorption of Na^+ (and the subsequent reabsorption of Cl^- and H_2O) and the secretion of K^+ and H^+ are increased. Na^+ reabsorption increases the osmolarity of extracellular fluids. This stimulates the hypothalamic osmoreceptor to release vasopressin from the posterior pituitary. Vasopressin leads to enhanced free-water reabsorption in the collecting duct, which expands extracellular volume and reduces plasma osmolarity. Vasopressin also acts on other tissues. In the vasculature, vasopressin increases intracellular Ca^{2+} and potentiates vasopressor responses.

DRUGS AFFECTING THE RAAS

Renin Inhibitors

Since renin catalyzes the first and rate-limiting step of the RAAS cascade, interruption of the generation of ANG II by renin inhibitors at this highly specific initial step of the cascade has long been a therapeutic goal. The inhibition of renin would have the advantage of preventing ANG II synthesis without concomitant accumulation of other peptides, such as kinins or substance P, as in ACE inhibitor treatment, and it would have the advantage of the absence of ANG II overexpression and stimulation of other ANG II receptor subtypes as in AT1 receptor antagonist treatment. Despite these theoretical advantages, the lack of oral availability, low efficacy, and high costs of development have thus far prevented renin inhibitors from becoming successful drugs. However, a potent nonpeptidic inhibitor of renin, Aliskiren, with acceptable oral bioavailability, has been synthesized. Aliskiren has been shown to decrease in a dose-dependent manner plasma renin activity, ANG I and ANG II levels in healthy volunteers, and blood

pressure in hypertensive patients. Large clinical studies comparing renin inhibitors with the other blockers of the RAAS will be needed to establish the true clinical utility of renin inhibition.

ACE Inhibitors

ACE inhibitors occupy the angiotensin-converting enzyme as false substrates, thus preventing the conversion of ANG I to ANG II and resulting in reduced levels of circulating and tissue ANG II. They also block the degradation of bradykinin and other vasodilatory peptides, which may have potential benefits in cardiovascular disease. ACE inhibitors affect capacitance and resistance vessels, reduce cardiac load as well as arterial pressure, improve endothelial function, and reduce left ventricular hypertrophy.

ACE inhibitors are well recognized as an important therapeutic step to control blood pressure in hypertensive patients and to reduce morbidity and mortality in patients with hypertension, congestive heart failure, or diabetes mellitus. They appear to possess unique cardioprotective benefits, even when used in patients without high blood pressure or left ventricular dysfunction. ACE inhibitors promote collateral vessel development and improve prognosis in patients who have had a coronary revascularization procedure. ACE inhibitors are also effective in the management of chronic renal diseases to delay the progression of renal failure.

AT1 Receptor Antagonists

The “sartan” family comprises a rather new group of pharmaceuticals (losartan, valsartan, candesartan, irbesartan, telmisartan, eprosartan), which all act as antagonists on the AT1 receptor. AT1 receptor antagonists are specific for the RAAS, selective for the AT1 receptor, and act independently of the ANG II synthetic pathway, allowing a more selective blockade of the AT1-mediated effects of ANG II compared with ACE inhibitors. However, by inhibiting the AT1 receptor-mediated negative feedback of ANG II on renin release in the kidney, these drugs may evoke an overstimulation of the AT2 receptor by enhancing ANG II levels in the plasma. An AT2 receptor-mediated increase in the production of vasodilators (nitric oxide, cGMP, prostaglandins) as well as the anti-growth features of this receptor might contribute to a further decrease in blood pressure and prevent hypertrophy and remodeling. AT1 receptor

antagonists do not inhibit the degradation of kinins and cough is not a frequent side effect.

The AT1 receptor antagonists are widely used as antihypertensive agents, especially in patients with type 2 diabetes or ACE inhibitor intolerance.

Aldosterone Antagonists

The mineralocorticoid hormone aldosterone is a product of the RAAS that contributes to the development of hypertension and myocardial hypertrophy and has the potential to cause edema through sodium and water retention. Spironolactone and its metabolite canrenone are antagonists of the aldosterone receptor and attenuate the effects of the hormone. However, spironolactone is associated with progestational and anti-androgenic side effects, such as gynecomastia and impotence, as a result of its binding to other steroid receptors. Eplerenone is the first agent of a new class of drugs known as selective aldosterone receptor antagonists, which provide effective and well-tolerated blood pressure reduction. Because eplerenone has little affinity for androgen and progesterone receptors, it produces fewer steroid-like effects (such as gynecomastia in men) than spironolactone. In addition to its action in lowering blood pressure, eplerenone appears to provide protection to the heart and kidney. Hyperkalemia is a dose-related adverse effect.

Other Drugs Influencing Renin Release

Several other drugs, which do not directly interfere with the cascade of ANG II synthesis, indirectly modify the rate of renin synthesis or release. Loop diuretics stimulate renin release by blocking the reabsorption of NaCl at the macula densa. Antihypertensive drugs in general increase renin release by decreasing arterial blood pressure, which in turn

activates baroreceptors. Sympatholytic drugs and β -adrenoreceptor antagonists decrease renin release by blocking the β -adrenoreceptor pathway, leading to a diminished sympathetic tone in the kidneys.

Figure 1 Causes of hyperthyroidism.

Biochemically, the cardinal feature of hyperthyroidism is a suppressed TSH. T4 and T3 levels are generally elevated, but in some cases only elevations in T3 are present (T3 toxicosis). Scanning using radionuclides reveals diffuse and increased uptake within the thyroid. In most patients with Graves' disease, elevated TRAB levels can be detected. Individuals with high TRAB levels and a large thyroid gland are likely to have a protracted course, with a very low chance of spontaneous remission. Individuals with a small gland and low TRAB levels have a moderate chance of spontaneous remission. Because Graves' disease does not commonly resolve spontaneously within a short period of time, treatment for hyperthyroidism is needed. Treatment approaches include antithyroid drugs, radioactive iodine (¹³¹-iodine), and surgery.

Medical Therapy

Antithyroid drugs remain the first line of therapy for children with Graves' disease in many centers. Mainstays of antithyroid therapy include the thionamide derivatives propylthiouracil (PTU) and methimazole (MMI). MMI is 10-fold more potent than PTU and has a longer half-life. Recommended doses for initial therapy are 5 to 10 mg/kg/day for PTU and 0.5 to 1.0 mg/kg/day for MMI; even lower doses may be effective for induction or maintenance therapy. To control the hyperthyroid state, PTU and MMI are typically given every 8 h. However, once-a-day dosing may bring remission as rapidly as do divided doses and is especially well suited for maintenance therapy. Because MMI pills (5 or 10 mg) are smaller than PTU tablets (50 mg), and because fewer MMI pills are generally needed, MMI is more convenient to take than is PTU.

Although MMI and PTU promptly inhibit hormone formation, they do not inhibit thyroid hormone release. Thus, levels of circulating thyroid hormones may remain elevated for several weeks as stored hormone is released. Until circulating levels of thyroid

hormones normalize, the signs and symptoms of hyperthyroidism may be controlled with beta blockers such as atenolol (25 or 50 mg once or twice a day) or propranolol (2.5–10.0 mg two or three times a day). Iodine drops also help to control hyperthyroidism more rapidly than does PTU or MMI alone; high doses of iodine acutely reduce thyroid hormone synthesis and release, a phenomenon referred to as the Wolf–Chaikoff effect. Clinical responses to PTU or MMI are usually seen after 4 to 8 weeks, at which time biochemical hypothyroidism often develops and the thionamide dose can be reduced by 30 to 50%. If hypothyroidism develops, the dose of MMI or PTU can be reduced further or levo-thyroxine can be given to correct the hypothyroid state.

Approximately 25% of children treated with PTU or MMI will develop minor complications, and less than 1% of children will develop serious complications. Minor complications include rashes, urticaria, myalgias, elevations in liver enzymes, leukopenia, arthritis, and lymphadenopathy. Serious complications include agranulocytosis, hepatitis, and vasculitis. Severe hepatotoxicity is more of a problem with PTU than with MMI.

In children, remission rates after several years of drug therapy are usually less than 30%. Importantly, remission rates are less in prepubertal children than in pubertal children. Although many clinicians will treat children with antithyroid medication for years, the likelihood of long-term remission can be predicted by observing responses to short-term (4–12 months) treatment. If remission occurs, long-term follow-up is needed. If remission does not occur, drug treatment can be restarted or definitive therapy can be selected.

Radioactive Iodine

Radioactive iodine is the most simple and cost-effective treatment for Graves' disease. Treatment is achieved when ¹³¹-iodine is trapped in thyroid cells, leading to thyroid cell destruction by internal radiation. It has been suggested that doses (administered activities) delivering 300 to 400 Gy (30,000–40,000 cGy or rads; 360–480 μCi/g of ¹³¹-iodine) are required to achieve hypothyroidism in adults. However, the thyroid gland of children may be more sensitive to ¹³¹-iodine than that of adults, and it is possible to achieve hypothyroidism using lower doses in children. Treating our patients, we have observed good responses using between 180 and 300 Gy (200–300 μCi/g) of ¹³¹-iodine.

Long-term cure rates are higher in patients treated with larger amounts of ^{131}I -iodine than with smaller amounts. In children treated with a single dose of 150 to 200 $\mu\text{Ci/g}$, hyperthyroidism persists in 5 to 20%, and 60 to 90% become hypothyroid. Hypothyroidism usually occurs within 2 to 6 months of treatment. If hyperthyroidism persists, additional courses of ^{131}I -iodine are indicated. After repeated treatments, 6 to 12 months may pass before hypothyroidism develops.

Responses to ^{131}I -iodine therapy are much less favorable in patients with large glands. Thus, we usually recommend surgery when the thyroid is more than 100 g. To determine thyroid volume in this setting, ultrasound is useful [volume = 0.52 (length \times depth \times width)].

Recent discussions have focused on the association of ^{131}I -iodine therapy of Graves' disease with the development or progression of ophthalmopathy in adults. In contrast to adults, children rarely develop severe ophthalmopathy and proptosis is generally mild. In the unusual setting where there is severe eye disease, adjunctive prednisone therapy or surgery should be considered.

Radioactive iodine is being used at progressively younger ages, yet we do not know whether there is an age below which high-dose ^{131}I -iodine therapy should be avoided. Risks of thyroid cancer after external irradiation are highest in children under 5 years of age and decline progressively with advancing age. Therefore, it may be prudent to avoid ^{131}I -iodine therapy in young children. It is also important to note that when children are treated with ^{131}I -iodine, higher doses that result in thyroid ablation and hypothyroidism should be used. Low doses of ^{131}I -iodine (<80 Gy, <100 $\mu\text{Ci/g}$) are associated with an increased risk of thyroid neoplasms. Yet if higher doses are used and result in complete destruction of the thyroid gland, the risk of thyroid cancer will be much less.

Surgery

Whereas subtotal (partial) thyroidectomy was advocated in the past for children and adults, total (near total) thyroidectomy is now recommended to reduce the risk of recurrent hyperthyroidism. In preparation for surgery, the child should be rendered euthyroid or hypothyroid. This is typically done with either PTU or MMI. One week before surgery, iodine is added to cause the gland to become firmer and less vascular, thereby facilitating surgery. The most frequent complications include pain and transient hypocalcemia.

Less common problems (1–4%) include hemorrhage, permanent hypoparathyroidism, and vocal cord paralysis.

Surgery is especially useful for patients with a large thyroid gland (>100 g) and for individuals who have not gone into remission with drug therapy and do not desire ^{131}I -iodine. Because of the intricacies involved, surgery should be performed by surgeons with expertise in performing thyroidectomies in children.

NEONATAL THYROTOXICOSIS

Thyrotoxicosis in neonates is a severe and life-threatening condition. If a mother has Graves' disease, there is a 1-in-80 chance that TRABs will be transferred to the fetus, resulting in intrauterine or neonatal hyperthyroidism. Rarely, neonatal thyrotoxicosis will persist.

If a mother with Graves' disease is taking antithyroid medications during pregnancy, fetal thyroid hormone synthesis will be inhibited, and this will prevent the development of intrauterine hyperthyroidism; however, the infant may be born with a goiter and hypothyroidism. At birth, circulating levels of T4 may be low and TSH may be elevated. In most cases, as the effects of antithyroid drugs wane, thyroid function normalizes within a week. Yet if there has been significant transplacental passage of TRABs, neonatal thyrotoxicosis will develop.

If a mother with a history of Graves' disease is not taking antithyroid drugs during pregnancy, the fetus may develop intrauterine hyperthyroidism. If not recognized, this may result in profound intrauterine thyrotoxicosis and growth retardation. Such infants may have prematurely fused cranial sutures, advanced skeletal ages, long-term learning problems, and/or mental retardation. If fetal hyperthyroidism is recognized by the presence of fetal tachycardia (heart rate >160 beats/min after 22 weeks), treatment of the mother with antithyroid drugs will reduce intrauterine thyrotoxicosis and improve fetal outcome.

Treatment of thyrotoxic newborns consists of antithyroid medications (PTU 5–10 mg/kg/day or MMI 0.5–1.0 mg/kg/day) and beta blockade (propranolol 1 mg/kg/day). Lugol's solution or saturated potassium iodide may be given (1–2 drops every 8 h) for 7 to 10 days to control biochemical hyperthyroidism more rapidly. After approximately 2 weeks of antithyroid drug therapy, thyroid hormone levels will decline. When thyroid hormone levels fall below normal, supplementary levo-thyroxine (37.5 $\mu\text{g/day}$ for term infants) is added to prevent hypothyroidism.

As TRABs are cleared from the infant's circulation, spontaneous recovery begins within 3 months and is usually complete by 6 months. Thus, treatment can be weaned after 3 months.

HYPERFUNCTIONING THYROID NODULES

Warm or hot nodules lead to excessive production of thyroid hormone and can be associated with clinical and biochemical hyperthyroidism. Hyperfunctioning nodules are most commonly solitary lesions. However, some children may manifest hyperthyroidism in the setting of TMGs.

The possibility of a hyperfunctioning thyroid nodule should be considered in individuals with thyroid asymmetry, high T4 levels, suppressed TSH levels, and the absence of antithyroid antibodies. Ultrasonography, which is indicated whenever thyroid asymmetry is detected, is useful in detecting solitary nodules or multinodular goiters. Scanning using radionuclides reveals uptake by the hyperfunctioning nodule and decreased uptake by normal thyroid tissue.

Whereas there is a chance of spontaneous remission of the hyperthyroid state in children with Graves' disease, the chance of spontaneous remission of a solitary hyperfunctioning thyroid nodule or a TMG is rare. Thus, definitive treatment is indicated. In adults, ablation of hyperfunctioning nodules with ¹³¹-iodine is often performed. With children, surgical excision of hyperfunctioning nodules is recommended because radiation-exposed normal thyroid tissue will remain after the hyperfunctioning nodule is ablated.

INFECTIOUS THYROIDITIS

Occasionally a child will present with hyperthyroidism, tenderness over the thyroid gland, and fever due to bacterial infection on the thyroid, a condition referred to as acute thyroiditis. This can be associated with a fistula connecting a pyriform sinus in the pharynx to the thyroid. Fevers can be high, and erythrocyte sedimentation rates and white counts can be elevated. Ultrasonography may reveal a local abscess. When thyroid radionuclide scanning is performed, reduced uptake is observed.

The offending bacteria consist of *Hemophyllus influenza*, oral flora, group A *Streptococcus*, or *Staphylococcus*. Thus, treatment with a beta lactamase-resistant antibiotic is recommended. For severe cases, hospitalization and intravenous antibiotic

administration is indicated because there may be lymphatic drainage into the mediastinal region. Surgical drainage is needed if a localized abscess develops and the response to antibiotics is poor. Because the infectious process results in destruction of thyroid tissue, there may be release of preformed thyroid hormone and hyperthyroidism will occur. The hyperthyroid state is usually transient, and treatment with antithyroid drugs is not indicated. If the patient becomes symptomatic, beta blockers may be used. After the child has recovered, a pharyngeogram may be performed to test for a patent pyriform sinus tract. Occasionally, the tract may close as a result of the infection. However, if the tract persists and acute thyroiditis recurs, tract resection is needed.

Viral infections of the thyroid may occur and result in subacute thyroiditis. In comparison with acute thyroiditis, subacute thyroiditis may be less severe. However, there may be fever, thyroid tenderness, and hyperthyroidism that may last for several weeks.

OTHER CAUSES OF HYPERTHYROIDISM

Hyperthyroidism can occur in Hashimoto's disease because autoimmune destruction of thyroid tissue can result in excessive release of thyroid hormone. Yet the hyperthyroid state is transient and is followed by hypothyroidism.

Thyrotoxicosis can occur when there is thyroid hormone ingestion. With severe ingestions, thyroid storm, heart failure, and seizure activity can occur. Treatment is supportive and involves the use of beta blockers. Epidemic thyrotoxicosis has also occurred following the ingestion of beef containing thyroid gland remnants.

Hyperthyroidism can result when individuals in areas of iodine insufficiency are given large doses of iodine via pharmaceuticals containing iodine or X-ray contrast material, a phenomenon referred to as the Jod-Basedow effect. Clinicians need to be aware that the commonly used, anti-arrhythmic drug Amiodarone contains large amounts of iodine and can result in hypo- or hyperthyroidism. Amiodarone-induced thyrotoxicosis can be due to iodine-induced thyroid hormone synthesis or to destructive thyroiditis.

Hyperthyroidism can develop in McCune-Albright syndrome, in which there are activating mutations of G proteins. Such individuals may have café-au-lait spots with irregular margins, bone lesions, and autonomous secretion of sex steroids and adrenal hormones.

TSH-producing pituitary adenomas are a rare cause of thyrotoxicosis in children. Affected individuals may present with clinical hyperthyroidism, goiter, and (occasionally) exophthalmos. Biochemical studies will reveal elevated T4 or T3 concentrations along with detectable or elevated TSH levels. Brain imaging studies are useful in visualizing pituitary adenomas. In contrast to Graves' disease or hyperfunctioning thyroid nodules, in which TSH levels remain suppressed, thyrotropin-releasing hormone testing reveals TSH and prolactin responsiveness when there is a TSH-producing pituitary adenoma. Treatment involves resection of the pituitary tumor.

CONDITIONS ASSOCIATED WITH HYPERTHYROIDISM

Several autoimmune disorders are associated with hyperthyroidism, including diabetes mellitus, juvenile rheumatoid arthritis, nephritis, and inflammatory bowel disease. Thus, individuals with these conditions should have thyroid status assessed during routine office visits and whenever there is a change in the status of the underlying illness. Urticaria is also associated with hyperthyroidism and may occur before or after the hyperthyroid state is recognized and treated. Hyperthyroidism should be considered in patients with attention deficit/hyperactivity disorder (ADHD) because symptoms can be similar in both conditions.

CONDITIONS THAT CAN BE CONFUSED WITH HYPERTHYROIDISM

Thyroid Hormone Resistance

When the thyroid hormone receptor is mutated, impaired tissue responsiveness results, leading to thyroid enlargement, elevated levels of T4 and T3 tachycardia, and behavioral problems. In contrast to primary disorders of the thyroid gland, TSH levels are normal or slightly elevated in this condition.

Most individuals with resistance to thyroid hormones have generalized thyroid hormone resistance. These individuals are eumetabolic and asymptomatic, with TSH levels in the normal range. In contrast, some individuals will have isolated pituitary thyroid hormone resistance. These individuals have symptoms of hyperthyroidism in that they are sensitive to the effects of increased thyroid hormone levels.

Because individuals compensate for thyroid hormone resistance by secreting more thyroid hormones, treatment is not necessary. However, patients with thyroid hormone resistance may be improperly diagnosed as having Graves' disease and ablation of the thyroid may be performed.

Familial Dysalbuminemic Hyperthyroxinemia

When free T4 values and TSH levels are normal and total T4 values are high, familial dysalbuminemic hyperthyroxinemia (FDH) needs to be considered. This autosomal dominant disorder is most commonly seen in Hispanic individuals and is due to increased affinity of albumin for T4, leading to increased circulating T4 levels and normal T3 values. In FDH and other conditions affecting thyroid hormone binding, the condition can be diagnosed by thyroid hormone-binding protein electrophoresis. Treatment is not needed, and the patient should be educated about the condition to avoid treatment by unsuspecting practitioners.

Thyroid Hormone and Heterophile Antibodies

Although T4- and TSH-level measurements usually accurately reflect circulating concentrations of the hormones, the serum of some individuals contains antibodies that interfere with the measurement of these hormones, resulting in falsely elevated determinations. These substances include thyroid hormone autoantibodies, heterophile antibodies (human anti-mouse antibodies), and rheumatoid factors. Interfering antibodies should be considered when clinical and laboratory findings do not agree.

CONCLUSION

With current diagnostic methods, it is possible to identify causes of hyperthyroxinemia and thyrotoxicosis in children and adolescents with a high degree of fidelity. Because of the profound effects that the hyperthyroid state has on a child, prompt and proper treatment is essential. Vigilance is needed to detect hyperthyroidism in the child with or without known risk factors for autoimmune thyroid disease. Clinicians also need to distinguish states of hyperthy-

oxinemia that do not require treatment from those pathological conditions that do.

Table I Clinical Implications of Subclinical Hyperthyroidism

-
- Impaired quality of life
 - Higher heart rate
 - Increased prevalence of supraventricular arrhythmias
 - Increased left ventricular mass
 - Impaired diastolic function
 - Impaired systolic function on effort
 - Increased cardiovascular morbidity and mortality
 - Reduced bone mineral density
 - Increased risk of fractures
-

important alterations involving the morphology and function of the cardiovascular system and/or bone and mineral metabolism (Table I). Various authors have reported that SH patients scored higher on a symptom rating scale (specifically designed for clinically overt hyperthyroid patients) than did euthyroid controls. Patients complained mainly of symptoms and signs suggestive of adrenergic overactivity. These findings clearly indicate that the term “subclinical hyperthyroidism” is a misnomer. In fact, SH is not merely a laboratory oddity but rather a mild tissue hyperthyroidism that may be particularly dangerous in the elderly.

Effects on the Cardiovascular System

Higher heart rate and increased prevalence of supraventricular arrhythmias have been reported in most of the clinical studies of patients with SH, with a three-fold increased risk of atrial fibrillation in elderly patients. SH has also been associated with relevant changes in left ventricular properties. Increased left ventricular mass, in some cases above the hypertrophic threshold, is a consistent finding in SH patients, variably associated with impaired diastolic function, systolic performance on effort, and exercise tolerance. Importantly, cardiovascular morbidity and mortality are significantly increased in patients with endogenous SH. Although the underlying mechanism(s) remains speculative, it is likely that increased left ventricular mass, heart rate, and supraventricular arrhythmias may play a major role in determining this increase.

Effects on Bone and Mineral Metabolism

Although clinically overt hyperthyroidism is a well-recognized risk factor for osteoporosis and fractures,

it is still debatable whether this is also the case for persistent SH. Serum concentration of osteocalcin and urinary excretion of markers of collagen bone degradation and reabsorption (pyridinoline cross-links, hydroxyproline, and telopeptide type I) were found to be increased in patients with SH. Congruent with these findings, some (but not all) studies showed a significant reduction in bone mineral density and an increased risk of fractures in women with SH; both features become more apparent during the postmenopausal period.

MANAGEMENT STRATEGIES

In general, the treatment of SH should be modeled according to the underlying etiology, the patient's age, and the presence of comorbidity. In patients with exogenous SH, in whom the L-T4 dose cannot be reduced (e.g., patients with high-risk thyroid cancer), beta-blocking drugs can attenuate the effect of adrenergic overactivity on the cardiovascular system, thereby mitigating cardiac abnormalities and improving quality of life. Conversely, in all cases where L-T4 may be tailored (i.e., in benign thyroid disease and in some cases of low-risk thyroid cancer), this is the mandatory treatment, eventually corroborated by beta blockade in the case of remnant adrenergic overactivity. The treatment of endogenous SH, similarly to that of overt hyperthyroidism, is aimed at redressing euthyroidism by means of antithyroid drugs, radioiodine, or surgery. In some selected patients, beta blockade may be an effective alternative. Similar considerations apply to the management of the effects of SH on bone and mineral metabolism. Bisphosphonates and/or estrogen may be used in postmenopausal women and in individuals who have a high risk of fractures.

In adipose and muscle capillaries, TG in chylomicrons and VLDL are hydrolyzed into FFA by endothelial-bound lipoprotein lipase (LPL). ApoCII is an obligatory cofactor for LPL, whereas apoCIII may interfere with LPL. FFA is then reesterified and stored in adipocytes or is oxidized for energy in myocytes. Chylomicrons and VLDL are remodeled into the short-lived, smaller, denser, CE-enriched chylomicron remnants (CMR) and VLDL remnants (also called intermediate-density lipoprotein [IDL]), respectively. CMR and some IDL are cleared by apoE-mediated endocytosis through hepatic remnant receptors. IDL can also be hydrolyzed by hepatic

lipase, making smaller, CE-rich, low-density lipoprotein (LDL) particles. Table I summarizes the proteins involved in TG metabolism.

CLINICAL IMPORTANCE OF HYPERTRIGLYCERIDEMIA

Triglyceride and Atherosclerosis

Moderate hypertriglyceridemia is probably an independent coronary heart disease (CHD) risk factor. The Prospective Cardiovascular Munster (PROCAM) study followed approximately 5000 men, ages 40 to 65 years, for 8 years and showed an increased risk of myocardial infarction (MI) or sudden cardiac death as TG increased from less than 200 mg/dl (<2.3 mmol/L) to 799 mg/dl (9.0 mmol/L). This association remained significant after adjustment for LDL and high-density lipoprotein (HDL) cholesterol and for other CHD risk factors. Furthermore, meta-analyses of more than 46,000 men followed for an average of 8.4 years and of more than 10,000 women followed for an average of 11.4 years showed that for a 1-mmol/L TG elevation, CHD risk increased by 32 and 76%, respectively. Adjustment for HDL cholesterol attenuated this CHD risk increase to 14% in men and 37% in women.

Complex mechanisms underlie the association of hypertriglyceridemia with atherosclerosis, and the complexity obscures ascertainment of a direct causal relationship. Proatherogenic metabolic and/or biochemical abnormalities, such as obesity, diabetes, decreased HDL cholesterol, increased small dense LDL, increased FFA, dysglycemia, hyperinsulinemia, increased plasma viscosity, increased inflammatory molecules, impaired fibrinolysis, and prothrombosis, are often associated with elevated TG. In addition, triglyceride-rich lipoproteins (TGRLPs) or their remnants may act directly in atherogenesis, contributing to arterial wall foam cell formation. It has been considered axiomatic by experienced clinicians that chylomicrons are not directly atherogenic, and rare reports of atherosclerosis in genetic hyperchylomicronemia are the exceptions that prove this clinical rule. In contrast, CMR, VLDL, and IDL appear to be atherogenic. Because postprandial FFA released from lipolysis impairs physiological endothelial response, a newer concept is that postprandial lipemia may independently predict CHD and other vascular disease, although the definition of "postprandial hypertriglyceridemia" and standardized sample preparation and assay conditions have not yet been established.

Table I Proteins Involved in Triglyceride Metabolism

| Protein | Function |
|---|--|
| Pancreatic lipase | Hydrolyzes dietary TG into monoglycerides and FFA |
| Fatty acid-binding protein | Transports FFA from intestinal lumen into enterocytes |
| Monoacylglycerol acyltransferase | Catalyzes conversion of acyl-CoA and 2-monoacylglycerol into diacylglycerol and CoA |
| Diacylglycerol acyltransferase | Catalyzes conversion of acyl-CoA and diacylglycerol into TG (the committed step in TG synthesis) |
| ApoB48 | Structural protein required for chylomicron synthesis |
| ApoB100 | Structural protein required for VLDL synthesis and ligand for LDL receptor |
| Microsomal TG transfer protein | Mediates assembly of TG with apoB48 and apoB100 to form chylomicrons and VLDL, respectively |
| ApoE | Ligand that mediates clearance of CMRs and some IDLs through hepatic remnant receptors |
| Lipoprotein lipase | Capillary endothelial-bound enzyme that liberates FFA from TG in chylomicrons and VLDL |
| ApoCII | Cofactor essential for LPL activity |
| ApoCIII | Inhibitor of LPL and hepatic lipase |
| Sterol regulatory element-binding protein-1 | Membrane-bound transcription factor that regulates fatty acid synthesis |
| Fatty acid synthase | Enzyme that catalyzes all of the steps involved in the conversion of malonyl-CoA to palmitate |

Hypertriglyceridemia and Pancreatitis

Very high TG resulting from elevated chylomicrons is associated with increased risk of acute pancreatitis. The mechanism underlying this association is uncertain, but the relatively unique capacity of the pancreas to produce an exocrine lipase might play a role. Most patients with pancreatitis from high TG probably have preexisting abnormal lipoprotein metabolism, and milder hypertriglyceridemia will frequently persist after recovery. Pancreatitis risk is accentuated by diabetes, pregnancy, estrogen use, alcohol consumption, and/or any factor that can abruptly increase plasma TG to more than 1000 mg/dl (>11.3 mmol/L). Hypertriglyceridemia-induced pancreatitis can be preceded by episodic nausea and epigastric pain, during which serum amylase might not exceed common diagnostic cut points. Specific exclusion of lipemic serum should be documented before accepting a report of "normal" amylase in a patient who presents with an acute abdomen. If this is not done, TG-related pancreatitis might be excluded in favor of another diagnosis. Associated clinical clues include eruptive xanthomata and/or lipemia retinalis. The onset of full-blown acute pancreatitis can be prevented by TG reduction through rigorous dietary fat restriction. Once pancreatitis has developed, treatment involves hemodynamic stabilization, cessation of oral intake (possibly with placement of a nasogastric tube), and control of any primary metabolic disturbances such as diabetes. With restriction of caloric intake, plasma TG can fall quite briskly. Plasmapheresis may be an option in extreme cases, although the benefit is very transient if the primary metabolic disturbance is not treated. The individual thresholds for developing pancreatitis can vary markedly, and some individuals can be symptom free and survive with apparently normal longevity despite very high plasma TG (>3500 mg/dl [>40 mmol/L]).

CLASSIFICATION OF HYPERTRIGLYCERIDEMIA

Primary Hypertriglyceridemia

It could be argued that during the third millennium, a classification system for TG disorders should be based on a molecular diagnosis. However, human genetics has uncovered the molecular basis of only a minority of TG disorders. Thus, the time-honored Fredrickson system of lipoprotein phenotypes is presented here because it remains an entrenched system

of diagnostic shorthand for lipidologists and clinical biochemists. Five of the six Fredrickson types contain elevated TG as an essential diagnostic feature.

Familial Chylomicronemia Syndrome (MIM 238600)

Familial chylomicronemia (type I hyperlipoproteinemia) is characterized by excess chylomicrons. Overnight-refrigerated plasma develops a creamy supernatant and a clear infranatant. Patients are usually diagnosed during early infancy, although occasionally some may go unnoticed until later in life, when pancreatitis or lipemia is noted. Clinical features include eruptive xanthomata, lipemia retinalis, hepatosplenomegaly, focal neurological symptoms (e.g., memory loss, inability to concentrate), and recurrent epigastric pain. Modern laboratory methods have eliminated the artifactual hyponatremia that used to be a feature of this condition. Fasting TG exceeds 1000 mg/dl (>11.3 mmol/L) and occurs together with low plasma LDL and HDL cholesterol. Causes of this syndrome include LPL deficiency, apoCII deficiency, and ill-defined heritable inhibitors of LPL.

LPL deficiency is the most common molecularly defined cause of familial chylomicronemia. LPL deficiency is an autosomal recessive condition, occurring with a frequency of 1 in 1 million and resulting from two defective alleles of the LPL gene. The biochemical diagnosis of LPL deficiency is established by finding markedly reduced LPL activity in postheparin plasma. Deficiency of the LPL cofactor apoCII is an autosomal recessive condition (MIM 207750) that is even less common than LPL deficiency. ApoCII deficiency is less clinically severe than LPL deficiency. ApoCII deficiency can be identified by isoelectric focusing, DNA sequencing of the APOC2 gene, or documenting the rescue of absent *ex vivo* postheparin lipolytic activity by the addition of normal serum.

Primary Mixed Hypertriglyceridemia (MIM 144650)

Primary mixed hypertriglyceridemia (type V hyperlipoproteinemia) is characterized by elevated VLDL and chylomicrons. Some consider this condition to be a part of a chylomicronemia continuum that includes type I hyperlipoproteinemia. Type V hyperlipoproteinemia is typically an adult disease with a frequency up to 1 in 1000. Clinical features may include eruptive xanthomata, hepatosplenomegaly, lipemia retinalis, and recurrent epigastric pain with or without pancreatitis. Laboratory findings include fasting TG that exceeds 1000 mg/dl (>11.3 mmol/L),

increased total cholesterol, and low LDL and HDL cholesterol concentrations. Although heterozygosity for the mutant LPL gene has on occasion been demonstrated, disease expression is usually associated with secondary factors such as alcohol, poor diet, obesity, diabetes, and hypothyroidism.

Familial Hypertriglyceridemia (MIM 145750)

Familial hypertriglyceridemia (type IV hyperlipoproteinemia) is probably polygenic or possibly autosomal dominant with variable penetrance. It seems to be the most common primary hypertriglyceridemia phenotype seen in clinical practice. It certainly is a frequent cause of mild to moderate hypertriglyceridemia. The main lipoprotein abnormality is increased VLDL. The molecular basis of the phenotype is unknown in most instances. Typically, patients have moderately elevated plasma TG concentration ranging from 200 to 500 mg/dl (2.3–5.7 mmol/L), usually with low HDL. Familial hypertriglyceridemia is associated with increased CHD risk and often with obesity, insulin resistance, hyperglycemia, hypertension, and hyperuricemia.

Secondary Hypertriglyceridemia

Some metabolic conditions are frequently, but not absolutely, associated with high TG. One interpretation of these associations is that patients who develop secondary hypertriglyceridemia might already have a subtle metabolic defect that is perhaps genetically determined and that creates susceptibility to clinical hypertriglyceridemia depending on the presence of a metabolic stress. Obesity is probably the most commonly associated clinical attribute in hypertriglyceridemic patients.

Alcohol Ingestion

Hypertriglyceridemia associated with alcohol intake is also due mainly to increased plasma VLDL, with or without chylomicronemia. Within the liver, ethanol is converted to acetate, and this has a sparing effect on fatty acid oxidation, resulting in increased hepatic TG production and enhanced VLDL secretion. In many individuals, plasma TG can remain within the normal range due to adaptive increase in lipolytic activity. However, ethanol can also impair lipolysis, leading to increased plasma TG.

Renal Disease

Nephrotic syndrome is characterized by an increase in apoB-containing lipoproteins, including VLDL.

The mechanism underlying this increase includes overproduction by the liver, which has also increased albumin synthesis to compensate for renal protein wasting. Also, with hypoalbuminemia, more FFA binds to lipoproteins, which might impair LPL. Uremia is associated with modest elevation in VLDL, reflecting impairment of lipolysis, possibly due to the toxic effect of uremic metabolites.

Pregnancy

Plasma TG normally rises during the third trimester of pregnancy by up to threefold due to increased hepatic secretion of VLDL and reduced LPL activity. The physiological increase in plasma TG has little clinical consequence. However, more pronounced TG increases have been reported in association with reduced or absent LPL activity, and with the apoE4/E2 genotype, with variable pregnancy outcome. Severe hypertriglyceridemia during pregnancy due to chylomicronemia is very rare but can be complicated by pancreatitis, which carries a significant risk of mortality for both the mother and the fetus.

Medications

Use of specific drugs has been associated with hypertriglyceridemia, which can be profound in susceptible individuals. Medications that commonly exacerbate hypertriglyceridemia include highly active antiretroviral combination therapies, oral estrogens, isotretinoin, beta blockers, thiazides, tamoxifen, and bile acid-binding resins. If a medication is considered to be an important determinant of hypertriglyceridemia, the indications for the particular treatment should be reviewed, particularly if the hypertriglyceridemia is marked. If dose reductions, changes in route of administration, and/or substitution with another class of medication are not possible, marked TG elevation should be treated with diet and/or pharmacological agents.

Other Causes of Secondary Hypertriglyceridemia

Hypothyroidism is usually associated with elevated LDL, but elevated TG may also be present, perhaps due to impaired lipolysis. Paraproteinemias, such as the hypergammaglobulinemia in macroglobulinemia, myeloma, lymphoma, and lymphocytic leukemias, and autoimmune disorders, such as systemic lupus erythematosus, may cause hypertriglyceridemia, possibly through immune-mediated interference of lipolysis.

TRIGLYCERIDE-LOWERING THERAPIES

Nonpharmacological Therapy

Patients with hypertriglyceridemia are frequently obese with insulin resistance, hypertension, and/or diabetes. Because these are also CHD risk factors, they should be identified and treated as part of a global risk factor reduction strategy. The marked sensitivity of plasma TG to energy balance means that treatment plans should include weight reduction, dietary modification, and exercise. Dietary modification should be aimed at weight loss, with decreased overall fat intake and a reduction in refined carbohydrates or so-called "high glycemic index" foods. In general, the severity of the hypertriglyceridemia dictates the severity of the fat restriction. For instance, in severe hyperchylomicronemia, recommendations are often restriction of fat to approximately 10 to 15% of total calories, with reductions in both saturated and unsaturated fat. In an adult, this represents 15 to 20 g/day of fat. The diet should include at least 5 g/day of polyunsaturated fat as a source of essential fatty acids, and fat-soluble vitamins must be provided. A specialized dietician can be very helpful in these circumstances.

For less severe hypertriglyceridemia, restriction of saturated fat together with increased aerobic activity may lead to substantial reductions in plasma TG. The National Cholesterol Education Program (NCEP) advises that carbohydrate and protein intake should be 55 to 60% and 15 to 20%, respectively, whereas total and saturated fat should be less than 30% and less than 7%, respectively, of daily calories.

Omega-3 fatty acids, such as eicosapentanoic and docosahexanoic acid, are components of both the Mediterranean diet and fish oils. Omega-3 fatty acids can reduce hepatic secretion of TGRLP. Ingestion of 3 to 4 g/day of omega-3 fatty acids, with caloric and saturated fat restriction, may reduce plasma TG by up to 20%. However, response to omega-3 fatty acids is not uniform when used as the sole TG-lowering therapy.

Pharmacological Therapy

In general, monotherapy with pharmacological agents should be attempted first, together with diet. Combination treatment may be required for refractory severe hypertriglyceridemia but should be attempted only with caution and with a plan for frequent follow-up and monitoring of serum creatine kinase and transaminases.

Fibric Acid Derivatives (fibrates)

Fibrates, such as gemfibrozil, bezafibrate, and fenofibrate, are a mainstay of treatment of hypertriglyceridemia. Fibrates can reduce plasma TG by up to 50% and can raise plasma HDL cholesterol by up to 20%, although these percentages are variable. The mechanism of action of fibrates is complex but includes modulation of the activity of peroxisome proliferator-activated receptor- α in the liver, with reduced hepatic secretion of VLDL and increased lipolysis of plasma TG, possibly related to decreased secretion of apoCIII. Gemfibrozil reduced CHD events in the Veterans Affairs HDL Cholesterol Intervention Trial. Fibrates can sometimes increase plasma LDL cholesterol concentration, and this may require a change to another drug or the addition of a second agent. Fibrates are generally very well tolerated, with very rare reports of hepatitis and myositis.

HMG-CoA Reductase Inhibitors (statins)

In addition to lowering LDL, statins used at higher doses can produce clinically significant TG decreases, probably by lowering hepatic secretion of apoB-containing lipoproteins. However, statins should not be considered as firstline therapy when TG is much above 500 mg/dl (5.7 mmol/L). An advantage of statins is the preponderance of clinical trial results indicating marked reductions in CHD end points. Like fibrates, statins are well tolerated but very rarely may cause myopathy and/or hepatic toxicity, often with sentinel elevations in creatine kinase and/or transaminases.

Niacin (nicotinic acid)

Niacin has pleiotropic, incompletely defined effects on lipoprotein metabolism that may include inhibition of hepatic VLDL secretion and stimulation of lipolysis. Niacin, when administered 3 g daily in divided doses, can lower plasma TG by up to 45%, raise plasma HDL cholesterol by up to 25%, and reduce plasma LDL cholesterol by up to 20%. Older clinical trials suggested a reduction in CHD events related to niacin treatment. However, niacin can cause lightheadedness, cutaneous flushing, and/or pruritus. These adverse effects can be minimized by initiating therapy at low doses and then gradually increasing the daily dose, along with the concomitant use of aspirin. Less common adverse effects include elevation of liver enzymes, gastrointestinal distress, worsening of glucose tolerance, and elevation of uric acid. Longer acting preparations of niacin may reduce the frequency and intensity of these adverse effects, but the clinical impression is that their TG-lowering effect may be less than that seen with crystalline niacin.

TARGET TRIGLYCERIDE GOALS

According to the recent NCEP guidelines, the primary aim of therapy when TG is more than 150 mg/dl (>1.7 mmol/L) is to attain the LDL cholesterol target for the CHD risk stratum. When TG is borderline high, emphasis should be placed on weight loss and exercise. For patients with moderately high TG, weight reduction, increased physical activity, and drug therapy may be considered in high-risk persons to achieve the NCEP targets. For patients with very high TG, the initial aim of therapy is prevention of acute pancreatitis through TG lowering by diet, medication, weight reduction, control of secondary metabolic factors, and increased physical activity. Once TG has been lowered to less than 500 mg/dl (5.7 mmol/L), attention may be directed to LDL lowering. The Canadian Working Group on Hypercholesterolemia and Other Dyslipidemias guidelines suggest TG of less than 266 mg/dl (3 mmol/L) in individuals with low CHD risk and TG of less than 177 mg/dl (2 mmol/L) in individuals with moderate to very high CHD risk, including those with diabetes mellitus and/or preexisting vascular disease.

action. Therefore, calcium should be given in conjunction with magnesium for several days until normal PTH responsiveness is restored. Treatment of severe hypomagnesemia consists of giving 2 g magnesium sulfate intravenously over 5 to 10 min initially. If serum magnesium is still low, 6 g magnesium sulfate can be infused in 5% dextrose/0.5% saline over 24 h. For chronic hypomagnesemia, magnesium oxide (250–500 mg by mouth two to four times daily) should be adequate.

Hypermagnesemia is a much less common abnormality than hypomagnesemia and is usually observed as result of magnesium overdose, for example, in obstetric practice when high-dose magnesium infusions are used for treatment of toxemia of pregnancy and in patients with renal failure who are receiving an antacid or enema containing magnesium. Hypermagnesemia can result in reversible hypocalcemia by mechanisms similar to those operating in hypomagnesemia. Tetany is unusual in this entity of hypocalcemia due to the concomitant hypermagnesemia. Treatment of moderate hypermagnesemia simply requires magnesium withdrawal to allow magnesium excretion by the kidneys. In cases of severe hypermagnesemia, intravenous calcium (100–200 mg over 5–10 min) will antagonize the toxic effects of magnesium in addition to raising serum calcium.

MANAGEMENT OF HYPOCALCEMIC EMERGENCY

Most authors agree that hypocalcemic emergency exists when corrected serum calcium is less than 7.5 mg/dl or in the presence of severe symptoms or

signs (e.g., tetany, seizures, severe hypotension, heart failure). The mainstay treatment in hypocalcemic emergency is parenteral calcium therapy. There are several forms of calcium available for intravenous administration (Table I). Calcium chloride has a much higher content of elemental calcium than does calcium gluconate (272 and 90 mg/10 ml, respectively). Therefore, administration of calcium chloride can raise serum calcium more rapidly than can calcium gluconate. However, calcium chloride has the disadvantage of being extremely irritating to the veins and soft tissues in case of extravasation.

As initial therapy, one or two ampoules, each containing 10 ml of 10% calcium chloride or 10 ml of 10% calcium gluconate, are diluted in 50 to 100 ml of 5% dextrose and given intravenously over 10 min. In a severe emergency situation (e.g., a patient with tetany), a 10-ml ampoule of 10% calcium gluconate can be infused directly over 4 min.

If hypomagnesemia is suspected (e.g., an alcoholic patient, a patient having diarrhea, a patient receiving diuretics), magnesium administration (e.g., magnesium sulfate [2 g intravenously]) is appropriate pending the results of serum magnesium. Oral calcium and a rapidly acting form of vitamin D, such as calcitriol, should be started simultaneously with intravenous calcium.

If the cause of hypocalcemia is likely to be longstanding or due to a permanent defect (e.g., hypoparathyroidism), continuous calcium infusion for a few days is indicated until the actions of oral calcium and vitamin D start. Different protocols exist regarding the concentration and rate of calcium drip. The recommended initial rate ranges from 0.3 to 2.0 mg elemental calcium/kg/h depending on the severity of the

Table I Parenteral Calcium Preparations

| Calcium preparation | Elemental calcium | Initial treatment | Remarks |
|--------------------------|--------------------------|--|--|
| Calcium gluconate (10%) | 90 mg per 10-ml ampoule | 1–2 ampoules in 50 to 100 ml of 5% dextrose over 5 to 10 min; one ampoule may be infused directly over 4 min in emergency situations | Less irritating to the veins than calcium chloride; therefore, more convenient for prolonged infusion ^a |
| Calcium chloride (10%) | 272 mg per 10-ml ampoule | 1–2 ampoules in 50 to 100 ml of 5% dextrose over 5 to 10 min | Raises serum calcium more rapidly than does calcium gluconate, but more toxic to the veins |
| Calcium gluceptate (10%) | 90 mg per 5-ml ampoule | 1–2 ampoules in 50 to 100 ml of 5% dextrose over 5 to 10 min | Useful in patients who cannot tolerate large volumes of fluid |

^aTen ampoules of calcium gluconate are added to 900 ml of 5% dextrose (i.e., 900 mg elemental calcium/L) to be infused at 50 ml/h (45 mg elemental calcium/h) and then rate titrated. If necessary, this solution can be infused as rapidly as over 4 to 6 h.

Table II Initial Management of Hypocalcemia

1. Confirm hypocalcemia by measurement of ionized calcium or total serum calcium corrected for the degree of hypoalbuminemia.
2. Measure serum magnesium, phosphorus, PTH, 25-hydroxy-vitamin D, and creatinine.
3. If corrected serum calcium is less than 7.5 mg/dl or in the presence of severe hypocalcemic symptoms, administer intravenous calcium (e.g., 1–2 ampoules of 10% calcium chloride or gluconate) in addition to oral calcium and calcitriol.
4. If serum calcium is still low and in long-term causes of hypocalcemia, start calcium drip for a few days until oral calcium and vitamin D actions start.
5. If hypocalcemia is mild with minimal symptoms and signs, if any start oral calcium and vitamin D.

case. The infusion rate is titrated according to serum calcium levels, which are monitored every 4 to 8 h to maintain serum calcium in the low-normal range. A simple protocol of calcium gluconate drip is shown in [Table I](#). A total infusion of 15 mg/kg calcium gluconate over 4 to 6 h will raise the serum calcium by approximately 2 to 3 mg/dl (0.5–0.75 mmol/L). Recommended calcium infusion rates should not be exceeded so as to avoid cardiac dysfunction. Cardiac monitoring is advisable in all patients, particularly those receiving digitalis due to their propensity for arrhythmias if the serum calcium level is raised excessively. Bicarbonate or phosphate should not be infused along with calcium because of possible intravenous precipitation of those calcium salts. Initial management of hypocalcemia is summarized in [Table II](#).

LONG-TERM TREATMENT OF HYPOCALCEMIA

The most severe form of chronic hypocalcemia is hypoparathyroidism, which is due mostly to surgical removal or vascular compromise of the parathyroid glands. In hypoparathyroidism, the physiological calcium-retaining effect of PTH in renal tubules is lacking. Therefore, the goal of therapy in hypoparathyroid states is maintenance of serum calcium in the low-normal range rather than in the mid- or high-normal range so as to limit hypercalciuria,

nephrolithiasis, and nephrocalcinosis. Among the oral calcium preparations available ([Table III](#)), calcium carbonate is the most commonly used because it offers the highest amount of elemental calcium (40%) per unit tablet weight. In addition, it is the least expensive. Calcium carbonate tablets are preferentially taken with food because their absorption is enhanced in an acid environment. Gastrointestinal side effects include bloating and constipation. If these occur, switching to calcium citrate is recommended. The latter formula is better absorbed and tolerated, but is more expensive and has less elemental calcium, compared with calcium carbonate. Treatment usually starts with daily doses of 1000 to 4000 mg elemental calcium divided into three or four doses. In hypocalcemia of renal failure, hyperphosphatemia is reduced by limitation of dietary phosphate and the use of phosphate-binding agents such as calcium carbonate and calcium acetate.

SIDE EFFECTS OF ORAL CALCIUM

The efficacy of calcium absorption from the gut declines as calcium intake increases, providing a protective mechanism against calcium toxicity. However, this adaptive mechanism can be overcome by high calcium intake (usually more than 4 g daily). The consequences of calcium toxicity are shown in [Table IV](#). Milk-alkali syndrome is a form of calcium toxicity initially described in patients consuming large

Table III Oral Calcium Preparations

| Calcium salt | Elemental calcium percentage | Remarks |
|--------------|------------------------------|---|
| Carbonate | 40 | Inexpensive; may cause bloating and constipation |
| Citrate | 30 | Well tolerated and absorbed; expensive |
| Lactate | 13 | Poor in elemental calcium |
| Gluconate | 9 | Poor in elemental calcium |
| Glubionate | 7 | Available in palatable liquid form (252 mg/10 ml) |
| Acetate | 25 | Given as phosphate binders in renal failure |

Table IV Complications of Calcium and Vitamin D Toxicity

amounts of dairy calcium milk and absorbable antacids for treatment of peptic ulcer disease. Nowadays, the syndrome is more commonly seen with administration of excessive doses of calcium carbonate. The syndrome consists of nausea, vomiting, renal failure, metabolic alkalosis, and hypercalcemia.

VITAMIN D THERAPY

The two precursor molecules of vitamin D are ergocalciferol (vitamin D₂) and cholecalciferol (vitamin D₃). In the liver, vitamin D is converted to 25-hydroxy-vitamin D, which requires further hydroxylation in the kidney to form the biologically active 1,25-dihydroxy-vitamin D (calcitriol). PTH activates the renal conversion of 25-hydroxy-vitamin D to 1,25-dihydroxy-vitamin D. Dihydroxycholesterol is an active synthetic analogue that does not require further metabolism and is rarely used nowadays.

Vitamin D is required for the treatment of most, if not all, cases of hypocalcemia for two reasons. First, it

improves the bioavailability of calcium present in food or calcium given as medication by providing optimal calcium absorption in the gut. Second, chronic hypocalcemic states are frequently associated with a decreased synthesis or function of one or more forms of vitamin D. For instance, in hypoparathyroidism, lack of PTH results in decreased synthesis of the active form of vitamin D, 1,25-dihydroxy-vitamin D. The latter is also decreased in severe renal insufficiency due to hyperphosphatemia and decreased functional renal mass. In end-stage liver disease, formation of 25-hydroxy-vitamin D is impaired. Selection of the vitamin D preparation depends on the specific abnormality in vitamin D synthesis and activation. Thus, in the hypoparathyroid states and renal disease, 1,25-dihydroxy-vitamin D is the most rational therapy. In severe hepatic disease, either 25-hydroxy-vitamin D or 1,25-dihydroxy-vitamin D could be used. In malabsorption, relatively large doses of any form of vitamin D are appropriate orally or intramuscularly (every 6 months).

Table V depicts the pharmacological properties of various vitamin D preparations. Vitamin D (either D₂ or D₃) is extremely lipophilic, has virtually extensive storage sites in fatty tissue, and has a long half-life of about 30 days. On the contrary, 1,25-dihydroxy-vitamin D is a polar compound, not stored in large amounts of fat, and has a short half-life of approximately 6 h. The time periods required to normalize serum calcium can be shortened considerably by starting treatment with loading doses. This policy is particularly useful in severe hypocalcemia when rapid normalization of serum calcium is warranted. For instance, calcitriol can be given in a loading dose of 4 µg daily for a few days and then in a maintenance dose of 0.5 to 1.0 µg daily.

Cost also plays a role in choosing vitamin D formulation. In general, cost parallels the biological activity. Thus, the precursor compounds, ergocalciferol (vitamin D₂) and cholecalciferol (vitamin D₃), are

Table V Vitamin D Preparations

| Preparation | Approximate daily dose (µg) for treatment of hypocalcemia | Onset of action (days) | Approximate time to normalize serum calcium | Time to reverse toxicity |
|---|---|------------------------|---|--------------------------|
| Ergocalciferol (vitamin D ₂), cholecalciferol (vitamin D ₃) | 1000–3000 (40,000–120,000 U) ^a | 10–14 | 4–8 weeks | 4–12 weeks |
| Calcifediol (25-hydroxy D ₃) | 50–225 | 7–10 | 2–4 weeks | 2–6 weeks |
| Dihydroxycholesterol | 300–1000 | 4–7 | 1–2 weeks | 3–14 days |
| Calcitriol (1,25-dihydroxy D ₃) | 0.25–2.5 | 1–2 | 3–7 days | 2–10 days |

^a1 µg = 40 U.

Table VI Treatment of Hypercalcemia Resulting from Calcium or Vitamin D Toxicity

| |
|---|
| 1. Aggressive hydration with normal saline |
| 2. In patients who cannot tolerate fluids, hemodialysis against a low-dialysis calcium bath |
| 3. Loop diuretics after adequate hydration |
| 4. Corticosteroids, prednisone (30–40 mg daily orally) or hydrocortisone (50 mg every 8 h), particularly in vitamin D-induced hypercalcemia |
| 5. Calcitonin (4–6 U/kg every 6–8 h subcutaneously) |
| 6. In severe cases, biphosphonate infusion (e.g., pamidronate, 90 mg) |

the least expensive, whereas 1,25-dihydroxy-vitamin D is the most expensive. 25-hydroxy-vitamin D₃ (calcifediol) is intermediate in cost.

VITAMIN D TOXICITY

Vitamin D toxicity virtually occurs more easily with the most potent agent, 1,25-dihydroxy-vitamin D, than with the inactive vitamin D forms. However, because of the short duration of action of 1,25-dihydroxy-vitamin D, its toxicity is reversed within a few days (Table V). On the other hand, toxicity due to excessive administration of vitamin D₂ and vitamin D₃ can be protracted and last for several months (Table IV). Symptoms and signs of vitamin D overdose are related mainly to those of the prevailing hypercalcemia and hyperphosphatemia (Table IV). Treatment of calcium or vitamin D overdose is shown in Table VI.

MONITORING OF THERAPY FOR CHRONIC HYPOCALCEMIA

Close monitoring of serum calcium is required initially every few days after starting oral therapy. Stable laboratory values are usually reached within 3 to 4 weeks. Subsequently, periodic measurement of serum calcium, phosphorus, and magnesium can be performed every 2 to 4 months. Urine calcium may be assessed shortly after initiation of therapy and then every 6 to 12 months to prevent the development of hypercalciuria and to keep urinary calcium at less than 350 mg/24 h. Frequently, hypoparathyroid patients whose serum calcium is maintained in the normal range have hypercalciuria due to the absence of PTH action on renal calcium reabsorption. Thiazide diuretics enhance calcium reabsorption in distal renal tubule and, therefore, limit the amount of urinary calcium. Thus, thiazides can be useful in many hypoparathyroid patients as adjunctive therapy to decrease hypercalciuria and calcium/vitamin requirements. In

advanced renal insufficiency, oral calcium, dialysate calcium, and calcitriol must be properly balanced to keep the calcium–phosphorus product within the normal range so as to avoid metastatic calcification. Acceptable targets are serum phosphorus of 4.5 mg/dl and total serum calcium of 10 mg/dl.

CONCLUSION

Hypocalcemia is a common disorder characterized by decreased levels of ionized serum calcium, the only biologically active form of calcium. The serum magnesium level should be assessed in every case of hypocalcemia and should be corrected if it is abnormal. Hypocalcemic emergency is a life-threatening condition occurring when severe symptoms exist and/or corrected serum calcium is less than 7.5 mg/dl. Intravenous calcium is life-saving in hypocalcemic emergency, and in many cases calcium infusion for a few days is required until actions of oral calcium and vitamin D are in effect. Calcium carbonate is the oral preparation of choice due to its high content of elemental calcium and low cost. Calcitriol is the most potent and rapidly acting vitamin D form, but its widespread use is limited by its high cost. In hypoparathyroid states, the goal of therapy is to maintain serum calcium in the low-normal range to avoid hypercalciuria. The latter can be limited by the administration of thiazide diuretics.

endogenous glucose production that occur primarily from the liver but also the kidney. Glucagon is a powerful and quick-acting stimulus for hepatic glucose production. The increase in hepatic glucose production is primarily through glycogenolysis, but gluconeogenesis becomes more important as hypoglycemia is prolonged. Glucagon responses are absent within 5 years' duration of T1DM, causing an increased reliance on epinephrine for defense against hypoglycemia. Growth hormone from the pituitary gland, cortisol from the adrenal cortex, and norepinephrine spillover from the sympathetic nervous system (SNS) also increase in response to moderate hypoglycemia but have modest metabolic effects. Pancreatic polypeptide (an index of parasympathetic nervous system activity), oxytocin, and vasopressin are also released during hypoglycemia but have no discernible metabolic effects.

Symptoms of Hypoglycemia

The symptoms of hypoglycemia can be separated into those that are neurogenic (autonomic) and those that are neuroglycopenic. Examples of neurogenic symptoms experienced when glucose levels fall below 60 mg/dl are tremulousness, palpitations, anxiety, sweating, and parasthesias. These symptoms are autonomic in origin and stem from increased sympathetic drive. For example, sweating and parasthesias are cholinergically mediated via sympathetic nerve fibers, and tremor is correlated with increased circulating levels of epinephrine. Symptoms that are neuroglycopenic generally occur at glucose levels of 50 mg/dl or less, result directly from brain glucose deprivation, and include difficulty in thinking, confusion, weakness, fatigue, seizures, coma, and death. Impairment of cognitive function occurs at glucose levels of about

45 mg/dl and can be responsible for accidents that are sometimes fatal.

HYPOGLYCEMIA AND T1DM

Persistent hyperglycemia has been determined to be the cause of long-term microvascular complications associated with T1DM. The Diabetes Control and Complications Trial, a landmark multicenter randomized clinical trial, was developed to determine the risks and benefits of tight glucose control. The results showed that tight glucose control, defined as hemoglobin A_{1C} (HbA_{1C}) $\leq 7.2\%$, obtained by using either multiple insulin injections or continuous subcutaneous insulin infusion prevented or delayed the progression of diabetes complications as compared with conventional treatment (HbA_{1C} $\geq 9.0\%$). However, patients with tight glucose control also suffered a threefold increase in the incidence of severe hypoglycemia (requiring outside assistance to recover) and coma. Ninety percent of all patients with T1DM experience symptoms of hypoglycemia. In T1DM, hypoglycemia is initially caused by insulin excess but can be potentiated by lack of food intake, physical activity, and autonomic dysfunction. Hypoglycemia-associated autonomic dysfunction is an acute failure of the autonomic response to hypoglycemia that is induced by prior episodes of hypoglycemia. This creates a situation where T1DM patients have reduced capability to defend against impending hypoglycemia. Unfortunately, hypoglycemia is the complication of diabetes most feared by diabetics. Consequently, the increased prevalence of hypoglycemia is the major roadblock preventing patients from realizing the benefits of tight glucose control.

HYPOGLYCEMIC UNAWARENESS

One component of hypoglycemia-induced autonomic dysfunction is hypoglycemic unawareness. Hypoglycemic unawareness occurs when an individual has reduced or a complete loss of symptoms that indicate the presence of hypoglycemia. The pathogenesis of hypoglycemic unawareness is multifactorial but includes a shifting of the glycemic threshold. That is, symptoms occur only at progressively lower glucose levels. If this threshold occurs below a critical level, hypoglycemic symptoms might not be activated and a patient might slip into a coma with little or no warning. Importantly, hypoglycemia unawareness can be reversed by meticulous avoidance of iatrogenic hypoglycemia.

Role of Antecedent Stress in Incidence of Hypoglycemia

Many studies have demonstrated the importance of antecedent hypoglycemia in the pathogenesis of hypoglycemic-associated autonomic dysfunction. Patients with tight glucose control typically have low glycemic thresholds due to the repeated exposure to prior hypoglycemia. Prior episodes of hypoglycemia cause a shift in the glycemic threshold that result in a progressive diminution of autonomic and neuroendocrine responses to subsequent episodes of hypoglycemia. As stated previously, the autonomic and neuroendocrine responses to hypoglycemia are necessary to stimulate the liver to release more glucose and to inhibit peripheral uptake of glucose in an attempt to defend against the falling glycemia. With a reduction in these defenses, combined with the absence of glucagon, T1DM patients are left particularly vulnerable to repeated hypoglycemia. [Tables III and IV](#) contain data from healthy individuals exposed to either day 1 clamped euglycemia or hypoglycemia followed by a subsequent bout of hypoglycemia on day 2. These data clearly demonstrate the blunted day 2 neuroendocrine and ANS responses and reveal the considerably greater amounts of glucose that had to be infused during the day 2 experiments to maintain the desired level of hypoglycemia.

Exercise is an important adjunct treatment of T1DM. Physical activity improves insulin sensitivity, helps in body weight maintenance, and can reduce postprandial hyperglycemia. Unfortunately, exercise is also associated with increased hypoglycemia in T1DM patients. This may be due in part to the fact that prior episodes of hypoglycemia also reduce the autonomic and neuroendocrine response to a subsequent bout of prolonged exercise. The reverse is also true, as prior prolonged exercise will blunt autonomic and neuroendocrine responses to next-day hypoglycemia. Also, one bout of exercise in the morning can even cause a blunted neuroendocrine and metabolic counterregulatory response to a second bout of exercise in the afternoon. Thus, insulin delivery (reduced) and carbohydrate intake (increased) during exercise following a hypoglycemic episode may have to be modified to prevent further hypoglycemia.

The mechanism(s) responsible for the blunting effect of prior episodes of hypoglycemia is unknown at this time. Cortisol is known to blunt SNS responses to stress in both animal and human experimental models. Therefore, prior increases in cortisol during hypoglycemia or exercise could be one factor that

causes blunted SNS responses to subsequent episodes of hypoglycemia or bouts of exercise.

CONCLUSION

A vicious cycle is generated for T1DM patients when intensive control results in iatrogenic hypoglycemia. An increased frequency of hypoglycemia leads to lower glycemic thresholds, blunted neuroendocrine and ANS responses, hypoglycemia unawareness, and (unfortunately) further episodes of hypoglycemia. Alterations in treatment that focus on preventing hypoglycemia but allow maintenance of tight control of blood glucose levels can add significantly to the quality of life for T1DM patients.

of cognitive function (2.5–3.0 mmol/L) are sometimes observed in everyday life conditions in some individuals.

VARIOUS FORMS OF NON-DIABETIC HYPOGLYCEMIA, DIAGNOSIS, AND TREATMENT

As reviewed in details elsewhere by Lefèbvre and Scheen, there are two principal forms of hypoglycemia: (1) exogenous hypoglycemia attributable to the administration (injection or ingestion) of a hypoglycemic compound and (2) endogenous hypoglycemia.

Exogenous Hypoglycemia

Insulin is by far the most frequent cause of hypoglycemia. In non-diabetic as well as diabetic patients, insulin has been used for homicidal or suicidal purposes. Severe unexplained hypoglycemia in a non-diabetic individual should always raise the possibility of an exogenous insulin administration, either suicidal or criminal. Such cases are encountered more frequently in the medical milieu or in the families or neighborhoods of diabetic patients. Inadvertent insulin administration to a hospitalized non-diabetic patient has also been reported. In psychiatric patients, purposely induced insulin shock therapy sometimes leads to prolonged hypoglycemia and irreversible brain damage. Factitious hypoglycemia due to clandestine self-administration of insulin must always be considered in the differential diagnosis of hypoglycemia; again, this situation is encountered more frequently in the relatives of diabetic patients, in the medical or paramedical profession, or in diabetic patients themselves. Similarly, oral antidiabetic agents, mainly sulfonylureas, can be involved in the pathogenesis of hypoglycemia in non-diabetic individuals: inadvertent administration, accidental ingestion (mainly in children), suicide attempt, and clandestine ingestion (a variety of factitious hypoglycemia). Alcohol ingestion may lead to hypoglycemia if it occurs in fasting conditions given that accidental ingestion of alcohol in children can induce severe hypoglycemia. Sometimes, alcohol favors the “reactive hypoglycemia” following sugar ingestion. Numerous other agents or drugs may induce hypoglycemia, including salicylates, quinine, β -receptor blocking agents, pentamidine, hypoglycins, ouabain, mebendazole, isoproterenol, disopyramide, tranylcypamine, haloperidol, clofibrate, and angiotensin-converting enzyme inhibitors.

Endogenous Hypoglycemia

Endogenous hypoglycemia may be organic or functional.

Organic Hypoglycemia

Insulinomas

Insulinomas are uncommon neoplasms, most often benign, that derive from the B cells of the islets of Langerhans of the pancreas. An insulinoma should be suspected in any patient presenting with the triad described by Whipple: symptoms precipitated by fasting or exercise, proven hypoglycemia associated with symptoms, and relief of symptoms by glucose. The demonstration of endogenous plasma insulin (and C-peptide) levels inappropriate to the prevailing blood glucose level is the cornerstone of the diagnosis. Simultaneous determination of blood glucose and plasma insulin (and C-peptide) levels after an overnight fast and, mainly, during a 24- to 48-h fast is probably the best procedure to demonstrate relative hyperinsulinism. When one is convinced of the diagnosis, one attempts to localize the tumor before sending the patient to surgery. Preoperative localization procedures include tomodensitometry, conventional ultrasonography, selective arteriography, magnetic resonance imaging, effluent vein catheterization, and (the most useful) endoscopic transduodenal ultrasonography. Surgical removal of the tumor is the first and obvious choice of treatment. It must always be accompanied by intraoperative ultrasensitive pancreas echotomography, particularly because there may be more than one tumor.

Medical management, mainly using diazoxide, is reserved for patients who do not accept surgery or in whom major contraindications for the operation exist. Streptozotocin, in association with fluorouracil or doxorubicin, is considered to be the most effective antitumor agent for treating the rare metastatic malignant insulinomas, possibly after surgical reduction of the tumor mass and/or removal of liver metastasis. Other therapeutic options have been reviewed by Lefèbvre and Scheen.

Extrapancreatic Neoplasms

Extrapancreatic neoplasms secreting a large form of insulin-like growth factor-II, known as “big IGF-II,” are usually large tumors present as masses in the mediastinum or the retroperitoneal space. They often have a mesenchymal origin but can originate from the liver, gastrointestinal tract, or pancreas or can be associated with lymphomas and leukemias. In these patients, hypoglycemia coexists with low or

undetectable insulin and C-peptide levels, whereas high circulating levels of big IGF-II are found. Surgery is the treatment of choice.

Neonatal and Infancy Hypoglycemia

Numerous inborn errors of metabolism can induce hypoglycemia in neonates and young infants. They include hereditary fructose intolerance, fructose-1,6-diphosphatase deficiency, phosphoenolpyruvate carboxykinase deficiency, some cases of galactosemia, and some of the 11 varieties of glycogen storage disease. Nesidioblastosis, now called "persistent hyperinsulinemic hypoglycemia of infancy" (PHHI), is a rare disease leading to persistent hypoglycemia of infancy. It is basically histologically characterized by the budding off from duct epithelium of endocrine cells and by the presence of microadenomas in the pancreas. The onset of symptoms of beta cell hyperplasia may occur during the first days of life but most commonly within the first 6 months. A few cases beginning with symptoms beyond 1 year of age have been reported. The group of Saudubray in Paris reported the features of 52 neonates with hyperinsulinism. Of these, 30 had diffuse B-cell hyperfunction and 22 had focal adenomatous islet cell hyperplasia. Among the latter, the lesions were in the head of the pancreas in 9, in the isthmus in 3, in the body in 8, and in the tail in 2 neonates. Partial pancreatectomy has been successful in curing 19 of the 22 neonates in whom this procedure has been proposed. Recent studies have shown that congenital hyperinsulinism with focal or diffuse nesidioblastosis can be associated with several mutations affecting the beta cell such as the genes encoding for the sulfonylurea receptor, the glucokinase enzyme, and glutamate dehydrogenase.

Other causes of hypoglycemia during infancy (more functional in nature) include erythroblastosis fetalis, infants of diabetic mothers, leucine-induced hypoglycemia, ketotic or ketogenic hypoglycemia, maple sugar urine disease, and adrenal hyporesponsiveness.

Functional Hypoglycemia

Alimentary Hypoglycemia

Alimentary hypoglycemia can occur 1 to 2 h after a carbohydrate-rich meal in individuals who have had a gastrectomy or who, for other reasons, have rapid gastric emptying. It is believed that the rapid dumping of carbohydrates in the upper small intestine elicits an excessive insulin release mediated by both the release of intestinal gut factors (e.g., GLP-1, GIP) and a rapid rise in blood glucose. The treatment is identical to that of spontaneous reactive hypoglycemia.

Spontaneous Reactive Hypoglycemia

Spontaneous reactive hypoglycemia is a poorly defined entity. The term is usually applied to a syndrome with the following features: (1) symptoms that resemble those seen in insulin-induced hypoglycemia (e.g., diaphoresis, tachycardia, tremulousness, headache) but that often are accompanied by other symptoms less typical of hypoglycemia (e.g., fatigue, drowsiness, feelings of incipient syncope, depersonalization, irritability, lack of motivation); (2) symptoms that may be episodic, sometimes aggravated by carbohydrate-rich meals; and (3) plasma glucose concentrations that drop to 45 mg/dl (2.5 mmol/L) or less at one or more of the half-hourly samples taken in a 5- to 6-h glucose tolerance test. Abnormal insulin secretory patterns have been reported in certain patients.

This entity has had a widespread vogue, particularly in the United States, over the past 30 years but has been said to be diagnosed more rarely elsewhere in the world. The American Diabetes Association and the Endocrine Society issued a joint statement to the effect that this entity is probably overdiagnosed. Indeed, the very existence of this condition has been called into question following several studies demonstrating that 25 to 30% of apparently healthy individuals without any hypoglycemic symptoms may exhibit low plasma glucose values on being given a glucose load. Furthermore, the similarity of the symptoms to those of hyperventilation, and indeed to those of other functional syndromes, emphasizes the need to reevaluate the whole matter of so-called functional or reactive hypoglycemia. The question of cause and effect has not been settled. It would be reasonable at the current time to restrict the diagnosis of reactive hypoglycemia to individuals in whom hypoglycemic blood glucose levels are demonstrated in samples taken after the sort of meals that are said to induce their symptoms. Furthermore, and as has been discussed by Lefèbvre, some patients have adrenergic responses after a meal or during oral glucose tolerance test (OGTT) without hypoglycemia. Such "adrenergic hormone postprandial syndrome" probably results from an altered glycemic threshold (a higher glucose level) for generating an adrenergic response. This results in confusion. A critical analysis of the reactive hypoglycemia syndrome can be found in the proceedings of an international symposium held in Rome in September 1986.

Diet is the first treatment of alimentary and reactive hypoglycemia. Simple sugars should be omitted and replaced by complex carbohydrates. If symptoms persist, small but frequent high-protein, low-carbohydrate meals should be tried. The pharmacological

treatment of choice is α -glucosidase inhibitors such as acarbose and miglitol.

Alcohol-Promoted Reactive Hypoglycemia

Alcohol-promoted reactive hypoglycemia can occur when insulinotropic sugars (e.g., glucose, saccharose) are ingested together with alcohol (e.g., beer, gin and tonic, rum and cola, whisky and ginger ale). Such mixtures should be avoided in susceptible individuals.

Other Causes of Functional Hypoglycemia

Other causes of functional hypoglycemia include discontinuation of total parenteral nutrition, an endocrine deficiency state (glucocorticoid, growth hormone, or glucagon deficiency), severe liver disease, profound malnutrition, prolonged muscular exercise, the autoimmune insulin syndrome (where hypoglycemia is considered to be the consequence of inappropriate release of insulin from insulin-antibody complexes), and the rare syndrome of antibodies directed against the insulin receptor (where hypoglycemia is attributed to an insulinomimetic action of the antibody).

CONCLUSION

Hypoglycemia in non-diabetic individuals is not a rare condition. It is diagnosed when the blood glucose level is lower than the lowest limit of normal, that is, lower than about 3 mmol/L (or 54 mg/dl), a value also corresponding to the threshold for symptoms in various experimental studies performed in healthy volunteers in whom mild hypoglycemia was induced using graded insulin infusion. Hypoglycemia can result from the administration (injection or ingestion) of a hypoglycemic compound (e.g., insulin, oral antidiabetic agents, alcohol, various drugs). It can also be endogenous in nature. Organic endogenous hypoglycemia can be due to an insulin-producing tumor (insulinoma) or an extrapancreatic neoplasm. In neonates and young infants, hypoglycemia results mainly from various inborn errors of metabolism or of nesidioblastosis, now known as the syndrome of persistent

hyperinsulinemic hypoglycemia of infancy. Functional hypoglycemia is called alimentary if it is due to gastrectomy or a too rapid gastric emptying. It is recognized as spontaneous reactive hypoglycemia if it occurs without any identified cause. Caution must be exerted in the diagnosis of this type of hypoglycemia. However, the diagnosis of reactive hypoglycemia can be made on the basis of a careful clinical and biochemical strategy. In such a case, simple therapeutic measures can be applied and the patient's quality of life can potentially be markedly improved.

are disrupted. A deletion of 11 nucleotides of the *rxn40* gene occurs at the translocation junction, and loss of function of this gene is responsible for at least part of the DiGeorge phenotype. Another partial transcript, called *nex2.2–nex3*, was also identified from this breakpoint. Both *rxn40* and *nex2.2–nex3* are deleted in all DGS patients with 22q11 deletions, and studies aimed to demonstrate hemizygoty and mutations in these genes in patients without deletions on 22q11 are required to prove their role in DGS. Deletion of the *UDF1L* gene (located on 22q11), encoding a protein involved in the degradation of ubiquitinated proteins, is present in all patients with the 22q11 deletion syndrome, which includes patients with DGS, velo–cardio–facial syndrome (VCFS), and the conotruncal anomaly face syndrome (CAFS). A smaller deletion removing exons 1 to 3 of the *UDF1L* gene was found in one patient with hypocalcemia, cleft palate, small mouth, low-set ears and interrupted aortic arch, syndactyly of the toes, and deficiency of

T lymphocytes. Patients with late-onset DGS have microdeletions in the 22q11 region and develop symptomatic hypocalcemia during childhood or adolescence with only mild phenotype.

Hypoparathyroidism is also a component of the neuromyopathies caused by mitochondrial gene defects: Kearns–Sayre syndrome (KSS), MELAS syndrome, and a mitochondrial, trifunctional, protein deficiency syndrome. KSS is characterized by pigmentary retinopathy and progressive external ophthalmoplegia before 20 years of age and is often associated with heart block or cardiomyopathy. MELAS syndrome consists of childhood-onset mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes. Both KSS and MELAS syndrome have been reported to occur with insulin-dependent diabetes mellitus and hypoparathyroidism. The molecular defects range from large deletions, rearrangement, and duplication of the mitochondrial genomes in many tissues (in KSS) to single-base mutations in one of the tRNA genes found only in a restricted range of cell types (in MELAS syndrome). Mitochondrial trifunctional protein deficiency is a disorder of fatty acid oxidation that is associated with pigmentary retinopathy, peripheral neuropathy, and acute fatty liver degeneration occurring in pregnant women carrying affected children.

Hypoparathyroidism has been reported to occur in 50% of patients with Kenney–Caffey syndrome. It is a congenital anomaly and is associated with parathyroid agenesis, growth retardation, and medullary stenosis of tubular bones. Genetic analysis of the PTH gene did not reveal abnormalities. Both dominant and recessive modes of inheritance have been described. The occurrence of hypoparathyroidism, nerve deafness, and a steroid-resistant nephrosis leading to renal failure, which has been referred to as Barakat syndrome, has been reported in four brothers of one family. An association of hypoparathyroidism with congenital lymphedema, nephropathy, mitral valve prolapse, and brachytelephalangy has been found in two brothers from another family. Molecular genetic studies have not been performed in these two families.

In most cases, the molecular defect responsible for isolated autosomal recessive hypoparathyroidism remains unknown. A homozygous deletion of the human homologue of the *Drosophila* glial cell missing gene *b* (GCMB located on chromosome 6p23) has been identified in a proband with parathyroid agenesis. *Gcm2*, the murine homologue of GCMB, encodes a transcription factor expressed exclusively in the parathyroid cells. Animal models have shown that mice deficient in *Gcm2* had mild hypocalcemia and

serum PTH levels similar to those of the wild type, with the thymus serving as auxiliary source for the peptide hormone.

Damage to the Parathyroid Glands

The most common cause of hypoparathyroidism is surgical damage to the parathyroids as a result of total thyroidectomy for thyroid cancer, radical neck dissection for laryngeal or esophageal cancer, or repeated parathyroidectomies for multigland disease. The incidence of permanent hypoparathyroidism is approximately 1 to 4%. Permanent hypoparathyroidism can be caused by damage of the blood supply to the parathyroid glands but also by inadvertent removal of parathyroid tissue (a rare event). A permanent hypoparathyroidism is suggested by prolonged hypocalcemia, which may develop immediately or weeks to years after neck surgery. In patients at a higher risk for developing permanent hypoparathyroidism, parathyroid tissue may be autotransplanted into the brachioradialis or sternocleidomastoid muscle at the time of parathyroidectomy or may be cryopreserved for subsequent transplantation if necessary. Transient hypoparathyroidism occurs when the damage to the parathyroid glands is reversible and other mechanisms of hypocalcemia after thyroid surgery also intervene. After surgery for primary hyperparathyroidism, transient hypocalcemia can occur for the suppression of normal parathyroids by hypercalcemia. These glands recover quickly, and the serum calcium level returns to normal within days. More prolonged hypocalcemia can occur in "hungry bone syndrome" due to severe hyperparathyroidism, where there is an increased uptake of calcium into remineralizing bones.

Hypoparathyroidism (rarely) may occur in patients with emochromatosis and iron overload, Wilson's disease, and neoplastic or granulomatous involvement of the parathyroid glands. Hypoparathyroidism has been described in a small number of patients receiving extensive radiation to the neck and mediastinum.

Autoimmune disease of the parathyroid glands can occur as an isolated condition or can be associated with other disorders in autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome. APECED, an autosomal recessive disorder that is also known as autoimmune polyglandular syndrome type 1 (APS1), is more frequent in Finns and Iranian Jews. It is characterized by a variable combination of destructive autoimmune phenomena leading to a failure of the parathyroid glands, adrenal cortex, gonads, pancreatic beta cells, gastric parietal cells and

thyroid gland, chronic mucocutaneous candidiasis, alopecia, vitiligo, keratopathy, and dystrophy of dental enamel and nails. In most cases, candidiasis is the first clinical manifestation to appear, usually before 5 years of age, followed by hypoparathyroidism before 10 years of age and later by primary adrenal insufficiency before 15 years of age. The etiology of APECED has been clarified and is due to loss-of-function mutations of the AIRE (autoimmune regulator) gene. It is located on chromosome 21q22 and encodes a 57-kDa protein with characteristics of a transcription factor.

Reduced Parathyroid Gland Function Due to Altered Regulation

Altered regulation of parathyroid gland function may be primary or secondary. Primary alterations now have an established genetic basis. Three rare genetic defects have been defined. The largest group involves the calcium-sensing receptor (CaR). The CaR, which belongs to a family of G protein-coupled receptors and cell surface receptors, regulates the secretion of PTH from the parathyroid glands and the reabsorption of calcium by the renal tubules in response to alterations in serum calcium concentration. Gain-of-function mutations in the CaR gene, leading to a constitutive activated protein (i.e., a receptor with a decreased set point for extracellular calcium concentrations), cause a functional hypoparathyroid state with hypocalcemia and hypercalciuria. The disorder is inherited as an autosomal dominant trait. Sporadic cases due to *de novo* activating mutations of the CaR have also been described. The consequence of the activated parathyroid glands is chronic suppression of PTH secretion, whereas the activated CaR in the kidney induces hypercalciuria. Although some patients have symptoms of hypocalcemia, these tend to be more mild and intermittent than might be expected. Many affected individuals are asymptomatic and are detected only on family screening after an affected individual has been identified. Clinically, it is important to distinguish these patients from those with other forms of hypoparathyroidism because treatment with vitamin D to correct hypocalcemia could lead to marked hypercalciuria, nephrocalcinosis, and renal impairment.

Isolated hypoparathyroidism has also been associated with abnormalities of the PTH gene. A heterozygous base substitution (T to C) in exon 2, leading to the substitution of arginine for cysteine in the signal peptide, has been described in a family with dominant isolated hypoparathyroidism. Functional studies have

shown that this mutation impairs the interaction between the nascent protein and the translocation machinery, and the cleavage of the mutant signal sequence by solubilized signal peptidase is ineffective. A homozygous mutation of the donor splice site of exon 2 and intron 2 of the PTH gene has been identified in one family with autosomal recessive isolated hypoparathyroidism. This mutation, involving a single base transition at position 1 of intron 2, results in loss of exon 2, which encodes the initiation codon and the signal peptide, and causes PTH deficiency. In another patient with autosomal recessive isolated hypoparathyroidism born to consanguineous marriage, a T-to-C mutation was found in the first nucleotide of codon 3 of the 25-amino acid signal peptide sequence, resulting in the substitution of serine with proline.

Secondary causes of impaired PTH secretion include maternal hyperparathyroidism. In this condition, the high concentrations of calcium in the maternal serum cross the placenta and inhibit PTH secretion by the infant's parathyroid glands. Hypocalcemia in the newborn usually develops by the third week of life and is often self-limited.

Hypomagnesemia due to defective renal tubular reabsorption of magnesium or intestinal absorption may impair secretion of PTH and contribute to hypoparathyroidism. This defect is corrected by magnesium treatment.

Impaired PTH Action

A bioinactive PTH able to cause hypoparathyroidism has not yet been described. More commonly, ineffective PTH action appears to be due to peripheral hormone resistance (pseudohypoparathyroidism).

CLINICAL MANIFESTATIONS

The predominant clinical manifestations of the disease are those related to hypocalcemia (Table II). In the acute setting, neuromuscular irritability, including perioral paresthesias, tingling of the fingers and toes, and spontaneous or latent tetany with grand mal seizures and laryngeal spasm, can be evident. Chronic hypocalcemia can be asymptomatic and usually recognized by routine blood tests. Patients with chronic hypocalcemia may have coarse hair, dry skin, muscle cramps, extrapyramidal signs, cataracts, alopecia, mental retardation, and personality disorders. Abnormal dentition, enamel hypoplasia, and absence of adult teeth may suggest that hypocalcemia has

Table II Signs and Symptoms of Hypocalcemia

been present since childhood. On ECG, a prolonged QT interval is often observed, and in patients with severe hypocalcemia, reversible congestive heart failure may occur. Nonspecific electroencephalographic changes may be observed.

The classic physical findings of hypocalcemia are also manifestations of increased neuromuscular excitability. Trousseau's sign is elicited after inflation of a blood pressure cuff above systolic pressure for 3 to 5 min. A positive response consists of the development of typical carpal spasm, with relaxation occurring 5 to 10 s after the cuff is deflated. Chvostek's sign is elicited by tapping over the facial nerve just anterior to the ear. The response ranges from twitching of the lip at the corner of the mouth to twitching of all the facial muscles on the stimulated side. Simple twitching at the corner of the mouth occurs in some normal persons, but more extensive muscle contraction is a reliable sign of latent tetany.

Calcification of basal ganglia or more widespread calcium deposits in intracranial structures may be detected on routine radiographs, computed tomography (CT) scans, or magnetic resonance.

LABORATORY INVESTIGATIONS

The biochemical hallmarks of hypoparathyroidism are low serum calcium and high serum phosphorus in the presence of normal renal function. Serum calcium levels are often approximately 6 to 7 mg/dl, whereas serum phosphorus levels are 6 to 9 mg/dl. Ionized calcium concentration is less than 1 mmol/L. Serum concentration of PTH is low or undetectable except in cases of PTH resistance, in which it is high-normal or elevated. Serum levels of 1,25-dihydroxy-vitamin D are usually low normal or low. The 24-h urinary

excretion of calcium is decreased except in cases of gain-of-function mutations in the CaR, where it is elevated. Nephrogenous cyclic AMP (cAMP) excretion is low, and renal tubular reabsorption of phosphorus is increased. Phosphorus excretion and urinary cAMP increase after administration of exogenous PTH with the exception of PTH resistance.

TREATMENT

The aim of treatment is to normalize extracellular ionized calcium concentration so as to abolish symptoms due to hypocalcemia and to prevent its long-term complications.

Chronic Treatment

Despite wide differences around the world in treatment modalities due to various availability of vitamin D and its analogues, the general idea is to supplement calcium and vitamin D metabolites so as to achieve stable normocalcemia.

Because of great variability in intestinal calcium absorption in adults, it is usually necessary to supply 1 to 2 g of elemental calcium daily. Calcium must be administered in divided doses with meals to minimize epigastric bloating and irritation. Calcium can be administered in several forms: 1 g of elemental calcium is present in 2.5 g calcium carbonate, 5 g calcium citrate, 8 g calcium lactate, or 10 g calcium gluconate. Calcium carbonate and calcium citrate are equally effective in obtaining appropriate serum calcium levels.

Ergocalciferol (vitamin D₂) and cholecalciferol (vitamin D₃) have been widely used at doses ranging from 1.25 to 10 mg daily. Their duration of action is very long due to their wide distribution in body fat; thus, responses to changes in these doses are very slow to manifest, and when intoxication is present, it persists for a long time. Therefore, during long-term treatment, it is necessary to measure periodically (every 3–4 months) serum calcium and phosphorus concentrations. In selected cases (e.g., previous history of kidney stones), urinary calcium and creatinine clearance should also be evaluated. If mild hypercalcemia develops, a reduction in the dose of vitamin D (and/or of calcium) is sufficient to restore serum calcium levels to normal, usually within 1 month. In the case of more severe hypercalcemia, treatment should be stopped and serum calcium should be monitored weekly; hydration and glucocorticoids can occasionally be started. Nowadays, calcitriol

[1,25(OH)₂D₃] is considered the treatment of choice. It is initially administered orally at a dose of 0.5 to 1 µg daily in divided doses. The dose should be carefully titrated to match the individual's need. In fact, during the first month of treatment, the required dose, when changed according to serum calcium levels as monitored every 3 to 4 days, may increase to as much as 1.5 to 2 µg per day. During chronic treatment, serum calcium and phosphorus should be checked every 3 to 4 months, keeping in mind that, because of the lack of PTH, renal tubular calcium reabsorption is decreased. Thus, hypercalciuria may occur with increased risk of nephrolithiasis. If hypercalcemia develops, treatment must be temporarily discontinued, with usual prompt restoration of normal serum levels.

Careful monitoring of serum calcium concentration is particularly needed when other drugs are administered to the patient. In fact, many different preparations may interfere with calcium and vitamin D absorption and metabolism, and these effects are amplified by the absence of counterregulatory action exerted by PTH. Thiazide diuretics enhance renal tubular calcium reabsorption and may induce hypercalcemia, whereas loop diuretics cause hypocalcemia by increasing calcium excretion. Moreover, glucocorticoids reduce intestinal calcium absorption by antagonizing vitamin D effects, cholestyramine inhibits vitamin D absorption, and agents such as aluminum and magnesium hydroxide reduce calcium absorption by promoting its precipitation in the gastrointestinal tract.

In pseudohypoparathyroidism, the risk of hypercalciuria is less present because the action of PTH on distal renal tubular calcium reabsorption is preserved. However, at the beginning of treatment, high doses are usually needed for the high prevalence of osteomalacia. During follow-up, while bone lesions are being repaired (as shown by a decline in serum alkaline phosphatase and a rise in serum calcium concentration), dose requirements progressively decrease.

Occasionally, some patients may experience unsatisfactory control, with ample fluctuations of serum calcium, despite the absence of dose variations. Poor compliance should be suspected, but variations in calcium intake and intestinal absorption problems should also be considered. Particular care must be taken in the management of hypoparathyroidism during the third trimester of pregnancy and puerperium. The dose of vitamin D will usually have to be reduced because of the actions of placenta, which can synthesize 1,25-dihydroxy-vitamin D₃, and of prolactin, which can stimulate 1α-hydroxylation.

In young patients, when hypoparathyroidism is diagnosed, the therapy regimen is similar to that described for adults. However, doses must be tailored to consider body weight. Calcium is usually initiated at the level of 30 to 50 mg/kg body weight and is gradually increased according to serum calcium levels. Also in children, the most used vitamin D preparation is calcitriol due to its effectiveness at nontoxic doses, shorter half-life, and more rapid correction of hypercalcemia when it occurs.

It must be remembered that vitamin D, in all its forms, can be a difficult drug to use. Unpredictable changes in therapeutic regimens may occur even after a long period of stable treatment; therefore, continued monitoring is mandatory.

Treatment after Surgery for Hyperparathyroidism

After surgery for primary hyperparathyroidism due to parathyroid adenoma, serum calcium usually falls to normal levels quickly, sometimes evolving to transient hypocalcemia. In general, no treatment is needed except for oral calcium supplementation if symptoms are present. Too aggressive supplemental calcium during the early postoperative phase may delay restoration of normal parathyroid function; this seems to be triggered by mild hypocalcemia. However, if preoperatively hyperparathyroid bone disease was present, so-called hungry bone disease usually develops. Serious hypocalcemia can be observed, requiring high doses of calcitriol (1–3 µg daily) and large calcium supplements for a long period of time.

Symptomatic patients should also be treated by intravenous calcium (2 mg/kg of elemental calcium over 10 min) and, in the case of recurrence of symptoms, by a more prolonged infusion (15 mg/kg of elemental calcium over 24 h, with half of the total amount administered during the initial 6 h). In general, 15 mg/kg of elemental calcium infused during 4 to 6 h is capable of increasing serum calcium concentration by 2 to 3 mg/dl. To reduce the amount of fluids, the concentration of the solution can be increased to as much as 200 mg of elemental calcium per 100 ml without the risk of irritating the vein. Particular care must be taken if the patient is taking medications such as digitalis (calcium may increase sensitivity to adverse effects of this drug such as arrhythmias); additives, such as phosphate and bicarbonate, must be avoided. A dramatic fall in vitamin D and calcium requirements will be observed after bone disease healing. In the case of multiple parathyroid excision,

long-lasting hypoparathyroidism will ultimately result.

Bone remodeling after parathyroidectomy may cause hypomagnesemia, which contributes to the risk of tetany by inhibiting PTH secretion by the remaining glands and by exacerbating hypocalcemic symptoms. In the instance of magnesium deficiency, the administration of 2.4 mg/kg body weight of the element over a period of 10 min may be required. Once magnesium has been repleted, stores are usually maintained through a regular diet. An oral supplementation of 300 to 600 mg daily may be necessary in the presence of diarrhea, fistulous drainage, or other abnormalities.

Future Trends

Studies are in progress to verify whether parenteral administration of the active form of PTH or oral administration of modified molecules could be used in the treatment of hypoparathyroidism. In patients with parathyroid hyperplasia or in those who underwent repeated neck explorations to identify the adenomas, parathyroid tissue can be autotransplanted into the brachioradialis or sternocleidomastoid muscle at the time of parathyroidectomy, or it can be cryopreserved for later transplantation if required.

Table I Clinically Relevant Hormones Secreted by the Pituitary Gland

| Anterior pituitary gland | Posterior pituitary gland |
|--|----------------------------------|
| Luteinizing hormone and follicle-stimulating hormone (gonadotropins) | Vasopressin/Antidiuretic hormone |
| Growth hormone | |
| Thyrotropin | Oxytocin |
| Adrenocorticotrophic hormone | |
| Prolactin | |

100,000 population, but this excludes those clinically insignificant lesions that have been reported at autopsy in up to 27% of individuals without an antemortem diagnosis of pituitary pathology. Primary pituitary carcinomas are extremely rare, but metastatic deposits at this site do occur, usually arising from malignancies of the lung or breast. Pituitary adenomas are divided into microadenomas (<1 cm) and macroadenomas (>1 cm) on the basis of size. In addition, there are a variety of classifications that determine the degree of invasiveness. Figure 1 shows the magnetic resonance imaging (MRI) appearance of a pituitary macroadenoma with significant suprasellar extension.

Pituitary adenomas may also be defined as functioning (70%) or nonfunctioning (30%). The former group produces systemic effects by secreting hormones into the bloodstream. The most common functioning pituitary tumors are prolactinomas, followed by those causing acromegaly and Cushing's disease, with gonadotropinomas and thyrotropinomas occurring only rarely. Both functioning and nonfunctioning tumors may result in hypopituitarism when there is insufficient normal pituitary tissue remaining. The typical sequence of hyposecretion starts with GH deficiency, followed by gonadotropin loss before progressing to loss of thyrotropin-stimulating hormone (TSH) and then adrenocorticotrophic hormone (ACTH) reserves. Mild hyperprolactinemia is often

present when the tumor itself does not secrete prolactin due to interruption of the influence of dopamine from the hypothalamus that normally inhibits prolactin release. Vasopressin deficiency in association with pituitary adenomas is extremely rare.

Pituitary Surgery/Radiotherapy

Hypopituitarism may be iatrogenic, and the incidence is approximately 10 to 15% posttranssphenoidal surgery. The effects of conventional radiotherapy may take many years to manifest fully; consequently, it is vital that those patients who are at risk for developing new endocrine deficiencies as a result of irradiation be reassessed every 1 to 2 years. Approximately 50% of patients will have evidence of hypopituitarism 5 years postradiotherapy.

Parapituitary Tumors

Parapituitary tumors may be intradural (e.g., craniopharyngiomas, gliomas, hamartomas, meningiomas) or extradural (e.g., chordomas, metastases, chondrosarcomas, Brown tumors), but all are less common than primary pituitary adenomas. Craniopharyngiomas account for up to 4% of all intracranial tumors, and although they are often thought to be childhood tumors, 50% of all craniopharyngiomas present in

Figure 1 Visual perimetry showing typical bitemporal hemianopia associated with optic chiasm compression.

patients over 16 years of age. They appear to follow a more aggressive course, particularly if onset is during childhood, with increased morbidity and mortality compared with patients with other pituitary or parapituitary lesions.

Pituitary Apoplexy

Pituitary apoplexy describes destruction of functioning pituitary tissue as a result of infarction and may arise due to ischemia or hemorrhage. The former usually arises in patients with preexisting macroadenomas, whereas the latter may occur as a complication of anticoagulant therapy or pregnancy (Sheehan's syndrome). Sheehan's syndrome is rare in the developed world. Early surgery has been advocated for this condition, but each individual case must be assessed separately taking into account the neurological deficit, visual loss, and medical comorbidity.

Inflammatory/Infiltrative Conditions

Lymphocytic hypophysitis is an autoimmune condition characterized by diffuse infiltration of the gland by inflammatory cells that predominantly, but not exclusively, occurs in women toward the end of pregnancy. The condition may present very acutely over a few days or more insidiously, and histological confirmation is required to be certain of the diagnosis. It may result in isolated anterior pituitary hormone deficiencies.

Infiltrative (e.g., hemochromatosis) and granulomatous conditions (e.g., sarcoidosis, histiocytosis X) can cause hypopituitarism; therefore, a high index of suspicion is needed for these conditions.

Infection

Communicable diseases such as tuberculosis must remain part of the differential diagnosis of hypopituitarism, and focal abscesses of the pituitary gland may occur rarely.

Head Injuries

Cranial trauma can cause disruption of the pituitary stalk, which results most commonly in diabetes insipidus; however, hyposecretion of any pituitary hormone is possible. Monitoring and frequent re-assessment of these patients are essential because the deficiencies may resolve over time.

Congenital Malformations/Empty Sella Syndrome

The so-called empty sella syndrome may be congenital secondary to arachnoid herniation through a diaphragmatic defect or may be acquired postsurgery, postradiotherapy, or post-pituitary infarction. Imaging in this condition reveals an enlarged empty pituitary fossa, but this finding does not by definition exclude the presence of a functioning tumor.

Genetic and Idiopathic Disorders

Isolated defects of single pituitary hormones have been described but are rare and usually do not progress to involve hyposecretion of other components of the gland. Examples include isolated ACTH deficiency and gonadotropin deficiency (Kallman's syndrome). Mutations in the PIT1 gene are an important genetic cause of hypopituitarism.

CLINICAL FEATURES

The clinical presentation of hypopituitarism varies according to exactly which endocrine deficiencies are present and also depends on the age at which pituitary insufficiency developed, that is, pre- or postpuberty. The clinical picture may also be influenced by the underlying pathology and whether the presentation is acute or chronic.

Patients with panhypopituitarism are classically pale due to lack of ACTH, have thin hair, display premature ageing of the skin with increased wrinkles, and lack secondary sexual characteristics. They frequently experience reduced muscle strength and increased fatigue, and they may exhibit psychological problems such as depression. This typical appearance is shown in [Fig. 2](#). The symptoms and signs may be

Figure 2 Sagittal MRI scan showing pituitary macroadenoma with extensive suprasellar extension.

divided into those due to direct mass effects of the tumor (if present) and those due to the endocrine deficiencies.

Tumor Mass Effects

Expansion of the tumor may be associated with visual field loss. Classically, a bitemporal upper quadrantanopia occurs first, progressing to a bitemporal hemianopia as a result of the tumor compressing the optic chiasm; however, a variety of defects can occur depending on which parts of the visual pathways are affected. Ongoing visual recovery can occur up to 6 months postdecompression, but established optic atrophy secondary to long-standing pressure on the optic nerves is a bad prognostic sign. Headaches may occur and are thought to be the result of the enlarging tumor stretching the dura; more rarely, obstructive hydrocephalus may develop. Cerebrospinal fluid rhinorrhea or cranial nerve palsies affecting the III, IV, or VI nerve may be seen if the tumor invades the sphenoid

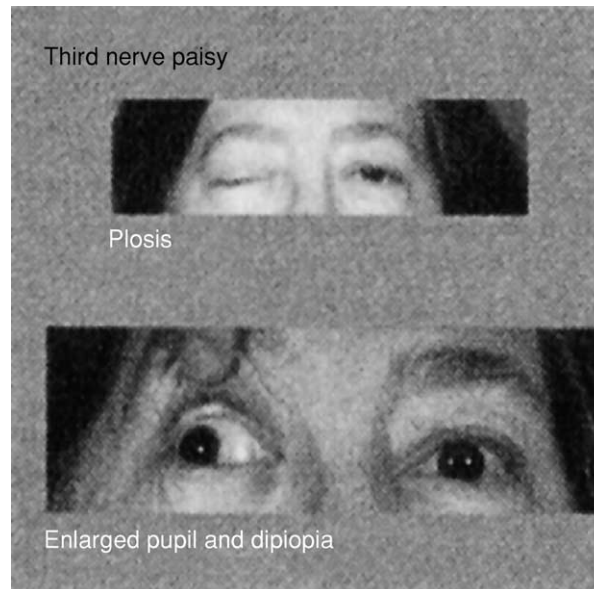

Figure 3 Patient with right third cranial nerve palsy secondary to infiltration of cavernous sinus by pituitary macroadenoma.

or cavernous sinuses, respectively. [Figure 3](#) shows a patient who developed a third cranial nerve palsy from a pituitary macroadenoma extending into the cavernous sinus. More extensive tumor infiltration into surrounding tissues can result in seizures and personality changes very rarely.

Symptoms and Signs Related to Endocrine Deficiencies

The typical presentation associated with deficiencies of each of the pituitary hormones is outlined in [Table III](#).

DIAGNOSIS

The diagnosis of hypopituitarism is dependent on the appropriate biochemical investigations being carried out in a patient where the clinical findings have raised the suspicion of pituitary insufficiency. The presentation in adult life is often subtle and insidious, with symptoms that overlap with both other medical conditions and the normal population; consequently, the diagnosis is frequently delayed unless the investigating physician retains a high index of suspicion for a possible underlying endocrine etiology.

In any patient with suspected pituitary or hypothalamic pathology, imaging of the area, ideally with MRI scanning and formal visual field assessment, is mandatory. These investigations help to assess for the presence of damage to the optic pathways, may assist in elucidating the underlying cause, and will

Table III Signs and Symptoms of Hypopituitarism

| Hormone deficiency | Clinical features |
|--|--|
| Growth hormone | Increased fatigue, reduced muscle strength and exercise capacity, impaired psychological well-being, reduced lean body mass, and increased cardiovascular risk |
| Luteinizing hormone and follicle-stimulating hormone | Women: oligomenorrhea/amenorrhea, infertility, dyspareunia, breast atrophy, and loss of libido Men: loss of libido, erectile dysfunction, testicular atrophy, infertility, and loss of secondary sexual characteristics |
| Thyrotrophin | Increased fatigue, weight gain, cold intolerance, dry skin and hair, constipation and muscle weakness |
| Adrenocorticotrophic hormone | Increased fatigue, anorexia, nausea and vomiting, weight loss, generalised weakness, hypoglycemia, and hyponatremia |
| Prolactin | Failure of lactation |
| Vasopressin | Polydipsia, polyuria and nocturia |

also help in planning ongoing management of the condition. Additional tests that may help to elucidate the likely etiology should be carried out as appropriate (e.g., serum ferritin, angiotensin-converting enzyme from serum or cerebrospinal fluid, pituitary biopsy).

Specific endocrine tests can be divided into those that assess either anterior or posterior pituitary function, and tests of anterior pituitary function can be further subdivided according to whether they are static measurements at a single point in time or dynamic tests that assess pituitary reserve more formally.

Basal Anterior Pituitary Hormone Assays

To gain the most information about each axis from a single blood test, the basal concentrations of both the pituitary hormone and the target hormone should be assayed:

- Luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol or testosterone (9:00 AM)
- TSH and free thyroxine
- ACTH and cortisol (9:00 AM)
- Prolactin
- Insulin-like growth factor-1 (IGF-1)

Testosterone and cortisol should be measured at 9:00 AM as a baseline because this is the time of peak secretion within the circadian rhythm. Most reference ranges have been devised for 9:00 AM samples, so it is easier to interpret and compare results taken at this time.

Dynamic Tests of Anterior Pituitary Function

The preceding basal pituitary assays can provide vital information, particularly when the pituitary component is appropriately elevated with a low target hormone indicating primary target organ failure. The situation is frequently more complex when either a low target hormone is found in conjunction with an inappropriately low pituitary hormone or ongoing monitoring is required for patients with known partial hypopituitarism. In these cases, dynamic testing may help to quantify pituitary reserve more accurately.

Assessing the Hypothalamic–Pituitary–Adrenal Axis

A 9:00 AM cortisol level of less than 3.6 µg/dl (100 nmol/L) is generally sufficient to diagnose adrenal insufficiency with confidence, whereas a level of 18.1 µg/dl (500 nmol/L) or more is indicative of adequate ACTH reserve. Patients with 9:00 AM values between these limits generally warrant further investigation.

It is important to be aware that oral estrogen therapy artificially raises serum cortisol levels by increasing cortisol-binding globulin, so it is recommended that any such medication be stopped for at least 6 weeks (or a transdermal preparation be substituted) before carrying out any biochemical assessment that relies on serum cortisol measurements.

The main tests employed in assessing ACTH reserve are the insulin tolerance test (ITT) and the short synacthen test (SST), both originally described during the 1960s.

Insulin Tolerance Test

Cortisol and GH are counterregulatory hormones; consequently, artificially inducing hypoglycemia is a useful stimulus by which to provoke their secretion. In the ITT, 0.15 IU/kg of soluble insulin is usually administered intravenously, and if the required peak cortisol level (usually 18.1–21.0 $\mu\text{g}/\text{dl}$ [500–580 nmol/L]) is achieved during the test, then that patient is determined to have sufficient ACTH reserve to mount an adequate response to acute stress. The test is contraindicated in those with epilepsy, ischemic heart disease, or postcraniotomy, and the majority of endocrinologists would not recommend its use beyond 70 years of age. Despite the potential hazards, the complication rate of the test remains very low when conducted by experienced personnel.

Short Synacthen Test

The SST is useful in diagnosing adrenal insufficiency but does not help any further with the differential diagnosis unless a plasma ACTH is measured simultaneously. Patients with established primary or secondary hypoadrenalism should not reach the required peak cortisol level (usually 21.0 $\mu\text{g}/\text{dl}$ [580 nmol/L]) 30 min following parenteral administration of 250 μg of synthetic ACTH. In patients who develop ACTH deficiency acutely (e.g., postsurgery), this test is not appropriate because it can take several weeks for the adrenals to involute following the loss of normal circulating ACTH levels. Given the excellent safety profile of the SST, most endocrinologists reserve the ITT for patients with borderline SST results or for cases where simultaneous assessment of GH is required.

The low-dose SST, using 1 μg of synthetic ACTH, has become increasingly popular during recent years as the 250- μg dose is seen as being so suprphysiological that false-negative results may occur. This dose is currently not routinely available, and further assessment of the test is required.

Additional Tests

The glucagon test has the advantage, as does the ITT, of being able to assess ACTH and GH reserves simultaneously, but the glucagon test provides a weaker stimulus for secretion of ACTH and GH than does the ITT and, consequently, is more often associated with false-negative results. Glucagon transiently increases the plasma glucose, and the test relies on the subsequent fall to create relative hypoglycemia as a stimulus for ACTH and GH release.

The caveat to the tests outlined previously is that in critically ill patients with suspected adrenal insufficiency, treatment should not be delayed while

investigations are carried out. In this setting, random ACTH and plasma cortisol measurements can be taken and parenteral high-dose hydrocortisone therapy can be quickly instituted. The results can then be reviewed retrospectively and steroid replacement can be continued if indicated, with any further assessment delayed until the acute illness has resolved.

Assessing the Pituitary–Thyroid Axis

Baseline assessment of TSH and thyroxine (free or total) is usually sufficient for the diagnosis of primary and secondary hypothyroidism. Measuring free thyroxine is essential if the patient is pregnant or taking oral estrogen therapy due to the increase in thyroid hormone-binding globulin that occurs. The TSH level in secondary hypopituitarism is rarely undetectable and in fact may be low, normal, or even mildly elevated. The main important differential diagnosis is from the so-called “sick euthyroid” syndrome, which is associated with critical systemic illness. Measurement of thyroxine-binding globulin may be helpful in complex cases because congenital deficiencies of this protein can occur, giving a similar result to secondary hypothyroidism.

The thyrotropin-releasing hormone (TRH) test (assessment of TSH response to administration of intravenous TRH) has been largely abandoned, due to its lack of diagnostic sensitivity and specificity, in favor of newer and more sensitive assays for TSH and thyroxine.

Assessing Growth Hormone Reserve

GH is secreted in a pulsatile fashion and is released in response to stress or exercise and at night during sleep. IGF-1 mediates many of the actions of GH, is released in response to GH secretion, and itself inhibits GH release at the level of the pituitary and the hypothalamus. Therefore, isolated GH measurements are generally meaningless, and approximately 30% of patients with GH deficiency would be missed if a normal IGF-1 were the sole criterion for diagnosis.

Tests to further assess GH may be subdivided into those using physiological methods and those relying on pharmacological agents to stimulate GH release.

Physiological Methods

These methods include urinary GH assessment, 24-h profiles of serum GH, and measurement of GH response during sleep or exercise. These techniques are very labor intensive, and because the results show significant overlap with normal controls, they are now seldom used clinically.

Pharmacological Methods

The ITT is still regarded as the gold standard for assessing GH reserve. The main second-line test until recently has been the glucagon test. Newer agents include arginine, growth hormone-releasing hormone (GHRH), and growth hormone-releasing peptides (GHRP) such as hexarelin. Clonidine testing has been largely discredited for diagnosing GH deficiency in adults. Although research is ongoing, there is increasing evidence that combinations of these newer tests may provide accurate results with the advantage of a more acceptable safety profile as compared with the ITT.

Assessing the Pituitary–Gonadal Axis

Usually, measurement of baseline LH, FSH, and testosterone or estradiol is sufficient to confirm hypogonadotropic hypogonadism. Estradiol is best measured during the follicular phase of the menstrual cycle, and testosterone is ideally measured on a 9:00 AM sample. Both sex steroids bind to sex hormone-binding globulin (SHBG); therefore, this may need to be assayed to accurately determine the amount of biologically active hormone present.

Women who are menstruating regularly are not, by definition, gonadotropin deficient, although the cycles may clearly be anovulatory. Ovulation can be assessed separately by measurement of a progesterone level on day 21 of the menstrual cycle. Management of subfertility due to hypopituitarism is discussed later in this article.

Dynamic tests (e.g., clomiphene test) are only indicated to distinguish hypothalamic disease from pituitary disease, but these are generally for academic interest and rarely alter clinical management.

Posterior Pituitary Assessment

It is vital that ACTH reserve has been fully assessed, and that glucocorticoid replacement has been instituted if appropriate, prior to formally assessing posterior pituitary function because cortisol is essential for the kidneys to handle and excrete a water load normally and so diabetes insipidus may be concealed in patients who are steroid deficient.

Paired plasma and urine osmolalities in combination with urea and electrolytes and accurate fluid balance may be sufficient to confirm a diagnosis of cranial diabetes insipidus (vasopressin deficiency); however, in less clear-cut cases, or where the differential diagnosis of nephrogenic diabetes insipidus or

primary polydipsia needs to be excluded, a formal water deprivation test may be required.

A variety of protocols for water deprivation tests have been described, but essentially they assess the response of urine output and osmolality to a period of fluid restriction followed by a dose of exogenous vasopressin. Plasma osmolalities and serial weights are also recorded. The tests must be carefully supervised to prevent patients from becoming dangerously dehydrated and to ensure that the fluid restriction is maintained.

Newer assays that offer more accurate measurements of endogenous vasopressin, normally present at very low concentrations in the circulation, may provide an alternative means of diagnosing diabetes insipidus, but currently these are not widely used.

TREATMENT

Treatment of pituitary insufficiency must involve addressing the underlying cause as well as commencing and optimizing appropriate hormone replacement therapy.

Treatment of Underlying Cause

Determining the etiology of the hypopituitarism will help to guide management of the underlying condition. Options may include the use of medical treatments or surgical intervention and/or radiotherapy.

Hormone Replacement Therapy

Treatment regimens generally involve replacing the target hormone rather than the pituitary or hypothalamic component of the pathway. The main exceptions to this are the use of recombinant GH and the treatment of infertility caused by hypogonadotropic hypogonadism.

GH Deficiency

During the final few decades of the past century, evidence accumulated that, contrary to the accepted doctrine, GH may have an important role to play in adulthood. During the 1990s, with the availability of recombinant GH eliminating the risks associated with GH derived from human cadavers, many adult patients with severe GH deficiency are now on appropriate replacement. GH is administered as a daily subcutaneous injection using a pen device that most patients master quickly. Treatment is commenced at low dose and titrated up slowly according to clinical

and biochemical (IGF-1) parameters. There is convincing evidence that GH replacement in GH-deficient adults is associated with significant improvements in mood, energy levels, and overall quality of life. An increase in lean body mass, with a reduction in fat mass and a resultant increase in exercise tolerance, is seen in patients receiving treatment. GH therapy is also associated with an improvement in the lipid profile and with long-term treatment results in improved bone mineral density in these patients at risk for osteoporosis.

LH/FSH Deficiency

The possible complications of estrogen therapy in postmenopausal women are well publicized and may lead women to refuse treatment. It is vital that each case is considered individually and that the patient is helped to make an informed decision because the severe long-term consequences of estrogen deficiency clearly outweigh the risks of such therapy, particularly in young women. Essentially any combined oral contraceptive pill, or any form of estrogen licensed for postmenopausal use (in combination with a cyclical progestagen to avoid endometrial hyperplasia and subsequent malignancy in women with intact uteri), is suitable, and the decision comes down to patient choice and physician familiarity. Many younger women prefer the combined oral contraceptive pill because it is more acceptable among their peers. Transdermal HRT preparations are also available. These have the advantage, compared with oral estrogen preparations, of not affecting cortisol-binding globulin and, consequently, not affecting the monitoring of hydrocortisone replacement.

Androgen replacement in men is usually initiated with intramuscular depot testosterone injections. Trough and/or peak levels are monitored, and the therapy is optimized by adjusting the dose or dose interval. Subcutaneous testosterone implants provide a more physiological profile and avoid the sharp peaks and troughs associated with intramuscular injections, but this must be balanced against the risk of infection and scarring at the site of implantation. Transdermal testosterone patches are available but can cause local skin irritation and are less popular than their estrogen counterparts, whereas oral testosterone has a very short half-life and is rarely recommended as the therapy of choice.

Restoration of fertility is usually possible in these patients by using gonadotropin or gonadotropin-releasing hormone (GnRH) to stimulate ovulation or spermatogenesis. If gonadotropin deficiency occurs prior to puberty, careful and gradual dose titration is

required to ensure that development occurs at an appropriate rate so that final height is achieved, secondary sexual characteristics develop normally, and there is sufficient time to cope with the usual psychological changes occurring during these years.

TSH Deficiency

Thyroxine replacement is the treatment of choice for secondary hypothyroidism, as it is for primary hypothyroidism, and the average adult replacement dose for a patient with total deficiency is approximately 100 to 150 $\mu\text{g}/\text{day}$. Treatment can usually be initiated at a dose of 75 to 100 $\mu\text{g}/\text{day}$, with the dose altered in 25- μg increments based on six weekly reassessments of the free thyroxine. In patients with severe hypothyroidism or coexisting ischemic heart disease, lower starting doses of 25 to 50 μg can be used. Triiodothyronine rarely is superior due to its more rapid onset of action and shorter half-life, but thyroxine is appropriate routinely. In primary hypothyroidism, TSH is a sensitive marker that can guide accurate replacement, but this is not the case in secondary hypothyroidism; the serum TSH may be low, normal, or even mildly elevated in this condition. Most endocrinologists aim for a replacement dose of thyroxine that results in asymptomatic patients and free thyroxine on the upper end of the normal reference range.

It is essential that patients receive adequate steroid replacement, if required, prior to commencing with thyroxine; otherwise, a potentially dangerous hypoadrenal crisis may be precipitated.

ACTH Deficiency

Hydrocortisone, the generic pharmaceutical name for cortisol, is generally accepted to be the glucocorticoid of choice for replacement therapy because it directly replaces the deficient hormone and can be easily measured in the plasma or urine. Alternatives include cortisone acetate or the synthetic glucocorticoids prednisolone and dexamethasone. Cortisone acetate must first be metabolized to cortisol to achieve its glucocorticoid effect; therefore, its onset of action is delayed compared with that of hydrocortisone, which has largely replaced it as the treatment of choice. Prednisolone and dexamethasone have a longer duration of action than does hydrocortisone and can be administered twice and once daily, respectively, but the inability to monitor steroid replacement with these drugs outweighs any advantages and makes them second-choice agents.

Traditional steroid replacement regimens have been reevaluated during recent years in light of increasing

evidence that they provide significantly supraphysiological doses and also poorly mimic endogenous cortisol secretion. The currently recommended starting replacement regimen is 10 mg of hydrocortisone on waking, 5 mg at lunchtime, and 5 mg during the early evening. Clearly, very few patients are average, and hydrocortisone replacement might need significant adjustment in individual patients depending on symptoms and the results of biochemical monitoring. Patients with secondary hypoadrenalism do not normally require mineralocorticoid supplementation because the renin–angiotensin–aldosterone pathway should be intact.

Prolactin Deficiency

Prolactin deficiency is rare because hypopituitarism is generally associated with mild hyperprolactinemia. When present, as in Sheehan's syndrome, it is associated with failure of lactation, but it is otherwise clinically silent.

Vasopressin Deficiency

Hyposecretion of vasopressin from the posterior pituitary results in partial or complete cranial diabetes insipidus. Desmopressin, a synthetic analogue of arginine vasopressin, is the replacement drug of choice and is available in oral, intranasal, and parenteral forms. Compared with endogenous vasopressin, it has a significantly longer half-life and is generally administered between one and three times per day. Desmopressin should be started at low dose and gradually titrated up until the polyuria is controlled. Monitoring paired urine and plasma osmolality, urea and electrolytes, and fluid balance is essential, particularly during the early stages and with dose adjustments.

MONITORING AND LONG-TERM REPLACEMENT

The aim of endocrine therapy in hypopituitarism is to achieve adequate replacement, ensuring that the patient is asymptomatic and able to lead a normal life, but also to avoid the potential complications caused by long-term exposure to supraphysiological doses of hormones.

The adverse effects of excess glucocorticoid replacement are well known; consequently, the aim of therapy increasingly is to provide an individual with the lowest dose of hydrocortisone possible to alleviate symptoms. Use of 24-h collections for urinary-free cortisol in combination with hydrocortisone day curves (varying from 3 points up to 10 points) can

help to guide exact replacement doses for a particular individual.

Supraphysiological thyroxine replacement is also increasingly being recognized as a significant problem due to the increased risk of atrial fibrillation, osteoporosis, and possible associations with dementia, but it is less easy to define in secondary hypothyroidism than in primary hypothyroidism, where TSH monitoring provides an accurate guide.

Excess androgen replacement can lead to clinically significant polycythemia, and monitoring of the hematocrit is recommended. Concerns also remain that testosterone replacement may exacerbate prostatic hypertrophy and malignancy. In view of this, although the current policy in the United Kingdom is not to carry out population screening for prostate cancer, most endocrinologists currently recommend biannual prostate-specific antigen (PSA) monitoring for men receiving androgen therapy.

Overreplacement with GH can, via sodium and water retention, lead to weight gain, peripheral edema, and carpal tunnel syndrome. Arthralgia and myalgia are also well recognized side effects of treatment. GH replacement leads to enhanced insulin resistance that may unmask previously undiagnosed diabetes and contribute to increased cardiovascular risk. The concern that GH therapy would be associated with an increased risk of subsequent malignancy has not been borne out by the evidence.

In patients with cranial diabetes insipidus and intact thirst responses, severe dehydration is usually avoided because adequate fluid intake is maintained. If patients complain of excessive thirst, 24-h records of fluid balance can help to guide a dose increase of desmopressin. Hyponatremia as a consequence of lack of free water excretion due to overtreatment with desmopressin is a potentially more serious complication of treatment. This can be avoided by regular biochemical monitoring when therapy is commenced and after any dose adjustment (paired urine and serum osmolality in addition to urea and electrolytes) in addition to advising patients that they should be aware of the effect of the drug wearing off (i.e., polyuria) 1 to 2 h before their next dose.

In patients with partial hypopituitarism, the potential for new deficiencies must always be borne in mind, particularly if the patients have received pituitary radiotherapy given that the lag time between irradiation and developing clinically significant endocrine deficiencies may be many years. In these patients, ongoing monitoring is essential.

Patients now take on average lower replacement doses of steroid than ever before, leaving them

potentially more vulnerable to hypoadrenalism when intercurrent illness occurs. Consequently, these patients must receive clear verbal and written advice on when and how to adjust their glucocorticoid replacement. It is also vital that patients' general practitioners and family members be made aware of the diagnosis, and most patients are advised to carry some form of identification, such as a medic alert bracelet, to assist medical staff if the patients lose consciousness. Mild intercurrent illnesses that are not associated with significant diarrhea, vomiting, or a fever generally do not warrant an alteration in steroid replacement. Patients should be advised to double their standard regimen in the event of a pyrexial illness and to seek medical assistance early if profuse vomiting or diarrhea is preventing the administration or absorption of oral hydrocortisone. Many patients have an emergency steroid pack consisting of a single vial of 100 mg of hydrocortisone that can be administered intramuscularly by a trained relative or visiting general practitioner. Severe illness or surgery usually necessitates hospital admission for regular parenteral hydrocortisone (50–100 mg intramuscularly every 6 h).

Hormone replacement regimens can be complex and require patients to actively participate in their treatment to achieve the best quality of life possible. Patient education is fundamental to achieving this aim, and charities such as the Pituitary Foundation (United Kingdom) and the Pituitary Tumor Network Association (United States), which offer advice and support to patients and relatives, are invaluable.

THE FUTURE

There is good evidence that patients with acromegaly and Cushing's disease are at increased risk for premature death, but there is increasing evidence to support the hypothesis that other patients with hypopituitarism have a mortality exceeding that of the background population. Studying this population is clearly

complex because it includes patients with a variety of endocrine deficiencies due to differing underlying pathologies who have received a selection of treatment modalities, but it appears that the premature mortality might not be entirely attributable to GH and other endocrine deficiencies but rather might reflect increased mortality from respiratory and vascular disease.

There is significant evidence that replacement therapy with dehydroepiandrosterone is beneficial in Addison's disease, but replacement therapy is also postulated to be of benefit in improving well-being in secondary hypoadrenalism. Further research is required to clarify these and other contentious issues.

HORMONE REPLACEMENT THERAPY IN THE PATIENT WITH HYPOPITUITARISM

Adrenocorticotropin Deficiency

Hydrocortisone is the drug of choice and is the firstline treatment in most countries. Hydrocortisone has traditionally been given in two doses: a larger dose of 20 mg on waking and a smaller dose of 10 mg taken with the evening meal. However, Esteban and colleagues convincingly demonstrated daily cortisol production rates in healthy individuals to be less than half of the previously accepted values. Other work has highlighted potentially detrimental effects on bone density and glucose tolerance of high tissue exposure to glucocorticoids, so a more tailored approach to therapy is now the norm. Many patients on twice-daily replacement regimens report fatigue or headache in the afternoon that is improved by taking their hydrocortisone in three divided doses, although quality-of-life assessments were unchanged with lowered total doses of hydrocortisone in one study. Therefore, doses are fine-tuned according to patient well-being and serum cortisol levels by many centers. Urine-free cortisol measurements are not useful because saturation of corticosteroid-binding globulin (CBG) following oral hydrocortisone results in supraphysiological urine-free cortisol excretion. The hydrocortisone day curve used by our institution consists of serum sampling for cortisol at time 0 before the first dose is given and then at 30 min and 1, 2, 3, 5, 7, 9, 9.5, 10, and 11 h, with hydrocortisone administered at the usual times, typically at 0, 5, and 9 h. The aim is to achieve adequate circulating levels of cortisol throughout the day without excessive peaks (e.g., >1000 nmol/L) or troughs (e.g., <100 nmol/L) before or after doses. Timing and size of dose may then be adjusted, and the hydrocortisone day curve may be repeated, to confirm appropriate cortisol levels. Therefore, a typical modern treatment regimen may provide a lower total dose of

hydrocortisone, typically 15 to 20 mg divided across three time points (e.g., 10 mg on waking, 5 mg at noon, and 5 mg at 5:00 to 6:00 PM).

If a hypopituitary patient is acutely unwell or requires surgery, hydrocortisone should be given via intermittent intramuscular injections. In the event of an emergency, 100 mg will provide full glucocorticoid cover for at least 6 h. Alternatively, hydrocortisone may be given as a continuous intravenous infusion of 1 to 3 mg/h.

The most commonly used alternative to hydrocortisone is cortisone acetate, which is widely used in Scandinavia and the Netherlands. Cortisone acetate has an approximate dose equivalence of 25 mg to 20 mg hydrocortisone. The absorption of cortisone acetate may be slower than that of hydrocortisone, and cortisone acetate is biologically inactive until conversion to cortisol by the enzyme 11 β -hydroxysteroid dehydrogenase type 1 (11 β HSD1). Furthermore, the net dehydrogenase activity of 11 β HSD varies among individuals, being increased in normal females compared with males, decreased in the presence of increased body fat in hypopituitary patients, and decreased in patients with type 1 diabetes mellitus. In addition, 11 β HSD1 is inhibited by growth hormone (GH) and insulin-like growth factor-1 (IGF-1) in hypopituitary adults and in acromegaly, resulting in a measurable reduction in circulating cortisol as well as in a fall in the urinary cortisol-to-cortisone metabolite ratio that reflects the relative dehydrogenase-to-reductase activity of 11 β HSD. In practical terms, patients receiving cortisone acetate replacement therapy may require further dose titration after the implementation of GH therapy. Other steroid preparations such as prednisolone may also be used in the place of hydrocortisone (dose equivalence 5 mg prednisolone to 20 mg hydrocortisone). However, in view of the inability to monitor plasma glucocorticoid levels in this drug, it should be used only in exceptional circumstances.

Table II Clinical Features of Pituitary Insufficiency

| Pituitary hormone | Adrenocorticotropin | Thyrotropin | Growth hormone | Luteinizing hormone/Follicle-stimulating hormone | Arginine vasopressin | Prolactin and oxytocin |
|----------------------------------|------------------------------------|-------------------|------------------------------|--|--|----------------------------|
| Effector hormone | Cortisol | Thyroxine | Insulin-like growth factor-1 | Estrogen / Progesterone / Testosterone | | |
| Clinical/ Laboratory findings | Fatigue, weakness | Fatigue, weakness | Fatigue, weakness | Men | Thirst | Failure of lactation |
| | Mental depression | Mental depression | Mental depression | Loss of libido | Polyuria | |
| | Anorexia, weight loss | Weight gain | Increased visceral adiposity | Erectile dysfunction | Polidipsia | |
| | | Constipation | | Hot flushes | Hypernatremia | |
| | Dizziness, Orthostatic hypotension | Cold Intolerance | Osteoporosis | Diminished facial and body hair | Increased serum osmolality with Inappropriately low urine osmolality | |
| | | Menorrhagia | Hyperlipidemia | | | Disinhibition of prolactin |
| | | | Reduced muscle strength | Fine facial wrinkles | | |
| | Nausea, vomiting | | | Gynecomastia | | |

| | | | Loss of libido | | Menstrual disturbance | |
| | | | Dyspareunia | | | |
| | | | Infertility | | Galactorrhea | |

Patient Education

Education is important for patients with ACTH deficiency. It is vital that these patients understand the rationale for treatment to ensure long-term compliance and also that they know how to adjust their treatment in the case of an emergency. The first dose should be taken on waking, and the last dose should be taken several hours before going to bed to ensure safe glucocorticoid cover for the waking hours but to minimize insomnia at night. Patients should also carry documentation, such as a steroid card or a medic alert bracelet, to alert others of their steroid requirement in the case of an emergency. Patients should understand that during intercurrent illness, their steroid requirements will increase; therefore, they should be confident about doubling their hydrocortisone dose during

pyrexial illness and should carry a vial of 100 mg hydrocortisone for intramuscular administration in the event of severe illness, vomiting, or diarrhea.

Antidiuretic Hormone Deficiency

Synthetic vasopressin (DDAVP) is available to be taken orally, nasally, or via subcutaneous injection. Dose and route of administration are altered according to the clinical setting as well as to objective fluid status and serum and urine osmolality and biochemistry. For example, in the acute clinical setting, where diabetes insipidus follows pituitary surgery, DDAVP is best administered via the subcutaneous route to provide a reliable predictable response. Very small doses (0.5–1 µg) will effectively control polyuria

Table III Basic Investigations for Diagnosis of Pituitary Hormone Deficiencies

| |
|--|
| ACTH |
| 9 AM cortisol |
| Insulin tolerance test |
| TSH |
| Free (or total) T ₄ |
| TSH |

| Basal IGF-1 |
| Insulin tolerance test |
| Arginine vasopressin |
| Synchronous serum and urine osmolality |
| Water deprivation test |

for up to 16 h. This is traditionally given at night to prevent nocturia and allow undisturbed sleep, with polyuria expected to restart late during the following afternoon if at all. In the nonacute setting, subcutaneous administration is inappropriate, so the oral or nasal route is chosen according to patient preference. DDAVP is best absorbed via the nasal route, allowing smaller doses to be used (typically 10–20 µg once or twice daily). However, this requires some experience and expertise in the technique of self-administration, and some patients will prefer the oral route. Oral DDAVP is less effective, such that larger doses are required and must be taken more frequently (100–300 µg taken two or three times daily). Doses of more than 200 µg have not been found to increase the antidiuretic effect significantly, although they may allow less frequent doses. Dose titration and patient education are required to achieve optimal symptom control, particularly at night, and to maintain a normal serum osmolality and sodium concentration. Slight undertreatment, with normal water homeostasis being maintained by thirst mechanisms, is the preferred approach. In those situations where ADH deficiency is accompanied by a reduced thirst threshold, it is necessary to carefully monitor body weight and urine output on a fixed dose of DDAVP and to adjust fluid intake accordingly.

Thyroid-Stimulating Hormone Deficiency

Thyroid hormone replacement has been practiced for more than a century. Animal-derived thyroid extract

was first given by mouth in 1892 and was widely used until the 1970s. More recently, synthetic levothyroxine sodium (L-thyroxine [L-T₄]) has become established as the preferred replacement drug. Recent trials have examined potential benefits of simultaneous administration of L-T₄ and triiodothyronine (T₃).

Healthy human thyroid secretes predominantly T₄ but also T₃, which accounts for approximately 25% of daily whole-body T₃ production. T₃ is responsible for most of the biological activity of thyroid hormone, and the majority is derived by deiodination of circulating T₄. The original desiccated thyroid extracts contained both L-T₄ and T₃ (approximately 121 and 20 µg, respectively), resulting in supraphysiological T₃ levels and a high incidence of adverse effects. Synthetic L-T₄ became available during the 1950s, and early studies showed it to be well absorbed and effective at maintaining serum T₄ levels. T₃ displays superior gastrointestinal absorption, but its short half-life results in a need for multiple daily dosing. As a result use of T₃ is largely restricted to thyroid cancer patients undergoing frequent isotopic imaging or treatment and to those patients with ischemic heart disease where gentle incremental increases in thyroid replacement are indicated. L-T₄ has a longer half-life, enabling once-daily dosing without major adverse consequences of occasional tablet omission.

Most authorities advocate L-T₄ as the preferred agent for thyroid replacement. Improvements in the sensitivity of TSH assays led to the recognition that previous L-T₄ doses induced suppression of TSH, with the average L-T₄ dose required to normalize TSH in the area of 1.6 µg/kg. In hypopituitarism, TSH is low or absent and is not a useful marker of adequacy of L-T₄ replacement. In these patients, measurement of circulating thyroid hormones supported by clinical assessment are the best guides to dose titration. Experience from patients with primary hypothyroidism indicates that doses of L-T₄ that normalize serum TSH commonly result in high normal or elevated free thyroxine (FT₄) levels, whereas T₃ levels are normal. This may be explained by the need for higher FT₄ levels to compensate for the absence of thyroidal T₃ secretion.

When starting L-T₄ replacement, consideration of the duration of hypopituitarism and the presence of comorbidities, particularly ischemic heart disease, is necessary. In young patients with short-duration TSH deficiency, a full replacement dose of L-T₄ may be initiated (typically a starting dose of 100 µg). To avoid precipitating cardiac events, a low dose (e.g., 25–50 µg) should be commenced and gradually

titrated against serum FT4 levels and clinical response in the elderly and in those with possible long-standing hypopituitarism. Occasionally, initiation of T3 followed by a crossover to L-T4 once safety is established is appropriate.

The serum FT4 level is the best method to assess status of L-T4 replacement in hypopituitarism. Changes in values following a dose are modest, but it is best to monitor immediately prior to the next dose. Consideration of increases in L-T4 replacement should be made for patients using oral estrogen therapy. Such treatment increases levels of circulating thyroid-binding globulin, resulting in a decrease in bioavailable FT4, and this phenomenon will not be evident if serum total thyroxine measurements are made. Dose requirements may fall with increasing age, perhaps related to reduced clearance in the elderly. In hypopituitary adults with growth hormone deficiency (GHD), conversion of FT4 to T3 may be reduced, and it is not uncommon for patients to require replacement L-T4 doses that result in elevated FT4 levels to generate normal T3 concentrations.

Other Issues

Generic and brand name L-T4 preparations are generally bioequivalent and interchangeable. However, prescribing practice does differ; in the United Kingdom, most authorities favor generic L-T4, whereas in the United States and some European countries, brand names are favored.

Excessive L-T4 replacement may be associated with adverse effects. Studies have indicated that replacement therapy results in lumbar spine bone loss in premenopausal women; however, it remains unclear whether fracture risk is increased. Doses of L-T4 that result in suppressed TSH in those with primary hypothyroidism are associated with a risk of atrial fibrillation and increased left ventricular mass.

It is recognized that a small subset of patients requiring L-T4 replacement continue to feel symptomatic despite normalization of FT4 levels. Because exposure to T3 may differ between tissues in such patients, the potential benefits of combined T4 and T3 replacement has been the focus of recent study. Early evidence in humans indicates that mood and psychological status may be improved in hypothyroid individuals receiving a combination replacement regimen. However, this approach must still be considered experimental, and until slow-release T3 preparations are available, use of T3 in routine replacement in hypopituitary patients will be limited.

Gonadotropin Deficiency

Males

The gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are responsible for gonadal sex steroid production and gamete production and maturation in both genders. Deficiency of LH and FSH results in absence of sperm (azospermia) and testosterone (the main circulating androgen) in the male. The goals of treatment of gonadotropin deficiency are to (1) induce secondary sexual characteristics in patients that have not had spontaneous puberty, (2) maintain or restore normal sexual function, and (3) restore fertility.

Effects of Testosterone Deficiency

Testosterone is an important regulator of body composition in postpubertal adults, and testosterone deficiency results in reduced lean body mass (predominantly skeletal muscle) and increased fat mass. Testosterone replacement in the male with hypogonadism results in correction of these abnormalities and normalization of body composition.

Evidence indicates an important role for testosterone in the regulation of bone mineralization. Cross-sectional data indicate an association between serum testosterone levels and bone mineral density (BMD), and induced hypogonadism results in decreases in BMD. Testosterone replacement in the male with hypogonadism results in substantial increases in BMD. However, the precise mechanisms of testosterone-mediated bone anabolism remain poorly understood. It has been suggested that the majority of effects are estrogen mediated following aromatization of testosterone.

Testosterone has important effects on behavior, and hypogonadism results in decreases in sexual interest, arousal, and the achievement of erections. Improved sexual function has been clearly demonstrated following testosterone replacement. In some studies, improvements in mood have been recorded following testosterone replacement in hypogonadism. Data regarding androgens and lipids are somewhat contradictory. Cross-sectional studies indicate a positive correlation between high-density lipoprotein (HDL) cholesterol and testosterone but indicate inconsistent relationships between testosterone and total and low-density lipoprotein (LDL) cholesterol. Similarly, both increased and decreased total, LDL, and HDL cholesterol have been reported following testosterone replacement in hypogonadal men. Other risk factors for cardiovascular disease may also be altered by androgen status. These include PAI-1,

fibrinogen, and antithrombin III as well as proteins C and S.

Growth of both facial hair and body hair is reduced in hypogonadism. Prostate cancer rarely occurs in testosterone-deficient men, and antiandrogen treatment can lead to regression of prostate carcinoma. Although testosterone replacement should be avoided in patients known to have carcinoma of the prostate, there is no evidence that appropriate replacement in the deficient male is associated with a greater risk than in the healthy population.

Replacement Treatment in Males with Gonadotropin Deficiency

Testosterone replacement should be considered in all males with gonadotropin deficiency resulting in low serum testosterone. The goals of treatment are to improve quality of life through restoration of normal circulating levels with a minimum of adverse effects. A number of routes of administration are available, and the choice should be tailored to the individual. Monitoring of testosterone therapy is based on measurement of serum testosterone levels and assessment of the clinical response. Supraphysiological circulating levels of total testosterone should be avoided because they may contribute to the development of adverse effects. These include changes in personality, acne vulgaris, gynecomastia, lipid disorders, polycythemia, and possibly prostate malignancy.

Modes of Testosterone Replacement

Oral preparations are subject to a high first-pass hepatic metabolism. A number of modified testosterone products have been tried with variable success, and large doses are necessary. Testosterone undecanoate is the only available oral preparation, and when it is taken it is absorbed through intestinal lymphatics, avoiding complete first-pass effects. The half-life is short, requiring more than a single daily dose, and individual pharmacodynamics vary considerably. The most reliable monitoring method is measurement of serum dihydrotestosterone. In most centers, oral testosterone undecanoate is reserved for those individuals in whom other modes of replacement have not been successful.

Intramuscular administration of testosterone esters is the most widely used method of testosterone replacement in the hypopituitary male. Esterification increases the half-life, with various esters resulting in different dosing interval requirements ranging from days to several months. Many preparations result in supraphysiological peaks immediately following administration, with falls to low levels prior to

subsequent dosing. The commonly used preparations are "Sustanon" (a mixture of propionate, phenylpropionate, and deconate esters), testosterone isocaproate, and testosterone enanthate. Usually, these preparations are administered every 2, 3, or 4 weeks and often require visits to a family practice or hospital clinic. The potentially longer acting testosterone buciclate is under development and may result in less frequent injections with a smoother serum profile.

Typically, subcutaneous implants are inserted on a 4- to 6-month basis, with 600 to 800 mg of testosterone the common dose range. Peak serum testosterone levels are seen 2 to 4 weeks postplacement, with a gradual decline thereafter. The main disadvantage is need for a minor surgical procedure. A variety of transdermal preparations have become available. Nonscrotal patches deliver testosterone via a permeation-enhancing vehicle, and a new patch is applied each day. Treatment with 2.5 to 5.0 mg of testosterone daily provides total serum testosterone levels within the normal range in the majority of hypopituitary adults. The patch should be applied at night because the majority of testosterone is delivered within the first 12 h, mimicking the normal circadian rhythm of testosterone levels. The major restriction relates to skin irritation that affects approximately 50% of people and has limited the use of this modality. A scrotal patch that delivers testosterone with less skin irritation is also available. Shaving of the site of application is required, and the patch must be changed daily.

More recently, a testosterone gel preparation that results in less skin irritation and more satisfactory serum levels has become available. It is likely that this preparation will be widely used when it becomes licensed throughout Europe and as availability increases. Buccal and sublingual preparations are also undergoing investigation.

Fertility Treatment in Gonadotropin Deficiency

The production of testosterone is governed by LH, and this axis is responsible for the induction of puberty and maintenance of secondary sexual characteristics. FSH, in addition to being needed for an adequate level of testosterone, is required for complete spermatogenesis. In patients with gonadotropin deficiency, use of FSH in addition to human chorionic gonadotropin (hCG, which has LH activity) will both induce puberty and restore fertility. Although hCG is exclusively available as urinary extracts, increasingly recombinant preparations of FSH are being used.

In prepubertal adults, a number of different protocols of gonadotropin administration have been

suggested, but a commonly used algorithm consists of the following:

1. hCG (2000 IU intramuscularly) three times weekly for 6 to 8 weeks to elevate the serum testosterone levels
2. FSH (37.5 IU intramuscularly) three times weekly to facilitate spermatogenesis

The semen should be analyzed monthly to assess response. If the response is suboptimal, doses may be doubled. In most cases, satisfactory serum testosterone levels and quality and number of spermatozoa are seen, but treatment may need to continue for up to 1 year. In postpubertal adults, treatment to restore fertility should be commenced with hCG (2000 IU) three times weekly. This may be sufficient to induce spermatogenesis alone, but addition of FSH is necessary in most patients. Our preferred practice is to administer high-dose FSH (300 IU) three times weekly and hCG (2000 IU) two times weekly to eliminate the need to increase the dose if increased spermatogenesis fails to occur after 4 months of therapy. Regardless of the dose used, an interval of at least 4 months is required to achieve an increase in sperm count and treatment should then be continued for a further 6 months or until conception is achieved. Because these agents are expensive efforts to cryopreserve, sperm should be made once levels are adequate.

Gonadotropin-Releasing Hormone Therapy

Pulsatile administration of gonadotropin-releasing hormone (GnRH) results in production and secretion of LH and FSH in patients with hypothalamic disorders provided that anterior pituitary function is preserved. Typically, a small infusion pump is worn and doses of GnRH (~25 ng/kg body weight) are delivered subcutaneously every 90 min. Adequate serum levels of the gonadotropins and testosterone are measurable in most patients after 7 days. Fertility should be assessed using seminal analysis after 4 months of treatment. Because pulsatile therapy is expensive and requires considerable effort, cryopreservation of sperm should be considered.

Females

The main circulating estrogen in the healthy premenopausal female is ovarian-derived 17 β -estradiol, and production rates are in the area of 100 to 300 μ g/day. In addition, estrogen production occurs in peripheral tissues from conversion of testosterone and androstenedione. Ovarian estrogen production is regulated by the gonadotropins, and in healthy women the

ovarian failure seen in the menopause results in a 10- to 20-fold increase in circulating FSH levels and a threefold increase in LH. In the hypopituitary female, absence of gonadotropins results in decreased circulating estrogen and progesterone levels and anovulation.

Effects of Estrogen Deficiency

Estrogen deficiency results in both short-term and long-term effects, and individuals vary in the pattern and severity of complications encountered. The majority of patients with hypopituitarism have had long-term gonadotropin deficiency, but those with new onset of hypothalamo-pituitary disease or surgery may experience variable degrees of vasomotor instability, fatigue, mood disturbance, and sexual dysfunction. The latter is principally related to atrophic change in vaginal epithelium.

Long-term consequences of estrogen deficiency are frequently seen in women with early onset of hypopituitarism who have not undergone estrogen replacement. The most important consequence is reduced bone mineralization resulting in increased risk of osteoporotic fracture. The development of osteoporosis in an individual depends on the peak adult bone mass achieved and the subsequent rate of bone loss. Genetic factors are the most important determinants of peak bone mass; however, estrogen deficiency throughout adolescence and early adulthood contributes to reduced bone mineralization. Thus, onset of estrogen deficiency both early in life and later (following achievement of peak bone mass) can affect bone health. BMD can be assessed using a variety of techniques, including quantitative computed tomography (CT), photon absorptiometry, and (more recently) dual-energy X-ray absorptiometry (DXA). The wide clinical availability and relative inexpense of DXA means that increasingly endocrinologists are using this tool to assess bone health and to monitor the effect of treatments in hypopituitary patients.

Dyslipidemia is the other major long-term consequence of estrogen deficiency. Circulating estradiol alters lipoprotein metabolism, resulting in reduced LDL cholesterol and increased HDL cholesterol. Use of estrogen replacement results in favorable effects on the lipid profile; however, androgenic progestins may counteract this in part.

Replacement Therapy in Females With Gonadotropin Deficiency

Hormone replacement therapy was first introduced for the treatment of menopausal symptoms some 30 years ago. Early preparations used unopposed

estrogen preparations that were typically taken for 21 days followed by 7 tablet-free days. This regimen resulted in endometrial hyperplasia and increased risk of endometrial carcinoma. Since the 1970s, estrogen replacement has been combined with cyclical progesterone, which normalizes or even reduces the risk of endometrial cancer. However, these treatments result in restoration of a menstrual bleed in the majority of women with intact uteri.

The aims of treatment of gonadotropin deficiency in the hypopituitary female are to counteract the features of estrogen deficiency, specifically maintaining bone and sexual health, and to assist fertility in some patients. In those not seeking fertility, estrogen replacement treatment should be tailored to the individual patient given that a number of different routes of administration are available, attesting to the fact that none is perfect.

Estrogen may be administered via oral, subcutaneous, and transdermal routes. Oral estrogens are in the form of natural estrogens (conjugated equine, estradiol valerate, and 17 β -estradiol) and typically are taken for 21 days followed by 7 tablet-free days. For the younger patient, the oral contraceptive preparations are slightly unorthodox, but we see no reason why they should not be used, especially given that they may allow the patient to feel more “normal” in relation to her peers. Oral preparations are subject to extensive first-pass hepatic metabolism, and large doses are required (typically 1–2 mg/day). To avoid endometrial hyperplasia, these should be combined with a progestin or the “Mirena” intrauterine device.

Transdermal preparations are usually applied twice weekly and contain 50 to 100 μ g of estrogen in cyclical combination with a progestin. Subcutaneous implants are inserted as a minor surgical procedure 6 times monthly and necessitate cyclical progestin treatment in those with intact uteri. Recently, selective estrogen receptor modulators (SERMs), including tibolone and raloxifene, have become available. These agents provide bone mineral effects with reduced effect on endometrial tissue, resulting in decreased or absent menstrual bleeding. However, raloxifene has little effect in treating the vasomotor symptoms of acute estrogen deficiency. In those intolerant of conventional estrogen treatment, consideration should be given to the use of a SERM to preserve bone health. The nonestrogenic compound tibolone provides an alternative treatment for postmenopausal symptoms and also exerts favorable effects on bone.

Monitoring of estrogen replacement is based largely on clinical response. In females with intact

uteri, it may be anticipated that a cyclical menstrual period will occur. Synthetic estrogens and conjugated equine estrogens do not result in predictable levels of circulating estradiol, and this commonly used measurement is of little practical benefit in patients using these preparations. Typically, estrogen replacement should be continued provided that there are no contraindications until the age of the natural menopause—approximately 51 years. Thereafter, the use of these compounds must be balanced against the potential adverse effects related to thromboembolism, breast cancer, and cardiovascular morbidity. For many years, estrogen replacement was considered safe and relatively free from adverse effects. Little information is available regarding specific use of estrogen compounds in hypopituitary females, and much of the safety data are derived from the postmenopausal population taking HRT. A recent study provided clear evidence that combined estrogen/progestin is associated with increased incidence of invasive breast cancer, thromboembolism, and coronary events in women ages 50 to 75 years, highlighting that these preparations should be tailored to each individual rather than used as a matter of routine.

Fertility treatment in the hypopituitary female requires ovulation induction using hCG and hMG/recombinant FSH. Typically, this is supervised through fertility clinics and may involve ovum storage and *in vitro* fertilization.

Growth Hormone Deficiency

Unlike glucocorticoids, thyroid hormone, and sex steroids, the use of GH replacement therapy in adult hypopituitarism is largely restricted to patients affected by a characteristic clinical syndrome. This syndrome includes reduced well-being with low energy levels, poor self-esteem, and social isolation; abnormal body composition with increased android (abdominal and visceral) fat and decreased lean body mass and total body water; osteopenia with reduced bone remodeling; and an adverse cardiovascular risk profile that includes dyslipidemia, hyperfibrinogenemia, and elevated levels of plasminogen activator inhibitor (PAI). As with other forms of endocrine replacement therapy, the goal of therapy is to maximize the clinical benefits while minimizing the risks of excess exposure. Early studies of GH replacement used weight and/or surface area GH doses, but it is now accepted that the dose of GH needs to be individually tailored to each patient. Several strategies exist for monitoring, although each strategy has important limitations.

Tolerability

In the early trials of GH replacement, symptoms related to sodium and water retention (edema, arthralgia, and myalgia) were common and required dose reductions in up to 40% of patients. However, even when GH doses are lowered due to adverse symptoms, biochemical markers of GH action, such as serum IGF-1, remain elevated in up to one-third of patients, suggesting that the absence of symptoms of GH over-treatment is a relatively crude method of judging excess GH exposure.

Clinical Monitoring

In theory, each of the features of the GH deficiency syndrome could serve as a marker of efficacy for dose monitoring, but correction of abnormal body composition has received most attention. Although these studies illustrate the value of body composition changes as a marker of GH efficacy, they also suggest that increasing the dose of GH due to persistent abnormal body composition may result in overtreatment, judged by biochemical markers of GH action. Similar conclusions may be drawn from studies of changes in well-being in response to GH replacement. Therefore, the question arises as to whether supra-physiological levels of serum IGF-1 have an adverse effect on adult hypopituitarism. Clinical experience with acromegaly, a condition known to be associated with excess morbidity and mortality and epidemiological data, regarding the risk of developing carcinoma of the prostate or breast would suggest that biochemical overtreatment should be avoided until more data are available.

Biochemical Monitoring

Potential candidates for the biochemical monitoring of GH dose include serum IGF-1, IGF-binding protein 3 (IGFBP-3), and acid labile subunit (ALS). Patients reporting symptoms of GH excess are more likely to have an elevated serum IGF-1 level than to have elevated IGFBP-3 or ALS, suggesting that IGF-1 is a more sensitive marker of GH action during GH replacement. Importantly, treatment protocols that specifically aim to avoid elevated serum IGF-1 levels are associated with similar clinical benefits to those observed in the original placebo-controlled studies. However, serum IGF-1 levels may not reflect "true" GH status; up to 30% of patients with severe GH deficiency have serum IGF-1 levels in the lower part of the age-adjusted normal range. Furthermore, in most studies, blood samples for serum IGF-1 are drawn during the early morning. The diurnal variation in serum IGF-1 levels seen with a single

nightly GH injection (a morning peak with a nadir at night) may lead to an artifactually high incidence of supraphysiological levels of serum IGF-1.

Gender Differences in Growth Hormone Responsiveness

Various studies indicate that clinical and biochemical responses to a given dose of GH are greater in men than in women, a discrepancy that is likely due, at least in part, to modulation of GH action by estrogen. Furthermore, there are data to suggest that the route of estrogen administration may affect the GH maintenance dose, with lower GH doses required in women taking transdermal, as opposed to oral, estrogen preparations.

Summary

There is no biological marker in adults that is the equivalent of linear growth in children by which to judge the efficacy of GH replacement. Most clinicians agree that GH is most appropriately commenced at low doses, building up slowly to the final maintenance dose. This, in turn, is best determined by a combination of clinical response and measurement of serum IGF-1, avoiding supraphysiological levels of this GH-dependent peptide.

release; the administration of prostaglandin synthesis inhibitors could impair renin release.

Several lines of evidence suggest that the primary defect responsible for the hyperkalemia in many patients resides in the adrenal gland. Angiotensin II and ACTH directly stimulate aldosterone release by the adrenal zona glomerulosa. Because the aldosterone response to angiotensin II and ACTH is impaired in many patients, the syndrome of hyporeninemic hypoaldosteronism (HH) may be of mixed causes.

DIAGNOSIS

The diagnosis of HH is considered for patients in whom hyperkalemia and metabolic acidosis are out of proportion to the degree of renal impairment (i.e., glomerular filtration rate >20 ml/min). "Pseudohyperkalemia" (e.g., hemolysis, thrombocytosis) should be excluded.

The next step is to demonstrate a normal cortisol response to ACTH stimulation. Then, the response of renin and aldosterone levels to stimulation (e.g., upright posture, sodium restriction) should be measured. Low renin and aldosterone levels establish the diagnosis of HH.

TREATMENT

Several different therapeutic regimens can be employed to lower the plasma potassium concentration. However, the physician should keep in mind that the majority of patients suffering from this syndrome are elderly and have associated conditions such

as diabetes mellitus, atherosclerotic cardiovascular disease, and hypertension.

Mineralocorticoid replacement, usually given as fludrocortisone acetate, is the mainstay of therapy. Large doses of the steroid, often as high as 0.4 to 1.0 mg daily, are frequently required to reduce the plasma level to normal. This observation suggests that the renal tubular cell is resistant to the action of mineralocorticoids, at least with respect to their effect on potassium secretion. Sensitivity to the sodium-retentive effects of fludrocortisone appears to be less affected given that marked sodium retention with edema, exacerbation of hypertension, and congestive heart failure are common consequences. In many patients, the administration of a loop diuretic may be required to prevent or treat these complications.

If the hyperkalemia fails to respond to fludrocortisone acetate, or if excessive sodium retention is encountered, a trial of potassium-wasting diuretics is desirable. In many patients, particularly those with a primary tubular potassium secretory defect, thiazide diuretics are effective. In some patients, sodium bicarbonate may improve potassium excretion and correct the hyperkalemia. If these measures fail, one can always employ a sodium-potassium exchange resin such as sodium polystyrene sulfonate.

In many patients, particularly those with only mild to moderate hyperkalemia, it is best not to institute any therapy but to check the plasma potassium concentration periodically to ensure that the hyperkalemia has not reached dangerous levels.

In all patients, drugs known to impair renal potassium excretion should be avoided. Volume contraction, which decreases distal sodium delivery, also should be prevented.

| Organic defects |
| Isolated GnRH deficiency |
| Pituitary tumors |
| Sheehan's syndrome |
| Empty-sella syndrome |
| Head trauma |
| Inappropriate prolactin secretion |

hypoestrogenic milieu might be seen in the genital tract. However, complains of hot flashes are uncommon. Hypothalamic anovulation may be related to some psychiatric conditions, especially anorexia nervosa. This is an uncommon psychiatric disorder that is usually diagnosed in adolescent and college-aged females. Anorexia nervosa is much more common in women with amenorrhea and therefore should be considered and ruled out in young patients undergoing evaluation due to anovulation. Several organic defects are related to a small but significant number of hypothalamic anovulatory females. Such disorders include pituitary tumors, Sheehan's syndrome (due to circulatory collapse), empty sella syndrome, and head trauma. Isolated gonadotropin-releasing hormone (GnRH) deficiency, which shares many biochemical features with functional hypothalamic anovulation, is characterized by a decrease in the secretion of endogenous GnRH. The disturbed secretion of GnRH leads to hypogonadotropic hypogonadism, eunuchoid features, incomplete development of secondary sexual characteristics, primary (as opposed to secondary in functional anovulation) amenorrhea, and, in some cases, anosmia. This disorder is the result of developmental or migratory-failure of GnRH neurons. Hypoplasia of the olfactory bulb can be identified in some patients.

CHARACTERISTIC OF FUNCTIONAL HYPOTHALAMIC ANOVULATION

Most women with functional hypothalamic anovulation have a history of normal onset of menarche with regular menstrual cycles between 26 and 35 days. These patients tend to be highly motivated and involved in stressful occupations. Changing lifestyles and an increasing emphasis on exercise, nutrition, and slenderness are expected to result in an increased incidence of hypothalamic anovulation. In some women, emotional or stressful events precede the onset of anovulatory amenorrhea. Other environmental and interpersonal factors (e.g., social maladjustment and psychosexual difficulties) can be identified during the first interview. Women with functional hypothalamic anovulation usually have low to normal body weight. Several studies have shown that these women have more psychological characteristics associated with eating disorders, such as a feeling of general inadequacy, insecurity, lack of control over life, and confusion in identifying and responding to food-related body sensations and emotional states. A thorough physical examination usually reveals normal secondary sexual development. Signs of other hormonal imbalances, such as thyroid enlargement, galactorrhea, and androgenic excess, should be searched for during the examination. A finding of such an endocrinological disorder usually challenges the diagnosis of functional hypothalamic anovulation.

PATHOPHYSIOLOGY OF FUNCTIONAL HYPOTHALAMIC ANOVULATION

The common underlying defect of these various disorders is the deficiency (or slowing in frequency) in the pulsated secretion of GnRH. When exogenous GnRH is administered to women with hypothalamic anovulation, luteinizing hormone (LH) and follicle-stimulating hormone responses are either normal or exaggerated, suggesting that the primary defect is at a central level with preserved function of the pituitary. A growing body of evidence indicates that an increase in endogenous opiate activity plays a significant role in reducing the pulsated GnRH secretion (and consequently LH) in functional hypothalamic anovulation. Blockage of endogenous opiate receptors by naloxone may increase LH pulse and amplitude in women with hypothalamic anovulation. Long-term treatment with opiate receptor antagonists may result in a spontaneous return of gonadotropin secretion and ovulatory function. Studies have demonstrated that blockage of the dopamine receptor with metaclopramide can also induce an increase in LH secretion.

Disruption of the reproductive function during chronic exposure to stress has been reported in both animals and humans. In humans, there is a functional association between chronic stress and the onset of ovulatory dysfunction and amenorrhea. Evidence links stress, chronic activation of the hypothalamic–pituitary–adrenal axis, and reproductive dysfunction with anovulation. In women with hypothalamic anovulation, there is a significant increase in daytime cortisol levels, a delayed or absent response in ACTH and cortisol secretion during noon meals, and a blunted response to corticotropin-releasing hormone.

Anovulation associated with nutritional factors and weight loss is a well-characterized clinical syndrome. The incidence of weight loss-related anovulation varies widely from series to series, depending on the population studied. It is well-known that the proper amount of fat is crucial for the timely development of menarche (total fat should comprise $\geq 17\%$ of body weight, corresponding to a body mass index of approximately 19 kg/m^2). Regular ovulation and menstrual cycles necessitate the maintenance of at least 22% of body weight as fat. Weight loss by self-enforced abstinence, starvation, chronic illness, or exercise leads to impaired GnRH secretion and peripheral impaired estrogen status.

Regular strenuous physical activity in women is often associated with anovulation and menstrual disturbances (e.g., delayed menarche, oligomenorrhea, amenorrhea, and luteal phase defect). Endocrinological status is affected by exercise, with some similarity to starvation-associated modifications. Two stress-related mechanisms have been implicated in amenorrheic athletes. Exercise-induced increases in β -endorphin levels influence the frequency and amplitude of LH pulses. Endurance exercise may also cause the release of corticotropin-releasing factor, inhibiting gonadotropin secretion and activating the adrenal release of corticosteroids and androgenic steroids. Although weight loss plays a crucial role in exercise-related anovulation, menstrual function may resume spontaneously during training, even if there is no change in body weight or composition.

MANAGEMENT

Because of the functional nature of hypothalamic anovulation, major emphasis should be placed on carefully conducted initial interviews, focusing on lifestyle and interpersonal relationships. Since spontaneous recovery is observed in some cases, expectant management with periodic reassessment is a viable option. For women with persistent anovulation,

a major concern is the long-term effect of hypoestrogenism on bone density. When significant osteopenia is observed, estrogen replacement therapy should be initiated. For women who are interested in fertility, a trial of clomiphene citrate is indicated. For those who fail to respond to clomiphene, the recommended and logical approach is ovulation induction by physiologic replacement therapy with pulsate GnRH.

CONCLUSION

The development of functional hypothalamic amenorrhea is linked to lifestyle and environmental stressors. Psychogenic, nutritional, or exercised-related factors cause a temporary shift into a “resting mode” of the reproductive cycle at the central level. Neuroendocrine factors, which appear to modulate reduced GnRH activity, include the opiate and dopamine neuronal system. In most women, reactivation of the hypothalamic unit occurs after lifestyle modification and accommodation of stress factors. Therapy is aimed at ensuring adequate bone density and resolving consequent infertility.

Figure 1 Normal hypothalamus. (A) The third ventricle is lined by the lateral hypothalamus that harbors the paraventricular nuclei. Inferiorly, the infundibulum carries nerve fibers to the pituitary stalk. (B) The nuclei of the hypothalamus are collections of ganglion cells; in this supraoptic nucleus, the neurons contain vasopressin immunoreactivity.

adult human they are ill defined. From animal studies, it is known that individual nuclei have important physiological functions; for example, there are specific nuclei implicated in hunger or satiety control, temperature regulation, olfaction, circadian rhythms, sexual drive, ovarian regulation, and parenting behaviors. However, functionally, a given hormone is often produced in more than one nucleus, and in many instances a single nucleus produces more than one hormone. These data raise doubts about the concept of individual nuclei as designated functional entities.

CLINICAL MANIFESTATIONS OF HYPOTHALAMIC DISEASE

Lesions of the hypothalamus cause headache, nausea, vomiting, somnolence, behavioral alterations, psychosis, and dementia. Hypothalamic destruction can result in bulimia or anorexia. Visual disturbance can result from oculomotor alterations or optic nerve damage. Hypopituitarism and diabetes insipidus are common manifestations. In severe cases, patients can develop hydrocephalus. Inflammation can result in meningitis.

Diabetes insipidus is the most common and often the initial manifestation. The presentation of hypopituitarism varies with age. In children, hypothalamic dysfunction may present with dwarfism. In adults, sexual dysfunction is the most common endocrine

complaint, with impotence in males and primary or secondary amenorrhea in females. If the disease is predominantly hypothalamic or causes interruption of the pituitary stalk, pituitary hypofunction is associated with hyperprolactinemia due to destruction of the dopaminergic neurons that maintain tonic inhibition of that pituitary hormone, and stimulation confirms an intact pituitary response. If the lesion causes destruction of hypophysial tissue as well as hypothalamic disease, there is a reduction of all basal pituitary hormones or more subtle changes with reduced response to stimulation.

Some tumors are associated with pituitary hormone excess. Occasionally, this is due to the production of hormones stimulating pituitary function, such as in hypothalamic gangliocytomas that secrete adenyhypophysiotrophic hormones. Alternatively, the clinical manifestations may be due to the production of substances that simulate or mimic pituitary hormones. For example, germ cell tumors associated with precocious puberty produce β -chorionic gonadotropin. Occasionally, patients manifest excessive secretion of vasopressin, resulting in the syndrome of inappropriate antidiuretic hormone.

DEVELOPMENTAL DISORDERS

The failure of development of areas of the hypothalamus can lead to variable clinical manifestations. Major defects are incompatible with life.

Septo-optic dysplasia or de Morsier's syndrome is a complex developmental disorder with variable manifestations of aplasia of the septum pellucidum, hypoplasia of the optic nerves, and endocrine dysfunction as well as vegetative alterations. The disorder results from mutations of a homeobox transcription factor, *Hesx1*, which is required for normal development of the affected regions of the central brain.

Kallman's syndrome is an X-linked developmental defect due to mutation of the *KAL-1* gene that encodes an extracellular glycoprotein, anosmin-1, that is expressed during the period of human organogenesis in the early olfactory system and is required for normal migration of gonadotropin-releasing hormone (GnRH)-containing neurons. This disorder results in gonadal insufficiency in males due to hypothalamic GnRH deficiency associated with anosmia.

Lawrence–Moon–Biedl syndrome is a highly polymorphic disorder that includes pigmentary retinopathy, mental retardation, spinal paraplegia and hypogonadism associated with obesity, and digital anomalies. The genetic basis is unknown and the variable clinical manifestations suggest incomplete penetrance with differential expression of the anomaly.

Prader–Willi syndrome is characterized by obesity, short stature, delayed puberty, infertility, mental retardation, muscle hypotonia, hypopigmentation, and seizure disorder. It has been linked with deletions of chromosome 15q11–q13. This region contains an imprinting center that regulates paternally expressed genes whose expression is lost; some cases are attributed to maternal uniparental disomy. However, the causative gene is unknown.

Wolfram's syndrome (WS) is characterized by diabetes insipidus, diabetes mellitus, optic atrophy, and deafness (hence the acronym DIDMOAD). This rare neurodegenerative disorder exhibits autosomal recessive inheritance due to compound heterozygous mutations of the *WFS1* gene, a member of a novel gene family that encodes wolframin, an endoglycosidase H-sensitive membrane glycoprotein that localizes in the endoplasmic reticulum. *WFS1* is expressed predominantly in selected neurons in the hippocampus, amygdala, olfactory tubercle, and superficial layer of the allocortex—components of the limbic system or structures closely associated with this system that account for the psychiatric, behavioral, and emotional abnormalities of this syndrome. Heterozygous mutations are associated with nonsyndromic, low-frequency sensorineural hearing loss affecting only the 2000-Hz and lower range. This is an unusual disorder that worsens over time without progressing to profound deafness.

Idiopathic growth hormone (GH) insufficiency is likely due to a defect in the synthesis or secretion of growth hormone-releasing hormone (GHRH) since most patients have normal pituitary GH somatotroph structure and hormone content, and they respond to GHRH administration.

HYPOTHALAMIC INFLAMMATION

Infectious Lesions

Acute and chronic infections of the hypothalamus are rare but they do occur, usually in association with sphenoid sinus infection, cavernous sinus thrombosis, otitis media mastoiditis, or peritonsillar abscess. Pituitary tumors have been associated with the development of pituitary abscess that can spread to the hypothalamus. It has been suggested that bony erosion by the tumor predisposes such patients to the spread of sinonasal infection. Rarely, infection results from vascular seeding of distant or systemic infection.

Noninfectious Inflammatory Lesions

Sarcoidosis is a multisystem granulomatous disease of unknown etiology. It has long been attributed to an infectious agent; however, none have been identified. Disease onset usually occurs in adults and there is a predilection for blacks and females. There are usually systemic manifestations, and neural involvement is rare; however, it can occur in the hypothalamus, usually involving the meninges at the infundibulum and floor of the third ventricle. The granulomatous inflammation has a subacute or protracted course of tissue destruction that may respond to steroid suppression, and there are rare reports of spontaneous resolution.

Neuroinfundibulohypophysitis is a rare inflammatory condition that affects the infundibulum, the pituitary stalk, and the neurohypophysis and may be part of a range of autoimmune disorders, including lymphocytic hypophysitis. Lymphocytic hypophysitis occurs mainly in women and most often presents in the later stages of pregnancy. Infundibulohypophysitis shows no sexual predilection and usually presents with diabetes insipidus. The cause is unclear.

A lesion similar to orbital pseudotumor characterized by chronic inflammation and fibrosis has been reported to involve the parasellar tissues associated with other sclerosing lesions, such as Riedel's thyroiditis, retroperitoneal fibrosis, and sclerosing cholangitis. The etiology and appropriate management of these disorders are uncertain.

METABOLIC LESIONS

Neurodegenerative Processes

Alzheimer's disease, Parkinson's disease, Huntington's chorea, and other neurodegenerative diseases can involve the hypothalamus, resulting in variable endocrine, behavioral, and vegetative abnormalities.

Systemic Processes

Wernicke's encephalopathy can alter hypothalamic function, but usually the manifestations are due to mamillary body degeneration. Hemochromatosis results in hypogonadotropic hypogonadism, but this is thought to be due to iron deposition in the pituitary gonadotrophs rather than a primary hypothalamic lesion.

CYSTIC LESIONS

Rathke's Cleft Cysts

These cysts originate in the remnants of Rathke's pouch of the pituitary. Rathke's cleft arises from the oropharynx and migrates upward with an anterior and posterior limb that ultimately give rise to the anterior and intermediate lobes of the adenohypophysis, respectively. In the human, the intermediate lobe is vestigial, and its remnants line small cystic cavities that are remnants of the cleft and usually <5 mm in diameter. When they enlarge and become detectable, they can cause symptoms. Initially the symptoms are hypopituitarism and diabetes insipidus, due to sellar compression. When they develop suprasellar extension, symptoms of hypothalamic involvement ensue. There are rare cases of purely suprasellar Rathke's cleft cysts, and occasionally abscess formation develops within these lesions.

They usually present in adults but do occur in infants and young children. Computed tomography (CT) scans reveal low-density cystic areas with capsular enhancement in most cases; the magnetic resonance imaging (MRI) appearance is variable. Morphologic examination reveals a cyst lining characterized by ciliated cuboidal or columnar epithelium resembling respiratory epithelium, with occasional goblet cells and squamous elements. The degree of ciliation and the propensity for squamous metaplasia distinguish these cysts from the neuroepithelial-derived colloid cysts of the third ventricle.

The management of these lesions involves surgical drainage with or without partial excision. The

recurrence rate is low. Most symptoms and signs are relieved postoperatively, but permanent hypopituitarism and diabetes insipidus require hormone replacement therapy.

Arachnoid Cysts

These lesions may be congenital anomalies or acquired cysts in the arachnoid of the sellar and suprasellar region. The cystic nature of these lesions evident on CT or MRI scans may make it difficult to distinguish them from other cysts that occur in this area. These cysts are filled with clear, colorless fluid and are lined by arachnoid laminar connective tissue with a single layer of flattened epithelium. These lesions are also managed by drainage, with partial cyst wall excision.

Dermoid and Epidermoid Cysts

Dermoid and epidermoid cysts arise from epithelial cells that are misplaced during embryologic development or, rarely, traumatically. Epidermoid cysts are also known as cholesteatoma. These epithelial cysts can occur intracranially, most commonly at the cerebellopontine angle but often in the suprasellar area.

The cystic nature of these lesions evident on CT or MRI scans may make it difficult to distinguish them from other cystic lesions in this area. Epidermoid cysts are lined by keratinizing squamous epithelium; dermoid cysts are distinguished by the additional presence of skin appendages, including hair follicles and sweat glands.

Management usually involves surgical resection. Complications include rupture with chemical meningitis due to keratin debris or the development of squamous carcinoma.

Aneurysms

Aneurysms of the carotid arteries can expand to give rise to masses in the suprasellar region that compress hypothalamic structures and result in endocrine and other hypothalamic manifestations. It is important to distinguish these from other cystic lesions prior to surgery.

Meningoencephalocele

Encephaloceles involving the hypothalamus have been reported to cause symptoms of a mass lesion with variable endocrine manifestations.

PRIMARY HYPOTHALAMIC NEOPLASMS

Craniopharyngioma

Craniopharyngiomas are thought to derive from the remnants of Rathke's pouch. They represent up to 13% of intracranial neoplasms and are the most common sellar tumor of childhood. They can occur at any age from infancy to old age, but the peak incidence is from 5 to 20 years. A second small peak occurs in the sixth decade. In some series, males are more often affected than females.

The majority of tumors occur in the suprasellar region; 15% have an intrasellar component. Craniopharyngiomas are usually cystic or may be cystic and solid, and approximately half have radiologically detectable calcification. Although they may be as small as 1 cm, the majority are much larger at the time of diagnosis. Grossly, they are well-circumscribed tumors but there may be little or no capsule at the interface with brain parenchyma. The lesions usually contain a thick oil-like fluid that is described as "black sludge." Cholesterol crystals and calcification may be seen grossly. Rarely, these tumors may contain bone and/or teeth. Microscopically, they are composed of cords or islands of epithelial cells in a loose fibrous stroma and with intervening cysts (Fig. 2). The epithelium usually has an outer palisaded layer, a midzone of stellate epithelial cells, and a superficial keratinizing layer. Masses of keratin often form the nidus for calcification. Occasionally, there is an inflammatory component. Microscopically, the borders are frequently irregular and may be associated with gliosis in the adjacent brain tissue.

Two subtypes of craniopharyngioma have been recognized; however, there is frequent overlap. The adamantinomatous type has a predominance of stellate components, which yields a pattern resembling the dental ameloblastic organ and is similar to that seen in adamantinomas. The papillary variant is less common, rare in children, and believed to have a better prognosis. It is characterized by solid or cystic growth of pseudopapillary squamous epithelium and lacks the palisading, fibrosis, and cholesterol accumulation that characterizes the typical craniopharyngioma.

Craniopharyngiomas are extremely infiltrative. They may cause extensive tissue damage, extending into the hypothalamus and as high as the third ventricle; obstruction of the ventricle may result in hydrocephalus. Rarely, craniopharyngiomas may

Figure 2 Craniopharyngiomas are composed of squamoid epithelium that derives from remnants of Rathke's pouch. The infiltrative lesions destroy hypothalamic parenchyma.

spontaneously rupture or form abscesses. Because of their highly infiltrative nature, they are often incompletely excised surgically. There is a 10–40% recurrence rate, particularly in younger patients. Many surgeons advocate postoperative radiation. There is a single report of malignant transformation of a craniopharyngioma. This occurred on the fifth recurrence after a 35-year history of disease and 8 years following radiotherapy.

Neuronal Tumors

Hypothalamic neuronal tumors are very rare neoplasms that have been reported in the literature as "gangliocytomas" or "ganglioneuromas." These lesions are composed of mature neurons resembling hypothalamic ganglion cells and are capable of producing hypothalamic peptides (Fig. 3). Some researchers prefer to consider these hamartomas because they occur in children and it is thought that they represent developmental anomalies. They are commonly called

ganglioneuromas or gangliocytomas because there is evidence that they represent neoplasms that have their onset in adulthood and are capable of continued growth. Such tumors have also been described in other parts of the brain as extrahypothalamic gangliocytomas. The term choristoma has been applied to describe collections of hypothalamic neurons within the adenohypophysis.

In addition to the usual symptoms of a hypothalamic mass lesion, some of these tumors are hormonally active and cause endocrinopathies that are usually mediated by the pituitary. They have been associated with acromegaly, precocious puberty, Cushing's disease, and amenorrhea-galactorrhea. The most common localization of these peculiar neoplasms is in the hypothalamus or tuber cinereum, with variable involvement of the third ventricle. They may be nodular, pedunculated, sessile, solid, or cystic. They may be within, attached to, or completely detached from the hypothalamus. These tumors may also be found within the parenchyma of the adenohypophysis. They vary from microscopic lesions composed of only a few cells and measuring a few millimeters to masses that measure more than 5 cm. In particular, hypothalamic hamartomas associated with acromegaly often present as a solitary intrasellar mass that mimics a simple pituitary GH-producing pituitary adenoma; microscopic examination reveals a gangliocytoma associated with a pituitary adenoma in such cases. They are composed

of randomly oriented large mature ganglion cells with large nuclei and very prominent nucleoli; binucleated and even multinucleated cells are seen. Most of the ganglion cells contain abundant cytoplasm, and Nissl granules are conspicuous at the periphery of the cell body. Some tumors have a glial stroma.

In patients with acromegaly, the ganglion cells may contain GHRH (Fig. 3B), glucagon, somatostatin, vasoactive intestinal peptide (VIP), corticotropin-releasing hormone (CRH), GnRH, or gastrin; associated pituitary adenomas generally contain GH but some patients have somatotroph hyperplasia and, rarely, no pituitary abnormality is identified. In patients with amenorrhea-galactorrhea, prolactin and VIP have been localized in the cytoplasm of ganglion cells. One patient had an associated lactotroph adenoma; another had a mixed GH- and prolactin-producing pituitary adenoma. Tumors associated with Cushing's disease contain CRH and may also express ACTH, β -lipotropin, and somatostatin; they have been associated with corticotroph hyperplasia or corticotroph adenoma. Children with precocious puberty have neuronal tumors that contain GnRH but may also contain immunoreactivity for CRH, β -endorphin, and oxytocin. Some gangliocytomas not associated with clinical evidence of hormone excess show multiple immunoreactivities, including positivity for VIP, galanin, α -subunit of glycoprotein hormones, somatostatin, and serotonin. In a few cases, there is

Figure 3 Hypothalamic gangliocytoma. (A) The tumor is composed of ganglion cells resembling those of the normal nuclei of the hypothalamus but lacking organization and containing abnormal binucleate neurons. (B) The tumor cells of this gangliocytoma associated with acromegaly contain GHRH immunoreactivity.

ultrastructural evidence of an intimate association between neurons and adenohipophysial cells, both adenomatous and nontumorous, supporting the theory of an endocrine relationship.

The pathogenesis of these lesions is not known. Their association with pituitary adenomas in some patients suggests that there may be a common causative mechanism. It has been suggested that sellar gangliocytomas may arise by abnormal differentiation during neoplastic proliferation of adenohipophysial cells. However, it is more likely that these tumors have a true hypothalamic origin. It may be that the same tumorigenic stimulus results in tumors of both hypothalamus and pituitary.

These tumors are diagnosed at the time of surgery and cure has resulted from complete surgical resection in several published cases. However, despite the apparent cure of the endocrine disturbance, there may be radiographic evidence of residual tumor. When surgery cannot accomplish total resection of the lesion, the prognosis is varied. Most of these neuronal tumors have an extremely low proliferative potential and the overall prognosis is good. A few have caused severe hypothalamic destruction and have resulted in the demise of the patient. Radiotherapy appears to ameliorate hormone excess in these patients, but it does not appear to be effective in preventing regrowth of the neuronal tumor.

Gliomas

Gliomas are neoplasms derived from and composed of neuroglial cells. They include astrocytomas and glioblastoma multiforme, oligodendrogliomas, and ependymomas. These tumors show a wide range of biologic behaviors.

Aggressive, rapidly lethal malignant gliomas or glioblastoma multiforme in the hypothalamus occur following radiotherapy for pituitary adenoma, craniopharyngioma, or suprasellar germinoma. These tumors can occur 5–25 years after conventional radiation doses of 42.5–66 Gy. Glioma of the optic nerve is rare and usually occurs in children or adolescents who are predisposed due to neurofibromatosis or Beckwith–Wiedemann syndrome.

The radiologic features vary with the tumor type. On CT scan, low-grade astrocytomas are low-density lesions that do not enhance with contrast; enhancement suggests malignant transformation, particularly if it is peripheral to a central hypodense area of necrosis, as seen in glioblastoma multiforme. On MRI, astrocytomas usually have high T2-weighted signal intensity.

The most common glioma in the sellar region is the pilocytic astrocytoma. Most common in children, hence the term juvenile type, this is a relatively discrete, often cystic mass with prominent enhancement on CT scan. These tumors usually arise in the wall of the third ventricle, where they displace and compress the optic chiasm; they may also arise in the optic nerve, usually at the chiasm. The low-grade lesions in children have a relatively good prognosis because they grow slowly, but chiasmal lesions can be more aggressive. In contrast, optic gliomas that occur sporadically in adults are usually rapidly fatal tumors.

Meningiomas

Meningiomas are tumors derived from the meninges and their derivatives in the meningeal spaces. They may arise from dural fibroblasts or pial cells, but the most common are of arachnoid origin. Approximately 20% of tumors of arachnoid and meningotheial cells occur in the sellar and parasellar area; they are most common in the sphenoid ridge and tuberculum sellae but also occur in the clivus. Occasionally, meningiomas have arisen in the sellar region following irradiation of the area for pituitary adenoma or craniopharyngioma. These tumors are more common in women than in men, possibly due to their expression of progesterone receptors and estrogen receptors.

Meningiomas are histologically diverse tumors. The more familiar types and the most common in the suprasellar hypothalamic area are the meningotheial, fibrous or fibroblastic, and transitional variants. Papillary patterns and anaplastic changes portend a more aggressive behavior and the possibility of metastases.

The management of these lesions is generally surgical resection. These highly vascular lesions can create problems with intraoperative bleeding.

Chordomas

Chordomas are rare lesions thought to derive from remnants of the notochord. They occur in the midline, most often in the sacral region, but also in the region of the clivus and occasionally in vertebrae and within the sella turcica. These slowly growing but locally aggressive neoplasms usually occur in patients older than 30 years of age, but patients with the unusual sphenoid lesions tend to be younger.

Chordomas are usually lobulated, calcified, and expansile osteolytic lesions that may cause characteristic elevation of the periosteum, in which case they may be suspected on the basis of the radiologic

findings. They have a characteristic gelatinous gross appearance and may have areas of calcification. Histologically, they are composed of large polyhedral cells with a characteristic bubbly or “physaliphorous” vacuolation. The tumor cells have immunohistochemical markers of epithelial differentiation, keratins and epithelial membrane antigen (EMA), as well as S100 protein and vimentin. Some exhibit positivity for carcinoembryonic antigen. High-grade sarcomatous areas may herald dedifferentiation and are sometimes seen in metastatic deposits. These aggressive variants are rare in intracranial chordomas. In contrast, the sphenoid-occipital region is the preferred site of the “chondroid” variant, which exhibits areas of cartilaginous differentiation that may dominate the histologic picture. These chondroid chordomas lack keratin and EMA positivity and are considered by some to be chondrosarcomas. This variant has a better prognosis than the usual clival chordomas.

Surgery is the preferred initial therapeutic approach; however, the location and extent of tumor may make complete extirpation impossible. Radiotherapy is indicated for incompletely resected lesions. Mean survival is approximately 4 or 5 years, and metastases to lung, liver, bone, and lymph nodes occur rarely.

Schwannomas

Tumors composed of spindle-shaped Schwann cells derive from cranial nerves; they are also known as neurilemmoma or neurinoma. Hypothalamic and parasellar schwannomas occur rarely. On CT scan, these lesions are visualized as sellar or parasellar masses that enhance with contrast and can mimic pituitary adenoma. They are hypovascular on angiography.

The morphology of these lesions in the pituitary region is identical to that of schwannomas elsewhere. These tumors are usually encapsulated and sometimes cystic lesions composed of spindle-shaped cells arranged in compact Antoni type A and loose Antoni type B areas. The former may exhibit palisading that leads to the formation of Verocay bodies. Immunohistochemical staining for S100 protein is strong in these lesions. Using electron microscopy, these tumors are recognized by the prominent basal lamina surrounding individual cells and by the characteristic “long-spacing” collagen of the stroma.

Similar to Schwannomas elsewhere, these lesions are usually benign and are amenable to surgical resection unless they involve critical structures in the parasellar region, in which case conservative surgical resection is indicated.

Germ Cell Tumors

These tumors are derived from germ cells that are residual along the midline; they are identical to germ cell tumors of the gonads and mediastinum. Intracranial germ cell tumors represent less than 1% of intracranial neoplasms, but in children they constitute up to 6.5% of such lesions. After the pineal, the suprasellar region is the second most common site of involvement. These tumors occur most often before the age of 20 years and occur more often in males than in females.

The most common type, the germinoma, is usually a well-demarcated tumor that has high density on CT scan and enhances with contrast. Teratomas may exhibit fat densities and calcifications that are recognized radiologically. Whereas the CT appearance of some of the other germ cell tumors may not be distinctive, MRI is more sensitive and can show features that are obscured on CT scan.

The classification of parasellar and intrasellar germ cell tumors includes teratomas, germinomas, embryonal carcinomas, endodermal sinus tumors, and choriocarcinomas. Germinomas and teratomas predominate, and mixed germ cell tumors that show features of more than one tumor subtype are frequent, usually germinoma combined with one of the other tumor types or a combination of embryonal carcinoma and immature teratoma, known as teratocarcinoma. Recognition of even minor components that are characterized by more aggressive elements can predict a worse prognosis and may alter management.

If the diagnosis is suspected preoperatively, biopsy can be performed to type the lesion and determine whether surgery or other modalities, such as radiation or chemotherapy, are indicated. Germinomas are uniquely radiosensitive and long-term remission is achieved in approximately 70% of patients. The recognition of more aggressive elements in mixed tumors can predict failure of radiotherapy. Other tumors are more aggressive, and despite surgery, radiation, and chemotherapy, they may recur or metastasize both within and beyond the central nervous system. Seeding via ventriculoperitoneal shunt may also result in dissemination.

Vascular and Mesenchymal Tumors

These tumors arise from vessel walls, fibrous connective tissue and fat, bone, and cartilage. They are rare in this area and can be benign or malignant.

The development of sarcoma in this region may be sporadic but more commonly is the result of previous

ionizing irradiation. There are several reports in the literature of osteosarcoma and fibrosarcoma of the sella developing 4–21 years after irradiation for pituitary adenoma or craniopharyngioma. These aggressive neoplasms result in the rapid demise of the patient.

SECONDARY NEOPLASMS

Pituitary Adenomas

Pituitary adenomas are common lesions, occurring in 20–27% of the population, and at least one-third of these give rise to clinical manifestations. Many of these tumors exhibit suprasellar or parasellar invasion involving the hypothalamus.

Metastatic Carcinoma

Cranial metastasis is a manifestation of a systemic and usually terminal malignancy (Fig. 4). The most common primary sites of these lesions are the lung, breast, and gastrointestinal tract. Most hypothalamic metastases are not associated with specific clinical symptomatology and are therefore found incidentally at autopsy. Patients may present with diabetes insipidus, and large tumors may cause headache, visual field defects, ophthalmoplegia, and ptosis. Rarely is there an endocrine manifestation, usually resulting in hypopituitarism. A few reported cases have identified hormone excess, and usually the culprit is ectopic ACTH production in a location that mimics primary pituitary Cushing's disease. A fascinating case of CRH production by a hypothalamic metastasis of prostate small cell carcinoma resulted in pituitary corticotroph hyperplasia.

Since these patients have disseminated malignancy, therapy is aimed at palliation. Surgical decompression with or without radiotherapy can relieve symptoms.

Lymphoma and Leukemia

Tumors of leukocytic, lymphocytic, or plasmacytic differentiation are usually systemic disorders. Very rarely, lesions in the region of the hypothalamus appear to be solitary and primary at that site. As in the central nervous system in general, lymphoma or leukemia are most often meningeal and extradural.

Lymphomas are seen on MRI as masses with signals of similar intensity to those of their surroundings on T1-weighted images, but they are hyperintense on T2-weighted views. They enhance with contrast media and usually in a uniform pattern.

Histologically, the lymphomas of the central nervous system resemble systemic lymphomas. They are almost always non-Hodgkin lymphomas with a diffuse rather than follicular pattern; the majority are B cell tumors. Plasmacytomas are composed of well-differentiated plasma cells.

Figure 4 Metastatic tumor. (A) In this case of Langerhans cell histiocytosis, the lesion infiltrates and destroys normal hypothalamus. (B) This metastatic small cell lung carcinoma has replaced the arcuate nucleus and invades the infundibulum and superior pituitary stalk.

Langerhans Cell Histiocytosis

The disorder formerly known as histiocytosis X, encompassing eosinophilic granuloma, Hand–Schüller–Christian disease, Letterer–Siwe disease, Langerhans cell granuloma, and several other eponymic variants, is now classified as Langerhans cell histiocytosis. This localized, multifocal, or disseminated proliferation of epithelioid histiocyte-like Langerhans cells is thought to be a reactive rather than neoplastic process with an immunologic aberration underlying its etiology. The classical presentation of Hand–Schüller–Christian disease involves the hypothalamus, and the disorder may involve the pituitary gland.

CT scans of Langerhans cell histiocytosis are characterized by ill-defined contrast-enhancing hypodense masses with areas of edema. MRI can detect the small multifocal lesions of this disorder more readily than CT scan; these lesions may be hypointense but can have slightly increased T1 contrast and intense T2-weighted images. Involvement of the pituitary stalk is characteristic of this disorder and may precede clinical manifestations of the disease.

Langerhans cells are characterized by an epithelioid, histiocyte-like appearance. They have kidney-shaped nuclei and abundant cytoplasm and stain for CD1 and S100 proteins. They are admixed with chronic inflammatory cells, foamy macrophages, and eosinophils. By electron microscopy, they contain pathognomonic Birbeck granules that allow a definitive diagnosis.

The prognosis of this disorder is variable. When systemic involvement is manifest, it is frequently lethal and apparently isolated lesions can progress rapidly to widely disseminated disease that is unresponsive to any form of therapeutic intervention. Surgery has been reported to be curative of localized lesions, and radiotherapy has been used postoperatively with success in cases of isolated involvement of this region.

increases a genetic transmission, and X-linked and autosomal KS pedigrees have been reported. The gene implicated in Kallmann syndrome, *Kal*, is located at Xp22.3. The protein encoded by the *Kal* gene, anosmin, shows structural homologies to proteins involved in the neural development. Anosmin is thought to function as a substrate adhesion molecule necessary for establishing normal connections between olfactory axons and the mitral cells of the olfactory bulb. Xp22.3 deletions and a number of different *Kal* point mutations have been described. The role of these mutations is unclear, especially when considering discordances in the phenotype of brothers bearing the same mutation.

In X-linked Kallmann syndrome, there is a well-demonstrated link between GnRH deficiency and the dysgenesis of the olfactory structure that can be anatomically evidenced by nuclear magnetic resonance in most patients. *Kal* mutations have not been found in normosomic patients; however, it is still unclear whether Kallmann syndrome and HH with normosomia are distinct entities. In addition to anosmia, a variety of abnormalities have been described in Kallmann syndrome. These include synkinesias, renal agenesis, sensorineural defects not observed in normosomic patients, and rarer defects such as cryptorchidism and eye movement disorders. Craniofacial palate defects can be present in both situations.

Although X-linked Kallmann syndrome is the best characterized form, autosomal mutations in genes not yet identified have been found to account for the majority of cases of this condition. In 106 patients studied at Massachusetts General Hospital, only 11% of the familial cases were X linked and less than 5% of the sporadic cases were found to bear mutations in the *Kal* gene. The most obvious candidate gene for GnRH deficiency is the GnRH gene; however, to date, alterations at 8p21–p12, where this gene is located, have not been demonstrated.

Neonatal adrenal insufficiency, caused by *DAX1* missense or nonsense mutations, is also associated with idiopathic hypogonadotropic hypogonadism (IHH). Because earlier diagnosis and adequate treatment of the adrenal insufficiency have allowed these patients to reach adult age, secondary hypogonadism has become a component of this syndrome.

Late Onset

An acquired form of isolated GnRH deficiency, defined as adult-onset IHH, has been described. These patients have a normal pubertal development followed by a clinical picture of hypogonadism. The endocrine profile is indistinguishable from that of patients with congenital GnRH deficiency, being characterized by low circulating levels of testosterone and an absence of the normal pulsatile pattern of gonadotropin. Most of these patients normalize their pituitary gonadal axis during pulsatile GnRH administration. This form differs from hypothalamic amenorrhea in that it lacks any precipitating factor such as exercise, stress, or weight loss and also is irreversible. However, in a small subset of patients, the gonadal function remains normal even after the cessation of GnRH therapy. These patients may represent an incomplete form of GnRH deficiency that is relieved by the priming effect of treatment or, alternatively, by forms of very delayed puberty.

The fertile eunuch syndrome is also thought to represent an incomplete form of GnRH deficiency. The pathophysiology of this disorder may be due to a secretion of endogenous GnRH sufficient to support spermatogenesis and testicular growth but not testosterone levels adequate for a normal virilization. Delayed puberty may also be a mild form of partial GnRH deficiency.

Functional

In these circumstances, the failure of GnRH to be released is transient and frequently leads to so-called

hypothalamic amenorrhea. A syndrome of functional GnRH deficiency is less recognizable in men mostly due to the lack of a clear clinical marker. There are some data to suggest that caloric restriction or strenuous physical exercise lowers testosterone levels.

Hypothalamic Amenorrhea

Idiopathic amenorrhea is a diagnosis of exclusion and generally refers to the cessation of menstrual cycles in young women without demonstrable organic abnormalities of the pituitary gonadal axis. Stressful factors are associated with the onset of hypothalamic amenorrhea such as emotional events, exercise, and weight loss. From a hormonal point of view, hypothalamic amenorrhea is characterized by hypoestrogenism with low-normal gonadotropin and normal prolactin (PRL) levels. The frequency and amplitude of the gonadotropin pulses are diminished, and in some cases a pubertal pattern with amplification of pulsatility of luteinizing hormone (LH) during sleep can be demonstrated. The pattern of ovarian steroid secretion varies in relation to the clinical situation. In severe cases, when only minimal changes in gonadotropin levels can be detected, hormonal ovarian activity is virtually absent. When gonadotropin pulses are still detectable, albeit diminished in number and amplitude, estrogens and androgens are measurable and spontaneous, although erratic menses may occur. The initial phases of hypothalamic amenorrhea are often characterized by an inadequate luteal phase.

There is increasing evidence that idiopathic amenorrhea can be the result of endocrine and metabolic responses to a restriction in food intake. Evidence of subclinical eating disorders has been shown in hypothalamic amenorrhea, particularly as reduction in fat intake. This circumstance also occurs in women with stable weight who are nonathletic, harboring levels of emotional distress or depression not different from those of menstruating controls. It is currently thought that stress may contribute to a disordered eating behavior but that it is not directly responsible for the menstrual alterations. Actually, weight loss observed in patients with eating disorders, particularly in those with anorexia nervosa, is the most obvious cause of hypothalamic amenorrhea, and a similar condition is also observed in women with low body weight and reduced fat stores such as female athletes.

The disruption of the physiological pulsatile secretion of GnRH neurons is probably due to changes in the activity of neuroendocrine circuits involving neuropeptides such as neuropeptide Y (NPY), opioids, corticotropin-releasing factor (CRF), and neurotransmitters (e.g., dopamine, noradrenaline,

γ -aminobutyric acid (GABA), serotonin). However, reliable evaluations of these factors cannot be made, so their role in the pathophysiology of hypothalamic amenorrhea is undefined.

Recently, the role of leptin, a peptidic hormone produced by adipocytes, has gained relevant importance in the regulation of the reproductive axis. Leptin is an indicator of nutritional status; thus, it may trigger changes in GnRH pulsatility in response to reduced fat stores. Whether the subtle alterations of adrenal function and the increased levels of β -endorphins found in patients with hypothalamic amenorrhea are of clinical relevance is still to be established.

Pathological Hyperprolactinemia

Patients with macroprolactinoma (i.e., adenoma diameter > 1 cm) suffer from a disorder of gonadal function due to both tumor mass effect and hyperprolactinemia, but in microadenoma patients or in drug-induced hyperprolactinemia, hypogonadism recognizes a functional origin due to neuroendocrine effects of elevated PRL levels that impairs pulsatile release of GnRH and ultimately that of gonadotropin. According to the hypothesis of Scanlon, it is possible that hyperprolactinemia enhances dopaminergic tone at the hypothalamic levels with a consequent inhibitory effect on gonadotropin release.

Organic

Structural lesions of the hypothalamus can interfere with the neuroendocrine regulation of GnRH. In these conditions, the impairment of gonadal function is almost invariably associated with deficiency of other pituitary functions. In children, the most common form of hypothalamic hypogonadism is craniopharyngioma presenting with visual field defects, growth failure, and/or diabetes insipidus. Other common hypothalamic tumors such as meningiomas, dysgerminoma, and gliomas are accompanied by hypogonadism. Secondary hypothalamic localizations of breast tumors in women and lung tumors in men may also determine secondary gonadal impairment generally associated with diabetes insipidus.

Infiltrative disorders of the hypothalamus, such as sarcoidosis, histiocytosis, and hemochromatosis, may also cause hypothalamic hypogonadism as well as radiotherapy for central nervous system (CNS) tumors or leukemia.

Miscellaneous Disorders

Secondary hypogonadism with the characteristics of HH is found in genetic conditions such as

Prader-Willi syndrome, Bardet-Biedl syndrome, and Moebius syndrome (i.e., the association of congenital ophthalmoplegia and facial paresis). In a single patient with this latter syndrome, the association with hypogonadism and anosmia has been reported. HH resistant to treatment with GnRH has been reported in a patient with Gordon Holmes spinocerebellar ataxia.

DIAGNOSIS

As a form of secondary hypogonadism, hypothalamic hypogonadism is characterized by signs and symptoms of gonadal failure, low levels of gonadal hormones, and low levels of gonadotropin. This latter finding is not absolute given that a single evaluation of follicle-stimulating hormone (FSH) and LH, particularly in the acquired forms, may display levels in the normal range. Actually, the marker of the hypothalamic disturbance is represented by alterations in gonadotropin pulsatility.

In general, the most severe forms of congenital hypogonadism in patients who show no evidence of puberty are associated with no detectable pulses of gonadotropin when examined by serial samples at 10- to 20-min intervals for 12 to 24 h. Pulses of normal frequency but of reduced amplitude attributed to impaired responsiveness of the GnRH receptors may also be observed.

In patients with acquired hypogonadism, the unpulsatile pattern of gonadotropin strongly suggests an organic cause or is associated with severe nutritional disturbances as in anorexia nervosa. In patients with the functional form, there is generally only a decrease in pulse frequency with a pattern similar to that observed during the early follicular phase of the cycle.

In patients with hypogonadotropic hypogonadism, the possibility of an organic disease of the hypothalamic-pituitary region must always be considered. Nuclear magnetic resonance imaging is always indicated in male patients and in females without a clear-cut history of functional amenorrhea. A determination of basal PRL levels must always be performed together with a gonadotropin assessment. Supranormal PRL levels, in the absence of other causes of hyperprolactinemia such as primary hypothyroidism, renal or liver failure, and treatment with antidopaminergic agents, render nuclear magnetic resonance imaging mandatory. In particular, marginally elevated PRL levels (i.e., in the range of 40–120 ng/ml) should be viewed as strongly suspected for a space-occupying lesion at the hypothalamic level that impairs the dopamine delivery to the lactotrophs. PRL levels above 120 ng/ml are diagnostic for a PRL-secreting adenoma.

When basal PRL levels have been carefully evaluated by means of at least three samples taken at bed rest and during saline infusion to avoid stress-related elevation of the hormone levels, dynamic tests such as thyrotropin-releasing hormone (TRH) injection are definitely of no value. When neuroradiology has identified an organic disease, an evaluation of the thyroid, adrenal function, and growth hormone (GH) secretion should be performed.

TREATMENT

The treatment of HH depends on the nature of the disease and on the goal to be achieved in relation to pubertal stage and desire of fertility. In prepubertal patients, gonadal hormones should be administered at low initial doses that are increased gradually to obtain the development of secondary sexual characters. In men, long-acting preparations of testosterone are effective, starting with 50 mg monthly and increased by 50 mg every 3 to 6 months. Alternatively, low doses of human chorionic gonadotropin (hCG) have the advantage of stimulating testicular growth.

In females, the therapy can be started with low doses of estrogens, for example, 5 µg of ethynyl estradiol to obtain breast development, followed by a cyclical therapy in combination with a progestin. During adulthood, different approaches should be followed depending on whether fertility is desired. If fertility is not desired, the goal of the treatment in men is to maintain virilization, normal sexual function, and adequate muscle and bone mass. Usually, 100 to 200 mg of long-acting testosterone esters are given every 2 to 4 weeks, although the dosage can be adjusted to obtain a testosterone level in the lower end of the normal range before the injection of the next dose. The disadvantage of this route of administration is an unfavorable pharmacokinetic profile often characterized by supranormal levels during the first week after the injection. Testosterone undecanoate, an orally administrable preparation, has an absorption that is influenced by diet composition.

The transdermal testosterone preparations applied to scrotal skin or, more recently, to nonscrotal skin provide an effective method of substitutive treatment with the drawbacks of high cost and frequent skin irritations. Testosterone implants are also an effective, albeit not readily available, way in which to treat hypogonadism.

In female patients, substitutive treatment is carried out with low-dose pills or with conjugated estrogens or transdermal estradiol associated with cyclic progestin to achieve endometrial protection. If fertility is desired,

the treatment has to be carried out with pulsatile GnRH, gonadotropins, or clomiphene citrate.

In men, pulsatile GnRH therapy is practically performed by subcutaneous route of injection through a portable pump, although intravenous administration produces the most physiological pattern of gonadotropin secretion. The dose per bolus is highly variable, ranging from 25 to 600 ng/kg delivered every 120 min. The dose is individually tailored to achieve normalization of testosterone and gonadotropin levels. This route of therapy is effective in obtaining spermatogenesis in the majority of patients, with treatments lasting up to 2 years or even longer in patients with very small basal testicular volume. When testicular volume reaches 8 ml, semen analyses are obtained.

Gonadotropin treatment is carried out by a combination of hCG and recombinant FSH. The starting schedule is 500 to 2000 IU of hCG two or three times weekly, followed after 6 months by FSH (75 IU three times weekly) in relation with testicular growth and induction of spermatogenesis. In patients with adult-onset HH, spermatogenesis may be induced by the use of hCG alone.

The main side effect of gonadotropin treatment is gynecomastia, which can be minimized by reducing hCG doses to keep testosterone levels at the lowest limit of the normal range.

The therapeutic approaches to achieving fertility in women are similar to those in men, but the treatment with gonadotropin in women is slightly less effective in terms of cumulative rate of contraception and is more tolerated in terms of multiple folliculogenesis than that with GnRH. The better results obtained by GnRH are probably due to the fact that it is possible to mimic the hormone dynamics of a normal

menstrual cycle and to achieve the maturation of a single follicle.

When ovulation by gonadotropin therapy is needed, treatment is started with 150 IU of FSH and the dose is increased until the levels of estradiol begin to rise. Follicular growth is monitored by ultrasound, and follicular rupture is induced by 10,000 IU of hCG. In patients with the acquired form of hypothalamic amenorrhea, induction of ovulatory cycles can also be attempted by clomiphene citrate (50 mg/day for 5 days).

Figure 1 Serum levels of FT4 and TSH in patients with central hypothyroidism. Dashed lines indicate the lower and upper limits of the normal ranges. The evident lack of correlation between TSH and FT4 demonstrates that quantitative impairment of TSH secretion does not completely explain the pathogenesis of CH and indicates the involvement of qualitative alterations of hypothalamic regulation in a large portion of CH patients, particularly those with prevalent hypothalamic defects.

role played by hypothalamic factors in the generation of circadian TSH rhythm.

The differential diagnosis of CH is indicated by circulating levels of immunoreactive TSH: High TSH is typical of patients with prevalent hypothalamic defects (HH), whereas low TSH indicates the almost complete lack of functional thyrotropes (pituitary or secondary hypothyroidism). In CH patients with normal TSH, important information on the entity of hypothalamic impairment can be obtained by TRH testing. Indeed, differential diagnosis of CH is one of the residual indications for TRH tests. Pure HH is characterized by delayed/exaggerated/prolonged responses of immunoreactive TSH after intravenous injections of TRH (0.2 mg), but net TSH responses >4.0 mU/liter can be considered indicative of a prevalent hypothalamic defect. Conversely, blunted TSH responses (<4.0 mU/liter) are typical of a prevalent pituitary defect.

Before giving the diagnosis of HH (or CH), one should exclude the presence of “nonthyroidal illnesses” leading to the biochemical picture of the low T3 syndromes. These conditions include acute (e.g., myocardial infarction, severe infections, and extended burns) and chronic (e.g., liver or kidney insufficiency) diseases, fasting (as in anorexia nervosa), or recovery from general surgery. They also occur in patients with

an intact hypothalamic–pituitary–thyroid axis. In contrast to HH, these conditions are generally characterized by low T3 but normal TSH and FT4. Reduction of circulating TSH and FT4 occurs only in prolonged and manifest disease states and is likely due to suppression of hypothalamic TRH gene expression.

CLINICAL PRESENTATION

Depending on the cause of CH, some characteristics of the disease may vary greatly. In general, CH of genetic origin is found in familial settings, the defect is congenital, and the onset generally occurs in early infancy with severe hypothyroid manifestations. In these cases, the defect is classically located in the pituitary, although a typical form of hypothalamic defect with mild CH manifestations is seen in patients with resistance to leptin. Genetic CH can be either isolated or combined with other pituitary hormone deficiencies (CPHD) and can be associated with growth disorders, delayed puberty, and/or neurological defects. Neonatal forms of CH are not recognized in the screening programs for congenital hypothyroidism based on TSH evaluation in dried blood spot, and neurological defects may become more severe if the clinical diagnosis and start of treatment are delayed. Nevertheless, several genetic forms of CPHD have delayed and progressive onset of hypothyroidism beyond the vulnerable period of central nervous system development during infancy and childhood.

Nongenetic CH is typically sporadic and acquired in most cases as the consequence of large sella tumors. Among the lesions potentially leading to CH, those more frequently associated with hypothalamic defects include large pituitary macroadenomas with suprasellar extension, craniopharyngiomas and suprasellar tumors, and those due to cranial irradiation, vascular accidents, and head traumas. In these situations, defects of posterior pituitary function with diabetes insipidus as well as visual field defects due to compression of the optic nerves may be concomitant. These lesions generally affect both pituitary and hypothalamic functions to various extents, leading to mild hypothyroidism, always combined with defects of other anterior pituitary hormones and frequently associated with high PRL levels due to stalk resection or compression. The association with signs and symptoms secondary to the altered secretion of other pituitary hormones (e.g., menstrual disorders, decreased libido, hair loss, galactorrhea, pallor, and altered lipid metabolism) or to local compression (visual defects,

headache, etc.) may cover the specific hypothyroid manifestations in several cases. Therefore, TSH and FT4 should always be included in the biochemical evaluation of patients with hypothalamic–pituitary diseases.

PATHOGENESIS

The pathogenesis of typical HH is due to defects affecting the function of hypothalamic TRH neurons. These defects occur in various pathological conditions, including large pituitary macroadenomas with suprasellar extension, craniopharyngiomas and suprasellar tumors (such as meningiomas or gliomas), cranial irradiation, vascular accidents (including Sheehan's syndrome), head traumas (including traumatic delivery), and infiltrative diseases (such as sarcoidosis). As shown in Fig. 1, quantitative impairment of TSH secretion does not completely explain the pathogenesis of CH, and it indicates the involvement of qualitative alterations of hypothalamic regulation in a large number of CH patients, particularly those with prevalent hypothalamic defects. Some patients with CH of hypothalamic origin have normal or even elevated circulating TSH levels. The lack of any sign of primary thyroid insufficiency (absent anti-thyroid autoantibodies and normal response to exogenous TSH injection) suggested that hypothyroidism in these patients may result from the secretion of biologically inactive TSH molecules. This hypothesis was indirectly supported by the blunted T3 response to endogenous TRH-stimulated TSH, despite exaggerated and prolonged responses of endogenous TSH to the tripeptide. The very low bioactivity of TSH molecules circulating in several patients with hypothalamic CH of various origins (idiopathic, secondary to pituitary or hypothalamic tumors, or due to cranial irradiation or Sheehan's syndrome) was obtained by different bioassays. The reduced bioactivity was due to an impaired binding of circulating TSH to its specific thyroid receptor. Chronic TRH treatment restored both TSH receptor binding and bioactivity, indicating that this hypothalamic factor is necessary for the secretion of TSH molecules with structural features essential for appropriate thyroid stimulation. Lectin affinity chromatography showed that the oligosaccharide structure of TSH molecules circulating in hypothalamic CH is altered. The description of TRH knockout mice with the same biochemical picture as that of patients with hypothalamic CH has given definitive support for the pathogenic role played by TRH deficiency in this syndrome.

Genetic alterations associated with HH in humans are limited to defects in the gene encoding leptin receptor (leptin-R), a typical cytokine receptor involved in the complex network regulating food intake and body weight. Homozygous or compound heterozygous mutations leading to the production of inactive leptin-R mutants have been shown to be associated with a complex phenotype that includes familial obesity and hyperphagia, short stature with growth hormone deficiency, and puberty defects with low gonadotropins and mild hypothyroidism. Hypothyroidism of these patients is typically of hypothalamic origin because they have normal/elevated immunoreactive TSH and delayed/prolonged responses of endogenous TSH to TRH. A possible explanation for the pathogenesis of CH in patients with leptin-R mutations may derive from *in vitro* experiments showing that expression and stimulation of leptin-R result in strong activation of the TRH promoter. Moreover, leptin stimulates release of TRH from primary culture of hypothalamic neurons in a dose-dependent manner.

Another gene possibly involved in human cases of isolated CH is the TRH gene. Indeed, TRH KO mice are viable and are considered the animal model of HH. Similar to what was previously seen in humans with HH, subnormal T3 increases occur in these mice after stimulation of endogenous TSH by TRH, despite an exaggerated response. This finding represents indirect evidence that TSH circulating in these mice is devoid of biological activity. Relative hyperglycemia is apparently the only associated abnormality in TRH KO mice and may represent a distinctive element useful for determining the possible involvement of the TRH gene in human cases.

TREATMENT

As for primary hypothyroidism, treatment of HH is based on the administration of L-thyroxine. Before starting L-thyroxine therapy, particular attention should be paid to possible concomitant corticotropin (ACTH) defects leading to partial adrenal insufficiency. Failure to recognize this concomitant defect may lead to acute adrenal insufficiency during the initial days of therapy. Therefore, screening for adrenal insufficiency, with evaluation of urinary free cortisol and/or low-dose ACTH testing (1 µg), is recommended for patients with HH. Alternatively, treatment with steroids may be advised before starting L-thyroxine.

L-Thyroxine replacement therapy should be tailored for each patient, as in primary hypothyroidism. Nevertheless, this goal is not easily reached for

HH patients because TSH measurement loses any value as a monitoring index. Therapy should be tailored in order to maintain FT₄ (and FT₃) concentrations in the mid-normal range, provided that blood for hormone measurement is withdrawn before the morning of L-thyroxine administration. Evaluation of parameters of thyroid hormone action (such as cholesterol, bone markers, or sex hormone-binding globulin), particularly those not affected by defects in other pituitary functions (e.g., soluble receptor of interleukin-2), could be helpful in case of doubts. Replacement doses range from 1.1 to 1.7 $\mu\text{g}/\text{kg}/\text{day}$ in more than two-thirds of patients and are relatively lower in those older than age 60.

by the ARN and EEN span overlapping neuroanatomical sites in the hypothalamus. Fourth, the onset and termination of appetite or hunger is triggered by discrete neural timing devices in the hypothalamus. Fifth, both the ARN and EEN are subject to moment-to-moment modulation by the internal milieu of hormones from adipocytes, gastrointestinal (GI) tract and endocrine glands, and neural signals from the GI tract.

NEUROANATOMICAL SUBSTRATE FOR ENERGY HOMEOSTASIS

The topography of the ARN and EEN circuitries and the clocks in the hypothalamus is described in this section (Figs. 1–3).

Neuroanatomical Sites Regulating Appetite

Arcuate Nucleus

The arcuate nucleus (ARC), located at the base of the hypothalamus on either side of the third cerebroventricle, is the most important site in the hypothalamic integration of energy balance. Distinct clusters of neurons in the ARC produce orexigenic peptides such as neuropeptide Y (NPY) coexpressed with agouti-related peptide (AgRP) and the amino acid γ -aminobutyric acid (GABA), galanin (GAL) and the opioid dynorphin, and pro-opiomelanocortin (POMC)-derived β -endorphin and α -melanocyte-stimulating hormone (α -MSH) coexpressed with cocaine- and amphetamine-regulating transcript (CART) (Fig. 3). One of the terminal fields of these orexigenic and anorexigenic signal-producing neurons is the paraventricular nucleus (PVN). In addition, NPY-, AgRP-, and GABA-coexpressing neurons communicate directly with POMC neurons in the ARC via their receptors: Y_1 , MC3, and GABA^A, respectively. NPY neurons also communicate with the orexigenic GAL- and dynorphin-producing neurons in the ARC. Thus, an interconnected orexigenic network of NPY and cohorts participates in the daily patterning of energy intake by two modalities: direct activation of Y_1/Y_5 receptors (R) in the PVN and indirect activation by coacting with AgRP and GABA to restrain release of the anorexigen, α -MSH, in the PVN. Furthermore, the ARC is strategically positioned outside the blood–brain barrier to process modulatory impulses from hormones secreted by adipocytes, the GI tract, and endocrine glands.

Interacting appetite-regulating pathways in the hypothalamic regulation of body weight. *Endocrine Rev.* 20, 68–100. Copyright 1999, The Endocrine Society.

Lateral Hypothalamus

Contrary to previous views, the lateral hypothalamus (LH) has been shown to relay excitatory influences to the orexigenic NPY system in the ARC–PVN axis. A distinct subpopulation of neurons producing melanin-concentrating hormone (MCH) and orexin (ORX) stimulate appetite by enhancing NPY release in the PVN. Apparently, these two orexigenic tracts also relay afferent hormonal and neural information on energy status in the body to the NPY ARC–PVN axis.

Ventromedial Hypothalamus

The ventromedial hypothalamus (VMH), including the ventromedial nucleus (VMN), is linked bidirectionally with the ARN in both the ARC and PVN. Because localized disruption of signaling in the VMN produces hyperphagia and leptin insensitivity, it is believed that the VMN restrains the ARN in the daily management of energy balance and may also be an integral component of the timing mechanism in the hypothalamus.

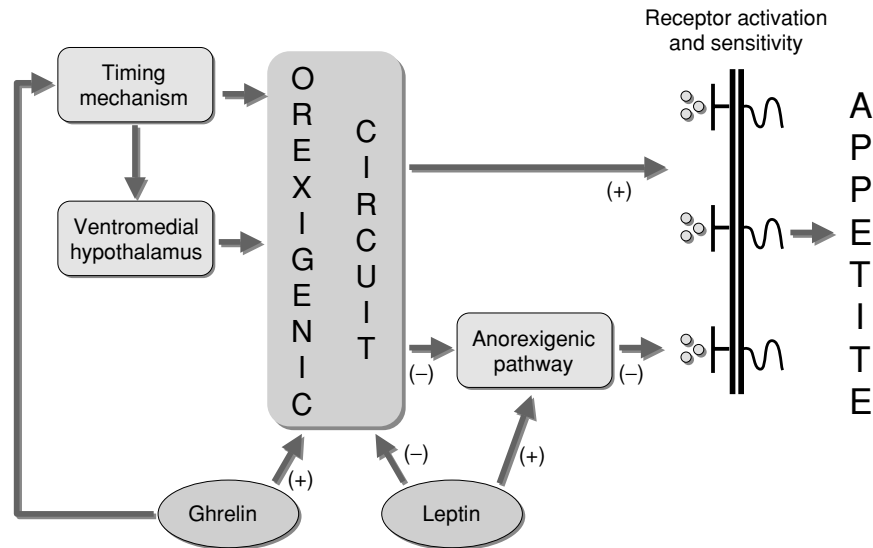

Figure 2 Schematic representation of the basic elements of the hypothalamic circuitry that regulates the daily pattern of feeding. The information from the brain-timing mechanism, entrained to external photoperiodic signals, and the internal clock, driven by hormonal signals (ghrelin), stimulates the orexigenic circuit either directly or indirectly through multisynaptic routes in the medial basal hypothalamus. This results in stimulation of appetite mediated by postsynaptic targets and curbs the tonic restraint of the anorexigenic circuit. Afferent hormonal signals from the periphery, gastric ghrelin and adipocytes' leptin, exert opposing affects on operation of the orexigenic and anorexigenic circuits to assist in timely initiation and termination of appetite. (+) = stimulatory; (-) = inhibitory. Adapted with permission from Kalra, S. P., Dube, M. G., Pu, S., Xu, B., Horvath, T. L., and Kalra, P. S. (1999). Interacting appetite-regulating pathways in the hypothalamic regulation of body weight. *Endocrine Rev.* **20**, 68–100. Copyright 1999, The Endocrine Society.

Paraventricular Nucleus

PVN and its two subdivisions, parvocellular PVN (pPVN) and magnocellular PVN (mPVN), are the terminal fields of the orexigenic and anorexigenic signal-producing neurons. The PVN consists of a heterogeneous population of neurons that fan out on either side of the roof of the third cerebroventricle in the hypothalamus. Target neurons that express postsynaptic receptors for propagation and transmission of signals to either initiate or terminate appetite are resident in the PVN.

Neuroanatomical Sites Regulating Energy Expenditure

Medial Preoptic Area

The medial preoptic area (MPOA) located rostral to the PVN is the only site shown to augment non-shivering thermogenic energy expenditure without affecting appetite. The MPOA is a component of the sympathetic nervous system (SNS), and neurons expressing leptin R transduce and relay energy expenditure information to the brown adipose tissue (BAT) in the periphery.

Neuroanatomical Sites for the Timing Mechanism

Suprachiasmatic Nucleus and the Basal Hypothalamus

Daily meal patterning is a highly regulated phenomenon. Although entrained to external cues of the daily photoperiod and seasonality, it is highly vulnerable to availability of food supply. Animals in the wild or laboratory rodents maintained on an *ad libitum* diet under a controlled light–dark cycle exhibit multiple high-amplitude feeding episodes in the arousal phase during the dark phase in nocturnal animals or during the light phase in diurnal animals. In contrast, humans and subhuman primates maintained in the laboratory consume a few timed meals during the daytime and early hours of the night. Two distinct neural timing mechanisms in the hypothalamus operate upstream from the ARN in the daily trigger of ingestive behavior. Two small round nuclei dorsal to the optic chiasm on either side of the third cerebroventricle, the suprachiasmatic nuclei (SCN), are major coordinators of the internal circadian organization for ingestive behavior. Destruction of the SCN results in unregulated feeding, apparently due to the loss of a “CLOCK”

Figure 3 Model showing the dynamics in the feedback circuitry involved in hypothalamic integration of appetite and energy expenditure. The primary components of the ARN, the orexigenic NPY and coexpressed GABA and AgrP in an interplay with the anorexigenic pathway emanating from POMC and CART coexpressing neurons, stimulate and terminate appetite in a timely fashion, as directed by the timing mechanism. NPY produced and released in the ARC–PVN axis displays two rhythmic efflux patterns (circadian and ultradian), as directed by two functionally opposing rhythmic afferent hormonal signals: leptin from adipocytes and ghrelin from the stomach. Also depicted is the rhythmic feedback relationship in the fat–stomach–pancreas axis in the periphery. See text for details. (+) = stimulatory; (–) = inhibitory; (±) = unresolved. Adapted with permission from Kalra, S., and Kalra, P. (2003). Rhythmic, reciprocal ghrelin and leptin signaling: New insight in the development of obesity. *Reg. Pept.* 111, 1–11.

transcription factor. However, uncoupling meal timing from the circadian clock in primates is regulated by neuronal PAS domain protein 2 (NPAS2) transcription factor in the forebrain sites, VMH, dorsomedial nucleus, subparaventricular zone, and LH. Apparently, a timely interplay between CLOCK and NPAS2 transcription factors, in response to incoming internal and external environmental information, initiates first the anticipatory synthesis and then the timely release of orexigenic peptides in the PVN (Figs. 1 and 2).

OPERATION OF THE HYPOTHALAMIC ARN

NPY and Cohorts

NPY, the most prominent, physiologically relevant, appetite-stimulating neurotransmitter in vertebrates, is produced by two discrete subpopulations of neurons in the hypothalamic ARC and in the brainstem (BS). It is released in the ARC–PVN axis to stimulate feeding by activating the Y_1/Y_5 R primarily in the mPVN. Increases in production and release of NPY, as seen in genetic models of obesity such as obese *fa/fa* Zucker rats and *ob/ob* mice, underlie hyperphagia accompanied by hyperinsulinemia, glucose intolerance, and hyperglycemia, a phenotype resembling the clinical metabolic syndrome. Infusion of NPY centrally stimulates an episodic pattern of feeding, rapid weight gain, and obesity. To replenish the energy depleted by fasting or diet restriction, episodic NPY secretion in the PVN is accelerated to sustain the appetitive drive. NPY is a physiological orexigenic signal because increased NPY synthesis, storage, and release in the ARC–PVN axis are triggered by the clock mechanism in anticipation of mealtime and NPY secretion subsides as food consumption is initiated. Blockade of the anticipatory rise in either synthesis or release suppresses feeding. Whereas feeding in the complete absence of NPY in null mutant mice is unchanged, the obesity in leptin-deficient *ob/ob* mice is suppressed and the magnitude of fasting-induced feeding is drastically curtailed, thereby implying a crucial role of NPY in induction of hyperphagia and obesity. Paradoxically, experimentally induced diminution in NPY release in the PVN produces unregulated hyperphagia and obesity. In fact, a low abundance of NPY up-regulates Y_1 R to render animals hypersensitive to NPY such that extremely low doses of NPY that are normally ineffective evoke near maximal stimulation of feeding. Germ line deletion of any one of the NPY receptors, Y_1 , Y_2 , or Y_5 , also results in unregulated feeding and late-onset obesity. Overall, an imbalance in NPY signaling locally in the ARC–PVN axis, elicited by either high or low NPY abundance, leads to altered eating patterns and obesity.

Although NPY is a primary player in the ARN, several other chemically distinct cohorts of disparate origin also assist in propagation of the innate appetitive drive. NPY neurons coexpress AgrP and GABA in the ARC and coexpress the adrenergic neurotransmitters, norepinephrine and epinephrine, in the BS. Whereas GABA coreleased with NPY in the PVN augments feeding synergistically by activation of

GABA^A and Y₁/Y₅ R, respectively, GABA and AgrP also attenuate the α -MSH-induced restraint on feeding via GABA^A R and MC3 R expressed locally in the ARC POMC neurons. Moreover, AgrP released in the mPVN antagonizes the melanocortin restraint on feeding by competitive antagonism at MC4 receptors.

Galanin, β -endorphin, MCH, and ORX are additional neuropeptides that either coact with NPY or stimulate NPY release to enhance feeding. Thus, the intricate relationship of NPY with a host of orexigenic cohorts represents a failproof system with ample backup to meet varied environmental challenges and sustain the instinctual appetitive drive for survival. Seemingly, a three-pronged action of NPY—direct stimulation of Y₁/Y₅ R in the mPVN, stimulation of the release of orexigenic opioid, β -endorphin, via elicitation of GAL release and GAL action on its own, and a curb on the restraint exercised by anorexigenic α -MSH and CART—initiates and sustains a robust appetite at mealtime. ORX and MCH stimulate feeding by eliciting NPY release in the PVN. This line of communication between ORX and MCH neurons in the LH, along with the synergistic effect of adrenergic transmitters coreleased with NPY from BS projections to the ARC–PVN axis, is apparently important in relaying the combined hormonal and neural information from peripheral visceral organs (Figs. 2 and 3).

REGULATION OF THE ARN

An interplay of afferent hormonal and neural pathways, under the direction of central clocks and energy demands of the organism, is fundamental for integration of various effector pathways in the ARN, as discussed in this section (Figs. 2 and 3).

Regulation by Afferent Hormonal Signals

The current view advocates timely reciprocal interaction between the afferent hormonal signals, the anorexigenic leptin and orexigenic ghrelin, in driving the ARN to enforce the daily patterns of food intake.

Adipocyte Hormone Leptin: An Anorexigen

It is now well established that leptin, produced by adipocytes and the stomach in the periphery and by a subset of neurons in the hypothalamus, is the predominant signal that restrains appetite and stimulates nonshivering thermogenic energy expenditure. Leptin mutant *ob/ob* mice and humans display unabated

phagia, abnormal weight gain, and obesity. Replacement of leptin either by giving daily injections or by increasing expression of leptin selectively in the hypothalamus with leptin gene therapy reinstates the tonic restraint on feeding and concurrently augments energy expenditure to normalize weight. Also, lack of leptin R, as in germ line mutant rodents or by conditional hypothalamic leptin R deletion, reproduces the obese phenotype and metabolic abnormalities. Reinstallation of leptin R by leptin R gene therapy in the ARC of these rodents normalizes energy homeostasis.

Leptin secretion from adipocytes in ultradian and circadian patterns assists in expression of the tonic restraint on the ARN. The daily peaks and valleys in secretion are abolished by increased adiposity with age and by lifestyle changes. Consumption of a calorie-rich diet results in increased ultradian leptin secretion and loss of the circadian pattern. These abnormal hormonal patterns are associated with pathological sequelae, leading to abnormal rate of weight gain, obesity, and metabolic disorders. Current evidence demonstrates that hyperleptinemia generates central leptin insufficiency, resulting in loss of tonic restraint on hypothalamic effector pathways and dysregulation of weight homeostasis. An increase in leptin availability selectively in hypothalamic sites by leptin gene therapy normalizes food consumption and weight homeostasis.

The tonic restraint on the ARN by leptin is mediated by the long form of leptin R expressed by orexigenic and anorexigenic signal-producing neurons of the ARN. Leptin inhibits the synthesis and secretion of the orexigenic NPY, AgrP, MCH, and ORX and enhances anorexigenic melanocortin signaling by increasing α -MSH release in the PVN. This concurrent dual mode of central action by postprandial leptin hypersecretion is pivotal in terminating the meal. Conversely, curtailed restraint resulting from low leptin levels during the pre-meal interval or in response to energy depletion by food restriction or fasting sets these neurochemical sequelae in motion in reverse order, that is, increased orexigenic and decreased anorexigenic signaling to propagate hunger and initiate the drive to the source of food. In addition, leptin restrains feeding by opposing ghrelin-induced stimulation of appetite and by synergizing with the gut peptide cholecystokinin (CCK).

Gut Hormones

Ghrelin: An Orexigen

Ghrelin is as effective an orexigen as is NPY. Increased circulating levels readily stimulate feeding,

and sustained high levels promote hyperphagia and adiposity. Ghrelin, produced in the stomach and in a discrete subpopulation of neurons located in the sub-PVN zone, is a putative physiological signal for generating hunger. Ultradian secretion of ghrelin from the stomach is accelerated during the pre-meal interval and by fasting. Unlike multiple leptin targets, central ghrelin targets are the ghrelin R expressing ARC NPY neurons only. Increasing ghrelin levels accelerate rhythmic NPY discharge in the PVN to stimulate appetite.

The orexigenic effects of ghrelin are regulated by leptin in two ways. Centrally, leptin restrains ghrelin-induced NPY release, and peripherally, it inhibits ghrelin secretion. Consequently, ghrelin hypersecretion during the pre-meal interval and fasting is due, in part, to attenuated leptin restraint on ghrelin secretion, and the postprandial rise in leptin secretion restores inhibition of ghrelin secretion peripherally and ghrelin-induced appetite centrally. It is highly likely that this dual action of leptin is crucial for suppression of ingestive behavior during the inter-meal interval.

Peptide YY 3-36

Peptide YY (PYY) is a member of the NPY family and is produced by endocrine cells of the gut. Peptide YY 3-36 (PYY3-36) levels rise in the circulation after a meal. Microinjection of PYY3-36 into the ARC inhibited feeding by reducing NPY release in the PVN through activation of inhibitory presynaptic Y_2 auto-receptors. Despite the contrary evidence that PYY3-36 levels are reduced in obese patients, it is possible that the postprandial rise of PYY3-36 may constitute one of the satiety signals to hypothalamic effector pathways.

Cholecystokinin and Glucagon-like Peptides 1 and 2

CCK has long been implicated as a putative satiety signal from the duodenum. CCK receptors on afferent sensory fibers of the vagus terminating in the nucleus of the tractus solitarius (NTS) in the brainstem mediate termination of a meal by CCK. Thus, a postprandial increase in CCK may reduce meal duration by relaying information via the gut-BS axis to the hypothalamus. However, the precise impact of this part hormonal, part neural route of communication on the motivational drive emanating in the hypothalamic ARN remains to be ascertained.

Like CCK, glucagon-like peptides (GLP-1, GLP-2, and oxyntomodulin), derivatives of posttranslational cleavage of prepro-glucagon in the intestinal mucosa and neurons in the NTS, are putative candidates for

a neurohormonal role in mediating postprandial satiety. GLP-1 and GLP-2 inhibit food intake after central administration, possibly mediated by feeding relevant hypothalamic sites, including the dorsomedial nucleus. Interestingly, postprandial gastric loading activated GLP1/GLP2-expressing neurons in the NTS that express leptin receptors, thereby implying that this GLP pathway represents a central leptin-responsive system that exerts a tonic restraint on appetite.

Pancreatic Hormones: Insulin

Insulin, secreted by beta cells of the pancreas, regulates glucose homeostasis and has been suggested to also act centrally to inhibit food intake. In the periphery, insulin stimulates leptin secretion from adipocytes. The observations that leptin and insulin secretion rise postprandially, hyperinsulinemia precedes hyperleptinemia in response to consumption of a high-fat diet, and leptin replacement alleviates hyperglycemia and hyperphagia that ensue after destruction of pancreatic beta cells are consistent with the view that it is leptin and not insulin that normally evokes the previously advocated central effects of insulin on energy homeostasis.

On the other hand, cross-talk between white adipose tissue (WAT) and the pancreas affects energy homeostasis indirectly. Normally, insulin stimulates leptin secretion and storage of excess energy as fat. Leptin (as an autocrine signal), in turn, restrains insulin secretion. However, consumption of a calorie-rich diet promotes hyperinsulinemia, hyperleptinemia, and obesity. This metabolic imbalance, especially hyperleptinemia, for extended periods engenders various disorders of metabolic syndrome. Reduction in adiposity generally reinstates the normal cross-talk between WAT and the pancreas and alleviates metabolic disorders.

Steroids

Glucocorticoids

The lipophilic steroids readily cross the blood-brain barrier to access target neurons in the hypothalamus. The glucocorticoids (corticosterone in rodents and cortisol in humans) secreted by the adrenal cortex stimulate appetite. Glucocorticoid therapy invariably promotes weight gain and adiposity. Stimulation of food intake is affected by increased hypothalamic NPY signaling facilitated by the ARC NPY neurons expressing glucocorticoid receptors. Furthermore, the observations that mRNA expression in the ARC NPY neurons and peptide levels in the PVN nerve terminals rise after glucocorticoid treatment, and that the daily increase in corticosterone secretion precedes the

onset of a meal, support a facilitatory role of glucocorticoids in the NPY-induced daily patterning of ingestive behavior.

Estrogens

The primary ovarian estrogen, estradiol 17 β , suppresses appetite and fat deposition. Whereas ovariectomy rapidly increases phagia and body weight, estrogen replacement reverses these effects. Estradiol 17 β decreases NPY release in the PVN, an action mediated by estrogen R expressed on ARC NPY neurons.

In summary, the interplay of the leptin–ghrelin–NPY loop, in conjunction with the modulatory influence of an array of signal molecules of hypothalamic and peripheral origin, represents the hardcore wiring of the basic dynamic machinery that initiates and terminates episodic feeding in vertebrates (Fig. 3). Normally, leptin tonically restrains feeding by restricting efflux of orexigenic NPY, GABA, and AgrP and increases (either directly or indirectly through NPY links) the release of anorexigenic α -MSH and CART in the PVN. Likewise, in the periphery, leptin tonically restrains ghrelin secretion from the stomach and blocks its central orexigenic action by opposing its excitatory effects on NPY release in the PVN. Consequently, meal initiation is a sequential neurohumoral event initiated first by removal of leptin restraint to allow increased synthesis and storage of NPY in the ARC–PVN axis and of ghrelin in the stomach preceding the impending hypersecretion. Thereafter, a trigger from the timing mechanism elicits episodic ghrelin release from the stomach. This peripheral orexigenic signal and the neural clock together accelerate rhythmic NPY discharge in the PVN to initiate feeding. Leptin hypersecretion postprandially reasserts the tonic restraint on NPY and ghrelin release and curtails feeding behavior. Thus, the ebb and flow in the tonic restraint imposed by leptin on information flow from the peripheral afferent and hypothalamic ARN generate the daily meal pattern.

ENERGY EXPENDITURE NETWORK

Hypothalamic SNS innervations relay signals that regulate general activity and nonshivering thermogenesis mediated by uncoupling protein-1 (UCP-1) in the BAT in the periphery. Obesity induced by ablation of the VMH decreases sympathetic tone, general activity, and thermogenic energy loss. Several sites in the anterior hypothalamus, including the

MPOA, are intimately involved in regulation of body temperature. It is now apparent that these sites are also involved in regulating nonshivering thermogenesis, an essential component of energy homeostasis. Injections of leptin readily increase general activity and nonthermogenic energy expenditure by activation of BAT UCP-1 signaling. Increased expression of leptin after microinjection of viral vectors encoding the leptin gene in various hypothalamic leptin R-expressing sites—the ARC, PVN, VMN, and MPOA—decreased adiposity and increased nonshivering thermogenic energy expenditure. However, unlike that observed in other hypothalamic sites, increased leptin transgene expression in the MPOA decreased adiposity by augmenting BAT-mediated thermogenesis without decreasing energy intake (Figs. 1 and 3). Thus, a leptin-responsive hypothalamic EEN network distinct from the ARN, originating in the MPOA and traversing caudally through several hypothalamic nuclei en route to BAT, is an integral component in the hypothalamic integration of energy homeostasis. The existence of distinct central pathways, the ARN and EEN, demonstrates that it is now possible to design therapies to curb weight gain and adiposity by increasing energy expenditure without interrupting normal food intake.

CONCLUSION

Multidisciplinary research has uncovered various aspects of the spatiotemporal patterning of the hypothalamic ARN driven by a host of internal factors (Figs. 1–3). Within the ARN, the orexigenic NPY and its cohorts in the ARC–PVN axis constitute the primary neural pathway for initiation and termination of a meal. To accomplish this complex task efficiently in a strict temporal fashion and in synchrony with external driving forces (food availability, photoperiod, and seasonality), the NPY system employs a distinct anorexigenic network composed of α -MSH- and CART-producing POMC neurons in the ARC. To monitor energy expenditure and metabolic efficiency in the body, the ARN is also intimately linked with the EEN and SNS in the MPOA and other hypothalamic sites for relay of neural efferents to the BAT, WAT, and GI.

At least three basic elements coordinate the operation of the ARN under the direction of external and internal environmental factors: (1) the intrahypothalamic timing mechanism, (2) innervations of MCH and ORX neurons from the LH for relay of afferent messages ascending the multisynaptic neural

pathway from the periphery, and (3) afferent hormonal signals from the periphery. Reciprocal circadian and ultradian rhythmic secretion patterns of leptin and ghrelin encode a corresponding pattern of NPY release in the PVN to regulate feeding. In addition, leptin restrains gastric ghrelin and pancreatic insulin secretion. Insulin, in turn, promotes leptin and possibly modulates ghrelin efflux. Thus, a dynamic interplay at two levels, one peripherally among adipocytes, stomach, and pancreas and the other among various components of the hypothalamic ARN and peripheral visceral organs, underlies the daily management of feeding behavior. Environmental challenges sustained over extended periods, particularly excess consumption of an energy-rich diet and a sedentary lifestyle, produce subtle and progressive derangements in feedback communication among peripheral visceral organs and the ARN. A major consequence of this disruption is positive energy balance promoting a gradual increase in adiposity, morbid obesity, and metabolic syndrome.

This new fundamental knowledge of the hypothalamic integrative processes at the cellular and molecular levels has elucidated a cohesive framework and identified vulnerable loci for designing therapeutic remedies to stem the onslaught of environmental obesity and metabolic diseases and, thereby, to enhance the quality of life and extend the life span.

Table II Hormones of the Hypothalamic–Pituitary Unit^a

| Hypothalamic hormone | Pituitary hormone | Target organ | Feedback hormone |
|----------------------|-------------------|--------------|--------------------------|
| GnRH | FSH | Ovary | Estradiol and inhibin |
| | LH | Testis | Testosterone and inhibin |
| TRH | TSH | Thyroid | T3 and T4 |
| GHRH | GH | Multiple | IGF-1 |
| Somatostatin | GH | Multiple | IGF-1 |
| CRH | ACTH | Adrenal | Cortisol |
| Dopamine | Prolactin | Breast | ? |
| AVP | ACTH | Adrenal | Cortisol |

^aAbbreviations used: ACTH, corticotropin; AVP, arginine vasopressin; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; IGF-1, insulin-like growth factor-1; LH, luteinizing hormone; GnRH, gonadotropin-releasing hormone; T3, triiodothyronine; T4, thyroxine; TRH, thyrotropin-releasing hormone; TSH, thyrotropin.

Anterior lobe or adenohypophysis: No physical connection exists between the adenohypophysis and the hypothalamus. Therefore, the interaction between these two organs is achieved through hypothalamic neurohormones that reach the anterior lobe through the portal circulatory plexus, the hypophyseal–portal circulation.

Intermediate lobe: Its significance is unknown. It appears especially prominent in the fetus and in pregnant women.

FUNCTIONS

The hypothalamic–pituitary unit has been shown to regulate a pleiotopic set of functions in the organism

(Table I). The majority of the hypothalamic–pituitary functions are endocrine in nature. To exert their actions, hormones must first be recognized by specific receptors on the surface of cells of target organs or tissues (Table II). Target organs, in turn, are capable of influencing the hypothalamic–pituitary unit through feedback loops, thereby promoting integration and coordination between peripheral organs and tissues and the hypothalamic–pituitary unit, which are essential for the maintenance of the finely tuned physiologic homeostasis.

Figure 1 Hypothalamic regions and cell groups within regions projected into the midsagittal section of the rat hypothalamus. AC, anterior commissure; AH, anterior hypothalamic nucleus; ARC, arcuate nucleus; DM, dorsomedial nucleus; DP, dorsal pre-mammillary nucleus; MB, mammillary body; ME, median eminence; MP, medial preoptic nucleus; OCH, optic chiasm; PE, periventricular nucleus; PP, preoptic periventricular nucleus; PV, paraventricular nucleus; SCH, supra-chiasmatic nucleus; SM, supra-mammillary nucleus; SO, supraoptic nucleus; PH, posterior hypothalamic nucleus; VM, ventromedial nucleus; VP, ventral pre-mammillary nucleus.

Cell Groups and Areas

Preoptic Region

The preoptic region extends from the basal forebrain and lamina terminalis to the level of the rostral half of the optic chiasm and continues into the anterior hypothalamus. Dorsally, it is bordered by the anterior commissure and the bed nucleus of the stria terminalis.

The cell-rich medial part of the preoptic region contains several cell groups, including the medial preoptic and preoptic periventricular nuclei, and contains gonadotropin-releasing hormone (GnRH) neurons. The lateral part is occupied by the medial forebrain bundle. In the midline, a circumventricular organ, the organum vasculosum laminae terminalis (also called the supraoptic crest) can be found around the tip of the third ventricle. The organ is outside of the blood-brain barrier.

Anterior Hypothalamus

The anterior hypothalamus is a continuation of the preoptic region and extends caudally to the level of the arising of the median eminence. Its medial part comprises the anterior periventricular, supra-chiasmatic, anterior hypothalamic, and paraventricular nuclei. The anterior periventricular nucleus contains somatostatin immunoreactive neurons projecting to the median eminence and dopaminergic neurons terminating in the posterior and intermediate lobe of the

pituitary gland (periventriculo-hypophyseal dopaminergic system). The supra-chiasmatic nucleus (a key structure in the control of biological rhythms) is situated just above the optic chiasm on the two sides of the third ventricle. It receives direct input from the retina and indirect neuronal input from the retina via the lateral geniculate body and from brainstem serotonergic neurons. The supraoptic nucleus is located along and around the lateral edge of the optic chiasm and is composed of magnocellular neurons. In humans, the supraoptic nucleus is situated above the rostral end of the optic tract. Neurons of this cell group synthesize oxytocin and vasopressin and project to the posterior pituitary. The paraventricular nucleus lies close to the two sides of the third ventricle, above the anterior hypothalamic nucleus. Magnocellular and parvocellular divisions can be distinguished. Magnocellular neurons synthesize oxytocin and vasopressin and project to the posterior pituitary. The cell group contains corticotropin-releasing hormone (CRH)- and thyrotropin-releasing hormone (TRH)-producing neurons that terminate in the median eminence as well as medium-sized neurons that give rise to long descending projections to the brainstem and spinal cord. The lateral part of this hypothalamic region contains the supraoptic nucleus and fibers and cells of the medial forebrain bundle. Caudally, the so-called retrochiasmatic area containing loosely

packed cells and fibers occupies the ventral part of the anterior hypothalamus. In both the medial and lateral parts of the anterior hypothalamus, magnocellular neurons form small groups (called accessory nuclei).

Middle Hypothalamus (Tuberal Region)

The middle hypothalamus, starting behind the retrochiasmatic area, ends at the level of the separation of the pituitary stalk. The medial basal part of the region contains the arcuate and ventromedial nuclei and the median eminence, whereas the medial dorsal part contains the dorsomedial nucleus. The lateral part is called the lateral hypothalamic area and is largely occupied by the medial forebrain bundle.

The arcuate (also called the infundibular) nucleus, made up of five subdivisions, is an elongated cell group in the most ventromedial part of the middle hypothalamus and posterior hypothalamus, mostly on the two sides of the third ventricle (infundibular recess). The cell group contains, in addition to several other neuropeptides, pro-opiomelanocortin-synthesizing neurons and growth hormone-releasing hormone (GHRH) as well as dopaminergic neurons. These latter two project to the median eminence, forming the tubero–infundibular pathway. The ventromedial nucleus is a major cell group composed of five subdivisions that contain morphologically and functionally distinct neurons with neuronal connections to various components of the limbic system. The dorsomedial nucleus divided into three subdivisions is caudal to the paraventricular nucleus.

Posterior Hypothalamus (Premammillary Region)

The main cell groups of the posterior hypothalamus, a relatively small part of the hypothalamus, are the ventral and dorsal premammillary, tuberomammillary, supramammillary, and posterior hypothalamic nuclei. The ventral premammillary nucleus is a small cell group in continuation with the ventromedial and partly the arcuate nuclei. The dorsal premammillary nucleus is located caudal to the ventromedial nucleus at the sides of the inframammillary recess of the third ventricle. The tuberomammillary nucleus is located in the most ventral and medial part of the posterior hypothalamus. Some neurons of the cell group synthesize histamine, providing the only source of neuronal histamine in the brain. The posterior hypothalamic nucleus is a fairly large group of cells occupying the dorsal part of the periaqueductal central gray. The unpaired supramammillary nucleus is dorsal to the mammillary body and projects to the

hippocampus, dentate gyrus, and medial septum diagonal band nuclei.

Characteristics of Hypothalamic Cell Groups

The hypothalamic cell groups are not at all homogeneous, and in most cases subgroups can be distinguished. For example, in the arcuate nucleus, there are dopamine, GHRH, enkephalin, galanin, substance P, γ -aminobutyric acid (GABA), atrial natriuretic peptide, neurotensin, gastrin-releasing peptide (GRP), and glutamate-containing neurons. The suprachiasmatic nucleus, representing a key structure of the biological clock, is composed of vasopressin, vasoactive intestinal peptide, somatotropin release-inhibiting hormone (SRIH), substance P, GABA, and GRP-containing nerve cells. The situation is further complicated by the colocalization of various neuropeptides in the same neurons. The functional significance of colocalization of substances in the nerve cells needs to be clarified.

The paraventricular nucleus is unique among hypothalamic cell groups in housing substantial populations of cells that participate in the control of anterior and posterior pituitary secretions and also is associated with the autonomic nervous system. This nucleus is the predominant source of CRH and TRH. Neurons of the cell group synthesize oxytocin and vasopressin for release into the general circulation from terminals in the posterior pituitary. A third major cell type contains neurons that give rise to long descending projections to the brainstem and spinal cord that include sensory and motor structures associated with the autonomic nervous system. These three visceromotor populations are essentially separate and exhibit a high degree of topographic organization. On this high degree of anatomical organization is imposed a somewhat imprecise manner of chemical coding.

The neurons of a cell group display rich intrinsic connections. A local network of fibers seems to be a common feature of hypothalamic nuclei. Local circuit neurons may synchronize the activities of peptidergic neurons in a hypothalamic nucleus to integrate or coordinate them as a functional unit.

Hypothalamic Connections

Intrahypothalamic Connections

A large number of intrahypothalamic connections exist between hypothalamic cell groups, and in most cases these connections are reciprocal. For example, arcuate neurons, in addition to projecting to the outer layer of the median eminence, project to several other

regions such as the ventromedial nucleus, lateral hypothalamic area, anterior hypothalamic area, and preoptic area and also receive afferents from the preoptic area, the ventromedial nucleus, and several other hypothalamic regions.

The abundant intranuclear connections, as well as the rich connections among the various hypothalamic cell groups, support the general impression that the hypothalamus should be considered a neuronal network of quasirandom internal connections. In this network, where the impulses leave the hypothalamus through the main axons, excitation can spread from a given focus in any direction and can establish an infinite number of closed, self-reexciting chains.

Extrahypothalamic Connections

Connections with Telencephalic and Diencephalic Structures

A large number of regions project to the hypothalamus, including various parts of the limbic system (e.g., amygdaloid complex, hippocampus, septum), thalamus, basal ganglia, and cortex. Although the hypothalamus receives a large amount of sensory input through the regions mentioned, there are also some more or less direct pathways. There is a direct projection from the retina to the hypothalamus, primarily to the suprachiasmatic nucleus. The effect of light on the hypothalamus, particularly on its control of the anterior pituitary, may be mediated by this pathway. Inputs from the olfactory bulb have relatively free access to the hypothalamus, although direct connections from the olfactory bulb to the hypothalamus are not known. The piriform cortex, which receives fibers from the olfactory bulbs, sends projections directly to the hypothalamus. Other olfactory pathways reach the hypothalamus mainly via the amygdala.

The efferent pathways of the hypothalamus appear to reciprocate several of the major afferent hypothalamic connections. Many such reciprocating connections are contained in the medial forebrain bundle, the dorsal longitudinal fasciculus, and the stria terminalis. These pathways appear to close neuronal circuits between the hypothalamus and several of the limbic forebrain structures. The major brain structures receiving hypothalamic efferents are the amygdala, hippocampus, and septum.

Hypothalamic Connections with the Brainstem

The hypothalamus has extremely rich connections with the brainstem. A significant part of the ascending fibers are aminergic, and they terminate in various hypothalamic cell groups. Noradrenalin-containing fibers arise from the medulla oblongata (from the

so-called A1 and A2 catecholaminergic cell groups) and pons (from the locus coeruleus). Adrenalin-synthesizing neurons are in the medulla oblongata (C1 and C2 adrenergic cell groups). Ascending serotonergic fibers arise from the pons and midbrain raphe nuclei.

Descending fibers from the hypothalamus, primarily from the paraventricular, arcuate, and medial preoptic nuclei, terminate in the brainstem and spinal cord.

Recent findings indicate that there are polysynaptic neuronal connections between hypothalamic structures and endocrine glands such as the gonads, adrenal, and pancreas. The neural connections of the hypothalamus are summarized in [Fig. 2](#).

The reciprocal connections of the hypothalamus with limbic forebrain structures and the brainstem are of such magnitude that it appears possible to interpret the hypothalamus, at least partly, as a way station in both the ascending and descending limbs of a polysynaptic neural circuit that extends between the limbic forebrain, on the one hand, and the primarily paramedian mesencephalic region, on the other. It may be assumed that the functional state of the hypothalamus is determined, to a significant extent, by the neural events that take place in the limbic structures and the lower brainstem, with both having a very integrated structural organization, including several reciprocal interconnections and neural circuits. In addition, they receive a vast amount of information from both the external and internal environments flowing in along neural and humoral pathways (there are hormone receptors in the hippocampus and amygdala). It should be mentioned that the hypothalamus itself also contains hormone receptors as well as several other types of receptors.

The extremely complex neuronal network of the hypothalamus and its reciprocal connections suggests that, apart from a few exceptions such as the supraoptico- and paraventriculohypophyseal system, there are not well-defined regions and pathways that are specifically and exclusively concerned with a discrete hypothalamic function. Of course, this does not exclude the predominance of one or the other hypothalamic area in the involvement of a particular hypothalamic function. Instead of a mosaic-type pattern, the hypothalamus can rather be envisaged as some kind of computer. This computer has a number of built-in programs, and its elements are involved in several processes. It elaborates the solution for each actual situation on the basis of a wealth of information that is partly stored and partly streaming in continuously. The results are then

Figure 2 A simplified drawing of the bidirectional neural connections within the hypothalamus (intranuclear and internuclear) and between hypothalamic and extrahypothalamic structures. The relations of the hypothalamus to the anterior and posterior pituitary are also indicated. (1) Neurons synthesizing hypophysiotropic neurohormones. (2) Portal capillary. (3) Neurons of the supraoptic and paraventricular nuclei terminating in the posterior pituitary.

distributed over a number of neural and humoral output channels.

Major Neuroanatomical Pathways Connecting the Hypothalamus with Extrahypothalamic Structures

Medial Forebrain Bundle

The medial forebrain bundle running longitudinally and occupying the majority of the lateral hypothalamus contains a high number of fibers with different destinations from hypothalamic nuclei and from limbic, cortical, and brainstem structures directed to hypothalamic cell groups. It also contains many fibers that just pass through the hypothalamus.

Stria Terminalis

The stria terminalis is a major pathway between the amygdala and the hypothalamus that provides reciprocal connections between the two structures.

Fornix

The fornix is a main link of the limbic system connecting the hippocampus, the septum, and the mammillary body. Some of its fibers deviate from the main bundle and terminate in the preoptic area as well as around the ventromedial nucleus of the hypothalamus.

Medial Corticohypothalamic Tract

The medial corticohypothalamic tract connects the hippocampus with the arcuate, ventromedial, and ventral premammillary nuclei.

Dorsal Longitudinal Fasciculus

The dorsal longitudinal fasciculus contains ascending and descending fibers connecting the dorsal hypothalamus and posterior hypothalamus with the periaqueductal central gray of the mesencephalon.

HYPOTHALAMUS–ANTERIOR–PITUITARY SYSTEM

Neurovascular Contact between the Hypothalamus and Anterior Pituitary

The connections between the hypothalamus and anterior pituitary are neurovascular (Fig. 3). Hypophysiotropic substances, called tropic hormone-releasing hormones (factors) or release-inhibiting hormones (factors), are produced by the hypothalamus. The chemically identified hypophysiotropic substances are CRH or corticotropin-releasing factor (CRF); GnRH, also called luteinizing hormone-releasing hormone (LHRH) or gonadoliberin; GHRH; SRIH, somatostatin, or growth hormone-inhibiting factor (GIF); TRH; and prolactin-inhibiting factor (PIF), at least one of which is dopamine (DA). These substances are transported by the hypophyseal portal vascular system to the anterior pituitary cells. The median eminence and the proximal part of the pituitary stalk are the site where the axons of the neurons synthesizing the hypophysiotropic neurohormones are very close to the portal vessels.

Location of Neurons Synthesizing the Hypophysiotropic Neurohormones and Projecting to the Median Eminence

Corticotropin-Releasing Hormone

The most prominent CRH-containing cell group of the hypothalamus is the paraventricular nucleus, mainly its medial parvocellular part. The vast majority of the CRH terminals in the median eminence and pituitary stalk arise from here.

Gonadotropin-Releasing Hormone

In general, there are two areas that contain a significant amount of immunoreactive GnRH nerve cell bodies

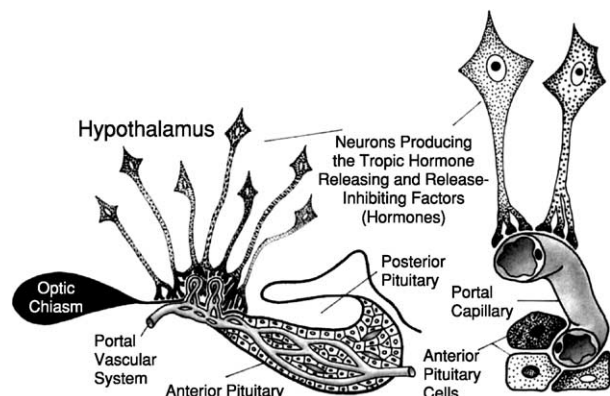

Figure 3 Schematic illustration of the neurovascular contact between the hypothalamus and the anterior pituitary.

projecting to the median eminence: (1) the septal-preoptic–suprachiasmatic region and (2) the mediobasal area of the middle hypothalamus and posterior hypothalamus, especially the arcuate and premammillary nuclei. But there are great variations in the number of such cells in these two regions of various species. In humans and primates, they are concentrated mainly in the second region. In the rat, many GnRH cells are in the medial preoptic area, the diagonal band of Broca, and the septal nuclei, whereas some cells are in the anterior hypothalamic area.

GnRH neurons originate in the medial olfactory placodal epithelium of the developing nose, migrate across the nasal septum, and enter the forebrain with the nervus terminalis, a cranial nerve that is a part of the accessory olfactory system and projects directly from the nose to the septal-preoptic area and hypothalamus. This migratory route for GnRH-expressing neurons could explain the deficiency of gonadotropins seen in hypogonadotropic hypogonadism with anosmia.

Growth Hormone-Releasing Hormone

The majority of the GHRH immunoreactive neurons projecting to the median eminence are in the arcuate nucleus.

Somatotropin Release-Inhibiting Hormone

SRIH immunoreactive neurons terminating in the median eminence are located mainly in the medial preoptic and anterior periventricular areas.

Thyrotropin-Releasing Hormone

Although TRH immunoreactive neurons are widely distributed in the central and peripheral nervous systems, those projecting to the median eminence are gathered mostly in the medial parvocellular division of the paraventricular nucleus.

Prolactin-Inhibiting Factor

At least one PIF is dopamine and is produced by the tuberoinfundibular dopaminergic neurons. These neurons are situated in the arcuate nucleus and in the ventral part of the anterior periventricular nucleus.

The location of neurons synthesizing the hypophysiotropic neurohormones and projecting to the median eminence is summarized in Fig. 4.

The hypophysiotropic neurons receive very significant neural input mediated by several chemical messengers. Various peptidergic, monoaminergic, and GABAergic axons terminate on perikarya and dendrites of these nerve cells, providing the structural basis for the assumption that the actions of the neurotransmitters or neuromodulators are at least partly

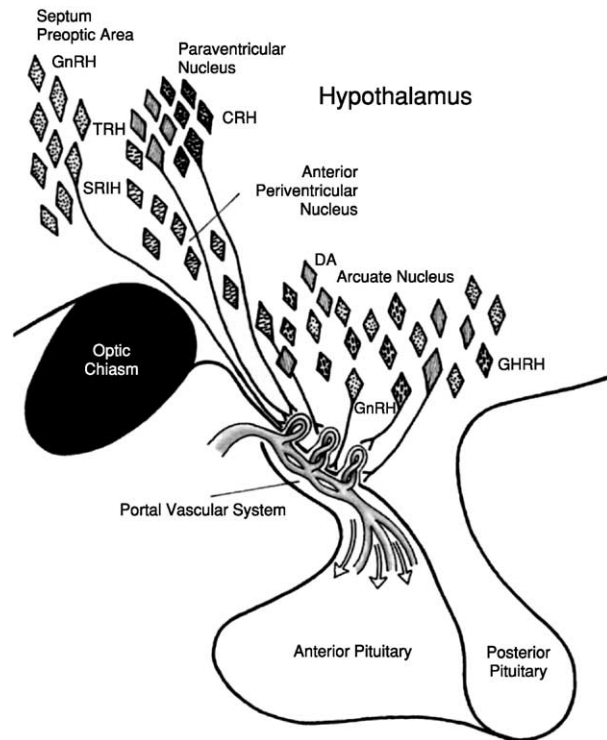

Figure 4 Schematic drawing of midsagittal section of the hypothalamo-pituitary unit showing the location of neurons producing hypophysiotropic neurohormones and projecting to the outer layer of the median eminence. CRH, corticotropin-releasing hormone; DA, dopamine; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; SRIH, somatostatin release-inhibiting hormone; TRH, thyrotropin-releasing hormone.

exerted directly on the structures producing the hypophysiotropic neurohormones. In addition, axons containing one or the other hypophysiotropic neurohormone form synaptic connections with neurons synthesizing the same peptide. This may be the morphological basis for an ultrashort feedback mechanism or may indicate an intrinsic circuit.

However, it should be kept in mind that neurons containing the trophic hormone-releasing or release-inhibiting neurohormones are widely distributed in the central nervous system; some of them are even present in other tissues. Not all of these neurons in the brain terminate in the hypothalamic median eminence and pituitary stalk; instead, some project to other brain structures.

Hypophysial Portal Vascular System

Besides the trophic hormone-releasing and release-inhibiting hormones, the portal vascular system represents the key structure required for the operation of

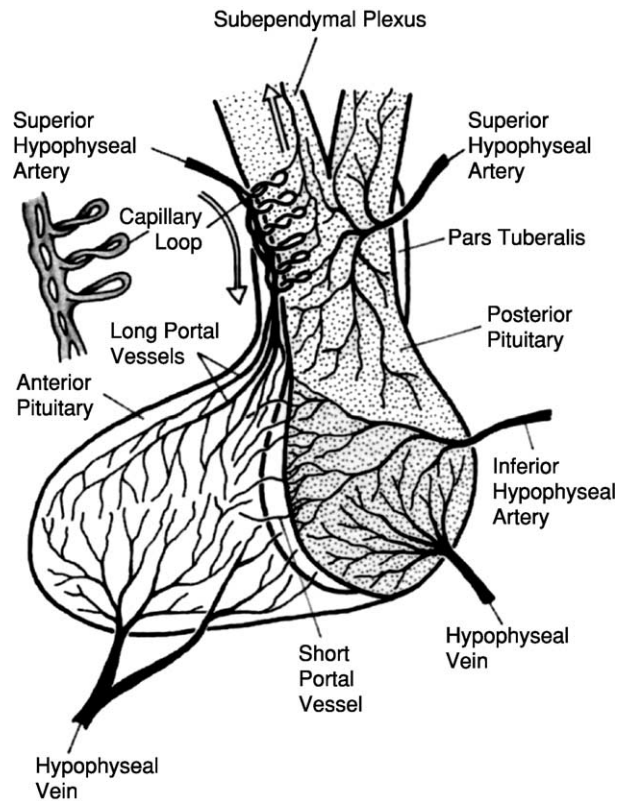

Figure 5 Schematic illustration of the hypophysial portal vascular system.

the neurohumoral (neurovascular) mechanism controlling pituitary trophic functions. It transports the substances released from the nerve terminals in the median eminence to the pituitary.

The main features of the hypophysial portal vascular system are the following (Fig. 5). The so-called superior hypophyseal arteries form a dense plexus, largely of precapillary character, within the so-called pars tuberalis, a small part of the pituitary gland. This plexus is especially dense on the contact surface between the median eminence and the pars tuberalis (mantleplexus). From this plexus arise the capillary loops that penetrate into the tissue of the median eminence and infundibular stem. The mantleplexus and capillary loops drain toward the portal vessels (some of the capillary loops drain toward the subependymal plexus of the third ventricle) that lie on the ventral surface of the pituitary stalk. These vessels are called the long portal vessels. Part of the blood from the posterior pituitary reaches the anterior pituitary by way of vessels known as short portal vessels. Each portal vessel supplies a certain part of the pituitary. Anastomoses between these vessels are rare. The majority of the portal blood is directed from

the median eminence toward the pituitary, but some blood may flow in the reverse direction, toward the hypothalamus.

The presence of tropic hormone-releasing and release-inhibiting substances in the portal blood is well documented, as is the fact that the concentration of these substances is much higher in the portal blood than in the peripheral plasma and that changes occur under certain experimental conditions.

Structure of the Median Eminence

The median eminence arising from the ventral surface of the tuberal region of the hypothalamus is a slight midline prominence. It continues into the pituitary stalk and represents the contact area between the nerve terminals of the neurons synthesizing the hypophysiotropic neurohormones and the precapillaries and capillaries of the portal vascular system. The inner surface of the median eminence is covered by ependymal cells. Two layers can be distinguished in the median eminence. The inner layer contains the fibers of the supraoptico- and paraventriculo-hypophysial system terminating in the posterior pituitary. The outer layer contains the tropic hormone-releasing and release-inhibiting hormones and the vessels of the portal vascular system. It must be mentioned that in addition to the terminals of the neurons synthesizing the hypophysiotropic neurohormones, there are many other neurons containing chemical messengers different from these compounds (most of them are also peptides, but “classic” neurotransmitters are also present), which also terminate in the median eminence. The functional significance of these other chemical messengers is not known. The possibility of interactions of the various substances at the median eminence level exists.

HYPOTHALAMUS-POSTERIOR PITUITARY SYSTEM

Magnocellular neurons of the supraoptic and paraventricular nuclei and parvocellular neurons of the paraventricular nucleus project to the posterior pituitary, forming the so-called supraoptico- and paraventriculo-hypophysial tract (Fig. 6). The neurons synthesize oxytocin and vasopressin. The hormones are synthesized in the cell bodies of the nerve cells and are transported down the axons of these neurons to their endings in the posterior pituitary. Some of the neurons make oxytocin and others synthesize vasopressin. Oxytocin- and vasopressin-containing cells are evident in both cell groups. Vasopressin- and

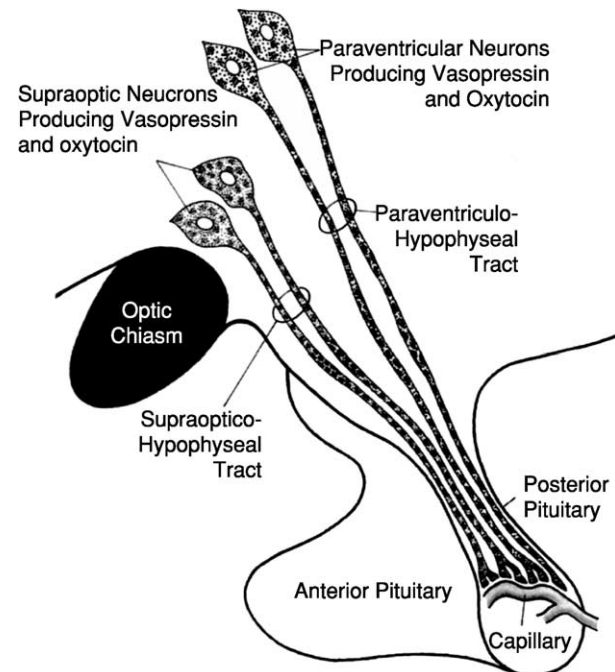

Figure 6 The hypothalamus-posterior-pituitary system.

oxytocin-producing neurons of the paraventricular nucleus project not only to the posterior pituitary but also to the brainstem and spinal cord and may be involved in cardiovascular control.

Neurosecretion

The term “neurosecretion” was originally coined to describe the secretion of hormones by neurons, but the term is now somewhat misleading because it became evident that nearly all neurons secrete chemical messengers.

BLOOD SUPPLY

The hypothalamic arteries arise directly from the circle of Willis (circulus arteriosus Willisii). Six major groups of arteries supply the hypothalamus. The arteries cover each other like shells in a mediolateral direction. The vessels entering at the midline supply the medial and basal parts of the hypothalamus, whereas those entering laterally supply the lateral and dorsal parts of the hypothalamus. None of the hypothalamic nuclei is supplied by a single artery.

Most of the hypothalamic veins enter into the anterior cerebral, basilar, and interpeduncular veins. The anterior cerebral vein drains into the basilar vein. The venous blood is drained by the basal vein, which enters the great cerebral vein of Gallen.

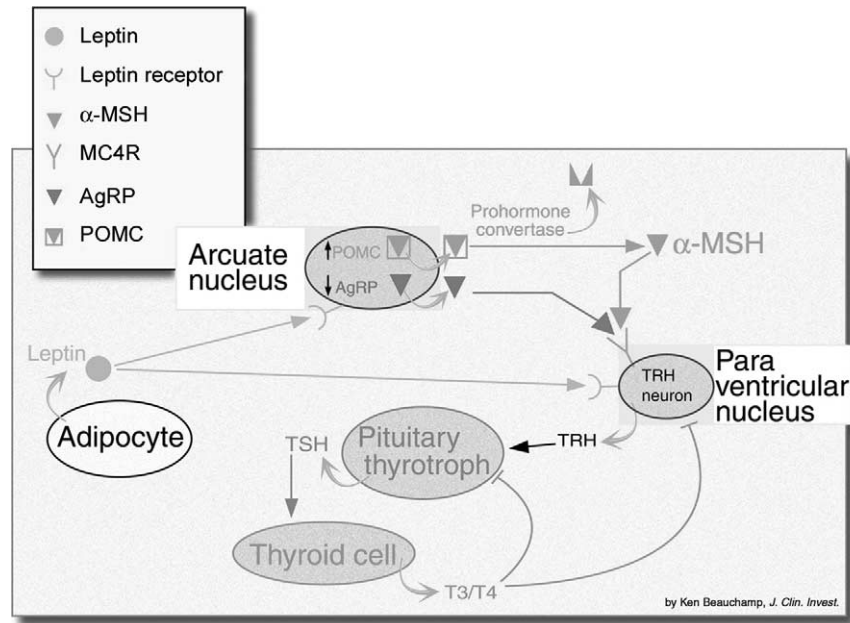

Figure 1 Interactions between the fat-derived hormone leptin and TRH neurons in the PVN. A sufficient level of leptin signaling is needed to maintain TRH expression in the hypothalamic PVN, which is necessary for normal production of TSH and production of thyroid hormone by the thyroid. Two mechanisms may be involved. In one, leptin regulates arcuate nucleus neurons expressing pro-opiomelanocortin (POMC) (induced by leptin) and AgRP (suppressed by leptin). These arcuate neurons project to TRH neurons, where they influence TRH expression by α -MSH (stimulatory) and AgRP (inhibitory) input on MC4Rs. Leptin may also act directly on TRH neurons through leptin receptors on these cells. In the absence of leptin signaling, the feedback action of T₄/T₃ at the hypothalamic level is impaired. Hence, although levels of T₄/T₃ may be low, TRH and TSH levels remain suppressed. Reprinted with permission from Flier *et al.*, *J. Clin. Invest.* **105**, 859–861 (2000).

hormone (TSH) secretion via specific high-affinity membrane receptors present on thyrotropes [TRH receptor type 1 (TRH-R1)]. The termination of TRH signals is probably mediated by a membrane-bound ectoenzyme termed TRH-degrading enzyme (TRH-DE) for its remarkable specificity to hydrolyze only TRH and closely related peptides. It is localized on lactotrophs, on which TRH-DE activity and mRNA levels are tightly regulated by thyroid hormone. In addition to TRH, thyroid hormone regulates TSH secretion via negative feedback action on TSH synthesis and release. T₄ is locally deiodinated by D2 to the biologically active thyroid hormone T₃. The negative feedback effect of T₃ is exerted via TRs expressed in the anterior pituitary. In addition to TRH-R1 and TRs, the TSH receptor appears to be present in the human anterior pituitary as well. It is expressed in a subpopulation of folliculostellate cells and is assumed to allow for ultra-short loop regulation of TSH secretion. Putative recognition of the TSH-R by TSH-R antibodies may have clinical relevance in Graves' disease.

Thyroid Gland

TSH acts on the thyroid gland by binding to the TSH-R, which is located on the plasma membranes of thyroid cells. It stimulates thyroglobulin gene expression, iodide uptake and organification, and hydrolysis of iodinated thyroglobulin stored in the luminal colloid. The endpoint of TSH action is the production and release of T₄ and some T₃ by the thyroid gland. In addition, the thyroid gland enlarges as a result of long-term stimulation by TSH. The molecular pathways involved in this trophic effect of TSH have been largely uncovered in the past decade. In addition to endocrine regulation, neural regulation of the thyroid gland is probably a modality. The thyroid gland is richly innervated by sympathetic, parasympathetic, and sensory nerve fibers that contain various neuropeptides, such as neuropeptide Y. Based on the distribution pattern of these fibers, a role for neural control in the regulation of local blood flow and in thyroid hormone synthesis and secretion has been postulated. Studies in rats have

shown multisynaptic contacts between hypothalamic nuclei and the thyroid gland. Thus, the hypothalamus may be involved in both neuroendocrine and neural regulation of the thyroid gland.

CONCLUSION

The HPT axis is a neuroendocrine feedback system allowing the organism to keep serum thyroid hormone concentrations within a narrow range by negative feedback of thyroid hormone at the level of the hypothalamus and anterior pituitary. In addition, it responds to various internal and external conditions, such as food deprivation and illness, with major changes in serum thyroid hormone concentrations. These changes can be seen as a useful adaptation of the organism to its environment. At the level of the hypothalamus, studies have demonstrated the importance of the thyroid hormone receptor isoform TR β 2 for negative feedback of thyroid hormone on TRH neurons in the PVN. The SCN generates the circadian rhythm in serum TSH, whereas the arcuate nucleus appears to be pivotal in the down-regulation of the HPT axis in response to food deprivation in rodents. Monosynaptic neural connections between the arcuate nucleus and TRH cells in the PVN are involved in this response. At the level of the pituitary, TRH signals are mediated by TRH-R1 and terminated by TRH-DE. The TSH receptor is expressed in folliculostellate cells of the human anterior pituitary,

which offers a substrate for ultra-short loop regulation of TSH secretion. At the level of the thyroid, TSH stimulates not only synthesis and release of thyroid hormone but also growth. The functional meaning of multisynaptic neural connections between the hypothalamus and the thyroid is unclear at present.

Table 1 Causes of Hypothyroidism

| |
|--|
| 1. Central (hypothalamic/pituitary) hypothyroidism |
| a. Loss of functional tissue |
| Tumors (pituitary adenoma, craniopharyngioma, meningioma, germinoma, glioma, metastases) |
| Trauma (surgery, irradiation, head injury) |
| Vascular (ischemic necrosis, hemorrhage, stalk interruption, aneurysm of internal carotid artery) |
| Infections (abscess, tuberculosis, syphilis, toxoplasmosis) |
| Infiltrative (sarcoidosis, histiocytosis, hemochromatosis) |
| Congenital (pituitary hypoplasia, septo-optic dysplasia, basal encephalocele) |
| b. Functional defect in TSH biosynthesis and release |
| Mutations in genes encoding for TRH receptor, TSH- β , or Pit-1 |
| Drugs: dopamine, glucocorticoids, L-thyroxine withdrawal |
| 2. Primary (thyroidal) hypothyroidism |
| a. Loss of functional thyroid tissue |
| Chronic autoimmune thyroiditis |
| Reversible autoimmune hypothyroidism (silent and postpartum thyroiditis, cytokine-induced thyroiditis) |
| Surgery and irradiation (^{131}I or external irradiation) |
| Infiltrative and infectious diseases, subacute thyroiditis |
| Thyroid dysgenesis |
| b. Functional defects in thyroid hormone biosynthesis and release |
| Congenital defects in thyroid hormone biosynthesis |
| Iodine deficiency and iodine excess |
| Drugs: antithyroid agents, lithium, natural and synthetic goitrogenic chemicals |
| 3. "Peripheral" (extrathyroidal) hypothyroidism |
| Thyroid hormone resistance |
| Infantile hemangioma |

childhood cases are caused by craniopharyngiomas (TSH deficiency in 53% of patients) or cranial irradiation (e.g., for dysgerminoma or hematological malignancies).

Adulthood

Adult cases of central hypothyroidism are most frequently due to pituitary macroadenomas (TSH deficiency in 10–25% of patients), pituitary surgery, or irradiation. TSH deficiency sometimes disappears after selective removal of a pituitary adenoma. Cranial radiotherapy for brain tumors causes hypothyroidism in 65% of patients, depending on the radiation dose, and its onset varies between 1 and 26 years after the irradiation. Radiotherapy for pituitary tumors is followed by hypothyroidism in at least 15% of patients (up to 55% when combined with surgery). Less

common causes are severe head trauma (TSH deficiency in 85% of patients), ischemic necrosis of the pituitary from postpartum hemorrhage (syndrome of Sheehan) or severe shock, pituitary apoplexy (hemorrhage in a pituitary adenoma), and lymphocytic hypophysitis. Lymphocytic hypophysitis is likely an autoimmune disease, presenting as a pituitary mass with hypopituitarism predominantly in women during pregnancy and the postpartum period.

Dopamine infusions in critically ill patients may cause central hypothyroidism by inhibition of pituitary TSH secretion. A huge excess of glucocorticoids (e.g., in Cushing's syndrome) also dampens TSH secretion. Removal of the dopamine or steroid excess restores TSH release. A transient inhibition of TSH release is observed after withdrawal of long-term T_4 treatment in TSH-suppressive doses, lasting for about 6 weeks.

PRIMARY HYPOTHYROIDISM

The hallmark of primary hypothyroidism is an elevated serum TSH. The pituitary senses the lower plasma concentrations of T_4 and responds by increasing the release of TSH. Primary hypothyroidism is a very prevalent disease worldwide, especially in iodine-deficient regions. It is also very common in iodine-sufficient regions. The incidence in the adult population is 4.1 cases per 1000 women per year and 0.6 cases per 1000 men per year. The most frequent causes are chronic autoimmune thyroiditis, followed by thyroidectomy and ^{131}I treatment. The incidence of congenital hypothyroidism is approximately 1 in 3500 newborns.

Childhood

Congenital primary hypothyroidism can be caused by structural loss of thyroid tissue due to thyroid agenesis or an ectopic thyroid gland or by functional defects in thyroid hormone biosynthesis due to loss-of-function mutations in genes encoding for the TSH receptor, the sodium iodide symporter, thyroglobulin, or thyroid peroxidase. Neonatal mass screening programs will detect nearly all cases of congenital primary hypothyroidism. Chronic autoimmune thyroiditis is relatively rare during childhood.

Adulthood

Hypothyroidism secondary to chronic autoimmune thyroiditis is caused mainly by destruction of

thyrocytes. Its atrophic variant is much more common than the goitrous variant. The incidence is higher in women than in men and increases with advancing age. Still other variants are silent or painless thyroiditis and postpartum thyroiditis (occurring in 4–6% of women during the first year after delivery and in up to 25% of patients with type 1 diabetes mellitus), which are mostly self-limiting diseases with spontaneous recovery. Another type of reversible autoimmune hypothyroidism is induced by treatment with the cytokines interleukin-2 and interferon- α , associated with the occurrence of thyroid peroxidase antibodies.

Hypothyroidism after subtotal thyroidectomy is less common after surgery for nontoxic or toxic nodular goiter (15% of patients) than after surgery for Graves' hyperthyroidism (40% of patients after 10 years). Most patients become hypothyroid during the first year after surgery. Likewise, hypothyroidism after ^{131}I therapy is less common in patients with toxic nodular goiter (6–13%) than in patients with Graves' hyperthyroidism (up to 70% after 10 years). External radiotherapy of the neck for lymphomas or head and neck cancer causes hypothyroidism in 25 to 50% of patients, depending on pretreatment with iodine-containing radiographic contrast agents, radiation dose, and duration of follow-up.

Hypothyroidism is rarely caused by thyroid infections or thyroidal infiltration during the course of invasive fibrosis, cystinosis, or amyloidosis. In contrast, hypothyroidism during the recovery phase of subacute thyroiditis is not uncommon. Iodine excess may induce hypothyroidism by failure to escape from the Wolff–Chaikoff effect. Sources of iodine excess include an iodine-rich diet (e.g., seaweed) and iodine-containing medications such as potassium iodide, kelp, topical antiseptics, radiographical contrast agents, and amiodarone. Lithium inhibits thyroidal iodide transport and release of thyroid hormones. Long-term lithium treatment results in goiter (up to 50% of patients) and hypothyroidism (20% of patients), usually occurring during the first 2 years of treatment and in patients with preexisting thyroid peroxidase antibodies.

“PERIPHERAL” HYPOTHYROIDISM

Hypothyroidism due to abnormalities outside the hypothalamus, pituitary, and thyroid is rare. In thyroid hormone resistance, a genomic mutation of the thyroid hormone receptor $\text{TR}\beta_1$ fails to transmit the proper signal, causing symptoms and signs of thyroid hormone deficiency in certain target tissues. Serum TSH and serum T_4 and triiodothyronine (T_3) are increased—a remarkable combination of test results. The disease is frequently detected only during adulthood. Three cases of infants with massive hepatic hemangioma and hypothyroidism with markedly elevated serum TSH have been described. The hypothyroidism was caused by high levels of type 3 iodothyronine deiodinase activity in the hemangioma tissue, which catalyzes the degradation of T_4 into the inactive reverse T_3 and the degradation of T_3 into the inactive $3,3'\text{-T}_2$.

There remains some controversy regarding the influence of severity of CH on long-term outcome. Most of the previous studies have reported significant differences in the outcome of patients with severe CH reflected by the type of CH, low or undetectable serum thyroxine (T4) concentrations, or delayed skeletal maturation at diagnosis. However, there was a significant overlap of the IQ score ranges of patients with severe and moderate forms of CH. Moreover, the lack of significant difference in studies with an onset of treatment within the first 2 weeks of life indicated that the influence of severity of CH can be compensated by an early onset of treatment, keeping the period without thyroid hormones as short as possible. Earlier studies had already shown that in some patients with CH the lower socioeconomic score is correlated with significantly lower IQ scores. Moreover, the maintenance of euthyroidism, as assessed by normal thyroid-stimulating hormone (TSH) levels reflecting the compliance of the patient or the family, was shown to be correlated with significantly improved development.

TREATMENT

During the first 10 years of neonatal screening, the recommendations for the initial L-thyroxine substitution dose ranged from 5 to 8 $\mu\text{g}/\text{kg}/\text{day}$, but soon follow-up studies demonstrated that the use of higher initial doses that were used in many European countries, and that led to a more rapid normalization of T4 and especially TSH levels, were correlated with a better long-term outcome. Subsequently, official treatment recommendations were changed to 10 to 15 $\mu\text{g}/\text{kg}/\text{day}$. Furthermore, studies comparing higher and lower doses of initial treatment demonstrated that by using the higher doses, no difference in the outcomes of patients with severe and moderate CH is detectable.

From these data, it can be concluded that the majority of patients with CH, in whom thyroid hormone substitution is started within the first 2 weeks of life with a dose of more than 10 $\mu\text{g}/\text{kg}/\text{day}$, will achieve a normal development and long-term outcome irrespective of the severity of CH at diagnosis, provided that normal TSH levels as well as thyroid hormone levels in the upper normal range are maintained with a good compliance to treatment.

DEFECTS OF THYROID HORMONE BIOSYNTHESIS

It is assumed that 15 to 25% of patients' primary CH is caused by loss-of-function mutations in genes

encoding proteins that are involved in the synthesis of thyroid hormones in thyroid follicular cells.

TSH is a prerequisite not only for normal thyroid hormone synthesis but also for proliferation. TSH acts via a seven-transmembrane glycoprotein receptor by activating G proteins. Accordingly, the inherited CH in the *hyt/hyt* mouse was shown to be caused by homozygosity for a loss of function mutation of the TSH receptor (P556L), leading to postnatal development of thyroid hypoplasia and severe CH. Partial resistance to TSH was identified in patients with euthyroid hyperthyrotropinemia. Subsequently, homozygosity or compound heterozygosity for several loss-of-function mutations of the TSH receptor has been identified in patients with CH. The phenotype includes a spectrum of severity ranging from mild forms to severe CH with "apparent athyrosis" on thyroid scan. With ultrasound studies, hypoplastic remnants of the thyroid are detectable; therefore, the phenotype is similar to patients with PAX-8 mutations. The mode of inheritance is autosomal recessive, but elevated TSH levels have been described in some of the heterozygous carriers.

Iodide transport at the basolateral membrane of the thyroid cell is the initial step of thyroid hormone biosynthesis. The transport is realized by a 13-transmembrane domain protein. After cloning of the gene encoding this protein, the sodium-iodide symporter (NIS), homozygous and compound heterozygous mutations of the gene have been identified in patients with CH. Different mutations result in reduced binding of Na^+ or I^- to the symporter, disturbed ion translocation, truncated NIS proteins, or a defect of NIS trafficking to the thyroid cell membrane. It seems that thyroid enlargement is not present at birth and that the development of nodular goiter, which has been described in patients with NIS mutations, occurs in later life.

Thyroperoxidase (TPO), located at the follicular side of the apical membrane, is a key enzyme in thyroid hormone biosynthesis catalyzing the iodination of tyrosine residues of the thyroglobulin molecule and the coupling of iodotyrosines to triiodothyronine (T3) and T4 in the presence of hydrogen peroxide (H_2O_2). The autosomal recessive inheritance of loss of function mutations of the TPO gene has been described in the majority of patients with CH, with a total organification defect demonstrated by perchlorate discharge tests. The systematic study of patients with severe CH and a normally developed or enlarged thyroid also revealed a high proportion (60%) of autosomal recessive inheritance of TPO mutations.

Thyroglobulin (Tg), a homodimeric glycoprotein, is involved in thyroid hormone synthesis and storage.

Autosomal recessive inheritance of Tg defects has been identified in only a few cases of CH, most likely due to the difficulties of performing mutational screening of the large Tg gene (>300 kb, 48 exons, open reading frame of 2748 AA). The human phenotype is characterized by variable degrees of severity of CH and goiter development when thyroid hormone replacement is delayed. Dominant inheritance of Tg mutations has been described as well, not in patients with CH but rather in patients with the development of goiter later in life.

The functional role of pendrin (PDS), an anion transporter, in the thyrocyte is the transport of iodide across the apical membrane into the follicular lumen. Pendrin is also expressed in the inner ear and kidney, where its exact functions are unknown. The phenotype of Pendred's syndrome is characterized by congenital sensorineural hearing loss, goiter, and (in only a minority of patients) overt CH. Autosomal recessive inheritance of mutations of the pendrin gene has been reported in familial cases of Pendred's syndrome in which some newborns presented with congenital deafness, hypothyroidism, and goiter.

The thyroid oxidases 1 (THOX1) and 2 (THOX2) have been identified as components of the H₂O₂ generating system of the thyroid. The genes encode for two very similar proteins with a fivefold higher expression of THOX 2. The putative structure of the proteins predict seven transmembrane domains, four nicotinamide adenine dinucleotide phosphate (NADPH)-binding sites, and a flavine adenine dinucleotide-binding site. A screening of patients with CH with organification defects revealed one patient with permanent CH and a homozygous mutation resulting in a truncated protein lacking the hydrogen-generating domains. In addition, three patients with transient hypothyroidism during the neonatal period were identified with monoallelic loss-of-function mutations of THOX2.

MOLECULAR DEFECTS OF THYROID ORGANOGENESIS

Even in patients with putative autosomal recessive defects of thyroid hormone biosynthesis, familial cases have been described only rarely and systematic molecular genetic studies of candidate genes of thyroid hormone biosynthesis in patients with normally developed or enlarged thyroid glands are scarce. Therefore, no data on the epidemiology of the various molecular defects of thyroid hormone biosynthesis or on the possible modes of inheritance are available.

Some studies have described autosomal recessive inheritance and familial dominant occurrence of thyroid dysgenesis. Moreover, an increased frequency of minor abnormalities of the development of the thyroid and pharyngeal derivatives has been described in first-degree relatives of patients with CH due to thyroid dysgenesis. Again, epidemiological data on the prevalence of familial thyroid dysgenesis are scarce, but it has become apparent that thyroid dysgenesis, at least in a subset of patients, is an inherited disorder.

Studies of mouse models with targeted disruption of genes involved in the development of the thyroid gland have provided insight into the molecular mechanisms of organogenesis and, thereby, the basis for molecular genetic studies in human patients affected by thyroid dysgenesis. In mice, normal organogenesis and migration have been shown to be dependent on the normal expression and interplay of at least three different transcription factors: NKX 2.1, PAX-8, and TTF-2. Furthermore, targeted mutagenesis of these transcription factors in mice has demonstrated associated developmental defects of other organs because none of these factors is exclusively expressed in the thyroid.

The PAX-8 gene belongs to a family of genes that is characterized by a highly conserved paired-box DNA-binding domain, which encodes for proteins that play an important role in the entire embryonic development. PAX-8 is expressed in the thyroid primordium, the mid- and hindbrain region, and the developing kidney. Mice homozygous for disruption of the PAX-8 gene are characterized by severe hypothyroidism and small hypoplastic thyroid remnants without follicular structures, whereas in heterozygous mice no abnormalities of thyroid development have been described. Screening for mutations in the PAX-8 gene of patients with CH has led to the identification of several patients with heterozygous mutations that have been inherited in a dominant fashion. Most patients do not present with other developmental defects, but in two unrelated male patients, one hypoplastic kidney and one renal agenesis were observed. The thyroid gland of the affected patients presents with different morphological phenotypes. Thyroid hypoplasia, cystic hypoplastic remnants, and ectopic thyroid were described, and the severity of hypothyroidism was mild to moderate.

FKHL15/FOXE1 (previously named TTF-2) belongs to a family of transcription factors characterized by a forkhead DNA-binding domain. FKHL15 is expressed in the thyroid, Rathke's pouch, pharyngeal structures, and hair follicles. In mice with homozygosity for targeted disruption of the *Ttf2* gene, both

thyroid agenesis and thyroid ectopy were identified, indicating that athyrosis and ectopy may be regarded as different degrees of severity of the same molecular defect in humans as well. Furthermore, these mice have a cleft palate that makes their feeding impossible; therefore, early neonatal death is unavoidable. Although screening of the FKHL15 gene of patients with CH without associated problems failed to demonstrate any mutation, the study of two siblings with so-called Bamforth syndrome, including athyrosis and CH, developmental delay, cleft palate, choanal atresia, bifid epiglottis, and spiky hair, demonstrated homozygosity of a loss-of-function mutation of the FKHL15 gene in both siblings. In another family, patients were described with a less severe and incomplete phenotype, indicating either partial activity of the gene or the presence of other modifiers. FKHL15 mutations seem to be a very rare cause of CH in humans, resulting in a specific syndrome with multiple manifestations in other organs.

The NKX2.1 (TTF-1, TITF-1, or T/ebp) gene encodes for a transcription factor of the homeobox domain containing genes of the NKX2 family. NKX2.1 is expressed in the thyroid, forebrain, basal ganglia, pituitary, and lung. Targeted disruption of both *Titf1* alleles leads to a complex phenotype of newborn mice. These mice die shortly after birth due to respiratory distress resulting from defective lung development with insufficient surfactant production, and they lack any thyroid tissue at birth (athyrosis). Because of the early death of homozygous mice, a study of hypothalamic-pituitary function or neurological testing could not be performed. The search

for mutations in the NKX2.1 gene in patients with CH did not reveal any abnormalities. In the investigation of the NKX2.1 gene in patients with CH, where the long-term outcome, despite an early onset of treatment and adequate doses, was unfavorable due to pulmonary complications, severe muscular hypotonia, and neurological symptoms defined as choreoathetosis, heterozygous mutations of the NKX2.1 gene were identified. The phenotype of thyroid and pulmonary manifestations covers a wide spectrum ranging from hyperthyrotropinemia to severe CH due to thyroid agenesis and severe neonatal RDS requiring ventilation to a slight increase in pulmonary infections, whereas choreoathetosis presents with less phenotypical variation. Familial benign choreoathetosis without accompanying pulmonary or thyroid disorders has been attributed to NKX2.1 mutations as well. In light of the severe phenotype of NKX2.1 knockout mice, homozygosity for NKX2.1 mutations in humans is probably not viable. The mechanism by which heterozygous mutations cause the phenotype is most likely haploinsufficiency. Although heterozygous NKX2.1 mice have been reported to be unaffected previously, a more recent study described abnormalities of thyroid function and neurological development in heterozygous mice. See [Tables I to IV](#).

CONCLUSION

Neonatal screening has resulted in early diagnosis and treatment of patients with CH. Subsequently, normal mental development and outcome have been documented in more than 90% of the patients who were

followed up to adolescence. In up to 10% of patients detected by screening programs, neuropsychological development below the normal range was observed. The following factors, which were correlated with a less favorable outcome, have been identified:

- a delay in the onset of therapy,
- an insufficient initial thyroid hormone dose,
- a poor socioeconomic environment,
- poor compliance with therapy,
- other associated defects or complications.

If therapy was initiated during the first 2 weeks of life with an adequate L-thyroxine dose (> 10 µg/kg/day), no difference in the development of patients with severe or milder forms of CH was observed. From recent studies, there is evidence that persistent developmental delay, mental retardation, and

neurological symptoms in some patients with early treatment of CH may be caused by the same molecular defect leading to an impaired development of the thyroid gland rather than by fetal or perinatal hypothyroidism. However, further research is needed to define these molecular mechanisms.

During the era of newborn screening, CH remains an apparent sporadic disease. However, with the normal outcome of patients with early diagnosis and treatment leading to a normal reproduction rate, it is possible that inheritance even of thyroid dysgenesis will become more prevalent. Virtually all industrialized countries now have neonatal screening programs for hypothyroidism in which capillary blood specimens (obtained from heel pricks) collected on filter paper soon after birth are analyzed for TSH or T4.

colleagues defined a plasma total T_4 at diagnosis of 43 nmol/L as the critical point below which the IQ becomes affected by CH.

Both Tillotson and colleagues and Derksen-Lubsen and Verkerk concluded that treatment factors did not appear to have an impact on developmental outcome. However, several recent more studies of children born during the 1990s and treated at a mean age of 14 days with 10 to 15 $\mu\text{g}/\text{kg}/\text{day}$ of T_4 showed that the developmental gap that existed between children with severe CH and controls has been closed. Both early and high-dose treatment appear to be necessary, but this remains controversial.

TREATMENT AND FOLLOW-UP

Most centers are now able to start treatment at a mean age of 9 to 14 days. The rationale for increasing the initial dose of T_4 was that, with 5 to 6 $\mu\text{g}/\text{kg}/\text{day}$, persistent elevations of thyroid-stimulating hormone (TSH) and persistent delay in bone maturation at 3 years were observed. The starting dose at many centers is now 10 to 15 $\mu\text{g}/\text{kg}/\text{day}$. This regimen promptly normalizes plasma TSH but is associated with plasma-free T_4 levels that can be above the reference range of most laboratories. However, it is important to recognize that the normal ranges of free T_4 and of total triiodothyronine (T_3) extend to much higher levels in infants than in older children and adults. In addition, with these starting doses, the mean plasma level of T_3 remains within the normal range, and objective signs of hyperthyroidism have not been documented.

Treatment must be started without waiting for the results of confirmatory tests. (In cases of doubtful diagnosis, treatment can be safely stopped at 3 years of age.) TSH, T_3 , and free T_4 will be checked 2 to 4 weeks later to ensure that thyroid hormones have risen to normal values and that TSH has normalized. Later, clinical and biological follow-up at least at 3, 6, 9, and 12 months will allow adjustment of the treatment during the first year of life. TSH has to be kept in the normal range but does not need to be suppressed, and free T_4 has to be kept near the upper limit of the normal range. Afterward, controls every 6 months will be sufficient so long as TSH and free T_4 remain in the normal range. The dose of T_4 will be titrated upward if the TSH rises and downward if TSH is consistently below the normal range and/or if T_3 is high. Bone mass is not compromised by the large doses of T_4 and high free T_4 levels during the first year of life. There is anecdotal evidence, but no published data based on objective measurements, of

excessive irritability during the first 2 years of life when T_4 levels are high.

Infants with dysmorphogenesis appear to generally need less T_4 than those with dysgenesis. Children with CH fed with soybean formulas may require a higher dose of T_4 because soy products interfere with T_4 absorption.

If an orthotopic thyroid gland was present on the initial nuclear medicine scan, and if there is no secondary rise in TSH requiring an increase in thyroid hormone doses after it has returned to normal, transient hypothyroidism should be suspected. In these cases, treatment should be discontinued at 3 years of age, when thyroid hormone insufficiency no longer has irreversible effects on brain development, and thyroid hormones and TSH should be measured 3 to 4 weeks later. If the TSH has not risen to a level exceeding 10 U/L, it should be tested again in another 6 weeks. If it remains normal, transient hypothyroidism is confirmed.

CONCLUSION

The most important aspect of the outcome of CH is developmental. Most children with CH have normal neuropsychological development (and normal physical growth) when they are treated early and with high doses of T_4 . Further studies of neurophysiological functions that are more sensitive to under- or overtreatment than is the measurement of IQ will probably lead to greater individualization of initial dose recommendations. In the meantime, starting as early as possible with 10 to 15 $\mu\text{g}/\text{kg}/\text{day}$ appears to be safe and seems to allow all children with CH, including those with a severe form of the disease, to achieve their full intellectual potential. In view of the excellent outcome of children with CH detected and treated shortly after birth, testing of cognitive functioning can be limited to those children who are diagnosed late and/or who have school difficulties.

newborns with sporadic permanent CH. Sensitive TSH assays have been shown to reduce the number of controls. This method is used in most countries of Europe and Japan as well as in developing countries with recent screening programs ongoing.

Some countries have a more ambitious program for screening: recognizing all forms of hypothyroidism by the measurement of T₄, TSH, and thyroid hormone-binding protein (TBG), but it is expensive and offers fewer advantages of detecting hypothalamo-pituitary hypothyroidism or deficiency of TBG. T₄ level is determined first, and a confirmation by TSH measurement is performed in the lowest T₄ values (10–20%) (in the Netherlands, an assessment of TBG is realized on the 5% lowest T₄ values). This method is also used in the United States. Furthermore, the screening results obtained by these measurements can be used to monitor the iodine supply in the newborn population. This is an important issue because there is still iodine deficiency in many European countries.

RESULTS

The mean incidence of CH observed in North America, Japan, and Europe was 1 per 3000 to 1 per 4000 births, without seasonal variations. CH had an ethnic background; the highest incidence, 1 per 1600 births, was observed in the Middle East due to the high prevalence of dys-hormonogenesis induced by consanguinity. Conversely, some ethnic groups were less affected, for example, people of African ethnic origin (incidence varying from 1 per 10,000 to 1 per 20,000 births in the United States). Etiologies observed in all series were similar, with the type being revealed by ultrasound or radionuclide scans: athyreosis, 30 to 40%; ectopy, 40 to 50%; dys-hormonogenesis, 15%; and hypoplasia, 5%. Athyreosis and ectopies had a feminine prevalence of 4 to 1; with dys-hormonogenesis being autosomal recessive, the sex ratio was 1 to 1. This genetic background is an argument for a genetic origin of CH, but only 2% were family cases in the French population.

The babies underwent screening on day 3 in combination with other disease screening. They were recalled on days 8 to 10, and L-T₄ treatment was started (10–15 µg/kg/day). The treatment was managed on blood test results; the thyroxine should be in the normal range within 2 weeks, and TSH should be normalized within 4 weeks and should remain in the normal range afterward to obtain the best long-term results. Probably, the first patients detected by screening 20 years ago have not reached an optimal achievement due to late onset of treatment and no

tight biological control; nevertheless, newly detected patients with CH could have a normal outcome.

Two other categories have been raised from the screening results: false-positive and false-negative cases. First, false positives are babies recalled for CH without permanent CH. Causes are multiple (e.g., transient hypothyroidism in preterm infant, iodine overload in mother or baby, autoimmune disease in mother). Isolated elevated TSH persisting over months should be investigated by ultrasonography or scintigraphy to display big ectopies or dys-hormonogenesis or to be checked for mutations of TSH receptor (TSHr). Second, false negatives are babies who are genuinely CH but who are not screened and recalled at the proper time; they are the failures of screening. The main causes of screening pitfalls are contaminated samples and human errors in either processing the sample or reporting the result. Furthermore, pituitary TSH deficiency cannot be detected by the measurement of TSH alone. CH could be missed by both methods in dys-hormonogenesis with iodine overload or in infants having an exchange transfusion prior to the screening.

PHYSIOPATHOLOGY

The physiopathology of CH by dysgenesis is still unknown. Recently, four genes—TTF1 and TTF2 (thyroid transcription factors 1 and 2), PAX8, and TSHr—have been shown to be mutated in some very specific instances. Mutations of these genes have been searched extensively in sporadic cases and were not found. Therefore, thyroid dysgenesis might be due either to a cascade of genes controlled by TTF1, TTF2, and PAX8 or to a multifactorial origin related to genetic background. Dys-hormonogenesis is related to mutation in genes of the biochemical pathway: NIS (symporter Na/iodine), TPO (thyroid peroxidase), thyroglobulin, desiodases (DI and DII), and Pendred syndrome (Pendrine).

best single assay for detection of hypothyroidism. Test characteristics of the serum TSH assay for the diagnosis of abnormal thyroid function are 98.8% sensitivity, 94.3% specificity, 83.9% positive predictive value, and 99.7% negative predictive value. The high diagnostic accuracy of the TSH assay is caused by the exquisite sensitivity of the pituitary for small changes in serum thyroid hormone concentrations. Because of the negative feedback of thyroid hormone on the TSH release from the pituitary, a fall in serum thyroxine will result in elevated TSH levels in serum, and a rise in serum thyroid hormone concentrations will suppress serum TSH.

Figure 1 depicts a flow diagram for the biochemical diagnosis of hypothyroidism. If TSH is normal, euthyroidism is nearly certain and no further tests are necessary. However, central hypothyroidism (due to TSH deficiency) may be overlooked because serum

TSH in this condition is usually normal or decreased. Fortunately, clinical examination provides sufficient clues to suspect hypothalamic or pituitary disease such as symptoms arising from space-occupying lesions in the sella or from overproduction of pituitary hormones. As a rule, lack of gonadotropins occurs before the onset of TSH deficiency; therefore, the presence of regular menstrual periods in women or normal potency in men renders central hypothyroidism unlikely. The low incidence of central hypothyroidism (2.7 per 100,000 persons per year) does not warrant routine free thyroxine (FT₄) measurements after a normal TSH test result.

If TSH is elevated, a decreased serum FT₄ value indicates overt hypothyroidism and a normal FT₄ points to subclinical hypothyroidism. In both instances, the thyroid gland itself is at fault (primary hypothyroidism). The very rare combination of elevated TSH and elevated FT₄ allows the diagnosis of thyroid hormone resistance or TSH-producing adenoma.

Figure 1 Flow diagram for the biochemical diagnosis of hypothyroidism. *, see text.

NOSOLOGIC DIAGNOSIS

The cause of the hypothyroidism may reveal itself in many instances from the history (e.g., recent delivery, exposure to iodine excess, family members with autoimmune thyroid disease, use of antithyroid drugs, thyroid surgery or ¹³¹I therapy) and physical examination (although most patients will have no goiter).

The presence of thyroid peroxidase antibodies in serum indicates chronic autoimmune thyroiditis.

Thyroid scans usually show low and inhomogenous uptake of the radioisotope. Preserved thyroidal radioiodine uptake and homogenous distribution of the tracer increases the likelihood of reversible hypothyroidism (due to iodine excess).

Spontaneous recovery of hypothyroidism occurs in the course of subacute and postpartum thyroiditis and sometimes during the first 6 months after subtotal thyroidectomy or ^{131}I therapy. It is exceptional in chronic autoimmune thyroiditis.

later. In this survey, 97 females with subclinical or overt hypothyroidism have been detected with a prevalence of 9.3% and a calculated incidence of 0.41% per year. The risk factors for the development of hypothyroidism were a raised TSH level and/or positive antithyroid antibodies. For females with a raised serum TSH, a mean annual risk for developing hypothyroidism of 26% over 10 years could be calculated.

In a prospective study of 82 female patients with known subclinical hypothyroidism, we investigated the natural course of this syndrome with regular evaluations at yearly intervals. Over a mean period of 9.2 years, 28% of the patients progressed to overt hypothyroidism, 68% remained in the subclinical state, and 4% reverted to a normal TSH. The incidence of overt hypothyroidism was correlated with the initial serum TSH concentrations. The calculated 10-year rate of overt hypothyroidism was 0% for TSH levels of 4 to 6 mU/L but was 43% for values of 6 to 12 mU/L and 77% for TSH levels greater than 12 mU/L (Fig. 1).

Figure 2 Clinical assessment of patients and controls with the clinical score by Zulewski and colleagues in subclinical hypothyroidism ($n = 93$), overt hypothyroidism ($n = 50$), and age-matched controls ($n = 80$). Only the patients with the most severe hypothyroidism (with low triiodothyronine [T3]) are clearly hypothyroid. The patients with subclinical hypothyroidism or with less severe hypothyroidism (normal T3) show just a few clinical signs. Adapted from Zulewski, H., Müller, B., Exer, P., Miserez, A. R., and Staub, J. J. (1997). Estimation of tissue hypothyroidism by a new clinical score: Evaluation of patients with various grades of hypothyroidism and controls. *J. Clin. Endocrinol. Metab.* **82**, 771–776.

CLINICAL MANIFESTATIONS AND BENEFITS OF TREATMENT

Symptoms

One of the most controversial aspects concerning subclinical hypothyroidism is whether affected patients are symptomatic and so may benefit from thyroid hormone replacement. Based on case control studies, nearly 30% of patients with subclinical hypothyroidism may have symptoms that are suggestive of thyroid hormone deficiency (Fig. 2). Symptoms and signs of hypothyroidism may be very vague and non-specific and so are easily overlooked in an individual patient. Five randomized, placebo-controlled intervention trials over a period of 6 to 12 months were published. These studies support the finding that patients with subclinical hypothyroidism may indeed have, in part, specific clinical signs and symptoms of hypothyroidism (Table I). Three of these studies reported significant improvement in signs and symptoms of hypothyroidism assessed by various clinical scores of hypothyroidism, whereas two other studies found no benefit of thyroxine therapy.

Table 1 Effect of Thyroxine Replacement Therapy on General Symptoms in Patients with Subclinical Hypothyroidism: Randomized Placebo-Controlled Trials

| Treatment duration (months) | n | TSH level (mU/L) | | Symptomatic response | Reference |
|-----------------------------|----|-------------------------|---------------------|--|--|
| | | before L-T ⁴ | on L-T ⁴ | | |
| 12 | 17 | 10.8 | 2.6 | Symptom score (Billewicz; $P < 0.05$) | Cooper <i>et al. Ann. Int. Med.</i> (1984) |
| 6 | 17 | 7.7 | 1.9 | Symptom score (Billewicz; $P < 0.01$) | Nyström <i>et al. Clin. Endocrinol.</i> (1988) |
| 10 | 18 | 12.1 | 4.6 | HRQL questionnaire ($P = \text{n.s.}$) | Jaeschke <i>et al. J. Gen. Int. Med.</i> (1996) |
| 12 | 31 | 12.8 | 3.1 | Symptom score (Billewicz, Zulewski; $P < 0.05$) | Meier <i>et al. J. Clin. Endocrinol. Metab.</i> (2001) |
| 6 | 23 | 8.0 | 3.4 | HRQL questionnaire ($P = \text{n.s.}$) | Kong <i>et al. Am. J. Med.</i> (2002) |

Note. The symptomatic response to thyroxine treatment was assessed by clinical scores based on Billewicz, W. Z., Chapman, R. S., Crooks, J., *et al.* (1969). Statistical methods applied to the diagnosis of hypothyroidism. *Q. J. Med.* **38**, 255–266, and Zulewski, H., Müller, B., Exer, P., *et al.* (1997). Estimation of tissue hypothyroidism by a new clinical score: Evaluation of patients with various grades of hypothyroidism and controls. *J. Clin. Endocrinol. Metab.* **82**, 771–776, as well as by quality-of-life scales.

Cognitive Function and Neuropsychiatric Dysfunction

Several studies suggest that subclinical hypothyroidism is associated with neuropsychiatric disease, with higher scores on scales of depression and anxiety in affected patients. Neuropsychiatric parameters (i.e., reaction time and figure identification), as well as memory scores, were significantly improved in four intervention trials assessing the effect of thyroxine treatment in patients with subclinical hypothyroidism (mean TSH levels at baseline: 7 to 12 mU/L).

Atherosclerosis and Cardiovascular Risk Factors

The relationship between subclinical hypothyroidism and atherosclerotic risk factors has been widely investigated, with major interest in serum lipid abnormalities. Several cross-sectional studies found serum lipid concentrations, mainly total cholesterol levels, to be within the normal range, whereas others detected significant elevations of total cholesterol and/or low-density lipoprotein (LDL) cholesterol concentrations, especially in smokers. In addition, reduced high-density lipoprotein (HDL) cholesterol levels were reported in some studies. Two meta-analyses reanalyzed the effect of several intervention trials and could demonstrate a beneficial effect of thyroxine on serum cholesterol levels. In analyzing 13 studies, Danese and co-workers reported favorable reductions of total cholesterol and LDL cholesterol levels, with mean decreases of 0.20 and 0.26 mmol/L, respectively. These findings were confirmed by two randomized, placebo-controlled studies reporting

significant reductions of total and LDL cholesterol concentrations in thyroxine-treated women with subclinical hypothyroidism (Fig. 3). Our “Basel Thyroid Study” is the first randomized trial that demonstrates a significant effect of thyroxine on total cholesterol and atherogenic LDL cholesterol levels. Based on this study, we calculated a relevant risk reduction of cardiovascular mortality of 9 to 31% in relation to the observed improvement in LDL cholesterol levels. Hence, subclinical hypothyroidism must be considered as a risk factor for the development of atherosclerosis and coronary heart disease. Many cross-sectional studies have suggested an association between subclinical hypothyroidism, or autoimmune thyroid disease, and atherosclerosis. A recent population-based survey reported that increased serum TSH is an independent risk factor for the development of aortic atherosclerosis and myocardial infarction. In this study, the risk of having atherosclerotic disease was twice as high in women with subclinical hypothyroidism than in euthyroid controls. The difference persisted after adjustment for age, body mass index, blood pressure, smoking status, and cholesterol levels. Further mechanisms are thought to be involved in the association between mild thyroid failure and cardiovascular disease. These include smoking, a hypercoagulable state, elevated lipoprotein and homocysteine levels, and endothelial effects of thyroid hormones.

Others

Myocardial function has been shown to be slightly impaired in patients with subclinical hypothyroidism. The identified functional abnormalities include impaired myocardial contractility and diastolic function,

Figure 3 Effect of thyroxine treatment on total cholesterol levels in subclinical hypothyroidism. Randomized placebo-controlled trials are shown in boxes. Adapted from Danese, M. D., Ladenson P. W., Meinert, C. L., and Powe, N. R. (2000). Clinical review 115: Effect of thyroxine therapy on serum lipoproteins in patients with mild thyroid failure—A quantitative review of the literature. *J. Clin. Endocrinol. Metab.* **85**, 2993–3001.

at rest or with exercise, with beneficial results after thyroid hormone replacement therapy. Furthermore, abnormalities in peripheral nerve function and neuromuscular activity, skeletal muscle abnormalities, intraocular pressure, and ovulatory dysfunction have been described.

DIAGNOSTIC AND THERAPEUTIC RECOMMENDATIONS

Screening

Screening for thyroid disease is still a controversial issue. TSH screening in women over 35 years of age has been shown to be cost-effective. Some authors favor TSH screening for thyroid dysfunction in asymptomatic adults, although others do not favor

this policy because the effects of subsequent thyroxine therapy are not beneficial in all patients with subclinical hypothyroidism. Subclinical hypothyroidism is a frequent finding in women over 40 years of age (affecting about 10% of the female population in this age group), and its clinical presentation may be subtle. Therefore, TSH screening should be advocated at least by a case-finding approach, focusing on patients visiting their physicians for unrelated reasons. Because smoking impairs both thyroid hormone secretion and thyroid hormone action, smoking status should be considered in the evaluation of patients in whom hypothyroidism is suspected.

Replacement Therapy with Thyroxine

The goal of treating patients with mild thyroid failure is to reverse clinical and metabolic alterations by

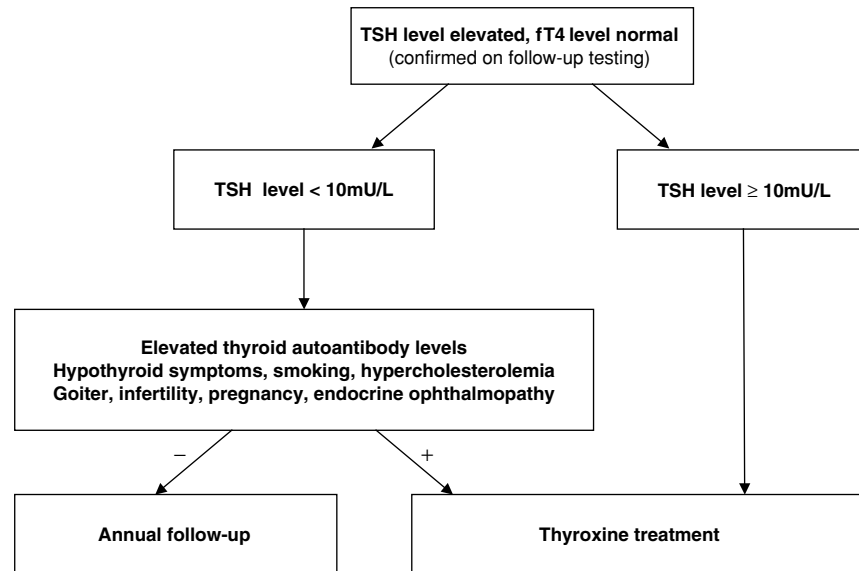

Figure 4 Algorithm for the management of patients with subclinical hypothyroidism.

hormone supplementation and to prevent progression of the subclinical form to the overt stage of hypothyroidism, with its considerable morbidity and possible mortality. Thyroxine treatment should be used in patients who have elevated TSH levels greater than 10 mU/L and measurable circulating thyroid autoantibodies. Furthermore, thyroxine therapy is indicated for patients at risk with special clinical conditions such as goiter, thyroidectomy, depression, infertility, and endocrine ophthalmopathy and hypercholesterolemia, particularly in the presence of other cardiovascular risk factors such as smoking and hypertension. In patients with minimal or moderate TSH elevations (<10 mU/L) with no clinical or metabolic changes, treatment can be withheld, but annual follow-ups are required (Fig. 4).

Overtreatment can produce overt or subclinical hyperthyroidism with its effects on morbidity (e.g., atrial fibrillation, osteopenia) and mortality. Therefore, fine-tuning of thyroxine replacement therapy with the goal of restoring serum TSH to physiological euthyroid levels is mandatory.

patients who develop hypothyroidism rapidly (i.e., when replacement therapy is discontinued in patients with primary hypothyroidism or after the gland is surgically removed) have more symptoms. In such patients, manifestations of overt hypothyroidism are present by 6 weeks. In general, older patients tend to have fewer symptoms and signs of hypothyroidism than do young adults.

In adults, common features of hypothyroidism include easy fatigability, tiredness, coldness, mild weight gain, constipation, menstrual irregularities, and muscle cramps. Drowsiness and slowing of intellectual and motor activity are often reported. Sensitivity to cold is suggested by the use of more blankets on the bed. Women frequently complain of hair loss, brittle nails, and dry skin. Periorbital puffiness may be present. Stiffness and aching of muscles may be attributed to rheumatism. Constipation may occur. Numbness and tingling of the extremities are frequent. Physical findings include cool dry skin, a puffy face and hands, a hoarse husky voice, and slow reflexes.

Clinical Features of Hypothyroidism in the Elderly

Hypothyroidism in the elderly is often atypical and elusive and often lacks the classic clinical features present in younger patients. This is due to a combination of several factors, including the insidious onset, the ambiguity of several signs and symptoms (e.g., fatigue, weakness, cold intolerance, dry skin, hair loss, constipation, poor appetite, depression and/or mental deterioration, hearing loss, cardiomegaly, congestive heart failure) that may be attributed to normal aging, and the frequent coexistence of several age-associated diseases.

The most relevant clinical findings that lead one to suspect hypothyroidism in the elderly are an unexplained increase in serum cholesterol, severe constipation, congestive heart failure (particularly when it presents as restrictive cardiomyopathy), and macrocytic anemia (as a consequence of folate deficiency or coexistent autoimmune gastritis and pernicious anemia).

CLINICAL ASPECTS OF HYPOTHYROIDISM DUE TO VARIOUS ETIOLOGIES

Primary Hypothyroidism

Primary hypothyroidism in adults results mainly from autoimmune thyroiditis, is more common in women than in men, and occurs between 40 and 60 years of

age. In these patients, clinical features of hypothyroidism may be accompanied by the typical goiter of Hashimoto's thyroiditis. When present, the goiter is usually firm in consistency, generally moderate in size, and often lobulated (although well-defined nodules are unusual).

Other organ-specific autoimmune diseases, such as insulin-dependent diabetes mellitus, Addison's disease, premature ovarian failure, celiac disease, hypoparathyroidism, and myasthenia gravis, may also coexist. Patients with primary hypothyroidism may also complain of vitiligo and alopecia. Primary autoimmune hypothyroidism may also occur as a component of either the type I or the type II polyglandular autoimmune syndrome. The specific association of primary hypothyroidism and primary adrenal cortical insufficiency is known as Schmidt's syndrome. The rare type I syndrome consists of at least two of the triad of Addison's disease, hypoparathyroidism, and chronic mucocutaneous candidiasis; other autoimmune disorders, such as alopecia, chronic autoimmune thyroiditis, and malabsorption syndrome, may also be present. Autoimmune thyroid disease is reported in 10 to 12% of these patients. Type I polyglandular autoimmune syndrome presents more often during childhood. The type II syndrome is more common and usually presents during adulthood. Addison's disease, Hashimoto's thyroiditis, and type 1 diabetes are the most common endocrine deficiencies found in these patients, although gonadal failure, pernicious anemia, and vitiligo are observed in a significant percentage.

Central Hypothyroidism

The clinical picture of central hypothyroidism varies depending on the severity of thyroid failure, the extent of associated hormone deficiencies, the age of the patient, and the nature of the underlying lesion. Central hypothyroidism is due to TSH deficiency caused by either hypothalamic or pituitary disease. The differentiation of central hypothyroidism from primary hypothyroidism is important for the institution of the proper therapy. The clinical features of central hypothyroidism are similar to those of primary hypothyroidism, although the former are generally less pronounced. The skin is pale and cool, but it is not as coarse and dry as in primary hypothyroidism. Periorbital and peripheral edema are uncommon in patients with central hypothyroidism. Loss of axillary, pubic, and facial hair, as well as thinning of the lateral eyebrows, is more pronounced. The tongue is not enlarged, and hoarseness of the voice is not as

prominent as it is in primary hypothyroidism. The heart tends to be small, and blood pressure is low. Atrophic breasts and amenorrhea are found in women. Body weight is more likely to be reduced than to be increased. Defects in growth hormone (GH) and gonadotropin secretion usually precede TSH insufficiency, and in most cases adrenocorticotropin hormone (ACTH) secretion is the last to be affected. Growth failure with delayed skeletal maturation results from GH deficiency in children. Hypoglycemia may occur. Gonadotropin insufficiency results in impotence, loss of libido, and diminished beard growth in men and results in amenorrhea, infertility, and atrophy of the breasts in women. ACTH deficiency leads to weakness, postural hypotension, and depigmentation of the areole and other normally pigmented areas of the skin. Symptoms and signs that arise directly from the hypothalamic or pituitary lesion may precede, accompany, or even obscure manifestations of pituitary failure. The manifestations of a sellar mass include headache and symptoms secondary to compression of adjacent structures with visual field disturbances and ophthalmoplegia.

DIAGNOSTIC ACCURACY OF THE CLINICAL FEATURES OF HYPOTHYROIDISM

Several attempts have been made to develop a clinical score system that, based on the most frequent symptoms and signs of hypothyroidism, could accurately predict the diagnosis of thyroid failure in individual patients.

During the 1960s, Billewicz and colleagues described a diagnostic index that scored the presence or absence of various signs and symptoms of hypothyroidism. However, at that time, modern laboratory thyroid function tests were not available to validate the diagnostic accuracy of such a score. More recently, Zulewski and colleagues proposed a convenient clinical score that is both easy to determine and sensitive for individual assessment of the severity of thyroid failure. The frequencies of the 14 more common symptoms and signs of overt hypothyroidism are shown in [Table I](#). The most frequent features in hypothyroid patients were prolonged ankle reflex (77%) and complaints about dry skin (76%). A reduced pulse rate and cold intolerance were recorded with a high frequency in euthyroid controls and so were excluded from this score. The sensitivity and specificity of each symptom and sign of hypothyroidism, and the analysis of their positive and negative predictive values, are shown in [Table I](#). [Table II](#) shows the scoring system

Table I Sensitivity and Specificity of the 14 Symptoms and Signs of Hypothyroidism and Analysis of Their Positive and Negative Predictive Values (Percentages)

| Symptoms and signs | Sensitivity | Specificity | Positive predictive value | Negative predictive value |
|--------------------|-------------|-------------|---------------------------|---------------------------|
| Ankle reflex | 77 | 93 | 92 | 80 |
| Dry skin | 76 | 64 | 68 | 73 |
| Cold intolerance | 64 | 65 | 65 | 64 |
| Coarse skin | 60 | 81 | 76 | 67 |
| Puffiness | 60 | 96 | 94 | 71 |
| Pulse rate | 58 | 42 | 50 | 50 |
| Sweating | 54 | 86 | 79 | 65 |
| Weight increase | 54 | 77 | 70 | 63 |
| Paresthesia | 52 | 82 | 75 | 63 |
| Cold skin | 50 | 80 | 71 | 61 |
| Constipation | 48 | 85 | 76 | 62 |
| Slow movements | 36 | 99 | 96 | 61 |
| Hoarseness | 34 | 87 | 73 | 57 |
| Hearing loss | 22 | 97 | 90 | 53 |

of symptoms and signs of hypothyroidism. Because a correlation analysis revealed a significant correlation of these scores with age, a simple age-correcting factor was defined by adding 1 point to the sum of symptoms and signs in women under 55 years of age. According to this analysis, the following diagnostic ranges for the clinical judgment with the age-corrected score were defined: hypothyroid, more than 5 points; intermediate, 3 to 5 points; euthyroid, 0 to 2 points.

ORGAN SYSTEM MANIFESTATIONS OF HYPOTHYROIDISM

Cutaneous Manifestations and Changes in the Connective Tissues

The cutaneous changes observed in hypothyroidism belong to the most classic and frequent findings of the disease ([Table III](#)). In more than 80% of patients with primary hypothyroidism, the epidermis is dry, rough, cool, and covered with fine superficial scales. This is an expression of decreased cutaneous metabolism, reduced secretion of sweat and sebaceous glands, vasoconstriction, thinning of the epidermis, and hyperkeratosis of the stratum corneum. The face is puffy, pale, and expressionless at rest ([Fig. 1](#)). The palpebral fissure may be narrowed because of blepharoptosis. The tongue is usually large, and some patients will complain of this problem. The tongue is smooth if pernicious anemia coexists. The voice is

Table II Scoring of Symptoms and Signs of Hypothyroidism

| | | Score | |
|-----------------------|--|---------|--------|
| | | Present | Absent |
| On the basis of | | | |
| Symptoms | | | |
| Diminished sweating | Sweating in the warm room on a hot summer day | 1 | 0 |
| Hoarseness | Speaking voice, singing voice | 1 | 0 |
| Paresthesia | Subjective sensation | 1 | 0 |
| Dry skin | Dryness of skin, noticed spontaneously, requiring treatment | 1 | 0 |
| Constipation | Bowel habit, use of laxative | 1 | 0 |
| Impairment of hearing | Progressive impairment of hearing | 1 | 0 |
| Weight increase | Recorded weight increase, tightness of clothes | 1 | 0 |
| Physical signs | | | |
| Slow movements | Observe patient removing his/her clothes | 1 | 0 |
| Delayed ankle reflex | Observe the relaxation of the reflex | 1 | 0 |
| Coarse skin | Examine hands, forearms, and elbows for roughness and thickening of skin | 1 | 0 |
| Periorbital puffiness | This should obscure the curve of the malar bone | 1 | 0 |
| Cold skin | Compare temperature of hands with that of examiner | 1 | 0 |

Note. For clinical judgment, add 1 point to the sum of symptoms and signs present in women under 55 years of age. Hypothyroid, more than 5 points; intermediate, 3 to 5 points; euthyroid, less than 3 points.

husky, low-pitched, and coarse due to the enlargement of the tongue and the thickening of the pharyngeal and laryngeal mucous membranes. The speech is deliberate and slow.

Hair Follicles and Nails

The hair is dry, dull, and coarse, and it grows slowly, becoming sparse and falling out readily. Loss of scalp, genital, and beard hair may also occur. Hair may be lost from the temporal aspects of the eyebrows (Queen Anne's sign). The nails, through retardation of growth, become thickened and brittle, striated in both transverse and longitudinal grooves, showing frequent deformities.

Table III Cutaneous Signs and Symptoms of Hypothyroidism (Percentages)

| Cutaneous manifestation | Frequency |
|---|-----------|
| Cold intolerance | 50–95 |
| Nail abnormality | 90 |
| Thickening and dryness of hair and skin | 80–90 |
| Edema of hands, face, and eyelids | 70–85 |
| Change in shape of face | 70 |
| Malar flush | 50 |
| Nonpitting edema | 30 |
| Alopecia | 30–40 |
| Pallor | 25–60 |
| Decreased sweat secretion | 10–70 |

Cardiovascular Changes

Lack of thyroid hormones causes multiple alterations in the cardiovascular system (Table IV). Bradycardia, cardiomegaly, and low-voltage complexes on the electrocardiogram (ECG) are well-known features. The decrease in pulse rate approximately parallels the decrease in the body's metabolic rate. Myocardial contractility is reduced. The cardiac output at rest is decreased due to reduction in both stroke volume and heart rate, reflecting loss of the inotropic and chronotropic effects of thyroid hormones. Peripheral vascular resistance at rest is increased, and blood volume is reduced. These hemodynamic alterations

Figure 1 Photographs of a hypothyroid patient.

Table IV Cardiovascular Signs and Symptoms in Hypothyroidism

| |
|---|
| Symptoms |
| Dyspnea |
| Decreased exercise tolerance |
| Angina |
| Signs |
| Low pulse rate |
| Increased systemic vascular resistance |
| Diastolic hypertension |
| Cardiomegaly |
| Pericardial effusion |
| Peripheral nonpitting edema |
| Low voltage ECG, nonspecific ST-T changes |

cause narrowing of pulse pressure, prolongation of circulation time, and decreased blood flow to the tissues. Arterial blood pressure is often mildly increased. Hypertension is present in 10 to 20% of patients with hypothyroidism. Diastolic hypertension is usually restored to normal after treatment. Few symptoms associated with the cardiovascular system are referred from patients with hypothyroidism. Exertional dyspnea and exercise intolerance are probably due to skeletal muscle dysfunction.

On physical examination, certain findings can suggest hypothyroidism. The heart rate is lowered, the pulse pressure is narrowed, and the carotid upstroke and left ventricular apical impulse are diminished. The heart sounds are diminished in intensity. This finding is due largely to effusion into the pericardial sac of fluid rich in protein and glycosaminoglycans.

Electrocardiographic Changes

Electrocardiographic changes include sinus bradycardia, prolongation of the PR interval, low amplitude of the P wave and QRS complex, alterations of the ST segment, and flattened or inverted T waves. Although suggestive of myocardial ischemia, these waveform changes often disappear during T₄ substitution therapy. Pericardial effusion is probably responsible for the low amplitude.

Respiratory Changes

Respiratory troubles are rarely a major complaint in hypothyroid patients. However, hypothyroidism may cause respiratory problems through (1) depression of the respiratory center in the brain, (2) disturbed neural conduction and/or neuromuscular transmission to the

respiratory muscles (due to hypothyroid neuropathy), (3) diseased respiratory muscle function (due to hypothyroid myopathy), and/or (4) changes in the alveolar-capillary membranes and the surfactant lining the alveoli, leading to impaired gas exchange.

Fatigue and dyspnea on exertion are frequent symptoms. Dyspnea is a frequent complaint of myxedematous patients, but it is also a common symptom among well persons. Congestive heart failure of separate origin, pleural effusion, anemia, obesity, and/or pulmonary disease may be responsible for dyspnea.

Gastrointestinal Changes

The gastrointestinal manifestations of hypothyroidism are listed in Table V. Poor appetite can be a leading symptom in hypothyroid patients. Anorexia can reasonably be interpreted as the reflection of a lowered food requirement. Although two-thirds of hypothyroid patients report weight gain, it is of modest degree and due largely to retention of fluid by the hydrophilic glycoprotein deposits in the tissues. True obesity is not a feature of hypothyroidism per se.

Constipation is frequently present and is the result of lowered food intake and decreased peristaltic activity. Atrophy of the gastric and intestinal mucosa and myxedematous infiltration of the bowel wall may be present at histological examination. Immune gastritis is often observed in hypothyroid patients with autoimmune thyroiditis. As many as 50% of patients with autoimmune hypothyroidism have achlorhydria, 25% have circulating antibodies directed against the gastric parietal cells or intrinsic factor, and 2 to 10% have pernicious anemia caused by impaired absorption of vitamin B₁₂.

Symptoms or signs of disturbed liver or exocrine pancreatic function are usually not encountered,

Table V Gastrointestinal Manifestations of Hypothyroidism

| |
|-----------------------------------|
| Symptoms |
| Anorexia |
| Gaseous distension |
| Constipation |
| Signs |
| Prolonged gastric emptying |

but biochemical tests may suggest disease. The association of liver disease and hypothyroidism is suggestive of a multisystem autoimmune disease affecting both the liver (e.g., chronic active hepatitis, primary biliary cirrhosis) and the thyroid. Structural liver damage is unusual in hypothyroidism per se. Serum glutamine–oxaloacetic transaminase (GOT), lactate dehydrogenase (LDH), and creatin–phosphokinase (CPK) levels are elevated in patients with hypothyroidism. These enzymes return to normal over 2 to 4 weeks during treatment. Urinary amylase levels may be increased.

Cerebral and Neurological Changes

Thyroid hormone is essential for the development of the central nervous system. Deficiency during fetal life or at birth causes hypoplasia of cortical neurons with poor development of cellular processes, retarded myelination, and reduced vascularity. Deficiency of thyroid hormone beginning during adult life causes less severe manifestations that usually reverse after treatment with thyroid hormone.

Table VI lists the numerous symptoms suggesting either neurological or psychiatric disorders in patients with moderate to severe hypothyroidism. In adult and elderly patients, mental changes may go unrecognized for a long time because of their slow development and because they may mimic cerebral atherosclerosis. However, an unusual complacency, fatigue, and pronounced somnolence or even lethargy, together with a prolonged reaction time, should suggest the possibility of hypothyroidism. All intellectual functions, including speech, are slowed. There is loss of

Table VI Neurological and Psychiatric Manifestations in Hypothyroidism

initiative, and slow-wittedness and memory defects are common. Myxedematous dementia in the elderly patient may be mistaken for senile dementia. Memory is undoubtedly impaired, and attention and the desire to think are reduced. The emotional level seems definitely low, and irritability is decreased. Except during the terminal stage, reasoning power is preserved. Sensory phenomena are common. Numbness and tingling of the extremities are frequent. Mono-neuropathies occur in hypothyroidism, as attested to by the high incidence of carpal tunnel syndrome (i.e., compression of the median nerve at the wrist). Nocturnal paresthesia and pain in the median nerve distribution in one hand or both hands is a common manifestation of this condition.

The tendon reflexes are slow, especially during the relaxation phase, producing the characteristic “hung-up reflexes.” This phenomenon is due to a decrease in the rate of muscle contraction and relaxation rather than to a delay in nerve conduction.

Electroencephalographic changes include slow alpha wave activity and general loss of amplitude.

Muscle–Skeletal Changes

Muscles

In patients with hypothyroidism, disordered muscle function often is the predominating feature of the clinical syndrome. Generalized muscular hypertrophy, accompanied by easy fatigue and slowness of movements, occurs in some myxedematous children or adults.

Muscle symptoms such as myalgia, muscle weakness, stiffness, cramps, and easy fatigability are very prevalent in hypothyroid patients. The symptoms are aggravated by exposure to cold. They are also prominent during the rapid onset of hypothyroidism after surgery or 131-iodine therapy.

Skeletal System: Calcium and Phosphorus Metabolism

In the adult skeleton, thyroid hormone deficiency decreases recruitment, maturation, and activity of bone cells, leading to decreased remodeling that is especially reflected in the impaired function of the osteoclasts. Despite this decrease in osteoclastic activity, trabecular bone volume and bone mineral density appear to be comparable to those in age-matched normals, presumably because of the corresponding decrease in osteoblastic activity. The concentrations of calcium and phosphorus in serum are usually normal, but calcium may be slightly elevated. Serum alkaline phosphatase levels are often decreased, as are serum osteocalcin

levels. Because the levels of parathyroid hormone are often slightly increased, some degree of resistance to its action may be present. Serum concentrations of 1,25-dihydroxycholecalciferol are also increased.

Hematological Changes

Anemia is present in as many as two-thirds of hypothyroid children and adolescents and in approximately one-third of adults with hypothyroidism. Anemia is usually mild. In two reports on a large series of patients with hypothyroidism from various causes, the incidence of anemia ranged from 32% to as high as 84%. Anemia in hypothyroidism may be a normochromic and normocytic anemia due to the diminished oxygen requirements and decreased production of erythropoietin, or it may result from a specific depression of the marrow that lacks thyroid hormone. The anemia may be macrocytic, sometimes from deficiency of vitamin B12. Folate deficiency from malabsorption or dietary inadequacy may also cause macrocytic anemia.

Granulocyte, lymphocyte, and platelet counts are usually normal in hypothyroidism. Hypothyroid patients may have bleeding symptoms such as easy bruising, menorrhagia, and prolonged bleeding after tooth extraction. The most frequent defects in hemostasis are prolonged bleeding time, decreased platelet adhesiveness, and low plasma concentrations of factor VIII and von Willebrand factor.

Changes in the Reproductive Tract

In both sexes, thyroid hormones influence sexual development and reproductive function. Infantile hypothyroidism leads to sexual immaturity, and juvenile hypothyroidism causes a delay in the onset of puberty followed by anovulatory cycles. Paradoxically, primary hypothyroidism may also cause precocious sexual development and galactorrhea.

In adult men, hypothyroidism may lead to impotence, lack of libido, and/or (rarely) testicular tubular involution. The testicles are histologically immature if hypothyroidism preceded puberty and show tubular involution if the onset of hypothyroidism was after puberty. In adult hypothyroid men, semen analysis is usually normal. In adult women, severe hypothyroidism may be associated with diminished libido and failure of ovulation. In general, hypothyroid women complain of menorrhagia as well as (occasionally) oligo and amenorrhea. Plasma gonadotropins are usually in the normal range in primary hypothyroidism,

and the pulsatile gonadotropin release during the follicular phase is normal, but the ovulatory surge of luteinizing hormone (LH) might not happen. Secretion of progesterone is inadequate, and endometrial proliferation persists, resulting in excessive and irregular breakthrough menstrual bleeding. The anovulation is reflected in the frequent finding of a proliferative endometrium. These changes may be due to a deficient secretion of LH. Mild to moderate hyperprolactinemia is a frequent finding in hypothyroid women with or without galactorrhea. It is attributed to the stimulatory effect of increased thyrotropin-releasing hormone (TRH) on prolactin secretion. Fertility is reduced, and spontaneous abortion may result, although many pregnancies are successful.

The literature contains many reports of pregnancy in untreated hypothyroid women. Euthyroid neonates born to hypothyroid mothers during pregnancy have been reported to achieve lower IQs later in life. When treatment has been started during pregnancy, a normal child is usually produced, but abortion is frequent in myxedematous women. Pregnancy-induced hypertension is two to three times more common in hypothyroid women. Low birthweight may be secondary to premature delivery for gestational hypertension. The incidence of various congenital abnormalities may be increased, but recent studies do not report an increased risk of fetal death or congenital anomalies with proper treatment.

Other Endocrine Glands

Hypothyroidism decreases GH secretion, and hypothyroid children have a dramatic retardation of growth. Retarded growth caused by hypothyroidism appears to result from deficient secretion of GH as well as from impaired action of GH. Many hypothyroid children have subnormal serum GH response to insulin-induced hypoglycemia. GH secretion is decreased in hypothyroidism related to an increase in hypothalamic-somatostatinergic tone and results in low serum insulin-like growth factor-1 (IGF-1) concentrations. Serum IGF-2, IGF-binding protein-1 (IGFBP-1), and IGFBP-3 also fall, whereas IGFBP-2 rises. These changes are reversible with treatment.

Thyrotroph hyperplasia caused by primary hypothyroidism may result in sellar enlargement, particularly when the condition has remained untreated for a long period of time. Patients with severe hypothyroidism may have an increase in serum prolactin level that

correlates with the level of serum TSH, and some patients develop galactorrhea.

Metabolic Changes

The decrease in energy metabolism and heat production is reflected in the low basal metabolic rate (BMR), decreased appetite, cold intolerance, and slightly lower basal body temperature. Measurement of the resting energy expenditure is rarely performed nowadays. In patients with complete athyreosis, it falls between 35 and 45% below normal. Both the synthesis and the degradation of proteins are decreased (the latter especially so), resulting in a nitrogen balance that is usually slightly positive.

In hypothyroidism, absorption of glucose from the gastrointestinal tract is slowed and peripheral glucose assimilation is retarded. At the same time, glycerol release from adipose tissue is slowed and the availability of amino acids and glycerol for gluconeogenesis is decreased. The oral glucose tolerance curve is characteristically flat, and the insulin response to glucose is delayed. Degradation of insulin is slow, so the sensitivity to exogenous insulin may be increased. Despite the easily demonstrable abnormalities in carbohydrate metabolism in hypothyroidism, clinical manifestations of these abnormalities are seldom conspicuous. A variety of abnormalities in plasma lipid concentrations occur in hypothyroidism (Table VII). Plasma free fatty acid concentrations are normal, whereas plasma concentrations of triglycerides, phospholipids, and low-density lipoprotein (LDL) cholesterol are well elevated. Biosynthesis of fatty acids and lipolysis is reduced. In general, the changes bear a reciprocal relationship to the level of thyroid activity.

The increased serum cholesterol may represent an alteration in the substrate steady-state level caused by a transient proportionally greater retardation in degradation than in synthesis. The increase of serum cholesterol is largely accounted for by an increase of LDL cholesterol. Interestingly, the LDL particles of

hypothyroid patients are also susceptible to increased oxidizability. The increase of high-density lipoprotein-2 (HDL2) cholesterol but not of HDL3 cholesterol is due to diminished activity of cholesteryl ester transfer protein and hepatic lipase (which is involved in the conversion of HDL2 to HDL3). The occasional modest increase of serum triglycerides has been related to decreased lipoprotein lipase activity in postheparin plasma.

| HDL2 cholesterol | Modest increase |
| HDL3 cholesterol | No change |
| Triglycerides | No change or modest increase |

mortality. Many physicians believe that it makes sense to allow hypothyroid patients who are dissatisfied with the outcome of restoring serum T4 and TSH to normal to increase the dose of T4 such that serum TSH is suppressed, in which case serum free T4 is likely to lie between 25 and 30 pmol/L. In this circumstance, it is essential that serum T3 be unequivocally normal.

Serum TSH concentrations are of no value in assessing the correct dose of T4 in patients with central hypothyroidism, and measurements of both serum T3 and T4 combined with a biochemical index of thyroid hormone action, such as soluble interleukin-2 receptors, have been suggested. In practice, however, physicians are likely to be influenced more by the well-being of their patients.

Starting Dose of Thyroxine

There is no evidence base for determining how T4 therapy should be initiated, but it is customary to prescribe 50 µg daily, increasing to 100 µg daily after 2 to 4 weeks. Measurement of serum T4 and TSH at 2 months after starting will dictate any further adjustment of dose. In the elderly, and particularly in those with symptomatic ischemic heart disease, a starting dose of 25 µg daily is advisable, with increments of 25 µg every 2 to 4 weeks, recognizing that the full replacement dose might not be achieved without coronary artery bypass grafting or angioplasty. In those individuals where hypothyroidism has developed rapidly and been detected early, such as following total thyroidectomy for thyroid carcinoma, a full replacement dose of 100 to 150 µg daily may be given from the outset.

Patients begin to feel better within 10 to 14 days of starting T4, even with doses as little as 25 µg daily. Reduction in body weight (rarely more than 10% and is due largely to fluid loss) and improvements in periorbital puffiness are among the early responses, whereas maximum improvement in hair and skin texture may take up to 3 months and reversal of the rare feature of cerebellar ataxia may take considerably longer.

Variation in Dose

Once T4 therapy is established, it is good practice to review patients annually and measure serum TSH, not only to ensure compliance but also to determine whether a change in dose is required. There is an increasing list of circumstances in which the dose of T4 might need to be adjusted, usually upward (Table I).

Table I Situations where an Adjustment of the Dose of Thyroxine May Be Necessary

| Increased dose required | |
|---|---|
| Use of other medication | |
| Phenobarbitone | Increased thyroxine clearance |
| Phenytoin | |
| Carbamazepine | |
| Rifampicin | |
| Sertraline ^a | |
| Chloroquine ^a | |
| Cholestyramine | Interference with intestinal absorption |
| Sucralfate | |
| Aluminum hydroxide | |
| Ferrous sulfate | |
| Calcium carbonate | |
| Dietary fiber supplements | |
| Pregnancy | Increased concentration of serum thyroxine-binding globulin |
| Estrogen therapy | |
| After surgical or iodine-131 ablation of Graves' disease | Reduced thyroidal secretion with time |
| Malabsorption (e.g., celiac disease) | |
| Decreased dose required | |
| Aging | Decreased thyroxine clearance |
| Graves' disease developing in patient with long-standing primary hypothyroidism | Switch from production of blocking to stimulating TSH receptor antibodies |

^aMechanism not fully established.

The most recently recognized are use of other medications such as chloroquine, sertraline, calcium carbonate, and estrogens either as the oral contraceptive pill or as hormone replacement therapy. Ingestion of dietary fiber supplements may reduce bioavailability of T4 by its adsorption onto wheat bran.

During pregnancy, most patients require an increase in T4 dose of some 50 µg daily, probably due to the increased concentration of T4-binding globulin. Therefore, it is important to measure free T4 and TSH during each trimester. It is also important to ensure that the appropriate dose is being taken pre-conception if pregnancy is planned because there is evidence that inadequately treated hypothyroidism in the mother may result in a reduction in the IQ of the offspring.

There are numerous manufacturers of T4 preparations, and from time to time there is divergence between the amount of active ingredients specified and the true content of the tablets. This possibility

should be entertained whenever a patient's serum TSH concentrations rise even though no new medication has been prescribed and the dose of T4 has been stable for many years.

SUBCLINICAL HYPOTHYROIDISM

By definition, affected patients have normal concentrations of serum T3 and T4 but have raised TSH, usually between 5 and 10 mU/L. They are normally asymptomatic but may have consulted because of tiredness and weight gain. Many have a family history of thyroid disease or another organ-specific autoimmune disease such as insulin-dependent diabetes mellitus or pernicious anemia. The consensus is that subclinical hypothyroidism represents the mildest form of thyroid failure and, as such, should usually be treated with T4. Those favoring therapy are most influenced by the knowledge that between 25 and 50% feel better when taking T4 and by the inexorable progression to overt thyroid failure of approximately 5% each year in those who possess antithyroid peroxidase antibodies—a risk that increases with higher serum TSH concentrations. Contrary to expectations, treatment of subclinical hypothyroidism, at least in those with serum TSH concentrations less than 10 mU/L, does not substantially improve the lipid profile.

TEMPORARY HYPOTHYROIDISM

Most patients with primary hypothyroidism require lifelong treatment with T4. There are, however, well-recognized situations in which the thyroid failure is transient and even short-term treatment with T4 is unnecessary. These include the recovery phase of subacute (de Quervain's), painless, and postpartum thyroiditis; Hashimoto's thyroiditis, particularly if excess iodine or iodine-containing drugs, such as amiodarone, have been implicated in the development of the thyroid failure; the neonatal period in children born to a minority of mothers with autoimmune hypothyroidism due to the transplacental passage of TSH receptor-blocking antibodies; and approximately 5% of patients with chronic autoimmune thyroiditis due to the disappearance of these same antibodies from the serum.

It is often not appreciated that hypothyroidism may be temporary if it occurs within 6 months of subtotal thyroidectomy or iodine-131 for Graves' disease. If T4 therapy is required at an early stage, a suboptimal dose of 75 µg daily should be prescribed. Measurement of serum T4 and TSH at 6 months will

indicate whether continued treatment with a higher dose is required (raised serum TSH) or whether T4 therapy can be stopped (low or normal TSH) and thyroid function can be reassessed 4 to 6 weeks later.

OTHER TREATMENTS OF HYPOTHYROIDISM

During the first part of the 20th century, the only treatment available for hypothyroidism was animal thyroid extract that contained both T3 and T4. Because of its variable potency, it was largely abandoned in favor of T4 alone. Recently, there has been a renewal of interest in treating hypothyroidism with both T4 and T3. This is the result of a study in 1999 by Bunevicius and colleagues, who showed that T3 and T4, when given in the ratio normally secreted by the thyroid gland, resulted in significant improvement in mood and neuropsychological function as compared with that resulting from a higher dose of T4 alone. Of greatest interest, this improvement occurred without suppression of serum TSH. Further evidence that monotherapy may be inadequate derives from recent observations that excess weight is gained by hyperthyroid patients who are rendered hypothyroid by ablative therapy and given T4 in a dose that simply restores TSH to normal. These results are not altogether surprising given that it is possible to restore euthyroid concentrations of thyroid hormones in most tissues of the hypothyroid rat only if a combination of T4 and T3 is infused. Therefore, it is likely that treatment of hypothyroidism in future years will be with a combination of synthetic T3 and T4 in the ratio of 1:10 and with the T3 in slow-release form to avoid cardiovascular adverse effects.

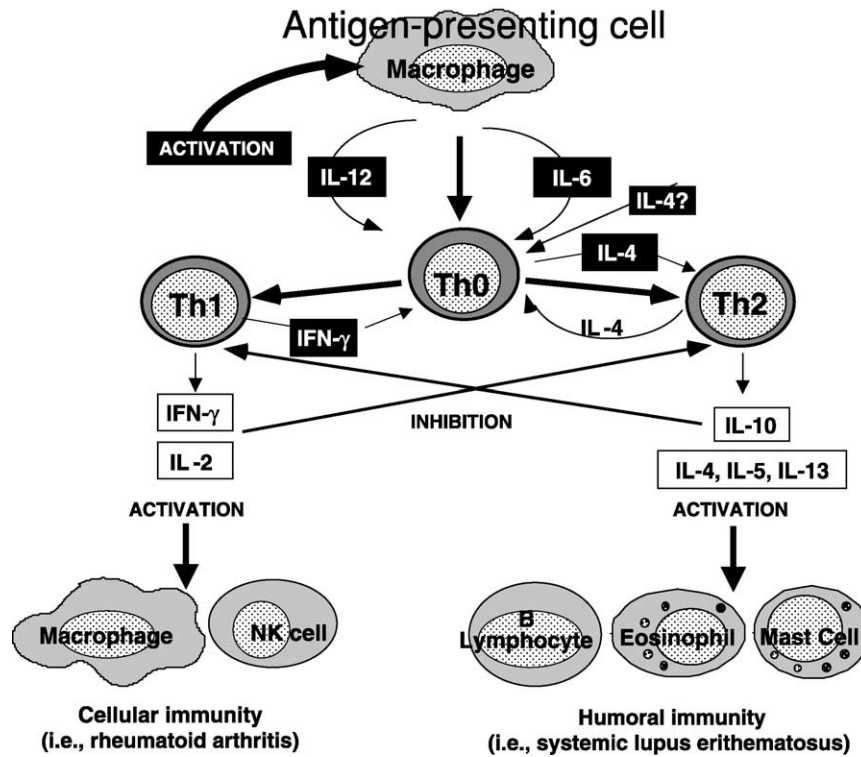

Figure 1 Role of Th1/Th2 cytokines in the regulation of cellular and humoral immunity.

variety of clinical manifestations of the disease as well as resistance to the biological therapies (TNF α blockers).

ENDOGENOUS STEROIDS AND MODULATION OF THE IMMUNE/INFLAMMATORY RESPONSE

An intricate balance between soluble mediators (cytokines), released by activated cells of the inflammatory/immune system, and products of the neuroendocrine system, such as neuropeptides and steroid hormones, maintains the homeostasis during the immune response. In general, the major inflammatory cytokines (IL-1, IL-6, and TNF α) stimulate the production of corticotropin-releasing hormone (CRH) in the hypothalamus. CRH release leads to pituitary production of adrenocorticotropic hormone (ACTH), followed by glucocorticoid secretion by the adrenal cortex and indirect perturbations of gonadal function.

Conversely, hormonal products of the hypothalamus–pituitary–adrenal (HPA) axis and hypothalamus–pituitary–gonadal (HPG) axis modulate the cytokine production (Fig. 2). For example, adrenal and gonadal androgens, in particular dehydroepiandrosterone sulfate (DHEAS) and both testosterone and dihydrotestosterone (DHT), have been found to repress

the expression and activity of the human IL-6 gene promoter, thereby supporting the concept of anti-inflammatory/immunosuppressive effects exerted by androgens. Conversely, physiological concentrations of estrogens exert immunoenhancing activities, at least on APCs and generally on the humoral immune response.

Notably, glucocorticoids are the most potent endogenous inhibitors of immune and inflammatory processes, including proinflammatory cytokine production. Peripheral levels of IL-6, and to lesser extent those of TNF α and IL-1 β , are tonically inhibited by basal levels of glucocorticoids. In chronic diseases, a condition of subclinical hypoadrenal function is detected. Therefore, in systemic autoimmune/inflammatory diseases, the use of glucocorticoids as low-dose oral administration or high-dose pulse therapy should be regarded as a sort of replacement therapy, with modulating effects on activated T-lymphocytes and macrophages.

SPECIFIC ROLES FOR VARIOUS HORMONES

Cortisol (Adrenal Hormone)

The multiple anti-inflammatory effects of cortisol and its synthetic derivatives have been studied extensively

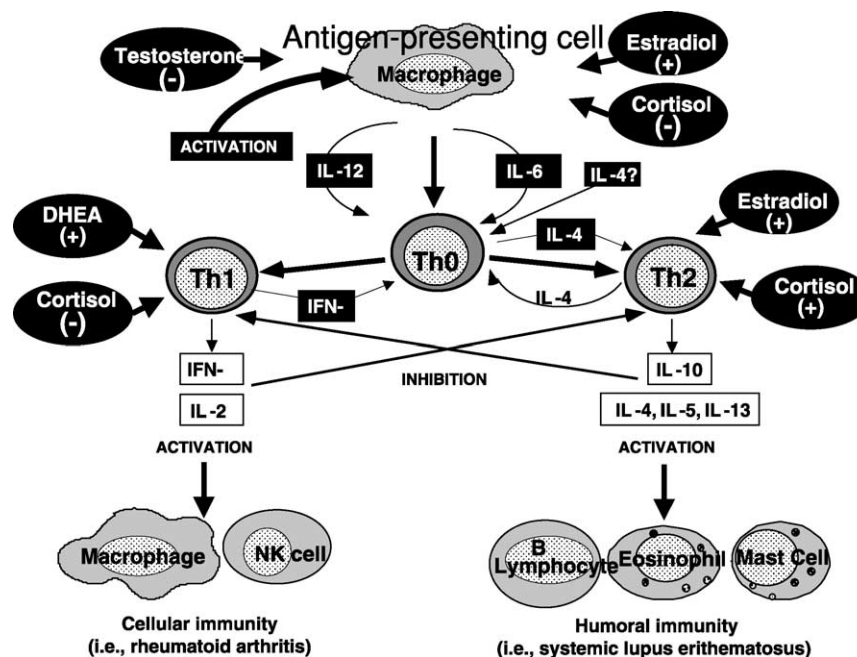

Figure 2 Hormonal effects on Th1/Th2 cytokines in the regulation of cellular and humoral immunity.

over the past 50 years. It is obvious that this hormone has multiple anti-inflammatory activities such as inhibition of cytokines, phagocytosis, the oxidative burst, and inducible cyclo-oxygenase (COX-2). In addition, cortisol *in vivo* induces a more Th2-directed immune response, with an increase of anti-inflammatory IL-10. It has been assessed that an approximately 5- to 10-fold variation in blood glucocorticoids (increase or decrease) is paralleled by oscillation of about the same magnitude in the number of activated B lymphocytes. With respect to the situation *in vivo*, this has been shown many times by glucocorticoid therapy in animals with arthritis and patients with RA. In conclusion, high physiological concentrations of cortisol at 10^{-6} to 10^{-5} M are anti-inflammatory and immunosuppressive (humoral response).

Dehydroepiandrosterone (Adrenal Hormone)

Two other adrenal hormones, which are secreted on ACTH stimulation, are dehydroepiandrosterone (DHEA) and its sulfated derivative DHEAS. DHEA is the active hormone that can be converted to downstream androgens in peripheral tissue cells such as macrophages. Because androgens such as testosterone have anti-inflammatory properties, DHEA and DHEAS, the androgen precursors, contribute to the hormone pool so as to maintain an anti-inflammatory

situation in the periphery when the gonadal glands undergo gradual involution during aging. Furthermore, DHEA may have its own intracellular receptor to exert direct anti-inflammatory effects in animals and humans.

Progesterone (Ovarian or Placental Hormone)

Progesterone exerts immunomodulatory activities. An immune response during the luteal phase of the ovarian cycle, as compared with the follicular phase, is shifted toward a Th2 type. Progesterone-mediated promotion of the Th2 response, inducing conversion of Th0 cells into Th2 cells, is indispensable for maintaining pregnancy.

In the presence of progesterone, lymphocytes from pregnant females produce a protein known as progesterone-induced blocking factor (PIBF), which alters the profile of cytokine secretion by stimulation of the cytokine Th2 production and inhibition of the cytokine Th1 production.

Androgens (Gonadal Hormones)

In general, androgens, in physiological concentrations, tend to suppress the immune responses. Functional androgen receptors have been found on monocytes/macrophages.

Recent studies have shown that both physiological (10^{-8} M) and pharmacological (or high physiological) (10^{-6} M) concentrations of testosterone inhibit IL-1 β secretion by PBMCs obtained from RA patients. In addition, physiological concentrations of testosterone inhibit IL-1 synthesis in primary cultured human synovial macrophages. In other studies, dihydrotestosterone has been found to repress the expression and activity of the human IL-6 gene promoter in human fibroblasts, thereby supporting the concept of anti-inflammatory/immunosuppressive effects of androgens. Testosterone treatment does not appear to directly affect isolated B or T cells. However, a follow-up study of SLE patients showed that testosterone suppresses both anti-double-stranded DNA IgG and total IgG production of PBMCs. Low serum and synovial fluid androgen levels were observed in RA patients.

Estrogens (Gonadal Hormones)

In general, estrogens in physiological concentrations serve to enhance immune responses and may act as an important stimulator of human humoral immunity. It was reported that 17 β -estradiol enhances IgG and immunoglobulin M (IgM) production by PBMCs in both men and women without altering cell viability or proliferation. A more recent study confirmed that 17 β -estradiol has the capacity to increase the production of polyclonal IgG, including anti-double-stranded DNA IgG in PBMCs of SLE patients, by enhancing B-cell activity via IL-10. Concerning the effects of estrogens on proinflammatory cytokine production (IL-1, IL-6, and TNF α), these effects seem to be bimodal, with decreased synthesis using pharmacological concentrations (10^{-6} M) and increased synthesis using physiological concentrations ($\leq 10^{-8}$ M). Recently, it was demonstrated that estrogens are able to enhance secretion of matrix metalloproteinases from human fibroblast-like synoviocytes. Functional androgen receptors have been found on monocytes/macrophages, lymphocytes, and fibroblasts. With respect to serum levels of estrogens in RA patients, they are not changed—in strict contrast to androgen levels. Increased hydroxylation of estrogens is observed in SLE serum and in RA synovial fluids.

Conversion of Steroid Hormones in Peripheral Target Cells

Because steroid hormones can be converted along defined pathways to downstream hormones in the periphery, multiple secondary effects may arise according to local regulation of steroid conversion. We have

recently demonstrated that conversion of DHEA occurs in macrophages and depends on the state of differentiation and presence of endotoxin. In postmenopausal women and aged men, the availability of adrenal DHEA is important to maintain a significant level of sex hormones in the periphery. It is not known whether, under certain circumstances, macrophages or other peripheral immune cells are able to synthesize steroid hormones in adequate amounts using cholesterol, as has been demonstrated in thymocytes. Furthermore, we do not exactly know the importance of, for example, degradation of cortisol by the 11 β -hydroxysteroid dehydrogenase in the synovial tissue, which changes the activity of the steroid hormones in the local microenvironment. Increased concentrations of estrogens are observed at the site of the immune-inflammatory reaction. For example, in synovial fluids of RA patients of both genders, increased estrogens and reduced androgens are found to be related to the increased activity of the metabolizing enzyme aromatase stimulated by local high concentrations of the major inflammatory cytokines (IL-1, IL-6, and TNF α).

Prolactin (Pituitary Hormone)

Prolactin modulates lymphocytes by activating T-lymphocyte and B-lymphocyte proliferation, stimulates IgG secretion, and increases cytokine secretion from various cells such as IL-1, IL-6, TNF α , and IFN- γ . Because of these stimulatory effects on immune cells, a proinflammatory role of prolactin was suspected in autoimmune diseases. Elevated levels of prolactin were associated with a more severe progressive systemic sclerosis, the active phase of SLE, RA, human autoimmune thyroid disease, and adjuvant arthritis. Hyperprolactinemia was associated with the presence of autoantibodies in otherwise healthy women, indicating the stimulating effect of this hormone on IgG. Furthermore, therapeutic prolactin antagonism with bromocriptine was found to have some beneficial effects on autoimmune disease in humans and animals that do not seem to depend on direct immunomodulating effects of bromocriptine.

In conclusion, the proinflammatory and immunestimulating role of prolactin has clearly been found in animal models of inflammatory diseases; however, this role in human diseases is still open for discussion.

Melatonin (Pineal Gland Hormone)

The indole hormone melatonin (N-acetyl-5-methoxytryptamine) is the main secretory product of the pineal gland. Melatonin is synthesized in a strictly

nocturnal pattern. Synthesis is directly coupled to secretion; both begin at dusk, continue through the night, and terminate at dawn. This rhythmic pattern of secretion is circadian and depends on the master biological clock that resides in the suprachiasmatic nucleus, the paraventricular hypothalamic nucleus, and its direct or indirect projections to the sympathetic preganglionic neurons in the spinal cord. Direct inhibitory effects of light on pineal activity may contribute to phasing of the onset and termination of melatonin production. Indeed, melatonin may participate in the coordination of circadian responses, reinforcing or complementing other entraining signals, and may coordinate a variety of seasonal photo-periodic responses. Melatonin is also an efficient free radical scavenger and antioxidant, both *in vitro* and *in vivo*.

Moreover, melatonin exerts a variety of effects on the immune system. In several species, pinealectomy or any other experimental procedure that inhibits melatonin synthesis and secretion induces a state of immunodepression that is counteracted by melatonin replacement. In general, melatonin displays an immunoenhancing effect. Melatonin is able to activate T lymphocytes, monocytes, natural killer (NK) cells, and neutrophils. Melatonin even activates Ab-dependent cellular cytotoxicity and enhances Ab responses *in vivo* (8, 12, 21–23). On the other hand, melatonin enhances splenic ornithine decarboxylase activity (an index of lymphatic cell proliferation) in rats. In animal models as well as in human and *in vitro* experiments, melatonin enhances inflammatory cytokine (e.g., IL-1, IL-2, IL-4, IL-5, IL-6, TNF α , GM-CSF, TGF- β , IFN- γ) and nitric oxide production.

IMMUNOMODULATION DURING PREGNANCY

Hormonal and related immune response changes observed during pregnancy and postpartum might contribute to the variations of disease activity in autoimmune diseases such as RA and SLE. During normal pregnancy, both free and total cortisol levels are increased and the circadian secretion persists, but evening levels do not decline as they do in nonpregnant women. Estrogens and progesterone are synthesized in great amounts and decrease metabolic clearance of cortisol by direct action on liver enzymes involved in its inactivation.

Because high concentrations of estrogens seem to exert immunosuppressive activities, this effect should at least partly account for the improvement of arthritic symptoms in pregnant patients. On the other hand, during pregnancy, prolactin reaches its highest levels during the third trimester. Optimal concentrations are required for maximal lymphocyte stimulation; however, lower or higher levels cause decreased or negative responses. Therefore, elevated prolactin concentrations during pregnancy and early lactation might induce immunosuppression.

The maternal production rate of the adrenal androgen DHEAS is increased at least two times during pregnancy, but serum levels seem to be unchanged. On the other hand, serum levels of gonadal androgens increase. Serum total testosterone reaches levels four to five times higher than those in menstruating women, whereas serum-free testosterone increases only during the third trimester.

The hormonal changes characterizing the pregnancy are primarily directed toward a reduction of the immune/inflammatory response and, at least in RA and (more recently) pregnancy and the postpartum period, have been suggested to represent a model of how abrupt changes in steroid hormone levels may regulate the immune response. Recently, the cytokine expression during pregnancy has seemed to shift toward a Th2-type profile; in particular, high levels of anti-inflammatory IL-10 are expressed in placental tissues. Similarly, the administration of corticosteroids seems to increase serum levels of IL-10 and generally seems to polarize toward a Th2-type cytokine pattern. Conversely, RA can flare up during the postpartum period because the levels of IL-10 decrease to normal or even subnormal concentrations following the decrease in gonadal and adrenal steroid serum levels.

In conclusion, it has been suggested that the plasma increase of estrogens, androgens, and cortisol during the third trimester of pregnancy may induce an improvement in RA as consequence of a suppression of the proinflammatory Th1-type cytokine pattern and a potentiation of the anti-inflammatory Th2-type cytokine pattern.

NEW PERSPECTIVES AND CONCLUSIONS

Recent studies showed that testosterone therapy dramatically suppresses the lymphocyte infiltration in,

and significantly improves the functional activity of lacrimal glands in the MRL/lpr female mouse model of Sjögren syndrome. A subsequent study showed that androgen treatment influences the expression of proto-oncogenes, with decreased bcl-2 and c-myc mRNA levels, as well as apoptotic factors in salivary and lacrimal tissues of the same model of Sjögren syndrome. Conversely, the recent observation of estrogen-induced decrease of apoptosis of PBMCs of SLE patients suggests that the presence of estrogens may allow survival of autoimmune cells. If sex hormones, as well as cytotoxic agents, do modulate synovial macrophage apoptosis in, for example, RA patients, such an approach would promise to be an important pathway of control in the arthritis.

The complex interactions and the molecular basis of common pathways between inflammatory/immunological and neuroendocrine circuits are matters of continuous and intensive research and may offer highly promising strategies for therapeutic manipulations of autoimmune diseases.

Figure 1 Stage of blastocyst implantation.

the secretory histological type. Progesterone, in cooperation with E_2 , initiates decidual transformation of the endometrium, induces prostaglandin E_2 production by endometrial macrophages, and causes stromal edema and angiogenesis in the endometrium. In addition, progesterone decreases uterine irritability and contractility and, together with hCG, suppresses immunological response that prevents embryo rejection by the maternal immunological system.

During embryo implantation, the uterine endometrium undergoes morphological and physiological changes to the host conceptus. The restricted period of time when the endometrium is receptive for the conceptus is called the "implantation window." The embryo being transferred to the uterus at an inappropriate time is not able to implant. In the normal human menstrual cycle lasting 28 days, the implantation window lasts between 19 and 24 days of the cycle. One of the earliest indexes for transmission of embryonic signals to the endometrium that surrounds the blastocysts is capillary permeability and local stromal edema. This leads to the changes in the endometrium termed "decidualization." During this process, endometrial stromal cells transform into large decidual cells that are rich in glycogen.

Attachment of the embryo to the endometrium is facilitated by the specific cell adhesion structures and molecules located on the apical epithelial plasma membrane.

Pinopodes

A characteristic feature for the status of endometrial receptivity is formation of the pinopodes. Pinopodes, a large cytoplasmic projection located on the apical surface of endometrial epithelium, are associated with changes in cell membrane morphology during the implantation window opening. Progesterone is responsible for the formation of these structures. Pinopodes are involved in facilitating adhesion of the blastocyst to the endometrial epithelium.

Trophinin/Tastin

Trophinin, together with its adhesion molecule tastin (trophinin-assisting protein), is additional protein responsible for trophoblast cell adhesion to the endometrial epithelium. Tastin is located in the endometrial cell membrane. The cytoplasmic domain of trophinin is bound to the cytoskeleton. The presence of highly concentrated areas of trophinin "patches" is believed to be adhesion sites for the embryo. The trophinin is expressed exclusively when the implantation window is opened.

Mucin: MUC1

MUC1 is an integral membrane glycoprotein. MUC1 has high molecular weight, a highly glycosylated extracellular domain, and a relatively short domain associated with the cytoskeleton. The endometrial expression of MUC1 is menstrual cycle dependent.

It is believed that MUC1 prevents adhesion of the embryo to endometrial epithelium and that only healthy blastocysts are able to decrease MUC1 expression leading to the contact of the cells. In addition to the endometrium, MUC1 is expressed in blastocyst during the preimplantation period.

Integrins

Cell-to-cell adhesion seems to be a crucial process in the course of implantation. Integrins are transmembrane glycoproteins responsible for this process. They are members of an immunoglobulin superfamily. Integrins are composed of two units: α and β . Between several types of integrins, heterodimers $\alpha_4\beta_3$ and $\alpha_v\beta_1$ seem to play an important role in the implantation. Integrin α_4 and integrin β_3 coexpress in the apical secretive endometrium when the implantation window is opened. For this reason, integrin β_3 is proposed to be a marker of uterine receptivity. Integrins are believed to be receptors for extracellular matrix components: fibronectin, collagen, and laminin. Because trophoblasts express oncofetal fibronectin, the presence of integrins on apical endometrial epithelial cells may have a major role in the initial process of embryo adhesion to decidual cells. Contact of the embryo with endometrium trigger the production of proteases by trophoblasts, and this is crucial for the next step of implantation.

INVASION

Proteases degrade the endometrial extracellular matrix, helping the embryo to invade the uterine wall. Matrix metalloproteinases and urokinase-type plasminogen activator are involved in extracellular matrix proteolysis. In addition, first-trimester cytotrophoblasts express specific enzymes called gelatinases, which are responsible for matrix degradation. Enzymes are controlled indirectly by cytokines and by interaction with the extracellular matrix. Proteolytic activity of invading trophoblasts is a result of balance between matrix metalloproteinases secreted by the embryo and specific inhibitors, including tissue inhibitors of metalloproteinases originating from decidua.

MARKERS OF IMPLANTATION

Trophoblasts and decidua produce lots of factors and their receptors affecting events associated with the process of implantation. Changes in the expression

of platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), insulin-like growth factor (IGF), transforming growth factor (TGF), IL-3, IL-4, IL-5, IL-6, IL-7, IL-8, IL-11, IL-12, and colony-stimulating factor (CSF) at the time of implantation were noted; however, their precise role in the implantation processes remains to be elicited. Because there are so many different factors involved in the process of implantation, it is worth determining which ones could be used as predictors of successful implantation. The issue is still open to debate, but leukemia inhibitory factor (LIF) and hemoglobin-binding epidermal growth factor (HB-EGF) are candidates for this function.

LIF expresses in endometrial epithelial cells just before implantation and immunoreactivity of LIF in the endometrium decrease when substances blocking implantation (RU486) are administered. The role of this cytokine in the process of implantation is confirmed by results showing that mouse lacking LIF become infertile. HB-EGF has been found in endometrial epithelial cells close to the place of embryo implantation.

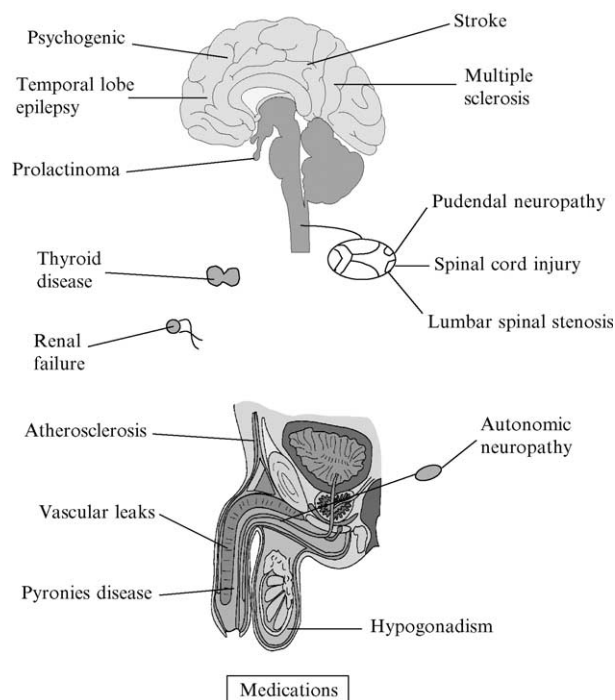

Figure 1 Causes of impotence.

disease are at major risk for developing either a myocardial infarction or a stroke over the subsequent 2 years. Autonomic neuropathy is another important cause. Persons with diabetes mellitus usually have a mixed cause of impotence, including vascular disease and neuropathic causes as well as increased collagen cross-linking.

Medications are a major cause of impotence. Impotence is produced by medications of nearly every category, including antidepressants (with the exception of trazadone), antihypertensives, antipsychotics, anticholinergics, H₂-receptor antagonists, anticonvulsants, and antiandrogens (digitalis, estrogens, spironolactone, megestrol acetate, ketoconazole, and gonadotropin-releasing hormone [GnRH] antagonists). Because older persons often receive multiple drugs, this cause becomes more common with aging. Tobacco smoking is commonly associated with impotence, both acutely due to the effects of nicotine on erection and chronically secondary to its role in the pathogenesis of atherosclerosis. Alcohol has, since the time of Shakespeare, been known to “provoke desire and inhibit performance.”

Multiple sclerosis, strokes, temporal lobe epilepsy, and spinal cord injury all are associated with impotence. Pituitary tumors (prolactinomas) and hyper- and hypothyroidism all can result in impotence.

Systemic disorders, such as chronic obstructive pulmonary disease (COPD) and renal failure, can lead to impotence. Oxygen therapy can reverse impotence in men with COPD.

Although psychogenic causes of impotence are relatively rare in older persons, they need to be considered in the differential diagnosis. Performance anxiety is commonly seen as an additive cause of impotence in men with early organic disease. Depression is the most common psychogenic cause of impotence. Widower’s syndrome is a unique condition in older men. In this case, the man’s wife dies and a female friend starts providing the widower with companionship as well as help with the housework and cooking. After a while, she suggests that it would be appropriate for him to reward these “services” by having intercourse with her. Although the man does not want the woman’s help to be withdrawn, he does not want to have a sexual relationship with her. To avoid having intercourse, he develops impotence.

TESTOSTERONE, IMPOTENCE, AND THE ANDROPAUSE

Longitudinal studies with the aging have clearly demonstrated that testosterone levels decline with aging. This is due predominantly to chaotic secretion of GnRH from the hypothalamus, but it also involves altered pituitary secretion of leutenizing hormone and decreased production of testosterone from the testes. In addition, there is an increase in sex hormone-binding globulin and a decrease in the apparent K_d of testosterone for this globulin. Thus, measurement of total testosterone in older persons gives a spuriously high value in functional terms. For this reason, it is now recommended that bioavailable testosterone be measured to give a true estimation of the tissue-available testosterone in older men.

Based on the measurement of bioavailable testosterone, the prevalence of hypogonadism is estimated to be between 3 and 5% at 40 years of age and between 34 and 70% at 70 years of age. Because testosterone is essential for the production of NO synthase in the penis, very low levels of testosterone are associated with complete impotence. Higher levels of testosterone are associated with the development of a soft erection. In persons with COPD, the erectile problems appear to be secondary to low testosterone and to hypoxia reducing the production of NO.

Low testosterone is also associated with a decline in libido. This is a more important effect of testosterone

than its effect on potency. Other effects of the declining testosterone with aging include decreased muscle mass and strength, increased fat mass, decreased memory, increased leptin, decreased hematocrit, decreased bone mass, and a decline in functional status. Testosterone replacement in older persons has been shown to decrease angina and enhance coronary artery dilatation. Low—not high—testosterone is associated with atherosclerotic disease.

At Saint Louis University, we have developed a screening test for the andropause (Table I). This test has good sensitivity and specificity for detecting persons with low bioavailable testosterone and can be used to follow the outcomes of therapy. The major false positive for this questionnaire is dysphoria, and all men who answer positively on this questionnaire should be screened for depression before being treated for testosterone deficiency. The Massachusetts Male Aging Study has developed a risk factor survey that also has good sensitivity and specificity. The Aging Males' Symptoms Rating Scale was developed in Europe. It is not specific for testosterone deficiency but covers a large range of symptoms experienced by older men.

MANAGEMENT OF IMPOTENCE

Table II lists the major modalities available for the treatment of impotence in older men. Phosphodiesterase-5 inhibitors represent the major advance in the management of impotence. These agents delay the breakdown of cyclic GMP and,

Table I The Androgen Deficiency in Aging Male (ADAM) Questionnaire

| (Circle one) | | |
|--------------|----|--|
| Yes | No | |
| | | 1. Do you have a decrease in libido (sex drive)? |
| Yes | No | 2. Do you have a lack of energy? |
| Yes | No | 3. Do you have a decrease in strength and/or endurance? |
| Yes | No | 4. Have you lost height? |
| Yes | No | 5. Have you noticed a decreased enjoyment of life? |
| Yes | No | 6. Are you sad and/or grumpy? |
| Yes | No | 7. Are your erections less strong? |
| Yes | No | 8. Have you noticed a recent deterioration in your ability to play sports? |
| Yes | No | 9. Are you falling asleep after dinner? |
| Yes | No | 10. Has there been a recent deterioration in your work performance? |

Note. A positive answer represent yes to question 1 or 7 or any three other questions.

Table II Management of Impotence in Older Men

 - (1) Semi-rigid
 - (2) Inflatable
 - b. Arterial surgery
 - c. Venous surgery
 - d. Angioplasty

thus, increase the vasodilatory efficacy of the NO released locally in the penile tissue. We originally demonstrated that pentoxifylline, a nonspecific phosphodiesterase inhibitor, reversed impotence in some men. Sildenafil (Viagra), a specific phosphodiesterase-5 inhibitor, reverses erectile dysfunction in 50 to 70% of men. It is slightly less effective at enhancing erectile dysfunction in older men than in younger men. The major side effects of sildenafil are gastroesophageal reflux, hypotension, alterations in vision, and death when given in conjunction with nitrates.

Direct injections of papaverine, phentolamine, or prostaglandin E₁ into the corpora cavernosa are more efficacious than phosphodiesterase-5 inhibitors at producing erections. Slow-release apomorphin (Uprima)

works through the central nervous system to increase erections. It is less effective than sildenafil.

Vacuum tumescence devices play a role in the management of impotence in older men who are interested in obtaining an erection once or twice a month. Better results with these devices are obtained in men who are in stable relationships.

Penile prostheses remain the gold standard for the treatment of impotence for many older men. In older men, the semi-rigid prosthesis is usually a better choice than the inflatable prosthesis.

THE PROSTATE AND IMPOTENCE

Radical prostatectomy for prostate carcinoma may result in impotence in approximately half of the patients, an untoward effect of surgery that appears to be operator dependent. In addition, many patients who have a prostatectomy also have either an orchiectomy or receive GnRH analogues to lower their testosterone. Hypogonadism in these patients not only decreases libido but also can cause hot flashes, night sweats, fatigue, muscle loss, osteoporosis, and a decline in hematocrit. In men without metastases following prostatectomy, if their PSA is zero for 3 to 5 years following surgery and they are hypogonadal, testosterone replacement into the low physiological range with careful monitoring of the PSA is becoming an acceptable practice.

COMPLEMENTARY MEDICINE AND IMPOTENCE

The phosphodiesterase inhibitor canthridin ("Spanish fly") is obtained from blister beetles. It produces

congestion of the corpora but also produces inflammation and hematuria. NO synthase is stimulated by ginsenosides that are derived from *Panax ginseng*. Ambien, an herbal preparation of *Ambra gnsea*, produces a very small stimulation of luteinizing hormone leading to miniscule increases in circulating testosterone. A number of these products are now used by older men.

Table I History of in Vitro Fertilization

| Year | Investigator(s) | Event |
|-----------|---|---|
| 1870–1880 | S. Schenk | Observed rabbit sperm stripping away cumulus cells from egg under the microscope |
| 1890 | Walter Heap | Successful transfer of fertilized rabbit oocytes flushed from donor rabbit to foster mother rabbit |
| 1930 | Gregory Pincus | Observed rabbit sperm penetrating the egg with binocular microscope |
| 1934 | Gregory Pincus and E. V. Enzmann | Mixed rabbit sperm and eggs and returned them to the fallopian tube with birth of young; fertilization not observed |
| 1944 | John Rock and Miriam Menkin | Harvested human eggs just before ovulation, combined them with human sperm, and observed the results |
| 1954 | Charles Thibault | Reported in vitro fertilization of rabbit eggs; first report of mammalian fertilization in vitro |
| 1959 | M. C. Chang | Fertilized rabbit eggs in vitro and transferred four-cell embryos with birth of healthy young |
| 1969 | Robert Edwards, Barry Bavister, and Patrick Steptoe | Human in vitro fertilization with embryo division |
| 1971 | Robert Edwards and Patrick Steptoe | First transfer of in vitro fertilization embryo with intent of establishing a pregnancy |
| 1978 | Robert Edwards and Patrick Steptoe | Birth of Louise Brown |
| 1992 | Gianpiero Palermo | Development of intracytoplasmic sperm injection |

Pincus began to study rabbit eggs and sperm under the binocular microscope. In 1944, Rock and Menkin reported in vitro fertilization of a human egg but did not intend to use the resulting embryo in an attempt to start a pregnancy. In 1967, Edwards and Steptoe began work on a technique for harvesting and fertilizing human eggs *in vitro* with the intention of treating infertile couples. Edwards reasoned that he could “simply pluck the egg from the ovary and fertilize it in the laboratory.” In 1969, Edwards, Bavister, and Steptoe reported that they had achieved human fertilization *in vitro*. The first IVF human pregnancies were achieved in 1975, although they were not successful in reaching term. Then, on July 25, 1978, Louise Joy Brown was born by caesarian section at Oldham General Hospital in England. Her birth was the first to demonstrate that conception in the laboratory could result in the birth of a normal baby. The first IVF baby in the United States was born in 1980. Shortly thereafter, in response to patient demand, numerous clinics offering ART procedures were established all over the world, ushering in a new epoch in helping infertile couples to achieve pregnancy.

IVF PROCEDURES

At first, most women treated with IVF procedures had damaged fallopian tubes. As confidence with the new technique increased, clinicians began to use IVF to treat other causes of infertility. Today, ART procedures are

used to help women with damaged fallopian tubes, endometriosis, couples who are infertile because of low sperm count or poor sperm function, unexplained infertility, and some genetic disorders.

Ovulation Induction

Edwards and Steptoe obtained a single egg, which would become Louise Brown, with a retrieval timed just before her mother’s natural ovulation. Today, most women are treated with follicle-stimulating hormone (FSH) to promote the maturation of multiple eggs before their retrieval. This treatment is known as “ovulation induction” or “controlled ovarian hyperstimulation.” FSH treatment for ovulation induction is administered by daily injection for several days, beginning on the third day of menstrual bleeding. Many women are treated with gonadotropin-releasing hormone (GnRH) agonists, GnRH antagonists, or oral contraceptives to suppress their hypothalamic–pituitary–ovarian axis and, consequently, their reproductive cycle. If there is evidence that the hypothalamic–pituitary–ovarian axis is not suppressed, FSH injection is not begun. Women undergo monitoring of their serum estradiol concentration and sonogram imaging to determine the growth of their follicles. When the largest follicle has a diameter of greater than 18 mm, the egg is approaching maturity. Final egg maturation is triggered by injection of human chorionic gonadotropin (hCG) or luteinizing hormone

(LH). The clinician retrieves the eggs 34 to 37 h after this final injection.

Egg Retrieval

Until the late 1980s, laparoscopy was used as the primary method of egg retrieval. To achieve pregnancy, some women would undergo multiple laparoscopies in a single year. Laparoscopic egg retrieval required about 45 min of general anesthesia and was more difficult when pelvic scars covered the ovaries. Today, physicians use ultrasound imaging to guide a needle through the vaginal wall to the ovary. Introduction of ultrasound-guided egg retrievals during the mid-1980s eliminated the need for laparoscopy and a full operating room to complete egg retrievals, allowing ART services to be provided in outpatient settings. Using ultrasound, each follicle is imaged on the display. The retrieval needle is passed through the needle guide, which is parallel to the vaginal ultrasound probe. The needle passes through the vagina and into the peritoneal cavity. The follicles are punctured, and their fluid is suctioned through the needle to a sterile container. The follicular fluid is brought to the embryology laboratory, where the eggs are identified under low-power magnification. The eggs are removed from the fluid, carefully examined by the embryologist, and evaluated for maturation. An egg must have completed its first meiotic division to be successfully fertilized. After the eggs are inspected, the embryologist places each egg in a small bubble of media along with a suspension of washed sperm.

Embryology Laboratories

Embryology laboratories have evolved greatly over the years. Most successful embryology laboratories have protocols to ensure quality control and to maintain a sterile, toxin-free environment. Techniques have been developed in the embryology laboratories to assist in fertilization, embryo growth, and embryo selection and safe transfer.

Fertilization

Expansion of assisted reproductive indications to help couples with poor sperm production or function led to methods of gamete micromanipulation to improve the chance of fertilization in the laboratory. A clear shell called the zona pellucida surrounds human eggs. Zona drilling and subzonal insertion were techniques used to help spermatozoa pass the zona pellucida

barrier and bind to the oocyte cell membrane. Working in Belgium in 1992, Palermo achieved fertilization of a human egg by injecting a sperm cell through the egg cell membrane into the cytoplasm, a procedure that became known as intracytoplasmic sperm injection (ICSI). Until then, many embryologists believed that intracytoplasmic injection of sperm would disrupt the basic mechanisms of fertilization. Palermo showed that an egg could be successfully fertilized by ICSI and that a healthy embryo and successful pregnancy could result.

Incorporation of ICSI techniques into the IVF procedures has allowed successful treatment of couples who in the past could only have been offered adoption or artificial insemination. A few living sperm cells retrieved from testicular biopsy or epididymal aspiration can be used for intracytoplasmic injection of oocytes. Use of laboratory techniques to overcome such natural barriers to fertility provoked concern that children resulting from these procedures might be adversely affected. Studies have shown that men with deletions or mutations of genes needed to produce spermatozoa are likely to pass on those traits when they have children by ART procedures. Some genetic traits associated with male infertility are closely linked to other inherited diseases such as cystic fibrosis. For these reasons, couples with severe male factor infertility are encouraged to seek genetic counseling as part of their preparation for infertility treatment.

Embryo Culture

Over the first 5 days after fertilization, the embryo grows rapidly from a single-cell zygote to a hollow ball of many cells, called a blastocyst. During this crucial interval, the embryo makes its transition from a metabolism based on maternal genes to its own genetic program. The media used for embryo culture is a simple solution of salts and nutrients. High-quality embryos can grow in this standard media with good implantation and pregnancy rates.

The metabolic needs of the embryo change as the embryo grows. Sequential culture uses media of different types depending on the stage of embryo development. These more complex media are used to respond to the changing metabolic requirements of the embryo. Coculture with human- or animal-derived cells is another way in which to create a dynamic culture system. In coculture, the cultured cells are thought to act as hosts for the developing embryos, conditioning the media in response to signals from the embryo. Although there is evidence from animal and human experiments supporting

the use of these systems, the evidence in humans is empirical.

Embryo Transfer

Over time, embryologists have learned to produce healthier embryos. In 1985, it was not unusual to transfer six to eight embryos in a single procedure. Today, to decrease the chance of multiple gestations, clinics commonly transfer no more than three high-quality embryos. Embryo transfer is typically done after 3 days of culture. In some cases, embryo culture may be extended to allow transfer of a single blastocyst. Some clinics will transfer more embryos if the overall embryo quality is poor. Embryos are transferred in a thin flexible straw that is threaded carefully through the cervix. The optimal transfer places the embryos in the mid-uterine cavity, together with a minimal amount of transfer media. The transfer is performed carefully to avoid uterine bleeding, which can decrease the chance of implantation. In most cases, the transfer procedure is painless. Embryo transfer may fail if the embryos become trapped in the cervical mucus or do not leave the transfer catheter. Each of these problems can be overcome by careful technique. Some clinicians use sonographic imaging to confirm intrauterine placement of the embryos.

A normal uterine cavity and endometrium will encourage implantation. A physician will often evaluate the patient's endometrial cavity with hysterosalpingogram or ultrasound imaging before the ART cycle begins. Endometrial polyps or fibroids inside the uterine cavity are frequently removed in preparation for treatment. Progesterone supplementation is used after embryo transfer to promote normal secretory endometrium. Embryo hatching is another way in which to assist implantation. Hatching is performed by making a slit in the zona pellucida just before the embryo is transferred. Hatching is thought to make it easier for the embryo to emerge from the zona and may improve signaling between the embryo and the endometrium.

Cryopreservation

As mentioned previously, to reduce the risk of a multiple pregnancy, most clinics transfer only two or three embryos. Because an average ART cycle produces more than three embryos, there are often healthy embryos left over after the transfer. It is possible to freeze the leftover embryos to preserve them. This process is called cryopreservation. If a couple does not achieve pregnancy after IVF, the partners can attempt pregnancy again by transfer of thawed embryos remaining from their first treatment cycle.

Pregnancy rates after cryopreservation and thaw of human embryos are less than those following a fresh embryo transfer. The chance of pregnancy will depend on the quality of the embryos and on the maternal age at the time that the embryos were frozen. Live births have occurred after as long as 7 years of cryopreservation, although in most cases couples will use their frozen embryos within a short time. For some couples, cryopreserved embryos have become objects of legal contention. Who maintains custody of the embryos if a couple divorces? Are frozen embryos property? Do frozen embryos themselves have any rights?

Treatment Success and Risks

Even though ART is expensive and invasive when compared with other therapies, ample empirical evidence supports the use of ART procedures for treatment of infertility. Live birth rates per initiated cycle vary internationally from 18 to 25%. Chance of success is greatest with younger maternal age and evidence of normal ovarian function. Women over 40 years of age or with high concentrations of FSH early in the menstrual cycle have little chance of achieving a live born child. Multiple pregnancy rates after ART treatment average 25 to 40% and can be as high as 60% in some series. The high rate of multiple pregnancy after ART treatment contributes to an increase in spontaneous pregnancy loss (25%), ectopic pregnancy (5%), and preterm delivery. Ovarian hyperstimulation syndrome occurs in 5% of cycles and is another significant consequence of ART treatment.

FUTURE IMPLICATIONS OF ART TECHNIQUES

It is likely that we have only just begun to see the direction that these technologies can take us. ART techniques, combined with a growing knowledge of molecular and cell biology, will allow further development of preimplantation diagnosis and possible preimplantation gene therapy. The goal of helping to reverse the effects of aging on reproductive potential may one day be realized through the application of techniques borrowed from cloning and stem cell research. Further improvement in embryo culture technique and embryo selection should increase the number of established pregnancies, reduce the number of multiple pregnancies and pregnancy losses, and further increase the live birth rate per initiated ART cycle.

ETHICAL CONCERNS

Some have expressed concern that the expense and risks of ART may outweigh the benefit to the few couples who achieve successful live births. Further concern about expense, risk, and commercialization arises if an egg donor or gestational surrogate, who bears procreative risk in return for payment, is involved. There is consensus that surrogates and donors should be paid for their services but not paid so much that the participants are blinded to their potential risks. In many countries, ART procedures are available only to those who can afford them. Does a society have responsibility to provide infertility care to all of its members as it would to any individual suffering with disease? Some governments have dictated the maximum number of eggs to be retrieved and fertilized and the maximum number of embryos to be transferred per case in an effort to decrease the chance of a multiple gestation. Is this intrusion on the right of individuals to have control over their medical care justified by a concern for patients' safety and the safety of their potential fetuses? Do governments have a right to limit the types of reproductive services available to their citizens?

In July 1978, after Louise Brown was born, religious leaders complained that doctors did not have the right to "play god." Steptoe replied, "I don't know what the fuss is all about. I'm just glad we were able to help Mrs. Brown to have such a happy healthy baby."

Today, because of ART, millions of couples and their physicians have had the joyful opportunity of echoing Steptoe's sentiment.

removal of their tumors. The distributions of the pathological origins of adrenal incidentalomas vary with several clinically important factors, including cancer history and mass size. Among patients with a history of cancer, three-fourths of the incidentalomas are metastases. In contrast, in non-cancer patients, more than 75% of adrenal incidentalomas represent benign tumors. In these patients, the most frequent diagnosis by far is that of a benign, hormonally inactive adrenal adenoma. Approximately 20% of all lesions are functional adrenal tumors. The most frequent sub-clinical disease is SCCS (5–17%). Pheochromocytoma is found in approximately 5% of patients, and (normo-kaliemic) Conn's syndrome is found in 2 to 5% of patients. ACC is an extremely rare tumor, with an estimated annual incidence of 0.5 to 2 cases per 1 million population. The prevalence of ACC in incidentaloma patients is related to the size of the mass. In surgical series, ACC accounts for 2% of tumors less than 4.0 cm, 6% of tumors 4.1 to 6.0 cm, and 25% of tumors greater than 6.0 cm. However, the prevalence of ACC is overestimated in surgical series because the suspicion of ACC is an indication for surgery. Moreover, the frequency of ACC is derived from highly selected patient populations and does not reflect the prevalence rate seen in population-based studies. The age and sex of the patient is not helpful in predicting the presence of ACC because it is found equally in both sexes and in all age classes.

DIAGNOSTIC APPROACH

The patient with an adrenal incidentaloma requires a complete history and physical examination, a biochemical workup, and (possibly) additional radiological studies. Careful evaluation holds the potential of early detection of a harmful underlying disease and can lead to a curative therapy, for example, in secondary hypertension or adrenal carcinoma. The diagnostic approach has two foci: endocrine activity and the risk of malignancy.

Endocrinological Investigation

Roughly 20% of all incidentalomas are functional (see Fig. 1, showing autonomous endocrine activity in adrenal incidentaloma). Several studies have shown that the risk of subclinical endocrine activity increases with size. Lesions smaller than 1 cm are generally nonfunctional. However, the prevalence of hormone excess increases to 40% in lesions that are 6 cm or larger. The goal of the studies has been to determine whether the patients have mild glucocorticoid excess

Figure 1 Prevalence of subclinical biochemical disease in patients with adrenal incidentalomas.

(SCCS), primary hyperaldosteronism (Conn's syndrome), or pheochromocytoma (Table II).

Significant autonomous cortisol secretion (SCCS) is found in 5 to 20% of patients. The spectrum of biochemical abnormalities depends on the amount of glucocorticoids secreted and ranges from only a slight attenuated diurnal cortisol rhythm to a complete atrophy of the contralateral gland. SCCS must be excluded in every patient scheduled for surgery to avoid postoperative adrenal crisis. The best means to uncover autonomous cortisol secretion is the short (overnight) dexamethasone suppression test, which rarely fails to detect SCCS. To reduce false positive results, we prefer a higher dexamethasone dose (3 mg instead of 1 mg). A suppressed serum cortisol concentration ($<5 \mu\text{g/dl}$ or 110 nmol/L) excludes significant cortisol secretion by the tumor. A positive low-dose dexamethasone requires a confirmatory high-dose dexamethasone

Table II Stepwise Endocrine Evaluation of a Patient with Adrenal Incidentaloma

| |
|--|
| Step 1: Screening test: Excluding endocrine activity |
| Serum cortisol after dexamethasone suppression (3 mg at 11 PM orally) |
| Serum potassium and plasma aldosterone/plasma renin activity ratio in hypertensive patients |
| 24-h urinary catecholamine excretion |
| Step 2: Confirming endocrine activity |
| Confirmation of SCCS by high-dose (8-mg) dexamethasone suppression |
| Confirmation of Conn's syndrome by determination of plasma aldosterone during saline infusion test |
| Confirmation of pheochromocytoma by repeat urinary catecholamine excretion |
| Step 3: Determining outcome/origin of hormone excess |
| SCCS: CRH stimulation test, urinary-free cortisol |
| Conn's syndrome: Upright posture test, selective adrenal venous sampling (optional) |
| Pheochromocytoma: meta-iodine-benzyl-guanidine (MIBG) scintigraphy, genetic testing (optional) |

suppression test (8 mg). Further workup should include a corticotropin-releasing hormone (CRH) test to evaluate the degree of hypothalamic-pituitary suppression, the analysis of the diurnal cortisol rhythm, and the measurement of urinary-free cortisol. Patients with low adrenocorticotrophic hormone (ACTH) concentrations who are not responding to CRH are at risk for adrenal insufficiency after surgery and require adequate substitution therapy. Increased values of urinary-free cortisol are a late finding usually associated with emerging clinical signs of Cushing's syndrome. Thus, determination of urinary-free cortisol is not an appropriate screening test for SCCS.

In patients with hypertension, serum potassium and a plasma aldosterone/plasma renin ratio should be determined to evaluate primary aldosteronism. A normal potassium concentration does not exclude primary hyperaldosteronism given that the majority of patients are normokaliemic under random conditions. A plasma aldosterone/plasma renin ratio greater than 30 (ng/dl to ng/ml/h) and a plasma aldosterone concentration (PAC) of greater than 20 ng/dl are highly suggestive of autonomous aldosterone production. The diagnosis of primary hyperaldosteronism has to be confirmed by the failure of fludrocortison to suppress aldosterone (0.1 mg fludrocortison every 6 h for 4 days, PAC on day 5 greater than 5 ng/dl, sampling midmorning after 2 h upright position) or following acute saline suppression (2 L of 0.9% NaCl solution infused i.v. over a period of 4 h; failure to suppress PAC $<6 \text{ ng/dl}$). Patients with an elevated PAC and plasma renin activity (PRA)/renin ratio may require further evaluation in a specialized center. Investigations may even include bilateral adrenal catheterization to prove that the incidentaloma is the source of the mineralocorticoid excess.

Pheochromocytoma among adrenal incidentalomas is found in approximately 5% of patients. Most patients do not show the typical clinical symptoms such as tachycardia, sweating, and headache, and up to 40% are completely asymptomatic. Because of the sequelae of undiagnosed pheochromocytoma, every patient should be evaluated by determination of 24-h urinary catecholamines that have a sensitivity and specificity of more than 90%. Measurement of plasma catecholamines is inferior, and a suppression test (clonidine test) is rarely required. Whether free plasma metanephrines are superior under random conditions has not yet been determined. Patients with elevated catecholamine excretion should undergo ^{131}I -metaiodobenzylguanidine (MIBG) scintigraphy for preoperative detection of multiple pheochromocytoma or metastasis.

Routine evaluation for androgen and estrogen production in patients with adrenal incidentalomas is not recommended. Especially determination of DHEAS has not been shown to be a very sensitive marker of ACC. In a recently published Italian multiple-center trial, DHEAS values were elevated in 17% of all patients with cortical carcinoma (28% in younger individuals, i.e., under 50 years of age). The sensitivity and specificity were 17% and 93%, respectively; negative and positive predictive values were 95% and 10%, respectively.

Adrenal Imaging

The size and appearance of an adrenal mass on CT or MRI helps to distinguish between benign and malignant lesions. A homogenous mass with a smooth border and an attenuation value of less than 10 Hounsfield units (HU) on an unenhanced CT study strongly suggests the diagnosis of a benign adrenal adenoma. Unfortunately, this information is often not available. Adrenal carcinomas are generally larger than 6 cm, are nonhomogenous, and show soft tissue density. Irregular margins and central necrosis or hemorrhage increase the probability of malignancy. However, benign pheochromocytoma may also present as a large nonhomogenous tumor with hemorrhage. Whether MRI is superior to CT in diagnosing and differentiating among adrenal masses remains uncertain. The recently developed chemical shift MRI (CSI) identifies benign adrenal adenomas with high lipid content by a typical signal intensity loss on chemical shift imaging relative to the liver. Recently, a sensitivity of 91% and a specificity of 94% were reported using CSI for differentiation between adenoma and metastasis, but its accuracy in ACC is uncertain.

Fine Needle Aspiration

In patients with adrenal incidentaloma who have no history of malignancy, fine needle aspiration (FNA) has no proven efficacy. FNA is not free of side effects and may lead to pneumothorax, frank retroperitoneal bleeding, or needle track metastasis in the case of ACC. The additional improvement of the new imaging techniques (CT and MRI) in characterization of adrenal masses should restrict FNA to few indications. In patients with a history of malignancy, FNA is a valuable tool (sensitivity and specificity of approximately 90%) and should be performed if the presence of adrenal metastasis may alter the therapy or prognosis. Pheochromocytoma should always be ruled out

prior to FNA because it may cause hypertensive crisis or even death.

THERAPEUTIC CONSIDERATIONS

Adrenal surgery has significant morbidity and mortality that must be taken into account during the decision-making process. The newly developed endoscopic adrenalectomy, with its low morbidity (5–10%) and mortality (<1%), may justify earlier surgical intervention. However, it has to be emphasized that in the published series, this operation was performed mostly in specialized centers with experienced laparoscopic surgeons. Surgical outcome may be significantly less favorable in centers without such specialization.

Treatment of the Functional Incidentally Detected Adrenal Mass

To prevent serious morbidity, hormonally active incidentalomas should be surgically removed. This strategy is undisputed for aldosterone-producing adenoma and pheochromocytoma. However, it remains doubtful whether all patients with SCCS benefit from adrenal surgery. There are data indicating that some patients with SCCS may develop metabolic derangement, including hypertension, weight gain, and insulin resistance, that could be attributable to autonomous cortisol secretion. Rarely, it may progress from subclinical disease to overt Cushing's syndrome. Surgery should be considered in patients with SCCS who have suppressed plasma ACTH and elevated urinary-free cortisol because progression to overt Cushing's syndrome is imminent. Adrenalectomy is also recommended in younger individuals (<50 years of age) and in patients who have metabolic disease of recent onset possibly related to the incidentaloma (e.g., obesity, hypertension, diabetes).

Treatment of the Nonfunctional Incidentally Detected Adrenal Mass

In patients with nonfunctioning incidentalomas, distinguishing between malignant and benign primary adrenal tumors dictates subsequent management. Variables to consider, according to the National Institutes of Health consensus conference (Fig. 2), are the size of the lesion, its radiographic characteristics, and its growth rate. More than 60% of incidentalomas less than 4 cm are benign adenomas, whereas less than 2% represent ACC. In contrast, the risk of adrenal carcinoma increases to 25% in lesions that are

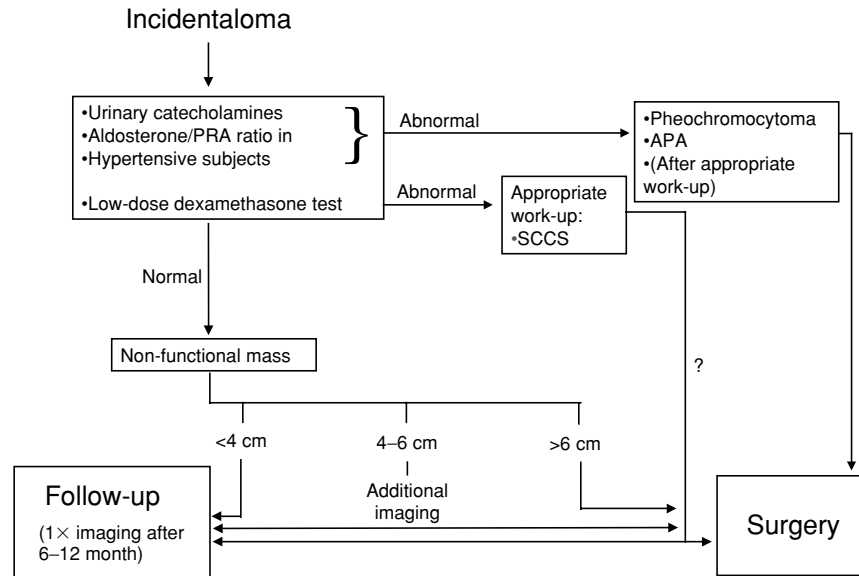

Figure 2 Diagnostic and therapeutic considerations for the treatment of patients with adrenal incidentalomas following the recommendations of the National Institutes of Health in its 2002 state-of-the-science statement.

6 cm or more in diameter, whereas benign adenomas account for less than 15%. Therefore, the generally accepted recommendation is to excise lesions that are more than 6 cm. Lesions that are less than 4 cm and appear to be defined as low risk by radiographic criteria are unlikely to have malignant potential and are generally not resected. For lesions between 4 and 6 cm, either close follow-up or adrenalectomy is considered a reasonable approach.

Data from several small series of patients indicate that approximately 85% of lesions remain stable, 5 to 30% of incidentalomas increase in size, and 3 to 4% decrease in size. In these series, the risk of the lesion being an ACC was extremely low. Based on these data, a repeat CT scan between 6 and 12 months after the initial study is reasonable. For data that do not increase in size, continued radiological evaluation is not recommended. Hormone excess may develop in less than 20% of cases when followed for up to 10 years, but this is unlikely in patients with lesions of less than 3 cm. Current evidence suggests repeat dexamethasone suppression and urinary catecholamine excretion testing for up to 3 to 4 years.

Cycles strongly suggest that a woman is ovulating. Cycle lengths of roughly 22 to 35 days are usually ovulatory, especially if accompanied by premenstrual symptoms such as bloating and breast tenderness. If a woman has menses more or less often, she probably is not ovulating or is ovulating infrequently. Amenorrhea (no menses) is suggestive of ovulatory dysfunction except in patients with uterine disease such as intrauterine scarring (Asherman's syndrome) or serious congenital uterine abnormality. Ovulation may be confirmed by measuring a serum progesterone level during the luteal phase of the cycle (about 1 week before a woman's next menses is due) or by charting the basal body temperature, by ultrasound of the ovaries, and/or by detection of luteinizing hormone (LH) surge, often using urinary LH detection kits. Absolute proof of ovulation is made by the occurrence of pregnancy.

Polycystic ovarian syndrome (PCOS) is the etiology of anovulation or oligo-ovulation in approximately 70% of cases. Other causes include hypothalamic dysfunction, hyperprolactinemia, age-related ovulation dysfunction, premature ovarian failure, and thyroid disease. Congenital adrenal hyperplasia (CAH) is a relatively rare cause of oligo-ovulation. Extremes of weight, such as that associated with anorexia or with obesity, may also lead to anovulation by producing hypothalamic dysfunction.

It is important to determine the cause of oligo-ovulation before embarking on a treatment plan. A diagnosis can generally be determined by clinical history and by measurement of serum thyroid-stimulating hormone (TSH), prolactin, follicle-stimulating hormone (FSH), and estradiol (E_2). Some clinicians find it useful also to measure serum testosterone, fasting blood sugar, and fasting insulin levels to confirm or refute a clinical suspicion of PCOS. However, the value of this additional testing is controversial. Measurement of the follicular phase 17-hydroxyprogesterone level will detect most cases of CAH.

Tubal Disease

Open and functional fallopian tubes are necessary for conception. Tubal and/or adhesive factors account for about 35% of all infertility cases. Infertility may result from complete blockage of the distal end of the fallopian tube (hydrosalpinx) as a sequelae of sexually transmitted disease, surgical intervention for management of ectopic pregnancy or other intra-abdominal conditions, nongynecological abdominal infection (uncommon), endometriosis

(uncommon), or a congenital anomaly (rare). Proximal obstruction may result from salpingitis isthmica nodosa or other inflammatory conditions, or it may be idiopathic. Peritubal adhesions or damage to the lining of the tube can impair tubal mobility, oocyte pickup, and/or sperm and embryo transport. Iatrogenic infertility occurs secondary to tubal sterilization.

The hysterosalpingogram (HSG) is typically used as the initial screen for the presence of tubal disease. In this fluoroscopic procedure, media placed through the cervix and into the uterine cavity can be seen passing through the fallopian tubes if they are patent. The presence or absence of tubal disease is most definitively confirmed by laparoscopy.

Endometriosis and Peritoneal Adhesions

Endometriosis is found more commonly in women with infertility than in women with normal fertility. Women with endometriosis may have an earlier onset of diminished ovarian reserve, possibly associated with ovarian endometriosis cysts (endometriomas). Immunological and genetic factors are also likely to be important in the pathogenesis and pathophysiology of endometriosis. Although there has been much debate, it is likely that even minimal endometriosis can reduce a woman's fertility. In cases of extensive endometriosis, tubal function may be compromised by tubal adhesions. Peritoneal adhesions may also interfere with tubal function. Endometriosis and peritoneal adhesions can be definitively diagnosed only by laparoscopy. Diagnostic laparoscopy should be performed only by surgeons who are generally capable of treating the disease they find at the initial diagnostic laparoscopy, a procedure called operative laparoscopy.

Uterine and Cervical Abnormalities

Abnormalities may be present in the cavity of the uterus where the embryo needs to implant and develop. These abnormalities include intrauterine adhesions, polyps, fibroids, and an abnormally shaped uterine cavity. Problems within the uterus can potentially interfere with implantation of the early embryo or increase the incidence of miscarriage.

The HSG is often used as an initial screen to determine whether the cavity of the uterus is anatomically normal. The saline hysteroogram (SHG) is a pelvic ultrasound done while injecting saline (salt water) through the cervix to outline the uterine cavity. Unlike the HSG, it allows visualization of the wall of the uterus as well as the cavity at the same time, a

difference that may be helpful in assessing the position of fibroids and in determining whether or not they are resectable through the hysteroscope. As a screen for abnormalities in the uterus, the SHG is a more sensitive and more specific screening test than is the HSG, using findings at hysteroscopy as the gold standard.

An inadequate progesterone effect on the uterine lining is called a luteal phase deficiency. Luteal phase defect may be due to either deficient progesterone production or inability of the uterine lining to respond to estrogen during the proliferative phase and/or to progesterone during the luteal phase. It is quite debatable how often a luteal phase defect can explain either infertility or recurrent miscarriage—if luteal phase defect explains these problems at all. Many infertility specialists no longer routinely do an endometrial biopsy because the information has not usually been helpful in improving live birth rates. Problems of implantation (e.g., endometrial receptor defects) may theoretically occur secondary to dysfunctional endometrium. Currently, however, there are no adequate tests to diagnose such theoretical conditions or specific treatments for such conditions.

Conditions within the cervix can contribute to infertility, but they are rarely the sole cause. Risk factors for cervical abnormalities may include cone biopsy and diethylstilbestrol (DES) exposure. Chronic infections may, in some cases, contribute to poor cervical mucus. Abnormalities of the cervical mucus may be diagnosed by the postcoital test (examination of the cervical mucus for the presence of motile sperm after intercourse). Many physicians do not recommend this test because its value in guiding infertility treatment is not clear. Its only role may be in diagnosing inadequate coital technique or frequency that can be based on sexual dysfunction, ignorance, and/or cultural/social/religious issues that can interfere with coitus and impair infertility.

Abnormalities of Sperm

A male factor is the sole cause for infertility in about 20% of couples and contributes to infertility in approximately 30 to 40% of other couples. Although a cause for decreased sperm quality may be determined in some cases, male subfertility is frequently idiopathic.

Azoospermia (absence of sperm in the ejaculate) may be classified as obstructive (e.g., congenital absence of the vas deferens, ductal obstruction, vasectomy) or nonobstructive. Most cases of nonobstructive azoospermia are due to primary testicular failure. Endocrine abnormalities such as hyperprolactinemia

that secondarily affect spermatogenesis are less common. Genetic disorders associated with azoospermia or severe oligospermia include Klinefelter syndrome (47,XXY) and microdeletions of the Y chromosome. Congenital absence of the vas deferens is associated with cystic fibrosis mutations.

Oligospermia may result from hormonal problems, retrograde ejaculation, varicocele, or a primary testicular problem with sperm production. Genitourinary infection may interfere with sperm function. Environmental factors such as medications, drugs, alcohol, tobacco abuse, and radiation may impair sperm production and function. Deficiency of trace elements such as zinc, folate, and selenium may impair sperm function. Antisperm antibodies may impair fertility in couples with unexplained infertility. In many cases, no treatable cause of poor sperm quality can be found.

A recent review of the effects of male age on semen quality and fertility concluded that increasing age is associated with a decline in semen volume, sperm motility, and sperm morphology but not with sperm concentration. There is most likely some decline in male fertility with age, particularly over 50 years of age, but results are confounded by female partner age. There is no age at which men cannot father a pregnancy. Thus, fertility is much more related to the age of the female partner.

The semen analysis is used as the basic screen for abnormalities of sperm. A semen analysis typically includes assessment of volume, concentration, motility, and morphology of the sperm. Other tests of sperm function may be used in some special circumstances.

Advancing Female Age

An age-related decline in female fertility begins many years prior to the onset of menopause despite continued regular ovulatory cycles. “Ovarian reserve” is a term often used to describe a woman’s reproductive potential with respect to ovarian follicle number and oocyte quality. The drop in fertility associated with diminished ovarian reserve is due to a depletion of eggs and to a decline in average egg quality. Although there is no strict definition of what may be considered advanced reproductive age, a decline in fertility on average begins for women in their late 20s or early 30s, becoming more pronounced after 35 and very pronounced after 40 years of age. However, the decline in ovarian reserve may occur much earlier for some women. Risk factors for early loss of ovarian reserve include smoking, family history of premature ovarian failure, significant ovarian pathology due to

severe endometriosis and/or pelvic adhesive disease, and previous ovarian surgery.

Once an older woman becomes pregnant, she has a markedly increased risk of spontaneous abortion, with the clinical spontaneous abortion rate being approximately 15% for women under 35 and 40% or higher for women over 40 years of age. The age-associated decline in female fertility and the increased risk of spontaneous abortion are most likely attributable to abnormalities in the oocyte that lead to aneuploid embryos (those with the wrong number of chromosomes). There is good evidence that aneuploid embryos will either arrest very early in development (before a woman even knows she is pregnant) or will miscarry, most commonly during the first trimester.

Because of the marked effect of age on success rates from infertility treatment, it is advisable for older women to begin evaluation sooner than do younger women. It is reasonable to pursue an infertility evaluation after only 6 months of attempting pregnancy because the consequences of undiagnosed infertility factors can be even more detrimental to women who have a limited time frame for achieving a successful pregnancy.

It is advisable to assess ovarian reserve in all women 35 years of age or over and in younger women with risk factors for early onset of diminished ovarian reserve or unexplained infertility. An assessment of ovarian reserve typically includes measurement of FSH and E₂ levels on the third day of a woman's menstrual cycle. A more sensitive marker of ovarian reserve is the clomiphene citrate challenge test (measurement of FSH the day after a 5-day course of clomiphene along with the day 3 measurements) and a count of small antral follicles in the early follicular phase.

Unexplained Infertility

In approximately 5 to 10% of couples seeking pregnancy, all of the preceding tests are normal, and in a much higher percentage of couples, only minor abnormalities are found. These couples are often said to have unexplained infertility. Couples with unexplained infertility may have problems with egg quality that have not been detected with any of the available tests. In other cases, couples with unexplained infertility may have a problem with the ability of the sperm to fertilize the egg, undiagnosed tubal dysfunction, or implantation failure. Ongoing studies are beginning to try to elucidate a genetic basis for unexplained infertility.

INFERTILITY TREATMENTS

Objectives for Managing Infertility

Cost-effective, evidence-based infertility management depends on an organized plan of diagnosis and treatment from the time of initial presentation. This includes the use of simpler, cheaper tests first and the establishment of a correct diagnosis, followed by simultaneous treatment of the man and woman using effective therapy. Whenever possible, treatment choices should be based on the available evidence regarding their efficacy and risks as well as on the wishes of the individual couple.

Ovulation Induction

The development of a single mature follicle is the goal of anovulatory women. If the cause of infertility is not lack of ovulation, the goal of ovulation induction is the development of multiple follicles (controlled ovarian hyperstimulation). Clomiphene is a selective estrogen receptor modulator (sometimes called an antiestrogen) that is administered orally for 5 days to induce ovulation. In anovulatory women with polycystic ovarian syndrome, clomiphene is expected to induce ovulation in approximately 80% of oligoovulatory or anovulatory women. The monthly pregnancy rate depends on the presence or absence of other infertility factors and may range from less than 5 to 20%. Twins occur in 10% or fewer of pregnancies, and triplets occur with a frequency of less than 1%. In women with PCOS who fail to ovulate on clomiphene alone, metformin plus clomiphene may achieve ovulation, particularly if women are obese or have evidence of insulin resistance.

Gonadotropin therapy involves daily injections of FSH and sometimes LH. This treatment will lead to ovulation in most women with polycystic ovarian syndrome and in patients with hypothalamic amenorrhea. Multiple pregnancy occurs with approximately 25% twins, 5% triplets, and 2% quadruplets. Severe ovarian hyperstimulation syndrome occurs in approximately 1% of patients, with moderate ovarian hyperstimulation occurring in 5 to 7% of patients. Gonadotropin treatment requires intensive ultrasound monitoring, and its cost is much greater than that of clomiphene. Therefore, it is typically used if treatment with clomiphene is unsuccessful.

For women with polycystic ovarian syndrome, ongoing pregnancy rates with laparoscopic ovarian drilling (a procedure that uses an electro-surgical needle or another energy source to destroy

androgen-producing ovarian stroma) after 6 to 12 months are similar to three to six cycles of ovulation induction with gonadotropins. Multiple pregnancy rates are lower with ovarian drilling. However, ovarian drilling requires a surgical procedure and carries a risk of adhesive disease. Furthermore, its impact on long-term ovarian reserve has not been studied adequately.

For women with hyperprolactinemia, the dopamine agonist bromocriptine leads to ovulation in approximately 80% of patients. Cabergoline, a long-acting dopamine agonist, is at least as effective as bromocriptine and appears to be better tolerated. Treatment of thyroid disease may lead to ovulation if abnormalities of thyroid function are detected on initial evaluation. Adrenal gland dysfunction is rare, but treatment may improve ovarian function.

Surgical Treatments

Tubal Surgery

Blocked fallopian tubes may be surgically opened and peritubal adhesions may be removed. The most important factor affecting success of tubal surgery may be the degree of damage to the lining of the tubes before surgery and the postoperative reformation of adhesions. Severe underlying intratubal pathology, such as intratubal adhesions, is not surgically correctable. Although some tubal problems are correctable by surgery, women with severely damaged tubes are so unlikely to become pregnant that *in vitro* fertilization (IVF) offers the best hope for a successful pregnancy (Table I). Very badly damaged obstructed tubes may

Table I Pregnancy Rates Following Treatment for Tubal Factor Infertility (Percentages)

^aAfter discontinuation of ovarian suppression medications.

fill with fluid, creating hydrosalpinges and resulting in live birth rates with IVF only half those for women without hydrosalpinges. For this reason, removal of hydrosalpinges should be considered before an IVF cycle. This operation, a salpingectomy, can almost always be performed laparoscopically. Tubal reanastomosis (typically done to reverse a tubal ligation) is generally a surgical procedure associated with a much better outcome than is repair of tubes damaged by infection or severe endometriosis.

Surgery to Diagnose and Treat Endometriosis

In some cases, the decision may be made to proceed with surgery to diagnose and treat endometriosis. It appears that laparoscopic treatment in skilled hands is as effective as laparotomy. For minimal and mild endometriosis, laparoscopic surgery probably improves live birth rates, although prospective data are limited and not all studies confirm this finding. The short-term increase in monthly fecundity with surgical treatment of minimal or mild endometriosis is probably lower than the monthly fecundity expected with treatments for unexplained infertility such as controlled ovarian hyperstimulation and intrauterine insemination (COH/IUI) and assisted reproductive technology. Therefore, sometimes these treatments are used empirically without laparoscopy, even if it is possible that endometriosis may be present. Although ovarian suppression is effective for management of pain associated with endometriosis, ovarian suppression is not indicated as a treatment for infertility, with the possible exception of ovarian suppression for 2 months in patients with severe endometriosis before IVF. The live birth rate may be increased if moderate or severe endometriosis is diagnosed and treated surgically (Table II). However, sometimes the long-term prognosis for these patients is poor with treatments other than IVF.

Surgery to Correct Uterine Abnormalities

There are no good trials to actually determine whether or not myomectomy is beneficial with respect to infertility. Myomectomy may improve the success of IVF if the myoma is distorting the uterine cavity. Some studies support, and many clinicians perform, myomectomies for documented uterine cavity distortion whether or not IVF is being considered. A potential complication of myomectomy is postoperative adhesions or subsequent need for cesarean section. Polypectomy may reduce the rate of miscarriage in couples undergoing IVF. Most uterine anomalies do not require surgical treatment of the uterus. A septate uterus should generally be treated hysteroscopically at the time of diagnosis, especially in a couple with recurrent miscarriage. Adenomyosis and DES exposure may affect the live birth rate of various infertility treatments but are not surgically correctable. Severe adenomyosis may contribute to infertility, but diagnosis can be difficult without a pathological specimen, and no medical or surgical treatments have been confirmed to improve pregnancy rates.

Treatments for Male Factor Infertility

Male factor infertility may be amenable to treatment of a specific cause if one is identified. For example, if a varicocele is palpable, surgery may be considered as a treatment option when semen analyses are abnormal. When a specific cause cannot be identified, male factor infertility is often treated by IUI or IVF. IVF is the treatment of choice for couples with severe male factor infertility. During an IVF cycle, it is possible to perform direct injection of a single sperm into each oocyte, a procedure known as intracytoplasmic sperm injection (ICSI). With this procedure, it has become possible to treat very severe cases of male factor infertility. Donor sperm can be used for women attempting conception who do not have a male partner and in cases of male factor infertility. Donor insemination is used much less frequently for male factor infertility since ICSI has become available.

Treatments for Age-Related Infertility

COH/IUI has limited efficacy for older women, yielding a delivery rate per cycle of 5% or less (range = 1.4–5.2%) for women over 40 years of age with infertility that is unexplained except by age. This compares with live birth rates per cycle of 17 to 22% for women under 35 and of 8 to 10% for women 35 to 40 years of age. Advancing age is associated with

reduced ovarian responsiveness to gonadotropins and poorer egg quality.

The presence of infertility factors such as male factor, tubal disease, endometriosis, and pelvic adhesions would argue for proceeding directly to IVF in women of advanced reproductive age. Pregnancy rates from IVF are higher—usually much higher—per cycle than with other treatments, including COH/IUI, surgery, and treatment of male factor infertility, but do decline significantly with age. According to the 2000 Society for Assisted Reproductive Technology (SART) report, live birth rates per cycle were 33% in women under 35, 27% in women 35 to 37, 18% in women 38 to 40, 10% in women 41 to 42, and 4% in women over 42 years of age. This age-related decline in IVF success is related to a decline in ovarian reserve.

Oocyte donation yields the highest live birth rate of any assisted reproductive technology (ART) treatment and is the treatment of choice for age-related infertility that is not addressed successfully by other treatments. Oocyte donation involves the retrieval of eggs from a woman with good ovarian reserve (typically a woman in her 20s or early 30s), fertilization of these eggs in the laboratory, and subsequent transfer of embryos to the woman who will carry the child. Pregnancy rates with oocyte donation are dependent on the age of the donor, not on the age of the recipient (Fig. 1). Pregnancy rates with donor oocytes are much higher than those with the usual infertile population due to the improved egg quality.

Figure 1 Live births per transfer for fresh embryos from patients undergoing *in vitro* fertilization with their own eggs or from donor eggs. Data are displayed by age of the recipient of the eggs. From the U.S. Department of Health and Human Services and Centers for Disease Control and Prevention. (2002). 2000 assisted reproductive technology success rates [national summary and fertility clinic reports].

Treatments for Unexplained Infertility

Proposed treatments for unexplained infertility include IUI, COH/IUI, and ART (Table III). Cycle fecundity with COH/IUI is expected to be lower when the diagnosis is unexplained infertility than when the diagnosis is anovulation. For anovulatory women, the treatment is correcting an identified problem, whereas in couples with unexplained infertility, it is quite possible that oocyte quality or sperm dysfunction may be present. Cycle fecundity is also expected to be lower if significant male factor is present than if the semen analysis is normal. Female age is one of the most important predictors of success.

Outcomes of Infertility Treatment and ART

Patients undergoing infertility treatment have a medical disease, infertility, with dysfunction of the hypothalamus, pituitary, ovaries, uterus, pelvis, male reproductive system, or other systems. They also are older than the population of women who can conceive without difficulty. Despite these important differences, babies resulting from infertility treatment generally are as healthy, or nearly as healthy, as the normal population. Any significant differences in outcomes result primarily from the increased rate of multiple pregnancy and associated prematurity. Therefore, reducing the multiple birth rate is an important objective of infertility specialists. For most infertile patients, the chances of having a healthy baby when they conceive following infertility treatment are not substantially different from those when they conceive spontaneously.

Table III Pregnancy Rates Following Treatment for Unexplained Infertility (Percentages)

| Treatment | Monthly Fecundity |

^aThese monthly fecundities reflect outcomes from prior to 1995. IVF success rates have improved since this time. See text.

Since the first IVF baby was born in 1978, more than 1 million babies have been born via IVF all over the world. Large national and international registries and numerous studies have concluded that IVF results in generally healthy babies. However, recently some studies have found a general increased risk of birth defects, prematurity, lower birthweight, and selected genetic birth defects in IVF babies. All of the studies and data can be faulted for shortcomings in their methodology, but a legitimate concern has been raised that will require better, larger, and longer follow-up studies to confirm that IVF babies have no clinically substantial increased risk of untoward outcomes. Patients should be counseled about these concerns, but data and studies supporting the usually positive outcomes for IVF babies are reassuring for most patients.

Decision Making in Infertility

Many factors must go into the decision regarding which infertility treatment is best for a given patient. These factors include the value that the patient and her partner place on various outcomes, for example, their own genetic baby, an IVF baby, a donor egg baby, a baby from a gestational carrier, adoption, and the decision to be “child free.” The financial and time cost, as well as the physical and emotional side effects and risks of treatment, must be weighed. Once this is done, the prognosis for each type of treatment and the risks of adverse outcomes need to be balanced. COH/IUI is often successful but carries the major risk of twins in approximately 7 to 10% of pregnancies with clomiphene and 20 to 30% of those with gonadotropins. Triplets occur in less than 1% of pregnancies with clomiphene but occur in up to 5 to 10% of those with gonadotropins. Surgery does not carry an increased multiple pregnancy risk but does carry surgical risk and may result in an increased risk of ectopic pregnancy in 1 to 30% of surgeries, depending on the degree of tubal damage. Furthermore, the monthly fecundity following tubal surgery is generally lower than that with other treatments, so it takes longer on average to conceive. IVF is much more successful than other treatments but is more expensive and carries a risk of approximately 30% for twins and 4% for triplet births for each pregnancy. The risk of multiple pregnancy with IVF can be reduced substantially by limiting the number of embryos that are replaced. Adherence to current guidelines regarding the number of embryos to replace is essential if the number of multiple pregnancies is to be reduced. Additional complications of premature babies and

pregnancy in women of advanced age must be considered, including the increased risk of birth defects and their management. Careful informed discussion with each patient and partner is necessary to review all of the potential options, prioritize them, and develop a treatment plan once the diagnosis is established.

SUMMARY AND CONCLUSION

Common causes of subfertility include ovulatory disorders, tubal disease, adhesions, endometriosis, uterine abnormalities, sperm dysfunction, and advancing female age. Infertility is unexplained after thorough evaluation in about 5 to 10% of cases, and only minor abnormalities are found in many other couples. The provision of cost-effective infertility treatment that is evidence based is a challenge given the limited number of well-designed trials of infertility treatments, rapid technological advances, and variance in couples' objectives, values, and ethical beliefs. Successful ovulation induction in anovulatory women is possible for nearly all women except in cases of ovarian failure. The effectiveness of tubal surgery is dependent on the degree of damage to the lining of the tube and the extent of pelvic adhesions. Surgical treatment of endometriosis can improve the live birth rate for some infertile couples. Male factor infertility may be amenable to treatment of a specific cause but is often empirical with use of IUI or IVF. Egg donation is currently the most effective treatment available for age-related infertility, ovarian failure, and when other treatments have not been successful. Couples with unexplained infertility may

be effectively treated with ovulation induction plus IUI or IVF.

resistance of gluconeogenesis. Thus, hepatic insulin resistance in type 2 diabetes occurs secondary to chronic hyperinsulinemia.

Adipose Tissue

White adipose tissue accounts for less than 10% of glucose uptake but plays a major role in whole body insulin sensitivity by releasing into the circulation various modulators of insulin action, including lipid products and hormones. Free fatty acids (FFAs) derived from adipocytes are elevated in obesity and type 2 diabetes and accumulate in muscle and liver, contributing to insulin resistance in these tissues. Mice with a selective deletion of the insulin receptor in brown adipocytes experience an age-dependent loss of intrascapular brown fat but increased expression of uncoupling proteins-1 and -2. In parallel, these mice develop a defect in insulin secretion, resulting in progressive glucose intolerance, without insulin resistance. These data demonstrate that the insulin receptor is required for brown fat formation throughout development and that brown fat regulates insulin secretion and glucose homeostasis.

Histological, immunohistochemical, and ultrastructural analyses of white adipose tissue in newborn fat insulin receptor knockout mice (FIRKO mice) reveal a marked decrease in adipose tissue area. This fat cell depletion resulted from a reduction of adipocyte volume (~90%), with a small decrease in the number of adipocytes. Electron microscopy analysis displays a normal pattern of adipogenesis in FIRKO mice, demonstrating that lack of insulin receptors is not associated with a selective impairment of the adipocyte differentiation process. Thus, the insulin receptor is dispensable for adipocyte differentiation but is necessary for the large extent of lipid storage in these cells. In addition, FIRKO mice display increased longevity, demonstrating an inverse relationship between high rates of adipose metabolism and life span.

Adipocytes also secrete cytokines (adipokines) that modulate peripheral insulin sensitivity. Tumor necrosis factor- α (TNF- α) is elevated in obese humans and rodents and has been shown to reduce insulin signaling by decreasing insulin receptor and IRS1 tyrosine phosphorylation. Mice harboring deletion of the genes encoding TNF- α or the TNF- α receptor are refractory to insulin resistance associated with diet-induced obesity or when crossed with genetically obese ob/ob mice. Resistin is another adipokine secreted from adipocytes, and the levels of this hormone are increased in obese mice and reduced after administration of the insulin-sensitizing peroxisome proliferator-activated

receptor- γ (PPAR- γ)-activating thiazolidinediones. Resistin also inhibits adipogenesis and, thus, plays a negative feedback role in fat cell formation.

Adipose tissue also secretes leptin, another hormone that positively influences metabolism and energy expenditure, and has profound effects on appetite. Inactivation of leptin production (ob gene in mice) or defects in the leptin receptor (db gene) results in autophagy, obesity, and severe insulin resistance. Similarly, transgenic ablation of white adipose tissue in mice leads to severe insulin resistance, elevated lipid levels, undetectable leptin concentrations, and diabetes, a phenotype reminiscent of generalized lipotrophic diabetes in humans. In these models, restoration of physiological serum leptin levels, either by leptin infusion, by transgenic overexpression, or by surgical implantation of white adipose tissue, reverses the diabetic and insulin-resistant phenotype. These results demonstrate that insulin resistance and diabetes in lipodystrophic mice can be caused by a deficiency of leptin secondary to a failure of adipocyte differentiation.

Adiponectin is also secreted from adipocytes in a regulated fashion. The expression of this adipokine is decreased in obese humans and rodents, and increased expression positively correlates with insulin sensitivity. Acute treatment of obese mice with adiponectin decreases plasma FFA, muscle, and liver triglyceride content and improves insulin resistance. In a knockout model of lipotrophic diabetes, insulin resistance was completely reversed by a combination of leptin and adiponectin infusion but was only partially reversed by either leptin or adiponectin alone.

Skeletal Muscle

Surprisingly, specific deletion of the skeletal muscle insulin receptor (MIRKO) yields mice with normal glucose and insulin levels but with dyslipidemia and increased adiposity. Although MIRKO mice display reduced insulin-stimulated muscle glucose uptake *in vitro* and during a euglycemic hyperinsulinemic clamp, glucose tolerance tests show near-normal glucose uptake. This discrepancy is likely due to increased insulin-independent glucose uptake. In this regard, muscle-specific ablation of the insulin receptor, coupled with a loss of insulin-like growth factor-1 (IGF-1) expression, results in severe insulin resistance in muscle. Interestingly, skeletal muscle insulin-responsive glucose transporter (GLUT4) null mice are also insulin resistant, demonstrating that downstream insulin action and glucose uptake, rather than

proximal insulin receptor signaling per se, is critical for muscle insulin resistance in mice.

Pancreatic Beta Cells

Insulin receptor knockouts in pancreatic beta cells (β -IRKO) display a phenotype similar to that of type 2 diabetes, having a selective loss of glucose-stimulated first-phase insulin secretion and progressive impairment of glucose tolerance. The loss of normal secretory function results from decreased expression of the critical glucose-sensing enzyme glucose kinase. These data directly demonstrate the insulin receptor functions in an autocrine feedback loop necessary for maintaining appropriate beta cell insulin secretion.

Brain

The insulin receptor is widely distributed throughout the central nervous system (CNS), especially in the hypothalamus and pituitary. Mice with CNS-specific disruption of the insulin receptor gene (NIRKO mice) show increased food intake, resulting in diet-induced obesity and insulin resistance. Thus, insulin action in the CNS appears to provide a negative feedback loop for postprandial inhibition of food intake and plays a central role in the regulation of body weight.

SIGNALING DOWNSTREAM OF THE INSULIN RECEPTOR

On activation, the insulin receptor can catalyze the tyrosine phosphorylation of numerous cytoplasmic proteins. The best characterized of these is the insulin receptor substrate family, consisting of four closely related members (IRS1 to -4) and three members of the Grb2-associated-binding proteins (Gab1 to -3). The IRS and Gab proteins appear to provide overlapping functions given that each can participate in the actions of various growth factors, cytokines, and developmental signals. The insulin receptor phosphorylates all four IRS family members on numerous tyrosine residues, in the process generating recognition sites for the interaction of effector proteins containing Src homology (SH2) domains. For example, IRS1 contains 21 putative tyrosine phosphorylation sites, several of which are located in amino acid sequence motifs that bind to SH2 domain proteins, including the p85 regulatory subunit of phosphatidylinositol (PI) 3-kinase, Grb2, Nck, Crk, Fyn, Csk, phospholipase C γ , and SHP2. IRS1 also contains more than 30 potential serine/threonine phosphorylation sites in motif

recognized by various kinases such as casein kinase II, protein kinase C (PKC), protein kinase B/Akt, Jun amino-terminal kinase (JNK), and mitogen-activated protein (MAP) kinase. The crucial role for these substrate proteins has been documented both in tissue culture model systems and by the use of homologous recombination in mice. In particular, disruption of the IRS1 gene results in growth retardation and mild insulin resistance, whereas IRS2 null mice display peripheral insulin resistance, impaired insulin secretion, and diabetes. Interestingly, the IRS1 null mice do not become diabetic due to pancreatic beta cell compensation. However, the IRS2 mice have a marked reduction in beta cell mass due to a marked inhibition of beta cell development. Although mice carrying an ablated IRS3 gene did not display any detectable phenotype, disruption of IRS4 resulted in modest growth retardation and mild insulin resistance.

Both physiological and pathophysiological regulation of IRS protein function occur at multiple levels. Several studies have shown that serine/threonine phosphorylation of IRS proteins can reduce insulin-stimulated tyrosine phosphorylation, demonstrating that serine/threonine phosphorylation functions in a feedback-inhibitory mechanism. In this regard, members of the MAP kinase superfamily are capable of catalyzing serine phosphorylations of the IRS proteins. Studies indicate that the stress-induced serine kinase JNK is one such kinase. JNK is stimulated during acute or chronic inflammation and in response to inflammatory cytokines such as TNF- α . JNK phosphorylates IRS1 and IRS2, Shc, and Gab1, and both IRS1 and IRS2 contain JNK-binding motifs. This motif mediates the specific association of JNK with IRS1, catalyzing the phosphorylation of a serine residue on the COOH-terminal side of the phosphotyrosine-binding (PTB) domain (Ser³⁰⁷ in [murine] IRS1, Ser³¹² in [human] IRS1). Phosphorylation of this residue inhibits the function of the PTB domain, disrupting the association between the insulin receptor and IRS1 and inhibiting tyrosine phosphorylation. This mechanism might explain, at least in part, the insulin resistance that occurs during trauma and obesity.

IRS serine/threonine phosphorylation may occur downstream of other kinases activated by inflammatory signals. High doses of salicylates are shown to reverse hyperglycemia, hyperinsulinemia, and dislipidemia in obese rodents by sensitizing the insulin-signaling pathway, including IRS protein tyrosine phosphorylation. The effect of salicylates is attributed to inhibition of I κ B kinase- β (IKK- β), resulting in decreased IRS serine/threonine phosphorylation. Importantly, heterozygous disruption of IKK- β protects

against the development of insulin resistance during high-fat feeding and in obese, leptin-deficient (*ob/ob*) mice. Although there is no physical interaction between IRS proteins and IKK- β , salicylates increase insulin-stimulated phosphorylation of IRS proteins in the liver, demonstrating that IKK- β inhibits insulin receptor function through the activation of an intermediate kinase(s) or through activation of NF κ B.

Whereas this type of feedback via serine/threonine phosphorylation accounts for relatively short-term desensitization, the IRS proteins also undergo long-term down-regulation. Prolonged insulin stimulation substantially reduces IRS1 and IRS2 protein levels through a 26S proteasome degradative pathway. Furthermore, insulin stimulates the ubiquitination of IRS2, and reduction of IRS2 by ubiquitin/proteasome-mediated proteolysis in mouse embryo fibroblasts lacking IRS1 dramatically inhibits the activation of Akt and ERK1/2 in response to insulin or IGF-1. The activity of the ubiquitin/proteasome system is also elevated in diabetes, promoting the degradation of the IRS proteins and exacerbating insulin resistance.

PHOSPHATIDYLINOSITOL 3-KINASE PATHWAY

Tyrosine phosphorylated IRS proteins engage several effectors that contain SH2 domains. In particular, the SH2 domains of type 1A PI 3-kinase regulatory subunits directly interact with tyrosine phosphorylated IRS proteins, resulting in the targeting and activation of the PI 3-kinase catalytic subunit. Once activated and/or appropriately targeted, this kinase generates PI 3,4,5P₃ in the plasma membrane and perhaps a small amount of PI 3,4,5P₃ in other intracellular membrane compartments. Generation of PI 3,4,5P₃ is essential for insulin-stimulated glucose uptake; glycogen, lipid, and protein synthesis; and changes in gene expression. There are several regulatory (p85 α , p85 β , p55/AS53, p55^{PIK}, and p50) and catalytic (110 α and 110 β) subunits of this lipid kinase. Surprisingly, genetic ablation of the p85 α regulatory subunit results in enhanced insulin sensitivity, probably due to excess levels of the other regulatory subunits compared with the catalytic subunit.

PI 3,4,5P₃ functions as a signaling intermediate that can target and activate the serine/threonine kinase PI-dependent kinase (PDK1). PDK1 contains a pleckstrin homology (PH) domain that has a high affinity and selectivity for PI 3,4,5P₃. PI 3,4,5P₃ also interacts with the PH domain of Akt. Akt is a substrate for PDK1, and phosphorylation on two carboxyl-terminal serine/threonine residues results in the activation of

the Akt kinase. Similarly, PDK1 can also phosphorylate an activating threonine residue in the atypical PKC isoforms, PKC λ and PKC ζ .

The Akt protein kinases exist as three isoforms, all of which are activated by phosphorylation on T³⁰⁸ and S⁴⁷³. On growth factor stimulation, Akt localizes near the plasma membrane, where it becomes phosphorylated on T³⁰⁸ by PDK1. Following phosphorylation and activation, Akt can remain associated with the plasma membrane or intracellular compartments, or it can translocate to the nucleus. Expression of constitutively active Akt stimulates glucose uptake in 3T3-L1 adipocytes, whereas Akt inhibition through the use of dominant negative mutants partially inhibits the insulin-stimulated glucose transport. Although Akt1 knockout mice have no significant alteration in whole body glucose homeostasis, Akt2 gene ablation results in moderate insulin resistance and impaired glucose tolerance. These data demonstrate that Akt2 plays an important role in insulin-regulated glucose metabolism but that Akt1 can partially compensate for the loss of Akt2 function.

PKCs are a large family of serine/threonine kinases that have also been implicated in several actions of insulin. There are three subgroups of PKCs: the classical cPKCs, the novel nPKCs, and the atypical aPKCs. Although these different family members appear to play overlapping but distinct roles, the aPKCs have been implicated in the stimulation of glucose uptake and protein synthesis by insulin in tissue culture model systems. Although the classical PKC α isoform has been ablated in mice and displays enhanced insulin sensitivity, atypical PKC knockout mice are not yet available.

PI 3-KINASE-INDEPENDENT PATHWAY

Although numerous studies have demonstrated that PI 3-kinase activation is necessary, several lines of evidence have suggested that additional signals are required to fully stimulate GLUT4 translocation and glucose uptake. For example, activation of PI 3-kinase by platelet-derived growth factor (PDGF), interleukin-4 (IL-4), or engagement of integrin receptors does not induce GLUT4 translocation in adipocytes despite activation of PI 3-kinase. In addition, two insulin receptor mutants have been identified that are capable of inducing PI 3-kinase activation but not GLUT4 translocation. These data suggest that although the PI 3-kinase pathway is necessary for insulin-stimulated GLUT4 translocation, this pathway is not sufficient and at least one additional signaling pathway is required.

A potential clue toward identifying the PI 3-kinase-independent arm of insulin action emerged from the idea that signal initiation might be segregated into discrete compartments in the plasma membrane. One candidate for such compartments is caveolae, that is, small invaginations of the plasma membrane containing caveolin that are a subset of lipid raft domains. These localized regions are enriched in lipid-modified signaling proteins, glycosylphosphatidylinositol (GPI)-anchored proteins, glycolipids, sphingolipids, and cholesterol. Insulin stimulates the tyrosine phosphorylation of caveolin, the major structural protein in caveolae. Investigation of this pathway reveals the phosphorylation of another insulin receptor substrate, the proto-oncogene c-Cbl. The insulin-stimulated phosphorylation of Cbl occurs only in cell lines that respond to insulin by changes in glucose and lipid metabolism and not in other fibroblast lines, despite the presence of Cbl and an active insulin receptor. The phosphorylation of Cbl requires the presence of the adapter protein APS that recruits Cbl to the insulin receptor. APS is a member of the Ink family of adapter proteins, containing both a PH domain and an SH2 domain. Once phosphorylated, the insulin receptor recruits APS via an interaction between the activation loop of the receptor and the SH2 domain of APS. On binding to the receptor, APS undergoes phosphorylation on a single tyrosine residue. This, in turn, recruits Cbl to the receptor-APS complex via an interaction with the SH2 domain of Cbl and leads to the tyrosine phosphorylation of Cbl on three residues.

The Cbl-associated protein (CAP) is identified in a two-hybrid screen using Cbl as bait and contains three carboxyl-terminal SH3 domains. CAP is expressed predominantly in insulin-sensitive tissues and in differentiated 3T3-L1 adipocytes but not in preadipocytes. Expression of the CAP gene is increased by the insulin-sensitizing thiazolidinedione (TZD) drugs. TZD activation of PPAR- γ directly activates the transcription of CAP through a PPAR- γ response element in the CAP promoter. Moreover, TZD-stimulated increases in CAP expression lead to a more robust phosphorylation of Cbl in response to insulin, establishing a potential primary link between TZD-induced insulin sensitization and insulin signal transduction.

The CAP protein is recruited with Cbl to the insulin receptor due to an interaction of its third carboxyl-terminal SH3 domain with Cbl and another direct interaction with APS through its amino- and carboxyl-terminal SH3 domains. The localization and stabilization of this signaling complex in lipid rafts appear to result from its association with the hydrophobic protein flotillin. This interaction is localized to

amino-terminal sequences of CAP that contain homology to the gut peptide sorbin, that is, the sorbin homology (SoHo) domain. Dominant interfering SH3 deletion mutants of CAP that bind to flotillin but not Cbl, or SoHo deletion mutants that bind to Cbl but not flotillin, interfere with the localization of Cbl to lipid rafts. Moreover, these mutants specifically block insulin-stimulated GLUT4 translocation and glucose uptake.

The SH2 domain of the small adapter protein CrkII also associates with tyrosine-phosphorylated Cbl and thereby becomes recruited to plasma membrane lipid raft subdomains. In addition to its amino-terminal SH2 domain, CrkII contains two tandem SH3 domains, the first of which constitutively interacts with the proline-rich domain of the guanyl nucleotide exchange factor, C3G. Consistent with this mechanism, insulin also recruits C3G to lipid rafts, a process that is blocked by expression of the dominant-interfering CAP mutant lacking the SH3 domains.

C3G can function as a guanine exchange factor (GEF) for several small guanosine triphosphate (GTP)-binding proteins, including Rap1 and R-Ras/TC21. In screens for small GTP-binding proteins that could potentially regulate insulin-stimulated GLUT4 translocation, the Rho family member TC10 has been identified. Overexpression of this protein has profound effects on insulin-stimulated GLUT4 translocation and glucose uptake. Moreover, C3G activates the exchange of GTP for guanosine diphosphate (GDP) on TC10 both *in vitro* and *in vivo*.

Unlike other members of the Rho family that undergo geranylgeranylation and interact with guanyl nucleotide dissociation inhibitors, TC10 is subjected to both farnesylation and palmitoylation in a manner analogous to that of H-Ras. These posttranslational modifications are responsible for the targeting of TC10 to lipid raft domains. Moreover, mistargeting of TC10 into non-lipid raft regions of the plasma membrane prevents its activation by insulin and alters the ability of TC10 to modulate insulin-stimulated GLUT4 translocation. In addition, disruption of the lipid raft with cholesterol-extracting drugs or by overexpression of inhibitory forms of caveolin completely blocks TC10 activation as well as the stimulation of glucose transport by insulin. Moreover, treatment of cells with the cholesterol-extracting drug β -cyclodextrin also blocks the stimulation of glucose transport.

TC10 also interacts with one of the components of the exocyst complex, Exo70, in a GTP-dependent fashion. Exo70 translocates to the plasma membrane in response to insulin via the activation of TC10,

where it assembles a multiprotein complex that includes Sec6 and Sec8 as well as other proteins that have not yet been identified. Overexpression of an Exo70 mutant blocks insulin-stimulated glucose uptake but not the trafficking of GLUT4 to the plasma membrane. However, this mutant does block the extracellular exposure of the GLUT4 protein. These data demonstrate that the exocyst may play a critical role in the targeting of the GLUT4 vesicle to the plasma membrane, perhaps directing the vesicle to the precise site of fusion.

CYTOSKELETON AND GLUCOSE TRANSPORT

It is well established that the cytoskeleton plays an important role in the stimulation of glucose uptake by insulin. Although the PI 3-kinase pathway can influence actin polymerization, changes occur in actin function that are PI 3-kinase independent. For example, insulin was reported to enhance the localization of the unconventional myosin (Myo1c) to GLUT4 compartments that are associated with actin filaments independent of PI 3-kinase activity. Overexpression of wild-type Myo1c enhances insulin-stimulated GLUT4 translocation, whereas expression of a dominant negative Myo1c mutant inhibits this action. Thus, Myo1c may function in a PI 3-kinase-independent insulin-signaling pathway controlling GLUT4 trafficking.

Microtubules have also been implicated in the regulation of GLUT4 translocation. Kinesin KIF5B is partially colocalized with perinuclear GLUT4, and expression of dominant negative kinesin mutants blocks outward GLUT4 vesicle movements. These events are not affected by specific inhibition of PI 3-kinase activity. Thus, insulin signaling appears to target and/or initiate the movement of GLUT4-containing membranes on microtubules via conventional kinesin (KIF5B) and subsequently actin through PI 3-kinase-independent mechanisms.

SNARE-MEDIATED GLUT4 VESICLE DOCKING/FUSION AND TRANSPORT ACTIVATION

It is well established that vesicle-mediated fusion with target membranes requires a high-affinity interaction between specific pairs of target membrane SNAP receptors (t-SNAREs) and those of vesicle membrane SNAP receptors (v-SNAREs). Considerable progress has been made in identifying the v-SNAREs and

t-SNAREs that facilitate GLUT4 vesicle translocation. VAMP2 or syntaptobrevin 2 is the predominant v-SNARE found in GLUT4 vesicles, whereas syntaxin 4 and SNAP23 function as the major t-SNAREs. Many of the accessory components of GLUT4 vesicles have been identified, and intensive efforts are under way to isolate the component of the various subcellular GLUT4 compartments. Adapter molecules that regulate the interaction between VAMP2 and syntaxin 4 have been identified and include Munc18c, Synip, and tomosyn.

As described previously, it is well established that insulin induces a redistribution of the GLUT4 protein from intracellular storage compartments to the plasma membrane. Although it was generally accepted that this was sufficient to account for the increase in glucose uptake, more recent studies have suggested that a second event is required for the acquisition of glucose transport activity, perhaps one dependent on the activation of the p38 MAP kinase.

INSULIN REGULATES GLUCOSE USE AND STORAGE

In addition to stimulating uptake, insulin directly regulates the use and storage of glucose. Following its transport into the cell, insulin can activate enzymes responsible for the oxidation of glucose and its storage as glycogen or lipid. The hormone also can inhibit enzymes that promote the breakdown of lipid or glycogen. Intracellular glucose undergoes a regulated phosphorylation step and is directed to a storage pathway involving glycogen synthesis or an oxidative pathway culminating in the rate-limiting enzyme pyruvate dehydrogenase in the mitochondrion. The resulting two carbon intermediates serve as substrates for *de novo* FFA synthesis and subsequent esterification with glycerol to form triglyceride. Numerous enzymes that control these pathways are regulated by insulin through processes that involve covalent modifications such as phosphorylation, allosteric regulation, or changes in gene expression.

The storage of glucose as glycogen allows for its rapid mobilization as a metabolic fuel. Glycogen can be metabolized to produce adenosine triphosphate (ATP) in the absence of oxygen and can produce more ATP per oxygen molecule used than does lipid when used under aerobic conditions. Thus, most tissues rely on glucose as their primary energy source under postprandial conditions and during times of stress or the initial stages of starvation. Insulin regulates glycogen metabolism primarily via the phosphorylation states

and activities of the enzymes that catalyze glycogen synthesis or breakdown. Glycogen synthase is inactivated by its phosphorylation at multiple residues. Phosphorylation of glycogen synthase occurs at nine different sites in a hierarchical fashion. These phosphorylations are catalyzed by a number of different kinases, including calmodulin-dependent kinases, casein kinase, cyclic adenosine monophosphate (cAMP)-dependent protein kinase (PKA), AMP-activated kinase, and glycogen synthase kinase.

Glycogen synthase kinase-3 (GSK3) plays a major role in the phosphorylation and inactivation of glycogen synthase. GSK3 is phosphorylated on Ser⁹ by the Akt protein kinase, which is activated by insulin via PDK1 as described previously. Phosphorylation at this site reduces the catalytic activity of the kinase. Thus, one mechanism by which insulin can increase the overall activity of glycogen synthase is through the inactivation of GSK3. Phosphorylation of glycogen synthase by GSK3 occurs in a sequential manner, beginning at Ser⁶⁵² (site 4), followed by Ser⁶⁴⁸ (site 3c), Ser⁶⁴⁴ (site 3b), and Ser⁶⁴⁰ (site 3a). The phosphorylation of glycogen synthase by GSK3 can occur only after the initial phosphorylation of site 5 (Ser⁶⁵⁶) that is catalyzed by casein kinase II.

Glycogen synthase can also be activated via direct dephosphorylation mediated by protein phosphatase 1 (PP1), the major phosphatase thought to stimulate glycogen synthase activation by insulin. PP1 can also dephosphorylate and inactivate glycogen phosphorylase and phosphorylase kinase. Because PP1 has relatively broad substrate specificity *in vitro*, a number of targeting subunits have been identified that facilitate the recruitment of the phosphatase to specific subcellular locales, including myofibrils, neuronal dendrites, nucleus, and glycogen particles. Four glycogen-targeting subunits of PP1 have been described. Although these share certain conserved structural domains for the binding of PP1, glycogen, and PP1 substrates, they vary in their interactions with the enzymatic machinery of glycogen metabolism, tissue distribution, and roles in glycogen metabolism.

G_M-Muscle Glycogen Targeting Subunit

The expression of PPP1R3a (G_M, R_{GL}) is restricted to striated muscle fibers and cardiac muscle. G_M is unique in that it possesses phosphorylation sites that have been implicated in the regulation of muscle glycogen synthesis by β -adrenergic stimuli and a large C-terminal region that is required for association with the sarcoplasmic reticulum. Phosphorylation of Ser⁶⁷, which lies within the PP1-binding

region, results in the dissociation of G_M from PP1, and this may contribute to decreases in glycogen synthesis due to increased intramyocellular cAMP. Two mouse models of targeted disruption of the PPP1R3a gene have been reported, and both animal models exhibit greater than 80% decreases in the levels of steady-state muscle glycogen, paralleled by decreased activity of glycogen synthase and increased glycogen phosphorylase. These data demonstrate that G_M plays a vital role in the regulation of glycogen metabolism in muscle. Paradoxically, one of the reported G_M knockout models develops severe glucose intolerance and insulin resistance and becomes obese with aging, whereas the other does not. This discrepancy may be due to differences in genetic background, suggesting that dramatic decreases in muscle glycogen alone are not sufficient to produce insulin resistance without the contribution of other genetic or environmental factors.

G_L

PPP1R4 (G_L) is a liver-specific glycogen-targeting subunit. This subunit is unique in that it does not bind glycogen synthase yet still appears to play a role in the regulation of hepatic glycogen synthase phosphatase activity. However, G_L possesses a unique high-affinity glycogen phosphorylase *a* binding region at its C terminus. The binding of active phosphorylase by G_L is thought to permit the allosteric inhibition of liver glycogen synthase phosphatase by phosphorylase *a* during periods of net glycogenolysis. Overexpression of G_L in primary hepatocytes leads to significant increases in steady-state glycogen. The expression of G_L is down-regulated during prolonged fasting and in streptozotocin diabetes and can be restored by refeeding or insulin treatment.

PTG

Protein targeting to glycogen (PTG, PPP1R5) is expressed in a variety of tissues that store glycogen. PTG is expressed most highly in adipose, liver, heart, striated muscle, brain, and kidney. PTG is known to bind glycogen synthase, glycogen phosphorylase, and phosphorylase kinase in addition to PP1 and glycogen. The binding of enzymatic substrates to PTG can occur in the absence of glycogen *in vitro* and is mediated by a single binding region in the molecule. Overexpression of PTG in Chinese hamster ovary cells stably expressing the insulin receptor, primary hepatocytes, 3T3-L1 adipocytes, cultured human muscle cells, or intact rat liver results in dramatic

increases in steady-state glycogen levels. However, unlike the other targeting subunits, overexpression of PTG seems to lock cells in a glycogenic mode, where they become resistant to the effects of glycogenolytic stimuli and glycogen feedback inhibition. Appropriate regulation of PTG expression is required to maintain the appropriate balance between glycogen synthesis and glycogenolysis. Targeted disruption of one allele of the gene for PTG results in moderate decreases in steady-state glycogen in adipose, heart, and liver, with some minor effects in white fiber striated muscle. Homozygous deletion of PTG results in embryonic lethality. PTG heterozygous mice develop glucose intolerance and mild insulin resistance, hyperinsulinemia, and hyperleptinemia with aging. This phenotype appears to arise from a repartitioning of fuel stores into lipid due to the decreases in whole body glycogen stores, thereby resulting in the accumulation of triglyceride in muscle and an attenuation of insulin signaling. The expression of PTG is down-regulated in rat liver due to fasting or streptozotocin diabetes and can recover on refeeding or insulin treatment, much like G_L . However, the changes in PTG expression occur much sooner on the commencement of fasting than do the changes in G_L expression.

REGULATION OF LIPID METABOLISM

The biosynthesis and breakdown of lipids are tightly regulated by insulin by modulating the activity of enzymes that catalyze the rate-limiting reactions of these pathways and by controlling expression of the genes encoding these enzymes. The hormone also stimulates the recruitment of fatty acids into tissues by hydrolysis of triacylglycerol derived from circulating very low-density lipoproteins and intestinal chylomicrons, which are by-products of hepatic lipid synthesis or dietary influx.

Under normal conditions, lipogenesis occurs predominantly in adipose depots and in the liver. Two coupled processes are involved: *de novo* fatty acid synthesis from two carbon intermediates and the subsequent esterification of activated fatty acids to glycerol to form triglyceride (the final lipid storage form). The rate-limiting step of lipogenesis is the carboxylation of acetyl-CoA to form malonyl-CoA, catalyzed by the enzyme acetyl-CoA carboxylase (ACC). The activity of this enzyme depends on its state of polymerization, which is favored by binding of the allosteric activator citrate. Aggregation of the monomer into the active polymeric form is also stimulated by the phosphorylation at a specific site in response to

insulin. Conversely, phosphorylation at alternate sites by cAMP-dependent PKA or by the AMP-activated protein kinase results in the depolymerization and deactivation of ACC. Insulin also promotes the dephosphorylation of these sites.

Oxidation of fatty acids occurs primarily in liver, as well as in cardiac and striated muscle, which uses fatty acids as a main fuel in the resting state. Insulin indirectly inhibits fatty acid β -oxidation by increasing malonyl-CoA production (via ACC activation). Malonyl-CoA allosterically inhibits the activity of carnitine palmitoyl transferase I, and this catalyzes the rate-limiting transport of activated fatty acids into the mitochondrion where oxidation takes place. In a similar fashion, feedback inhibition by malonyl-CoA and long-chain fatty acyl CoA esters also affects ACC activity by triggering depolymerization of the active polymer.

The integrated coordination of lipogenesis and β -oxidation by insulin also occurs at the level of gene expression, mediated by two main transcription factors. These *trans*-acting factors include isoforms of the sterol receptor enhancer-binding proteins (SREBPs) and PPAR- γ . SREBPs participate with other *trans*-acting factors, such as the upstream stimulatory factors, to mediate the effects of insulin on the expression of various genes involved in hepatic lipid metabolism, such as that encoding fatty acid synthetase. SREBP2 appears to be involved in hepatic cholesterol metabolism because its overexpression results in increased synthesis of hydroxymethylglutaryl (HMG)-CoA reductase and farnesyl pyrophosphate synthase. The role of SREBP1 in fatty acid/triglyceride metabolism seems to be restricted mainly to the liver, although it likely plays an important role in adipocyte cholesterol metabolism. SREBP null mice show no changes in adipose mass, or in the expression of acetyl-CoA carboxylase or fatty acid synthetase, although the up-regulation of hepatic lipogenic genes during fasting/refeeding is prevented.

PPAR- γ is a nuclear hormone receptor present mainly in adipose tissue, but it is also expressed at low levels in liver. PPAR ligands include prostaglandins, fatty acids, and the synthetically derived thiazolidinediones. PPAR- γ expression is induced by insulin, and its promoter is itself *trans*-activated by SREBP1. PPAR- γ expression is critical for adipocyte differentiation and is required for the *trans*-activation of adipocyte gene products involved in lipid metabolism, including acetyl-CoA synthetase, adipocyte fatty acid-binding protein, fatty acid transport protein, the glycerolneogenic enzyme phosphoenolpyruvate carboxykinase (PEPCK), and lipoprotein lipase (LPL).

This nuclear receptor also increases insulin sensitivity in cells and *in vivo*, explaining the antidiabetic effects of the PPAR- γ -activating drugs.

The circulating levels of insulin required to inhibit lipolysis are far below those required to stimulate glucose uptake into muscle. This physiological property results in an initial inhibition of fatty acid release into the circulation from adipose depots, and increased uptake of dietary-derived lipids by the peripheral tissues occurs following ingestion of a meal. Lipolysis in the fat cells is catalyzed by the enzyme hormone-sensitive lipase (HSL) in a mechanism that requires the translocation of the enzyme from the cytoplasm to the periphery of the lipid droplet. Upon phosphorylation by PKA, the enzyme undergoes catalytic activation and is translocated to the lipid droplet by a mechanism involving the PKA substrate perilipin. The phosphorylation of perilipin results in a dispersion of the normal perilipin "coat" around the lipid droplet, thereby potentially increasing the accessible surface area of the droplet to HSL activity. Insulin prevents the phosphorylation of HSL primarily by attenuating cAMP signaling via activation of cyclic nucleotide phosphodiesterase 3B, which catalyzes the conversion of cAMP to 5'-AMP. Insulin also increases the dephosphorylation of HSL and inhibits the phosphorylation of perilipin. Regulation of HSL localization also involves the docking protein lipotransin, and HSL is capable of interacting with lipotransin after phosphorylation by PKA, thereby allowing for its docking at the outer surface of the lipid droplet. Lipotransin possesses an intrinsic ATPase activity that allows for a dissociation of the complex after docking, permitting HSL to proceed with the catalysis. Insulin may freeze the HSL-lipotransin complex at the docking site, thereby preventing the dissociation step that is required for HSL to catalyze triglyceride hydrolysis.

The release of dietary- or hepatic-derived fatty acids from circulating lipoprotein complexes is catalyzed

by LPL, which catalyzes the rate-limiting step in the hydrolysis of lipoprotein-associated triglycerides to yield FFAs and 2-monoacylglycerol. Insulin appears to increase the expression and release of LPL from fat cells. Insulin stimulation of LPL activity occurs by both wortmannin-sensitive PI 3-kinase and rapamycin-sensitive p70 S6-kinase-signaling pathways.

with its receptor, whereas the IGFs act via complex interactions involving the IGF-binding proteins (IGFBPs). These transport the IGFs with high specificity and affinity in serum and extracellular fluid toward their target cells and do not bind insulin. Less than 1% of serum IGF-I is present in unbound form. The IGFBPs show pronounced changes in their expression patterns, from embryonic through fetal, postnatal, and adult life. In mammals, six structurally related binding proteins (IGFBP-1 to IGFBP-6) have been characterized, and recently several groups of proteins with structural and functional similarities to the IGFBPs, designated IGFBP-related proteins, were discovered. IGFBP-1, -3, and -4 bind IGF-I and IGF-II with comparable affinity, whereas IGFBP-2, -5, and -6 have lower affinity for IGF-I than for IGF-II. In addition to their role in transporting, storing, and modulating the bioactivity of the IGFs, the IGFBPs likely also act as modulators of some physiological actions of the IGFs. Several cell types secrete specific proteases that cleave particular IGFBPs, resulting in reduced IGF binding and an increase in IGF availability to the receptor.

Three distinct receptors mediate the actions of insulin and the IGFs at the target cells. The insulin receptor is a tyrosine kinase that specifically binds insulin and shows a considerably low affinity for the IGFs. For the IGFs, two different receptors have been characterized: the so-called type 1 and type 2 IGF receptors. Like the insulin receptor, the type 1 IGF receptor (IGF-1R) is a heterotetrameric glycoprotein with two α -subunits and two β -subunits. The IGF-1R shows 57% amino acid sequence identity to the insulin receptor. The extracellular α -subunits have cysteine-rich domains that confer IGF-binding properties. The β -subunits contain a short extracellular domain, a transmembranal domain, and an intracellular tyrosine kinase domain. The IGF-1R has a high affinity for IGF-I, binds IGF-II with about three times lower affinity, and has an affinity for insulin that is 100 times lower. The type 2 IGF receptor is also the cation-independent mannose-6-phosphate receptor (M6P-R), which in mammals exhibits an additional IGF-II binding site. Therefore, it is also called the IGF-2R/M6P-R and is structurally different from the type 1 IGF and the insulin receptor. The IGF-2R/M6P-R shows a high affinity for IGF-II, a minute affinity for IGF-I, and no affinity for insulin. The receptor certainly serves to internalize and degrade IGF-II. Because neither genetic nor biochemical evidence supports a signaling function for the IGF-2R/M6P-R for certain, it is well accepted that its physiological role is primarily to remove IGF-II

from the circulation. Thus, most if not all effects of IGF-II are mediated via the IGF-1R.

In summary, the IGF system, in contrast to that of insulin, shows an extraordinarily high degree of complexity. It consists of the hormones IGF-I and IGF-II (and some variants), at least six different binding proteins, specific IGFBP proteases, and the type 1 and type 2 IGF receptors.

EVOLUTION OF INSULIN AND THE IGFs

Insulin

In mammals, the only production sites of insulin are the beta cells in the pancreatic islets that secrete insulin into the systemic circulation. The main stimulus for insulin secretion is meal ingestion. After binding to the insulin receptor, insulin acts as a metabolic hormone and exerts acute anabolic effects. In liver, insulin promotes synthesis and storage of glycogen and inhibits glycogenolysis, gluconeogenesis, and ketogenesis. It further enhances protein and triglyceride synthesis. In addition, insulin promotes protein and glycogen synthesis in muscle and lipid storage in adipose tissue. The most important net result of these anabolic effects is that insulin maintains a normal blood glucose concentration.

Insulin and its receptor occur in representatives of all vertebrate classes. As in mammals, insulin is produced in a subpopulation of the pancreatic islet cells, and many groups have elaborated that the most powerful stimulus for its secretion is food intake. In all vertebrates that exhibit an exocrine pancreas surrounding the islets (e.g., mammals, birds, reptiles, amphibians, osteichthyes, chondrichthyes), the islets contain insulin, glucagon, somatostatin, and PP cells. However, the islets of cyclostomes, which lack an exocrine pancreas, consist only of numerous insulin and infrequent somatostatin cells. At the evolutionary level of protochordates such as *Branchiostoma lanceolatum*, where no endocrine islets have yet evolved, insulin is present in the endocrine cells of the intestinal mucosa.

The tertiary structure of the insulin molecule (A chain, B chain, and cysteine bridges) is fully conserved in vertebrates, but the primary amino acid sequences may differ among the vertebrate classes. Still, the insulin sequences of human and hagfish, a cyclostome, share 61% amino acid identity. Throughout the vertebrates, the essential amino acid residues in the putative receptor-binding region are quite well conserved. The role of insulin in nonmammals is less well defined

than in mammals, but there is increasing evidence that it also acts mainly as a metabolic hormone. This is indicated, for instance, by studies in bony fish that have shown that islectomy results in severe hyperglycemia. However, the blood glucose level-stabilizing effects of insulin develop more slowly in ectotherms than in mammals.

The conservative evolution of the hormone insulin, its receptor, its functional mode, and its presence in all vertebrates and protochordates emphasize the major impact of the chief action of insulin—maintenance of the blood glucose level.

Insulin-like Growth Factors

The IGFs show pronounced differences in their distribution patterns and physiological roles when compared with insulin. In contrast to insulin, IGF-I and IGF-II are expressed in several organs, do not circulate in free form but rather attached to the binding proteins, and stimulate normal growth and development by selectively promoting mitogenesis and differentiation and by inhibiting apoptosis via the IGF-1R. However, insulin and the IGFs share about 50% amino acid sequence homology, and proinsulin and the IGFs exhibit similar tertiary structures. Furthermore, insulin and IGF-I cross-react with each other's receptor, although with lower potencies. Thus, questions arise as to how and why such a complex hormonal system (hormones, receptors, and binding proteins) like that of the IGFs arose during chordate evolution, whether insulin and the IGFs show specializations in different vertebrate classes, and whether insulin and the IGFs stem from a common evolutionary precursor.

Insulin-like Growth Factor I

According to the "classical" somatomedin hypothesis already raised in 1972 by Daughaday and others, growth hormone (GH) stimulates skeletal growth via IGF-I produced in the liver under the influence of GH and secreted into the circulation. From there, IGF-I reaches its target tissues or cells, where it interacts with the IGF-1R. Thus, the physiological role of IGF-I is defined as endocrine. However, soon after its discovery, it was demonstrated that IGF-I, in contrast to insulin, is expressed ubiquitously. In most if not all of these tissues, GH also induced IGF-I production. Recently, it was shown that complete and selective inactivation of the IGF-I gene in the livers of mice by using the Cre/loxP recombination system led to reduction of serum IGF-I by 75%. Surprisingly, this pronounced decrease in serum IGF-I did not

significantly affect postnatal body growth. Important conclusions can be drawn from these experiments. First, the results confirm that liver is the principal source of circulating IGF-I, but a significant amount is probably derived from extrahepatic sites. Second, the level of endocrine IGF-I seems to be not essential for postnatal growth and development. Third, autocrine/paracrine effects of local organ-specific IGF-I probably are more important than is generally assumed.

In birds, reptiles, amphibians, and bony fish as well, liver is the major source of endocrine IGF-I but extrahepatic sites also express IGF-I. These have been analyzed comprehensively by our group in the bony fish tilapia, where we identified parenchymal cells, such as islet D cells, gastro-entero-endocrine cells, renal tubular cells, interrenal cells, chondrocytes, gill chloride cells, granulosa cells in the ovary, Sertoli cells in the testis, and brain neurons, as production sites. When combining and comparing the results from studies on the distribution of IGF-I throughout the vertebrate line of evolution, this list seems to be valid for mammals, birds, reptiles, amphibians, bony fish, and cyclostomes as well. Thus, the production of the hormone IGF-I in numerous organs likely is the rule throughout the vertebrate lineage of evolution. Although our knowledge of the distribution of the IGF-1R is more limited because studies on this topic have been performed only in birds, amphibians, and bony fish, evidence is increasing that the receptor may as well show an ubiquitous occurrence. The probable coexpression of the IGF-1R and its ligand may suggest that autocrine/paracrine actions of IGF-I also play a role in nonmammals. This notion is supported by studies in birds that show interactions between LH and intraovarian IGF-I in follicle development. Similarly, in the bony fish ovary, the local production sites of IGF-I depend on the stage of follicle development and the IGF-I binding is seasonally dependent. However, at present, we cannot judge whether paracrine effects of IGF-I in nonmammals are of similar importance as they are in mammals.

As in mammals, GH and the nutritional status regulate the hepatic production of IGF-I in birds, reptiles, amphibians, and bony fish. Limited evidence indicates that the synthesis of IGF-I in extrahepatic sites of nonmammalian vertebrates may also be GH dependent. An increase in IGF-I mRNA after GH application has been reported for cartilage in amphibians and bony fish and for testes and gills in bony fish. As in mammals, target-specific hormones, such as gonadal steroids and glucocorticoids, might

also regulate IGF-I in organ-specific cells of non-mammalians, as has been demonstrated in birds and bony fish.

The growth-promoting action of IGF-I and its related role during development seem to be the most prominent functions of IGF-I in nonmammalian vertebrates, as they are in mammals. However, further effects of IGF-I comparable to those in mammals have been established, including the significant role of IGF-I in male and female reproductive processes that has been recognized in birds and bony fish. The IGF-I system also shows specializations in certain vertebrates that are most pronounced in bony fish. Here, IGF-I plays an important role in osmoregulation as well as during parr-smolt transformation of salmonids, that is, the process whereby the metabolism is changed in preparation for the movement from fresh water to sea water. However, our current stage of information is too limited to allow any conclusion on further analogies or potential differences to the situation in mammals or to point to the evolutionary level of appearance of particular types of regulation.

Insulin-like Growth Factor II

For a long time, it has been thought that in adult humans (and other mammals), the IGF-II gene is expressed solely in liver and choroid plexus, but recent studies indicate further sites of IGF-II production such as ovary, chondrocytes, and endocrine pancreas.

The presence of IGF-II in extrahepatic sites, especially in ovary and endocrine pancreas, has also been demonstrated in birds, reptiles, and amphibians. Most information on IGF-II in nonmammalian vertebrates is available for bony fish. CDNA sequences encoding IGF-II (prepro-)hormones have been characterized from numerous species. Some peculiarities exist regarding IGF-II in osteichthyes. First, the IGF-II prepro-hormones exhibit between 85 and 92% amino acid sequence homology to each other. Thus, among bony fish, the homologies of the IGF-II prohormones are higher than those of the IGF-I prohormones. Second, in osteichthyes, our group has shown that all organs that express IGF-I mRNA also express IGF-II mRNA, which contrasts the situation in mammals. Third, in this context, the findings of the Gutierrez group in Barcelona, Spain, who recently reported specific IGF-II binding to purified receptor preparations from trout embryos, may be of special interest. Whether or not these results in fact indicate a particular physiological impact of IGF-II in bony fish remains to be clarified.

IGF-II appears at the evolutionary level of chondrichthyes (Fig. 1). In 1994, our group identified IGF-II-like peptides by their immunoabsorption properties that were different from mammalian and nonmammalian insulin in a ray, *Raja clavata*, and the Steiner group in Chicago cloned cDNA sequences encoding distinct IGF-I and IGF-II prepro-hormones

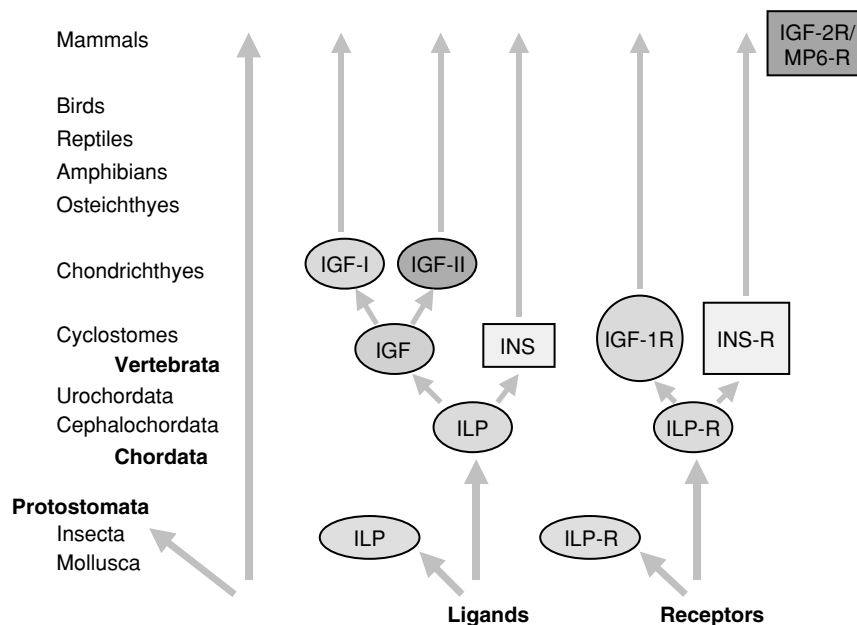

Figure 1 Model of the evolution of the insulin and the IGF system. Adapted from Reinecke, M., and Collet, C. (1998). The phylogeny of the insulin-like growth factors. *Int. Rev. Cytol.* **183**, 70.

from a shark (*Squalus acanthias*). Thus, both IGFs are present in elasmobranchians, and the duplication of the proto-IGF gene probably occurred prior to the divergence of the chondrichthyes (Fig. 1).

The IGF-2R/M6P-R seems to have a unique evolution. Regarding the nonmammalian vertebrates, several studies have identified the cation-independent M6P-R in birds and amphibians, but mammalian or avian IGF-II failed to bind to the receptor. Thus, no binding site for IGF-II seems to reside on the M6P-R at the phylogenetic level of birds and amphibians. Based on these results, Reinecke and Collet proposed that the acquisition of a high-affinity binding site for IGF-II on the M6P-R is a “recent” evolutionary event and appeared with the origin of mammals (Fig. 1). In line with this notion, our group could identify no type 2 IGF receptor, but only the type 1 IGF receptor, in bony fish. In sharp contrast to the other studies is the specific IGF-II binding to purified receptor preparations from trout embryos that was recently described because this would suggest the presence of an IGF type 2 receptor at the evolutionary level of osteichthyes. Whether this result implies that specific and functionally significant IGF-II receptors exist in bony fish must be the topic of further research that also needs to consider adults.

Since its detection, thousands of studies have dealt with the potential physiological role of IGF-II. However, we are far from understanding more than basal parameters. In contrast to IGF-I, the expression of IGF-II in mammals is species dependent. In rodents, the amount of IGF-II mRNA in tissue and the level of serum IGF-II are higher during fetal life than during postnatal life. In agreement, even high serum levels of IGF-II in postnatal rodents exert minimal effects. In contrast, human serum levels of IGF-II are low during ontogeny but increase after birth. Little is also known about the regulation of IGF-II in serum or tissue because GH, in contrast to IGF-I, is a negligible regulator of IGF-II in mammals and studies in nonmammalians are virtually nonexistent. Only in bony fish has some limited evidence been presented that GH may regulate the expression of IGF-II, a possibility that would contrast the situation in mammals. Although after GH treatment the levels of IGF-II mRNA in liver and in several extrahepatic sites of seabream remained unchanged, in rainbow trout liver the amount of IGF-II mRNA was significantly elevated after GH treatment *in vivo* and *in vitro*. Because methodological differences may account for this discrepancy, there is no reason to exclude a possible role for GH in the regulation of IGF-II in bony fish to date.

In general, IGF-II mimics the effects of IGF-I on various target cells. Humbel, whose group was the first to identify the amino acid sequences of both IGFs, wrote in 1990, “Nature is a sphinx presenting us with IGF-II as a riddle.” Later, Gluckman and Ambler stated, “The failure to demonstrate clear roles for IGF-II remains a major dilemma in growth physiology.” Even more recent reviews did not dare to define any physiological role for IGF-II in mammals or to claim laconically, as Le Roith did in 1997, that “the physiological role of IGF-II is unknown.” Nevertheless, when considering the potential physiological role of IGF-II, several ideas come to mind.

1. One might regard IGF-II as a functionless evolutionary relic. In favor of this hypothesis is the fact that throughout the vertebrate line of evolution, both IGF-I and IGF-II bind to the type 1 IGF receptor. After binding, IGF-II exerts the same effects as does IGF-I, although with marked lower potency.

2. We witness the evolution of the peptide hormone IGF-II. Although over some million years, the evolution of the IGF receptors had stagnated, an IGF-II-binding domain appeared on the M6P-R with the origin of mammals (Fig. 1), and we cannot know whether specific physiological functions of IGF-II will evolve during the next million years of evolution.

3. IGF-II at first evolved as a quite meaningless hormone. In other words, it appeared but did not impair any physiological process. However, the differences between the regulation of IGF-II in mammals and that in nonmammalian vertebrates are not trivial. The additional regulation of IGF-II bioavailability by the IGF-2R/M6P-R in mammals may well have its significance. Thus, Reinecke and Collet proposed that “particular aspects about mammalian physiology allow or even demand additional methods of tightly controlling IGF-II levels.” For instance, the IGF-II-binding domain on the M6P-R may have evolved to protect mammals against otherwise harmful effects of IGF-II. This hypothesis is supported by the involvement of IGF-II in tumor genesis and the recent suggestion to consider the IGF-2R/M6P-R as a promising candidate tumor suppressor gene.

Evolutionary Appearance of (proto-)IGF, Type I Receptor, and IGF-Binding Proteins

The Steiner group has presented strong evidence that all components of the IGF system (ligand, receptor,

and IGF-BPs) appeared concurrently at the evolutionary level of cyclostomes. Several studies of other groups support these findings.

1. Both an insulin gene and an IGF gene have been identified in the Atlantic hagfish *Myxine glutinosa*. Like the mammalian prepro-IGFs, the hagfish prepro-IGF contains a signal peptide; B, C, A, D, and E domains; and all residues necessary to maintain the typical tertiary structure. In its A and B domains, hagfish IGF shows equal (70%) homologies to those of (h)IGF-I or IGF-II and so is considered as proto-IGF. Therefore, the gene duplication that gave rise to the proto-IGF gene from insulin probably occurred subsequently to the divergence of the cephalochordates from the main lineage leading to the vertebrates but prior to the origin of the agnatha some 550 million years ago (Fig. 1).

2. cDNA cloning indicates that two distinct receptor sequences exist in hagfish. One cDNA sequence appears to encode the insulin receptor, and the other appears to encode an IGF type 1 receptor. Thus, the IGF-1R likely also has its origin around the time of the insulin/IGF duplication (Fig. 1). Above the phylogenetic level of cyclostomes, consistently separate insulin receptors and IGF-1R that show a high degree of overlap in the signaling pathways are present.

3. The Australian group of Upton has detected three IGF-BPs in a lamprey, suggesting that the IGF-BPs may have arisen in evolution simultaneously with or soon after the divergence of IGF from insulin.

Thus, two hormones of quite different functions have evolved in the lowest vertebrate class. One is involved in carbohydrate metabolism, and the other is essential for growth, differentiation, and development. The appearance of these separate hormone systems was probably driven by the need to uncouple the short-term regulation of nutrition from the long-term regulation of growth and development.

Furthermore, the concomitant appearance of proto-IGF and the binding proteins suggests that the first IGF-BPs may have fulfilled instant functional roles. Their capability to block the potential of the proto-IGF to bind to the insulin receptor, and so to exert insulin-like activities, certainly is the most fundamental one. However, their potency to provide particular tissue and/or developmental specificities for the newly evolved IGF may have also been of immediate importance.

Evolutionary Divergence of Insulin, IGF-I, and IGF-II

Two separate duplication events gave rise to insulin and the IGFs as they are present in bony fish, amphibians, reptiles, birds, and mammals. The divergence of IGF-I and IGF-II apparently is the by-product of a large partial chromosomal duplication involving chromosome 11 and its translocation to chromosome 12. As outlined previously, distinct IGF-I and IGF-II genes first appear in chondrichthyes, whereas a single proto-IGF gene with equal sequence identity to and characteristics of mammalian IGF-I and IGF-II has been identified in the agnathan *M. glutinosa*. Thus, the duplication of the proto-IGF gene likely occurred between the radiation of the lineages leading to the extant cyclostomes and cartilaginous fish.

The current idea of the origin of the proto-IGF gene (Fig. 1) is based on studies in protochordates. From the cephalochordate *Branchiostoma californiense*, the amphioxus, the Steiner group has cloned an insulin-like peptide (ILP) cDNA and shown that it is a single-copy gene. The deduced pro-ILP contained B, C, and A domains as expected for insulin and a C-terminal extension similar to the D and E domains in pro-IGFs. ILP was equally (48%) related to human insulin and IGFs. Amphioxus is estimated as an extant relative of the invertebrate progenitors from which the vertebrates have developed. Thus, it is generally assumed that the ILP gene is ancestral to both vertebrate insulin and IGFs and that the insulin/IGF duplication occurred after the radiation of the cephalochordates but prior to the emergence of the agnatha. The biological role of ILP is indicated by the cDNA cloning of the associated receptor from the amphioxus. The ILP receptor is a membrane-bound receptor kinase, and its amino acid sequence is about 49% and 47% identical to that of the human insulin receptor and IGF-1R, respectively. The ILP receptor contains the structural components necessary for binding and activation by mammalian insulin and IGF-I. Consequently, the Steiner group hypothesized that, in analogy to the ILP gene, the ILP receptor gene is an extant representative of an ancestral receptor gene that had duplicated and diverged into the vertebrate insulin and IGF-1R genes during the transition from protochordates to vertebrates.

The previously described prevailing model of insulin and IGF evolution (Fig. 1) that suggests an origin for the IGFs postdating the cephalochordates appears to be sound. However, in 1997, McRory and

Sherwood reported the characterization of distinct prepro-insulin and a prepro-IGF cDNAs cloned from the urochordate *Chelyosoma productum*. The deduced peptides show characteristics of vertebrate insulin and IGF. However, the pronounced amino acid sequence identity of the urochordate insulin and proto-IGF is higher than that with insulin or IGF sequences in other species. In particular, the sequence identity between insulin and proto-IGF in the evolutionary highly variable C domain is very high. As was first argued by Chan and Steiner in 2000, these results somewhat contradict the assumption that the urochordate genes are true orthologues of the vertebrate insulin and IGF genes. Therefore, further studies in various species of protochordates have to be performed to unravel this discrepancy.

Evolution of the IGF-Binding Proteins

In mammals, each of the six different IGFbps has its own well-characterized properties in delivering the IGFs to their receptors. Some IGFbps show higher IGF-binding affinity, whereas others promote the IGF-receptor interaction. In general, a particular IGFbp can exert both inhibitory and stimulatory actions. These depend on the particular physiological context and target cell. In contrast, our knowledge of the number and nature of the IGFbps in nonmammals is limited, and the results obtained are not consistent. This may in part reflect differences in IGFbps present among the species investigated, but differences in nutritional status and developmental stage or technical differences may also play a role.

In chicken, four circulating IGFbps with molecular weights of 28, 34, 41, and 60 kDa have been identified. Furthermore, the cDNAs encoding two IGFbps have been cloned. The deduced amino acid sequences show 66 and 83% overall sequence identity to mammalian IGFbp-2 and IGFbp-5, respectively. Like in mammals, the chicken 28-kDa IGFbp is up-regulated by fasting. The binding activity of a chicken 36-kDa IGFbp increased after glucocorticoid treatment, as observed for mammalian IGFbp-1. IGFbps sized between 20 and 60 kDa were identified in representatives of all major reptilian groups. In amphibians, a 28.4-kDa IGFbp that is 97% identical to rat and human IGFbp-5 has been found in the frog *Xenopus laevis*, and a single 50-kDa IGFbp has been found in the toad, *Bufo woodhousei*. Simultaneously with the serum IGF-I level, that of the toad IGFbp changed with the seasons.

Like in mammals, only a minor portion of IGF-I circulates in unbound form in bony fish. As estab-

lished by the Dickhoff group in Seattle, Washington, the amount of free IGF-I is 0.3% in coho salmon. Three different IGFbps have been detected in serum of coho salmon, striped bass, goby, tilapia, barramundi, and trout. Based on their molecular weights (23–28, 30–34, and 40–50 kDa, respectively), it has been postulated that the fish IGFbps are related to mammalian IGFbp-1, -2, and -3, respectively. In striped bass, a fourth IGFbp with a molecular weight of 85 to 90 kDa has been detected. Recently, the Duan group first cloned bony fish IGFbp in zebrafish. The zebrafish IGFbp had a molecular size of 28.4 kDa, showed 52% sequence identity with human IGFbp-2, and significantly inhibited IGF-I-stimulated cell proliferation and DNA synthesis.

Like in mammals, IGFbps are produced not only in bony fish liver but also in extrahepatic sites. In striped bass, a 30-kDa IGFbp was found in brain, gills, bone, heart, skeletal muscle, kidney, gut, spleen, and gonads, whereas liver expressed an additional 24-kDa IGFbp. Increasing evidence indicates that the serum levels of the fish IGFbps are regulated by the metabolic and hormonal status, as they are in mammals. In goby, the serum levels of the 29- and the 31-kDa IGFbps depended on the insulin status, and in coho salmon, the serum level of the 41-kDa IGFbp was GH dependent. Similarly, *in vitro* experiments performed in striped bass by the Bern group in Berkeley, California, showed that the modes of release of the 24- and the 30-kDa IGFbps from liver slices into the medium were differentially regulated by GH and other hormones such as insulin and thyroxin. Because fasting in striped bass and goby also affected the lower molecular-weight IGFbps, further functional similarities between fish IGFbps and their mammalian counterparts exist.

Although no IGFbps have been described to date in chondrichthyes, three IGFbps have been detected in the serum of a lamprey species (*Geotria australis*): a major form at 50 kDa and minor forms at 32 and 28 kDa.

In summary, it can be stated that IGFbps likely occur in all vertebrate classes. At least three IGFbps seem to be present: generally a higher molecular-weight IGFbp of 40 to 50 kDa and two smaller IGFbps in the size range of 24 to 34 kDa. Thus, the molecular weights of the nonmammalian IGFbps are within similar ranges as their mammalian counterparts. Furthermore, nonmammalian IGFbps seem to be expressed in liver and extrahepatic sites, and several similarities in the regulation of the IGFbps in mammals and nonmammals, especially in bony fish, are obvious. Therefore, different classes of IGFbps seem to be

conserved among the vertebrate classes, suggesting that the IGF-BPs play fundamental roles in modulating the bioavailability of the IGFs throughout the vertebrate line of evolution. This is also stressed by the likely simultaneous appearance of proto-IGF and IGF-BPs in evolution. Although the ability of the IGF-BPs to inhibit insulin-like activities of the IGFs probably is their most fundamental role, their potential impact in tissue-specific and developmental regulation as it is present in mammals, as well as the evolutionary level of its appearance, still awaits clarification in nonmammalians.

INSULIN-LIKE PEPTIDES IN THE PROTOSTOMIAN LINEAGE

ILPs occur not only in the deuterostomian line of evolution but also in protostomian invertebrates. A family of insulin-related peptides has been detected in mollusks and the Bombyxins and other ILPs in insects. The organization of the domains of the various ILPs is similar or identical to that of (pro-)insulin and the IGFs, including the six cysteine residues important for maintenance of the secondary and tertiary structure in vertebrate insulin and IGFs.

Molluscan Insulin-Related Peptides

Five different members of the molluscan insulin-related peptide (MIP) family have been characterized from the pulmonate snail *Lymnaea stagnalis*. In contrast to insulin and the IGFs, the MIPs seem to be essentially produced in neuroendocrine cells of the central nervous system, the light green cells (LGCs). Because the LGCs are involved in body growth and metabolism, it is assumed that the MIPs play a role in the regulation of growth and differentiation as their mammalian counterparts are. The MIP genes contain introns at positions matching those in the vertebrate insulin genes. The level of sequence similarity in the B and A domains among the members of the MIP family is lower than that among the members of the deuterostomian insulin/IGF family. Thus, the MIPs likely constitute an ancient family of peptides and, as recently put forward by Smit and colleagues, have experienced multiple gene duplications, mutations, unequal crossing-overs, and (partial) gene conversions. In 2001, Lardans and colleagues characterized an insulin receptor-related receptor in an embryonic cell line from the snail *Biomphalaria glabrata*. The receptor had the typical structure of a tyrosine kinase receptor with extracellular, transmembrane, and cytoplasmic regions

and showed a wide distribution throughout the snail body.

Insect Insulin-like Peptides

As the first member of this hormone family, Bombyxin, a small insulin-related peptide of about 5 kDa, was isolated from the brain of the silkworm (*Bombyx mori*). The overall sequence identity of Bombyxin A2 with human insulin is 50% in the A domain and 32% in the B domain. It is produced mainly in medial neurosecretory cells of the central nervous system but also occurs in several extracerebral sites. The Bombyxin genes, which have been cloned from the silkworm, constitute five families of structurally related genes. The members of each family are closely related structurally. The presence of multiple Bombyxin gene copies, coupled with the lack of introns, is in marked contrast to the vertebrate insulin and IGF genes. The widespread expression pattern of Bombyxin(s), which resembles that of IGF-I in vertebrates, led to the assumption that the hormone is involved in insect growth, development, and differentiation. Recently, Masamura and colleagues showed that glucose stimulates the release of Bombyxin and that the hemolymph levels of both glucose and Bombyxin are regulated by starvation and refeeding. These data suggest that Bombyxin probably is a metabolic hormone in insects and that glucose may be a common nutritional stimulus for the release of deuterostomian insulin and insect ILPs.

Thus, the role of insulin/ILPs in regulating the switch from the catabolic to the anabolic state, thereby maintaining the blood glucose level, likely evolved before the divergence of the protostomian and deuterostomian lineages of evolution.

The well-characterized ILPs in the fruitfly *Drosophila* (DILPs) also have a domain structure similar or identical to that of mammalian insulin. Their amino acid sequences and domain structure both are more closely related to mammalian insulin than to IGFs. However, the ubiquitous expression of DILP2, which is most similar to insulin, resembles that of IGF-I in vertebrates. The insulin-signaling pathway has been characterized in *Drosophila* and in a nematode. The whole pathway from the receptor down to the serine/threonine kinases is highly conserved in evolution. The *Drosophila* insulin receptor homologue (DInr) has almost equivalent sequence identity to the vertebrate insulin and IGF type 1 receptors, and its overexpression leads to an increase in growth, cell size, and number. Brogiolo

and colleagues recently showed that the *Drosophila* genome contained seven genes encoding ILPs that were expressed in a tissue- and stage-specific manner. Overexpression of one of the ILP genes enhanced growth in a DInr-dependent manner. Based on these results, it has been proposed that nutritionally regulated ILPs in *Drosophila* coordinate growth at the neurosecretory and local levels.

Thus, the protostomian ILPs seem to function as regulators of growth and body size. Indeed, it is likely that the conformation of the protostomian ILPs is similar to that of the deuterostomian insulin and IGFs, having changed little since the two lineages last shared a common acoelomate ancestry.

insulin secretion is observed. A high rate of hormonal release is then eventually achieved.

As emphasized in what follows, the insulinotropic action of D-glucose is causally linked to the capacity of the hexose to act as a nutrient and to increase the rate of adenosine 5'-triphosphate (ATP) generation in insulin-producing cells. This fuel concept also applies to the insulin-releasing action of other nutrients mentioned previously. In the case of amino acids, however, the following more nuanced situation prevails. Certain amino acids (e.g., L-leucine, L-glutamine, L-asparagine) also owe their insulinotropic capacity to their role as nutrients in the islet B cells. However, they may also act as allosteric activator of mitochondrial glutamate dehydrogenase and, as a result, facilitate the catabolism of endogenous amino acids in the islet cells. For instance, such is the case for a transported but nonmetabolized analogue of L-leucine. Moreover, other amino acids, which are potent insulin secretagogues, are poor nutrients but stimulate insulin release as a result of their accumulation in the islet cells. Such is the case for cationic amino acids (e.g., L-arginine, L-ornithine), which, through their accumulation inside the islet cells, provoke a depolarization of the plasma membrane and a resulting gating of voltage-sensitive calcium channels.

Immediate and Direct Effects of Hormones and Neurotransmitters

Two examples of the immediate and direct effects of hormones on insulin release are mentioned here. First, adrenaline inhibits insulin secretion evoked by D-glucose or other insulin secretagogues. This effect is suppressed by α -adrenergic blocking agents and coincides with a lowering of the cyclic AMP (cAMP) content in islet cells. It was proposed that, by inhibiting insulin release under conditions of stress and exercise, adrenaline would be better able to mobilize D-glucose from the liver and to mobilize free fatty acids and glycerol from adipose tissue.

Second, certain gastrointestinal hormones, such as glucagon-like peptide 1, potentiates insulin release evoked by D-glucose and other nutrient secretagogues. This is attributable to activation of adenylate cyclase, with a resulting increase in the cAMP content of islet cells. The term "hormonal enteroinsular axis" was proposed to indicate that the enhancement of insulin secretion by hormones released from the intestinal tract may account for the fact that hyperinsulinemia caused by D-glucose is more marked when the sugar is given orally rather than intravenously.

Likewise, vagal stimulation of insulin release could be a significant feature in the process of food intake and digestion. Cholinergic agents indeed augment insulin secretion evoked by D-glucose. This process involves occupancy of islet cells' muscarinic receptors, activation of phospholipase C, hydrolysis of polyphosphoinositides, and liberation of diacylglycerol and inositol 1,4,5-triphosphate with resulting activation of protein kinase C and mobilization of intracellular Ca^{2+} .

Long-Term Regulation of Insulin Release

Insulin release evoked by D-glucose is decreased in islets prepared from starved animals. It occurs at an abnormally high rate in islets from obese animals. Several hormones also affect the secretory responsiveness of the endocrine pancreas in a delayed manner. This may account for alteration of insulin release in situations such as pregnancy and lactation, acromegaly, hypo- or hypercorticism, and hypo- or hyperthyroidism. Finally, the long-term regulation of insulin release also involves ontogenic factors, as documented by the changes in islet secretory behavior found in fetal and neonatal life or aging.

RECOGNITION OF SECRETAGOGUES

As alluded to previously, the B cell is equipped with a number of receptors involved in the recognition of adrenergic factors, cholinergic neurotransmitters, and gastrointestinal hormones. By analogy, it had been proposed that each nutrient secretagogue may bind to a specific receptor possibly located at the B-cell plasma membrane. For instance, a previously widespread view postulated the presence of a stereospecific glucoreceptor in islet cells. However, a more pedestrian metabolic hypothesis eventually prevailed, postulating that the insulinotropic capacity of D-glucose is causally linked to its role as a nutrient in islet cells. This was then extended to other nutrient secretagogues and defined as the fuel concept for insulin release.

The key argument in support of this metabolic hypothesis for glucose-stimulated insulin secretion resides in the finding that the α -anomer of D-glucose, which is a more potent insulin secretagogue than β -D-glucose, is also more efficiently metabolized in pancreatic islets. As a matter of fact, the metabolism of D-glucose in isolated pancreatic cells or in purified islet B cells displays a number of uncommon features, all of which optimize the increase in ATP generation

rate resulting from the stimulation of islet cells by this hexose. A few examples of such features follow.

First, the concentration of D-glucose rapidly equilibrates across the plasma membrane of the B cell thanks to the efficiency of the glucose carrier GLUT2 (and GLUT1 in human B cells). Second, the phosphorylation of D-glucose in islet B cells is catalyzed not solely by an ubiquitous low- K_m hexokinase but also by a high- K_m glucokinase. As a result of these two features, the rate of D-glucose phosphorylation increases rapidly and sensibly in response to a rise in the extracellular concentration of the hexose. The regulation of D-glucose phosphorylation in the B cell also involves a number of other mechanisms such as a sequential synarchistic regulation by ATP, induction and repression of glucokinase, feedback inhibition of hexokinase by glucose 6-phosphate, intracellular translocation of glucokinase, intervention of a glucokinase regulatory protein, balance between glucose phosphorylation and dephosphorylation (by glucose-6-phosphatase), and binding of hexokinase isoenzymes to mitochondrial porin, with this process modifying kinetic properties (e.g., sensitivity to glucose 6-phosphate), coinciding with a preferential use of mitochondrial ATP for phosphorylation of D-glucose, and allowing a direct coupling between hexose phosphorylation and mitochondrial respiration.

Second, for the rate of glycolysis to keep pace with the rate of D-glucose phosphorylation, activation of key glycolytic enzymes takes place in glucose-stimulated B cells. For instance, such is the case for the activation of phosphofruktokinase by fructose 2,6-bisphosphate. Incidentally, the regulation of phosphofruktokinase activity in islet cells also displays the specific feature of an apparent resistance of fructose 6-phosphate,2-kinase to cAMP.

Finally, a preferential stimulation of mitochondrial oxidative events in either isolated islets or purified B cells exposed to increasing concentrations of D-glucose represents an essential feature of the B-cell glucose-sensing device. This phenomenon is attributable mainly to a Ca^{2+} -induced activation of key mitochondrial dehydrogenases such as the FAD-linked glycerophosphate dehydrogenase and 2-ketoglutarate dehydrogenase complex. Therefore, it should be considered as a secondary phenomenon caused by the accumulation of Ca^{2+} in the B cells. It optimizes the yield of ATP generated through the catabolism of D-glucose given that the mitochondrial oxidation of pyruvate provides the major fraction of such an ATP generation and is necessarily coupled with the oxidative modality of glycolysis.

COUPLING MECHANISMS

In the process of nutrient-stimulated insulin release, the coupling between metabolic events and more distal events in the secretory sequence appears to be multifactorial. Emphasis is currently placed on the closing of ATP-sensitive K^+ channels caused by the increase in the cytosolic ATP/adenosine diphosphate (ADP) ratio in nutrient-stimulated B cells. The closing of these channels then leads to depolarization of the plasma membrane and the subsequent opening of voltage-sensitive Ca^{2+} channels. The facilitated entry of Ca^{2+} into the B cell and the cytosolic accumulation of this divalent cation then acts as a trigger for the release of secretory granules.

A stimulatory effect of D-glucose on insulin release can still be documented, however, in cells exposed to both diazoxide (to maintain the K^+ channels in their open configuration) and a high extracellular K^+ concentration (to nevertheless cause depolarization of the plasma membrane). This finding points to the participation of other mechanisms in the stimulus-secretion coupling for glucose-induced insulin release. In this perspective, the following considerations should be underlined.

First, an increase in the ATP generation rate might not represent the sole factor coupling the catabolism of nutrient secretagogues to the remodeling of ionic fluxes in the islet cells. For instance, nutrient-induced changes in the redox state of islet cells and their intracellular pH may also participate in nutrient-stimulated insulin release.

Second, the cytosolic accumulation of Ca^{2+} may lead, via calmodulin, to the activation of adenylate cyclase in pancreatic islets. Pancreatic islets indeed contain calmodulin (about 0.1 pmol per islet). This protein binds to a particulate fraction derived from the islets and stimulates adenylate cyclase activity in this subcellular fraction, with both phenomena being activated by ionized calcium. Thus, a calcium-dependent stimulation of adenylate cyclase by endogenous calmodulin may contribute to the accumulation of cAMP evoked by insulin-releasing agents in the islet cells. cAMP should be considered as a modulator of the insulin secretory response to nutrient secretagogues. Its synthesis and breakdown are catalyzed by adenylate cyclase and phosphodiesterase, respectively. cAMP activates a protein kinase, leading to an apparent increase in the responsiveness of the effector system for insulin release to cytosolic Ca^{2+} .

Finally, in nutrient-stimulated B cells, as in response to cholinergic agents, breakdown or otherwise accelerated turnover of inositol phospholipids takes

place. The accelerated generation of polyphosphoinositides in nutrient-stimulated islet cells may result from a rise in cytosolic ATP production, whereas the stimulation by nutrients of the hydrolysis of inositol-containing phospholipids is currently ascribed to activation of phospholipase C through an increase in the cytosolic Ca^{2+} concentration. Enhanced phospholipid metabolism may then lead to the mobilization of calcium from nonmitochondrial intracellular stores by inositol 1,4,5-triphosphate and activation of protein kinase C by diacylglycerol.

EFFECTOR SYSTEM

The increase in the cytosolic concentration of ionized calcium caused by D-glucose or other insulin secretagogues triggers the exocytosis of secretory granules by causing the activation of a microtubular-microfilamentous system. The participation of this effector microtubular-microfilamentous system in the process of insulin release has been documented by a number of ultrastructural, biochemical, functional, and cinematographical studies.

Microtubules (21–25 nm in diameter) are considered to represent the cytoskeleton of B cells. They are scattered in the cytoplasm. They can be found between rows of aligned secretory granules. They are thought to provide oriented pathways for back-and-forth saltatory movements of secretory granules. They are also prominent in the ectoplasmic area. At that level, the cell web occupies cytoplasmic areas of variable thickness (50–300 nm) just beneath the plasma membrane and extends into the core of microvillous processes. It consists of a network of actin-like microfilaments (4–7 nm in diameter) generally disposed to form irregularly shaped polygons. This contractile cell web acts as a sphincter, either restricting or favoring the access of secretory granules to their exocytotic site at the plasma membrane.

The tools most commonly used to interfere experimentally with the function of the microtubular-microfilamentous system include mitotic spindle inhibitors (e.g., colchicine, vincristine), microtubule stabilizers (e.g., D_2O), and the microfilamentous modifier cytochalasin B.

At the exocytotic site, the fusion between the limiting membrane of insulin secretory granules and plasma membrane and subsequent fission of the fused membrane seem to involve an anion-osmotic process in which the insertion at the plasma membrane of an anion transport system derived from the limiting membrane of the secretory granules allows for the

entry of anions (e.g., Cl^- , OH^-) into the lumen of these granules, followed by their osmotic fission. This process also accounts for the release of several granules aligned along an oriented microtubular pathway, a phenomenon known as the chain release of secretory granules or compound exocytosis.

PATHOLOGICAL ASPECTS

Defective insulin release is a typical feature of diabetes mellitus. In insulin-dependent diabetes, it results from an autoimmune destruction of insulin-producing cells. In non-insulin-dependent diabetes, the deficiency of insulin release may be caused by a number of distinct site-specific anomalies. Indeed, virtually each step in the process of insulin secretion may be affected by inherited or acquired factors. For instance, a defect in the conversion of proinsulin to insulin and C-peptide may result in the release of large amounts of proinsulin, which is virtually devoid of hypoglycemic action. On the most distal step of the secretory sequence, a defect of the microtubular apparatus may be responsible for a sluggish secretory response to D-glucose in certain animal models of type 2 diabetes.

In most but not all patients with type 2 diabetes, the endocrine pancreas displays a preferential impairment of its secretory responsiveness to D-glucose, as distinct from other nutrient or nonnutrient insulin secretagogues. Site-specific defects responsible for such a situation include (1) a decrease in the number of B cells suitably equipped with sufficient GLUT2 carriers, (2) a nonsense mutation of the glucokinase gene, (3) excessive activity of glucose-6-phosphatase leading to an ATP-wasting futile cycle in the reaction catalyzed by hexokinase isoenzymes and glucose-6-phosphatase, and (4) a deficient activity of the mitochondrial FAD-linked glycerophosphate dehydrogenase, the key enzyme of the glycerol phosphate shuttle. Moreover, glycogen accumulation takes place in the B cell in situations of chronic hyperglycemia. It is held responsible for the secondary process of so-called B-cell glucotoxicity or incompetence. Two typical phenomenological aspects of this process consist in a paradoxical early and transient decrease in insulin release and the perturbation of its anomeric specificity in response to the rapid intravenous administration of D-glucose to patients with type 2 diabetes.

Excessive secretion of insulin can also occur in certain pathological conditions. Such is the case, for instance, in individuals bearing an insulinoma or in

patients with persistent hyperinsulinemia during childhood.

PHARMACOLOGICAL ASPECTS

The therapeutic agents currently used to modify insulin secretion belong to two classes. First, to enhance insulin release in non-insulin-dependent diabetic individuals, either hypoglycemic sulfonylureas (e.g., tolbutamide, glibenclamide) or meglitinide analogues (e.g., nateglinide, repaglinide) are given orally. These antidiabetic agents display a common configuration and act by causing a direct closing of ATP-sensitive K^+ channels without affecting the ATP content of insulin-producing cells.

Second, to prevent excessive insulin secretion in certain pathological conditions, diazoxide and related drugs are used. They cause a direct opening of ATP-sensitive K^+ channels and, hence, inhibit insulin release caused by D-glucose and other secretagogues. This effect of diazoxide is abolished in the presence of hypoglycemic sulfonylureas or meglitinide analogues.

The destruction of insulin-producing cells (e.g., in patients bearing an insulinoma) can be achieved by selective β -cytotoxic agents, especially streptozotocin.

in a linear fashion through the range of physiological glucose concentrations seen in the postprandial state. Maximal insulin output is achievable *in vitro*, but has been difficult to demonstrate in human subjects.

The glucose–insulin relationship is also altered by previous exposure of the beta cell to glucose, which can result in two important consequences, dependent on the duration of exposure. The first is a phenomenon that provides evidence for beta cell memory—if the beta cell is exposed to a prior glucose stimulus, repeat glucose stimulation results in a magnified insulin secretory response. This response is influenced by the magnitude and duration of the prior stimulus, as well as its proximity in time to a subsequent glucose exposure. The second phenomenon occurs after prolonged exposure to elevated glucose concentrations, which results in diminished insulin secretion, so-called “glucotoxicity.” Glucotoxicity has been associated with reduced expression of beta cell genes in experimental *in vitro* models; however, the mechanisms for both of these time- and concentration-dependent effects are not well understood. Nevertheless, the pathways that explain both beta cell memory and glucotoxicity are potential regulatory targets for therapeutic action.

***In Vitro* Insulin Secretion**

Distinct patterns of first- and second-phase insulin secretion are clearly observed *in vitro* in models that range from isolated islets of Langerhans to the perfused pancreas. This very characteristic pattern, which has been considered the hallmark of the physiological insulin response to glucose, has been shown to be important in two ways. First, as a marker for normal beta cell function—the loss of first-phase insulin secretion has been used experimentally, and clinically to a lesser extent, to evaluate people at risk for the development of type 1 and type 2 diabetes. Second, first-phase secretion has been shown to be necessary for the normal regulation of hepatic glucose production. Thus, attempts to understand the mechanisms for this typical response to glucose stimulation continue to preoccupy investigators. Two different models have been suggested to explain the first-phase response, a “storage-limited model” and a “signal-limited model.” In the first model, a signal releases a distinct and limited group of secretion granules to form the first phase. In the second model, the signal(s) is (are) biphasic, resulting in a secretory pattern that reflects the cumulative signal(s). These models are not mutually exclusive. Direct observation of insulin secretion granules in beta cells supports the concept

of an immediately releasable pool of granules found close to the plasma membrane. This appears to be a well-defined cluster of granules that are set to fuse or may already be fused with the plasma membrane, the first step in the exocytosis of insulin molecules.

***In Vivo* Insulin Secretion**

Complexity of Assessment of Insulin Secretion *in Vivo*

The simplest measure is the circulating insulin concentration, which provides useful information but is limited in its ability to accurately reflect insulin secretion by the pancreas. This is because peripheral circulating insulin, which is the usual measurement obtained in clinical settings and small animal models, is influenced by a number of potential confounders. Three physiological phenomena play a role in influencing peripheral plasma insulin concentrations.

Extraction

The liver extracts 50–60% of the insulin presented to it from the pancreas in a single pass. Thus, peripheral insulin concentrations are markedly diminished compared with the amount that is secreted into the prehepatic circulation.

Dilution

Peripheral insulin concentrations are further decreased by the dilution that occurs after the entry of insulin into the portal system from the pancreas and again as the hepatic effluent joins the general circulation. This further alters the quantitative relationship between insulin concentrations in the periphery and their pancreatic source.

Clearance

Insulin is metabolized by the liver and also the kidneys. As with all circulating molecules, serum concentrations are a function of both the rate of secretion and the rate of clearance. Thus, impaired insulin clearance will increase circulating insulin concentrations. Although decreased clearance of insulin occurs in pathological conditions such as renal failure, it is also a consequence of insulin resistance in otherwise healthy subjects.

Methods to Evaluate Insulin Secretion *in Vivo*

The methods that have been developed to evaluate insulin secretion in whole animals are based on dealing with the three problems outlined above. C-peptide is cosecreted with insulin in equimolar quantities from

the beta cell and is therefore an excellent marker for insulin secretion, especially because this peptide is not extracted by the liver (metabolism of C-peptide occurs predominantly in the kidney). Thus, measurement of C-peptide allows researchers to bypass the effect of the liver in insulin extraction and provides a more direct measurement of beta cell function. Clearance must be addressed as well, all the more so because C-peptide clearance is different from that of circulating insulin. This is factored into the assessment of insulin secretion using a mathematical solution known as deconvolution, first introduced by Eaton and elegantly applied by Polonsky, to distinguish between the secretion and clearance components of circulating C-peptide. The mathematical treatment of insulin secretion assessment also takes into account the dilution phenomenon that takes place after hormone release. This work and similar approaches have shown that the average insulin secretory rate in lean, healthy individuals is close to 30 units per day.

MODULATORS OF INSULIN SECRETION

The Local Milieu: Influence of Other Islet Cells

The beta cell is surrounded by other endocrine cells in the islets of Langerhans, which have the distinction of also being involved in the regulation of metabolism and uniquely—as first demonstrated by Samols—with the potential ability to influence the secretion of their neighbors. The alpha and delta cells are the next largest contributors to islet cell mass, secreting glucagon and somatostatin, respectively. Both glucagon and somatostatin modulate insulin secretion: glucagon is an insulin secretagogue and somatostatin is an inhibitor of insulin secretion. It is not clear whether these modulatory effects are achieved locally by paracrine cell-to-cell interactions or by a local endocrine effect when the hormones are released into the islet microcirculation and transported within this vasculature from their secretory origin to target cells. Finally, these hormones might influence each other by the classical endocrine route, by entering the general circulation before returning to the islet and affecting their neighboring cells.

Endocrine Modulators: Incretins

The complexity and elegance of normal physiology are illustrated further by the incretin phenomenon.

An entero-insular axis was hypothesized when it was found that glucose stimulation of insulin secretion was increased if the same glucose concentrations were achieved by glucose ingestion rather than intravenous infusion. This indicated that enteric factors, humoral (incretins) or nervous, enhance the beta cell response to glucose or meals; indeed, the incretins can be seen as a mechanism to prepare the islets for an influx of nutrients yet to be absorbed from the gastrointestinal tract. Numerous enteric peptides have been considered as candidates for the role as the physiological incretin. These include gastrin, cholecystokinin, glucose-dependent insulinotropic polypeptide (GIP), and glucagon-like peptide-1 (GLP-1). GLP-1, a peptide secreted by gastrointestinal L cells, is the prime candidate and is the basis for a new class of anti-diabetic agents being developed to treat type 2 diabetes. GLP-1-like agents or those that slow the clearance of the endogenous peptide have hypoglycemic activity by enhancing glucose-stimulated insulin secretion and suppressing glucagon secretion.

Nutrient and Neural Modulators

Nonglucose nutrients also modulate insulin secretion in the presence of glucose in the medium or circulation. These include essential amino acids such as arginine and leucine. Free fatty acids (FFA) also have a complex interaction with beta cell function, not dissimilar to that of glucose. Acute elevation of FFA (or ketones) increases insulin secretion, but chronic exposure appears to diminish insulin release. Multiple neural modulators also regulate insulin secretion. The islets of Langerhans are densely innervated. Insulin secretion is enhanced by cholinergic stimulation; adrenergic input inhibits beta cell function. Both α 1- and α 2-adrenergic receptors mediate the inhibition of insulin secretion. There is also evidence that many neuropeptides, such as galanin, neuropeptide Y, and vasoactive intestinal polypeptide, may play a role in modulating insulin secretion.

PATTERNS OF INSULIN SECRETION

The study of the patterns of insulin secretion have contributed to the understanding of the normal physiology of the beta cell and also provide clinicians with tools with which to define dysfunction. An example of this is the characteristic loss of first-phase insulin secretion in both patients with type 2 diabetes and patients in the earliest phases of type 1 diabetes, prior to clinical presentation. Another characteristic feature

of normal beta cell function is the oscillatory pattern of insulin secretion. Unlike many other hormones secreted in pulsatile fashion, insulin secretion occurs in a highly regular pattern under basal conditions. A variety of patterns of insulin secretion have been identified; their characteristics depend on the experimental model and the frequency of sampling (more frequent sampling is necessary to identify high-frequency oscillations). In isolated islets, the period of insulin oscillations ranges from 3 to 15 min and the oscillations are of low amplitude. In human subjects, high-frequency oscillations in insulin concentrations measured in the peripheral circulation also have a period of 6–12 min (Fig. 1). These are highly regular oscillations that are entrainable by glucose both *in vitro* and *in vivo*. *In vivo*, it has also been shown that insulin oscillations are entrainable by nonglucose secretagogues. Low-frequency oscillations (period is 80–150 min) have also been identified in humans. These ultradian insulin oscillations are superimposed on the large postprandial increases in insulin secreted after meals. Both low- and high-frequency insulin oscillations have been shown to lose their regularity in people with diabetes and indeed

Figure 1 Three-minute moving average of plasma insulin concentrations in a normal subject injected with serial incremental intravenous glucose boluses at 29 min intervals (arrows). The doses of glucose range between 10 and 40 mg/kg. The data are detrended and presented with a fitted sine wave (using the frequency and amplitude of the dominant 15 min period derived from spectral analysis). This figure illustrates a number of points made in this article: (1) High-frequency insulin oscillations are intrinsic to normal human subjects in the fasting state. (2) There is an insulin response to acute elevation in glucose concentrations; even small increases in glucose concentrations result in dramatic increases in insulin secretion in normal subjects that increase in a dose- or concentration-response pattern. (3) There is an entrainment of insulin oscillations by the glucose boluses to the rhythm of the injections. The period for oscillations in this model is usually ≈ 10 min. In the example shown here, the oscillations are entrained to a period of 15 min in this normal subject.

both lose their ability to be entrained by glucose in type 2 diabetic subjects.

RELATIONSHIP BETWEEN INSULIN SECRETION AND INSULIN RESISTANCE

Role of Insulin Resistance in Regulating Insulin Secretion

Circulating insulin concentrations are greatly influenced by the concomitant degree of insulin sensitivity *in vivo*. It has been known for years that obese subjects who are insulin resistant have elevated serum insulin concentrations. This has led to the concept that insulin resistance must be associated with a signal to the beta cell that enhances insulin secretion. The mechanism for this signal is a subject of debate, though a simple formulation would place glucose at the center of this physiological phenomenon, in the following way: start with a given insulin concentration and effectiveness in an *in vivo* model and increase the level of insulin resistance in this model. Insulin action will be diminished and as a consequence glucose concentrations will rise slightly. Even small changes in glucose concentrations enhance insulin secretion, thus increasing circulating insulin levels and restoring insulin action so that glucose concentrations return toward baseline. A new steady state with hyperinsulinemia is established. This hyperinsulinemia, though a somewhat crude measure of insulin resistance, has been used by epidemiologists as an effective marker of insulin resistance. Despite the logic and simplicity of this hypothesis, data in dogs suggest that glucose may not be the signal for the hyperinsulinemia of insulin resistance. This important question remains to be resolved.

Assessment of Insulin Secretion *in Vivo* in the Presence of Insulin Resistance

As pointed out above, the close tie-in that exists between the beta cell and the periphery where insulin resistance is played out alters the way in which researchers look at insulin secretion. As an example, consider a prospective study of the physiology of insulin secretion in two subjects, one of whom gained weight after the start of the study. The development of obesity will result in increased insulin resistance and thus also insulin secretion. How could the subjects' insulin secretion rates be compared and how could possible beta cell dysfunction in the obese subject,

who is now at greater risk for diabetes, be tested for? A decrease in insulin secretion as a marker of beta cell dysfunction would not be obvious in the more resistant person if one looked only at the absolute insulin secretion rates or insulin concentrations—these would likely be higher than those of the lean subject even as secretion is beginning to fail. This problem can be dealt with by taking into account the degree of insulin resistance at each time point in the study when insulin secretion is measured. Such an approach was developed by Kahn and Bergman and is known as the disposition index. The disposition index is the product of insulin secretion and insulin sensitivity. The disposition index deals with the problem of evaluating insulin secretion in the presence of different degrees of insulin resistance and allows comparison of insulin secretion in the example described here.

reduced, although not to the same extent as is body weight. Whether there are functional deficiencies in these tissues remains to be determined.

To determine the role of serum IGF-I versus the autocrine/paracrine IGF-I in growth and development, liver IGF-I-deficient (LID) mice were generated. Tissue-specific deletion of the IGF-I gene in the liver did not affect postnatal growth and development, either because the residual serum IGF-I was enough to promote growth or because locally produced IGF-I contributes to growth. The ternary complex that carries IGF-I (and IGF-II) in the serum consists of an acid labile subunit (ALS), IGF binding protein-3 (IGFBP-3), and IGF. When LID mice were crossed with ALS nullizygous mice, serum IGF-I levels were reduced by more than 90%, probably because ALS is required to stabilize IGF-I in serum, and the mice exhibited significant growth retardation. This result suggests that there is a minimum threshold of serum IGF-I that must be maintained to support normal growth. Alternatively, or in addition, LID/ALSKO mice may be deficient in delivery of serum IGF-I to tissues. The role of local tissue IGF-I production will be more clearly elucidated as tissue-specific knockouts in extrahepatic tissues are developed.

Insulin-like Growth Factor-II

Homozygous deletion of the IGF-II alleles in mice results in 40% growth retardation from embryonic day 11 through adulthood. This result is consistent with the concept that IGF-II is primarily a fetal growth factor, an idea initially suggested by the fact that serum IGF-II decreases dramatically during the early postnatal period in rodents. The findings of growth retardation throughout life are also of interest in that IGF-II knockout mice do not show “catch-up” growth, suggesting an enduring effect of embryonic growth retardation. As with IGF-I, IGF-II expression is regulated by tissue-specific tropic agents, including follicle-stimulating hormone (FSH) in ovarian granulosa cells; ACTH in fetal adrenal cells; glucocorticoids, thyroid hormone, and glucose in hepatic cells; and glucose in a pancreatic beta cell line. IGF-II produced in muscle also plays an important role in skeletal muscle myoblast differentiation *in vitro*. In the circulation, IGF-II is normally a 67-amino acid polypeptide. However, patients with nonislet cell tumor hypoglycemia occasionally release a larger precursor form of IGF-II from the tumors that contains a 21-amino acid extension (E peptide). This so-called “big IGF-II” may cause hypoglycemia in these patients by

preventing IGFBPs from neutralizing circulating IGFs. As a result, there is sufficient free big IGF-II to bind to and activate insulin receptors, resulting in fasting hypoglycemia.

RECEPTORS

The Insulin-like Growth Factor-I Receptor

The IGF-I receptor (IGF-IR) is encoded by a single gene greater than 100 kilobases long that contains 21 exons. The structure of the IGF-IR closely resembles that of the insulin receptor (IR). In both cases, the gene encodes a single precursor protein in which the amino-terminal α -subunit is followed by the carboxy-terminal β -subunit. During maturation of the precursor, the α - and β -subunits are proteolytically separated and then joined together by disulfide bonds. Two such α - β hemireceptors are attached to each other via disulfide bonding of the α -subunits. Thus, the mature IGF-IR is a heterotetramer, consisting of two extracellular α -subunits attached to each other, with each α -subunit attached to a membrane-spanning β -subunit. The α -subunit binds the ligands extracellularly. The β -subunit consists of the juxtamembrane region, containing sequence motifs that are also found in the IR and that bind to important intracellular substrates, followed by the tyrosine kinase domain. There is approximately 84% similarity between the amino acid sequences of the IGF-IR and IR tyrosine kinase regions. The most divergent region between the two receptors is the cytoplasmic carboxyl-terminus domain of the β -subunit.

IGF-IR Function

When IGFs bind to the IGF-IR, receptor autophosphorylation of the β -subunit and activation of its tyrosine kinase occur. A family of molecules called insulin receptor substrates (IRS 1–4) bind to the juxtamembrane region of the β -subunit of the ligand-activated receptor and become phosphorylated on tyrosine residues. The phosphorylated IRS molecules then bind to and activate SH2 domain-containing proteins, including Grb2 and PI3K. The adapter protein Grb2 then activates the SOS/Ras/Raf/mitogen-activated protein (MAP) kinase pathway. MAP kinase, a major IGF-I-activated isoform that is termed extracellular signal-regulated protein kinase (ERK), and PI3K activate phosphorylation and dephosphorylation cascades, leading to changes in levels of proteins important in DNA synthesis and cell division. IGF-I increases cyclin D1 levels in a number of cell types by mechanisms such as increased cyclin D1 gene

transcription and increased cyclin D1 mRNA stability, with the latter being effected via a PI3K-dependent mechanism. IGF-I also increases cyclin E expression. In addition, IGF-I decreases the levels of p27 cyclin-dependent kinase inhibitor through PI3K, an effect that could be mediated at several levels, including posttranscriptional control. IGF-I also increases the levels of cdk-2. Through these combined actions, IGF-I speeds the transition from G1 to S in the cell cycle. In addition to IRS molecules, IGF-IR can bind to and tyrosine phosphorylate Shc, which (much like IRS) can activate Grb-2.

IGF-I also inhibits cellular apoptosis by (1) increasing phosphorylation of BAD, (2) increasing phosphorylation of the forkhead transcription factor, and (3) increasing transcription of the anti-apoptotic bcl-2 gene. Mechanisms for these actions of IGF-I include stimulation of ERK, PI3K, and 14-3-3 pathways to promote BAD phosphorylation; stimulation of PI3K/Akt to increase forkhead phosphorylation; and stimulation of both the p38 stress-activated protein kinase (a MAP kinase isoform) and PI3K/Akt pathways, leading to cyclic AMP response element-binding protein (CREB) phosphorylation and increased bcl-2 promoter activity.

Activation of the PI3K pathway has also been shown to mediate certain effects of IGF-I on cellular differentiation. In brown adipose cells, IGF-I induces expression of uncoupling protein and GLUT4 by stimulating PI3K and ERK, respectively. IGF-I promotes osteoblast differentiation, as evidenced by IGF-I activation of the osteocalcin promoter in a protein kinase C (PKC)-dependent mechanism. More recently, IGF-I was found to stimulate myoblast differentiation by promoting calcineurin signaling. Moreover, IGF-I induction of p21, a cdk inhibitor, was shown to be involved in myoblast differentiation.

Mannose-6-Phosphate/IGF-II Receptor

The IGF-II receptor (IGF-IIR) is characterized by its ability to bind IGFs as well as mannose-6-phosphate (M6P) residues on lysosomal enzymes. Its affinity for IGF-II is much greater than that for IGF-I, and unlike the IGF-IR, the IGF-IIR does not bind insulin at all. This receptor does not appear to transduce IGF-II signals *in vivo*. Rather, it is thought to actually decrease IGF-II signaling by internalizing IGF-II and promoting IGF-II degradation. Supporting this view, M6P/IGF-IIR gene-deleted mice are larger than controls. Consistent with a growth inhibitory role, microsatellite instability in the M6P/IGF-IIR gene

has been described in various cancers, including stomach, colon, and endometrium. Thus, the M6P/IGF-IIR may play a significant role as a tumor suppressor by mediating IGF-II degradation. The IGF-IIR also activates transforming growth factor (TGF)- β 1 from a precursor molecule, which could also lead to growth inhibition.

INSULIN-LIKE GROWTH FACTOR-BINDING PROTEINS

Six distinct IGFbps that bind IGFs with high affinity have been described. IGFbps are well conserved, including cysteine residues that may be important for IGF binding. IGFbps are produced by multiple tissues in highly regulated ways. They are secreted into the circulation, and several lines of evidence from cell culture and *in vivo* studies suggest that IGFbps also act at or near their site of production. In serum, the overwhelming majority of IGF is found as a 150-kDa complex that includes IGFBP-3 and ALS. Association of IGFs with this complex is thought to protect the IGFs from degradation and tissue clearance and to increase their half-life in serum. IGFbps other than IGFBP-3 may be part of a 50-kDa complex in serum that, through transcytosis mechanisms not fully characterized, may facilitate transfer of IGFs from the circulation to interstitial space and target cells. Free IGFs may also cross endothelial barriers.

As mentioned previously, IGFbps also are synthesized to act locally. At the target cell level, IGFbps modulate the effects of the IGFs and/or act independently of the IGFs and the IGF-IR. Experimentally, both inhibitory and stimulatory effects of IGFbps on IGF action have been reported. Intensive effort has been devoted to explaining these results. Because IGFbps in solution have a higher affinity for IGFs than does the IGF-IR, IGFbps can prevent the binding of IGFs to the IGF-IR and inhibit IGF action. However, modification of IGFbps lowers their affinity for IGFs. Dephosphorylation of IGFBP-1, attachment of IGFBP-3 to the cell surface, and attachment of IGFBP-5 to the extracellular matrix (ECM) lowers their respective affinities for IGFs, potentially enhancing the delivery of IGFs to the IGF-IR.

Several IGF-independent actions have been reported for IGFbps. IGFBP-1 contains an Arg-Gly-Asp (RGD) tripeptide that allows it to interact with the integrin- α 5- β 1 receptor. Deletion of this RGD sequence from IGFBP-1 prevented it from

stimulating cell migration. Binding of IGFBP-1 to integrin receptors on breast cancer cells activated a signaling cascade in which FAK was dephosphorylated, disrupting attachment of the cells to the ECM and causing apoptosis.

IGFBP-3 was reported to increase the ratio of the pro-apoptotic bax to the anti-apoptotic bcl-2 in p53-deficient breast cancer cells. When these cells were challenged with ionizing radiation, their apoptosis rate was higher than in cells not treated with IGFBP-3. The presence of IGFs in these cultures was apparently excluded, suggesting an IGF-independent effect. In contrast, IGFBP-4 and IGFBP-5 have been reported to promote survival of certain cells in IGF-independent ways, although the mechanisms underlying these effects are not known. Of particular importance will be the definitive identification and characterization of cell surface receptors for IGFBPs. Of great interest also are recent results showing that IGFBP-3 and IGFBP-5 are translocated into the nucleus via the importin- β subunit. The consequences of this action are not known, but they suggest novel direct effects of IGFBPs on nuclear events such as gene expression.

EVOLUTIONARY ASPECTS OF INSULIN AND IGF-I SIGNALING

The nematode *Caenorhabditis elegans* and the fruitfly *Drosophila melanogaster* both contain homologues of the mammalian insulin/IGF signaling system. Recently, interesting phenotypes have been reported to result from mutations in these genes. Loss of function mutations of the IR/IGF-IR orthologue Daf-2 in *C. elegans* gives rise to dauer larvae. The dauer state shows reduced metabolic activity, perhaps an expected result, and also has a prolonged life span. The dauer state is naturally entered during periods of food deprivation and other environmental stresses. These studies suggest an intriguing mechanism in which caloric restriction may increase life span by decreasing insulin signaling. This mechanism has a mammalian counterpart, in which calorically restricted rodents have increased life span in conjunction with reduced levels of serum insulin and IGF-I. Loss of function mutations of age-1, the PI3K homologue, also extend life span in nematodes. In contrast, mutations of Daf-16, a homologue of the mammalian FOXO forkhead transcription factors, and of Daf-19, a homologue of the mammalian PTEN phosphoinositide phosphatase that inhibits PI3K, can negate the effect of the Daf-2

mutation. These results further substantiate the role of insulin/IGF-I signaling in nematodes.

In *D. melanogaster*, the homologue of the IRS family of molecules, known as CHICO, has been shown to play an important role in cell proliferation and overall body growth. Moreover, loss of function mutation of CHICO also extends life span. The precise signaling cascade leading to CHICO action is not fully understood, however, because the *Drosophila* IR homologue (DIR) binds directly to many of its downstream signaling substrates via its carboxyl-terminal extension. This is in contrast to the mammalian IR and IGF-IR, which use the IRS family of docking proteins to activate downstream molecules such as PI3K and Grb-2.

CONCLUSION

This article has briefly described the essential structural and functional features of components of the IGF system and has described some newer findings on the mechanisms and evolutionary conservation in the insulin and IGF signaling pathways. Reviews listed in the bibliography should be consulted for more in-depth treatment of these and other areas related to IGF physiology.

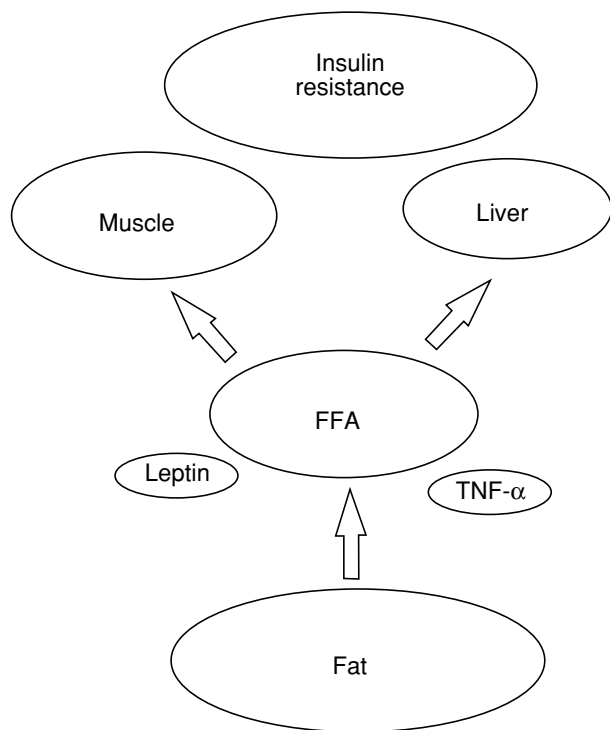

Figure 1 Proposed mechanism of obesity-induced insulin resistance. Excessive fat accumulation (obesity) is associated with increased plasma free fatty acid (FFA) levels that cause insulin resistance in skeletal muscle and in the liver. Other less likely mediators of obesity-induced insulin resistance are leptin and tumor necrosis factor- α (TNF- α).

elevated plasma FFA levels were followed (after a delay of several hours) by an increase in intramyocellular triglyceride concentration (IMCL-TG) suggested another explanation, namely that FFAs needed to enter muscle cells, be reesterified there, and accumulate as IMCL-TG before causing insulin resistance. There has been some progress in understanding how accumulation of IMCL-TG can interfere with insulin action. For instance, the FFA-mediated increase in IMCL-TG and the development of insulin resistance are accompanied by a several-fold increase in diacylglycerol (DAG) concentration and protein kinase C (PKC) activity in muscle (PKC β and δ in human muscle and ζ in rat muscle). DAG is likely to accumulate during triglyceride formation or breakdown and is a potent allosteric activator of PKC. PKC, on the other hand, is a serine/threonine kinase and has been shown to interfere with insulin signaling by serine phosphorylating the insulin receptor substrate 1 (which in turn will decrease tyrosine phosphorylation of IRS-1, causing insulin resistance). PKC, however, is probably not the only serine kinase activated by FFAs. A role for I κ B-

kinase (IKK- β), another serine kinase, was suggested by the recent demonstration that FFA-induced insulin resistance could be prevented in IKK- β knockout mice with high doses of acetyl-salicylic acid (an inhibitor of IKK).

FFAS: PUTATIVE PROMOTERS OF ATHEROSCLEROSIS

Acute increases of plasma FFAs also result in dramatic decreases of I κ B in human muscle. I κ B is the inhibitor of NF κ B. On phosphorylation (by IKK or perhaps by PKC), I κ B is released from NF κ B, ubiquitinated, and degraded. Detachment of its inhibitor frees NF κ B to translocate from the cytosol to the nucleus and to initiate transcription of several genes that have been linked to the onset of atherosclerosis. Thus, it appears that FFAs, and perhaps other substrates as well, may be able to cause both insulin resistance and atherosclerosis. This could provide part of the explanation for the well-established increase in atherosclerotic vascular diseases in insulin-resistant states.

FFAS AND INSULIN SECRETION

Acute elevations of plasma FFA concentrations have long been known to stimulate insulin secretion. Long-term effects, on the other hand, have remained somewhat controversial. Some studies with animal islets and isolated perfused pancreas have shown a biphasic effect of FFAs: initial stimulation of insulin secretion

Figure 2 Defects of glucose use produced by FFAs. The inhibition of carbohydrate (CHO) oxidation (defect 1) is the earliest demonstrable defect. It develops during the initial hour of lipid infusion but does not affect insulin-stimulated glucose uptake. The inhibition of glucose transport and/or phosphorylation (defect 2) develops after 2 to 4 h, whereas the inhibition of glycogen synthesis (defect 3) develops after 4 to 6 h of high plasma FFAs. E.C., extracellular; I.C., intracellular.

followed by inhibition after 24 to 48 h. Other *in vitro* studies, however, have shown the opposite, namely, potentiation of glucose-stimulated insulin secretion for as long as 72 h. In normal human subjects, FFAs potentiate glucose-stimulated insulin secretion for as long as 48 h. Moreover, acute suppression of basal FFAs decreases insulin secretion in nondiabetic and diabetic individuals, indicating that plasma FFAs support between 30 and 50% of basal insulin secretion. It has been suggested that high plasma FFA levels are lipotoxic. However, it is unlikely that physiological elevations of plasma FFA levels (<1.5 mmol/L) are lipotoxic to beta cells. If that were the case, one would expect that individuals with elevated plasma FFA levels (i.e., nearly all obese individuals) would develop type 2 diabetes when in fact only approximately 15 to 20% ever become diabetic. This argument is based on the following consideration. Given that increased plasma FFAs cause insulin resistance, either insulin or glucose concentrations, or both, need to increase to compensate for this resistance. Because compensation by hyperglycemia (i.e., diabetes) occurs in only 15 to 20% of individuals, it follows that FFA-mediated insulin resistance is compensated by FFA-mediated insulin secretion in the remaining majority.

FFA AND TYPE 2 DIABETES

In healthy individuals, FFA-mediated insulin resistance is matched quantitatively by FFA-induced stimulation of insulin secretion (Fig. 3). (For example, a 10%

Figure 3 Proposed role of free fatty acids (FFA) in the development of type 2 diabetes. In obese individuals with a genetic predisposition for development of type 2 diabetes (e.g., first-degree relatives of patients with type 2 diabetes), high plasma levels of FFAs cause insulin resistance (indicated by heavy black lines) that cannot be completely compensated by increased insulin secretion (indicated by broken lines). Plasma glucose levels will increase as a result of the partially uncompensated insulin resistance. The resulting hyperglycemia will increase glucose uptake by mass effect and by enhancing insulin secretion.

increase in insulin resistance is associated with a 10 to 15% increase in insulin secretion. The slightly greater degree of insulin secretion than insulin resistance is needed because of the hyperbolic relationship between insulin resistance and insulin secretion.) Because of the perfect match between FFA-mediated insulin resistance and insulin secretion, there is no need for blood glucose to rise. Pre-diabetic individuals (e.g., first-degree relatives of patients with type 2 diabetes mellitus) might not be able to compensate adequately because of impaired insulin secretory responses to FFA. (In patients with overt type 2 diabetes mellitus, deficient insulin secretory responses to FFA have been demonstrated.) Thus, in obese pre-diabetic individuals, increased plasma FFA levels may add another burden of insulin resistance to an already weakened beta cell system, accelerating its breakdown and the development of hyperglycemia.

PHYSIOLOGICAL AND PATHOPHYSIOLOGICAL CONSIDERATIONS

The FFA-associated peripheral and hepatic insulin resistance can have important physiological functions. For instance, during starvation, rising plasma FFAs produce peripheral insulin resistance that preserves precious carbohydrate resources for oxidation by the central nervous system. The rise in FFAs, caused by an increased maternal fat deposition during the early part of pregnancy and by increased plasma levels of lipolytic gestational hormones, results in insulin resistance of the mother and preserves carbohydrates for the growing fetus. In obesity, on the other hand, the FFA-induced insulin resistance becomes counterproductive because there is no need to spare glucose. Moreover, the chronic insulin resistance of obesity is associated with several cardiovascular risk factors, including hypertension, dyslipidemia, abnormal blood coagulation, and fibrinolysis. FFA-mediated activation of the $I\kappa B/NF\kappa B$ pathway may be one connection between FFA-induced insulin resistance and these cardiovascular risk factors.

pulsatile release of PGF into uterine venous blood. A countercurrent transport mechanism between the uterine vein and the ovarian artery ensures efficient movement of PGF from the uterine vein to the ovarian artery and, hence, to the CL. PGF then triggers the release of additional amounts of oxytocin from the CL, which in turn heightens the amplitude of PGF pulses. The sequel to this positive feedback loop is prolonged high-amplitude pulses of PGF and functional and structural loss of the integrity of the CL.

SIMILARITIES AND DIFFERENCES BETWEEN THE IFN- τ AND RELATED IFNS

IFNs were discovered because of their abilities to protect cells from viral infection. There are two kinds. IFN- γ is a dimeric protein with two identical subunits of approximately 146 amino acids and is unrelated to the type I IFN to which the IFN- τ belongs. IFN- γ is an inflammatory cytokine produced mainly by immune cells but also, curiously, by the pig trophoblast, where its function remains unknown. The type I IFNs are an extensive grouping of related genes found throughout vertebrates and include the IFN- α , - β , - ω , - κ , and - δ as well as the IFN- τ . Many subtypes, including the IFN- τ , are represented by multiple genes. The three-dimensional structure of their proteins is based on a bundle of five α -helices. The hallmark of the entire grouping is their potent antiviral activity, which is usually evident in the picomolar range of concentrations, but they usually also possess antiproliferative and complex immunomodulatory properties. Subtle variations in properties, which have been widely documented, are likely based on the manner in which each IFN interacts with the two subunits of the common receptor and activates the intracellular signal transduction system.

Table I lists some of the properties that the IFN- τ has in common with other type I IFNs where comparisons have been made. Importantly, there is as yet no evidence that the IFN- τ is superior in this regard. Where the IFN- τ differs from the IFN- α , - β , and - ω , in particular, is in the lack of inducibility of its genes in response to virus, its localized expression in one epithelial cell layer (trophectoderm), and its very high rate of production over a few days of conceptus development. It is likely that what sets the IFN- τ apart and has provided it with the status of a hormone of pregnancy is its presence in the appropriate place, in the required amounts and at the correct time, to prevent CL regression. As a general rule, *cis*-regulatory

elements of genes govern expression patterns in space and over time. What makes the IFN- τ uniquely different from other IFNs, therefore, is likely to be embedded in the control elements of its genes.

EVOLUTION OF THE IFN- τ AND ITS PROMOTER ELEMENTS

Based on base substitution rates, the first IFN- τ gene, *IFNT*, originated by a single duplication from an IFN- ω , *IFNW*, some 36 million years ago in the lineage leading to the current cattle, deer, giraffes, and their relatives. As a consequence, these genes do not occur, nor are they necessary components of the pregnancy recognition systems that are encountered, outside of the ruminant, even-toed ungulates. The duplication event that provided the progenitor *IFNT* was either accompanied by or closely followed by changes in the promoter regions of the gene that led to expression in the trophectoderm. The initial alteration in the promoter was presumably followed by selection of additional mutations that provided the current genes with the proper combination of *cis*-regulatory elements to drive high rates of transcription within the trophectoderm. Certainly, the *IFNT* genes do not possess well-organized viral response elements comparable to those found in IFN- α and - β genes, and their promoter regions diverge markedly in overall sequence from those of their close relatives, the *IFNW* genes.

Two regions of the promoter unique to *IFNT* have been inferred to be important for expression in the trophectoderm. One is a distal A/T-rich element situated approximately -358 to -322 bp from the transcription start site, which has not been studied in detail, and the other is a complex Ets-2/AP1-binding site in the proximal region (-91 to -69) of the promoter. Neither element is encountered in the *IFNW*. The transcription factor Ets-2 strongly transactivates *IFNT* promoters through the proximal

site, whereas mutation of the Ets-2 *cis*-element blocks transcription.

IFNT expression is detectable but low at the blastocyst stage of bovine embryo development, but it increases markedly *in vivo* a few days later, coincident with the elongation of the conceptus and steeply rising progesterone concentrations in the mother. Expression then begins to fall as the trophoctoderm cells attach to the uterine wall. Little is known about the underlying causes of these changes, although the initial up-regulation may be driven by maternal factors present in uterine secretions.

The author has argued previously that the emergence of the *IFNT* in the pecoran ruminants and of contrasting systems in other groups of mammals for maintaining the life span of the CL is the result of intense genetic conflict at the trophoblast–maternal interface. There is insufficient space to discuss the arguments here. Nevertheless, it seems likely that the progenitor *IFNT* gene was, at its birth, a minor player in the mix of mechanisms used to combat transmission of pathogens to the fetus. The elevation of the IFN- τ to an essential placental hormone must have coincided with the gradual acquisition of powerful trophoblast-specific enhancer elements in its genes. This unique mechanism for trophoblast signaling appears to have evolved hand in hand with the unique synepitheliochorial placentation of the ruminants.

INTERFERON- α AND THE ENDOCRINE SYSTEM

Previous studies indicated that the action of IFN- α requires its binding to specific receptors on the cell surface. This binding may share sites common to those of peptide hormones such as adrenocorticotropin hormone (ACTH) and thyroid-stimulating hormone (TSH). The elevation and detection of ACTH and endorphin-like substances from lymphocytes infected with the Newcastle disease virus (NDV) were the first demonstration that the immune system is capable of producing peptides that can signal the neuroendocrine system. Cells of the immune system communicate with each other through direct contact and through secreted cytokines. However, production of cytokines is not restricted to immune cells. Cytokines, including IFN- α , are also produced in the brain. They exert direct effects on the brain and endocrine organs, and they cause the production and secretion of ACTH by inducing the corticotropin-releasing factor (CRF). Intracerebroventricular (i.c.v.) injection of IFN- α decreases the plasma level of glucocorticoid, which can be prevented by naloxone pretreatment. Moreover, i.c.v. injection of CRF and CRF antagonist has been reported to mimic and block, respectively, the IFN- α -induced suppression of splenic NK activity. These results suggest that IFN- α in the brain activates the CRF system through central opioid receptors and thereby suppresses NK cytotoxicity predominantly through splenic sympathetic innervation.

Both clinical observations and experimental studies in the laboratory have demonstrated a stimulative effect of IFN- α on adrenocortical secretion. In addition, sequential similarities among human leukocyte IFN- α , ACTH, and melanotropic-stimulating hormone (MSH) have been observed. These structural similarities may explain the presence of common functional characteristics found between immunological activity and MSH-ACTH-like activity of a pepsin-derived peptide of IFN- α . The proposed homology between MSH-ACTH and human leukocyte IFN- α is consistent with many research findings and would explain the observed cross-reactivity between MSH-ACTH antisera and human leukocyte IFN- α .

It has been shown that systematic (i.e., intraperitoneal [i.p.]), central (i.c.v.), and local administration of IFN- α within the hypothalamic paraventricular nucleus (PVN) elicited both acute and chronic suppression of hypothalamus-pituitary-adrenocortical secretion in the rat. In view of the inhibitory effects of glucocorticoid hormones on immune activity, this

suggests that IFN- α may exert positive feedback effects on its own immunopotentiating activity by decreasing adrenocortical secretion. In another study, the preceding observations were confirmed by demonstrating that adrenocortical activity was inhibited following hybrid recombinant human IFN- α preparation. It was also shown that IFN- α decreased the electrical activity of electrophysiologically identified neurosecretory PVN neurons. These PVN neurons project to the median eminence that regulates the adrenocortical secretion; that is, IFN- α participates in the regulation of adrenocortical secretion.

The endocrine system, the immune system, and the CNS are affected by psychological factors, including stress and mental illnesses, that can lead to altered immunocompetence and incidence of disease. Two mechanisms have been proposed to explain this phenomenon: (1) an indirect neuroendocrine communication mediated by the secretion of glucocorticoid and/or other hormones that regulate the production and secretion of IFN- α and (2) a direct neural influence on the endocrine and immune systems mediated by the autonomic and central nervous systems. In turn, activation of the endocrine system, the immune system, and IFN- α generates signals that alter CNS neural activity and modulate neuroendocrine secretory events, thereby providing feedback regulation of immune activity.

EFFECT OF INTERFERON- α ON OTHER SYSTEMS

IFN- α was given to healthy human volunteers, resulting in the slowing down of CNS activity, as assessed by increased reaction time to stimuli presented at random intervals. In rodents, IFN- α injections depressed open-field activity and caused weight loss. The brain areas participating in feeding behavior are thought to be in the hypothalamus. IFN- α may reach high concentrations in the pons and hypothalamus, where the BBB is more permeable. IFN therapy elicits sensory and motor disorders, fever, anorexia, confusion, depression, and sleep disorder. From these reports, it is apparent that IFN- α has remarkable effects on the endocrine system, the immune system, the CNS in general, and the hypothalamus in particular as well as on sites of the somatosensory, motor system, and limbic system. It has been suggested that IFN- α is one of the messengers responsible for the bidirectional communication that links both the immune and endocrine systems with the CNS.

Thermoregulation

Fever is initiated as a result of the activation of thermosensitive neurons located mainly in the preoptic/anterior hypothalamus (PO/AH) area by unknown mechanisms. When IFN- α is intravenously (i.v.) or i.c.v. injected in rabbits, cats, and mice, it produces fever that does not involve production of the endogenous pyrogenic substance interleukin-1 (IL-1). Therefore, IFN- α has also been identified as an endogenous pyrogen. The PO/AH area is suggested as the most probable site of pyrogenic actions. IFN- α is believed to modulate the thermosensitive neuronal activity in the PO/AH neurons by decreasing the neuronal activity of warm sensitive neurons while increasing the activity of cold sensitive neurons. The same IFN- α doses had no effect on thermally insensitive neurons. The effects of IFN- α on the thermosensitive neurons were blocked by the opiate antagonist naloxone but were not blocked by a dose of sodium salicylate (an antipyrogen agent), which had effectively blocked the neuronal responses to endotoxin and leukocytic pyrogen. The fever induced by IFN- α injection may be explained in part by the effects of IFN- α on PO/AH thermosensitive neurons that involved the opiate receptor mechanism. It appears that IFN- α in the brain may affect the activity of PO/AH neurons and produce fever by a two-step mechanism. The first step involves the immediate action on the opioid receptors. The second step consists of the release of prostaglandins. Another study that investigated the effects of IFN- α on the phenomenon of morphine-induced hypothermia found that IFN- α prevented the development of tolerance to the hypothermic effects caused by morphine.

Appetite Regulation

Appetite regulation is a profoundly complex process that involves the endocrine system and the CNS via an endogenous metabolite that regulates food intake. The major CNS sites participating in the control of food intake are thought to be the lateral hypothalamus (LH), the PVN, and the ventromedial hypothalamus (VMH). It has been suggested that the VMH is a "satiety center" responsible for producing the sensation of fullness, whereas the LH is a "feeding center" involved in initiating food intake. The hypothalamus also acts as a neuroendocrine transducer site in relation to the control of food intake, involving a balance between a number of neuropeptides and neurotransmitters. Together, these sites are also known to contain neurons that sense endogenous metabolic parameters, such as glucose, and participate

in the control of food intake as well as in energy balance.

In general, IFN- α therapy was shown to elicit anorexia that resulted in the loss of more than 15% of the patients' body weight. A similar decrease in food intake following IFN- α treatment was found in animals. Specifically, IFN- α -induced feeding suppression may involve excitation of glucose-sensitive neurons in the VMH and decreased neuronal activity in glucose-sensitive LH neurons (considered a "hunger center"). A study investigated whether the loss of appetite, one of the major side effects of IFN- α therapy, is mediated by the operation of IFN- α on LH neurons. The investigators used central (i.c.v.) and systemic (i.p.) IFN- α application and simultaneously recorded LH neuronal activity and food intake in conscious rats treated for 3 weeks with IFN- α . In therapeutic doses, IFN- α elicited a reversible dose-related decrease of both food intake and body weight. The decrease in food intake following IFN- α injections was correlated with a depression of LH neuronal electrical activity. Because direct brain application (i.c.v.) and systemic (i.p.) IFN- α treatment caused identical responses, it is postulated that IFN- α suppresses food intake by a direct action on LH neurons. These results suggest that IFN- α , which is endogenously produced by the brain, is involved in the regulation of feeding.

Local application of IFN- α to identify glucose-responsive cells in the VMH was altered in appropriate ways to explain the cytokine-induced anorexia. Others have reported that microiontophoretic application of IFN- α produced both suppression and excitation in VMH neurons, depending on the dose, and suppression in the LH neurons. Similarly, opposing observations between LH and VMH, induced by morphine, have been reported. The reciprocal interaction between LH and VMH in mechanisms of hunger and satiety has been documented extensively; therefore, it is possible that IFN- α affects both VMH and LH in a reciprocal (push-pull) manner in regulating food intake. This agrees with the suggestion by some researchers that cytokine-induced suppression of food intake involves the excitation of glucose-sensitive excitatory neurons in the VMH and the inhibition of glucose-sensitive neurons in the LH. IFN- α elicited excitatory effects on some glucose-sensitive neurons that were stimulated by morphine and by endogenous opioid peptides. Furthermore, naloxone prevented the excitatory neuronal responses to microiontophoretic applications of IFN- α in the VMH recorded from electrophysiologically identified glucose-sensitive neurons.

Opioid System

The effects of opiate peptides on the secretion of IFNs and other cytokines have generally been described as stimulatory and bimodal. β -endorphin and Met-enkephalin increase the production of IFN- γ , whereas morphine suppresses release of IFN- γ . Similarities have been demonstrated among the structures of pro-opiomelanocortin, β -endorphin, and IFN- α that link IFN- α with opiates. Other evidence linking IFN- α with opiates is provided by experiments showing that lymphocytes stimulate IFN- α inducers to produce ACTH and endorphin-like substances. Opiates and ACTH exhibit similar antigenic reactions, suggesting that these peptides have some common structural properties as well as an affinity for ^3H -morphine-binding sites in mouse membranes obtained from the brain. IFN- α , but not IFN- β or IFN- γ , binds to opiate receptors and shares some pharmacological properties of opiates such as production of analgesia, reduction in motor activity, and catatonia. These effects are reversed or prevented by the opiate antagonist naloxone.

Interaction between IFN- α and morphine has been demonstrated with single injections of morphine in mice that reduced the level of serum IFN- α induced by poly I:C or endotoxin. Moreover, the opiate antagonist naloxone, when given prior to IFN- α treatment, prevents the analgesia and catatonic behavior produced by IFN- α given alone. This evidence suggests that the effects of IFN- α on CNS activity are mediated via a number of different mechanisms, some of which may be antagonized by naloxone. To test the possibility of whether IFN- α exerts its effects via opiate receptors, electrophysiological recordings were made from two preparations: (1) the guinea pig ileum and (2) several neurophysiological procedures (evoked field potentials and single-cell recording) from different brain areas. In the neurophysiological experiment using single-unit recording, IFN- α elicited excitation in cortical neurons and in many VMH neurons. However, in some of VMH cells, IFN- α elicited the opposite effect; that is, it decreased the firing rates of these cells. Naloxone failed to antagonize the IFN- α -induced excitation but was able to antagonize the IFN- α -induced inhibition. This observation suggests that IFN- α action on these two preparations might be mediated not via opiate receptors but rather via IFN- α receptors. However, not all possibilities were tested in these experiments. In brain slice preparation, IFN- α elicited both an increase and a decrease in the firing rate recorded from the anterior hypothalamus (AH) and VMH, respectively. Both responses were blocked

by naloxone. These studies suggest that there are at least three different functional and/or receptor sites for IFN- α within the CNS: (1) an inhibitory site where IFN- α produces reduction in the neuronal activity and naloxone reverses the IFN- α effects that may be mediated by the μ -receptor type, (2) an excitatory site where IFN- α produces excitation in the neuronal activity that the opiate antagonist naloxone reverses (i.e., a naloxone-dependent site) and may represent the kappa or delta receptor sites, and (3) an excitatory site where IFN- α produces excitation in the neuronal activity that is not antagonized by naloxone.

CLINICAL UTILITIES OF INTERFERONS

Interferon- α

IFN- α administered subcutaneously (s.c.) has demonstrated a surprisingly wide range of efficacy in hematological malignancies, including tumors of presumed B-cell, T-cell, and myeloid lineages. In some diseases, such as hairy cell leukemia and chronic myelogenous leukemia, IFN- α is broadly effective.

Kaposi's Sarcoma

High-dose (27–36 MU) human recombinant IFN- α -2a every day (q.d.) achieved a major response in 12 of the 26 evaluable Kaposi's sarcoma (KS) patients, with 5 of these showing histologically confirmed complete responses with dose and blood levels important factors in responses. The addition of zidovudine in AIDS-associated KS is sometimes efficacious.

Lymphoma

IFN- α -2b plus chlorambucil is superior to chlorambucil alone in advanced follicular lymphoma and low-grade lymphoma. IFN maintenance therapy in diffuse large cell lymphoma improves duration of complete remission and survival and prolongs remission after fludarabine monophosphate therapy in low-grade non-Hodgkin's lymphoma. However, IFN- α as maintenance therapy is not useful in aggressive malignant lymphoma when more intensive chemotherapy (CHOP-BLEO regimens) has been employed during induction.

Polycythemia Vera

IFN- α is superior to phlebotomy in controlling the pathological expansion of erythroid elements and all of the clinical aspects of polycythemia vera (PCV), and it corrects peripheral thrombocytosis in essential thrombocythemia.

Chronic Myelogenous Leukemia

IFN- α has significant activity in chronic myelogenous leukemia (CML), with best results at dosages of 5 M IU/m²/day. Early-stage, Philadelphia + CML, hematological response rates are 70 to 80%, and cytogenetic response rates are 50% (approximately 20% of which are complete). IFN- α -2a daily continuously and intermittent low-dose cytosine arabinoside (Ara-C) are superior to the results using IFN alone in CML. IFN also effectively treats CML relapse during the chronic phase after bone marrow transplantation. Cytoreductive/myeloablative treatment followed by unmanipulated peripheral blood stem cell transplantation and low-dose IFN- α can result in long-term survival in newly diagnosed CML patients.

Hairy Cell Leukemia

IFN- α , by its direct action on hairy cells, has been shown to be extraordinarily effective with doses as low as 150,000 to 500,000 IU/m²/day, sufficient to maximize biomarker neopterin levels.

Virus Infections

IFN- α acts too slowly to arrest acute viral infections, but IFN- α has proved to be useful in some chronic viral infections. Some patients form neutralizing antibodies that block the effects of the IFN; these appear to be relatively more common after recombinant IFN- α -2 than after IFN derived from human cells.

Hepatitis C

In randomized controlled trials using s.c. IFN, 3 MU IFN- α -2b three times per week (t.i.w.) normalized ALT levels and eliminated hepatitis C virus (HCV) RNA in 53% of the treated and none of the untreated patients. Comparing recombinant IFN- α -2a with no treatment, 20 treated cases (66.7%) normalized serum aminotransferase levels within the first 4 months of treatment, compared with 1 case in the untreated group. However, reactivation or breakthrough frequently occurred afterward (20% in both cases). Reinforced regimens (6 MU q.d. \times 12 days, 6 MU t.i.w. \times 22 weeks, 3 MU t.i.w. \times 24 weeks) as opposed to standard regimens (3 MU t.i.w. \times 24 weeks) produced sustained response (ALT normalization) in a limited number (18%) of previously untreated patients and reduced the risk of cirrhosis (1%) after 18 months. In patients with compensated HCV-related cirrhosis, IFN- α -2b 3 M IU t.i.w. showed biochemical response in 6 of 47 treated patients and 0 of 39 control patients. However, a 48-week course of IFN therapy usually fails to achieve sustained response and did not significantly improve the 3-year outcome. Serum

HCV RNA is better than ALT at predicting long-term cure after IFN- α therapy in chronic HCV. Pegylated IFN- α -2b provides a higher virological response in patients infected with genotype 1. In patients with chronic HCV, once-weekly peginterferon α -2a plus ribavirin was tolerated, as was IFN- α -2b plus ribavirin, and produced significant improvements in the rate of sustained virological response, as compared with IFN- α -2b plus ribavirin or peginterferon α -2a alone. Certain features of HCV infections predict success or failure of IFN therapy. Clinical and serum biochemical response to IFN- α in chronic HCV is associated with a loss of detectable HCV genome from serum. Short-term and sustained responses were predicted independently by lobular structure on pretreatment liver biopsy and by short disease duration. IFN does not seem to affect overall or event-free survival of patients with HCV-related cirrhosis, whereas it seems to prevent the development of hepatocellular carcinoma.

Hepatitis B

In a randomized controlled trial, IFN- α -2a (10 M IU/m² t.i.w. \times 6 months) was significantly better than no treatment in producing a sustained loss of HBeAg in hepatitis B virus (HBV) chronic carriers. A total of 10 of 31 (32%) 4-month-treated patients and only 1 of 14 (7%) control patients became negative for serum HBV DNA/DNAp, which can induce remission in approximately one-third of chronic HBV patients. In addition, 5 M IU recombinant IFN- α -2b for 12 weeks decreased viral replication and tripled the spontaneous seroconversion rate observed in chronic HBV/active viral replication patients. However, IFN- α therapy induces HBeAg seroconversion in only approximately one-third of patients, leaving the majority of patients with persistent disease. However, data from three previously published multicenter, randomized, controlled trials were insufficient to establish a presumed beneficial effect of IFN- α -2a on disease progression and survival.

Multiple Sclerosis

Recently, high-dose recombinant IFN- α -2a (9 M IU intramuscular [i.m.] every other day [q.o.d.]) reduced the relapse rate by 83% and active magnetic resonance imaging (MRI) scans over 6 months. However, attack rates rapidly returned to pretreatment values when therapy was stopped. The apparent difference between the results of this small but well-conducted Italian study and prior studies with IFN- α in multiple sclerosis (MS) relate to IFN dose used in earlier trials (1 M IU nIFN- α s.c. q.d.; 3 M IU nIFN- α s.c. twice

weekly [t.i.d.] for 2 months and then weekly; 2 M IU recombinant IFN- α -2 s.c. t.i.w., differences in trial design, or the selection of more severely affected patients with SP MS).

Interferon- β

The use of IFN- β has been largely confined to MS. A phase III study in RRMS showed that 8 M IU of recombinant IFN- β -1b (Betaseron) s.c. q.o.d. decreases attacks by 30% and decreases brain inflammation as assessed by serial quantitative MRI. Another phase III clinical trial using recombinant IFN- β -1a (6M IU weekly i.m. [30 μ g Avonex]) showed a 38% reduction in the proportion showing progression, an 18% reduction in relapse rate, and a 33% reduction in average number of active (gadolinium [Gd]-enhancing) lesions on MRI. Patients receiving IFN- β -1a (Rebif) (22 or 44 μ g t.i.w. s.c.) in a phase III study had reduced relapse rates for 4 years with reduced new T2 lesion number and lesion burden. However, 6 to 40% of IFN- β -treated patients generate neutralizing antibodies in those patients who appear to lose both clinical benefits and MRI-defined responses.

Interferon- γ

Immune IFN- γ acts in the defense of the organism against foreign pathogens via cellular immunity mediated by macrophages. It is a product of T-helper 1 (Th1) cells that can modulate the function of Th2 lymphocytes. In general, the Th1 cytokines stimulate the body's cellular immunity in viral infections. INF- γ is potentially antiviral, antibacterial, antiproliferative, antitumor, and antiallergic. However, the clinical use of s.c. IFN- γ has been relatively limited. INF- γ can decrease healing time by 50 to 60% in human papillomaviruses (*Condylomata acuminata*). It can clear the damage caused by refractory nontuberculous mycobacterium infection. There can be a beneficial effect of IFN- γ in chronic granulomatous disease. INF- γ is contraindicated in MS. In general, MS lymphocytes secrete excess amounts of IFN- γ .

CONCLUSION

INF- α produced in the brain exerts direct effects on the endocrine system by activating the neurosecretory hypothalamic neurons and regulates the hypothalamic-pituitary-adrenocortical axis by activating the CRF system via a positive feedback effect. INF- α injection produces fever and regulates thermosensitive

single PO/AH neurons. The effects of IFN- α on the thermosensitive neurons are prevented by naloxone. This suggests that IFN- α mediates the activity of PO/AH neurons and produces fever via opiate receptors and subsequently by prostaglandins release. INF- α injection activates the sympathetic nerves innervating components of the immune system, resulting in suppression of splenic NK cells' activity. Furthermore, using electroencephalogram (EEG), evoked potential and single-cell recording procedures demonstrate that IFN- α has a direct effect on neuronal populations as well as on hypothalamic single-cell activity. INF- α -induced suppression of feeding (anorexia) is correlated with IFN- α -induced excitation of VMH glucose-sensitive neurons and decreased activity in LH glucose-sensitive neurons. Therefore, IFN- α may serve as a regulatory mediator among the CNS, the endocrine system, and the immune system. Immunological therapy uses cytokines such as IFNs to treat various hematological malignancies and infectious ailments as well as autoimmune diseases. Overall, the IFNs, primarily IFN- α and IFN- β , have surprisingly wide applications in biology because of their pleotropic activities. New parenteral delivery systems that allow sustained serum levels, or novel delivery systems that avoid systemic side effects, may well increase the applicability of these interesting biological compounds.

Figure 1 Regulation of IL-2 production through TCR and CD28/CTLA-4 signaling.

Gads, Grb2, and SLP-76 to catalytic enzymes such as phospholipase $C\gamma 1$, phosphatidylinositol 3-kinase, and Vav. These enzymes activate calcineurin, protein kinase $C\theta$, ERK1/2, JNK, and other molecules, leading to further activation of a set of transcriptional factors, including nuclear factor of activated T cells, activator protein 1, and nuclear factor κB , which are involved in IL-2 promoter activation. In addition to these transcriptional regulators, stabilization of IL-2 mRNA is another important role of the second signal through CD28. This leads to greatly enhanced IL-2 production in the presence of the second signal. These activation signals also induce the expression of the CTLA-4 molecule, which is another B7 receptor with much higher affinity for the B7 molecule than CD28, on the activated T cell surface. Unlike CD28, CTLA-4 induces the T cell inactivation signal and down-regulates IL-2 production to limit the excess immune response. Clinically, the immunosuppressive drugs cyclosporin A and FK506 inhibit IL-2 production

by disrupting the TCR-induced signal cascade on calcineurin.

Interestingly, TCR signals in the absence of the second signal do not induce IL-2 production but instead lead to inactivation of the T cells, resulting in an anergic state.

INTERLEUKIN-2 RECEPTORS

Interleukin-2 receptor α (IL-2R α) chain (CD25), which was initially identified as IL-2R, is a type I membrane protein whose molecular weight is 55 kDa. The expression of the IL-2R α chain is tightly restricted to peripheral activated T and B cells, triple-negative thymocytes, and bone marrow pre-B cells. Whereas the IL-2R α chain itself has no signal-transducing activity, functional high-affinity IL-2R is composed of the IL-2R α chain and other two indispensable subunits, the IL-2R β chain and the IL-2R γ

Figure 2 Schematic structure of the IL-2 receptor complex on human peripheral blood cells. Two pairs of cysteine residues and WS motifs that are conserved in the cytokine receptor family are indicated as horizontal lines and shaded boxes, respectively.

chain (Fig. 2). IL-2R β chain (CD122) and IL-2R γ chain (CD132) are also type I membrane proteins of 75 and 64 kDa, respectively, and they belong to the cytokine receptor family, which is characterized by the presence of a cytokine receptor domain of approximately 210 amino acids in the extracellular region. This domain is separated by two homologous type III fibronectin subdomains. The first subdomain is characterized by the presence of two pairs of cysteine residues at the N-terminal part and the second subdomain has a consensus tryptophan-serine-X-tryptophan-serine motif (WS motif). Several patterns of IL-2 receptor complex and human peripheral blood cells expressing these receptors are shown in Fig. 2. Cytokine receptor family members are also characterized by the absence of intrinsic tyrosine kinase activity. Non-receptor-type tyrosine kinases Janus kinase 1 (JAK1) and JAK3 are associated with IL-2R β chain and IL-2R γ chain, respectively, and these PTKs trigger the IL-2-induced signaling cascade. Since the IL-2R γ chain was found to be shared with other cytokines, including IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21, it is called the common γ chain (γ c). Furthermore, mutations of the γ c gene cause human X-linked severe combined immunodeficiency, which is characterized by a complete or profound T and NK cell defect.

BIOLOGICAL ACTIVITIES OF INTERLEUKIN-2

IL-2 was identified as a growth factor for T cells activated by antigens and its biological functions have been extensively investigated. IL-2 is a survival factor of activated T cells and acts by inducing the expression of anti-apoptotic proteins, such as Bcl-2 and Bcl-X_L. In addition to its growth promotion and survival factor functions, IL-2 induces CTL activation and differentiation. In addition to its effects on T cells, IL-2 can promote the growth and differentiation of activated B cells. During B cell differentiation, IL-2 is involved in the regulation of immunoglobulin J-chain expression. IL-2 also augments the cytolytic activity of NK cells.

Previous reports have shown a different dimension to IL-2. Negative actions of IL-2 on T cells, such as an induction of activation-induced cell death (AICD), have been demonstrated. Indeed, mice with defective IL-2 or a functional IL-2R complex do not show signs of immunodeficiency. However, an accumulation of hyperactivated T cells was observed and various autoimmune diseases developed in these mice. Thus, the major role of IL-2 *in vivo* is thought to be the termination of T cell responses and maintenance of tolerance

by inducing AICD, leading to the homeostasis of T lymphocytes.

THERAPEUTIC USE OF INTERLEUKIN-2

Human PBL treated with IL-2 *in vitro* show cytotoxic activity against some tumor cells. These MHC-independent cytotoxic cells are called LAK cells. Furthermore, IL-2-activated tumor-infiltrating lymphocytes (TIL) from human tumors seem to have more a potent killing activity against autologous tumors *in vitro* than LAK cells. In some cases of advanced metastatic melanoma and renal cell carcinoma, high-dose IL-2 therapy, with or without adoptive immunotherapy using LAK, TIL, or chemotherapy, is effective at regressing tumor growth. However, further clinical trials are required to improve survival rates and the toxicities accompanying high-dose IL-2 treatment.

In addition to clinical research on IL-2 treatment for malignant tumors, clinical trials using IL-2 as adjunctive therapy with highly active antiretroviral therapy (HAART) against human immunodeficiency virus (HIV)-infected patients is under way.

Immune-based therapy with IL-2 combined with HAART increased CD4⁺ T cell counts, leading to improved immune responses, and it is hoped that it may improve the clinical symptoms and survival of HIV-infected patients.

human AF372214, mouse M20572) (see also Table I). Several potential transcriptional control elements, glucocorticoid-responsive element (GRE), an AP-1 binding site, multiple response element (MRE), a *c-fos* serum-responsive element (*c-fos* SRE) homology, a *c-fos* retinoblastoma control element (RCE) homology, a cyclic AMP (camp)-responsive element (CRE), a nuclear factor for IL-6 (NF-IL6, also known as CCAAT/enhancer-binding protein β [C/EBP β] binding site), and an NF- κ B-binding site, were identified within the IL-6 promoter region. Several polymorphisms within IL-6 gene and its promoter region have been reported. One of these, -174C/G promoter region polymorphism, is suggested to associate with serum level IL-6 concentration and pathogenesis of some diseases such as rheumatoid arthritis and human immunodeficiency virus-dependent Kaposi's sarcoma.

RECEPTOR FOR IL-6 AND SIGNALS

Receptors for IL-6 Family Cytokines

The IL-6 receptor consists of an α chain (IL-6R α) (CD126) and gp130 (CD130) (Fig. 2). Extensive mutagenesis studies revealed that IL-6 has three distinct receptor-binding sites referred to as sites 1, 2, and 3. Site 1 is important for the binding of IL-6R α . Sites 2 and 3 are used for recruitment of gp130. Both IL-6R α and gp130 are required for the high-affinity binding site for IL-6. IL-6 family cytokines, including IL-11, LIF, CNTF, cardiotropin-1 (CT-1), OSM, and cardiotropin-like cytokine/neurotrophin-1/B-cell stimulatory factor-3 (CLC/NNT-1/BSF-3), share gp130 as a signal-transducing subunit for the receptor complex (Fig. 2). Functional redundancy is one of the characteristic features of cytokines. For example, IL-6, LIF, and IL-11 can induce acute phase protein production in hepatic cells or the differentiation of the mouse leukemic cell line M1. Sharing the common signal transducer gp130 is one of the mechanisms through which the functional redundancy of the IL-6 family cytokines is mediated. The binding of IL-6 family cytokines leads to the homodimerization of gp130 or the heterodimerization of gp130 with other gp130-related receptors (i.e., the LIF receptor and the OSM receptor). IL-6R α , IL-11R α , CNTFR α , and cytokine-like factor-1 (CLF) are not thought to transmit signals given that they have very few or no amino acid residues in their cytoplasmic domains.

Receptor Conversion Model

A soluble form of cytokine receptors often functions as a competitive inhibitor for the ligand. However, sIL-6R α (soluble form of IL-6R α , which can be released

Figure 2 Illustration showing that gp130 is a common signal transducer for IL-6 family cytokines. Receptor complexes of IL-6 family cytokines consist of specific α chain (IL-6R α , IL-11R α , CNTFR α , and CT-1R α) and β chain (gp130, LIFR, and OSMR), which mediates signaling. Individual domains of extracellular regions of receptors are presented as globular drawings. The binding of IL-6 to the receptor induces the formation of hexameric ligand–receptor complex composed of two each of IL-6, IL-6R α , and gp130. Precise stoichiometry for other cytokines are not well studied. CT-1R α has not yet been identified. m, mouse; h, human.

by receptor shedding or secretion after translation of an alternatively spliced mRNA), when complexed with IL-6, can activate signals in the cells expressing only gp130 receptor subunit on which IL-6 alone cannot act. CLF was found as a secreted protein; therefore, it was considered as a ligand rather than as a receptor. However, CLF can form a complex with CLC/NNT-1/BSF-3 and acts as a ligand to signals through CNTFR α , LIFR, and gp130. This system shows a striking similarity to that of IL-12 (Fig. 3). IL-12 consists of a disulfide heterodimer of a 35-kDa (p35) subunit, which is a cytokine, and a 40-kDa (p40) subunit, which is a soluble form of the cytokine receptor. Therefore, IL-12, generally accepted as a kind of cytokine, is actually a complex of a cytokine and a soluble form of its receptor. Thus, in certain cases of cytokine and receptors, the complex of soluble form of cytokine receptor and its ligand acts as a novel cytokine.

gp130 and Signaling Molecules

gp130 is a single transmembrane glycoprotein with a molecular mass of 130 to 150 kDa. Based on the presence of conserved domains, gp130 is defined as belonging to the type I cytokine receptor superfamily. The other receptors for the IL-6 family cytokines, including the IL-6R α chain, all belong to the type I

cytokine receptor superfamily, with the exception of CNTFR α , which is a GPI-anchored receptor. In its intracellular region, gp130 contains regions known as box1 (I⁶⁵¹WPNVDP of human sequence) and box2 (V⁶⁹¹SVVEIEANDKKP), which are conserved among the members of the type I cytokine receptor superfamily (Fig. 2). The homodimerization or heterodimerization of gp130 results in the activation of the gp130-associated JAKs (JAK1, JAK2, and TYK2) through these two regions. Subsequently, gp130 is phosphorylated on tyrosines and the phosphorylated gp130 recruits signal-transducing molecules, such as SHP2 and STAT3, and activates them to transmit signals downstream (Fig. 4).

Any one of four tyrosines (Y767, Y814, Y905, or Y915) of gp130, each of which has a glutamine at position +3 of the tyrosine motif (YXXQ), is required for the tyrosine phosphorylation of STAT3. Y905 and Y915 in the YXPQ motif are required for the tyrosine phosphorylation of STAT1. After tyrosine phosphorylation, STAT3 forms a homo- or heterodimer with STAT1, enters the nucleus, and regulates the expression of a set of genes.

On stimulation of gp130, SHP2 is tyrosine phosphorylated and interacts with Grb2, which is constitutively associated with Sos, a GDP–GTP exchanger for Ras. Gab family proteins are tyrosine phosphorylated and interact with SHP2 and PI-3 kinase in

Figure 3 Illustration of ligand-receptor system of IL-12 resembling that of IL-6, CNTF, and CLC/NNT-1/BSF-3. IL-12 is a heterodimer of 70 kDa, consisting of disulfid linked subunits of p35 and p40. p35 is significantly homologous to IL-6 and is predicted to have bundled four α -helices structure. p40 is homologous to CNTFR α and IL-6R α . IL-12R β 1 and IL-12R β 2, which contain conserved cysteine sequences, WSXWS motifs, and box1 and box2 motifs, are closely related to gp130 and LIFR.

response to gp130 stimulation. A mutation of tyrosine759 of gp130 reduces the interactions between SHP2 and Grb2 and between SHP2 and Gab1 and

diminishes the activation of ERK MAP kinase, suggesting that SHP2 mediates signals to the ERK MAP kinases through Grb2 and the Gab proteins.

Figure 4 Schematic representation of IL-6 signaling. Distinct tyrosine residues of gp130 are involved in different signal transduction pathways. Y759 elicits SHP2-mediated pathways, whereas Y767, Y814, Y905, and Y914 each can elicit STAT3-mediated pathways. Y759 was also shown to interact with SOCS3. SHP2, MAPK, SOCS, and PIAS proteins were shown to be involved in negative regulation of signals.

STAT3 is required for the induction of SOCS1 and SOCS3 expression in gp130 signaling. Members of the suppressor of cytokine signaling (SOCS) family, also referred to as JAK binding (JAB) and as STAT-induced STAT inhibitor (SSI), are characterized by a conserved SOCS box and an SH2 domain. SOCS3 may act as a negative regulator by interacting with gp130 directly, whereas SOCS1 inhibits the signaling by interacting with JAKs. Mutating tyrosine 759 of gp130 resulted in enhancement of gp130-mediated signaling both *in vivo* and *in vitro*, suggesting that SOCS3, in addition to SHP2, is involved in the tyrosine 759-dependent negative regulation of gp130 signaling.

An Src family tyrosine kinase, Hck, associates with an acidic region of gp130. Protein inhibitor of activated STAT3 (PIAS3) interacts directly with phosphorylated STAT3 and reduces its DNA-binding activity, thereby inhibiting the transcription of its target genes.

BIOLOGICAL FUNCTIONS OF IL-6

Biological Functions Observed *in Vitro*

IL-6 was identified as one of the factors acting on B cells to induce immunoglobulin production. Besides its role in inducing B-cell differentiation, IL-6 induces T-cell growth and differentiation, differentiation of the myeloid leukemic cell line M1 into macrophages, megakaryocyte maturation, neural differentiation of PC12 cells, development of osteoclasts, and acute phase protein synthesis in hepatocytes. IL-6 acts as a growth factor for myeloma/plasmacytoma, keratinocytes, mesangial cells, renal cell carcinoma, and Kaposi's sarcoma. STAT3 signaling plays a central role in several biological functions of the IL-6 family cytokine.

Acute Phase Response *in Vivo*

A large body of work using transgenic and knockout mice has addressed the *in vivo* functions of IL-6 family cytokines (Table II). These experiments confirmed some of the biological functions of IL-6 observed *in vitro*. For example, IL-6-deficient mice showed impaired acute phase response. This result clearly demonstrated the importance of IL-6 in acute phase response. Furthermore, blocking the individual signals elicited from gp130 by the knock-in technique showed that STAT3 plays the central role in acute phase response and that SHP2 negatively regulates it.

Immune Responses *in Vivo*

The significance of IL-6 in B-cell development was implicated in experiments *in vitro*. IL-6 transgenic mice of C57BL/6 origin develop massive plasmacytosis. Abnormal B-cell expansion was also observed in the IL-6 and sIL-6R α double transgenic mice. All of these data confirmed the importance of IL-6 in B-cell development. Because gp130 is involved in both cell growth and the differentiation of B cells into plasma cells through STAT3 activation, chronic B-cell activation by deregulated IL-6 expression may be one of the major pathogenesises of these diseases. In support of these observations, IL-6-deficient mice showed impaired antigen-specific antibody production and mucosal immunoglobulin A (IgA) production. IL-6-deficient mice also display dysfunction in diverse systems (e.g., type 1 helper T-cell [Th1] development) and protection against *Listeria monocytogenes* and *Mycobacterium tuberculosis*.

Hematopoiesis

IL-6 and some colony-stimulating factors, such as IL-3, M-CSF, and GM-CSF, synergistically promote the growth of hematopoietic progenitor cells *in vitro*. Consistently, IL-6-deficient mice showed decreased number of hematopoietic progenitor cells by testing *in vivo* spleen colony-forming assays (Table II). IL-6 induces the *in vitro* megakaryopoiesis synergistically with IL-3. The observations that IL-6-deficient mice had reduced megakaryocyte progenitor cells and that IL-6 transgenic mice had increased mature megakaryocytes support *in vitro* results.

Bone Metabolism

Osteoporosis is a major cause of morbidity in older people. A decrease in sex hormones with aging is suggested to contribute the age-related increase of IL-6 and to stimulate osteoclastic bone resorption. In the presence of dexamethasone, IL-6 could induce osteoclast formation *in vitro*, suggesting that the increase of bone resorption caused by estrogen withdrawal may be explained by an effect of IL-6. The finding that IL-6-deficient mice are resistant to bone loss induced by ovariectomy supports this view.

Effects on Nervous System

Central nervous system (CNS) cells express both IL-6 and IL-6R α . To demonstrate the role of IL-6 in CNS, transgenic mice expressing IL-6 in CNS

Table II Phenotypes of Knockout Transgenic, and Knock-in Mice

| | Phenotypes |
|---|--|
| IL-6 KO | Reduced TD antibody production and mucosal IgA response BFU-E ↑, CFU-S ↓ Th1 response ↓ Acute phase response ↓ Bone loss by estrogen depletion Impaired hepatocyte regeneration |
| IL-6 TG | Plasmacytosis, plasmacytoma |
| sIL-6R α TG | Acute phase response ↑ |
| IL-6/sIL-6R α double TG | Plasmacytoma Extramedullary hematopoiesis Hepatocellular hyperplasia |
| gp130 (dominant negative) TG | Reduced TD antibody production Normal hematopoiesis |
| gp130 KO | d12.5-perinatal lethality BFU-E, CFU-GM ↓ Heart abnormality |
| gp130 (postnatally) KO | Not severe defect on antibody response Thrombopoiesis ↓ Acute phase response ↓ Defect in lung, heart, liver, and nerves |
| gp130 (heart specific) KO | Normal heart development |
| gp130 (SHP2 signal deficient) KI | Augmented TD antibody production Normal hematopoiesis Th1-type cytokine production Acute phase response ↑ Arthritis dependent on age |
| gp130 (STAT3 signal deficient) KI *point mutation | Perinatal lethality Reduced TD antibody production Normal hematopoiesis Th2-type cytokine production |
| gp130 (STAT3 signal deficient) KI *truncation | Impaired TD antibody production and mucosal IgA response Acute phase response ↓ Gastrointestinal ulceration Severe joint disease |
| gp130 (all signal deficient) KI | Perinatal lethality Reduced TD antibody production Normal hematopoiesis |

Note. KO, knockout; TG, transgenic; KI, knock-in; d, days postcoincidence; TD, thymus dependent; BFU-E, erythroid burst-forming unit; CFU-GM, granulocyte-macrophage colony-forming unit; CFU-S, spleen colony-forming unit.

were generated. These mice showed reactive gliosis throughout the CNS. Furthermore, significant neurodegeneration, including the loss and damage of neurons in the hippocampus formation and cerebellum, was observed.

The IL-6 family cytokines may play an important role in nerve regeneration after trauma *in vivo*. In double transgenic mice expressing both IL-6 and IL-6R α ,

regeneration of the autoximized nerve was strikingly accelerated compared with nontransgenic controls.

DISEASES

IL-6-Related Diseases

A possible involvement of IL-6 in disease was first seen in patients with cardiac myxoma. These patients

have a variety of autoimmune symptoms, including hypergammaglobulinemia, the presence of autoantibodies, and an increase in acute phase proteins, all of which disappear after the resection of the tumor cells. The finding that myxoma cells produce high levels of IL-6 led to speculation that overproduction of IL-6 might play a critical role in the development of autoimmune symptoms. Rheumatoid arthritis patients have high levels of IL-6, LIF, IL-11, and OSM in their synovial fluid, and increased amounts of sIL-6R α are implicated in the pathogenesis of juvenile chronic arthritis. The possible involvement of IL-6 in autoimmune diseases is suggested; collagen-induced arthritis (CIA) is mild in the IL-6-deficient mice. Neutralizing anti-IL-6R α antibody ameliorates the joint disease in murine CIA. Experimental autoimmune encephalomyelitis is suppressed in the IL-6-deficient mice. Pristane-induced autoantibody production is dependent on IL-6. Patients with multiple myeloma, a malignant plasma cell tumor, have higher than normal levels of IL-6, sIL-6R α , and OSM, suggesting the involvement of IL-6 in plasmacytogenesis. In fact, IL-6 transgenic mice developed plasmacytoma in the Balb/c genetic background. Furthermore, pristane-induced plasmacytogenesis is dependent on IL-6. The overexpression of IL-6 has also been shown in connection with other diseases, including osteoporosis, Castleman's disease, and several autoimmune diseases. Lamina propria cells from patients with Crohn's disease or ulcerative colitis show increased production of IL-6. Blocking IL-6 signaling suppressed the experimental colitis in various animal models of Crohn's disease. Interestingly, human herpes virus 8 (HHV8 or Kaposi's sarcoma-associated herpes virus), which has been found in Kaposi's sarcoma lesions, carries the viral counterpart of IL-6, vIL-6, and vIL-6 is implicated in promoting the course of Kaposi's sarcoma.

Therapies

Several approaches have been taken to interfere with the formation of the receptor complex to prevent the pathogenic activity of IL-6 family cytokines. These approaches include the design of gp130 antagonist based on the mutational studies and the development of monoclonal antibody targeting IL-6 and IL-6R α . A cocktail of three different anti-IL-6 antibodies or a chimeric anti-IL-6 antibody consisting of the antigen-binding variable region of the murine

anti-IL-6 antibody and the constant region of a human IgG1 κ immunoglobulin have been given to patients with rheumatoid arthritis, multiple myeloma, and Castleman's disease. These strategies enabled the rapid clearance of serum IL-6. The endogenous IL-6 production never reached its pretreatment value during the treatment period, and C-reactive protein (CRP) levels decreased to below the detection level in nearly every patient. No human antibodies to the chimeric antibody were induced. Thus, this therapy greatly improved the patients' disease status with low toxicity, low immunogenicity, and a long half-life. A similar approach was taken with a humanized anti-human IL-6R α antibody. This therapy improved the conditions of patients with Castleman's disease and certain autoimmune diseases. Therefore, these therapies using chimeric antibodies could be useful tools in treating diseases that are caused by the deregulation of IL-6.

Postnatal Growth and Development

Growth in Infancy

At birth, premature neonates (who account for 30% of neonates showing IUGR) tend to show more symmetric IUGR than asymmetric IUGR. Neonates from alcohol-consuming mothers demonstrate a more severe degree of symmetric growth retardation. Nevertheless, there is no convincing evidence that either the auxological data or the body proportionality at birth among infants with a given degree of growth retardation varies as a function of the cause of that growth retardation.

Longitudinal studies of postnatal growth in infants born SGA have shown that catch-up growth (recognizable by an increase in height velocity) is identified immediately after birth, with a variability of magnitude among individuals. Although the majority of catch-up growth occurs during the first 6 months, catch-up growth for height is often more gradual and can take up to 2 years, followed by a normal pattern of development. However, approximately 10% of the children

born SGA will remain short (<-2 SD) at 2 years of age, and most will have a higher risk of short stature later in life.

Mechanisms regulating catch-up growth are still poorly understood. Improvements in perinatal care and nutrition are largely responsible for the decrease in the incidence of growth failure, which fell from 25 to 10% during the past 25 years or so.

Birth weight, birth length, gestational age, and parental height have been identified as factors influencing catch-up growth. Although the serum levels of IGF-1, insulin-like growth factor-binding protein-3 (IGFBP-3), and leptin are significantly reduced and growth hormone (GH) is significantly increased at birth compared with those of normal birth-weight neonates for all gestational ages studied, none of these hormonal parameters is predictive of catch-up growth. These hormonal parameters are within normal limits at 1 month of age and thereafter. In addition, no relationship has been found between hormones levels at birth and any given etiology of IUGR. However, lowered serum IGF-1, IGFBP-3, and leptin are found in IUGR showing a low PI, suggesting that intrauterine nutrition strongly influences the levels of these parameters. During early neonatal life, serum IGF-1 levels also appear to be regulated by nutritional factors given that an increase in serum IGF-1 levels during the first 3 months of life has been found to be correlated with weight gain during that time and, therefore, with the increased nutrient intake after intrauterine nutrient deprivation.

Growth in Childhood until Adulthood

After the end of puberty, the mean adult height, weight, and head circumference are significantly lower in the SGA population than in the normal birth-weight population. When adjusted for target height, a significant deficit (-4 cm) in final height is found for both male and female individuals, with 14% of them presenting with short final stature (<-2 SDS) compared with individuals of normal birth weight. Parental height and birth length SDS are the strongest determinants of individual final height and height gain in individuals born SGA. No other variables, such as sex, gestational age (37–42 weeks), birth-weight SDS, PI at birth, and risk factors during pregnancy associated with IUGR (e.g., pregnancy-induced hypertension, smoking, a history of SGA in offspring), are seen to be predictive of adult height. Thus, the major influence of parental height (with a greater influence of maternal height) on adult height is evident.

Data concerning the onset, duration, and pace of puberty are not available in large series of individuals.

It seems that puberty in girls occurs at a normal age given that their mean age of menarche is comparable to that of the normal birth-weight population. It has also been shown that the differences between the final height SDS and the prepubertal height SDS are similar for SGA and normal birth-weight groups, suggesting that final height in the SGA population is not influenced by puberty and that the pubertal growth spurt is normal in this population.

Growth Hormone Treatment of Short Stature Children Born SGA

Therapy with recombinant human GH in a supraphysiological dose (0.06 mg/kg/day) has been shown to increase significantly growth velocity in non-GH-deficient prepubertal children with marked short stature and born SGA. In most studies, the first-year treatment induces a mean result of a nearly doubling of the pretreatment growth rate. During the subsequent years of GH treatment, although height velocity is increased significantly compared with baseline values, therapeutic efficacy tends to diminish. Nevertheless, the growth rate after 3 years of treatment remains higher than the baseline growth rate prior to treatment. In most studies, mean height is increased by nearly 2.0 SDS over the first 3-year treatment period in prepubertal children. It has been demonstrated that after 5 to 6 years of GH treatment, nearly every child achieves a height within the normal range and in conformity with the target height SD score without excessive bone maturation advancement. The amplitude of the initial growth response to treatment depends on the GH dose (positive dose-response correlation) and the age of the child (with a younger child being more responsive). However, the impact of early treatment on adult height remains to be determined.

Current clinical experience has shown that on cessation of treatment during the prepubertal period, some children maintain a normal growth rate, whereas others show a slowing in growth rate resulting in a lower final height prognosis compared to those at the end of the treatment period. This suggests that a second GH treatment period may be necessary.

Treatment of short children born SGA does not have a current optimal treatment protocol. A 0.5-SD increment in adult height, even when treatment is given later in patients close to pubertal onset, has been demonstrated. Continuous versus intermittent regimens, as well as higher versus lower dose GH regimens, are under investigation to evaluate the safety and efficacy of the growth response so as to optimize final height of short children born SGA.

The effects of GH are not limited to skeletal growth. Indeed, GH has a profound effect on carbohydrate, lipid, and protein metabolism. In these children, GH treatment is well tolerated, particularly with regard to glucose as evaluated by the levels of glycosylated hemoglobin and glycemia during an oral glucose tolerance test. A potential positive metabolic effect, with an increase in muscle mass observed in these children following 3 years of GH treatment, has also been shown. However, although a reversible decrease in insulin sensitivity after the interruption of treatment has been shown, there is concern regarding the possibility of persistent effects of long-term GH treatment on insulin sensitivity in these children. Further studies are required to define a treatment regimen that will optimize safely the long-term outcome on final height and on metabolic aspects.

Neurodevelopmental Outcome

Subtle neurological and developmental disabilities have been described in individuals born SGA, and a small head circumference at birth has been found to be associated with poorer neurodevelopmental outcome during childhood. Moreover, a small adverse effect of IUGR on cognitive performance has been shown during childhood and early adulthood, even after adjustment for head circumference and for parental socioeconomic and educational status.

The exact causes of these developmental abnormalities are not known with certainty. Experimental data show that undernutrition during vulnerable periods of brain development may have long-term effects on brain architecture and differentiation that can affect learning and memory. Whether prolonged IGF-1 deficiency induced by fetal undernutrition *in utero* might alone cause deleterious effects on normal brain and cognitive development remains to be explored. Furthermore, the role of recurrent episodes of asymptomatic hypoglycemia that might be observed during the neonatal period should also be investigated, as should measures to prevent hypoglycemia during this critical period so as to minimize the risk of subsequent neurodevelopmental deficits.

Long-Term Metabolic Consequences

Over the past decade or so, evidence that demonstrates a significant association between reduced fetal growth and the later development of metabolic and cardiovascular diseases has grown. However, despite several hypotheses that have been proposed, the mechanisms

underlying this unexpected association remain to be clarified.

Cardiovascular and Metabolic Complications Associated with Reduced Fetal Growth: Knowledge from Epidemiological Studies

The unexpected and long-term deleterious effect of reduced fetal growth was initially observed by Barker and colleagues. This group first reported that a low birth weight was significantly associated with an increased risk for the later development of cardiovascular disease or type 2 diabetes. Other epidemiological studies performed in Pima Indians and Caucasian individuals later confirmed this observation, suggesting that the association holds true regardless of whether the study populations are genetically predisposed to type 2 diabetes.

The independent effect of thinness at birth, as assessed by the PI, and the lack of association with gestational age on these complications observed in several studies strengthen the deleterious effect of reduced fetal growth, rather than prematurity, on this association.

Numerous epidemiological studies have demonstrated that being born with a low birth weight is also associated with hypertension or dyslipidemia. In all epidemiological studies, reduced fetal growth has been shown to be an independent risk factor for these complications; more specifically, it has been found to be independent of the usual confounding factors such as obesity and family history of metabolic diseases. Nevertheless, it should be pointed out that this association is sharply amplified by obesity and/or familial history of type 2 diabetes. Thus, reduced fetal growth should be considered as a contributing factor, whereas the other known risk factors remain unequivocal.

What Are the Mechanisms Underlying This Association?

Does Insulin Resistance Play a Role in the Metabolic Complications Associated with Reduced Fetal Growth?

The hypothesis of a critical role of insulin resistance in the metabolic complications associated with *in utero* undernutrition has been well documented during the past few years. This hypothesis was first proposed by the San Antonio group, which pointed out the importance of insulin resistance in this association. These authors suggested that insulin resistance could be the central pathological process underlying the development of the whole syndrome, similarly to what is observed in syndrome X. The significant association between a low birth weight and hyperinsulinemia during adulthood observed in several epidemiological

studies strongly suggests the development of insulin resistance. Moreover, using the euglycemic hyperinsulinemic clamp method, it has been demonstrated that type 2 diabetes associated with a low birth weight requires insulin resistance as described in the classical form of type 2 diabetes.

In a case-control study, our group showed that young adults (20 years of age) born SGA demonstrated hyperinsulinemia under oral glucose tolerance tests (OGTTs) in comparison with age-matched individuals born with normal birth size. Using the euglycemic hyperinsulinemic clamp method, we later confirmed that hyperinsulinemia observed in these young adults reflects insulin resistance. Individuals born SGA demonstrated a peripheral glucose uptake that was significantly decreased in comparison with controls. Using the minimal model method, Flanagan and colleagues also confirmed that insulin resistance is associated with intrauterine growth retardation as early as 20 years of age. Other epidemiological studies have shown that hyperinsulinemia associated with low birth weight was observed in Caucasian and Indian children, suggesting that it could develop from the prepubertal period. These observations point to the early development of insulin resistance in this situation.

The Role of the Adipose Tissue

These observations suggest that the insulin resistance is the primary defect responsible for the metabolic abnormalities associated with reduced fetal growth. Hence, the original mechanism should be searched among those directly responsible for the development of insulin resistance itself. In keeping with this assumption, considering a strong contribution of adipose tissue represents an original and reasonable hypothesis.

It is now well established that adipose tissue plays a key role in the development and worsening of insulin resistance and its complications. The strong interaction between these two components is clearly demonstrated by the close relationship that exists between obesity and the development of syndrome X.

Reduced fetal growth severely alters the perinatal development of adipose tissue. Newborns born SGA show dramatically reduced body fat mass. This reduction reflects mostly decreased fat accumulation in the adipocytes, as suggested by the low triglyceride content. However, most of these newborns will show catch-up growth during infancy. This catch-up growth also involves the adipose tissue, as demonstrated by the noticeably increased body mass index (BMI) during the first year of life. There is now accumulating

evidence that the increased growth velocity of the adipose tissue could persist beyond catch-up. This would suggest that reduced fetal growth and the subsequent catch-up would alter body composition. In our study population, we could demonstrate that the relative increase in BMI persists until adulthood. This persistent development of adipose tissue leads to a significantly increased percentage of body fat mass at 21 and 24 years of age in comparison with controls.

In addition, we demonstrated that this abnormal development of adiposity is associated with hormonal and metabolic abnormalities. The insulin resistance observed in young adults born SGA also involves the adipose tissue, and leptin production was dysregulated either during the catch-up growth period or during adulthood. These observations are of interest because leptin, known to regulate body fat mass, has been shown to be involved in the control of insulin sensitivity.

The Role of Catch-Up Growth

Catch-up growth is a physiological process observed in the majority of children born SGA during the first years of life. However, it has been speculated that catch-up might increase the risk of insulin resistance later in life. Indeed, it has been shown that children born SGA who displayed efficient catch-up growth during infancy showed increased body fat mass with a more central fat distribution in comparison with children born with normal birth size. This increased growth velocity of adiposity persists until adulthood, as evidenced by the relative increase in BMI (expressed in SDS) from childhood to adulthood, leading to a significantly increased percentage of body fat mass at 25 years of age in individuals born SGA in comparison with controls.

In persons born SGA, insulin resistance is sharply amplified by obesity. Several studies have clearly demonstrated that individuals who were thin at birth but subsequently developed obesity during childhood or adulthood are at the highest risk for developing insulin resistance and cardiovascular disease. On the contrary, a study performed in rural Gambian adults did not show any evidence of metabolic or cardiovascular disease in persons born who had a low birth weight and who remained lean during adulthood and were fed with a low-fat diet.

Although the relationship between catch-up in weight and the later development of insulin resistance has been clearly demonstrated, catch-up in height does not appear to influence the long-term metabolic outcome. Insulin resistance parameters are not related to linear growth in children born SGA. It has been

shown in prepubertal children that insulin resistance is found only in those children born SGA in whom catch-up growth in height is associated with a high BMI. This points to the deleterious effect of preferential catch-up of weight over height, rather than the catch-up phenomenon by itself, on the long-term metabolic consequences.

Although the catch-up growth process needs to be carefully followed in children born SGA with respect to the usual clinical practices tending to promote catch-up during early childhood, there is no evidence that these practices might be modified.

Thrifty Phenotype, Thrifty Genotype, Genotype-Phenotype Interactions: How Can This Association Be Explained?

Two major hypotheses came into view from the initial epidemiological studies to explain such an unexpected association. Both of them come from the original theory of the “thrifty genotype” proposed by Neel in 1962. To explain the high prevalence of type 2 diabetes in Western populations, Neel hypothesized that genes that would favor survival during a time of famine would become detrimental when food supply is abundant. This theory encompasses the two major components of the current association: undernutrition and the later development of metabolic complications.

The Barker group first proposed an alternative to the thrifty genotype hypothesis: the “thrifty phenotype” hypothesis, in which environmental factors play a critical role. These authors introduced the concept of “fetal origins.” According to the “programming”-process, they proposed that “alteration in fetal nutrition and endocrine status results in developmental adaptations that permanently change structure, physiology, and metabolism, thereby predisposing individuals to cardiovascular, metabolic, and endocrine diseases in adult life.”

From data collected on Pima Indians, McCance and colleagues proposed another alternative to the thrifty genotype and thrifty phenotype: the “surviving small baby genotype.” They hypothesized that, given the high mortality associated with reduced fetal growth, selective survival of children genetically predisposed to insulin resistance and type 2 diabetes provides an explanation for this association. This hypothesis clearly favors the genetic contribution. More recently, the same group reported data that support this hypothesis: in Pima Indians, a strong relationship was observed between a low birth weight in children and an increased prevalence of type 2 diabetes in their fathers, suggesting a paternal inheritance of genes controlling either fetal growth or glucose

homeostasis. In keeping with the idea of the contribution of genetic factors, Hattersley and Tooke proposed the “fetal insulin hypothesis,” suggesting that genetically determined insulin resistance could result in low insulin-mediated fetal growth as well as in insulin resistance during childhood and adulthood. However, the same authors acknowledged the importance of both genetic and environmental factors in the control of fetal growth.

CONCLUSION

Investigations performed during the past decade or so have identified the independent association between reduced fetal growth and later development of metabolic and cardiovascular complications. By means of a prospective research program based on case-control studies, our group has shown the early development of insulin resistance during adulthood that seems to be the key component underlying this unexpected association. Although the mechanisms responsible for the development of insulin resistance in this situation remain unclear, we collected some evidence in favor of an active contribution of adipose tissue. From a broader point of view, the hypothesis suggesting that this association could be the consequence of interactions between a detrimental fetal environment and genetic susceptibility remains most an attractive one but needs to be confirmed.

antiarrhythmic amiodarone and the radiographic contrast agent ipanoic acid.

Because iodine is a scarce but essential element, iodine deficiency occurs in many geographic areas, creating serious defects in thyroid function. It has been estimated that one-third of the world's population may be at risk. Therefore, widespread programs for supplementing iodine intake have been instituted. Daily intake of 100 to 200 μg I is considered optimal for humans. It is common in many societies to take supplemental iodine in the form of iodized salt (0.001–0.008% I as KI or KIO_3) to ensure adequate iodine intake.

THYROID IODINE

Hormonogenesis

Iodide Transport

Iodine is a major component (65.3%) of thyroxine (T_4), the primary hormone secreted by the thyroid gland. Thus, it is indispensable for thyroid hormonogenesis. Given the very low natural abundance of iodine, it is not surprising that the thyroid possesses an efficient mechanism for concentrating iodide from the circulation. The concept that iodide itself is concentrated by the thyroid independently of its subsequent metabolic fate developed as a result of early studies employing radioiodide together with drugs that block organic iodine formation. The iodide transport system is present in the thyroids of all vertebrates and normally maintains a concentration of iodide in the thyroid 10- to 50-fold greater than in the circulation; this value can reach several hundred in highly stimulated glands. Inorganic iodide, however, normally comprises less than 1% of the total iodine in the gland. The thyroid contains large stores of hormone, and more than 95% of thyroid iodine is organically bound as hormone or hormone precursors. Nevertheless, iodide transport is an essential first step in the biosynthesis of hormone. Pharmacological blockade of iodide transport by the competitive inhibitor perchlorate can completely inhibit hormonogenesis. Iodide entry into the thyroid is probably rate limiting for organic iodine formation under normal iodide loads.

Evidence for a sodium-dependent iodide transporter had become available by the 1970s, but it was not until 1995 that Carrasco and co-workers, after several years of intensive investigation, succeeded in cloning the rat thyroid NIS. They showed it to be an intrinsic membrane protein of 618 amino acids with 13 presumptive transmembrane domains. Subsequently,

human NIS (hNIS) was found to have 84% sequence identity with rat NIS. hNIS has been mapped to chromosome 19p. Immunofluorescence shows NIS to be localized in the basolateral membrane of thyroid follicular cells. NIS is present in other iodide-concentrating tissues such as salivary, gastric mucosa, and mammary. Nontransporting cells transfected with NIS show iodide uptake with many of the properties previously shown for thyroid cells, for example, inhibition by perchlorate and a strict requirement for Na^+ . Iodide transport is an energy-requiring process. The driving force, as in other Na^+ -coupled cotransporters, is the energetically downhill movement of Na^+ across the membrane. The Na^+ gradient is maintained by Na^+/K^+ ATPase in the membrane. Excess iodide, which inhibits iodide transport and other thyroid functions, decreases the expression of NIS mRNA. NIS alone cannot explain all of the iodide-accumulating properties of the thyroid. The thyroid has a second iodide compartment, the follicular lumen, not directly regulated by NIS. Pendrin is the product of the gene defective in Pendred syndrome, a genetic disorder associated with goiter and deafness. Pendrin has been characterized as a sodium-independent ion transporter that localizes to the apical membrane of the thyroid but that is not expressed in extrathyroidal tissues that concentrate iodide. It has been suggested that pendrin is the apical iodide transporter.

Iodination and Coupling

The major function of the thyroid gland is to synthesize and secrete the iodine-containing hormones T_4 and triiodothyronine (T_3). These are formed from diiodotyrosyl (DIT) and monoiodotyrosyl (MIT) residues within the backbone of thyroglobulin (Tg), a large (660-kDa), dimeric, thyroid-specific glycoprotein. The structural formulas of the iodinated amino acids found in Tg are shown in Fig. 1.

The iodotyrosines are the most abundant iodinated amino acid components of Tg, but they have no biological activity. They act as precursors to the biologically active hormones. Iodotyrosines are not normally secreted but rather are deiodinated within the gland to release iodide, which then becomes available for reuse in the iodination of tyrosyl residues in Tg. Diiodotyrosine, isolated from coral in 1905, was the first naturally occurring organic iodine compound to be identified. Normal human Tg varies widely in iodine content, depending on iodine intake; values as low as 0.1% and as high as 1.1% have been reported. In one study, the numbers of iodo-amino acid residues per molecule of human Tg containing 0.52% iodine were as follows: MIT, 6.5; DIT, 4.8; T_4 , 2.3; T_3 , 0.3. It

Figure 1 Structures of the major iodinated amino acids in thyroglobulin. Published with permission from Taurog, A. (2000). Hormone synthesis: Thyroid iodine metabolism. In "Werner and Ingbar's The Thyroid" (L. E. Braverman and R. D. Utiger, eds.), 8th ed., pp. 61–90. Lippincott Williams & Wilkins, Philadelphia.

is evident that formation of T₄ is greatly favored over that of T₃. The hormone content of Tg varies with its iodine content, but within wide limits normal regulatory processes ensure that the hormones are secreted in appropriate amounts. This regulation breaks down when iodine intake becomes rate limiting.

Iodide, the form in which iodine enters the thyrocyte, must first be oxidized to a higher oxidation state before it can iodinate tyrosine. Both the oxidation and iodination are catalyzed by thyroid peroxidase (TPO), a ~110-kDa, transmembrane, glycosylated hemoprotein. Autoradiographic evidence indicates that iodination occurs in the follicle lumen, probably at the apical surface of the follicle cells. Iodination of Tg requires that four separate components (TPO, H₂O₂, iodide, and Tg) be brought into close proximity. Evidence from various sources indicates that the apical membrane is the most likely site for this to occur. The transmembrane region of TPO is located near the carboxyl end of the molecule, with most of the molecule oriented toward the follicular lumen. hTPO contains 933 amino acids and approximately 10% carbohydrate. The hTPO gene resides on chromosome 2 and consists of 17 exons and 16 introns, covering at least 150 kb. TPO is a member of a family of animal peroxidases that includes myeloperoxidase and lactoperoxidase. The crystal structure of myeloperoxidase has been determined and serves as a useful guide for the structure of TPO.

Like all hemoprotein peroxidases, TPO is completely dependent on a source of hydrogen peroxide for its activity. The H₂O₂ generating system in the thyroid involves a membrane-bound, flavoprotein enzyme, NADPH oxidase, with some similarity to one of the components (gp91^{Phox}) of the NADPH oxidase in neutrophils, a system that has been characterized in great detail. Further details of the thyroid H₂O₂-generating system remain to be established.

The heme iron in native TPO and other peroxidases is in the ferric form (FeIII). The reaction product of the native enzyme with H₂O₂, known as compound I, is two oxidation equivalents above the native state. Compound I reacts with iodide in a two-electron oxidation to form an iodinating species. The best evidence indicates that the active iodinating species is enzyme-bound hypoiodite (EOI) and that iodination of tyrosine occurs by electrophilic substitution.

In addition to iodination, TPO catalyzes the coupling reaction. In the thyroid gland, coupling refers to the reaction between two DIT residues or between one MIT residue and one DIT residue within Tg to form T₄ or T₃, respectively. The suggestion that DIT is the biological precursor to T₄ was made in 1927 by Charles Harington, the English chemist who first elucidated the structure of T₄ and synthesized it. T₄ had been isolated and crystallized by E. C. Kendall in 1914 at the Mayo Clinic. Several years later, Kendall erroneously reported that T₄ was an indole derivative. He named it thyroxyindole, later shortened to thyroxin and then modified to thyroxine. Thus, the name "thyroxine" is based on a misconception of its structure. It remained for Harington to demonstrate that T₄ was an amino acid with a unique diphenyl ether structure (Fig. 1).

A mechanism for the coupling of two molecules of DIT to form T₄ was first proposed by Johnson and Tewksbury in 1942 and was extended soon after by Harington. It involved oxidation of DIT to a free radical and interaction of two DIT radicals through a quinol ether intermediate to form T₄. This formulation of the coupling reaction involved free DIT. Later studies indicated that peptide-linked DIT is the precursor to T₄ and that coupling of two molecules of DIT occurs within the matrix of the Tg molecule. The native structure of Tg plays a major role in the coupling reaction. It is likely that the unique structure of Tg has been selected for maximum T₄ formation at low levels of iodination. A hypothetical coupling scheme for the formation of T₄ is shown in Fig. 2.

The scheme proposes that two DIT radicals, generated within the protein matrix through the oxidative

Figure 2 Proposed coupling scheme for intramolecular formation of T₄ within the thyroglobulin (Tg) molecule. The major hormonogenic site at tyrosyl residue 5 is indicated. Published with permission from Taurog, A. (2000). Hormone synthesis: Thyroid iodine metabolism. In "Werner and Ingbar's The Thyroid" (L. E. Braverman and R. D. Utiger, eds.), 8th ed., pp. 61–90. Lippincott Williams & Wilkins, Philadelphia.

action of TPO, couple to form a quinol ether intermediate. This unstable intermediate then rearranges to form T₄ at the site contributing the inner ring (known as the acceptor or hormonogenic site) and dehydroalanine at the site donating the phenolic ring (the donor site). Favored acceptor and donor sites are most likely dictated by the structure of Tg. Tyr 5 is well established as a favored acceptor site in several species. Other

proposed acceptor sites in human Tg are Tyr 2554 and Tyr 2747. Donor sites are more difficult to identify. Evidence supports Tyr 130 as one likely possibility. It is noteworthy that the hormonogenic residues are located near the extreme ends of the molecule. This may facilitate proteolytic cleavage and release of T₄ and T₃.

Why Iodine?

The only established function of iodine in vertebrates is its role in the biosynthesis of thyroid hormones. To earlier investigators, this unique association implied that iodine played some essential role in the action of thyroid hormones. In 1957, Szent-Gyorgi proposed that the hormonal effect of T₄ might be related to the heavy atom perturbation effect of its constituent iodine atoms, an effect that involves the specific electronic properties of the higher halogens, iodine and bromine. However, during the next decade, it was demonstrated that entirely halogen-free analogues of T₄ and T₃, in which iodine is replaced with methyl or isopropyl groups, showed biological activity. The most active of these, 3,5-dimethyl-3'-isopropyl-L-thyronine, showed approximately 20% of the activity of T₄. These observations suggested that it is the size of the iodine atoms, rather than their electronic properties, that is most important for hormonal activity. With the development of the receptor hypothesis of hormone action, attention was focused more on the overall three-dimensional shape of the thyroid hormones than on the specific chemical properties of the iodine atoms. The binding of the hormone, inducing a specific and functional conformational change in the receptor, was considered to be the initiating event in hormone activity.

However, the strong dependence of an essential hormone such as T₄ on a scarce resource such as iodine raises the question: Why iodine? One can only speculate, but it seems likely that biosynthetic mechanisms for producing a molecule with the particular conformation of T₄ are much better adapted for iodine-substituted aromatic rings than for alkyl- or bromine-substituted rings. The diphenyl ether structure so characteristic of T₄ occurs only rarely among compounds produced by animals. Biosynthesis of such a molecule is greatly facilitated by the ortho diiodo-phenolic grouping in DIT, the precursor to T₄.

Autoregulatory Effects of Iodide

The major regulator of thyroid function is thyroid-stimulating hormone (TSH), acting through its receptor in the basolateral membrane. Its effects are

generally stimulatory. An opposing type of regulation, unique to the thyroid gland, is the ability of the thyroid to protect itself against a sudden excess of iodide through iodide inhibition of processes involved in hormonogenesis. These include TSH-induced cyclic AMP (cAMP) accumulation, iodide organification, iodide transport, H₂O₂ generation, hormone secretion, thyroid blood flow, thyroid growth *in vivo* and cell proliferation *in vitro*, glucose and amino acid transport, and protein and RNA biosynthesis.

Wolff–Chaikoff Effect

Administration of small to moderate acute doses of iodide to rats or humans does not influence the uptake of simultaneously administered radioiodide by the thyroid. As the iodide doses become progressively larger, however, inhibition of iodination of tyrosyl residues begins to occur. The decreasing yield of organic iodine from increasing doses of inorganic iodide is known as the Wolff–Chaikoff effect. The inhibitory effect depends on the maintenance of a critical intracellular level of iodide in the thyroid. Normally, the inhibition is relieved within hours after the administration of a single large dose of iodide because the thyroid iodide level decreases rapidly as plasma iodide is lost in the urine. Because the inhibition is transient, the phenomenon is frequently referred to as the acute Wolff–Chaikoff effect.

Chronic Iodide Excess

However, when rats or humans are exposed chronically to high doses of iodide, thyroid iodination does not remain inhibited. Escape from Wolff–Chaikoff inhibition occurs after about 48 h through adaptation of the iodide transport system. The adaptation occurs through an iodide-induced decrease in iodide transport activity such that intrathyroidal iodide concentrations become insufficient to sustain a Wolff–Chaikoff effect even at high plasma iodide concentrations. The decrease in iodide transport activity is attributable to inhibition of expression of the NIS symporter gene by excess iodide.

Mechanisms of Iodide Inhibition

Most, if not all, of the inhibitory effects of iodide are reversed by thionamides such as MMI and PTU; therefore, it has been proposed that these effects are mediated by organic iodocompounds. Such compounds were sought for many years, and the major candidates are now considered to be iodolipids. Addition of iodine to the double bonds of unsaturated fatty acids, particularly arachidonic acid and 22:6 (ω 3) fatty acid, can produce a variety of products, mainly

lactones, that by themselves can mimic the inhibitory effects of excess iodide *in vitro*. Prominent among these is the arachidonic acid product, 6-iodo-8,11,14-eicosatrienoic acid- δ -lactone (δ -iodolactone), which has been proposed to mediate the iodide-inhibitory effects on thyroid cell growth.

Another type of inhibitory lipid is α -iodohexadecanal (α -IHDA), formed by the addition of iodine to the vinyl ether group of plasmenylethanolamine. α -IHDA inhibits H₂O₂ generation in thyroid cell and membrane preparations, and it has been proposed as the mediator of the Wolff–Chaikoff effect. It would be of interest to know whether it also mediates adaptation to chronic iodide excess (escape from the Wolff–Chaikoff effect). Although the biosynthesis of iodolipids in the thyroid requires iodide oxidation, it is uncertain whether thyroid peroxidase is involved. Many of the inhibitory effects of iodide occur at the basolateral membrane, whereas TPO-catalyzed oxidation and iodination typically occur at the apical membrane. Unsaturated fatty acids probably require a higher iodide level for iodination than do tyrosyl residues of proteins.

Iodine-Induced Thyroid Disorders

Although the thyroid normally has intrinsic autoregulatory mechanisms that allow it to adapt to excessive iodine intake, these mechanisms appear to fail in some individuals. Two human disorders that appear to involve a malfunction of the thyroid autoregulatory mechanism are briefly discussed in what follows.

Iodine-Induced Hyperthyroidism

Iodine-induced hyperthyroidism is seen most commonly when iodine supplementation is introduced in iodine-deficient areas and also in individuals receiving iodine-containing drugs. In both cases, the vast majority of individuals do not develop hyperthyroidism. Those with multinodular goiters seem to be most vulnerable, but the condition also arises in individuals with diffusely enlarged, or even seemingly normal, glands. It has been proposed that some defect in the autoregulatory mechanism of the thyroid must be involved. Presumably, the Wolff–Chaikoff effect is not operative in affected individuals because there is a failure of the autoregulatory signal that normally turns off iodination and hormonogenesis in the presence of excess iodide. The failure of this turn-off signal might be due to a diminished sensitivity to iodide. The signal that normally down-regulates iodide transport may also be faulty so that excess iodide continues to be transported into the gland.

Iodine-Induced Hypothyroidism

Most humans exposed to chronic high doses of iodine remain euthyroid. However, some euthyroid individuals become hypothyroid in response to such treatment, very likely as a result of some underlying thyroid disease. Included in this group are euthyroid patients with Hashimoto's thyroiditis, a history of postpartum or subacute thyroiditis, or a history of treatment for Graves' disease. Iodine-induced hypothyroidism may be regarded as a failure of escape from Wolff-Chaikoff inhibition in individuals with high concentrations of circulating iodide. Presumably in such cases, the iodide transport mechanism is not down-regulated by excess iodide as would normally be expected, and the thyroidal intracellular iodide concentration continues to exceed the level required for inhibition of iodination.

EXTRATHYROIDAL IODINE

Deiodination of T_4 and T_3

T_4 is the major thyroid hormone secreted by the thyroid, which is the sole source of T_4 . The metabolically active form of the hormone, T_3 , is secreted at

only about 10% the rate of T_4 . However, T_3 secretion from the thyroid comprises only about 20% of the total T_3 production in humans. The remaining 80% is formed extrathyroidally by 5'-monodeiodination of T_4 (outer ring deiodination). This reaction is catalyzed by two different deiodinase enzymes: type I (D1) and type 2 (D2). D1, located mainly in liver, kidney, and thyroid, also catalyzes removal of an inner ring iodine from T_4 and T_3 to form the inactive metabolites 3',5',3-triiodothyronine (reverse T_3) and 3-3'-diiodothyronine (T_2), respectively. D1 serves to provide T_3 to plasma and to inactivate T_4 and T_3 . D2 is located primarily in the central nervous system (CNS), pituitary, and brown fat and acts to release T_3 intracellularly in these tissues as well as to provide T_3 to plasma. Both D1 and D2 contain a critical selenocysteine residue at the active center. A third selenocysteine-containing deiodinase, D3, catalyzes only inner ring deiodination of T_3 and T_4 . It is located in the CNS, placenta, and skin and acts only to inactivate thyroid hormones. Through the action of the various deiodinases on T_4 , T_3 , and their metabolites, most of the hormonal iodine secreted by the thyroid is returned to the body iodide pool (see Fig. 3).

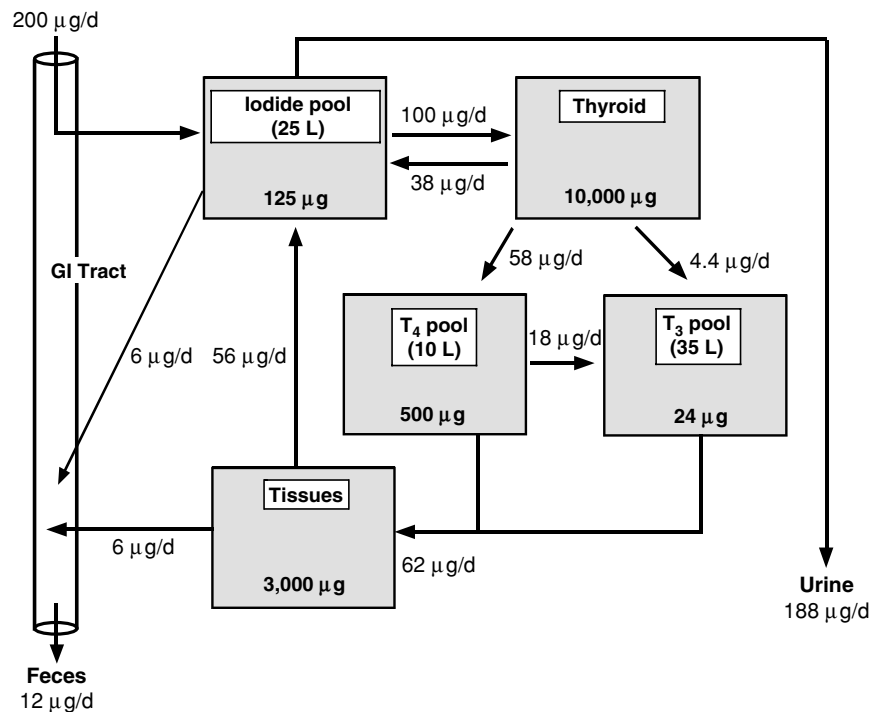

Figure 3 Iodine metabolism in 70-kg human in a state of iodine balance. d, day. Adapted from Larsen, P. R., Davies, T. F., and Hay, I. D. (1998). The thyroid gland. In "Williams Textbook of Endocrinology" (J. D. Wilson, D. W. Foster, H. M. Kronenberg, and P. R. Larsen, eds.), 9th ed., pp. 389–515. Saunders, Philadelphia.

Iodine Kinetics

Figure 3 shows the distribution of iodine among various compartments of the body as well as the daily flux of iodine from one compartment to another. The numerical values are approximations of normal means for individuals on an iodine intake of 200 $\mu\text{g}/\text{day}$. Such values can vary widely, even within a given study, and the numbers in Fig. 3 should be viewed with discretion. The values for the secretion rate of T_4 (58 $\mu\text{g I}/\text{day}$) and T_3 (4.4 $\mu\text{g I}/\text{day}$) may be the least variable because homeostatic mechanisms in the pituitary–thyroid axis and within the thyroid normally prevent wide fluctuations in hormone secretion.

Most of the iodine in the body is stored in the thyroid in the form of iodotyrosines and iodothyronines within Tg. Iodine used for thyroid hormone synthesis is drawn from the iodide pool, which is replenished primarily by iodide absorbed from the gastrointestinal tract but also by iodide coming from the thyroid (iodide leak) and from deiodination of iodothyronines in various tissues. The iodide taken up by the thyroid (estimated at 100 $\mu\text{g}/\text{day}$) is used largely for the synthesis of T_4 and T_3 , with the rate of T_4 secretion exceeding that of T_3 by about 10-fold. The distribution volume of T_4 is approximately that of the extracellular fluid (about 10L), whereas T_3 enters cells much more readily and has a distribution volume of about 35L. In the circulation, both hormones are tightly bound, largely to specific proteins, such that only about 0.02% of the total T_4 and 0.3% of the total T_3 are present as free hormones. Reflecting this tight protein binding, the half-life of T_4 in the circulation of humans is about 7 days, whereas that of T_3 is about 1 day.

Direct measurement of the iodine content of extrathyroidal tissues is very tedious, and reliable values based on confirmed methodology are unavailable. Mathematical modeling suggests that extrathyroidal iodine may comprise about 30% of total body iodine. It is not clear in what tissues or in what form most of this iodine exists.

The main avenue for excretion of iodine from the body is the kidney. Fecal excretion normally accounts for less than 10% of total iodine excretion. Urinary iodine is almost completely in the form of iodide. Fecal iodine in humans includes both iodide and organic iodine. Because urinary iodine accounts for more than 90% of total iodine excretion, it closely reflects iodine intake; therefore, measurement of

urinary iodine is a very convenient means of assessing iodine intake in human populations.

Renal clearance of iodide in adult humans is about 30 to 40 ml/min and is independent of the plasma iodide concentration. Thus, on low iodine intakes, the kidney does not adapt to the decreased plasma iodide level. All of the adaptation occurs in the thyroid and in the thyroid–pituitary axis. Thyroid clearance of iodide, normally approximately 20 ml/min in humans, increases markedly in iodine deficiency, allowing more efficient use of the available iodine.

Acknowledgments

I am indebted to Dr. Jan Wolff for many helpful suggestions and to Dr. Marguerite Hays for assistance in the preparation of Fig. 3.

On release into the circulation, the thyroid hormones attach to several binding proteins made by the liver and are then transported to their major targets.

The only clearly established role for iodine is as a component of the thyroid hormone molecules. However, iodine may also influence the breasts, since experimental iodine deficiency reportedly may be associated with mammary dysplasia.

Amounts of Iodine Required

Experimental and clinical observations have produced recommendations for daily iodine intake. These are based on calculations of daily thyroid hormone production and metabolism in balance studies, the

amount of thyroxine required for adequate replacement in subjects who are athyreotic, and metabolic disposal rates. [Table I](#) shows recommendations by the Food and Nutrition Board of the U.S. National Academy of Sciences for daily iodine intake. The World Health Organization, the International Council for the Control of Iodine Deficiency Disorders (ICCIDD), and UNICEF have recommended almost identical values. Setting an upper limit for iodine ingestion has been more difficult. The Food and Nutrition Board recommended 1100 µg/day as a safe dose for adults. Most people can tolerate much higher doses without apparent ill effects. Large amounts of iodine inhibit the thyroid's ability to make thyroid hormone, producing goiter and hypothyroidism, but many people can tolerate several milligrams per

day. People with autoimmune thyroid diseases, such as Graves' disease and Hashimoto's disease, and many of their relatives are more sensitive to iodine excess.

Assessment of Iodine Nutrition

Urinary Iodine Concentration

Over 90% of ingested iodine eventually appears in the urine. Thus, in the steady state, the urinary iodine excretion is a good marker of iodine nutrition. For epidemiological purposes, the concentration itself, in micrograms per liter, is usually satisfactory for gauging the nutritional status of a community. Changes in hydration affect the urinary iodine concentration in individuals but these tend to smooth out in the population median. Occasionally, urinary iodine is expressed as micrograms of iodine per gram of creatinine, but other nutritional abnormalities, such as low protein intake, influence creatinine excretion and the concentration alone is satisfactory and simpler.

The urinary iodine concentration is the single most useful test in assessing populations. [Table II](#) relates median urinary iodine concentration to different degrees of iodine nutrition; for deficiency it also presents an index of its severity and, therefore, the priority for corrective action. Urinary iodine concentration also detects excess as well as deficiency.

Thyroid Size

Iodine deficiency diminishes thyroid hormone production. The pituitary responds with increased TSH

secretion, causing the thyroid to increase hormone production, and the gland enlarges as part of this adaptive response. The degree of enlargement, called "goiter," is proportional to the severity of the iodine deficiency and can be assessed by palpation, classifying it as "no enlargement," "palpable goiter," or "visible goiter," the latter two constituting the "total goiter rate." Thyroid enlargement is one of the earliest and most apparent features of iodine deficiency and palpation is a simple technique that requires some skill but no special instruments. Rapid surveys can be carried out in schools. When the iodine deficiency is severe, such surveys provide a quick and satisfactory basis for recognizing the presence of iodine deficiency and the need for its correction. This was the most common form of assessment for much of the 20th century. However, as iodine nutrition has improved, the degree of thyroid enlargement in such surveys has become more subtle and the results have become correspondingly less accurate.

Ultrasonography provides a quantitative and reproducible assessment of thyroid size. The technique is simple. Portable instruments can easily be used in the field and require only several minutes for each measurement. Normative data exist for iodine-sufficient individuals, related both to age and to body surface area, and can be used for comparison.

TSH

Serum TSH rises with iodine deficiency and the threat of hypothyroidism. In populations the median serum TSH increases, but frequently remains within the normal range of the TSH assay, unless the iodine deficiency is quite severe. For this reason, the TSH is not a very sensitive indicator of iodine deficiency in the general population, but its use in newborns is an exception. Most developed countries have neonatal screening for early detection and treatment of congenital hypothyroidism, which occurs in approximately 1 in 4000 births in iodine-sufficient

Table II The Median Urinary Iodine Concentration as an Index of Community Iodine Nutrition

| Median urinary iodine concentration ($\mu\text{g/liter}$) | Corresponding approximate iodine intake ($\mu\text{g/day}$) | Iodine nutrition |
|---|---|---------------------|
| <20 | <30 | Severe deficiency |
| 20–49 | 30–74 | Moderate deficiency |
| 50–99 | 75–149 | Mild deficiency |
| 100–199 | 150–299 | Optimal |
| 200–299 | 300–449 | More than adequate |
| >299 | >449 | Possible excess |

populations. Iodine deficiency causes transient neonatal hypothyroidism and a resulting rise in TSH, so the incidence of transient hypothyroidism, as detected on neonatal screening, increases and correlates with the degree of deficiency in the community. Introducing neonatal screening only to detect iodine deficiency is not cost-effective, but if this program is already in place, valuable information about iodine nutrition can be obtained.

Serum Thyroglobulin

The normal thyroid secretes small amounts of thyroglobulin into the bloodstream, detectable by serum assays. Increased thyroid activity from any cause (including iodine deficiency) increases serum thyroglobulin and this correlates well with the degree of iodine deficiency. Urinary iodine is a more practical measure for iodine nutrition, but the serum thyroglobulin is worth considering if blood is being obtained for other purposes.

Serum Thyroid Hormone Levels

Iodine deficiency causes the median serum T4 to decrease and the serum T3 to increase. However, these changes may be subtle and the altered values may still be within the normal range. In practice, these have not been cost-effective measures to assess population iodine deficiency.

Radioactive Iodine Uptake

Iodine deficiency increases the thyroid's uptake of iodine and this can be demonstrated by administering a tracer dose of radioactive iodine (^{131}I or ^{123}I). The test is cumbersome, particularly in the field, and is not recommended for assessing the iodine nutrition of a population.

Survey Technique

School-age children are a convenient group to study, because they are easy to assemble and reflect recent rather than remote iodine nutrition in a community. The study sample must be representative, take into account the degree of homogeneity within the population being sampled, and address school attendance, rural location, and socioeconomic status. Failure to consider these factors may lead to an unrepresentative survey that does not sufficiently assess the poorer, remote rural areas that are likely to harbor the worst iodine deficiency. The most important sample is the urinary iodine. The most spartan surveys can simply collect urine samples and transfer them to a central laboratory. More extensive data may include an estimate of thyroid size, particularly if obtainable by

ultrasonography. Many countries select a few sentinel sites and monitor them periodically to detect trends.

CONSEQUENCES OF IODINE DEFICIENCY

Thyroid hormone, and therefore iodine, is essential for health. The thyroid hormones modulate many chemical reactions in the body and are necessary for development of the brain and proper growth. Failure to have adequate iodine causes goiter, hypothyroidism, cretinism, reproductive failure, decreased child survival, iodine-induced hyperthyroidism, and socioeconomic deprivation. Some details follow.

Goiter

Thyroid enlargement is an early and easily recognized feature of iodine deficiency. It results from increased TSH stimulation. It can be regarded as an adaptation, and if the iodine deficiency is mild, further damage does not necessarily follow. Goiter is not the worst result of iodine deficiency, but it is not inconsequential. The enlarged thyroid may compress adjacent structures, requiring eventual surgery or other treatment. Prolonged thyroid hyperplasia causes thyroid nodules (lumps), which may occasionally be malignant or become autonomous and overproduce thyroid hormone.

Damaged Reproduction

This is the most severe consequence of iodine deficiency. Its spectrum begins with infertility and includes complications of pregnancy and neonatal death. The need for iodine increases in pregnancy to supply the fetus and also because maternal renal losses are greater. The iodine-deficient pregnant woman may experience gestational hypertension, abnormal fetal presentation, stillbirths, and goiter.

Her offspring faces additional severe risks, with death being the worst. Several epidemiological studies have shown dramatic improvement in child survival with correction of iodine deficiency. For example, child mortality decreased by 50% after iodization of irrigation water in China. Other studies found that child survival increased when iodine was administered during pregnancy and during the first 6 months of life. An extensive literature shows similar results in animals, where stillbirths and abnormal progeny are a common consequence of iodine deficiency.

The developing brain needs thyroid hormone for proper maturation. It is particularly vulnerable

during the second and third trimesters of pregnancy and the first 2 years of life, a period when myelination of the central nervous system is most active. Failure to have adequate thyroid hormone during this critical period can result in permanent mental retardation. In fact, iodine deficiency is the most common cause of preventable mental impairment.

The extent of the brain damage varies over a wide spectrum. Occasionally, it is subtle, requiring specific testing to show impairment. At the other end is cretinism, characterized by severe mental retardation, various other neuromuscular abnormalities, short stature, and deaf-mutism. The incidence of cretinism in severely iodine-deficient areas is uncertain, because many die early or are secluded by defensive family members. Some severely deficient villages have reported incidences of >10% and in such communities the probability is great that most of the population has some degree of impairment.

Iodine-Induced Hyperthyroidism

This complication occurs when thyroids that were previously iodine deficient produce excess hormone on exposure to increased iodine intake. It happens most frequently in older individuals whose long-standing goiters have developed autonomous nodules. These nodules try to use every atom of iodine to make thyroid hormone and are independent of pituitary control. When exposed to an increased iodine supply, they make thyroid hormone at an accelerated rate and the individual becomes hyperthyroid. Countries or areas that correct previous iodine deficiency can expect some increase in hyperthyroidism in the following years. Fortunately, this trend is usually short-lived and the individual can be adequately treated by the usual techniques available for hyperthyroidism from other causes. Although this complication is regrettable, its damage to the community is mild compared to that from continuing iodine deficiency and iodine-induced hyperthyroidism should never be used as an argument for preventing the correction of iodine deficiency. This complication occurs because of preceding iodine deficiency, so it is reasonable to regard it as another of the iodine deficiency disorders.

Socioeconomic Damage

Iodine deficiency not only hurts the individual, but also the community in which he or she lives. Hypothyroid people are less efficient, less productive, and more prone to illness. Their domestic animals risk

similar complications from iodine deficiency and they have more stillbirths and produce fewer eggs, less meat, and less wool. Correction of iodine deficiency in a community can result in dramatic improvement in work performance, per capita income, and school performance. For example, one meta-analysis concluded that an average of 13.5 IQ points were lost from moderately severe iodine-deficient communities when compared with iodine-sufficient peers.

MEANS FOR CORRECTING DEFICIENCY

Vehicles available for delivering iodine to deficient communities include salt, vegetable oil, water, tablets, drops, and occasionally others. The following features are important in selecting a vehicle: (1) provision of physiological amounts of iodine at regular, preferably daily, intervals; (2) easy distribution; (3) affordable cost; (4) acceptability to target population; and (5) safety. In principle, the problem is straightforward: the population is deficient, so iodine must be provided; the critical issue is to see that the prescribed iodine reaches the target correctly.

Iodized Salt

Salt is the preferred vehicle for fortification with iodine in most circumstances. Everyone needs salt. It is limited in location and one of the few items that many otherwise self-sustaining communities cannot provide for themselves. The technology for iodization is simple and its implementation is safe.

Potassium iodide (KI) and potassium iodate (KIO_3) are the usual fortificants, containing, respectively, 77 and 59% of their weight as iodine. Iodate is generally preferred, especially in developing countries, because it is more stable under conditions of storage and distribution, especially in poorer quality crude salt. Most countries with warm climates or low-quality salt specify iodate; iodide is used mostly by a few countries in North America and Europe.

A variety of techniques for fortifying salt with iodine exist. The most basic is to mix dry potassium iodide or potassium iodate with salt by hand or simple machinery. More often, a solution of potassium iodate or iodide is sprayed or dripped onto salt as it moves on a conveyor belt.

The most common levels for fortification are 20–50 mg iodine/kg salt (20–50 ppm). Daily salt consumption varies widely among populations, but in most instances is between 5 and 10 g/day. Thus, 5 g

iodized at 30 ppm provides the 150 μg recommended for iodine sufficiency. Several other factors affect these calculations. In many countries, especially developed countries, most ingested salt comes from processed foods and that added at the table is relatively minor. For example, estimates for the United States are that only approximately 15% of dietary salt is added at the table and the salt for most processed food is not iodized. Another factor is the loss of iodine between production and consumption of salt. Losses are heavily influenced by the quality of the salt and conditions and duration of its storage before consumption. Under most conditions, such losses are <30%, but occasionally virtually all the iodine will have disappeared by the time it is consumed. Different cooking practices may also cause losses from iodized salt.

Success in implementing the use of iodized salt varies tremendously. Countries that import all their salt can achieve effective iodization by enforcing strict quality control at the borders or at designated processing plants. This situation has made it possible for a number of countries, e.g., Nigeria and Zimbabwe, to achieve universal use of iodized salt fairly quickly. Other countries may have numerous salt deposits scattered throughout their territories and introducing iodization into the local salt trade is a much more daunting task.

Iodized Oil

Iodinated vegetable oils have been used as X-ray contrast materials for over 70 years. The most common of these, Lipiodol, has 480 mg of iodine per milliliter. Its first use for prophylaxis in iodine deficiency, in the 1950s, proved dramatically effective. For the next 20 years, its administration was principally by intramuscular injection, with a single dose providing adequate coverage for several years. Subsequently, oral use has been more popular. Capsules containing 200 mg iodine, one or two capsules per administration, provide satisfactory coverage for approximately 1 year. Iodized oil has the advantage of bringing iodine supplementation instantly to the subject on administration and avoids the complexities of altering commercial patterns of salt. Its greatest use has been for women and young children with moderate to severe deficiency, to buy time while awaiting the implementation of effectively iodized salt. The disadvantages are that iodized oil requires direct contact with each person, is more expensive than iodized salt, and provides uneven amounts of iodine over the duration of its effects, with a large amount being lost in the first few days. Well over 50 million people have received

iodized oil and it remains a useful alternative under specified conditions.

Iodized Water

Water, like salt, is necessary for all humans, regardless of geographic or socioeconomic situation. As in salt, the addition of iodine to water can provide a constant physiologic dose.

Several approaches have been used. One of the simplest is to add a concentrated iodine solution to vessels containing drinking water. A program using this approach has been used in schools and homes in northern Thailand for several decades. Addition of iodine to running drinking water has been used in several countries (e.g., Italy, Malaysia, Thailand) by diverting some water through a bed containing iodine as crystals or on a solid support and then reintroducing it to the main stream. Another approach uses diffusers, commercially available polypropylene baskets containing iodide that is slowly released into a water source, such as wells. Finally, an innovative system in western China periodically drips potassium iodate into irrigation water. Follow-up studies have shown impressive benefits to people and domestic animals, at a cost of approximately US \$0.02 per person per year.

Molecular iodine (I_2) has powerful bactericidal properties and is frequently used for water purification. Many communities needing water purification are also iodine deficient, so a system delivering molecular iodine can solve two problems at the same time.

Iodine Tablets and Solutions

Tablets containing potassium iodide are occasionally used for iodine supplementation. They can be taken daily at 100 or 200 μg , weekly at 1 mg iodine, or at less frequent intervals up to several months, in correspondingly larger doses. The aim is to provide approximately 150 μg iodine per day. The smaller doses may be used as supplements in special circumstances, such as pregnancy, and are also frequently incorporated into antenatal vitamin and mineral preparations. Some countries, such as the United States, stockpile tablets containing 65 or 130 mg potassium iodide to block thyroidal uptake of radioactive iodine in case of a nuclear event, but these amounts are far too excessive for routine prophylaxis against iodine deficiency.

Even remote health posts in developing countries frequently have iodine solutions for topical antiseptics. These can be appropriately diluted and used for iodine supplementation, again aiming at approximately

150 µg iodine per day. Such programs can be quite effective, but require responsible oversight to see that the correct dose is actually taken.

Choice of Iodine Vehicle

Iodized salt is by far the favored vehicle for most situations. It does not require individual contact, is technologically simple, is low in cost, and provides a constant daily supplement. However, implementation of an effective iodized salt program is not always easy. In some countries, it requires a massive reorganization of the salt trade, so that an iodization step can be reasonably interpolated. For countries that import salt or have only a few large producers, introducing iodization is usually straightforward. Other countries may have many small salt farmers scattered over a large area who harvest the product simply and sell it locally. Some progress has been made by iodizing their product through cooperatives and other methods, but with only partial success.

When iodized salt cannot be effectively introduced within a reasonable time, other methods need to be recruited. Oral iodized oil can be distributed rapidly through community health systems and provides a stopgap while awaiting salt iodization. Iodized water should be considered, depending on water sources and appropriate supervision. Iodized tablets and solutions are effective for individuals, but require careful administration.

Many other vehicles have been occasionally used and may have a niche in certain locales. Examples are brick tea, sugar, candy, fried bananas, and fish sauce. For each, one must ask whether its iodization will reach the right part of the population, especially the poor, women, and children, and in the right amounts. A possible danger is that several different forms of iodine supplementation may converge in an individual and produce iodine excess.

IODINE DEFICIENCY DISORDERS CONTROL PROGRAMS

Organization

Correction of iodine deficiency occasionally occurs passively by so-called “silent prophylaxis.” Better transportation and better availability of iodine-containing foodstuffs can bring this about, but it is unrecorded, uncontrolled, and subject to many changes and commercial trends that will not be recognized. A much more effective approach is to have an organization, usually the Ministry of Health in the government,

take charge of the program and its components, especially implementation, education, and monitoring.

Both the problem of iodine deficiency and the means for correcting it are issues of public health and are usually the responsibility of the national government. Their place within the Ministry of Health may vary depending on its structure, but usually fall within a unit for nutrition or a unit for maternal and child health. The most successful programs have had a defined structure within the Ministry of Health, with a specific program for control of iodine nutrition, a designated officer responsible, and a specified budget and work plan. Many countries have decentralized health activities and budgets to provinces and regions and large states may have their own separate units, but these will depend on the central government for direction and support.

Although the Ministry of Health is usually the leader in the government programs, many other sectors, both governmental and private, are involved in issues relating to iodine nutrition. Within the government, they include other ministries, especially education, agriculture, and commerce, and, from the private sector, health professionals, the salt industry, public advocacy groups, and the general population itself, particularly in those areas affected by iodine deficiency. Many countries have developed national committees or coalitions for the elimination of iodine deficiency. These can take different forms, according to the unique political and cultural characteristics of a country. Often in developing countries, the Ministry of Health chairs a committee of members representing other governmental ministries and appropriate parts of the private sector. Such committees are usually advisory, but provide political support for the national effort and promote advocacy. In other countries, the nongovernmental members of the committee may assume a more important role. At the far end of the spectrum, some countries have entirely private groups that have taken responsibility for certain aspects of the program, especially monitoring. In this capacity, they inform the government of the situation and urge appropriate action when necessary. International organizations strongly advise the formation of such national coalitions, as a means for keeping the government and public informed and for championing corrective action as necessary.

Communication and Education

These are key activities in a program of iodine deficiency disorder (IDD) elimination. Education should take place at all levels, especially for political authorities,

health professionals, the salt industry, and the iodine-deficient population itself. Messages should be appropriate to the audience. For the political authorities, the economic consequences of iodine deficiency often have more impact than does human suffering. For others, such as mothers, awareness of the damage to their children provides a strong incentive for using iodized salt. Health professionals should be taught the grave consequences of iodine deficiency and the relatively easy means for its correction. The general public must be made aware of the damage that iodine deficiency can bring, to create a demand for iodized salt. This, together with enforcement of laws, can make universal salt iodization a reality.

The content of the communication message needs attention. Goiter is the most obvious result of iodine deficiency and is a good marker for it, but is by no means the worst consequence: the damage from neonatal mortality and mental retardation greatly exceeds that from goiter. Therefore, the message must turn from spotlighting goiter and emphasize damage to the developing human instead. The communication campaign must be quick to refute myths and rumors, such as iodized salt causing sterility. Usually iodization will increase the cost of salt and the community must be persuaded that the benefits are worth this investment.

The most effective means of communication vary with the local situation and culture and should be pitched accordingly. Frequent activities are an annual IDD Day with parades, speeches, and demonstrations, radio and television spots, promotional leaflets and literature, and appearances at political and professional meetings.

Monitoring

The availability of iodine can change frequently and unpredictably with alterations in the physical, political, commercial, and cultural landscape. Natural disasters and civil unrest can disrupt salt plants and distribution patterns, a new government may overturn established patterns of health care and regulatory enforcement, changes in the management and structure of salt companies may profoundly affect the market for iodized salt, and understanding and concern about iodine nutrition and the importance of iodized salt may wax and wane with policy makers and consumers. Because at least some of these factors are likely to occur in any country, careful monitoring of iodine nutrition is essential to maintain effective optimal iodine intake in a population.

Nutrition

The techniques for monitoring nutrition are the same as those for assessment, described above. The most

useful is the urinary iodine concentration in representative members of the population. Surveys should be carried out periodically, every 2–5 years. The results should be made public. Deviations from acceptable levels should be recognized and the causes sought.

National coalitions can contribute greatly to monitoring, especially in countries that have weak or non-existent central programs. The national coalition can urge the government to carry out mandated monitoring, review the results, and insist on corrective action when necessary. In some countries, professional groups in the private sector have taken the responsibility upon themselves to carry out monitoring and alert the country to the results through the media. For example, in Argentina, a committee of the Federated Endocrine Societies oversees and reports on cyclical monitoring in the different provinces of the country.

Lack of monitoring has been a major cause of failure in programs that were initially successful. Almost all countries in Latin America had developed programs for correction of iodine deficiency through iodized salt over a generation ago, but virtually all of them failed, in large part because of inadequate monitoring. Fortunately, the past 15 years have seen a great improvement and most of those countries appear to have become iodine sufficient, but they still need data and regular monitoring to confirm these impressions.

Salt

The other important target of monitoring is the iodine content of salt. This is best measured at several levels, first at production, with standard quality-assurance procedures, and more importantly, at the household level. Sanitary inspectors can visit market places and collect salt samples as part of their routine work. These can be measured in a laboratory, the results can be shared with the producer, and any deviations can be corrected. Government inspectors at all levels—production, market, importation—should reject batches of salt without the prescribed iodine content.

A popular monitoring approach is to select representative schoolchildren, obtain urine samples, palpate for goiter (although this is less important), and have them bring salt samples from their homes for testing of iodine content. Such surveys can be carried out quite rapidly and assess both the process (iodized salt) and its impact (iodine nutrition). In large diverse countries, sentinel sites can be used to reflect changes in specific regions.

GLOBAL STATUS

With only a few possible exceptions, every country in the world has had iodine deficiency at some time in its

history. Seawater contains less than 0.05 ppm iodine, but because of its extremely large volume, it is the world's largest deposit. On land, distribution is quite uneven. The largest concentrations are found in occasional natural deposits, especially in northern Chile, and in association with oil and gas deposits (e.g., in Japan). Severe iodine deficiency occurs in new mountains (e.g., the Andes, Alps, Himalayas), in zones with frequent flooding (e.g., India, Bangladesh), and in far inland areas (e.g., Central Asia, Central Africa). However, other places are not immune and even inhabitants of small islands (e.g., the Azores, Cape Verde) may have significant deficiency. Thus, inadequate iodine is the baseline condition for most parts of the world and poses a constant threat, unless corrected either by natural means, i.e., availability of foods from iodine-sufficient regions, or by intention—i.e., prophylactic programs, usually with iodized salt.

The global extent of iodine deficiency has been estimated periodically over the years. Initially, most figures were based on the presence of goiter by palpation, a fairly crude marker. The World Health Organization in 1999 offered a summary of 191 countries, based largely on goiter; it concluded that iodine deficiency was a public health problem in 130 of those countries and that another 41 could not be

categorized because of insufficient data, leaving only 20 countries iodine sufficient. The people at risk, i.e., living in countries with iodine deficiency, numbered 2.2 billion, approximately 38% of the world's population. Thirteen percent, or 740 million, had goiter. Seventy-five percent of the countries had legislation for iodized salt and 68% of households used iodized salt.

The ICCIDD maintains a database (www.iccidd.org) that attempts to classify the iodine nutrition status of each country, based principally on representative urinary iodine concentration data. Many countries have incomplete information, so their designation is arbitrary and needs constant adjustment. Table III offers a rough overview of global iodine nutrition, classified by region. This compilation summarizes more detailed data that distinguish different levels of deficiency and also lumps the category of "likely deficient" with "deficient," and "likely sufficient" with "sufficient." Assignment to a category is based on available monitoring data, with the greatest emphasis on urinary iodine, but also taking goiter prevalence into account. Here each country is considered as a unit. If a significant part of the country had iodine deficiency, the country was labeled deficient, even though not all inhabitants have iodine deficiency. For that matter, not all of the inhabitants of countries listed

as sufficient are necessarily free of deficiency. China is a good example: the great majority of the population appear to be iodine sufficient, but Tibet remains deficient.

With these limitations, [Table III](#) gives a broad picture of where iodine deficiency persists. Overall, approximately 50% of the world's population lives in a country with significant iodine deficiency and should be considered at possible risk for its consequences. In all regions except the Americas and the China/Far East Region, most of the world's population live in iodine-deficient countries. Large countries, such as India (some deficiency) and China (largely sufficient), weigh heavily in these calculations. Of the 159 countries considered in this survey, 84 are deficient, 72 sufficient, and 3 have excess iodine.

Household use of iodized salt has remained at approximately 70% worldwide. Data collected by UNICEF in 2000 give figures by region (the designation of regions is slightly different than that in the ICCIDD database and the UNICEF compilation does not have entries for developed countries). The regional breakdown is as follows: Latin America and the Caribbean, 81%; East Asia and the Pacific, 80%; Middle East and North Africa, 70%; sub-Saharan Africa, 68%; South Asia, 55%; and Central and Eastern Europe, 28%.

OBSTACLES TO THE GLOBAL ELIMINATION OF IODINE DEFICIENCY

The past decade has seen remarkable progress in working toward the elimination of iodine deficiency. At the same time, approximately half the world's population still live in countries that harbor some deficiency. In 1990, the World Summit for Children, sponsored by the United Nations and attracting heads of state from most countries in the world, pledged the virtual elimination of iodine deficiency by 2000. That goal failed. A second conference, in May 2002, repeated the pledge, changing the target date to 2005. Reaching it is theoretically possible, but depends on accelerated action from countries and international agencies.

The correction of iodine deficiency is conceptually straightforward. People lack iodine, so they need to obtain it. A choice of good methods for providing iodine exists. Of these, iodized salt is preferred, but the alternatives are also acceptable. Iodized salt has been in use for 80 years. Some countries have adopted it with dramatic success. Why, then, does iodine deficiency continue in so much of the world?

Countries and their inhabitants are unique. Even though a country may share the same geography and ethnic mix as its neighbors, it may differ in many ways that influence the success of an iodization program. Some of the more common reasons that programs are not successful are as follows:

Difficulties in Implementing Iodized Salt

As already pointed out, some countries have numerous remote salt deposits that are easily mined and sold locally. Other countries have only a few large salt producers, but those do not comply with the law. Still others import their salt, but its iodization is not enforced, and much also enters as contraband.

The compliance and cooperation of the salt industry are crucial to successful iodization. Producers need education on its importance, assistance with technical issues, and constructive actions to make it economically attractive. They must be assured of a market for iodized salt, especially if it costs much more than the non-iodized products. The consumer must learn to demand iodized salt because of its health benefits, even if the price is greater.

Lack of Awareness

Consumers, salt producers, and government officials must appreciate the damage from iodine deficiency and the importance of its correction. All levels need vigorous communication efforts.

Insufficient Data

Information about iodine nutrition is fragmentary, not only in the developing world but also in many socio-economically advanced countries. Baseline surveys are necessary in order to plan action. Countries such as Australia and New Zealand have recognized their current iodine deficiency only recently. Other countries, such as Canada, though unlikely to be deficient, do not have recent national data. If a government is unwilling or unable to obtain such information, then other groups, such as endocrinologists, universities, or independent national coalitions, should.

Inadequate Government Support

The government is ultimately responsible for the public health of its citizens, including their iodine nutrition. Policy makers must be convinced of the importance of iodine nutrition and of the means for its correction and this effort may require extensive

lobbying. The government should have specific laws and enabling regulations to support universal salt iodization and should designate responsibility to a specific unit with sufficient budget to carry out the program. Often government support is strong during periods of great publicity and activity by the unit, but this enthusiasm may taper with new personnel or budget constraints.

Poor Monitoring

Because iodine deficiency is a chronic condition, it needs regular long-term monitoring. The government must provide for follow-up surveys and respond promptly to any reports that the control program is not working. National coalitions can help to keep iodine nutrition in constant view and to prod the government when lapses in control occur.

SUMMARY

People need iodine because it is an essential component of the thyroid hormones, which influence a variety of vital biochemical reactions in the body. Insufficient iodine, and therefore insufficient thyroid hormone production, causes pregnancy complications, neonatal and infant death, mental retardation, goiter, hypothyroidism, deaf-mutism, and low economic productivity. The recommended daily intake for an adult is 150 μg , with larger amounts recommended during pregnancy and lactation. The best measure of iodine nutrition is the urinary concentration of iodine.

Salt is the most effective vehicle for delivering iodine to a deficient population and can be iodized by simple inexpensive techniques. Other delivery systems are iodized vegetable oil, iodized water, and iodine tablets. Success in achieving iodine sufficiency depends on an effective program, usually the responsibility of the Ministry of Health and supported by many other sectors, both public and private, especially health providers and the salt industry. Key components in the program are communication, education, and monitoring of both iodine nutrition and salt iodine content.

Approximately half of the world's population lives in countries with iodine deficiency and risks its consequences. Most of these individuals are in the developing world, but many in Western Europe also continue to be deficient. Approximately 70% of households in the developing world use adequately iodized salt. The United Nations and heads of states have pledged virtual elimination of iodine deficiency by the year 2005, but achieving this goal requires an intensified effort.

^{123}I is excellent for thyroid imaging because it delivers far less radiation to the thyroid than does ^{131}I , has a short half-life (13 h), and does not emit destructive beta radiation. Furthermore, its gamma radiation emission energy (159 keV) is ideally suited to thyroid scanning. The use of ^{123}I has been superseded for most routine thyroid imaging by Technetium-99m, an isotope that is actively transported by the sodium iodide symporter, with radiation characteristics similar to those of ^{123}I but with the advantages of minimal cost and ready availability due to its widespread use in nuclear medicine.

Biological Effects of ^{131}I

When ^{131}I is incorporated into thyroid tissue, the emission of beta particles results in ionization of the thyroid cell, leading directly to the damage of DNA and essential proteins, such as enzymes, and indirectly to the production of free radicals. The early effects of ^{131}I include necrosis of follicular cells and vascular occlusion that fully develop over a period of weeks to months. Long-term effects include shorter cell survival, impaired replication of surviving thyroid cells with atrophy and fibrosis, and a chronic inflammatory response resembling Hashimoto's thyroiditis. These later effects account for the development of hypothyroidism even years after treatment. The extent of loss of thyroid function, and therefore of the disease state, can be controlled to some extent by the amount of ^{131}I administered.

RADIOACTIVE IODINE UPTAKE IN THYROID FUNCTION TESTING AND IMAGING

In the past, measurement of radioactive iodine uptake by the thyroid was commonly used to assess thyroid function. The development of sensitive *in vitro* thyroid function tests and the decrease in normal values for thyroidal radioiodine uptake consequent to an increase in dietary iodine intake have largely rendered this technique obsolete.

Radioiodine uptake measurement, however, remains an important technique in evaluating the hyperthyroid patient. Its main roles are to distinguish subacute or silent thyroiditis from Graves' disease, to provide information regarding the feasibility of radioiodine therapy, and to aid in dose calculation at centers using calculated doses of ^{131}I .

Thyroid scanning (scintigraphy) allows visualization of the thyroid gland and functioning tissue elsewhere in the body. Therefore, it is valuable in

many clinical situations, including identifying the cause of hyperthyroidism, evaluating thyroid enlargement, the functionality of thyroid nodules, postoperative evaluation of differentiated thyroid cancer, and localization of ectopic thyroid tissue.

HYPERTHYROIDISM

^{131}I is increasingly used as first-line therapy for Graves' hyperthyroidism and is the treatment of choice for patients with relapsed hyperthyroidism after antithyroid drug treatment and toxic nodular goiter. Because adequate thyroidal iodine (and hence ^{131}I) uptake is a prerequisite for ^{131}I therapy, it is not an appropriate treatment modality for thyroid-stimulating hormone (TSH)-dependent hyperthyroidism and for other causes of hyperthyroidism with low iodine uptakes such as thyroiditis. The objective of ^{131}I therapy is to destroy sufficient tissue to cure hyperthyroidism. This may be achieved by rendering the patient either euthyroid or hypothyroid. ^{131}I typically takes 6 to 8 weeks to produce its effects, and euthyroidism is expected 3 to 6 months after ^{131}I administration. If this is not achieved, a second dose of ^{131}I is usually administered. The degree of lasting remission is close to 100% after one or more doses, and there is much more predictable shrinkage of goiter, often with complete disappearance, than can be achieved with antithyroid drugs.

Much attention has focused on achieving euthyroidism by adjusting the dose of ^{131}I , but there is little consensus regarding the most appropriate dose regimen. The regimens include repeated low doses (80 MBq), fixed doses of 200 or 400 MBq, and doses calculated on the basis of the size of the thyroid, the uptake of radioiodine, or the turnover of radioiodine. There is no evidence that giving a calculated dose of ^{131}I will achieve euthyroidism but not hypothyroidism, and calculated doses have the disadvantages of inconvenience (> 1 hospital visit required) and higher cost, so many centers use a single fixed dose. The lifetime chance of becoming hypothyroid following ^{131}I is at least 50% with a lifelong requirement for thyroxine replacement.

THYROID CANCER

The affinity of differentiated thyroid cancer for iodine is the basis for the use of ^{131}I for both the detection and the treatment of recurrent thyroid cancer in patients following initial surgical treatment (thyroidectomy). The main indications for ^{131}I therapy are the

ablation of residual thyroid tissue after thyroidectomy, the treatment of locoregional recurrence, and distant metastases that involve the lung and bones almost exclusively. The precise protocols for ^{131}I scanning and treatment are complex and controversial and have been reviewed extensively elsewhere.

NONTOXIC GOITER

Although thyroidectomy remains the standard treatment for large nontoxic goiters that compress the trachea, it may be contraindicated in the elderly or in goiter recurrence after previous thyroid surgery. In such cases, ^{131}I represents an effective alternative to surgery. Studies have shown that ^{131}I , administered in doses similar to those used in hyperthyroidism, is effective in reducing goiter size by approximately 40% in patients with nontoxic goiter. Initial concerns that ^{131}I treatment may lead to thyroid enlargement and worsening of airways obstruction in the short term have proved to be groundless. However, hypothyroidism may occur, as may the development of Graves' disease, which has been described in 5% of cases.

SAFETY AND SIDE EFFECTS

^{131}I treatment has been shown to be safe. Concerns about increased cancer risk are largely unfounded, with population studies showing no overall increase in the incidence of cancer or cancer mortality except for a small increase in the absolute risk of small bowel and thyroid cancer. Furthermore, there is no evidence to suggest any reduction in fertility or any problems in the offspring of women treated before pregnancy. The only absolute contraindications are pregnancy and breast-feeding. Pregnancy should be excluded before ^{131}I administration and should be delayed for 4 months after therapy. Relative contraindications include the use of ^{131}I in patients under 20 years of age, in whom it should be used with caution, and the presence of thyroid eye disease, which can potentially be worsened by ^{131}I but easily prevented by the use of corticosteroids.

Permanent hypothyroidism is the only common complication of ^{131}I treatment, occurring in at least 50% of patients given high doses (≥ 400 MBq) by 1 year and in at least 50% of those given lower doses (≤ 200 MBq) by 25 years. It is dose dependent, and its

incidence remains at 2 to 3% per year many years after therapy. Rarer complications include radiation thyroiditis, thyrotoxic crisis, and early paradoxical increase in goiter size.

membrane is stretched. Other gating mechanisms include interaction with substrates (Ca^{2+} , ATP) and other proteins (G proteins, calmodulin), chemical modification (phosphorylation), and physical stimuli (temperature, pH).

Generally speaking, voltage-gated channels have strict ion selectivity. The Na^+ channels distinguish Na^+ from K^+ and the K^+ channels discriminate K^+ from Na^+ . In contrast, ligand-gated channels show much weaker selectivity among ions (Li^+ , Na^+ , K^+ , and Cs^+ in the case of cation channels) and some of the cation channels also conduct Ca^{2+} . This may be related to the fact that changes in membrane potential influence all of the voltage-gated channels, whereas functional sites of the ligand-gated channels are localized mainly to small postsynaptic regions.

MOLECULAR STRUCTURE

Ion channels are transmembrane proteins. Over the past 20 years, molecular cloning has revealed the primary structures of a number of ion channels. Many of them are composed of subunits. The voltage-gated Na^+ channel is composed of the main α -subunit and the smaller β -subunits. The voltage-gated K^+ channel and nicotinic AChR are formed by four and five homologous subunits, respectively. The ATP-sensitive K^+ channel is a hetero-octamer comprising the pore-forming subunits and the regulatory subunits (sulfonylurea receptors). Structures composed of several subunits may have been advantageous during evolution to allow subtle tuning of the channel functions.

The three-dimensional (3D) structure of ion channels had been only speculative, based on analyses of the predicted amino acid sequences (hydrophobicity, α -helicity, etc.), effects of site-specific mutations on channel functions, and interactions with toxins or proteins. Studies using X-ray crystallography, however, elucidated the 3D structure of ion channels, including the Cl^- channel, the voltage-gated K^+ channel, and the glutamate receptor channel (partial structure), at atomic resolution. Furthermore, analyses using electron microscopy, together with a computational method, revealed the 3D structure of the nicotinic AChR.

Ion Permeation Pathway

The ion conduction pathway is not a simple cylindrical pore. At the mouth of the pore, there are charged amino acid residues attracting permeating ions (for example, negatively charged glutamic acid residues for Ca^{2+}). The pore wall is somewhat hydrophilic, so

most of the water molecules surrounding the ion (hydration shell) are taken away. Then, the ion passes through the narrowest part of the channel pore. The amino acid residues in the narrowest part are critical determinants of ion selectivity. The diameter of the narrowest portion of the ion-conducting pore is usually 3–7 Å, which can be estimated by measuring the permeability of organic cations of various sizes.

Gating Mechanism

Primary amino acid sequences of many voltage-gated channels show a characteristic arrangement of several positively charged amino acid residues in the fourth hydrophobic segment (S4). To sense the changes in membrane potential, there must be a charged structure in the electrical field, i.e., within the membrane. Therefore, the structure for voltage sensing was assumed to be a transmembrane segment. An X-ray study of the voltage-gated K^+ channel identified the structure of the “voltage-sensor paddle,” which contains S4. The voltage-sensor paddle operates like a hydrophobic cation attached to a lever, enabling the change in membrane potential to open and close the pore.

As for the ligand-gated channels, the structural studies of AChR suggested that binding of a ligand to the receptor site (located on the intersubunit interface) causes a twist in the subunits (rotation around the central axis), which opens the gate.

FUNCTIONS OF ION CHANNELS

The major functional roles of the ion channels can be categorized as follows: (1) The opening of ion channels leads to rapid breakdown of the electrochemical gradient prebuilt by transporters, which results in rapid changes in cellular potential. (2) Ions are taken into cells through the ion channels down the electrochemical gradient and pumped out to the other side of the cells. This results in a net flux across the epithelial cells (transepithelial transport). (3) Many ion channels mediate Ca^{2+} influx, which evokes various Ca^{2+} -dependent cellular responses. (4) Some channels function as molecular sensors (for mechanical stress, temperature, etc.), which are essential for cellular homeostasis.

As the history of ion channel research shows, the best-known functions of ion channels are the generation and propagation of action potentials in excitable cells and the synaptic transmission in the nervous system. The classical example is the neuromuscular junction, which was a favorite preparation for

electrophysiologists for many years. When acetylcholine is released from presynaptic nerve terminals of the motor nerve, acetylcholine molecules diffuse across the synaptic cleft and bind to the nicotinic AChR on the muscle cell membrane. Opening of the AChR then causes Na^+ influx, which results in depolarization of the potential of muscle cells. The neighboring Na^+ channels sense the depolarization and are activated to allow more Na^+ influx, spreading out the depolarization and finally generating the action potential. The voltage-gated Ca^{2+} channels also contribute to the action potentials. Although the principle of synaptic transmission in the central nervous system (CNS) is essentially the same as in the neuromuscular junctions, some synapses are inhibitory in the CNS. When the postsynaptic ligand-gated channels are Cl^- channels (GABA_A receptors and glycine receptors), the cellular potential response is usually hyperpolarizing (becoming more negative), thus inhibiting the generation of action potentials.

Ion channels are also essential for the release of neurotransmitter or the excretion of hormones. When the action potentials reach the nerve terminal, the voltage-gated Ca^{2+} channels open to mediate Ca^{2+} flux, which through a complicated cascade induces the fusion of synaptic vesicles to the plasma membrane and induces neurotransmitter release. Hormones are released in a similar way. Ca^{2+} is also essential for the contraction of muscles. In the case of the heart, Ca^{2+} that enters cardiac muscles through the voltage-gated Ca^{2+} channels activates the ryanodine receptors (also called the Ca^{2+} release channel), which in turn release Ca^{2+} from the sarcoplasmic reticulum (Ca^{2+} -induced Ca^{2+} release). Note that in the case of skeletal muscles, the Ca^{2+} channels are directly linked with the ryanodine receptor; the conformational changes of the former induced by cell excitation (action potential generation) trigger openings of the latter, releasing Ca^{2+} , which causes muscle contraction (excitation–contraction coupling).

The *N*-methyl-D-aspartic acid (NMDA) receptors (one type of GluR) are usually blocked by Mg^{2+} . But when the membrane potential becomes depolarized, the Mg^{2+} block is relieved. Because the NMDA receptors pass Ca^{2+} well, repetitive activation of the NMDA receptor leads to substantial Ca^{2+} influx into neurons. This activity-dependent Ca^{2+} influx is essential for some types of neuronal plasticity, including long-term potentiation in the hippocampal CA1 region.

Ion channels are also essential for transepithelial transport in many tissues. When Na^+ is reabsorbed in the kidney, for example, Na^+ enters from the apical (luminal) side into the epithelial cells down

the electrochemical gradient through the amiloride-sensitive epithelial Na^+ channel (which is different from the voltage-gated Na^+ channel) and then Na^+ is pumped out to the basal side.

When cells experience environmental changes, such as osmotic and mechanical pressures, metabolic stress, temperature, and various chemical stimuli, they must handle the changes. When cells are exposed to a low osmotic pressure, they become swollen, but their cellular volume returns to normal. This volume regulation is mediated by a volume-sensitive Cl^- channel, which is activated by stretches of the cellular membrane.

The ATP-sensitive K^+ (KATP) channels are inhibited by intracellular ATP and activated by MgADP. Increased glucose metabolism elevates the cytoplasmic concentration of ATP, which closes the KATP channels. In the case of the pancreatic beta cells, the closure of the KATP channels leads to exocytosis of insulin-containing granules through elevated Ca^{2+} mediated by the voltage-gated Ca^{2+} channels.

There are also ion channels that are activated by high and low temperatures, high Na^+ concentration, high H^+ concentration, and reduction–oxidation states.

REGULATIONS

Similar to other proteins, ion channels are subject to regulation by G proteins, protein kinases, calmodulin, and other proteins. Studies of the ion channels tagged with green fluorescent protein indicate that the activity of ion channels is regulated by changing the number of functional channels by inserting them into or removing them from the plasma membrane.

RELATED MOLECULES

Ion channels are proteins imbedded in the lipid bilayer and they can move anywhere unless they are anchored by other proteins. Such scaffold proteins are important not only for anchoring but also for putting functional components together so that signal transduction will be rapid and efficient. One good example is PSD95, which is located in the postsynaptic densities. There are many kinds of functional molecules, including cytoskeletal molecules attached to PSD95, that make a functional complex (referred to as the “signalplex”).

RELATED DISORDERS

Because ion channels are closely related to the ion transport mechanism and electrical activity, it is natural to

assume that dysfunction of ion channels leads to various kinds of disorders. Ion channels are targets of autoimmune disorders, including myasthenia gravis (against nicotinic AChR at neuromuscular junctions; causes muscle weakness), Lambert-Eaton syndrome (against Ca^{2+} channels at nerve terminals; causes muscle weakness), and Isaacs' syndrome (against K^+ channels of motor nerves; causes spontaneous muscular twitching).

Genetic studies of inherited diseases have identified an increasing number of gene mutations associated with a wide variety of diseases. The first major discovery was the identification of the cystic fibrosis transmembrane regulator (CFTR). CFTR has a complicated molecular structure similar to that of transporters, but is an anion channel conducting both Cl^- and HCO_3^- . CFTR is expressed in the apical membrane of epithelial cells of the intestine, airways, sweat glands, pancreas, etc. Because CFTR is crucial for various transepithelial transport processes, mutations of CFTR cause impairments in epithelial salt and fluid secretion as well as reabsorption.

Mutations of voltage-gated channels are also associated with several kinds of diseases. Mutations of the skeletal muscle Na^+ channels cause myotonia and periodic paralysis. Mutations of the cardiac Na^+ channel cause the long QT syndrome and Brugada syndrome. Other types of long QT syndrome result from mutations of K^+ channels (HERG, minK, and KCNQ1). Mutations of the brain Na^+ channels are associated with seizure disorders (generalized epilepsy with febrile seizure plus, severe myoclonic epilepsy of infancy). There are multiple channel phenotypes that arise from the Na^+ channel mutations, but a relatively common channel phenotype is impaired inactivation, which allows Na^+ currents to flow in continuously. The persistent Na^+ influx results in depolarization of muscle cells or neurons, leading to excessive muscle contraction, arrhythmia, and seizures.

Mutations of the gene encoding the voltage-gated Ca^{2+} channels are associated with neurological disorders. They include familial hemiplegic migraine, episodic ataxia 2, and spinocerebellar ataxia 6. There are mouse counterparts of the ataxic disorder and some mice also exhibit seizure disorders. Analyses of neuronal network functions of the mouse models suggest that mutations of the Ca^{2+} channels impair transmission at some synapses, but leave others relatively spared. This uneven involvement of the mutational effects may disrupt the well-balanced interactions between excitatory and inhibitory neuronal networks,

thus causing the paroxysmal disorders, in addition to the chronic progressive disorders.

THERAPEUTIC VIEW

Ion channels are usually on the cell surface and relatively easily accessible and thus are good pharmacological targets. Actually, many commonly used drugs act on ion channels.

The Na^+ channels have been a good target for therapeutic purposes. Blocking of nerve conduction in peripheral nerves prevents, for example, pain signals from entering the CNS. Lidocaine and other local anesthetics can block the Na^+ channels when they are open and temporarily prevent the channels from re-opening. A similar mechanism is hypothesized for the use of lidocaine to prevent ventricular arrhythmia. Once the cardiac Na^+ channels open, lidocaine inhibits them from opening successively. As seen from these examples, drugs acting on the Na^+ channels should be state-dependent, that is, acting on channels only in the open or related states. If they act on Na^+ channels in both an open and a closed state, they would cause muscle weakness, drowsiness, and other side effects. The blockers of the voltage-gated Ca^{2+} channels (" Ca^{2+} blockers") are widely used for the treatment of hypertension. The K^+ channel openers are used for the treatment of hypertension and ischemic heart disease.

Ligand-gated channels are also targets for commonly used drugs, which include muscle relaxants (succinylcholine, pancuronium) acting on nicotinic AChR and sedative-hypnotic drugs (diazepam) acting on GABA receptors.

PERSPECTIVES

The study of ion channels has a relatively long history. In the past, electrophysiology (function) used to lead biochemistry/molecular biology (structure/molecule). However, this order has become reversed. Genome analyses have revealed many candidates for ion channels whose functions are yet unknown. Surprisingly, some of these "orphan" ion channels have turned out to be molecules playing essential roles, for example, in sensing temperature. Further analyses of novel channels, together with the development of specific drugs, will contribute to a better understanding of the basic mechanism of the human body and also to better medical treatments.

after a mean dose as low as 100 mGy to the thyroid. There was no evidence for a threshold dose below which the effect disappeared, although at doses higher than 1500 cGy the risk per gray decreased, probably because of cell killing, but the overall risk remained elevated.

In a study of 2634 patients at a Chicago hospital whose thyroids received a mean dose of 590 mGy for benign diseases during childhood, approximately 60% developed thyroid nodules and 15% developed thyroid carcinoma during 40 years of follow-up.

In most studies, the latency period between the time of radiation exposure and the appearance of the thyroid nodule ranges between 5 and 15 years. In the pooled analysis of seven studies mentioned previously, only two cases were seen within 5 years of exposure; the risk clearly increased 5 to 9 years after exposure, peaked at 15 to 19 years after radiation exposure, and then declined, although an excess risk was still apparent at 40 years follow-up.

Taken together, these studies demonstrate that the risk of thyroid cancer after exposure to external radiation is indeed very high and that the thyroid gland is very sensitive to radiation, especially during childhood.

In case of external radiation to the head and neck for malignant disease, the dose delivered to the thyroid is usually greater than that delivered for the treatment of benign conditions. In this situation, the risk of thyroid tumor may still be increased, but the risk per gray decreases. This finding has been attributed to cell killing, which decreases the number of cells that may become neoplastic and explains the high frequency of hypothyroidism observed after large dose irradiation.

High-dose radiation therapy to the neck (>20 Gy), such as the one used in Hodgkin's disease, results in high rate of hypothyroidism but also in an increased risk of thyroid cancer. The final outcome of the thyroid damage is probably related to the distance between the thyroid gland and the radiation field. If this is far from the thyroid, as in the case of thoracic or abdominal radiation fields in children, the thyroid gland may receive radiation doses of some 100 mGy, not enough to produce hypothyroidism but sufficient to trigger thyroid cancer.

Radiation-induced thyroid carcinoma from external sources has also been noted after accidental contamination. Indeed, thyroid carcinoma was the first solid malignant tumor found to be increased among Japanese atomic bomb survivors. After the bombing in Hiroshima and Nagasaki in 1945, the body dose was due mainly to external irradiation (X rays and

neutrons). The health consequences were studied in a cohort of 94,000 survivors and of 26,000 individuals who resided in Hiroshima and Nagasaki shortly after the bombing. A total of 225 thyroid cancers were diagnosed between 1958 and 1987 among the 79,972 survivors who were alive and free of cancer as of January 1958 and who had radiation dose estimates. From the Lifespan Study of atomic bomb survivors in Hiroshima and Nagasaki, it is known that little risk is carried for exposures after 20 years of age and that almost none is carried for exposures after 40 years of age.

Factors Affecting Sensitivity to Develop Radiation-Induced Thyroid Cancer

Age and Sex

A major risk factor is a young age at the time of irradiation. The risk of thyroid cancer after external irradiation in children under 5 years of age is twofold higher than that in children treated between 5 and 9 years of age and is fivefold higher than that in children treated between 10 and 14 years of age. In the Japanese atomic bomb survivors, the excess risks (ERs) of thyroid cancer were 9.5, 3.0, 0.3, and 0.2 in the age categories of 0–9, 10–19, 20–39, and over 40 years of age, respectively, at the time of the bombing. The ERs were not significant for survivors exposed over 15 to 20 years of age.

Gender does not seem to influence the risk of developing radiation-induced thyroid cancer. Although females are two to three times more likely to develop both benign and malignant thyroid nodules after irradiation, this finding reflects the higher natural incidence of thyroid nodules and cancer in the female general population.

Genetic Predisposition

Several clinical observations suggest that genetic predisposition, such as defects in the DNA repair mechanisms, may affect the risk of developing radiation-induced thyroid cancer. Patients who experience one radiation-related cancer are more likely to develop a second radiation-related cancer. Sibling pairs exposed to radiation develop thyroid tumors more often than would be expected by chance. The risk of thyroid cancer in individuals treated with radiotherapy during childhood for a cancer (other than neuroblastoma) is 3 to 10 times higher than that in children treated for benign conditions. Those treated for neuroblastoma have a fivefold risk of thyroid cancer compared with those treated for other

cancers, suggesting a common predisposition for neuroblastoma and thyroid cancer.

A search for genes predisposing to radiation-induced thyroid cancer is in progress in pedigrees with the recurrence of thyroid cancer. No linkage has been found with genes already known to be involved in thyroid tumorigenesis such as *ras*, *p53*, and *RET/PTC*.

THYROID DISORDERS AFTER EXPOSURE TO RADIOACTIVE IODINE

The role of radioactive iodine administered for medical uses in the development of thyroid cancer has been addressed in a few studies that found no significant risk and led to the conclusion that ¹³¹I is safe both as a diagnostic and a therapeutic tool. However, most patients of these studies were treated during adulthood, whereas the post-Chernobyl epidemic of thyroid cancer occurred mainly in children and adolescents, suggesting that the young thyroid is particularly sensitive to the effect of radiation. This event has renewed concern about the carcinogenic risk of medical use of ¹³¹I, at least in young patients.

Radioactive iodine (¹³¹I) has been used in clinical practice for many years, both for the diagnostic evaluation of thyroid disorders and for treatment of benign and malignant conditions (hyperthyroidism and metastatic thyroid cancer, respectively). The radiation dose delivered by ¹³¹I to the thyroid is 1000- to 10,000-fold higher than that delivered to other tissues. Thus, even a relatively low amount of ¹³¹I may deliver a significant radiation dose—potentially carcinogenic—to the thyroid gland. Increasing the radiation dose beyond a few hundred MBq increases the likelihood of obtaining cell killing and decreases the possibility of tumoral changes.

The dose of radioiodine administered to the patient is very large (on the order of >100 mCi) in the treatment of thyroid cancer when the dose used is intended to kill all thyroid cancer cells. The dose is smaller (<20–25 mCi) in the treatment of thyrotoxicosis when the intent is to produce hypothyroidism. In these conditions, the radiation doses are sufficiently high to kill the cells; thus, no unwanted secondary thyroid disease occurs.

Low doses of iodine isotopes are used as a tracer for diagnostic evaluation of the thyroid gland. In this situation, no cell killing is observed and thyroid cell damage is theoretically possible. However, no convincing evidence of subsequent thyroid disorders has been provided.

The most informative analysis in this setting was performed in Sweden with 34,104 people exposed to diagnostic doses of ¹³¹I during the period from 1950 to 1969, for a mean thyroid dose estimate of 110 cGy. A small increase in the number of observed thyroid cancers ($n=67$) was found with respect to the expected number ($n=50$). However, the increase was confined to individuals undergoing thyroid scans for suspicion of thyroid cancer. When the analysis was limited to individuals tested for reasons other than thyroid cancer, no increase was observed.

In the same Sweden cohort, a subset of 1005 women was compared with 248 matched controls regarding the incidence of thyroid nodules. The average length of follow-up was 26 years, and the average age at exposure was 26 years. No difference was found in the two groups; the incidences of nodules were 10.6 and 11.7, respectively.

The conclusion drawn from the study with the Sweden cohort is that diagnostic use of ¹³¹I has no health effect on the thyroid. However, it should be noted that only a minority of the individuals exposed were children.

Also after treatment of hyperthyroidism with ¹³¹I, no evidence of an increased risk of thyroid cancer has been reported. In another study conducted in Sweden with 10,552 adult patients (mean age 57 years) followed for a mean period of 15 years, the relative risk (RR) of thyroid cancer was not increased significantly (RR = 1.29, 95% confidence interval [CI]: 0.76–2.03). The average estimated radiation dose to the thyroid was 100 Gy.

In a study carried out in the United States, it appears that after a mean follow-up of 21 years, ¹³¹I treatment was not linked to thyroid cancer deaths (standard mortality ratio [SMR] = 1.02) or to the development of any specific cancer with the exception of thyroid cancer (SMR = 3.94, 95% CI: 2.52–5.86). The SMRs were 2.08 in patients with Graves' disease and 6.53 in those with toxic nodular goiter. The excess number of deaths was small (observed/expected ratio of 27/10), and the underlying disease, rather than radiation, seemed to play the major role.

This conclusion is not surprisingly. The high dose delivered in the case of hyperthyroidism is frequently sufficient to produce hypothyroidism through cell killing. Indeed, the risk of hypothyroidism at 2 years increases linearly with the thyroid dose for radioactive concentrations ranging from 0.9 to 8.3 MBq/g.

As in the case of diagnostic use of ¹³¹I, also in the case of hyperthyroidism, the patients treated were mainly adults. In a few hundred children treated with ¹³¹I, no significant increase in the incidence of

thyroid cancer has been observed. However, in view of the high sensitivity of the young thyroid gland to radiation, it is probably advisable not to use ^{131}I in treating hyperthyroidism in young children and adolescents.

So far as treatment of differentiated thyroid cancer with ^{131}I is concerned, there is a low but significant risk of secondary effects on other organs (mainly testis, ovary, and bone marrow) when cumulating high radiation doses during several treatment courses.

THYROID EFFECTS OF THE CHERNOBYL NUCLEAR DISASTER

The explosion of one of the reactors at the nuclear power plant in Chernobyl, Ukraine, occurred in April 1986 and released large amounts of radioactive particles into the atmosphere, including ^{131}I (32–46 Mci), ^{132}I (27 Mci, resulting from the decay of technetium-132), and ^{133}I (68 Mci). Most likely, radioiodines were released intermittently over a period of 10 days after the accident. The most contaminated territories were southern Belarus, northern Ukraine, and the Bryansk and Kaluga regions of southern Russia.

Volatile radioactive isotopes could be first inhaled and, after being deposited on the ground, ingested. The time at which ingestion occurred varied considerably, but the milk chain, particularly in children, was the major route of ingestion; at this time, short-lived isotopes of iodine were no longer present. Several factors contributed to the high radiation exposure of the population. Immediate protective countermeasures, such as advising and evacuating the people at risk and distributing iodine prophylaxes, were not undertaken. Furthermore, the most contaminated regions were in a state of moderate iodine deficiency, and this is responsible for increased iodine uptake. All of these factors combine to give enough of an explanation as to why the most serious health consequence of the disaster was thyroid cancer and why children were affected the most.

In the case of radioactive contamination, the thyroid gland is a critical organ at risk. Its contamination depends on the magnitude of contamination, the amount of radioactive iodine taken up by the gland, and the thyroid mass itself. Furthermore, whatever the level of contamination, the thyroid dose is always higher in children than in adults. The thyroid dose is dependent on the final concentration, namely the ratio between radioiodine uptake and thyroid mass. The uptake in children is similar to that in adults except that the thyroid mass is smaller and the thyroid

dose per gram of tissue is greater—and is extremely higher in newborns and very young children.

Post-Chernobyl Thyroid Cancer

As a result of the accident, a tremendous increase in the number of cases of childhood papillary thyroid cancer has occurred in the subsequent years, starting in 1992. The magnitude of this increase and the geographical and temporal distribution of the cases strongly suggest that thyroid cancer was due to the reactor explosion and particularly to the huge amount of iodine radioisotopes released. The increase in the number of cases of thyroid carcinoma in children and adolescents has been observed starting from 1990, only 4 years after the Chernobyl accident, in southern Belarus and northern Ukraine, and from 1994 in southern Russia. More than 1000 cases of thyroid cancer have been reported among approximately 2 million children younger than 15 years of age who were exposed to radioactive fallout. In the Gomel region, the most contaminated area of Belarus, the incidence between 1986 and 1996 was 13 per 100,000 children per year compared with a baseline incidence of less than 1 per 100,000 children per year.

Although dosimetric data are imprecise, the mean thyroid dose has been estimated to be nearly 700 mSv in Belarus. In Ukraine, 79.0% of the children received a thyroid dose less than or equal to 300 mSv, 10.5% received between 300 mSv and 1 Sv, and 10.5% received more than 1 Sv. As a means of comparison, in children exposed to external irradiation, the risk of thyroid cancer was significant even for thyroid doses as low as 100 mSv.

In most of the children who developed thyroid cancer, the estimated thyroid dose has been less than or equal to 300 mGy. However, an excess thyroid cancer incidence has been observed even in areas where the mean thyroid dose in children was estimated to be 50 to 100 mGy.

Genetics of Post-Chernobyl Thyroid Cancer

Molecular biology investigation of post-Chernobyl tumors shows some peculiarities. Ras and p53 genes are not involved in their pathogenesis. Rearrangements of the RET proto-oncogene are found in nearly 70% of the cases, a percentage higher than that observed in naturally occurring papillary carcinomas. Also, the subtype of RET/PTC rearrangement has a peculiar pattern. Several studies have reported that

RET/PTC 3 (and more rare variants of RET/PTC 3) is the form more frequently expressed in radiation-induced tumors, rather than RET/PTC 1, which is predominant in naturally occurring cases. A correlation has also been established between the solid variant of papillary tumors and the activation of RET/PTC 3.

These data indicate that RET/PTC activation may be the direct result of radiation-induced DNA damage. Because RET/PTC is also frequently found in pediatric papillary thyroid cancer without known exposure to radiation, it is also possible that age per se may play an important role. Alternatively, one can speculate that virtually all pediatric papillary thyroid cancers are radiation-induced cancers that develop in individuals with an increased susceptibility to spontaneous background radiation.

OTHER THYROID CONSEQUENCES OF RADIATION EXPOSURE

Thyroid cancer and benign thyroid nodules after radiation exposure occur as stochastic effects. Depending on the radiation dose, deterministic effects, hypothyroidism, and acute thyroiditis are also possible. Another documented consequence of radiation is the possibility of developing autoimmune thyroid disorders.

Hypothyroidism is caused by radiation doses on the order of more than several gray to the thyroid. Such levels are observed mainly after radioiodine therapy for benign thyroid diseases, such as Graves' disease and toxic nodular goiter, and in this case hypothyroidism is the objective of treatment.

Spontaneous hypothyroidism (or subclinical hypothyroidism) has been reported in atomic bomb survivors in Nagasaki. Among 2587 individuals, spontaneous hypothyroidism was diagnosed in 43 (27 of whom were thyroid antibody positive and 16 of whom were thyroid antibody negative) without sex differences. Because an association was observed between thyroid dose and the prevalence of antibody positive (but not antibody negative) spontaneous hypothyroidism, the last conceivably stemmed from an underlying autoimmune thyroid disorder. This concept is supported by the finding that the frequency of radiation-associated hypothyroidism in patients treated for malignant lymphoma decreased significantly when radiation therapy was combined with chemotherapy and immunosuppressive agents.

After external irradiation to the head and neck, the occurrence of thyroid autoimmunity has been

reported in several studies. An increased incidence of thyroid antibodies was found in individuals who received radiation for benign disorders during childhood. Variable degrees of thyroid lymphocytic infiltration have been reported in more than two-thirds of individuals who received radiation several years before thyroidectomy for nodular thyroid lesions. In patients who received radiation of the neck for Hodgkin's disease, 3% or more developed Graves' disease (a 7- to 20-fold excess risk) and 1% developed thyroiditis.

Hypothyroidism has also been reported after exposure to internal radiation (radioactive iodine). In the people exposed to the fallout from the Marshall Islands accident, hypothyroidism was noted within 10 years after the accident. In this instance, most of the cases were not associated with autoimmune thyroid reaction.

On the contrary, an increased prevalence of antithyroid antibodies (19.5%) without hypothyroidism has been reported in children living in a Belarus village heavily contaminated by the post-Chernobyl radioactive fallout, compared with children living in a noncontaminated village (3.8% prevalence). The susceptibility to developing thyroid autoimmunity increased with age at the time of exposure; in the female sex, it reached its maximum during the pubertal age, suggesting that puberty (estrogen) has a cumulative effect on radiation in the development of thyroid antibodies in females. This study was conducted only 6 to 8 years after the Chernobyl accident, and this may be the reason why cases of overt hypothyroidism were not found. However, the possibility of developing thyroid failure later is very likely in this population.

The release of thyroid antigen from damaged thyroid cells is regarded as the possible mechanism triggering the autoimmune reaction after radiation injury, regardless of the modality of thyroid exposure.

typically of the extracellular domains, cytokine receptors are broadly classified into four subfamilies. The type I or hemopoietic cytokine receptors bind IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, GM-CSF, G-CSF, erythropoietin, growth hormone, prolactin, and oncostatin M. Their extracellular domain has two fibronectin type III modules, the hinge region between which is believed to be the site for ligand contact. The WSXWS (Trp-Ser-X-Trp-Ser) motif is also found in type I receptors (except prolactin and growth hormone) and is located close to the plasma membrane. The cytoplasmic tails of these type I receptors contain two special motifs: a well-defined box 1 and a not so well-defined box 2. Reports suggest that the box 1 and box 2 domains are important for association with and activation of Janus kinases (JAKs). The type II (interferon, IFN) family receptors include receptors for IFN- α/β (which share a common receptor), IFN- γ , and IL-10. Tumor necrosis factor receptors (TNFRs I and II), as well as receptors for Fas, nerve growth factor, and CD40, are examples of type III cytokine receptors. Cytokine receptors bearing immunoglobulin-like structures are classified as type IV receptors, and the IL-1 receptor proteins are a prototype for this family.

How a given cytokine affects cell function depends on the cell type, its state of differentiation, and the stage in the cell cycle. A given cytokine can exert multiple effects on the same cell (pleiotropic effects), many cytokines can perform the same set of actions on a given cell type (redundant effects), and one cytokine can exert antagonistic or synergistic effects on the action of another cytokine (combinatorial effects). Some of these properties can be explained by the similarities and differences in signaling machinery expressed by distinct cell types at different times during the cell cycle. For example, redundancy in cytokine action may be attributed, at least in part, to the sharing of common signal-transducing receptor chains by several cytokine receptor complexes. A given receptor complex recruits only particular JAK species and activates only selected signal transducer and activator of transcription (STAT) proteins. The association of JAKs and STATs with different receptors in the context of signaling by different cytokines permits different cellular effects to be elicited using a limited repertoire of intracellular signaling molecules. It may be speculated that the existence of different associated proteins (e.g., chaperones, adaptors) in different cell types may then permit cross-talk among different pathways in a regulated yet interdependent fashion, perhaps accounting for the pleiotropism of cytokine actions.

JANUS KINASES: STRUCTURE AND DOMAINS

Downstream signal transduction events from the cell surface can be mediated by protein tyrosine kinases (PTKs) through either intrinsic receptor tyrosine kinases (RTKs) or recruitment of nonreceptor protein tyrosine kinases (non-RTKs). The JAK subfamily is structurally unique among the more than 10 non-RTK subfamilies (e.g., Src, FAK, Syk, Fes, Tec) that are known. JAKs derive their name from the fact that they possess a catalytic tyrosine kinase domain (JH1) juxtaposed to a second inactive tyrosine kinase-like domain (JH2)—in an analogy to Janus, the mythological two-headed “keeper of gates.” The second JH domain (JH2) is nonfunctional and is often referred to as the “pseudokinase” domain. The other unique feature of JAK proteins is the absence of any Src homology domains (e.g., SH2, SH3), a characteristic feature of other nonreceptor PTK proteins. Four members of the JAK family protein are known in mammals and have been designated JAK1, JAK2, JAK3, and Tyk2. JAK1, JAK2, and Tyk2 are more or less expressed ubiquitously, whereas JAK3 is almost exclusively expressed in hematopoietic tissue. A *Drosophila* JAK has been identified and is called Hopscotch. More recently, piscine JAKs from zebrafish and carp have also been cloned. Alternately spliced versions of JAK2 and JAK3 have been identified, and it has been speculated that they may have a role as natural dominant-negative forms of these proteins.

In each JAK protein (size in the range of 1124–1187 amino acid residues in humans), the nonconserved amino terminal is followed by seven highly conserved domains termed JAK homology domains (JH domains), beginning with JH7 at the amino terminus and ending with JH1 at the carboxy terminus. JH1 is the active tyrosine kinase domain and shares considerable homology with the kinase domains in other PTKs. JH2, the adjacent kinase homology domain, is a nonfunctional domain because it lacks specific amino acids required for kinase activity. Saharinen and colleagues described a regulatory role for this domain in JAK2 function, perhaps through its interaction with the catalytic kinase JH1 domain. The function of the other JH domains is still not understood and is the subject of intensive investigations. Several recent reports suggest a role for the JH7–JH6 region in binding to cytokine receptor chains. It is likely that these domains interact with different adaptor or binding proteins in the context of different receptors and so confer specificity on respective signaling pathways.

JANUS KINASES: ACTIVATION, MECHANISM OF ACTION, AND SUBSTRATES

Typically, JAKs reside in the cell in an inactive form. Cytokine binding to cell surface receptors leads to receptor chain dimerization/oligomerization, followed by recruitment of JAKs to the cytosolic face of the receptor complexes. Exactly how the JAKs are activated is still being investigated, but a popular model is one of tyrosine phosphorylation by JAKs in trans bound to the separate but now adjacent receptor chains that come close together on receptor chain dimerization/oligomerization triggered by ligand binding. JAK activation by tyrosine phosphorylation can include the participation of other receptor or nonreceptor PTKs. Inactivation of protein tyrosine phosphatases (PTPs), such as by the PTP inhibitor orthovanadate, has been used extensively as a mechanism for “ligand-independent” JAK activation.

Cellular ligands that activate JAKs include, but are not limited to, cytokines and growth factors. Specific cytokines signal through specific receptors and activate specific JAKs. Thus, IL-3 activates mainly JAK2, IL-9 activates mainly JAK3, and IFN- γ activates JAK1 and JAK2. IL-6, CNTF, OSM, and LIF all activate JAK1, JAK2, and Tyk2. JAKs then phosphorylate specific tyrosine residues on the receptor chains and create docking sites for the binding of SH2 domain-containing proteins, most importantly STAT family members. STATs are then phosphorylated on key tyrosine residues, and they dimerize and make their way to the nucleus, where they up-regulate target genes. Although JAKs are capable of phosphorylating STATs, other PTKs (including Src) also have a role in this event. JAKs do not seem to exhibit any specificity per se regarding which STATs they activate. In light of this, Rane and Reddy proposed the JAK–Src–STAT model, where JAKs have a predominant role in creating docking sites for STATs, and either Src or JAKs can then phosphorylate STATs. It is noteworthy that docking sites created by JAKs on cytokine receptors have also been shown to bind other substrate proteins such as Shc, Src kinases, and PI-3 kinase, thereby mediating cross-talk among different signaling pathways.

REGULATION OF JAK ACTIVITY: ROLE OF PHOSPHATASES AND THE SOCS PROTEIN FAMILY

As a pathway critical to several key functions performed by the cell, the JAK–STAT pathway

can be expected to be tightly regulated. The kinase–phosphatase theme for phosphorylation–dephosphorylation of signaling molecules is a general approach to regulate many cellular activities. PTPs, which dephosphorylate tyrosine residues on activated JAKs, are emerging as potential candidates regulating JAK activity, and it is very likely that more than one PTP can play a role in regulating the activity of a particular JAK, depending on the cell type and the cytokine context. SH2 domain-containing phosphatases-1 and-2 (SHP-1 and SHP-2) are by far the most well-studied PTPs. Other PTPs, such as TC-PTP, PTP-1b, and PTPeC, have been implicated in the down-regulation of activity of one or the other JAK.

An exciting new development in the field is the discovery of a family of proteins that negatively regulate JAK activity. The suppressor of cytokine signaling (SOCS) proteins are a family of small, cytokine-inducible, SH2 domain-containing proteins. Eight members of this family (SOCS-1 to SOCS-7 and CIS) in mammals, and three members in *Drosophila*, have been identified. Some of them have been shown to bind the JAK kinase domain and so down-regulate catalytic activity. A second mechanism for down-regulation of JAK activity by SOCS proteins is through a C-terminal domain in these proteins, the SOCS box, which has been suggested to target bound proteins for ubiquitination and subsequent proteosomal degradation. The SOCS box has been shown to be present in more than 20 proteins besides those in the SOCS protein family itself. Perhaps these additional proteins may serve as regulators of pathways other than the JAK–STAT pathway. Moreover, cytokines themselves transcriptionally up-regulate the expression of SOCS proteins as part of a negative feedback loop.

NEW INSIGHTS: JANUS KINASES AND CYTOKINE RECEPTORS IN LIPID RAFTS

Thermodynamic parameters govern complex biochemical phenomena, and this holds true for signal transduction within cells as well. There is now a growing understanding that multiprotein signaling events, such as those outlined previously, take place within minutes in the context of preformed supramolecular assemblies. Such preformed assemblies—at the level of the plasma membrane—of various signaling components in close proximity make for a more thermodynamically efficient model for signal transduction, in contrast to an initial state with free-floating reactants in the cytosol or in the plane of

the plasma membrane. Recent research has led to the elucidation of organized microdomains within the plasma membrane that specialize in signal transduction. Originally described during the 1950s as microscopic invaginations or “caveolae” in the plasma membrane, such regions are now more commonly referred to as lipid rafts. These raft microdomains are enriched in cholesterol and sphingolipids, contain integral raft proteins (caveolins, flotillins, and stomatins), and have an elaborate repertoire of signaling pathway components. The function of caveolae and rafts has now been confirmed in cholesterol trafficking and various signaling pathways (e.g., T-cell antigen receptor, B-cell receptor, platelet-derived growth factor [PDGF], Ha-Ras, insulin receptor, EphrinB1). The raft-signaling hypothesis proposes that most, if not all, signaling events are initiated at the level of plasma membrane rafts that contain the receptors and associated signaling components in a preassembled supramolecular form. Exactly how the lipid partners play a role in these events is being investigated.

During recent years, components of the JAK–STAT pathway have also been identified in preassembled complexes in lipid rafts in the plasma membrane, and there is growing functional evidence to suggest that cytokine-induced STAT signaling is initiated at the level of such lipid rafts. Various investigators have reported the existence of cytokine receptor chains (gp130, IFN- γ R α , IFNAR-1, and IL-2R α), JAKs (JAK1, JAK2, and Tyk2), and STATs (STAT1 and STAT3) within lipid rafts. That the integrity of the caveolar structure is required in JAK–STAT signaling has been demonstrated in the context of IL-6–STAT3, IFN- γ –STAT1, bradykinin–STAT3, and prolactin–STAT5a signaling. We have proposed the “raft–STAT signaling hypothesis” and believe that this is a general mechanism that operates in the broader context of cytokine- and growth factor-induced JAK–STAT signaling.

JANUS KINASES: PATHOLOGICAL IMPLICATIONS

In mice, JAK1 or JAK2 disruption or deletion invariably results in a phenotype incompatible with life. JAK3 knockout mice exhibit severe hematopoietic anomalies with grossly immunocompromised

phenotypes. In humans, no pathology has been attributed to absent or decreased endogenous activity of JAK1, JAK2, or Tyk2—probably because, as in mice, disruption of their function causes ubiquitous defects that are incompatible with life. JAK3 mutations in humans are expected to cause defects in the immune system, and indeed several patients with severe combined immunodeficiency syndrome (SCID) have been shown to have mutations on the JAK3 locus. Aberrant overactivation of JAK activity has also been implicated in malignancies, including acute lymphoblastic leukemia. Aberrant SOCS activity has been demonstrated to have a role in inflammatory bowel diseases and in gastrointestinal cancers and leukemias, among other diseases.

ETIOLOGY AND PATHOGENESIS

The endocrine regulation of testicular or ovarian functions is performed by the gonadotropic hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), secreted by the gonadotropic cells of the anterior pituitary gland, the function of which is regulated via gonadotropin-releasing hormone (GnRH) released by the hypothalamus. In men, due to LH and FSH deficiency, the testicular functions of testosterone production and spermatogenesis are impaired under conditions of insufficient GnRH release (e.g., in Kallmann's syndrome and IHH). In women, the same applies to estrogen production and ovulation. For the X chromosomal recessive variant of the disease, the underlying mechanism of defective GnRH release has been described as impaired migration of GnRH neurons from the nasal olfactory epithelium to their proper anatomical location in the basal hypothalamus, a process that occurs during normal embryonic development. The gene responsible for this phenomenon is located on the short arm of the X chromosome (Xp22.3) and is called *KAL-1*. The corresponding protein seems to be an extracellular regulator of the directed outgrowth of axons and is called anosmin-1 (after the clinical feature of anosmia found in Kallmann's syndrome). Nevertheless, pedigrees of patients suggest an autosomal dominant and autosomal recessive inheritance as well, and most patients (65%) represent sporadic cases. Well-documented familial case reports demonstrate that Kallmann's syndrome, IHH, and isolated anosmia without concomitant deficient GnRH release can be regarded as manifestations within the spectrum of one underlying disease since these disorders are found in close relatives. Genes currently recognized

to be involved in congenital hypogonadotropic hypogonadism include *KAL-1*, the GnRH receptor, *DAX-1*, and *PROP-1*. Furthermore, sporadic cases of mutations in *ANK-1*, *SF-1*, *FGFR-1*, *LHX-3*, and *HESX-1*, as well as the leptin (*Ob*) gene, the leptin receptor (*Ob-R*) gene, and the prohormone convertase-1 gene, have been reported. However, a genetic basis for IHH has been established in less than 30% of cases; thus, several autosomal and X-linked genes await description.

CLINICAL FEATURES

The clinical hallmark of Kallmann's syndrome and IHH is the absence or incompleteness of pubertal development accompanied by symptoms of hypogonadism (Table I). Male patients often present with uni- or bilateral maldescendent testes; sometimes, orchidopexy has been performed during childhood. The scrotum is usually hypoplastic, bearing small, soft testes (in contrast to Klinefelter's syndrome, in which the testes are small and firm). Other clinical features of prepubertal hypogonadism are underdevelopment of the penis and prostate; the absence or scarceness of pubic, axillary, or body hair; lack of beard growth; eunuchoid proportions of the body (arm span > body height in males); and a female distribution of fat tissue. Sexual activities are often undeveloped or are reduced, and the patients are infertile. A long-standing deficiency of sex steroids will often cause reduced bone density and slight anemia. Since estrogen production is low as well, gynecomastia is a rare finding. Females with Kallmann's syndrome or IHH display a delay in puberty, primary amenorrhea, and often short stature.

Table I Symptoms of Kallmann's Syndrome and Idiopathic Hypogonadotropic Hypogonadism (Prepubertal Onset)

| Organ / function | Males | Females |
|---------------------------|--|---|
| Larynx | No voice mutation | Infantile |
| Skin | Female hair pattern, low sebum production | Scarce pubic hair, low sebum production |
| Bones | Eunuchoidal body proportions, osteoporosis | Often small stature, osteoporosis |
| Breasts | Rarely gynecomastia | Underdeveloped |
| Erythropoiesis | Slight anemia | Slight anemia |
| Muscles | Underdeveloped | Underdeveloped |
| External genitalia | Infantile | Infantile |
| Prostata/uterus | Underdeveloped | Underdeveloped |
| Testes/ovaries | Small volume, often maldescended | Small volume, mostly primordial stage |
| Spermatogenesis/ovulation | Not initiated | Not initiated |
| Mood | Often depressed | Often depressed |
| Libido | Not developed/sexual infantilism | Not developed/sexual infantilism |

In patients with Kallmann's syndrome, anosmia is found due to an inability to perceive olfactory stimuli; this is a result of aplasia or hypoplasia of the olfactory bulbs and tracts. The insensitivity relates to aromatic substances, whereas stimulants of the trigeminal nerve, such as ammonia, are perceived. The clinical feature of anosmia is notably absent in IHH, which is otherwise similar to Kallmann's syndrome. Rare anomalies associated with Kallmann's syndrome are impaired hearing, a cleft lip or high arched palate, synkinesis of the extremities, and unilateral renal aplasia. Within the cardiovascular system, malformations such as a double-outlet right ventricle or malposition of the great vessels have been described. There is significant clinical variability with regard to severity and time of onset: Minor forms with partial pubertal development or a late onset during adulthood have been described along with the fully expressed disease. In women, the X-linked form demonstrates penetrance of high variability. It has to be considered that in women a partial development of sexual characteristics can occur due to gonadotropin-independent adrenal steroidogenesis, which does not have a major impact on the development of males.

ESTABLISHMENT OF DIAGNOSIS

If the clinical picture, physical exam including genitalia, and patient's history lead to the suspected diagnosis of Kallmann's syndrome or IHH, basal serum levels of the gonadotropins, testosterone, and estradiol will yield valuable information. Typically, patients with Kallmann's syndrome or IHH have markedly low levels of the previously mentioned parameters (hypogonadotropic hypogonadism). The responsiveness of gonadotropins to a GnRH stimulus (100 µg intravenously, remeasured after 30 and 45 min) is often poor or absent, which should not immediately be interpreted as a disorder at the pituitary level. The gonadotropic cells in the anterior pituitary often require a certain period of "priming" by means of subcutaneous application of GnRH in a pulsatile manner: For 7 days, 5 µg of GnRH is released every 90–120 min using a portable minipump. If the gonadotropin response (increase in LH and FSH levels ≥ 3 IU/liter) to a GnRH bolus is normalized, then the hypothalamic origin of the hypogonadism is indicated. When there is permanent resistance to GnRH, a pituitary disorder or mutation of the GnRH receptor must be suspected.

Putative anosmia can be examined by standardized sets of olfactants that should contain mucosal irritants and gustatory stimuli as controls. If these are not

available, coffee and perfumed soap can be used as aromatic substances and vinegar may be used as the control.

Hypogonadal endocrine disorders require the assessment of other hormone axes that might also be affected: The levels of thyroid hormones and TSH, insulin-like growth factor-1 and growth hormone, cortisol, and prolactin should be determined. The diagnostic workup should include imaging procedures, such as ultrasonography of testes, prostate/ovaries, and uterus as well as magnetic resonance imaging of the hypothalamic-pituitary region, to exclude intracranial neoplasms. Measurement of bone density and bone age (in prepubertal patients) should be performed as well.

Because Kallmann's syndrome is a genetic disorder, a meticulous family history and genetic counseling in cases of desired paternity/maternity are paramount. Sequencing of the *KAL-1* gene and description of polymorphisms/mutations are recommended not only for scientific reasons but also because they may be helpful in counseling the patient and family.

DIFFERENTIAL DIAGNOSIS

The most important clinical entity related phenotypically to Kallmann's syndrome and IHH is the constitutional delay of puberty (CDP). It presents with hormone profiles similar to those of the previously discussed diseases, and often there is a familial history. To differentiate CDP from Kallmann's syndrome or IHH, a 36-h GnRH pump test followed by a GnRH stimulus is a feasible method. In cases of CDP, but not Kallmann's syndrome or IHH, short-term "priming" is sufficient to provoke a significant LH release (≥ 3 IU/liter). When response is lacking, the test should be performed for 7 days. Moreover, CDP is not linked to anosmia.

Secondary GnRH deficiency may occur in cases of tumors in the region of the diencephalon, in granulomatous illnesses, hemochromatosis, histiocytosis, after trauma/fracture of the skull base, in ischemic or hemorrhagic lesions, and after radiotherapy. Severe cases of malnutrition, such as in Crohn's disease, malabsorption syndrome, anorexia nervosa, and chronic diseases, can cause hypothalamic malfunction. This may also be the case with social deprivation.

Congenital disorders concomitant with hypogonadotropic hypogonadism due to inadequate GnRH release are the Prader-Labhart-Willi, Bardet-Biedl, and Laurence-Moon syndromes, some entities within the category of cerebellar ataxias, and congenital adrenal hypoplasia (the latter often caused by mutations in

the *DAX-1* and *SF-1* genes, which are found in IHH as well).

Hypogonadotropic hypogonadism may also occur in pituitary disorders: Although hypothalamic GnRH release is intact, gonadotropins are not released. This can be due to tumors (e.g., prolactinoma), isolated LH or FSH deficiency, aplasia of the pituitary, or chronic diseases/externally caused damage. In rare cases, GnRH receptor mutations can cause insensitivity to this stimulating hormone. In some families with IHH, this has been determined to be the underlying cause.

Often presenting with a clinical picture similar to that of Kallmann's syndrome or IHH but with hypergonadotropic hypogonadism is Klinefelter's syndrome, which is found in males and caused by one or more additional X chromosomes. The Ullrich–Turner syndrome (single X chromosome) in females is associated with hypergonadotropic hypogonadism as well and may, in some cases, morphologically resemble the picture of gonadotropin deficiency.

THERAPY

Treatment Modalities

Patients with Kallmann's syndrome or IHH present with a deficiency of sex steroids. Induction of puberty

and rapid achievement of a higher level of general physical well-being and activity can be obtained by substitution of testosterone in males and estrogens/gestagens in females (Table II). Testosterone administered to males will be aromatized to estrogens physiologically, thus initiating the necessary dual influence of both sex steroids (especially on bone tissue). After sexual differentiation and development have been achieved, the induction of reproductive functions should be discussed with the patient. Direct substitution of sex steroids is not helpful in this instance; For therapy, the administration of gonadotropins [LH/human chorionic gonadotropin (hCG) and FSH injections subcutaneously] or GnRH (via the previously described minipump) is essential (Table III). In males, the induction of spermatogenesis and, thus, achievement of fertility can be obtained within several months in most cases. Some cases may require treatment for approximately 24 months. The time to first appearance of sperm in the ejaculate correlates negatively with testis volume at the onset of therapy. Cryptorchidism or markedly subnormal testicular size represent no contraindication for this therapy. It is advisable to initiate spermatogenesis soon after or during puberty since reinitiation of fertility in later years will occur more rapidly. Regarding testis

Table II Modalities of Sex Steroid Substitution in Kallmann's Syndrome/IHH

| Substitution in males | | | |
|--|--------------------------------|--|-----------------------------------|
| Application | Preparation | Dosage | |
| Intramuscular injection | Testosterone enanthate | 200–250 mg every 2–3 weeks; for induction of puberty, a 4-week interval may be appropriate | |
| Intramuscular injection | Testosterone cypionate | 200 mg every 2 weeks; for induction of puberty, a 4-week interval may be appropriate | |
| Transdermal application | Testosterone gel | 50–100 mg per day | |
| Scrotal skin (i.e., Testoderm) | Transdermal testosterone patch | One membrane per day may be inappropriate due to small scrotum | |
| Nonscrotal skin (i.e., Androderm) | Transdermal testosterone patch | One or two patches per day | |
| Orally, with meals | Testosterone undecanoate | Two to four capsules of 40 mg per day; not recommended for induction of puberty | |
| Subcutaneous implantation | Testosterone implants | Three to six implants (200 mg per rod) per 6-month period | |
| Substitution in females | | | |
| Preparation | Application | Dosage | Time frame |
| Estradiol valerate | Oral | 0.2 mg per day | 0–6 months |
| Estradiol valerate | Oral | 0.5 mg per day | 6–12 months |
| Estradiol valerate + chlormadinonacetate | Oral | 1.0 mg per day (days 1–25); 2.0 mg per day (days 14–25) | Second year of therapy |
| Estradiol valerate + chlormadinonacetate | Oral | 1.5 mg per day (days 1–25); 2.0 mg per day (days 14–25) | Third year of therapy |
| Common bi- or triphasic oral ovulation inhibitor | Oral | Depending on preparation | Fourth year of therapy and onward |

Table III Treatment Modalities to Achieve Fertility in Kallmann's Syndrome / IHH

| Substance | Modality | Dosage | Gender |
|---|---|---|--|
| GnRH or Human choriongonadotropin in combination with Human menopausal gonadotropin or in combination with Purified or recombinant FSH | Pulsatile subcutaneously by minipump Subcutaneously or intramuscularly Subcutaneously or intramuscularly Subcutaneously or intramuscularly | 5–20 µg/pulse every 2 h 1000–2500 IE two or three times per week 150 IE three times per week 150 IE three times per week | Females and males Males Males Males |

volume, a longer duration of treatment is required in patients who have not undergone spontaneous partial puberty or in those who have been diagnosed with cryptorchidism. After successful induction, spermatogenesis can be maintained at a lower level by administration of hCG alone. This regimen represents an alternative to switching to testosterone substitution.

Because healthy boys have a significant increase in reproductive hormones during the early postnatal period, it has been debated whether postnatally diagnosed hypogonadotropic hypogonadism should be treated during early infancy to induce later penile and testicular growth. Thus, Leydig cell proliferation and germ cell differentiation could be improved and lead to better treatment results in later life.

In women, pulsatile GnRH administration to induce follicle growth and ovulation is preferred to injections of gonadotropins since the risk of ovarian overstimulation and pregnancies with multiple fetuses is reduced. Pulsatile treatment in females should be preceded by substitution of steroids to provide normally developed reproductive organs. Thus, the induction of ovulation and a later pregnancy are supported. Once the desire for offspring has been fulfilled, therapy may be changed to sex steroid substitution. During pregnancy, no substitution therapy is needed since during the first 7 to 8 weeks after implantation the functional capacity of the corpus luteum is preserved by hCG secreted by the trophoblast. After the luteal-placental shift, sex steroids are secreted by the placental trophoblast and the decidua. Additional hormone substitution is contraindicated since fetal development may be irrevocably disturbed.

Genetic counseling should be given to patients who desire to have children since there are reports of transmission of the disease to the offspring.

Monitoring Substitution Therapy

Men

In men, regular surveillance is required during androgen substitution therapy to ensure that the patient is well adjusted and to avoid side effects. This applies to behavioral aspects, somatic properties, and laboratory parameters. Because testosterone is metabolized by 5 α reduction to 5 α -dihydrotestosterone or by aromatization to estrogens, the metabolic activity of these steroids should be considered as well. As with other hypogonadal patients receiving androgens, patients with Kallmann's syndrome or IHH report increased beard growth, indicated by a higher frequency of shaving. A male pattern of pubic hair growth will develop. Muscles and physical strength are gained and as body weight increases in lean body mass, the fraction of fat will diminish. Gynecomastia can be caused by increased aromatization to estrogens, especially during therapy modalities leading to high peak levels (i.e., intramuscular injections of short-acting testosterone esters). In this event, the testosterone dose must be adjusted. Sufficient androgen substitution will lead to increased physical and mental activity, alertness, and vigor. Conversely, low levels can be accompanied by lethargy, inactivity, and depressed mood. These symptoms are often described by patients receiving intramuscular testosterone esters. Especially in older patients, in whom induction of puberty is achieved after a psychosocial adaptation has occurred, major psychological changes can lead to restructuring of family and partner relationships. This often requires intensive counseling not only for the patient but also for relatives.

When determining the effects of substitution therapy, the intrinsic pharmacokinetic profiles of different testosterone preparations must be considered. The time at which a sample is obtained is as important

as the time period since the last administration. If injection therapy is chosen, intervals rather than doses should be adjusted accordingly.

Serum estradiol should be assessed when serum levels of testosterone are high, especially when a patient is being treated with enanthate or cypionate ester, and intervals should be prolonged if the serum estradiol level is too high. Bioavailable fractions of testosterone can be estimated from total serum testosterone and SHBG levels.

Because testosterone is a well-known stimulator of the erythropoietic system, the red blood cell count will increase. Supraphysiological levels of testosterone can lead to polycythemia, requiring dose reduction to prevent patients from experiencing embolic or thrombotic events. Because replacing testosterone in hypogonadal patients will increase their bone density, this parameter should be assessed prior to treatment and every 2 years thereafter.

The incidence of prostate carcinoma and benign prostate hyperplasia increases with age. Hence, every patient, especially males older than age 45, should be examined carefully. Rectal palpation, serum prostate specific antigen (PSA) levels, and a transrectal ultrasonographic examination (a transpelvic ultrasonography does not provide exact volume determination) provide the experienced physician with the means for diagnostic accuracy. In the course of treatment, these parameters should be assessed at least yearly. Additional information concerning a functional parameter can be obtained by uroflow measurement. Testosterone increases prostate volume in hypogonadal men, but only to the extent of prostate size in age-matched controls. These parameters must be monitored as well in patients receiving GnRH or gonadotropin substitution. It is likely that prostate growth is pharmacogenetically influenced by the CAG repeat polymorphism of the androgen receptor gene. Since shorter alleles facilitate enhanced androgen action, one might consider determining the polymorphism and, consequently, adapting surveillance and testosterone dose.

Women

When pregnancy is not desired, in most cases hormone substitution is provided by orally active agents (Table II). Metabolic side effects are well-known from oral contraceptives and should be considered when monitoring therapy. Side effects include impairment of glucose tolerance, an increase in low-density lipoprotein cholesterol and triglycerides, and an increase in thromboembolic events (especially in smoking women). Endometrial effects and induction of menstrual bleeding should be carefully observed.

The development of benign and malignant changes in breast tissue has to be taken into account. Hormone substitution in women will have a positive effect on bone tissue, leading to formation of higher bone mass and preventing osteoporosis. Regarding psychosocial effects, the same phenomena as described for men can occur in women. Cessation of therapy can be discussed after reaching the age of menopause.

In cases of GnRH or gonadotropin substitution, follicular development has to be closely monitored. Overstimulation should be avoided and contraceptive measures should be taken if multiovation occurs.

the near steady-state input of fuels in the blood during starvation. They first reassessed the rate of urinary excretion of nitrogenous compounds and ketone bodies in humans undergoing prolonged starvation and then combined these studies with measurements of arteriovenous concentration differences with regional blood flow rates and calculated exchange rates of substrates, oxygen, and carbon dioxide. These studies led to the demonstration in 1967 by Owen *et al.* that β -OHB and AcAc could replace glucose as the predominant fuel for brain metabolism during prolonged starvation. The extent and importance of ketone body metabolism in sparing glucose utilization by the brain during starvation were not previously appreciated. The dominant role that ketone body metabolism plays in fuel homeostasis was thereby established.

Much of human history involves a search for food, with long periods of prolonged hunger when food was not available. Human metabolism thus developed mechanisms to cope with starvation. The use of stored fat reserves and their conversion to ketone bodies as a source of energy surely played a dominant role in the survival of the human species. The ability of ketone bodies to maintain life through their capacity to supply fuels, maintain electrolyte conservation, promote gluconeogenesis, and maintain acid–base balance during starvation has diminished in significance since humans are usually in the fed or early postprandial states. It is ironic, considering human history, that in the United States and many technologically advanced nations, obesity, and not starvation, has become the major health problem. Public health officials warn that obesity is reaching epidemic proportions in many developing countries and is likely to lead to an equally dire epidemic of diabetes, hypertension, and related heart disease and stroke. With the ready availability of food, the significance of ketone bodies as a source of fuel in normal human metabolism has thus diminished. In fact, to most individuals not familiar with the nuances of whole body metabolism, ketone bodies are unhealthy reminders of diabetes and not an important metabolic fuel required for survival during starvation. It is of note that there is a renewed interest in ketone bodies due to the popularity of diets that are high in fat and protein and nearly devoid of carbohydrate, being recommended by some for weight reduction for obese individuals. In fact, the key to one popular diet, *Dr. Atkins Diet Revolution*, is the maintenance of high levels of ketosis both before and after meals! However, clinical studies of obese people consuming a very-low-carbohydrate but high-fat and

high-protein diet show that they develop only trivial elevations of blood β -OHB concentrations.

BIOCHEMISTRY OF KETOGENESIS AND KETOLYSIS

After CoA was discovered and accurate methods for measuring β -OHB, AcAc, and acetone became available, knowledge regarding ketogenesis quickly grew. It was soon recognized that ketone bodies were not just intermediates in the oxidation of fatty acids but rather end-products that require their own enzymatic machinery for synthesis. The formation of ketone bodies occurs primarily in the liver via the following enzymatic reactions, all of which are present in the mitochondrial matrix, except for the spontaneous decarboxylation of AcAc to acetone, which occurs in the blood.

The reactions of ketone body synthesis are as follows:

1. $2 \text{ Acetyl CoA} \rightarrow \text{Acetoacetyl CoA} + \text{coASH}$
2. $\text{Acetoacetyl CoA} + \text{Acetyl CoA} \rightarrow \beta\text{-Hydroxy-}\beta\text{-methylglutaryl CoA}$
3. $\beta\text{-Hydroxy-}\beta\text{-methylglutaryl CoA} \rightarrow \text{Acetoacetate} + \text{acetyl CoA}$
4. $\text{Acetoacetate} + \text{NADH} \leftrightarrow \beta\text{-Hydroxybutyrate} + \text{NAD}$
5. $\text{Acetoacetate} \rightarrow \text{Acetone} + \text{CO}_2$

The enzymes of ketone body synthesis are as follows: (1) Acetoacetyl CoA thiolase; (2) β -hydroxy- β -methylglutaryl CoA synthase; (3) β -hydroxy- β -methylglutaryl CoA lyase; (4) β -hydroxybutyrate dehydrogenase; and (5) Spontaneous decarboxylation.

The major source of ketone bodies is the oxidation of fatty acids in the liver. The kidney can synthesize, oxidize, and excrete ketone bodies. The pathway of ketogenesis in the renal cortex is different from that in the liver. A small quantity of AcAc can be synthesized from ketogenic amino acids during starvation. In addition, minute quantities of β -OHB can be synthesized by the central nervous system. The enzymes involved in the hepatic synthesis of ketone bodies are listed above. Although small quantities of acetoacetyl CoA may arise from the last four carbons of long-chain fatty acids during β -oxidation, the bulk of acetoacetyl CoA is formed from a head-to-tail condensation of two molecules of acetyl CoA via reversal of the acetoacetyl CoA thiolase reaction. Another acetyl CoA molecule combines with AcAc-CoA to form β -hydroxybutyrate- β -methylglutaryl CoA (HMG-CoA) via the action of HMG-CoA synthetase. Generation of HMG-CoA simultaneously generates a proton; for each molecule of HMG-CoA committed to AcAc formation, one proton is released into the body fluids. HMG-CoA synthetase is nearly exclusively localized to the liver. In the next step in ketogenesis, HMG-CoA

lyase cleaves HMG-CoA to form free AcAc and acetyl CoA. AcAc, the parent ketone body, can be converted to β -OHB by mitochondrial β -hydroxybutyrate dehydrogenase.

Ketone bodies can be used for energy by most tissues. The exceptions are the liver as well as tissues that have no mitochondria, such as red blood cells and the lens of the eye. The liver produces ketone bodies but has an undetectable or low activity of succinyl CoA:acetoacetyl CoA transferase, the major enzyme involved in ketone body degradation. Thus, hepatic activation of AcAc for hepatic oxidation is minimal and ketone bodies are released into the blood. The enzymes involved in the degradation of the major ketone bodies, AcAc and β -OHB, in this sequence are listed below. The catabolism of acetone is more complex and is discussed below.

The reactions of ketone body degradation are as follows:

1. β -Hydroxybutyrate + NAD \leftrightarrow Acetoacetate + NADH + H⁺
2. Acetoacetate + succinyl CoA \leftrightarrow Acetoacetyl CoA + succinate
3. Acetoacetyl CoA + CoASH \leftrightarrow 2 Acetyl CoA

The enzymes of ketone body degradation are as follows: (1) β -hydroxybutyrate dehydrogenase; (2) Succinyl CoA:acetoacetyl CoA transferase; and (3) Acetoacetyl CoA thiolase.

There are several differences in the metabolism of ketone bodies in the kidney and in the liver. There is negligible activity of HMG-CoA synthase in the kidney cortex. In addition, the kidney possesses considerable activity of succinyl CoA:acetoacetyl CoA transferase, an enzyme that is absent in the liver. Both organs have acetoacetyl CoA thiolase. The liver can synthesize and release both AcAc and β -OHB into the blood (but it cannot metabolize the ketone bodies further), whereas the kidney synthesizes these compounds by reversing the thiolase reaction. However, net renal ketogenesis is low compared to the rate of ketone body synthesis in the liver.

One important factor in the oxidation of ketone bodies is the concentrations of AcAc and β -OHB in biological fluids. AcAc enters the cell from the extracellular fluid or can be produced in the mitochondria from β -OHB by β -hydroxybutyrate dehydrogenase. Since this reaction reduces NAD to NADH, β -OHB has a greater caloric value than AcAc (4.5 kcal/g versus 4.0 kcal/g). The overall rate of conversion of β -OHB to AcAc is also determined by the oxidation–reduction state (NAD/NADH) of cells in the tissue using the ketone bodies. This ratio can be influenced by a number of factors, including the rate of energy utilization by the tissue and the extent of fatty acid oxidation

that generates both NADH and FADH₂ directly in the mitochondrial matrix. Mitochondrial activation of AcAc in the brain, skeletal muscle, and heart is catalyzed by succinyl CoA transferase, which uses the CoA from succinyl CoA. Acetoacetyl CoA is then cleaved by acetoacetyl CoA thiolase into two molecules of acetyl CoA and the acetyl CoA then enters the tricarboxylic acid (TCA) cycle for oxidation to CO₂.

Succinyl CoA:acetoacetyl CoA transferase is detected in all tissues with mitochondria except the liver. The synthesis of acetoacetyl CoA via this enzyme occurs at an energy cost since the succinyl CoA that is the CoA donor in this reaction would normally be converted to succinate via succinyl CoA synthase in the TCA cycle, generating a molecule of GTP. The highest activity of succinyl CoA:acetoacetyl CoA transferase is in the myocardium > brain > kidney > other tissues. Acetoacetyl CoA thiolase is present in both the mitochondria and the cytosol. In the mitochondria, it promotes the cleavage of AcAc-CoA into acetyl CoA for oxidation in the TCA cycle.

A significant proportion of the AcAc that is produced is converted to acetone by nonenzymatic decarboxylation. Furthermore, an acid environment promotes AcAc decomposition to acetone. For each molecule of AcAc decomposed to form acetone, one H⁺ is consumed in the formation of CO₂. Acetone production is directly related to the concentration of AcAc that is present in the blood; during diabetic ketoacidosis, approximately 50% of the AcAc produced is converted into acetone. Acetone has a relatively slow rate of turnover, in part due to the large pool of acetone in the body during protracted hyperketonemia. Acetone is converted irreversibly to acetol and then to propyleneglycol (1,2-propanediol). Propanediol is converted to pyruvate, a gluconeogenic precursor. Thus, acetone metabolism violates the general rule that fatty acids (other than propionate) cannot support glucose synthesis in mammals.

The potential importance of acetone metabolism during starvation and diabetes has largely been ignored. Several reports demonstrated that acetone was present in blood, breath, and urine. Although it has been long held that the blood of patients suffering from diabetic ketoacidosis contained little free acetone, Sulway and Malins reported strikingly elevated concentrations of free acetone in the bloodstream of 27 diabetic patients admitted to the hospital in diabetic ketoacidosis. These observations have been neglected by most investigators studying ketone body metabolism. However, there is a general consensus that the overall importance of acetone as a precursor (or fuel) is minor compared to AcAc and β -OHB.

PHYSIOLOGY OF KETONE BODY METABOLISM

It became evident early in the medical history of metabolic research that both starvation and diabetes mellitus generated states of hyperketonemic acidosis. However, the diabetic state was much more severe and resulted in death. Furthermore, the degree of acidosis and vulnerability of the diabetic patients varied widely. Starving humans usually develop a steady state of ketone body synthesis and catabolism, whereas diabetic patients usually develop severe hyperketonemia (ketosis) and progressively deteriorate to death. Since insulin therapy did not become available until 1921, there is an extensive and sad literature documenting this problem. Ketosis develops when glucose oxidation is suppressed and fat catabolism is accelerated. Diet and physical activity also influence the rapidity and degree of ketosis. Strenuous exercise can also cause a rapid rise in the concentration of ketone bodies in the blood; however, rest and relatively small quantities of glucose rapidly decrease blood ketone body concentrations to normal in nondiabetic individuals.

Occasionally, an obese individual with type 2 diabetes will develop ketoacidosis that is indistinguishable from a lean, insulin-dependent, type 1 diabetic patient. Hydration may diminish the degree of ketonemia and ketonuria in normal patients and in diabetic patients. However, once severe diabetic ketoacidosis develops, rehydration, though it decreases the concentration of blood glucose, has only a marginal effect on hyperketonemia and acidosis.

There are different degrees of hyperketonemia so it is important to distinguish the ketosis that occurs during starvation from that which occurs due to catastrophic diabetes. During starvation, ketone bodies are synthesized to provide fuels. Their production rates are equal to their oxidation and excretion rates and a steady state for ketone body metabolism occurs. This is "physiologic hyperketonemia." In contrast, during progressive diabetic hyperketonemia, there is an uncontrolled mobilization of stored fuels in excess of tissue needs due to inadequate insulin action and an overabundance of catecholamine, glucagon, growth hormone, cortisol, etc. The blood is then flooded with an overabundance of fuels. In addition to the hyperketonemia, there is hyperglycemia, acidosis, azotemia, and dehydration. This form of catastrophic catabolism is "pathologic hyperketonemia." It is clearly distinct from physiologic ketosis of starvation. In diabetic ketoacidosis, death ensues if not interrupted by the administration of insulin, fluids, electrolytes, and eventually glucose.

During starvation, when the blood insulin concentration is low and the hypoglycemic counterregulatory hormonal concentrations are high, lipolysis occurs and fatty acids are mobilized from triglycerides stored largely in adipose tissue. Long-chain fatty acids are not water-soluble and are bound to albumin for transport to the liver. After crossing the hepatic cellular membranes, some of the long-chain fatty acids become activated to fatty acyl CoA and undergo repeated steps of β -oxidation, generating acetyl CoA. In the process of β -oxidation, fatty acids yield approximately one-half of their chemical energy, with the remainder of their initial chemical energy in ketone bodies. In the liver during fasting, considerable concentrations of fatty acids undergo β -oxidation, supplying all the energy needs of this tissue. This takes place because β -oxidation of fatty acids occurs in the mitochondrial matrix and generates both NADH and FADH₂ during the process. The change in the mitochondrial redox state decreases the TCA cycle flux, resulting in a transient rise in the concentration of acetyl CoA. The major metabolic fate of this acetyl CoA is to form ketone bodies. Thus, ketone bodies act as a relief valve for the product of the oxidation of fatty acids by providing an alternative route for the disposal of the acetyl CoA. In muscle and other tissues with mitochondria, acetyl CoA derived from the cleavage of fatty acids is oxidized to CO₂ for energy. Ketone bodies have another important metabolic role that is not well understood; like fatty acids, all three ketone bodies induce insulin resistance.

URINARY KETONE BODY AND AMMONIUM EXCRETION

Urinary ammonium excretion during starvation is directly related to ketonuria (Fig. 1). In humans, the maximum rate of ammonium excretion occurs after 7 to 8 days of starvation. After approximately 18 days of starvation in well-hydrated volunteers, urinary ammonium becomes the principal urinary nitrogenous product. It is of interest to note that the caloric value of protein is greatest when amino acid nitrogen is lost in the urine as ammonium since the synthesis of urea in the urea cycle in the liver requires 4 ATP molecules for each molecule of urea produced. Thus, the most energetically efficient way to excrete urinary nitrogen is as ammonium.

Ketonuria generally peaks after 7 days of starvation in humans and thereafter plateaus, with the maximum rate of excretion of AcAc and β -OHB of 110–120

Figure 1 Daily urinary excretion of β -OHB (shaded bars) and AcAc (white bars) versus ammonium nitrogen (mean \pm SEM) in five obese men and women during 18 days of total starvation when only water, salts, and multivitamins were given. Relationship between total ketonuria and urinary NH_4^+ : $r > 0.95$.

mmol/day. This measurement is complicated by the fact that the accumulation of AcAc in the urinary bladder and/or after collection and storage of the urine may cause some decomposition of AcAc to acetone (acetone is generally not routinely determined in the analysis of ketone bodies). When the daily rates of ketone body excretion were measured very close to the time that the urine collection was completed, the rate of β -OHB excretion was approximately 100 mmol/day (this value peaked at 7–8 days). The rate of excretion of AcAc (19 mmol/day) peaked at approximately the same time during starvation; there are slight decreases in the excretory values of AcAc, β -OHB, and ammonium in the urine as starvation progresses.

As noted above, β -OHB is the predominant ketone body excreted in the urine of humans (a ratio of 5:1 in the urine after prolonged fasting). Depending on

the urinary volume, the concentration of AcAc and β -OHB in the urine is usually approximately 10–20 times that of blood. Whereas AcAc is the minor component of these two ketone bodies, only AcAc reacts with the semiquantitative reagent nitroprusside, so that the routine analysis of ketone bodies using the convenient test strip severely underestimates the actual concentration of ketone bodies in biological fluids since it does not react with β -OHB, the major ketone body in biological fluids.

Early studies performed using dogs and humans suggested that there was a maximal rate of renal tubular reabsorption of ketone bodies. However, when more exacting analytical methods were used to measure the concentration of AcAc and β -OHB in blood and urine, no maximal renal reabsorptive rates for AcAc and β -OHB were found during starvation or diabetic ketoacidosis. The rate of urinary excretion of these freely filtered compounds was limited by the linear increase in their renal reabsorption (Fig. 2). The fractions of both AcAc and β -OHB reabsorbed and excreted per 100 ml glomerular filtrate by starving, obese patients at the height of ketonemia are approximately 80 and 20%, respectively. The same results were found during diabetic ketoacidosis. The excretion of acetone is uniquely low because acetone is soluble in both aqueous and lipid media and thus there is no concentration gradient between the renal parenchyma and the urine.

Since there is no renal threshold for ketone bodies, their loss in the urine was puzzling. Furthermore, these compounds are lost as anions and need to be neutralized by the excretion of NH_4^+ . Thus, the loss of urinary nitrogen as ammonium should cause wasting of the lean body mass. Subsequently, it was shown that humans can derive only 93% of their energy requirements from fat but need a minimal amount of glucose to maintain (or spark) fuel homeostasis. The kidneys provided approximately one-half of the newly synthesized glucose during prolonged starvation; this glucose is used to supply part of the fuel for the central nervous system. The source of the amino and amide groups used to titrate the acidity of the tubular urine caused by the excretion of ketone bodies is glutamine, mobilized to the kidney from the muscle. The removal of the two nitrogen groups from glutamine results in the generation of α -ketoglutarate, which enters the citric acid cycle and is used to synthesize glucose. Thus, renal gluconeogenesis and ammoniogenesis are coupled, since ketonuria requires the excretion of ammonium. Ketonuria appears to be a critical biological phenomenon rather than a waste of water-soluble fuels.

Figure 2 Rates of ketone body (AcAc + β -OHB) reabsorption and excretion in 12 obese (1 male and 11 female) volunteers during prolonged total starvation. GFR, glomerular filtration rate. Data are expressed as means \pm SEM. Reprinted from Sapir, D. G. and Owen, O. E. Renal conservation of ketone bodies during starvation. *Metabolism* 24, 23–33, 1975, with permission.

After a few days of starvation, the minimal rate of fat oxidation amounts to approximately 3 g/kg fat-free lean body mass. Thus, a male human with a body weight of 80 kg and a fat-free mass of 64 kg mobilizes approximately 192 g of stored triglyceride daily. Urinary ketone body excretion should amount to approximately 12 g/day. Approximately 47% of the chemical composition of ketone bodies is oxygen; only approximately 6–7 g ($100\% - 47\% = 53\%$; $12 \text{ g} \times 0.53 = 6.4 \text{ g}$) of the ketone body is derived from the highly reduced fatty acids contained in triglycerides. Thus, each day during starvation, only 3% of the fatty acid carbon mobilized from the triglycerides of adipose tissue for energy metabolism is lost in the urine as ketone bodies. In an 80 kg male, the fat mass is approximately 16 kg so that the daily loss of 0.04% of the total fat mass is trivial when there is a constitutional need for gluconeogenesis. Renal function during starvation is thus an extraordinary form of fuel conservation that ensures that other essential functions, including gluconeogenesis, are balanced at a trivial cost to total body energy reserves.

During the first hours of rehydration therapy for severe diabetic ketoacidosis, the quantity of ketone bodies in the urine can be extrapolated to a maximum of approximately 1920–2400 mmol/day. This is 16–20

times greater than that observed during starvation and would be impossible to maintain for more than a few hours. Nonetheless, urinary excretion of these freely filtered anions is limited by the increase in their renal tubular reabsorptive rates. Heightened excretory rates of AcAc and β -OHB during diabetic ketoacidosis are due to the increased filtration load of these ketone bodies. The excretion of the ammonium needed to maintain the electroneutrality required among patients suffering from moderate ketoacidosis has been extrapolated to be approximately 109 to 773 mmol/day (~ 1.5 – 10.8 g N per day) and is inversely related to arterial pH. This high level of ammonium excretion is not coupled to a contribution of glucose to blood by the kidneys because glucosuria induces a net loss of glucose.

BLOOD KETONE BODIES

There are no other substrates present in the human blood that can change so drastically as ketone bodies and still be compatible with life. After an overnight fast, the concentration of AcAc in the blood is approximately 0.05 mmol/liter. Two hours after breakfast, the concentration of AcAc can fall on occasion to approximately 0.01 mmol/liter. The relative change in the concentration of β -OHB in the blood is comparable. Acetone is practically absent from the blood during brief fasting or postprandial periods unless an individual has been eating a high-fat, carbohydrate-free diet. Prolonged starvation causes an exponential rise in AcAc to approximately 0.60 mmol/liter during the first 3 days of starvation and in β -OHB to approximately 4.50 mmol/liter during the first 10 days of starvation (Fig. 3). An additional mild increase in the concentrations of AcAc and β -OHB occurs as fasting progresses. The concentration of total ketone bodies in the blood plateaus at approximately 6–8 mmol/liter after approximately 18 days of starvation. The ratio of AcAc to β -OHB after this duration of starvation is approximately 1:3 to 1:5. Occasionally, the blood AcAc concentration of a fasting patient will be greater than 2.00 mmol/liter and the β -OHB will be greater than 12.00 mmol/liter. At the highest concentrations of ketone bodies in the blood during starvation, the arterial pH is usually approximately 7.34. The concentration of acetone changes from approximately 0.25 mmol/liter after 3 days of starvation to approximately 1.37 mmol/liter after 21 days of starvation. The range of total ketone body concentration from the postprandial period to prolonged starvation can vary approximately 770-fold (0.02 to 15.4 mmol/

Figure 3 Blood substrate concentrations in 37 obese subjects during prolonged total starvation. Values are expressed as means \pm SEM. Plasma acetone was measured in 15 different lean and obese volunteers. The 6 lean individuals had greater venous plasma acetone, AcAc, and β -OHB concentrations than the obese subjects after 3 days of fasting. The 3 obese volunteers had venous plasma acetone concentrations of 0.29 ± 0.041 mmol/liter and 1.37 ± 0.19 mmol/liter after 3 and 21 days of fasting, respectively. FFA, Free fatty acids.

liter). Greater variation occurs in severe diabetic ketoacidosis with blood AcAc concentrations >6 mmol/liter, β -OHB concentrations >20 mmol/liter, and acetone concentrations >12 mmol/liter. The arterial pH in decompensated diabetic patients can be as low as 6.5. Nonetheless, patients in this catastrophic and morbid state of diabetic ketoacidosis can be resuscitated. Thus, the range for total ketone bodies in the blood from the postprandial state to diseased states can vary at least 1900-fold (0.02 to 38.00 mmol/liter) and life can be maintained.

It was not ketone body concentrations in the blood or urinary excretion rates that refocused the understanding of hepatic metabolism during starvation; it was urinary nitrogen excretion. There was simply not enough nitrogen from amino acid catabolism excreted to account for its share of the assumed 100–125 g/day

of glucose needed to be synthesized via hepatic gluconeogenesis during starvation to provide the needed fuel for the brain (Fig. 4). This discrepancy in the level of urinary nitrogen excretion during starvation eventually caused investigators to speculate that the brain may be able to use alternative fuels, ketone bodies, as a source of energy.

KETONE BODY PRODUCTION AND UTILIZATION RATES

The rate of production of ketone bodies by the liver can be measured by catheterization, isotopic dilution, or magnetic resonance spectroscopic techniques. These methods measure different things. With catheterization techniques, the arteriovenous concentration differences are combined with regional blood flow rates to provide an estimate of the net release or uptake rate of ketone bodies (the Fick principle). Isotopic dilution techniques measure total body equilibration exchange and oxidation rates of these compounds. Usually the values obtained for production rates using tracer techniques are greater than those derived from catheterization studies because tracer techniques measure the total body exchange rates, whereas catheterization techniques determine the net balance of the substrate measured across an organ or vascular bed. Nuclear magnetic resonance detects the labeling of metabolic end-products present in tissues. An additional problem with the measurement of the production and utilization rates of ketone bodies involves the manner in which the data are expressed. When hepatic ketone body production is high and peripheral tissue consumption of ketone bodies is high (especially in the brain), correcting the data to standard body surface areas or body weights introduces potential inaccuracies. This is because a starving person with a body weight of 140 kg and a height of 188 cm does not have a brain or liver that is proportionally enlarged. Also, diet and exercise may have influences on hepatic ketone body production rates. An individual consuming a ketogenic (high-fat, low-carbohydrate) diet is more likely to have higher production rates of AcAc and β -OHB than someone eating the usual balanced diet when both individuals are studied after an overnight 12 h fast. Obviously, the time since the last meal and the presence of metabolic diseases influence these measurements. With the preceding caveats, the following production rates are presented.

When a balanced diet is consumed, total ketone body production after an overnight fast ranges from 0.06 to 0.47 mmol/min/1.73 m² (70 kg body weight

Figure 4 The mean quantities of nitrogenous compounds excreted daily in five obese men and five obese women undergoing total starvation for 36 days. The components are “stacked” so that their sum can be visualized. TUN, total urinary nitrogen. Reprinted from Owen, O. E., Smalley, K. J., and Jungas, R. L. (2001). Starvation. *In* Handbook of Physiology (L. S. Jefferson and A. D. Cherrington, eds.) Chapter 39, Section 7, Vol. 2, pp. 1199–1225. Copyright 1999 by American Physiological Society. Used by permission of Oxford University Press, London, UK.

was equated to 1.73 m² body surface area). The production rates slowly rise hourly as food deprivation continues. After 2–4 days of total starvation, the rate increases to approximately 0.75 to 1.77 mmol/min/1.73 m² (70 kg). During the first few days of starvation, urinary ketone body excretion is at a low level and there is some accumulation of these compounds in the body fluids. However, the majority of AcAc plus β -OHB is oxidized to CO₂. Despite progressive fasting for 17–24 days, the rate of production of ketone bodies is constant at 0.75 to 1.62 mmol/min/1.73 m² (70 kg). Only approximately 84% of the ketone bodies that are produced are oxidized; the rest are excreted in the urine or exhaled as acetone. After a few days of starvation, ketone body oxidation can account for 37–44% of the CO₂ production rate or greater than 30% of the energy requirements of a human based on O₂ consumption.

There is a linear relationship, up to 2–4 mmol/liter, between the rate of ketone body production and the concentration of AcAc plus β -OHB in the blood. However, at higher concentrations, such as those found after more prolonged starvation, the concentrations of ketone bodies in blood do not reflect production rates. Thus, there is a dissociation between ketone body production rates and blood concentrations after approximately 3 days of starvation (Fig. 5). The wide range of discordance between production and concentration is more marked among patients suffering from

diabetic ketoacidosis. The primary route of ketone body removal during starvation is oxidation by peripheral tissues. However, several investigators have reported impaired ketone body oxidation rates in diabetic animals during ketoacidosis.

Several mechanisms are responsible for this dissociation between hepatic ketone body production rates and peripheral blood ketone body concentrations during starvation. First, there must be a high rate of hepatic ketone body production to remove fatty acids from the blood during starvation. Second, ketone bodies are not evenly distributed in the extracellular and intracellular water space; they have restricted

Figure 5 The relationship between total ketone-body blood concentrations and production rates in lean and obese starving volunteers and in diabetic patients during ketoacidosis.

volumes of distribution. Third, there is a limited rate of oxidation of ketone bodies by peripheral tissue. Finally, augmented renal retrieval of ketone bodies contributes to the hyperketonemia of starvation and to diabetic ketoacidosis. However, during the hyperketonemia induced by starvation, the rates of production and removal of AcAc and β -OHB eventually equilibrate, reaching a steady-state level. In uncontrolled diabetic ketoacidosis, ketone body production and removal rates do not equilibrate and death results from progressive ketoacidosis.

One facet of ketone body metabolism that has not been fully appreciated is that hepatic production rates of AcAc and β -OHB are approximately the same after an overnight fast, a 3-day fast, and a 21- to 42-day fast and during diabetic ketoacidosis; i.e., hepatic AcAc production equals hepatic β -OHB production. It is the algebraic sum of preferential extraction and/or release rates of AcAc and β -OHB plus decomposition of AcAc to acetone and the influence of pH that dictate the AcAc to β -OHB ratio in peripheral blood. Another important point regarding normal hepatic ketogenesis relates to hepatic gluconeogenesis and glycogenolysis (Fig. 6). These processes are inversely related in normal hepatic metabolism. There is a reciprocal relationship between the quantity of glucose derived from glycogenolysis and that produced by gluconeogenesis. Thus, when the quantity of glucose derived from glycogenolysis is high, the quantity produced by gluconeogenesis is low and vice versa. In addition, there is a

reciprocal relationship between total hepatic glucose release and ketone body release. After an overnight fast when glucose release is high, ketone body release is low. During prolonged starvation when hepatic ketone body production is at a high level, total glucose production (entirely from gluconeogenesis) is at a low level. These normal reciprocal relationships are absent in patients suffering from diabetic ketoacidosis.

EXTRAHEPATIC EXCHANGE OF KETONE BODIES

The uptake and (or) release of AcAc and β -OHB across peripheral vascular beds have been estimated by multiplying the arteriovenous concentration differences by the regional blood flow rate or by employing isotopic tracer techniques. However, determining the ketone body exchange or utilization rates using arteriovenous concentration difference measurements has inherent limitations. Blood flow rates are usually difficult to measure with the analytical accuracy needed to exactly quantify exchange rates. Furthermore, the extraction or release of a substrate may vary among individuals. For example, the blood flow rates of lean and obese individuals differ in responses to starvation and diabetes mellitus. Nonetheless, some general statements hold true for the measurement of ketone body metabolism in human tissues during starvation and other physiological and disease states.

Figure 6 Net splanchnic glucose and ketone body production rates in lean men and women after an overnight fast and after a 3-day fast. Hepatic glucose output excludes that quantity derived from recycled lactate and pyruvate, but this quantity of glucose is extracted from the caloric equivalent expressed as kcal/min/1.73 m². The total caloric equivalents of fuels released into the blood are equal, but the quantities of glucose and ketone bodies have a reciprocal relationship. PPD, propanediol.

The seminal study on ketone body utilization by extrahepatic tissues in humans was reported in 1967, when Owen *et al.* demonstrated that during prolonged starvation β -OHB and AcAc replaced glucose as the predominant fuel for the brain (Fig. 7). Previous studies of brain metabolism showed that the only energy-yielding substrate consistently extracted from the blood by the human brain was glucose. However, the quantity of carbohydrate stored in the human body is limited and can supply glucose for tissues such as the brain and other glucose-utilizing tissues for approximately 1 day. During starvation, the liver produces glucose from amino acids derived from the proteolysis of muscle protein, from glycerol derived from lipolysis, and from acetone that has been derived from AcAc. Recycling lactate and pyruvate to glucose (the Cori cycle) provides no net gain of glucose for

Figure 7 Fuels consumed by the brain after overnight (fed) and starved states. Arteriovenous concentration differences multiplied by brain flow rates were used to calculate oxygen equivalents in three obese volunteers who underwent 38 to 41 days of total starvation. Extraction of β -OHB plus AcAc by the brain could provide approximately 66% of the energy requirements of the brain after prolonged starvation. The mean quantity of α -amino nitrogen exchanged by the brain during this study was statistically insignificant.

oxidation by peripheral tissues. The amount of nitrogen excreted in the urine reflects amino acid catabolism. Under these conditions, humans excrete far less nitrogen than would be required if hepatic gluconeogenesis supplied the central nervous system with glucose as the only fuel source.

Cahill first recognized the paradox between the amount of glucose required by the brain if it were the only fuel and the quantity of nitrogen excreted from the body during prolonged starvation. He suggested that it was likely that fuels (ketone bodies) other than glucose were oxidized by the brain during starvation. Owen *et al.* confirmed this hypothesis. After a 38- to 41-day fast, obese volunteers underwent catheterization to measure the exchange rates across the brain and liver of AcAc, β -OHB, glucose, free fatty acids, amino acids, O_2 , CO_2 , and other substrates. This study showed for the first time that during prolonged starvation, β -OHB and AcAc replace glucose as the predominant fuel for brain metabolism (Fig. 7). Subsequently, other researchers have demonstrated that ketone body extraction from arterial blood occurs after brief and intermittent periods of fasting. The initial study performed on three obese volunteers was the key report that modified scientists' concept of the flux of fuels during starvation. It established the textbook concept that the metabolism of ketone bodies is a major adaptation to starvation since their oxidation by the brain spares the need to use glucose in that tissue. This preserves muscle protein since there was less of a requirement for hepatic gluconeogenesis from amino acids.

Striated muscle is the most metabolically active tissue in humans. In normal adults, skeletal muscle weighs approximately 20–35 kg, but in individuals with a large muscle mass, this figure may be increased by a factor of 2 or 3. However, in contrast to the physically active states, resting muscle metabolism (with fat and skin) accounts for only 40% of the energy requirements in the resting state. The total metabolic requirement per unit mass (or volume) of forearm muscle in lean humans during rest is indistinguishable from that in obese humans during rest. Obese humans have a slightly higher concentration of AcAc and β -OHB in the blood after an overnight fast, but the total quantity of ketone bodies extracted in the obese subjects is approximately the same as for lean individuals. After an overnight fast, ketone bodies provide only 5–10% of the energy requirements for muscle. After 3 days of fasting, the arterial ketone body concentration increases 10- to 20-fold. AcAc extraction by muscle rises to a greater extent than β -OHB extraction despite a higher concentration of

β -OHB. At this stage of starvation, ketone bodies are the major fuels of respiration, supplying approximately 50–85% of the energy requirements for muscle. The preferential extraction of AcAc over β -OHB becomes more marked as starvation is prolonged. During prolonged starvation, muscle extracts AcAc and releases β -OHB. The sum total of ketone body utilization by striated muscle is grossly diminished after prolonged starvation although arterial concentrations of AcAc and β -OHB are both significantly higher. This is due to a suppression of ketone body oxidation in muscle by fatty acids, which spares AcAc and β -OHB for metabolism by the central nervous system. Thus, ketone bodies are only marginally oxidized by striated muscle during heightened ketonemia; the majority of AcAc extracted by the forearm is converted to β -OHB.

Net renal exchange of AcAc and β -OHB after 21 days of starvation cannot account for ketonuria. This suggests that the kidneys, like the liver, are ketogenic as well as gluconeogenic organs. The quantity of fatty acids extracted from plasma during prolonged starvation can account for the renal excretion of AcAc and β -OHB, as well as the renal synthesis and consumption of ketone bodies.

In 1945, Medes and co-workers noted that ketone body formation was not exclusively a liver function, but may occur in tissues that metabolize acetate. Kidney preparations readily synthesized AcAc and β -OHB from [^{13}C]acetate. However, the concurrent rate of ketone body oxidation was high and they surmised that renal ketogenesis would not yield ketone bodies released to the bloodstream. In 1969, Weidemann and Krebs reported that slices of kidney cortex from starved rats removed more [^{14}C]oleate than could be oxidized, based on the amount of oxygen consumed by the tissue. Oleate increased ketogenesis by six- to sevenfold, but the maximum rates of renal ketogenesis were $\sim 20\%$ of the maximum rates observed for liver when calculated on a weight-to-weight basis. This suggests that the rate of renal ketogenesis is $\sim 2\%$ of the hepatic ketogenic rate, which is in agreement with the results of other researchers. In addition, Weidemann and Krebs reported that renal ketogenesis and gluconeogenesis were coupled. Brady *et al.* studied the distribution of ^{14}C in β -OHB and concluded that a minimum of 11–17% of the ketone bodies formed in diabetic, ketotic rats were derived from extrahepatic tissue, presumed to be the kidneys. Subsequent work showed that ketone bodies presumed to be produced in the kidneys entered the bloodstream before being

excreted in the urine. Owen *et al.* reported that the kidneys of a starving human may extract or release AcAc, β -OHB, or both. However, the mean renal exchange rates for four obese subjects who starved for 21 days and underwent catheterization studies were not significantly different from zero but were different from values reported previously for obese individuals fasting for 35–41 days. Because there was no renal removal of AcAc or β -OHB from the arterial blood in the presence of gross ketonuria, net renal ketogenesis was $\geq 51 \mu\text{mol}/\text{min}$ or $\sim 2\%$ of net hepatic ketogenesis. If the kidneys are producing, utilizing, and excreting AcAc and β -OHB, simultaneous net balance and isotopic techniques will have to be combined to quantify these processes in humans in states of augmented ketogenesis.

It is known that hepatic gluconeogenesis and ketogenesis are related. Furthermore, the interplay among ammoniogenesis, ketonuria, and gluconeogenesis has been well documented. However, the interrelationship of renal gluconeogenesis and ketogenesis, which may account for the ketonuria, has not been clearly defined. It is known that the liver synthesizes glucose and ketone bodies and releases these fuels into the blood. It is probable that the kidneys synthesize glucose and release it into the renal venous blood but synthesize ketone bodies and release AcAc and β -OHB primarily into the urine, accompanied by ammonium excretion.

The energy requirement of myocardial muscle is far less than that of striated muscle. The oxidation of ketone bodies by the heart increases after birth when the availability of these compounds increases. Mother's milk has a high fat content and nursing infants have mild ketonemia. However, ketone bodies account for only a small amount of the myocardial oxygen consumption during early childhood. In newborn lambs, carbohydrates provide 69–89% of the energy for the heart and ketone body utilization is negligible. However, fatty acids and ketone bodies become the dominant fuel source for the juvenile lambs. Substrate selection in the isolated heart perfused with physiological concentrations of fuels showed that fatty acids supplied approximately 50% and AcAc contributed approximately 25% of the substrates needed. In addition to serving as a fuel for the myocardium, ketone body utilization may improve the mechanical performance of the heart and the metabolic efficiency of oxygen use. Free fatty acids and ketone bodies compete as fuels but the quantities of AcAc and/or β -OHB oxidized by the heart during prolonged starvation cannot be very great.

CONCLUSIONS

Humans are unique among the animal kingdom for their enlarged brain size to body size ratio. The brain has high energy requirements that must be met from extracranial sources. In the fed and postprandial periods, glucose is the dominant energy-yielding fuel for brain metabolism. During progressive starvation, glucose availability is limited and β -OHB and AcAc become the predominant fuels utilized by the brain. The liver contributes a finite quantity of ketone bodies to the blood. Muscle, an avid consumer of ketone bodies early in starvation, switches to fatty acid oxidation and preferential extraction of AcAc and release of β -OHB during prolonged starvation. The kidney conserves a majority of AcAc and β -OHB that undergoes glomerular filtration, but excretes enough ketone bodies in the urine to promote ammoniogenesis and accompanying gluconeogenesis. Ketone bodies have a wider range of change in concentration than any other fuel transported in the blood. In summary, during starvation, the liver produces, the brain consumes, the kidney mostly conserves, and muscle decreases its use of ketone bodies to maintain fuel homeostasis. The sum of these processes dissociates ketogenesis and ketonemia. The physiologic hyperketonemia of starvation is an important survival mechanism for humans.

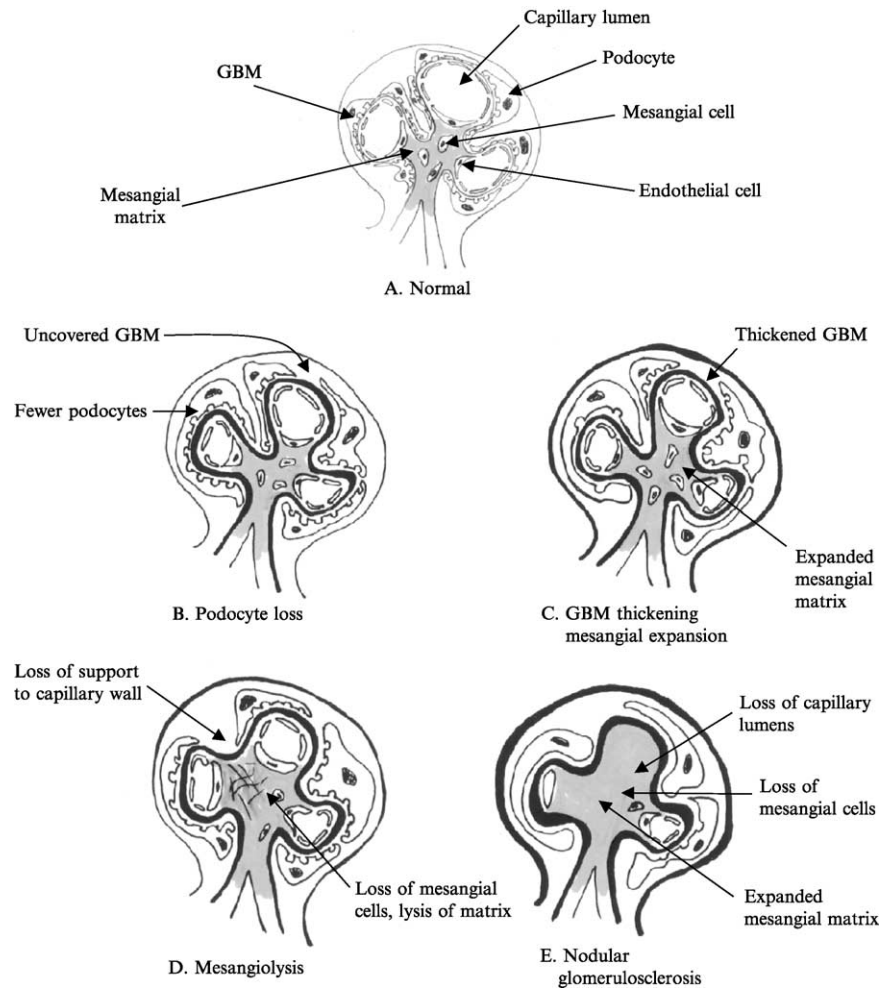

Figure 1 Evolution of diabetic nephropathy. The figure depicts the components of a normal glomerulus (A) and the changes that develop (B–E) as diabetic nephropathy progresses. GBM, glomerular basement membrane.

metabolic state in which elevated blood sugar concentrations, changes in insulin levels and the response to insulin, other hormones and growth factors, and circulating and intracellular lipids may contribute to the rate of progression of disease. The effects of hyperglycemia are the best studied. Hyperglycemia directly contributes to injury of podocytes and mesangial cells, and it stimulates an increase in the synthesis of matrix proteins that lead to scarring. Clinical studies in patients with both type 1 and type 2 diabetes show that improved glycemic control will slow the rate of progression of diabetic nephropathy. Many patients with diabetes develop high blood pressure. High blood pressure injures the walls of blood vessels, including the delicate capillaries of the glomerulus. Control of high blood pressure reduces this injury and slows the rate of progression of renal disease. Although treatment of high blood pressure with any effective agent is

of benefit, the use of medications that reduce the exposure of the kidney to angiotensin II appears to have the greatest benefit. This implies that angiotensin II directly affects the injury of the glomerulus beyond that which is due to high blood pressure.

CLINICAL COURSE

Diabetic nephropathy develops slowly over time in patients with diabetes mellitus. Approximately 10 to 15 years after the onset of hyperglycemia, overt proteinuria identifies those patients with the disease. Once significant proteinuria develops, end-stage renal failure develops in 2 to 6 years. Patients with diabetic nephropathy who are treated with hemodialysis have a worse prognosis than do nondiabetic patients. The lipid abnormalities associated with

renal failure, greater difficulties with blood pressure management, and ongoing problems with glycemic control contribute to progression of other complications of diabetes, particularly cardiovascular disease. Recent studies have shown that early attention to glycemic control, smoking cessation, and hypertension management can alter the rate of progression to renal failure, so it is imperative that diabetic patients at risk for future development of nephropathy be identified and treated aggressively. The subsets of patients with diabetes mellitus who are at increased risk for the future development of diabetic nephropathy develop microalbuminuria. A urinary screening test will identify this subgroup approximately 5 years after the onset of hyperglycemia in type 1 diabetic patients. Patients with type 2 diabetes should be screened at the time that the diagnosis of diabetes is made. Although the exact cause of microalbuminuria is not known, some have suggested that it is a surrogate marker for those individuals with an increased genetic risk for developing progressive renal disease when they have diabetes mellitus.

TREATMENT

Most of the emphasis on treatment is in the identification of individuals at risk for future development of renal disease by measuring urinary albumin excretion rates. In those with microalbuminuria, an angiotensin-converting enzyme inhibitor (ACEI) should be prescribed and the dose should be adjusted to reduce the albumin excretion rate as much as possible. In diabetic patients with hypertension, other medications should be added to the ACEI as needed to reduce blood pressure below 130/85. Aggressive measures should be undertaken to manage weight, encourage daily exercise, and control blood sugar levels as close to the normal range as possible. Efforts should be made to get those patients who

smoke to stop. Similarly, emphasis should be placed on treating lipid disorders because this will reduce the rate of progression to renal failure and will reduce morbidity and mortality from cardiovascular disease. Once renal failure has developed, patients with diabetic nephropathy can be managed by peritoneal dialysis, hemodialysis, or renal transplantation.

conditions associated with an increase risk of renal stone disease.

Calcium-Containing Stones

Calcium-containing stones account for more than 70% of all renal tract stones. From a physicochemical point of view, the fact that they form is hardly surprising given that urine is almost always in a state of supersaturation for calcium salts. Factors that predispose to the development of idiopathic calcium stones include increased urinary concentrations of calcium and oxalate, alterations in inhibitors of stone formation, and nidus for stone formation.

The concentration of urinary calcium is increased by low urine volume and hypercalciuria. Low urine volume promotes stone formation by increasing the concentration of urinary calcium and by decreasing the urine flow rate. Hypercalciuria is commonly transmitted in an autosomal dominant fashion. Absorptive hypercalciuria is the most common cause of hypercalciuria and is postulated to be due to hyperresponsiveness to vitamin D in the jejunal mucosa. Resorptive hypercalciuria due to primary hyperparathyroidism occurs in approximately 5% of individuals with recurrent stone formation. Primary renal hypercalciuria due to a defect in renal tubular calcium reabsorption occurs in 5% of individuals with recurrent stone formation. A diet high in sodium is associated with increased urinary calcium excretion.

The sources of oxalate are the metabolism of amino acids (e.g., serine, glycine, hydroxyproline), metabolism of ascorbate, and dietary intake (10–20%). Oxalate is excreted renally. The urinary concentration of oxalate is much lower than that of calcium. Increases in absolute excretion of oxalate result in larger proportional changes in urinary oxalate concentration when compared with calcium. Increased

absorption of oxalate is seen with a low-calcium diet and enteric hyperoxaluria. The latter occurs with malabsorption syndromes associated with small bowel resection or Crohn's disease. Calcium is bound by

free fatty acids allowing increased colonic absorption of unbound oxalate. Inherited hepatic enzyme defects, primarily hyperoxaluria types I and II, are associated with severe hyperoxaluria that commonly presents during childhood with multiple kidney stones and may lead to renal failure.

Citrate is an important inhibitor of stone formation. Urinary citrate forms a soluble complex with calcium and decreases the concentration of free calcium available for crystal formation. Citrate also inhibits crystal propagation by unknown mechanisms. Hypocitraturia can occur as an isolated finding or may be due to chronic systemic metabolic acidosis, renal tubular acidosis, hypokalemia, a high-protein diet, and possibly a high-sodium diet.

Urinary glycoproteins inhibit stone formation at various stages. These proteins include Tamm–Horsfall protein, bikunin, nephrocalcin, and a urinary form of prothrombin fragment 1. The possible role of abnormal glycoproteins in recurrent stone formation is under investigation.

Uric acid is the product of purine metabolism. A diet high in purines can lead to hyperuricosuria and uric acid crystals that act as nidus for calcium oxalate precipitation and promote calcium stone formation.

Uric Acid Stones

Pure uric acid stones are uncommon. They are radiolucent. The factors that predispose to the development of uric acid stones are the urine concentration of uric acid and low urine (pH < 5.5). Low urine volume increases the risk for uric acid stones by the same mechanisms discussed previously for calcium stones. Chronic hyperuricosuria is associated with gout, a high-purine diet, and inborn errors of metabolism. Acute hyperuricosuria may occur during treatment of myeloproliferative disorders.

Struvite Stones

Struvite stones are composed of magnesium ammonium phosphate. These stones develop in the context of urinary tract infection with organisms that produce urease (e.g., *Proteus*, *Klebsiella*, *Serratia*, *Mycoplasma*). The urinary pH and concentration of ammonia are increased by the breakdown of urea. Struvite stones grow rapidly, particularly in areas of the pelvicalyceal system that do not drain adequately, and may form stag-horn calculi. These stones usually present with symptoms of urinary tract infection. Struvite stones are difficult to treat because they are themselves infected.

Cystine Stones

Cystine stones develop as a result of cystinuria, an autosomal recessive trait associated with decreased proximal tubular reabsorption of cystine and other amino acids. Low urine volume and acidic urine promote stone formation.

INVESTIGATION OF PATIENTS WITH KIDNEY STONES

There is some controversy as to how extensively to investigate patients who have passed a single kidney stone. The controversy is centered around the low mortality and relatively low morbidity of the condition as well as the lack of specific therapy for most forms of renal stone disease. Many clinicians favor the institution of general therapeutic maneuvers without investigation. The European Association of Urology has suggested a classification for stone formers based on frequency of stone passage and relative risk of recurrence. This classification can be adapted to direct investigation.

Analysis of the calculus, where possible, is the cornerstone of the investigation and rational therapy of nephrolithiasis. Patients with infection-related (struvite) stones and cystine stones can be readily identified and treatment can be planned. Patients who make uric acid stones are at high risk for recurrence and require detailed investigations as to the cause of their hyperuricosuria. For calcium stone formers, the European Association of Urology classification divides patients according to whether they are first-time or recurrent stone formers, whether or not there are residual stone fragments, and (for those recurrent stone formers) whether their disease results in rare (mild) or frequent (severe) passage of stones. Also highlighted for aggressive management is a group of patients who are at a predetermined specific risk for recurrence (e.g., primary hyperparathyroidism).

Table III suggests a rational approach to investigation in patients who have passed a single stone. This will detect patients with hyperuricemia and hypercalcemia as well as those with infected urine. The presence of a low bicarbonate level with a urine pH that is not maximally acidified would suggest the presence of renal tubular acidosis.

For patients who have frequent stone passage or a significant number of residual stones visible on radiographs, an attempt to establish the lithogenicity of the urine is a reasonable strategy. Commercially available software can calculate the relative supersaturation for calcium oxalate and calcium phosphate if required.

Table III Basic Investigations Following Passage of a Single Stone

| |
|---|
| Serum analysis |
| Complete blood count |

| Electrolytes, bicarbonate, creatinine, urea |
| Ionized calcium, ^a phosphate |
| Parathyroid hormone |
| Urate |
| Urine analysis |
| Urine culture |
| Urine pH |

^aOr calcium corrected for albumin concentration.

Table IV outlines those additional 24-h urinary investigations that may be useful for recurrent stone formers. Optimal values for these parameters for minimal lithogenicity are shown in parentheses.

RATIONAL THERAPY FOR KIDNEY STONE DISEASE

The treatment of kidney stones can be divided into general and specific measures. The power of general advice in terms of fluid intake and diet should not be underestimated. It has been suggested that the “stone clinic effect” can result in a 5-year reduction in new stone passage of 60%.

Table IV Suggested Investigations for Frequent Stone Formers

| | |
|-------------------------------|--|
| Acidified urine (6 mol/L HCl) | |
| Calcium | (<7.5 mmol male) (<6 mmol female) |
| Phosphate | (<35 mmol) |
| Oxalate | (<350 μmol) |
| Standard urine | |
| Volume | (>2.5 L) |
| Sodium ^a | (50–100 mmol) |
| Creatinine ^b | (7–16 mmol male) (5–14 mmol female) |
| Urate | (<4.5 mmol) |
| Citrate | (>2.5 mmol) |
| Magnesium | (>3.0 mmol) |

Note. Number in parentheses indicate desirable values for low urine lithogenicity.

^aTo assess compliance with dietary recommendations.

^bTo establish accuracy of 24-h collection.

Dietary Intervention

Given that stone formation is the end result of the process of crystal formation, aggregation, and growth from a supersaturated solution, the most rational therapy would be to modify the solution such that the potential energy for crystal formation within the solution is lowered. The logical way in which to do this is to increase fluid intake. Consumption of enough fluid such that the daily urine volume is greater than 2 L has been associated with significantly reduced rates of stone formation in large observational studies over prolonged periods of time. Furthermore, a randomized prospective study performed by Borghi and colleagues at the University of Parma, Italy, demonstrated that kidney stone patients randomized to drink enough fluid to generate a urine volume greater than 2 L/day had a significantly lower rate of recurrence of their stones than did the group of patients randomized to receive no strict fluid prescription. In addition, the time to recurrence was significantly longer in the fluid-treated group.

From large observational studies, it appears that many different beverages provide some protection against stone formation. Data exist to support the beneficial effects of coffee (both caffeinated and decaffeinated), tea, beer, and wine in this regard. In contrast, the ingestion of grapefruit juice and apple juice was shown to increase the risk of stone formation in men followed in the Health Professionals Follow-up Study. Grapefruit juice also increased the risk of stone formation in women observed as part of the Nurses' Health Study; however, the mechanism of this effect is unclear.

Although it would seem to be intuitive that a reduction of calcium in the diet would reduce the frequency of kidney stones, that is not the case. The most compelling evidence of the failure of a low-calcium diet to ameliorate renal stone disease came from a prospective randomized study in men performed by Borghi and colleagues. This landmark study compared a diet containing 100 mmol/day of calcium with a diet containing 30 mmol/day of calcium. Members of the latter group were also required to lower their sodium intake to approximately 50 mmol/day and their animal protein intake to 52 g/day. The group on the normal-calcium, low-sodium, low-protein diet had a significantly reduced risk of recurrent stone formation, although the effect took more than 3 years to become manifest.

Few well-designed studies have addressed other dietary components. The combination of a low-protein, high-fiber diet was not shown to be preventive

of recurrent calcium oxalate stones in a prospective study performed under the auspices of the Kaiser Permanente Medical Care Program.

Pharmacological Intervention

Calcium Stones

The optimal initial treatment for idiopathic hypercalciuria is the administration of a thiazide diuretic such as hydrochlorothiazide or chlorthalidone (12.5–50.0 mg/day). Thiazide diuretics indirectly and directly increase calcium reabsorption in the proximal and distal tubules. Randomized trials have shown a 20% risk reduction for the development of new calcium oxalate stones. Routine monitoring for serum electrolyte abnormalities is necessary. Hypokalemia can lead to hypocitraturia and so must be avoided. If hypercalciuria persists, amiloride (5 mg/day) may be added to further reduce calcium excretion and correct hypokalemia. Potassium citrate (30–80 mEq/day) is indicated for patients with hypocitraturia. Urinary citrate is increased by decreased reabsorption induced by alkalinization. Patients with hyperuricosuria are at risk for the development of uric acid crystals that serve as a nidus for calcium oxalate crystal formation and have been shown to benefit from administration of allopurinol. Oral calcium and cholestyramine have been considered to bind oxalate and diminish urinary oxalate; however, there is no strong evidence for their use in idiopathic calcium oxalate stones. Oral calcium to bind oxalate and potassium citrate to correct acidosis may be beneficial in enteric hyperoxaluria.

Uric Acid Stones

The most important aspect of the pharmacological management of uric acid stones is alkalinization of the urine to a range of 6.0 to 6.5. Potassium citrate (30–80 mEq/day) is preferable to sodium bicarbonate because it avoids the sodium load. During potassium citrate therapy, the urine pH must be monitored and not allowed to rise above 7.0 because this will promote the formation of calcium phosphate stones.

Struvite Stones

Struvite stones are chronically infected. Treatment of struvite stones with antibiotics may help to reduce the rate of growth of the stones; however, definitive therapy for struvite stones usually involves surgical excision of the stones.

Cystine Stones

Cystine stones are treated with the usual general measures of increased fluid intake and restriction of

sodium intake. Alkalinization of the urine to a pH above 7.0 using potassium citrate increases the solubility of cystine. If these measures are not effective in reducing the rate of stone formation, penicillamine, tiopronin, and captopril may be effective. These medications cleave the disulfide bond and increase the solubility of cystine.

Surgical Intervention

The surgical management of renal stone disease has been revolutionized by the advent of extracorporeal shock wave lithotripsy (ESWL) and the growth of endourological procedures. Invasive surgery is rarely required except in cases of complicated infected stones. The success rate of ESWL is close to 95% for individual cases. Concerns about the procedure relate to possible long-term complications (although the procedure has been in use for more than 15 years) and to the fact that failure to clear all of the stone fragments after lithotripsy will inevitably lead to an increased risk of recurrence. For ESWL to be effective, the patient must not be too large or too small for the machine. The stone must be targetable and amenable to fragmentation by the shock wave. Once the stone has been broken, there must be a clear drainage pathway given that the presence of ureteric obstruction is a contraindication to ESWL. Not infrequently, ancillary procedures, such as ureteric stenting and endourological fragment removal, are required after ESWL. [Table V](#) details several other situations where ESWL may be less suitable.

Although the shock wave can be delivered externally (as in ESWL), direct application of the shock to the stone is possible using minimally invasive techniques such as percutaneous nephrolithotripsy (PCNL). Under these circumstances, a scope is passed through a percutaneous nephrostomy and fragmenting energy is applied directly to the stone. For ureteric stones, endourological procedures using rigid or flexible ureteroscopes are more likely to be successful than is ESWL alone.

Acute complications of ESWL are infrequent. Loin pain and ureteric obstruction from stone fragment passage (steinstrasse) occur in approximately 6 and 2.5% of cases, respectively. Rarer complications include renal hematoma and direct shock wave damage to other viscera. Long-term development of hypertension has been reported by several groups and is the subject of ongoing investigations. Similarly, reduction in renal function following bilateral ESWL has led to recommendations that a period of

Table V Situations Where Alternatives to ESWL May Be Required

| Situation | Explanation | Alternative |
|---|---|--|
| Cystine stones | Resistant to fragmentation | Medical management |
| Struvite stones | Infected, hardcore | Combined strategy |
| Ectopic kidney (including renal transplant) | Targeting problem | PCNL |
| Pregnancy | Safety concerns | Conservative management until after delivery |
| Large stones (> 2.5 cm) | Risk of steinstrasse or multiple residual fragments | PCNL |
| Bleeding diathesis | Risk of hemorrhage | Correction of problem, medical management, or direct surgical approach |

months be allowed to pass before a second kidney is treated by this method.

The removal of stones by ESWL or other surgical methods should not be considered a cure of the renal stone disease. Close attention to medical management is required to prevent recurrence, either from growth of residual stone particles or from *de novo* stone formation in a susceptible individual.

Management of Acute Renal Colic Due to Stone Passage

The passage of a kidney stone is usually associated with severe pain, hematuria, and nausea and vomiting. Frequently, the person is unable to find a comfortable position and can be seen to be writhing on the bed. This is in contradistinction to persons with severe peritonitis who usually lie very still and resist movement. Despite being called “colic,” the pain of stone passage is usually constant and may be in the flank or radiate to the groin. Radiation to the groin area suggests that the stone is in the middle or lower part of the ureter.

If the stone is passed, it should be sent for analysis. Other important investigations in the acute setting should be designed to rule out urosepsis and obstruction as well as to exclude other diagnoses. Helical computed tomography scanning offers high sensitivity and specificity for the diagnosis of ureteric stones and can provide significant information if nephrolithiasis is not the correct diagnosis. Investigations aimed at determining the cause of the kidney stones can be delayed until the acute episode is over.

Patients with acute renal colic can be managed supportively. Kidney stones smaller than 5 mm can

be expected to pass spontaneously over the course of 48 h with symptomatic relief. It should be remembered that disappearance of symptoms does not always imply stone passage, and a confirmatory test is required if the stone is not voided. Indications for surgical intervention during the acute phase include nonpassage of an obstructing stone, urosepsis with obstruction, and ongoing pain. Acute interventions may include percutaneous nephrostomy followed by ESWL, percutaneous lithotripsy, and cystoscopy with retrieval of the stone. Invasive surgery is rarely required.

protects this sensitive protein against inactivation at 37°C.

CPN is also an anaphylatoxin inactivator because it cleaves the C-terminal Arg of C3a, C4a, and C5a, but their rates of hydrolysis differ. The Gly-Arg bond of C5a is cleaved approximately 10 times slower than the Ala-Arg terminus of C3a.

Human CPN is considered to be life-sustaining, since no individuals whose blood completely lacks this enzyme are known. For example, inhibition of CPN activity in guinea pigs resulted in sudden death after complement activation when the generated anaphylatoxins were not inactivated.

In humans, low enzymatic activity may be important in the protamine-reversal syndrome. Protamine, when given to neutralize the effects of heparin after extracorporeal circulation, can trigger a catastrophic reaction: pulmonary vasoconstriction, bronchoconstriction, and systemic hypotension. Protamine is a potent inhibitor of this carboxypeptidase (CP) and can also stimulate the generation of kinins and anaphylatoxins; consequently, the inhibition of anaphylatoxin or kinin inactivation may contribute to the protamine reversal syndrome.

Plasma CPN activity may be an aid in the diagnosis of myocardial infarction where the blood level of creatine kinase (CK) released from heart muscle is measured. CPN cleaves the C-terminal lysine residue from either the M or B subunit of CK to yield des-Lys MM or MB isoforms when separated electrophoretically. A variation in blood carboxypeptidase N activity may affect this CK isoform ratio.

Although CPN cleaves the C-terminal Arg of kinins (see Fig. 1), it preferentially hydrolyzes C-terminal Lys, an important function in the regulation of plasminogen activation. CPN can reduce plasminogen binding to cells because C-terminal lysine residues on cell surface proteins are plasminogen "receptors." As bound plasminogen is more efficiently activated, CPN effectively lowers plasminogen binding to cells and thereby influences plasminogen activation.

No individuals have been reported to completely lack CPN but a 65-year-old patient and his sister had only 20% of normal activity. He suffered from weekly occurrence of angioedema. Other members of the family had angioedema, urticaria, hay fever, and asthma, but only slightly depressed CPN levels. An analysis of the 50 kDa subunit genomic DNA from the 65-year-old patient revealed a frameshift mutation in exon 1 that was not present in any of 128 normal controls.

CARBOXYPEPTIDASE U

Carboxypeptidase U (CPU; thrombin activatable fibrinolysis inhibitor, TAFI; plasma CPB; CPR; EC 3.4.17.20) is another B-type CP synthesized in the liver and secreted into the blood. In contrast to CPN, it is normally in plasma as an inactive proenzyme of 60 kDa bound to plasminogen. CPU is proteolytically activated during coagulation to the active 35 kDa form by the thrombin-thrombomodulin complex, but it is unstable and rapidly inactivated at 37°C or by further proteolytic cleavage. The primary

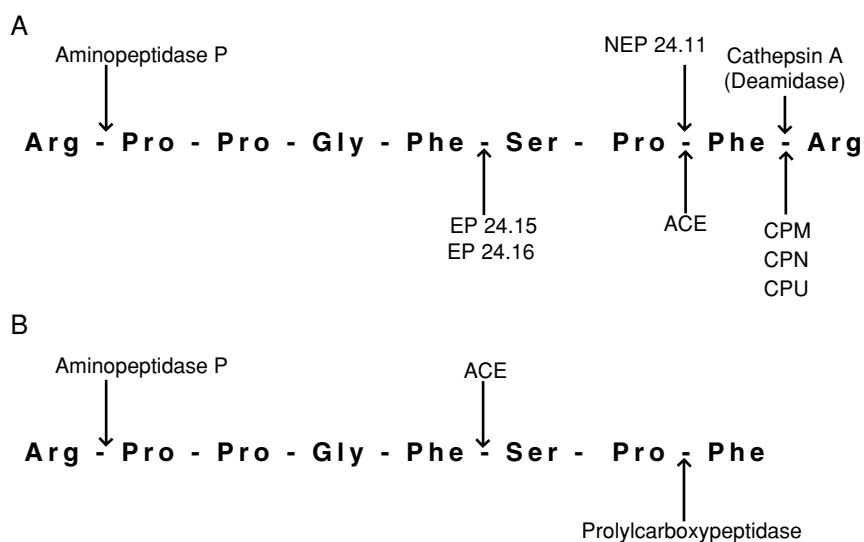

Figure 1 Bonds hydrolyzed in bradykinin (A) and des-Arg⁹-bradykinin (B) by peptidases.

role of CPU is to down-regulate plasminogen binding and activation by cleaving C-terminal Lys residues from cell surface proteins and in fibrin clots.

Regarding the potential function of CPU as a kininase, one of the first groups to identify the enzyme utilized bradykinin as a substrate and studies of the purified enzyme confirmed these findings. However, the reported K_m of bradykinin is extraordinarily high (10 mM), even though it was lower than that of all other substrates ($K_m = 63\text{--}290$ mM). This brings into question the physiological relevance of CPU as a kininase, although serum degrades bradykinin fivefold faster than can be accounted for only by CPN. Because CPU is normally a proenzyme and is unstable after activation, CPU may be a significant kininase only in certain circumstances, such as shortly after initiation of the coagulation cascade.

CARBOXYPEPTIDASE M

Early studies indicated that tissues and urine contained CPN-like activity, but it was assumed that the 50 kDa active subunit would enter organs and attach to plasma membranes or be excreted. When the active CP that cleaved basic C-terminal amino acids was purified from human urine and from placental membrane fractions, it became clear that this was not the case. Purification, cloning, and engineering of recombinant enzyme revealed that this enzyme had a different specificity and structure than those of CPN. Owing to its membrane attachment, it was called carboxypeptidase M (CPM).

CPM is a glycoprotein (23% carbohydrate by weight) with a molecular weight of 62 kDa anchored to the plasma membrane via a glycosylphosphatidylinositol tail. CPM is present in many tissues including kidney, lung, placenta, brain, intestine, peripheral nerves, and blood vessels and in cultured cells such as endothelial cells, fibroblasts, and Madin-Darby canine kidney cells. It is a differentiation-dependent cell surface antigen on white blood cells. The enzyme can be released from the membrane and soluble CPM is found in various body fluids including amniotic fluid, seminal plasma, and urine.

CPM has a pH optimum in the neutral range (6.5–7.5) ideally suited to cleaving peptides at the cell surface. There are no known endogenous inhibitors of the enzyme; thus, it is considered to be constitutively active on the cell surface. Tested with a variety of synthetic and endogenous peptides, CPM cleaved C-terminal arginine in preference over lysine, but the penultimate amino acid residue can also dramatically

affect the rate of hydrolysis. The naturally occurring peptide substrates of CPM include bradykinin, Arg⁶- and Lys⁶-enkephalins, dynorphin A_{1–13}, and epidermal growth factor (EGF). Of the substrates tested, bradykinin has the lowest K_m (16 μ M) and the second highest specificity constant (k_{cat}/K_m).

As a widely distributed ectoenzyme, CPM can participate in a variety of processes, such as control of peptide hormone activity at the cell surface and degradation of extracellular proteins and peptides. It may also carry out the second step in prohormone processing, (i.e., removal of C-terminal Arg or Lys residues from peptides released from prohormones by convertases), if and when incompletely processed peptides are released from secretory granules. Because many peptides work in an autocrine or a paracrine fashion, the location of CPM on the plasma membrane near peptide receptors makes it well suited to control their activities locally.

Within the kinin system, CPM can either inactivate or alter the specificity of kinin peptides by cleaving the C-terminal Arg⁹ as mentioned above for CPN. Because CPM is localized on the cell surface, close to the B₁ and B₂ receptors, it is well suited to this important role. Indeed, it has been shown that CPM-like activity on the surface of human lung microvascular endothelial cells was up-regulated approximately twofold by treatment with interleukin-1 β and interferon- γ ; these conditions increased B₁ receptor responses approximately fourfold. When BK stimulated these cells, the resulting nitric oxide release was prolonged and enhanced because CPM converted the peptide to des-Arg⁹-BK to activate the B₁ receptor. These effects were then blocked by a CP inhibitor or by a B₁ receptor antagonist.

CPM efficiently removes the C-terminal Arg from EGF and may also cleave other growth factors that contain a C-terminal Arg or Lys [e.g., other EGF-like peptides, nerve growth factor (NGF), amphiregulin, hepatocyte growth factor, erythropoietin, macrophage-stimulating protein]. Although the role of the C-terminal basic residue of these factors has not been investigated in detail for most of them, a C-terminal Arg residue is required for association of EGF and NGF with their respective binding proteins.

The role of the up- or down-regulation of CPM in the differentiation of monocytes to macrophages and of B₁ lymphocytes is unknown, but a subject to be investigated further. The released free Arg, as a substrate for the inducible nitric oxide synthase, may provide more nitric oxide in inflammation, possibly just as the related enzyme carboxypeptidase D does in a mouse macrophage cell line.

In the lung, the presence of CPM on type I cells, which constitute 93% of the total alveolar surface, indicates that it may have protective functions here. This enzyme is also readily mobilized from the cell surface. The pulmonary synthesis or release of CPM may be up-regulated in disease states as the enzyme levels in bronchoalveolar lavage fluids were elevated almost fivefold in patients with pneumocystic or bacterial pneumonia or lung cancer.

The functions of CPM in other locations have not been explored. For example, in the placenta it may protect the fetus from maternally derived peptides. CPM in central nervous system (CNS) myelin and in Schwann cells in peripheral nerves may participate in the growth or maintenance of neurons.

KININASE II

Kininase II (ACE)-type activity, the enzymatic release of Phe⁸-Arg⁹ from BK, was detected first with a *Clostridium histolyticum* preparation and then by an enzyme separated from a membrane-enriched fraction (microsomal) of homogenized kidney and also from human plasma. Originally, ACE was discovered by Skeggs and colleagues in the 1950s in horse plasma. It converted the inactive Ang I decapeptide released by renin—called at that time hypertensin or angiotensin—to the active vasoconstrictor octapeptide Ang II.

After the discovery of kininase II in 1965–1967, it was reported in 1970–1971 that the same enzyme cleaves both BK and Ang I by releasing Phe-Arg from BK and His-Leu from Ang I; thus, it is a peptidyl dipeptide hydrolase called peptidyl dipeptidase I. The conclusion that the two activities were due to the same protein was not readily accepted because different amounts of Cl⁻ ions are needed to cleave Ang I or BK. The lack of chloride inhibited Ang I conversion by 93%, but the hydrolysis of BK was reduced by only approximately 50%. The discovery of two independent active site domains of ACE led to the finding that some substrates and inhibitors react preferentially with just one of the two active sites, with different Cl⁻ requirements.

The K_m of BK is much lower than that of Ang I (0.1–1 μM versus 10–50 μM), which, taken with the turnover number (k_{cat}), indicates a higher specificity constant with BK than with Ang I for human ACE; generally, ACE (kininase II) is considered to be the most important human kininase.

In addition to Ang I and BK, ACE cleaves a variety of bioactive peptides *in vitro*. Thus, beyond hydrolyzing C-terminal dipeptides, it released *in vitro* C-terminal tripeptides, e.g., from des-Arg⁹-BK, protected

C-terminal tripeptides [e.g., from substance P, luteinizing hormone-releasing hormone (LHRH)], protected C-terminal dipeptide (e.g., substance P), and even protected N-terminal tripeptide (e.g., of LHRH). Compared to other ACE substrates, it is likely that the Arg⁶-Phe⁷ of Met⁵-enkephalin-Arg⁶-Phe⁷ is split off with the highest turnover number by the N-domain active center of ACE. The N-domain of ACE hydrolyzes *in vivo* the tetrapeptide Ac-Ser-Asp-Lys-Pro, which is involved in the control of hematopoietic stem cell proliferation by preventing their recruitment into S phase.

After molecular cloning of the somatic form of ACE, two homologous domains were identified, the N- and C-domains; this was taken as an indication for the duplication of an ancestral gene. The germinal, testicular form has only one domain. The highest (89%) sequence similarity of the two domains of human ACE occurs around the active sites. The catalytic sites contain the canonical zinc-binding motif HEXXH. There is a high level of sequence similarity, 80–90%, in both the nucleotide and amino acid sequences, between the somatic mammalian ACE cDNA sequences cloned from different species.

ACE is an ectoenzyme anchored to the plasma membrane by a C-terminal transmembrane domain; most of it is exposed at the extracellular surface of the cell. There are two ACE isoforms; the somatic form of approximately 150–180 kDa is in endothelial, epithelial, and neuronal cells and the smaller isoform (90–110 kDa) is present in germinal cells. Germinal ACE contains 732 amino acids, compared to 1306 in somatic ACE, and corresponds to the C-domain of somatic ACE with a single active site. Germinal ACE has the same hydrophobic transmembrane peptide and cytosolic domains as somatic ACE. The inactivation of the ACE gene in the homozygous male mouse leads to reduced fertility attributed to inactivation of the germinal form of ACE. Somatic ACE is highly expressed, for example, in the plasma membrane of vascular endothelial cells in the lung oriented to metabolize circulating substrates. ACE concentration is probably even higher on the microvilli of the brush borders of absorptive epithelia of the small intestine, placenta, and kidney proximal tubules. T lymphocytes and fibroblasts also contain ACE. In brain, ACE is highly expressed in the choroid plexus, which may be the source of ACE in cerebrospinal fluid, and in ependyma, subfornical organ, basal ganglia (caudate putamen and globus pallidus), substantia nigra, and pituitary. Neuronal ACE and the endothelial and epithelial forms of the enzyme have the same specificities and are not distinct isoenzymes.

Soluble ACE is found in many biological fluids such as serum, seminal, amniotic, and cerebrospinal fluids, released from cell membranes by a class of enzymes called secretases.

The high carbohydrate content of both ACE domains has frustrated attempts to crystallize the enzyme. Finally, in 2003, the crystallization of the human testicular ACE, and thus, the C-domain of ACE without the hydrophobic transmembrane and intracellular domains, was reported. The enzyme was complexed with the inhibitor lisinopril. Although the first orally active ACE inhibitor, captopril, was synthesized on the basis of an assumed similarity to carboxypeptidase A, the structure of the crystallized enzyme resembled instead the other kininase II-type enzyme NEP, despite the lack of sequence homology. The active site is at the bottom of a groove in ACE; this may explain the rather limited size of the peptides that ACE can hydrolyze, consisting usually of less than a dozen amino acids.

Because both CPN and ACE are metallopeptidases, in initial experiments some inhibitors of BK breakdown by CPN, such as metal sequestering agents, inhibited both enzymes. Of other ACE inhibitors, the structures of two snake venom peptides that potentiated BK were reported at a meeting in 1969. The pentapeptide BPP_{5a} from *Bothrops jararaca* had a single C-terminal proline, whereas the undecapeptide from *Akistrodon halys blomhoffii* had a C-terminal Pro-Pro sequence. A synthetic nonapeptide, teprotide—found in snake venom originally—also had C-terminal Pro-Pro sequence and it became the first ACE inhibitor to be tested clinically. When this ACE inhibitor was given intravenously to patients, it not only lowered the elevated blood pressure, but was also beneficial in congestive heart failure.

The studies on kininase inhibition and BK potentiation led to the synthesis of ACE inhibitors that are given orally to millions of patients to treat hypertension and a variety of clinical conditions in which the effects are not related to lowering the blood pressure. These conditions range from congestive heart failure to diabetic nephropathy. ACE inhibitors lower the mortality and morbidity after heart failure and they even reduce its incidence. Many laboratory and clinical findings attributed at least part of the results with ACE inhibitors to enhancing the effects of BK. In addition to being involved in BK metabolism and potentiating the effects of B₂ agonists via ACE, some of the ACE inhibitors can directly activate the B₁ receptor of des-Arg-BK followed by the release of nitric oxide, in the absence of the peptide ligand in cultured endothelial cells.

THE ANGIOTENSIN METABOLITES

Some of the Ang metabolites, enzymatic breakdown products (see Fig. 2), are active on their own. Some of them mimic Ang II, whereas others antagonize the effects of Ang II. Two of them are mentioned here because they potentiate BK, probably by interacting with ACE, but not necessarily acting as inhibitors only.

Ang (1-7) (des-Phe⁸-Ang II) is a substrate of the N-domain, but an inhibitor of the C-domain of ACE. Another enzymatic product of Ang I hydrolysis, Ang (1-9) (des-Leu¹⁰-Ang I), inhibits both domains of ACE; both Ang (1-7) and Ang (1-9) can enhance BK's effect on the B₂ receptor.

SERINE CARBOXYPEPTIDASES

A serine carboxypeptidase-type enzyme, called deamidase, cathepsin A, lysosomal protective protein, or lysosomal CPA, also cleaves BK at the Phe⁸-Arg⁹ bond as shown *in vitro*. This enzyme has an acid pH optimum for CP and esterase activities, but deamidates amidated C-terminal amino acids (e.g., substance P) at neutral pH.

Another serine CP, the lysosomal Pro-X CP (prolylcarboxypeptidase or angiotensinase C), inactivates desArg⁹-BK, the ligand of the B₁ BK receptor, at the Pro⁷-Phe⁸ bond (see Fig. 1). Prolylcarboxypeptidase occurs in abundance in neutrophils; this may have some bearing on B₁ receptor activity, as it is up-regulated by agents promoting inflammation. Thus, this enzyme may be an inactivator of the B₁ receptor agonists. The same bond is also hydrolyzed in Ang II both by Pro-X-CP and by an enzyme called ACE2 with sequence similarities to ACE, but it is not inhibited by ACE inhibitors (Fig. 2).

AMINOPEPTIDASES

Aminopeptidases have two different functions in kinin metabolism. A blood-borne aminopeptidase, present also in tissues, converts Lys-BK to BK by cleaving the Lys⁰-Arg¹ bond. A second aminopeptidase, called aminopeptidase P, but originally referred to as "prolidase," is present in erythrocytes, kidney, lung, and other tissues. It inactivates BK by cleaving at Arg¹-Pro². Rat tissues have the highest concentrations of this enzyme; human tissues apparently express much less aminopeptidase P.

In contrast to ACE and NEP, which are bound by a transmembrane peptide as type I and type II transmembrane enzymes, aminopeptidase P is membrane-bound via a glycosylphosphatidylinositol anchor. Its molecular weight is approximately 90–95 kDa. As with

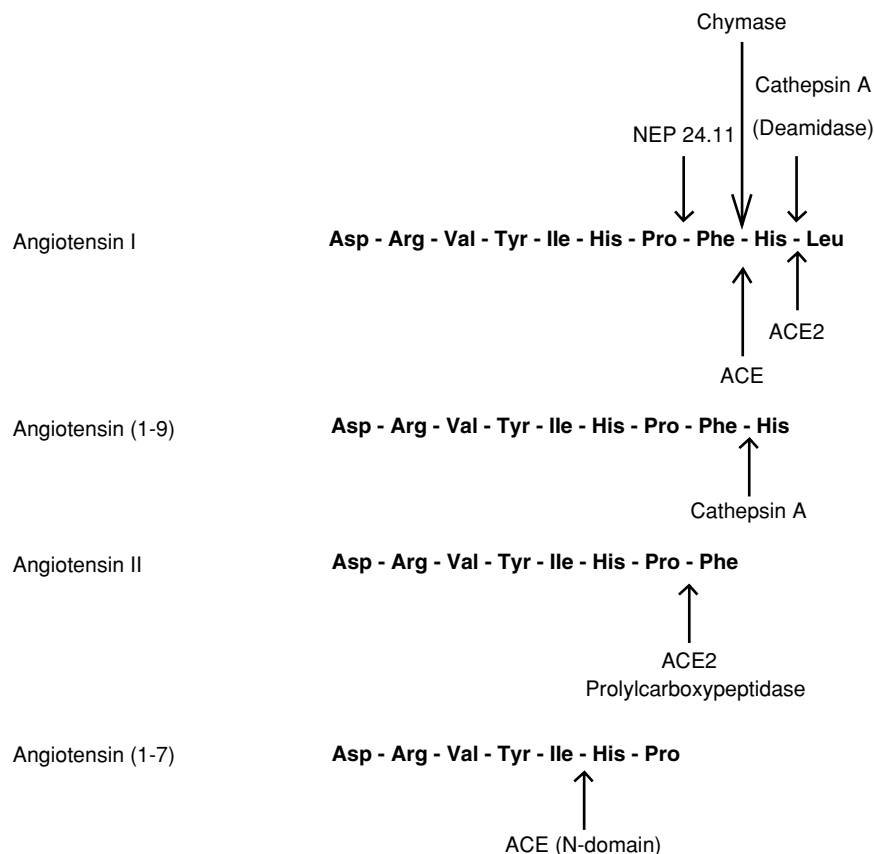

Figure 2 Peptide bonds hydrolyzed in angiotensins by peptidases.

some other peptidases, it forms dimers or even oligomers. Aminopeptidase P, a zinc metallopeptidase, can be activated by Mn^{2+} with some substrates and is inhibited by chelating agents. Other inhibitors include sulfhydryl compounds. Interestingly, many ACE inhibitors also inhibit aminopeptidase P, although with a higher K_i (in the micromolar range) and Mn^{2+} enhances this inhibition. This is likely to be due to the presence of Pro or Pro-like structures in the ACE inhibitors and to the effective zinc-binding moieties.

NEUTRAL ENDOPEPTIDASE 24.11

Neutral endopeptidase 24.11 (neprilysin, NEP) is a zinc metallopeptidase with a single active site containing the HEXXH sequence to bind Zn^{2+} . The enzyme is a single-chain protein of 742 amino acids and, as a type 2 membrane protein, is bound via an uncleaved N-terminal signal peptide.

NEP is distributed widely; its expression in vascular endothelial cells is low, but epithelial cells, especially in microvillar structures, are rich in NEP. Its presence in the CNS has been investigated in detail

because neuropeptides are among its substrates. The relevance of the high concentration of NEP in the male genital tract, especially in prostate gland, is not known. NEP under the name “common acute lymphoblastic leukemia antigen” (CALLA or CD10) is present in lymphoblasts and also in neutrophils. Of the solid tumors, NEP is highly expressed in malignant liver cells of rats and humans.

NEP cleaves peptides at the N-termini of hydrophobic amino acids and as such it is a second kininase II-type enzyme that releases the C-terminal Phe⁸-Arg⁹ of BK. It was first discovered as an endopeptidase that cleaves the B-chain of insulin, but its substrates include enkephalins, endothelin, atrial natriuretic peptide, substance P, and a chemotactic peptide.

Purified human NEP was used to establish the kinetics of hydrolysis of BK. The k_{cat} for BK is higher with NEP than with ACE but because of the much higher K_m (120 μM versus 0.2 μM) the specificity constant, k_{cat}/K_m , of NEP is lower (40 $\mu M^{-1} \text{ min}^{-1}$ versus 3667 $\mu M^{-1} \text{ min}^{-1}$).

The NEP level in circulating blood plasma is normally low, but increases 60- to 80-fold in adult

respiratory distress syndrome with septic pneumonia. Inhibition of NEP in rat bronchial epithelium markedly enhances bronchoconstriction induced by substance P and BK. BK-induced bronchoconstriction in asthmatic patients is augmented by NEP inhibitors. Indirect actions of BK are also influenced by NEP inhibition, because when BK releases substance P from nerve endings, it is subsequently cleaved by NEP.

Microvascular leakage in guinea pig airways and enhanced myocardial blood flow after sensory nerve stimulation in the rat heart were potentiated by NEP inhibitors, possibly through blocking BK inactivation.

An NEP inhibitor has been used to successfully treat young boys suffering from acute watery diarrhea. The results were attributed to blocking the breakdown of endogenous enkephalins acting on δ -opioid receptors.

Because of the increased reactivity to the combined administration of inhibitors of two peptidases, several compounds that inhibit both NEP and ACE, or ACE and aminopeptidase, have become available. Extensive reports deal with the clinical and laboratory experimental results with the dual ACE and NEP inhibitors, for example, with omapatrilat (Vanlev).

Endothelin-converting enzyme, an NEP-related peptidase with some sequence similarity, also cleaved BK at the Pro⁷-Phe⁸ bond, albeit with a K_m approaching 1 mM.

ENDOPEPTIDASES 24.15 AND 24.16

Endopeptidase 24.15 (EP24.15; thimet oligopeptidase) and endopeptidase 24.16 (EP24.16; neurolysin) are closely related (80% similarity and 63% identity in amino acid sequences) zinc metalloenzymes that contain the HEXXH zinc-binding motif. They are active at neutral pH and cleave a number of biologically active peptides *in vitro*. Both enzymes are abundant in brain and have been purified from rat brain homogenates.

EP24.15 is a 78 kDa protein containing 687 amino acid residues and is expressed at highest levels in brain and testis. When EP24.15 was purified from rat brain, it was determined that the enzyme was identical to two other enzymes named earlier, endopeptidase A, originally described as a kininase, and Pz-peptidase, which cleaved a synthetic substrate of collagenase. EP24.15 is activated by low concentrations of thiols, which convert an inactive multimer, with a blocked catalytic site, to an active monomer by disruption of intermolecular disulfide bridges. EP24.16 does not have these -S-S- bridges.

Tissues such as spleen, liver, kidney, lung, adrenal, and thyroid also contain EP24.15 activity. Although

the enzyme apparently lacks both a signal sequence and a membrane-binding motif, an estimated 10–25% of activity is associated with the plasma membrane fraction of a number of tissues.

EP24.16 is a 704-amino-acid protein that, like EP24.15, is present in both plasma membrane-associated (10–20% of activity) and soluble forms. In addition, EP24.16 is found in mitochondria. After EP24.16 was isolated from rat brain and sequenced, its identity to some other proteins, including a soluble Ang II-binding protein from porcine liver and a microsomal endopeptidase from rabbit liver, was revealed. The enzyme has also been purified from rat ileum and kidney and a variant, called EP24.16B, has been isolated from rat testis.

Both enzymes share most of their natural substrates and preferentially cleave them at the carboxyl side of hydrophobic amino acids. BK is hydrolyzed at the Phe⁵-Ser⁶ bond. Other peptides, such as Ang I, opioids, gonadotropin-releasing hormone, substance P, and neurotensin, are also cleaved *in vitro* by both of the enzymes. These substances are hydrolyzed at the same bond by both enzymes, except for neurotensin, which is inactivated at Arg⁸-Arg⁹ by EP24.15 and at the Pro¹⁰-Tyr¹¹ bond by EP24.16.

Because of the predominantly cytosolic nature of these two enzymes, their roles as kininases are not clear. With the advent of specific, biologically stable enzyme inhibitors, investigators found that the enzymes can be kininases. An inhibitor of both EP24.15 and EP24.16 potentiated the increase in permeability of pial (brain surface) microvasculature induced by BK *in vivo*. This suggests that one or both enzymes can moderate BK's effect on the blood-brain barrier, possibly in cases of inflammation.

The formation of BK 1-5 in the medium of cultured bovine aortic endothelial cells after incubation with BK was inhibited 45% by an EP24.16 inhibitor and 18% by an EP24.15 inhibitor. Thus, even a transiently extracellular location of these enzymes on endothelial cells would allow them to function as kininases in the vasculature.

EPILOGUE

The very short half-life of kinins *in vivo* (seconds) pointed to the importance of their enzymatic metabolism but the acceptance of this conclusion took decades. It also follows that limited conclusions can be deduced from measuring circulating kinin levels, as kinin's actions are more likely paracrine or autocrine in nature. Only a long time after the discovery of the "original" kininase, CPN, were some of its functions

in the body, for example, on plasminogen activation, clarified.

The induction of so-called Chagas' heart disease by *Trypanosoma cruzi* has been found to be promoted by BK in mice. It was suggested that changes in kininase levels can affect parasite infectivity and thus the outcome of the disease.

ACE inhibitors, which have become widely used, originated from studies performed *in vitro*. The obvious consequence of the seemingly opposite, dual actions of kininase II or ACE on BK and Ang I was that its inhibitors block the release of Ang II while they can enhance the effect of BK. Because related peptidases cleave different active peptides, compounds that inhibit both ACE and NEP when tested clinically could block Ang I, BK, and atrial natriuretic peptide hydrolysis.

presentations, a number of patients can achieve significant virilization and go undiagnosed until adulthood. These patients can be discovered incidentally during the workup of a malignancy but are usually diagnosed on the occasion of their evaluation for infertility.

Serum levels of the male hormone testosterone are normally low in prepubertal boys and begin to rise during early puberty. In boys affected with Klinefelter's syndrome, a decreased capacity of the testes to secrete testosterone becomes evident in many cases as puberty continues. Therefore, testosterone levels tend to be either low-normal or frankly decreased in adult patients. This occurs despite an elevation above normal values of the circulating levels of luteinizing hormone (LH), the hormone that normally stimulates testosterone production by the testes. Because of the lack of testosterone, affected patients rarely become normally virilized. On the other hand, the levels of the female hormone estradiol, which is also normally secreted by the human testes, are usually elevated in Klinefelter's patients. These anomalies result in an imbalance between the two sex hormones, with increased estradiol levels and diminished testosterone values producing a hormonal milieu favorable to the development of bilateral gynecomastia. This is observed in more than 90% of Klinefelter's patients.

DIAGNOSIS AND GENETIC BASES

Postpubertal men with Klinefelter's syndrome exhibit the clinical manifestations listed previously accompanied by a consistent hormonal profile. This profile essentially consists of elevated circulating levels of the two hypophyseal hormones, LH and follicle-stimulating hormone (FSH), together with low levels of the sex hormone testosterone. The typical Klinefelter's patient also exhibits complete azoospermia. However, several variants of the syndrome have been described, with a variable and often less severe degree of both gynecomastia and testosterone insufficiency. Patients with a less severe phenotype are frequently diagnosed at a later age because symptoms of decreased libido and potency, which accompany the fall in testosterone levels seen in adult patients, appear later in life. Therefore, milder forms of the disease can be revealed as late as 45 years of age.

Once suspected on the basis of the clinical and hormonal presentation, confirmation of the diagnosis of Klinefelter's syndrome relies on the demonstration of an abnormal karyotype. Indeed, the genetic basis of Klinefelter's syndrome is an abnormal number of sex chromosomes. In the normal human, a normal karyotype consists of 22 pairs of autosomes (non-sex

chromosomes) and one pair of sex chromosomes. The pair of sex chromosomes should be XX in the female and XY in the male, with the Y chromosome bearing the gene(s) responsible for male sexual differentiation. Therefore, each and every cell of a normal human female should have 46 chromosomes, with two X sex chromosomes (the karyotype being 46,XX), whereas the cell of a normal human male should have 46 chromosomes, with both an X and a Y sex chromosome (the karyotype being 46,XY). As stated earlier in the defining paragraph, there are a number of chromosomal abnormalities associated with Klinefelter's syndrome that have in common the display of at least one supplementary X chromosome. Therefore, a typical Klinefelter's karyotype is 47,XXY. Variants can be 48,XXXY, 48XXYY, or even 49,XXXYY, and they can probably explain the somewhat variable clinical expression of the disease.

The origin of these chromosomal abnormalities is a failure of the sex chromosomes to separate during the formation of the gamete, that is, the spermatozoid in the male or the ovum in the female. When a gamete possessing such an extra X chromosome is fertilized, the resulting zygote will bear an extra X chromosome, either from paternal origin (30% of cases) or from maternal origin (more often). One etiological factor that could potentially account for the nondisjunction of sex chromosomes is the maternal age. However, a genetic predisposition may also exist. Finally, affected patients frequently present 46,XY/47,XXY mosaicism, which is the second most common karyotype seen in Klinefelter's syndrome after 47,XXY. A mosaic state refers to those patients in whom only a subset of cells exhibit the abnormal karyotype. This can be explained by the successful elimination of the extra X chromosome in some cells at the early stages of embryo formation. Of note, mosaicism could account for the milder forms of Klinefelter's syndrome.

TREATMENT

The treatment of patients suffering from Klinefelter's syndrome is essentially constituted by the replacement of the sex hormone testosterone when there is evidence that an affected individual's own testosterone production is insufficient. This is best achieved by intramuscular injections of depot preparations of testosterone at the average frequency of every 2 to 4 weeks. Frequency of administration depends on the dosage required and the degree of testosterone insufficiency. Oral preparations of testosterone are also available. However, the levels of circulating testosterone achieved in the patients with such preparations

are inconsistent from day to day, rendering the proper administration difficult. In addition, the occurrence of abnormal liver function tests, as well as of hepatic tumors, has been reported with orally administered testosterone. For this reason, and also because parenteral administration of testosterone is more effective in virilizing the patient, oral preparations are generally avoided.

Adequate virilization of affected patients can be achieved almost universally with the appropriate hormonal substitution. When treating adolescent males, special care should be given to avoid premature bone maturation that will occur with testosterone treatment. This is achieved by the administration of low doses of testosterone until the full growth potential of these individuals has been reached. In contrast, testosterone treatment will not correct gynecomastia if the latter is already present. The treatment of choice when gynecomastia is psychologically disturbing to the patient is reduction mammoplasty.

Klinefelter's patients are also usually azoospermic and, hence, infertile. The natural fertility potential of these patients is nonexistent. However, assisted reproductive technologies, and more specifically intracytoplasmic sperm injection (ICSI), offer Klinefelter's patients the possibility of fathering children. In the few successful cases of ICSI reported so far, mature spermatozoa were obtained either directly from testicular aspiration or from the ejaculate. To date, all infants born from Klinefelter's fathers after ICSI have had normal karyotypes because a high percentage of mature spermatozoas retrieved from Klinefelter's patients are chromosomally normal. However, one report showed clearly that in Klinefelter's patients, spermatozoa with the abnormal karyotype can also reach maturity and so could theoretically fertilize the egg. Therefore, the potential to transmit the chromosomal abnormality of the father to the offspring remains a major concern related to these therapeutic approaches. This concern raises the necessity of beginning to evaluate the chromosomal status of sperm before using it for assisted reproductive technologies.

ASSOCIATED ABNORMALITIES AND COMPLICATIONS

Associated abnormalities include disorders of thyroid function, but clinically significant thyroid insufficiency

is uncommon. However, the early belief that boys affected with Klinefelter's syndrome may exhibit an increased frequency of learning disabilities as well as behavioral problems is erroneous. Adults with Klinefelter's syndrome as a group are not different from normal controls in terms of level of education, employment, socioeconomic status, or criminal behavior.

Complications include an increased risk of cerebrovascular disease (stroke) as well as an increased incidence of breast cancer. Indeed, the risk of carcinoma of the breast in Klinefelter's patients is 20 times higher than that in normal men and one-fifth that in women. There is no obvious reason for this increased risk because gynecomastia per se does not represent a premalignancy. A role for the presence of an extra X chromosome has been suggested, as has a role for the hormonal milieu. Other complications encountered in Klinefelter's patients include an increased incidence of diabetes and an increased risk of osteoporosis. This latter complication is probably related to the imbalance in sex hormone concentrations.

Figure 1 Regeneration of NAD^+ by conversion of pyruvate to lactate permits glycolysis to continue under anaerobic conditions.

explain the higher risk of lactic acidosis than with metformin. Lactic acidosis complicating metformin (dimethylbiguanide) occurs much less commonly, with most cases being reported among patients in whom biguanide therapy is contraindicated (e.g., renal impairment or hypoxic states).

TREATMENT AND PROGNOSIS

General Medical Care

Serious initiating or aggravating conditions (e.g., cardiogenic shock) often dictate the poor prognosis of acute severe lactic acidosis. Accordingly, intensive supportive care and correction of precipitating factors are important.

Bicarbonate

Despite controversy surrounding the benefits of alkali therapy, intravenous sodium bicarbonate remains the mainstay of treatment. High doses of bicarbonate may be required to elevate arterial pH; hemodialysis has been advocated in the management of the resulting sodium and volume overload. Hemodialysis will also remove metformin but the role of dialysis in treating metformin accumulation has been questioned.

Table 1 Pathological Causes of Lactic Acidosis

| |
|---|
| Type A |
| <ul style="list-style-type: none"> • Shock (e.g., septic, cardiogenic) • Respiratory failure • Tonic-clonic epileptic convulsions • Toxins (e.g., cyanide, carbon monoxide) |
| Type B |
| <ul style="list-style-type: none"> • Diabetes mellitus (e.g., in association with diabetic ketoacidosis—rarely severe) • Hepatic failure • Drugs [e.g., biguanides, salicylates, isoniazid, sorbitol (in parenteral feeds)] • Toxins (e.g., ethanol, methanol) • Congenital disorders [e.g., myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) syndrome (due to point mutation in mitochondrial DNA at position 3243 in the tRNA^{LEU(URR)} gene)] |

Other Measures

The value of alternative therapeutic approaches (e.g., using the pyruvate dehydrogenase stimulator dichloroacetate or Carbicarb, which contains equimolar amounts of sodium bicarbonate and sodium carbonate) remains unclear.

ETIOLOGY

LCH is a disease of unknown etiology. Although pulmonary LCH in adults has been reported to be of nonclonal origin, biopsies from lesions in children, with either single-system or multisystem involvement, has demonstrated proliferation of a single LC clone. Several cytokines, such as granulocyte-macrophage colony-stimulating factor, interferon- γ , interleukin-1 (IL-1), and IL-10, were also found to be expressed by LCs in LCH lesions. The pattern of cytokine expression induces the recruitment of LC progenitors and in addition favors their maturation and rescue from apoptosis, resulting in the accumulation of pathologic LCH cells. Moreover, ILs, tumor necrosis factor α (TNF α), and cluster designation 40 ligand (CD40L) are also produced by T cells inside the lesion, indicating immunologic dysfunction as a possible cause of the disease.

Chromosomal abnormalities of the type showing chromosomal breakage were found in peripheral blood lymphocytes when they were stimulated with phytohemagglutinin. Multisystem involvement was reported to be associated with a higher incidence of chromosomal breakage (13.4%) than single-system involvement (6%). However, it remains unclear whether this difference results as a secondary effect of cytokine production or as an inherent chromosomal instability. Parental solvent exposure, perinatal infections, and a family history of thyroid disease were also reported as being associated with an increased incidence of the disease.

CLINICAL MANIFESTATIONS

There is a wide spectrum of clinical manifestations of the disease and almost every system can be involved; however, involvement does not necessarily indicate dysfunction. Organ infiltration commonly causes distress and disability, but is of prognostic importance only if vital functions are affected. LCH can be stratified according to system involvement as a single-system disease or as a multisystem disease. A single-system disease may involve only a single site, e.g., a single bone lesion, isolated skin disease, or a solitary lymph node, or may involve multiple sites, e.g., multiple bone lesions and multiple lymph node involvement. Multisystem disease is a multiple-organ disease, with or without dysfunction.

Bones

LCH frequently affects the bones. The majority of lesions are asymptomatic but can also present as a

painful swelling; lytic skull lesions are the most frequent finding in children, whereas the jaw is more commonly involved in adults. Other bone sites frequently affected include the femur, vertebrae, ribs, pelvis, humerus, and extremities. Clinical examination usually reveals a soft and sensitive protuberance. Skull lesions are not always lytic but they may extend intracranially or impinge on the dura. Patients with such lesions are at greater risk for developing central nervous system (CNS) infiltration and/or diabetes insipidus (DI). Periorbital disease is usually accompanied by proptosis but optic nerve compression is rare. Skeletal lesions can be detected with X rays, which are superior to radioisotope scans, showing well-defined osteolytic areas, a periosteal reaction that resembles malignancy, and a sclerotic areola in healing lesions.

Skin and Oral Mucosa

Skin rash is very common in infants and may present in any part of the body as brown to purplish papules (Hashimoto-Pritzker disease), resembling healing chickenpox; these lesions heal spontaneously within the first year of life without therapy. Adult patients may develop a red or brown papular rash or crusted dermal areas scattered over the trunk, often healing with depigmentation. Lesions in the perianal region, in the genitalia, in the scalp, or behind the ears are often ulcerative, are associated with great distress, and are usually treated as skin infections before the final diagnosis of LCH is made. Scalp rash can be mistaken for cradle cap, seborrhea, or severe dandruff. In the mouth, LCH often presents as gingival hypertrophy or ulcerative lesions on the soft or hard palate, buccal mucosa, tongue, and lips.

Lymph Nodes and Thymus

LCH frequently infiltrates the lymph nodes. Involvement of the cervical nodes usually presents as soft, matted nodal groups with accompanying lymphedema. Infiltration of the mediastinal lymph nodes presents as nodular enlargement, making histological examination mandatory for differential diagnosis from infections or neoplasia. The abdominal glands can also be affected, whereas Waldeyer's ring affection can cause obstruction of the upper airways. Additionally, LCH infiltration of regional nodes draining solitary skin or bone lesions is not uncommon. Thymic involvement can be detected either as an enlargement on chest X ray or as morphological changes on biopsy.

Lungs

Pulmonary LCH runs an unpredictable and variable course, occurring less frequently in children than in adults, in whom it may be related and/or exacerbated by cigarette smoking. Clinical presentation varies from an asymptomatic pattern to a progressive disease that leads to respiratory failure. Children usually present with tachypnea or dyspnea, whereas spontaneous pneumothorax resulting from a bulla rupture is common in adults. The cystic/nodular pattern of lung involvement, with a tendency to form large cavities and widespread fibrosis, leads to lung destruction and appears as “honeycombing” on chest X ray. Diagnosis is confirmed from the findings on biopsy or in bronchial washings.

Ears

Aural involvement usually presents with discharge either from external otitis due to skin involvement of the aural canal or from polypoid tissue extension into the canal from an adjacent bone infiltration. Differential diagnosis between these two conditions is mandatory as external otitis should be treated with topical regimens, whereas polyps may require curettage. The middle ear can also be affected, sometimes resulting in deafness in persistent cases with ossicle damage. Involvement of the mastoid bones may also occur.

Liver and Spleen

Liver involvement is associated with hepatomegaly and hepatic dysfunction, leading to hypoalbuminemia, ascites, edema, coagulopathy, and, rarely, hyperbilirubinemia. Splenomegaly, when present, can be massive and may lead to cytopenia due to hypersplenism that may require splenectomy if systemic treatment has failed.

Bone Marrow and Peripheral Blood

Bone marrow involvement affects mainly children with multisystem disease and is usually associated with involvement of the lymphoreticular system and the skin. However, bone marrow infiltration has been found even in patients with single-site involvement. A mild anemia of chronic disease is the most common finding, although neutropenia and thrombocytopenia might also occur, whereas a normal blood count does not exclude bone marrow infiltration. A reversal of the CD4⁺/CD8⁺ ratio is also a very common finding in the acute phase of the disease.

Gastrointestinal Tract

Gastrointestinal (GI) manifestations from LCH are rare, with the most frequent presenting symptoms being malabsorption and diarrhea. Although endoscopic examination may reveal involvement of the stomach, the diagnostic evaluation of the rest of the GI tract is difficult because of the intermittent pattern of the disease.

Endocrine System and Central Nervous System

Anterior pituitary dysfunction has been described in up to 20% of patients with LCH, usually associated with DI. However, anterior pituitary function has not been systematically studied in adults; most information has been obtained from studies in children. Anterior pituitary deficiency in LCH is almost always associated with DI; only a few cases of pituitary hormone insufficiency without DI have been described in the literature. Although DI may predate the diagnosis of LCH, it usually develops at approximately 12 months of age, with a range that can extend to many years from diagnosis. Associated features are multisystem disease with skull vault defects and, notably, temporal bone or orbital lesions with intracranial tumor extension. Growth hormone deficiency (GHD) occurs in approximately 40% of affected children and has been related to histiocytic infiltration of the hypothalamus. GHD is frequently the first endocrine defect in addition to DI, with a median latency of approximately 1 year from diagnosis. Growth retardation, although previously described, is thought to be an infrequent presentation of LCH, but GHD should always be considered in children with LCH and DI. As adults with GHD may show an increase in well-being and a favorable metabolic profile in response to GH therapy, assessment of GHD may be an important part of the evaluation of adult patients with LCH.

There are only a few reports on gonadal function in patients with LCH, as most studies have been of prepubertal children. Although the early studies in adults with LCH and DI failed to demonstrate abnormalities of gonadotropin secretion, a few cases of amenorrhea in adults have been described. Similarly, thyroid hormone deficiency can be a major component of anterior pituitary dysfunction in patients with LCH. Adrenocorticotrophic hormone (ACTH) deficiency presents mostly in the context of generalized pituitary involvement, although a few cases of isolated ACTH deficiency have also been described.

Imaging studies of patients with LCH and CNS involvement have shown that more than one type of

lesion may be present in 87% of individual patients, including patients with DI. In addition, abnormalities of the hypothalamo-pituitary axis (HPA) were observed in 68% of patients with CNS lesions and in 81.5% of patients with DI [infundibular thickening, partial or complete empty sella with a lack of posterior pituitary bright spot on T₁-weighted magnetic resonance imaging (MRI) sequences, or a pituitary mass lesion]. Morphological changes in the HPA are optimally demonstrated by MRI with administration of gadolinium-dimeglumine gadopentetate. A small pituitary or empty sella has also been described in cases of combined anterior and posterior pituitary insufficiency. However, anterior pituitary dysfunction may also occur in the absence of structural changes on imaging and has been attributed to microinjury leading to vascular impairment and scarring. Other possible mechanisms include cytokine modulation from adjacent osseous lesions or an autoimmune effect.

Efforts to identify predictors of late endocrine sequelae in children with LCH showed that dynamic endocrine pituitary testing was not a useful predictor. Neither the site of involvement nor the extent of the disease was associated with further endocrine deterioration. Therefore, it seems that only DI in association with markedly abnormal hypothalamo-pituitary imaging identifies patients with LCH at higher risk for anterior pituitary dysfunction. As DI is associated with multisystem disease and progression that may be greatly delayed, such patients should be receiving regular and prolonged follow-up to identify such dysfunction and provide adequate replacement.

Diabetes insipidus with structural changes in the HPA often heralds the involvement of other parts of the brain with more global neurological or neuropsychological sequelae, depending on the location of the involvement. The signs and symptoms of none-endocrine hypothalamic involvement range from disturbances in social behavior, appetite, and temperature regulation to abnormal sleeping patterns. Further abnormalities, such as disturbances in thermoregulation and adipisia, can make DI difficult to treat and complicate the overall management of these problematic cases. This is particularly significant when there is also memory impairment and problems with compliance. More serious problems from CNS involvement, though of rare incidence, include mass lesions in the brain parenchyma or choroid plexus (resulting in hydrocephalus), space-occupying masses from neighboring bone or meningeal lesions, and diffuse infiltration of the cerebellum, leading to ataxia and visual problems.

Thyroid gland involvement is rare, with only a few reported cases involving goiter and in some cases hypothyroidism. Pancreatic infiltration has also been reported but without apparent dysfunction.

In summary, adult patients with LCH presenting with DI are at high risk for anterior pituitary hormonal deficiency and hypothalamic involvement, especially when accompanied by abnormal HPA imaging. Endocrine abnormalities should be actively sought in patients with LCH, as their recognition and management play important roles in the treatment of this difficult condition.

EVALUATION OF PATIENTS

Any patient presenting with either single- or multiple-site disease should be evaluated to determine the extent of the disease and subsequent treatment plan. A detailed history and complete clinical examination are always mandatory in a patient suffering from LCH. Imaging studies should include X rays of the chest and long bones (skeletal survey) and, if orbital and/or mastoid involvement is suspected or neurologic dysfunction is present, computed tomography scans of the head or spine and pelvis should be performed. A complete blood count, erythrocyte sedimentation rate, C-reactive protein, liver function tests, serum electrolytes, and urinalysis are also mandatory. A water restriction test is indicated in any patient with symptoms suggestive of DI. The final diagnosis is established with biopsy of lesions and demonstration of positive immunostaining for CD1a and S100 protein. Birbeck granules can be identified only with electron microscopy and should be used in any case where the diagnosis is in doubt.

TREATMENT

Two prospective studies in children, LCH-I and LCH-II, have established some general treatment guidelines that can also be applied to adults. The selection of treatment chiefly depends on the extent of the disease, which must always be evaluated carefully after a systemic diagnostic approach.

Patients with single-site involvement, such as skin and lymph nodes, can be treated either with prednisone or with a combination of prednisone and velban (vinblastine). The same treatment approach can be used in single, non-CNS bone lesions in which curettage of the infiltrated site is also an efficient therapy. However, in mandibular lesions and with tooth involvement, it is advisable to avoid surgical excision since medication may lead to regression of the lesions. Painful or recurrent bone lesions may also respond to intralesional steroid injection, which for safety reasons are preferably performed under radiographic guidance. Single-site involvement concerning only skin lesions can also be treated with a topical nitrogen mustard and sometimes may respond to topical steroid application. Additionally,

single steroid treatment may decelerate or even halt the process of the disease in adults suffering from the nodular pattern of pulmonary LCH.

Single-medication treatment, such as prednisone or radiation, is not effective in multiple bone lesions or multisystem disease. The treatment protocol of the LCH-III study suggests that these patients should be treated with prednisone and velban for 6 or 12 months.

The LCH-II study showed that VP-16 (etoposide) did not offer any additional therapeutic benefit concerning response, survival, or reactivation frequency, either as monotherapy or in combination with velban and prednisone. Therefore, and in view of its potential leukemogenicity, VP-16 is not included in the standard initial treatment of LCH-III.

According to the LCH-III protocol, patients with multisystem disease and subsequent risk for other organ involvement are randomly divided into treatment groups with either velban–prednisone–6-mercaptopurine or this three-drug combination with methotrexate, initially intravenously and orally during the maintenance phase. If a patient presents recrudescence of the disease after 6 weeks of treatment or does not respond to therapy, it is suggested, according to the LCH-S (salvage) study, that treatment proceed with the use of the purine analogue cladribine (2-CdA) for 4–6 months depending on the response of the patient. Some reports showed that 2-CdA, which can provide both cytotoxic and immunosuppressive effects, is a potent medication in adults with bone, skin, lymph node, pulmonary, and CNS involvement. (The protocols of the LCH-III and LCH-S studies are available from the Histiocytosis Association of America.)

Regarding endocrine involvement, systemic chemotherapy appears to be of little benefit in controlling the progression of the disease over the long term, although focal radiotherapy may halt local disease progression in terms of mass effects. Radiation therapy can also be used in vertebral lesions or lesions of the femoral neck with a risk of fracture or collapse. Other treatments that could be used systemically in the future include anti-TNF α agents, which are

undergoing testing, bone marrow transplantation, and anti-CD1a, which has been used in diagnostic evaluation but also seems promising as a possible therapeutic approach.

Laron Syndrome

see Growth Hormone Insensitivity

Fat Mass and Gender Influence Serum Leptin Concentration

The two major factors that determine serum leptin concentrations in humans under conditions of consistent food intake are fat mass and gender. Leptin is positively correlated with fat mass in adults, children, and newborns and is therefore increased in obesity. *LEP* gene expression is greater in larger adipocytes than in smaller adipocytes and leptin secretion is strongly correlated with fat cell volume. Therefore, the elevation in serum leptin results from the release from a greater number of fat cells and increased leptin synthesis in the larger adipocytes of obese subjects.

Serum leptin is significantly greater in women than in men with the same amount of body fat. One explanation for this finding is that women have a significantly greater subcutaneous adipose tissue mass relative to visceral adipose mass than men. *LEP* gene expression/leptin production is greater in subcutaneous than visceral adipocytes. Sex steroids also regulate leptin production. Testosterone reduces serum leptin in hypogonadal men and leptin levels decrease as serum testosterone increases during pubertal development in boys. Estrogen, in combination with anti-androgens, increases leptin in male-to-female transsexuals and testosterone decreases leptin in female-to-male transsexuals, independent of changes in adipose tissue mass. *In vitro*, estradiol stimulates, and dihydrotestosterone inhibits, leptin production in human visceral adipose tissue pieces in culture for 48 h.

Energy Intake Regulates Serum Leptin Levels

Energy intake can regulate serum leptin concentrations independent of effects on adipose tissue mass. With standard timing for food intake (three meals per day in humans), leptin levels are reasonably constant from day to day, exhibiting a maximal daily variation of approximately 30%. However, serum leptin falls with short-term fasting (24 h) and increases within 4–5 h of refeeding. Maintenance of euglycemia with dextrose infusion prevents the fasting-induced drop in leptin, implicating insulin and/or glucose as the nutritional signal that is recognized by the adipocyte for leptin synthesis. In a prolonged study of energy restriction (moderate and severe), changes in serum leptin were best correlated with changes in glycemia.

Serum leptin exhibits a diurnal profile that is entrained to food intake. The peak in serum leptin occurs at ~0200 h, in both lean and obese subjects under standard living conditions. Day/night reversal shifts

the peak in serum leptin by 12 h. A shift of 6.5 h in meal timing without a change in light or sleep cycles shifts the leptin peak 5–7 h, suggesting that the nocturnal peak in serum leptin is a delayed postprandial response induced by after-meal excursions in glucose and insulin. The macronutrient content of meals also regulates serum leptin levels. High-fat/low-carbohydrate meals (60%/20%) over the course of 1 day reduce leptin levels. High-fat/low-carbohydrate meals induce smaller insulin and glucose excursions than meals of standard fat/carbohydrate content, again implicating insulin and glucose in the nutritional regulation of leptin production.

The regulation of leptin production by glucose and insulin has been directly demonstrated using the euglycemic–hyperinsulinemic clamp. Serum leptin is elevated by the end of prolonged clamps (9 h) at physiologic insulin or within 4–8 h with supraphysiologic insulin concentrations in humans. The synthesis of hexosamines within the adipose tissue is one link between insulin-stimulated glucose uptake/metabolism and leptin production. In rodents, infusion of glucosamine, uridine, or free fatty acids during a 3 h euglycemic–hyperinsulinemic clamp increased muscle uridine diphosphate-N-acetylglucosamine (UDP-GlcNAc), muscle *Lep* gene expression, and serum leptin, compared to saline-infused controls clamped under identical conditions. In transgenic mice overexpressing glutamine:fructose-6-phosphate amidotransferase (GFAT), the rate-limiting enzyme in hexosamine biosynthesis, serum leptin and adipose tissue *Lep* gene expression is significantly increased. In subcutaneous adipose tissue of obese humans, UDP-GlcNAc is increased 3.2-fold compared to lean subjects and there is a significant positive relationship between adipose tissue UDP-GlcNAc and body mass index. An increase in hexosamine biosynthesis in cultured human subcutaneous adipocytes increases leptin release and inhibition of GFAT activity reduces glucose-stimulated leptin release.

The Sympathetic Nervous System Inhibits Leptin Release from Adipocytes

Leptin-induced activation of the sympathetic nervous system has been postulated to be a negative feedback signal for leptin synthesis. As a mimic of the activation of the sympathetic nervous system, isoproterenol infusion in human subjects significantly reduces serum leptin. This finding is in agreement with animal data indicating that catecholamines inhibit leptin production, although the mechanism through which this occurs has not been elucidated. *In vitro*, catecholamines

inhibit leptin production from 3T3-L1 cells and cultured human adipose tissue pieces.

LEPTIN AND BODY WEIGHT REGULATION

The Leptin Receptor

The hypothalamic leptin receptor (Ob-Rb) is a member of the class I cytokine receptor family. As with other cytokine receptors, binding of leptin to its receptor activates an associated janus kinase (JAK), which phosphorylates tyrosines within the leptin receptor itself and signal transducer and activator of transcription (STAT) proteins associated with the receptor. Phosphorylated STAT proteins dimerize and translocate to the nucleus to initiate gene transcription. STAT-3 is the major STAT protein activated by the hypothalamic leptin receptor in mice. Binding of leptin to its receptor has also been reported to activate phosphatidylinositol-3-kinase, phosphodiesterase-3B, and members of the mitogen-activated protein kinase superfamily. Low-level expression of Ob-Rb has been detected in cells other than those in the hypothalamus and it has been shown that leptin activates AMP-activated protein kinase in skeletal muscle.

In addition to the hypothalamic leptin receptor Ob-Rb (long receptor isoform) described above, five other leptin receptors have been identified, all encoded by alternative splicing of the *Lep* gene. The extracellular domain of all leptin receptors is identical; however, the intracellular domains terminate at different lengths. Due to the truncated intracellular domain, the short leptin receptors lack the box 2 motif necessary for STAT protein interaction and these leptin receptors do not phosphorylate STATs. Ob-Ra is the most abundant and widely distributed of the short receptor isoforms and has been found on most cell types in the body. Ob-Ra is highly expressed in the choroid plexus where it functions to transport leptin across the blood–cerebrospinal fluid barrier. The Ob-Re receptor isoform, lacking an intracellular domain and a transmembrane domain, circulates in the blood as a leptin-binding protein, prolonging the half-life of the hormone.

Leptin-Activated Central Neural Pathways

Leptin receptor is detectable in many areas of the CNS but is highly expressed in the arcuate, paraventricular, ventromedial, and dorsomedial nuclei of the hypothalamus, which is responsible for integration of the numerous neural signals regulating energy intake.

Leptin is detectable in cerebrospinal fluid but leptin likely accesses the arcuate nucleus directly from the blood within the median eminence, which lacks the tight junctions characteristic of the blood–brain barrier. In the arcuate nucleus, leptin reduces the expression of neuropeptides that stimulate food intake and increases expression of neuropeptides that inhibit feeding. As such, leptin suppresses neuropeptide Y and agouti-related peptide expression in one type of neuron and induces the expression of α -melanocyte-stimulating hormone in proopiomelanocortin neurons. These neurons innervate other nuclei within the hypothalamus and also communicate with other areas of the brain. Leptin-binding neurons in the arcuate nucleus also mediate the effects of leptin on the sympathetic nervous system and hypothalamic pituitary axes.

Leptin Induces Weight Loss in Mice

The role of leptin in regulation of body weight was first demonstrated in C57BL/6J *ob/ob* mice, which have no detectable serum leptin due to a T-to-C substitution in codon 105 of the *Lep* gene that changes arginine to a premature stop codon. The defective protein is not released by the adipocyte. In *ob/ob* mice, the lack of leptin causes hyperphagia, cold intolerance, and morbid obesity. Daily intraperitoneal injection of recombinant leptin resulted in a dose- and time-dependent decrease in body weight of *ob/ob* mice. Weight loss was mediated by an increase in metabolic rate and locomotor activity, as well as a reduction in food intake. Leptin also reduced body weight in lean C57BL/6J heterozygotes (+/?) and lean wild-type mice, although much higher doses of leptin were needed. In lean mice, leptin administration had no effect on body temperature or locomotor activity but did reduce food intake. Leptin treatment also lowered insulin and glucose in *ob/ob* mice. Since these initial experiments, many investigators have observed that leptin, either peripherally or centrally administered, effectively reduces food intake to stimulate weight loss in most animal models of obesity, with the exception of those with inactivating leptin receptor mutations.

C57BL/KsJ *db/db* mice are hyperphagic, morbidly obese, and diabetic due to a mutation in the hypothalamic leptin receptor gene. A nucleotide substitution (G to T) generates a new splice donor within an exon of the short receptor (Ob-Ra). This new splice donor competes with the upstream splice donor of the long form of the receptor, resulting in alternative splicing and the insertion of a premature termination signal in

the long form of the receptor. The truncated long receptor protein is unable to associate with STAT proteins, interrupting JAK/STAT signaling and resulting in obesity in *db/db* mice. Exogenous leptin administration to C57BL/6J *db/db* mice does not result in weight loss at any concentration tested. A different leptin receptor mutation was identified in Zucker *fatty* (*fa/fa*) rats. An A-to-C substitution changes glutamine-269 to a proline in the extracellular domain of the receptor, reducing the amount of receptor on the cell surface and its capacity to signal. In obese Koletsky rats, a third receptor mutation, T2349A in codon 763 of the leptin receptor gene, creates a premature stop codon just before the transmembrane domain. Leptin treatment does not induce weight loss in either Zucker *fatty* rats or Koletsky rats.

LEPTIN THERAPY FOR WEIGHT LOSS IN HUMANS

Leptin and Leptin Receptor Mutations Cause Obesity in Humans

Mutations in the human *LEP* gene were first identified in children of a consanguineous Pakistani family. In these subjects, deletion of a guanine nucleotide in codon 133 results in a frameshift and a truncated leptin protein, which is degraded by the proteasome and not released into the blood. A third child from an unrelated family (at least five generations back) has been found to have the same *LEP* gene mutation. The lack of leptin in these children causes hyperphagia and extreme early onset morbid obesity. A second *LEP* gene mutation, a C-to-T substitution in the first base of codon 105 changing arginine to tryptophan, was identified in a Turkish family. In three subjects homozygous for the mutation, serum leptin was very low but detectable. The low leptin in these subjects results in hyperphagia, morbid obesity, and hypogonadism. One subject also exhibited low sympathetic tone.

As with mutations in the *LEP* gene, mutations in the leptin receptor in humans are rare. A G-to-A substitution in the splice donor site of exon 16 has been identified in three sisters of a Kabilian family. This mutation results in a truncated leptin receptor lacking the transmembrane and intracellular domains. The mutant extracellular domain is present at high concentrations in the blood; acting as a leptin-binding protein to greatly increase serum leptin concentrations. This leptin receptor mutation results in early onset morbid obesity, hyperphagia, and hypothalamic hypogonadism.

Leptin Induces Weight Loss in Humans with *LEP* Mutations

Farooqi and colleagues have demonstrated that subcutaneous administration of recombinant leptin is an effective long-term therapy for obesity in the three children lacking leptin due to *LEP* gene mutations. With treatment for up to 4 years (0.01 mg/kg lean body weight), leptin therapy induced significant weight loss via a reduction in caloric intake. Weight loss in these children was associated with a reduction in insulin, serum triglycerides, and cholesterol. Leptin treatment also improved T cell proliferation and increased CD4⁺ T cell number and function, which was severely impaired in the absence of endogenous leptin production. Adults with congenital leptin deficiency or leptin receptor mutations are prepubertal. Leptin replacement was permissive for the progression through puberty of the oldest child (treatment started at age 10 years) but has not induced precocious puberty in the younger children (3 and 4.5 years old) during the first year of treatment.

Leptin Resistance

Inactivating mutations in the leptin and leptin receptor gene in humans are rare and not the cause of obesity in the general population. Rather, it has been observed that serum leptin levels are elevated in obese subjects. This observation has led to the hypothesis that obese individuals are “leptin resistant”; i.e., these subjects do not respond to the weight-reducing actions of leptin. Leptin resistance is dependent on the premise that the major function of leptin is to oppose increases in body weight. Flier and colleagues have noted that from an evolutionary perspective, it is difficult to conceive of a mechanism that would limit food intake in times of excess. Therefore, they hypothesize that the major function of leptin is to signal the reduction in energy intake associated with fasting rather than the excess storage of energy in times of food abundance. Evidence for this proposal is derived from the observation that the reduction in leptin with fasting is associated with metabolic, hormonal, and behavioral changes promoting energy conservation and increased energy intake. Leptin administration during fasting prevents these adaptations to food restriction. The concept of leptin resistance is compatible with the role of leptin as a signal of energy deprivation. It is conceivable that the central nervous system in obese individuals does not properly receive or process the leptin signal generated by the adipose tissue, despite elevated serum leptin levels. This would

result in metabolic adaptations to conserve energy and increase energy intake. Several explanations for leptin resistance have been put forth.

High-fat feeding in rodents decreases the effectiveness of intraperitoneal or intravenously injected leptin to induce weight loss, although the response to leptin administered directly to the brain is maintained. Therefore, high-fat feeding appears to cause a defect in access of leptin to the central nervous system. An alternative interpretation is that the palatability of the high-fat diet provides a neural signal for increased consumption that is stronger than the signal for decreased food intake provided by intraperitoneally or intravenously administered leptin. The fact that central leptin administration could overcome this palatability signal may be the result of activation of additional neural pathways that inhibit food intake with central injection.

Suppressors of cytokine signaling (SOCS) are a group of genes rapidly activated following STAT binding in the nucleus. SOCS proteins act in a negative feedback loop to limit intracellular cytokine signaling. SOCS-3 is a potent inhibitor of leptin receptor-initiated JAK/STAT signal transduction in cultured cell lines. Leptin also induces SOCS-3 mRNA expression in the hypothalamus. SOCS-3 message is increased in leptin-binding neurons in the hypothalamus of Agouti mice. Agouti mice are resistant to central leptin administration, suggesting that the increased SOCS-3 expression could cause leptin resistance in these animals. The role of SOCS-3 in leptin resistance in obese humans is not known.

Leptin Therapy in Obese Adults without Leptin Deficiency

Modest leptin-induced weight loss has been achieved in obese subjects with normal adipose leptin production. In a study conducted by Heymsfield and associates, 47 obese subjects underwent 24 weeks of twice daily injections of leptin (0.1–0.3 mg/kg body weight) or placebo. There was statistically significant weight loss with the highest dose of leptin tested (mean \pm SD 7.1 ± 8.5 kg, $n = 8$). It is important to note that the dose of leptin needed to induce weight loss in leptin-replete subjects is greater than 10 times that needed in the children with *LEP* gene defects. As discussed above, serum leptin concentrations increase in parallel with body fat in all obese individuals who do not have a *LEP* gene mutation. This apparent “resistance” to the weight-reducing effects of endogenously produced leptin suggests that exogenous leptin administration would be ineffective in decreasing body

weight. The demonstration that leptin therapy can induce weight loss in leptin-replete subjects suggests that leptin resistance is relative and can be overcome with high-dose treatment. However, whether these subjects would become resistant to the weight loss effects of the therapeutic dose of leptin over longer treatment periods is not known.

As discussed above, Flier and colleagues suggest that the major role of leptin is to decrease with prolonged fasting/starvation and initiate processes to conserve energy and maintain body weight. Therefore, the reduction in leptin with caloric restriction during a diet would be counterproductive to the attempt to lose weight. In a controlled study in which subjects lost 10% of body weight, circulating triiodothyronine and thyroxine levels and total daily energy expenditure were reduced. Administration of recombinant leptin to these subjects normalized thyroid hormone levels and increased total energy expenditure. These observations support a role for leptin as opposing weight loss and suggest that leptin therapy may be a useful augmentation to weight loss induced by diet and exercise or other pharmacologic treatment.

EFFECT OF LEPTIN ON OTHER PHYSIOLOGIC PROCESSES

In addition to its role in body weight regulation, leptin has been implicated as a regulatory signal in a variety of other physiological processes. Many of these functions of leptin are mediated through the central nervous system, although the presence of leptin receptors on numerous nonneural cells suggests that leptin may have direct effects on these cells and tissues.

Leptin, Glucose Homeostasis, and Lipid Metabolism

Leptin improves insulin sensitivity directly and independently of its effects on food intake and body weight. In rodents, insulin and glucose are reduced shortly after the initiation of leptin treatment, before significant reductions in body fat content are observed. With long-term leptin administration resulting in weight loss, insulin and glucose are reduced to a greater extent than in pair-fed controls. Intracerebroventricular leptin acutely enhances whole body glucose uptake in mice, suggesting that leptin influences insulin sensitivity through central mechanisms. Leptin therapy also reverses insulin resistance and diabetes in two different transgenic models of lipodystrophy through mechanisms not related to reductions in food intake.

Leptin increases lipolysis in white adipose tissue both *in vivo* and *in vitro*. This effect of leptin results from centrally mediated activation of the sympathetic nervous system as well as a direct effect of leptin on adipocytes. Hyperleptinemia in rats does not result in the release of free fatty acids into the blood but rather the oxidation of fatty acids within adipocytes. Leptin has also been observed to stimulate fatty acid oxidation in rodent muscle via activation of AMP-activated protein kinase.

Humans with congenital lipodystrophy have low to undetectable serum leptin levels due to the lack of subcutaneous adipose tissue. Leptin replacement therapy improves glycemic control and decreases triglyceride levels, resting metabolic rate, and self-reported daily food intake.

Leptin and Reproductive Capacity

Successful reproduction requires an extensive investment of energy. Leptin serves as a permissive signal that energy stores are sufficient for the increased demand for energy during reproduction. *Ob/ob* mice lacking leptin as a signal of energy stores are infertile. Leptin treatment reverses infertility in *ob/ob* mice and accelerates the onset of puberty in normal mice. During starvation, when endogenous leptin levels in mice are low, exogenous leptin maintains LH release and estrous cycle periodicity. In humans, the age of menarche is inversely related to serum leptin concentrations. Humans with *LEP* gene defects have hypothalamic hypogonadism and remain prepubertal. Leptin therapy in these subjects increases gonadotropin secretion and the progression through puberty. Overall, these observations suggest that leptin is a coordinating signal to the central nervous system that energy stores are sufficient to support the higher energy needs associated with reproduction.

Maternal serum leptin increases during pregnancy in both rodents and humans and this increase is not due solely to the increase in fat mass. Human placenta synthesizes leptin, which contributes to the elevation in maternal leptin levels during pregnancy. The role of increased leptin during pregnancy is not yet known. It is possible that the increase in leptin might regulate maternal–fetal energy metabolism or that leptin may act in a paracrine/autocrine manner on placental or fetal growth.

Leptin and Immune Function

Nutritional deprivation suppresses immune function and malnutrition predisposes to death from infectious

diseases. Leptin appears to be a coordinating signal for activation/inactivation of the immune response during times of energy excess or deprivation. Leptin administration prevents the starvation-induced reduction in immune function in mice. Leptin also stimulates the proliferation of T cells *in vitro*, an effect mediated by direct interaction of leptin with leptin receptor isoform Ob-Rb expressed on the T cell. The number of CD4⁺ T cells and their function was severely impaired in children lacking endogenous leptin due to *LEP* gene mutations. Leptin treatment improved T cell proliferation and activity in these children.

Leptin and Bone Formation

Obesity is protective against bone loss and fractures. A role for leptin as mediator of this protective effect is supported by the observations that leptin administration reduces ovariectomy-induced bone loss in rats and increases bone mineral content and bone density in *ob/ob* mice. That these effects are the result of a direct effect of leptin on bone is inferred from observations that leptin promotes differentiation of bone marrow stromal cells to osteoblasts and promotes mineralization of these cells. Leptin also inhibits osteoclast generation from blood mononuclear cells. In contrast to observations that leptin promotes bone formation, leptin-deficient *ob/ob* and leptin-resistant *db/db* mice have significantly greater bone mass than wild-type littermates. Intracerebroventricular administration of leptin to *ob/ob* mice results in bone loss in these animals. A unifying hypothesis for these disparate findings suggests that the central effects of leptin to decrease bone formation are offset by its peripheral effects to promote bone growth. The importance of this finding is that during periods of starvation, low leptin levels result in suppression of the hypothalamic–pituitary–adrenal and hypothalamic–pituitary–gonadal axes and bone would be lost. However, the low leptin levels in the brain then also activate pathways that protect the skeleton during starvation. The mechanisms by which the hypothalamus regulates bone formation have not yet been elucidated.

Leydig Cell Pathology

see Androgen Insensitivity Syndrome

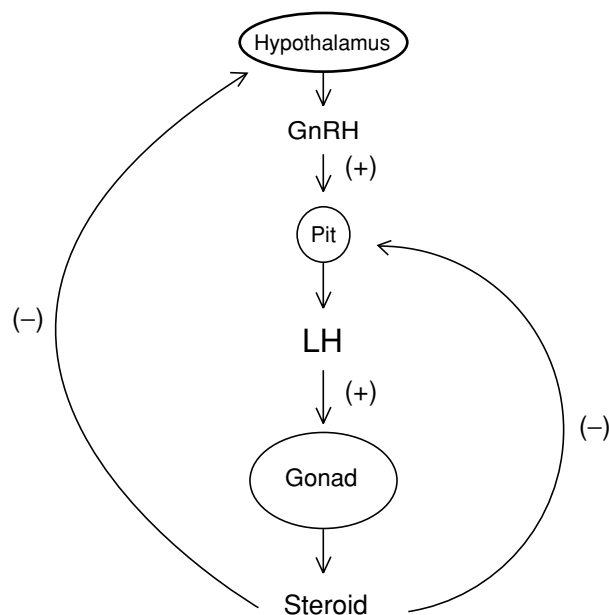

Figure 1 This schematic is a general introduction to the concept of the regulation of LH secretion and action. The hypothalamus secretes GnRH, which acts on the pituitary gland (Pit) to stimulate (+) the secretion of LH. LH stimulates (+) the gonad to secrete steroids that act on the hypothalamus (right-hand side of figure), pituitary gland (left-hand side of figure), or both to inhibit (-) the secretion of LH.

are composed of cells that exclusively synthesize either FSH or LH. The gonadotropes are stimulated by the hypothalamic polypeptide, GnRH. Only one hypothalamic secretagogue stimulating the synthesis and secretion of both gonadotropins has been identified, although two releasing hormones, one for each gonadotropin, were initially postulated; the term gonadotropin-releasing hormone, rather than luteinizing hormone-releasing hormone, is used throughout this article. The secretion of this hypothalamic secretagogue is episodic and regular. GnRH is released by neurons that terminate on the blood vessels running along the pituitary stalk. These vessels constitute a specialized form of the circulatory system called a portal system. Portal systems are characterized as special veins that arise in one organ system and terminate in another before returning to the heart. They carry the pulses of GnRH to the gonadotropes in the pituitary gland and stimulate the synthesis and release of LH. Accordingly, LH is also released from the pituitary gland in pulses. Changing the pattern of the GnRH pulses results in concurrent changes in the pattern of pulsatile secretion of LH. GnRH binds to a G protein-coupled membrane receptor on the surface of the gonadotrope, activating the $G_{q/11}$

proteins, which, in turn, stimulate phospholipase C. This enzyme generates inositol 1,4,5-triphosphate and diacylglycerol. The increased levels of these intracellular messengers activate protein kinase C (PKC) and increase intracellular calcium also. PKC and calcium regulate the expression of the β -subunit gene, whereas the secretion of LH is regulated by the increase in intracellular calcium.

During pregnancy, the placenta in equines and primates synthesizes and secretes an LH-like gonadotropin, chorionic gonadotropin (CG), that has more oligosaccharide moieties and a longer amino acid chain in its β -subunit. These modifications confer a longer half-life on CG in the circulation, leading to a more sustained action. Human CG has been used both diagnostically and therapeutically to investigate the action of LH.

RECEPTOR AND RECEPTOR DEFECTS

The receptor for LH has been described in several mammalian species and is found predominantly in the gonads of each sex. Although LH receptors, identical to those of the gonads, have been found in tumors as well as normal nongonadal tissues, the function of these nongonadal receptors is unclear and a fuller discussion must await future investigation. The LH receptor (85–95 kDa) is a member of the family of G protein-coupled receptors; like all members of this receptor family, it is composed of three domains: a transmembrane domain, an extracellular domain, and an intracellular domain. The transmembrane domain is composed of seven hydrophobic stretches of 20–25 amino acids that form α -helices traversing the cellular membrane alternating between intracellular and extracellular loops. The extracellular domain of the receptor binds LH, which, in turn, causes the intracellular domain to activate the G_s protein. This is the first step in an intracellular cascade that continues with the activation of the enzyme adenylyl cyclase and the production of cyclic AMP (cAMP). In turn, protein kinase A (PKA) is activated and phosphorylation of the transcription factor CREB (cAMP regulatory element-binding protein) leads to the expression of genes coding for several factors regulating the cellular functions of proliferation, differentiation, and survival. This pathway has been expanded to include various isoforms of adenylyl cyclase, phosphodiesterase, and anchoring proteins of PKA. Other transcription factors, e.g., stimulatory protein 1, upstream stimulatory factor, and estrogen receptor α and β , have been shown to be activated by high intracellular

concentrations of cAMP. In addition, CREB can be phosphorylated by kinases other than PKA.

The gene encoding the receptor for LH contains 11 exons, and 13 splice variants have been identified. The last exon encodes the transmembrane and intracellular G protein-activating domains. The extracellular LH-binding domain has much of the heterogeneity of the protein. Several mutations of the LH receptor have been identified and the mutations result either in constitutive activation or in inactivation. Activating mutations of the LH receptor in boys results in precocious puberty observed at 1 to 4 years of age. Activating mutations in girls do not lead to precocious puberty because the gonadotropin FSH is necessary to stimulate folliculogenesis. Mutations that completely inactivate the LH receptor in boys result in genetically male infants displaying female external genitalia but having abdominal testes and lacking Müllerian structures. Mutations that do not completely inactivate the LH receptor in boys, however, result in male infants with micropenis sometimes associated with hypospadias, but the intra-abdominal testes have few, if any, androgen-secreting Leydig cells. In girls, inactivating mutations of the LH receptor, either complete or incomplete, result in normal primary and secondary female characteristics, but also result in amenorrhea because LH is required for folliculogenesis.

ACTION IN THE OVARY

Before discussing the role of LH in the ovary, a description of folliculogenesis is necessary. During fetal development of the female mammal, the primitive germ cells in the putative ovary enter meiosis and arrest in the prophase of meiosis I. Each oocyte is surrounded by a single layer of granulosa cells, and soon after formation, these primordial follicles enter a resting phase. The mechanisms that stimulate the primordial follicles to initiate folliculogenesis are unknown, but the process begins at once and continues until all follicles are depleted from the ovary. During fetal life in primates and ruminants and within the first 2 weeks after birth in rodents, some of the primordial follicles are activated and become primary follicles. Two layers of cells develop around the oocyte: the outermost are the theca cells that are separated from the innermost layers of granulosa cells by a basement membrane.

The rupture of the follicle, along with the release of the oocyte and some of the granulosa cells surrounding it, is called ovulation. During the periovulatory period, anti-inflammatory factors are produced and appear

to aid in rapid healing and vascularization of the ruptured follicle. The theca and granulosa cells remaining in the ruptured follicle differentiate into luteal cells, forming the corpus luteum, which characterizes the luteal phase of the ovarian cycle. If no pregnancy occurs, after a finite time specific to each species, the corpus luteum dies, marking the end of the luteal phase. The rapid involution of the corpus luteum is called luteolysis and is regulated by specific factors. Luteolysis is necessary before a subsequent ovarian cycle can begin. The follicular phase, ovulation, the luteal phase, and luteolysis constitute the ovarian cycle and LH plays some role in all phases of the cycle.

LH has three functions in the ovary: (1) stimulation of androgen synthesis during the follicular phase; (2) stimulation of ovulation; and (3), following ovulation, differentiation of the thecal and granulosa cell remnants of the ruptured follicle into luteinized cells. The luteal cells constitute the steroidogenic cells of the corpus luteum, shifting from predominantly estrogen-producing cells to progesterone-producing cells.

LH binds to its receptor on the theca cells of the follicle and stimulates the synthesis of androgens. Steroidogenesis begins with the movement of cholesterol from its storage site on the outer mitochondrial membrane to the inner mitochondrial membrane, where the cytochrome P450-associated enzyme removes the side chain of cholesterol, producing pregnenolone. This mobilization of cholesterol is the rate-limiting step in steroidogenesis and LH regulates the production of a protein called steroidogenic acute regulatory (StAR) protein. The tertiary structure of this 30 kDa protein has a domain containing a cholesterol-binding hydrophobic tunnel that may permit StAR to shuttle cholesterol across the mitochondrial membranes. The steroids are lipid-soluble, unlike cholesterol, and the steroidogenic enzymes are readily accessible for production of the androgen, androstenedione. This androgen diffuses out of the thecal cells and into the granulosa cells, where the enzyme aromatase, stimulated by FSH action, converts androstenedione into estradiol. As the theca and granulosa cells of the maturing follicle proliferate, a greater amount of estradiol is produced. The estradiol, as stated earlier, inhibits the pituitary secretion of LH, but the number of LH receptors on each granulosa cell is also increased under FSH stimulation. An increase in hormonal receptors is generally associated with an increase in sensitivity to the hormone; that is, the cell can detect and respond to lower concentrations of the hormone. With the increased number of LH receptors on the theca and granulosa

cells, only those follicles with sufficient gonadotropin stimulation will continue folliculogenesis. Once the circulating estradiol produced by the antral follicle is elevated, this steroid causes an abrupt release, or surge, of LH from the pituitary (see Fig. 2). The surge of LH causes ovulation by increasing the expression of PKA and increasing the inositol lipid hydrolysis that activates PKC, shifting the pattern of gene expression in the granulosa cells. The shift results in the suppression of cell division of the granulosa cells, utilization of these cells, signaling of the oocyte to reenter meiosis, and rupture of the follicle wall.

After ovulation, the luteinized granulosa and theca cells remaining in the ruptured follicle begin to

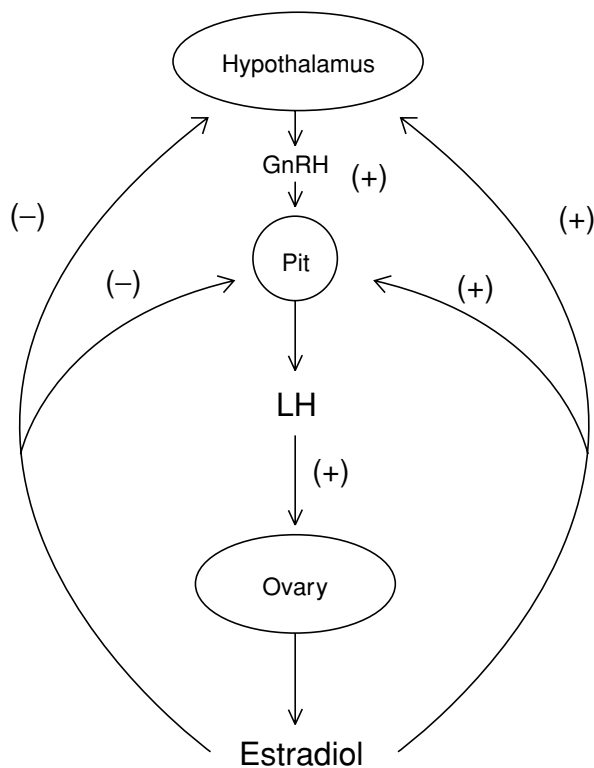

Figure 2 The feedback mechanism regulating LH in the female mammal. The hypothalamus secretes GnRH, which acts on the pituitary gland to stimulate (+) the secretion of LH. This enzyme converts androstenedione, produced by the theca cells of the follicle under LH stimulation, into estradiol. During early folliculogenesis when the growing follicle is small, the low concentrations of estradiol act on the hypothalamus, pituitary gland, or both to inhibit (-) the secretion of LH (left-hand side of figure). Prior to ovulation, the high concentration of estradiol in the blood, due to the increased number of steroidogenic cells in the large antral follicle, causes the sudden release of LH, which causes the follicle to rupture and release the oocyte. This surge of LH is marked by a sudden release of GnRH (+) from the hypothalamus and/or of LH directly (+) from the pituitary (right-hand side of figure). This latter action of estradiol in the female mammal is an example of positive feedback.

synthesize progesterone. Although the luteal cells of some species, e.g., human, are able to produce small amounts of estrogen, the cellular differentiation shifts the steroidogenic pathway in the luteal cell to produce primarily—or in some species only—progesterone. This steroid maintains the endometrium of the uterus in readiness to accept the blastocyst, if fertilization of the oocyte occurs. The corpus luteum under LH regulation continues to survive for a specific period of time, depending on the species. If, on one hand, no blastocyst is formed, then the corpus luteum involutes through programmed cell death. If, on the other hand, implantation of a blastocyst occurs, in the case of primates and horses, chorionic gonadotropin secreted by the blastocyst and later by the placenta binds to the LH receptors on the corpus luteum, rescuing it from luteolysis and maintaining the production of progesterone. This placental gonadotropin in women is called human chorionic gonadotropin (hCG); it has 30 more amino acid residues and is more glycosylated than LH. Because of these differences, hCG has a greater potency and a longer half-life in the circulation than LH itself. The placental CG prevents luteolysis.

In most mammalian species, however, removal of the uterus results in a delay of luteolysis. From studies using the techniques of hysterectomy and vascular anastomosis, the initiation of luteolysis occurs when prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) from the uterus enters the ovarian artery from the utero-ovarian vein by counter-current exchange. This avoids degradation of $PGF_{2\alpha}$ by the lungs if it were to be transported by the veins to the heart and then to the lung. Luteolysis is due to an interaction of the uterus and ovary, but the precise trigger for the release of $PGF_{2\alpha}$ remains unknown.

ACTION IN THE TESTIS

LH has only one site of action in the adult testis, its receptor on the surface of adult Leydig cells, to which it binds, stimulating the production of the androgenic steroid, testosterone. Before continuing with the effects of testosterone on spermatogenesis, a brief review of the testicular structure and spermatogenesis is necessary. The adult mammalian testis is an ovoid structure covered by a capsule called the tunica albuginea. The parenchyma of the organ is composed of two compartments, the seminiferous tubules and the interstitium between the tubules. The seminiferous tubules contain the epithelium where spermatogenesis takes place. The interstitium contains the Leydig cells, fibroblasts, macrophages, nerves, blood, and lymphatic vessels.

Steroidogenesis begins in the Leydig cell as it does in the theca cell of the ovary with the movement of cholesterol from its storage site on the outer mitochondrial membrane to the inner mitochondrial membrane, where the cytochrome P450-associated enzyme removes the side chain of cholesterol, producing pregnenolone. This mobilization of cholesterol is the rate-limiting step in steroidogenesis and LH regulates the production of StAR protein. The tertiary structure of this 30 kDa protein has a domain containing a cholesterol-binding hydrophobic tunnel that may permit StAR to shuttle cholesterol across the mitochondrial membranes. The steroids are lipid-soluble, unlike cholesterol, and the steroidogenic enzymes are readily accessible for production of the androgen, testosterone. This androgen is a major stimulator of spermatogenesis in the adult male mammal.

Spermatogenesis consists of a series of processes: stem cell renewal, germ cell proliferation, and spermiogenesis. Stem cell renewal is the mechanism that guarantees that a large and undiminishing number of undifferentiated germ cells are continually available for subsequent waves of spermatogenesis throughout the lifetime of the male animal. The spermatogenic stem cells are called type A spermatogonia and, depending on the species, one or more type A spermatogonia have been identified. In addition to renewing their population, the type A spermatogonia also produce more differentiated spermatogonia, often referred to as type B spermatogonia. These latter cells, depending again on species, may produce one or more generations of differentiated spermatogonia. The final generation of differentiated spermatogonia divide and produce the primary spermatocytes. The spermatocytes are the germ cells that undergo meiosis and the products of this specialized cell division are the haploid spermatids. The spermatids enter spermiogenesis, during which the nuclear contents condense, the specialized lysosome, the acrosome, is formed, a tail is produced, and the amount of cytoplasm is reduced. Spermatogenesis requires approximately 2 to 3 weeks to complete, depending on the species of mammal.

Spermatogenesis can be thought of in two ways. First, the series of processes can be viewed as the production of one or more haploid spermatids. In older literature, this is often referred to as the quality of spermatogenesis. Second, the number of spermatids produced is often referred to as quantitative spermatogenesis. This notion is based on the clinical observation that a low number of spermatozoa in the ejaculate of a man is often associated with infertility.

Exactly what that low number is and how it plays a role in fertility is unclear, but it may reflect a need for a large number of spermatozoa to begin the long journey through the female reproductive tract to ensure that enough sperm arrive at the oocyte to effect fertilization.

Before leaving the topic of spermatogenesis and the seminiferous epithelium, the Sertoli cell must be introduced. These cells are the only somatic component of the epithelium and provide the cytoarchitecture of the seminiferous epithelium, nourish the germ cells, and secrete the hormone inhibin B. All hormonal effects on the seminiferous epithelium and on spermatogenesis are mediated by the Sertoli cells. The androgen receptor has been demonstrated conclusively to be in Sertoli cells only and not in germ cells.

Dr. Phillip E. Smith demonstrated the central role of the pituitary to stimulate spermatogenesis in adult rodents and primates nearly 60 years ago by. Surgical removal of the pituitary gland of adult rats led to a decrease in testicular weight and the seminiferous epithelium comprised Sertoli cells and germ cells as mature as spermatids. Hypophysectomy of adult rhesus monkeys resulted in a precipitous decline in testicular size associated with the complete regression of the seminiferous epithelium to the extent that the tissue comprised only Sertoli cells and type A spermatogonia, that is, only stem cells. Further experiments on adult rodents and monkeys have confirmed Dr. Smith's earlier observations. In a study using a GnRH receptor antagonist, which suppresses all gonadotropin secretion, chemical hypophysectomy achieved the same results as observed by Dr. Smith using a surgical hypophysectomy. Namely, the rodent seminiferous epithelium comprised Sertoli cells and germ cells as mature as spermatids, whereas the primate seminiferous epithelium comprised only Sertoli cells and stem spermatogonia.

Physiological replacement of testosterone in rats that had been previously rendered hypogonadotropic results in full restoration of the seminiferous epithelium containing the normal number of spermatogenic cells. Testosterone alone is sufficient to stimulate spermatogenesis in this and related species. Replacement of testosterone in hypogonadotropic, hypogonadal rhesus monkeys, however, results in stimulation of testicular growth but to less than normal size. The gonadal growth is due primarily to the stimulation of spermatogenesis by androgen, but morphometric analysis of the seminiferous epithelium of the monkeys revealed that the smaller testicular size was accounted for by a deficit in the numbers of all differentiated, or

type B, spermatogonia. Replacement of FSH in testosterone-treated hypophysectomized adults results in a greater number of all four generations of type B spermatogonia. These observations led to the conclusion that testosterone alone stimulates spermatogenesis, but FSH is necessary to restore spermatogenesis completely in primates. This action of FSH in primates is posited to be the rescue of the differentiated spermatogonia from programmed cell death.

Testosterone is also secreted into the circulatory system and transported to the male reproductive tract, stimulating growth and differentiation. The androgen also causes the increased body size, muscle mass, and behavior characteristic of male mammals. In the case of humans, beard growth and male pattern baldness are also manifestations of testosterone action. Testosterone acts to reduce the secretion of LH; that is, it exerts a negative feedback on LH secretion by the pituitary (see Fig. 3). One distinct pathway for negative feedback has been described in male mammals. In this pathway, found in male primates and sheep, testosterone, or perhaps one or more of its metabolites (estradiol or dihydrotestosterone), acts in the central nervous system to reduce the frequency of GnRH pulses produced by the hypothalamus; this reduction, in turn, reduces the frequency of LH pulses from the pituitary gland. The details of the nervous system pathways involved in the negative feedback of testosterone on LH remain to be elucidated. Studies in male rodents clearly establish the negative feedback system between LH and testosterone, but little consensus exists on whether androgen or its metabolites act on the central nervous system, the pituitary gland, or both.

FETAL DEVELOPMENT OF THE MALE REPRODUCTIVE SYSTEM

Fetal development of the male reproductive system requires the presence of a testis capable of secreting two hormones, testosterone and Müllerian inhibiting hormone. The formation of a testis requires the action of a gene product, testis determining factor (TDY). This factor causes the undifferentiated gonad to develop into a testis. If this factor is absent or defective, a testis will not form and a female phenotype will be produced. The fetal testis produces testosterone, which stimulates the Wolffian ducts to differentiate into the male reproductive tract consisting of the epididymis, vas deferens, seminal vesicle, and prostate.

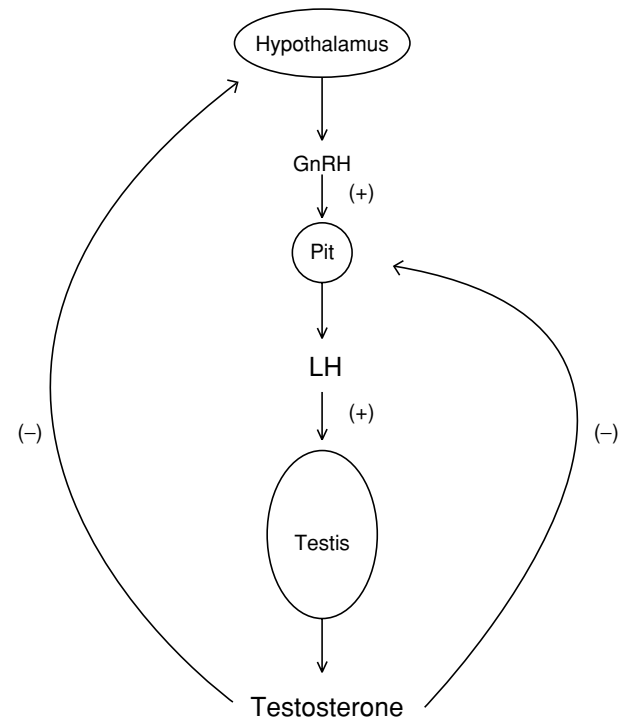

Figure 3 The negative feedback (-) of the androgen testosterone on LH secretion in male mammals. The hypothalamic factor GnRH stimulates (+) the pituitary gland to synthesize and secrete LH. LH, in turn, stimulates the Leydig cells of the testis to synthesize testosterone, which freely diffuses from the cell into the circulation. Testosterone modulates the frequency of the GnRH pulse from the hypothalamus and this latter event reduces the amount of LH secreted by the pituitary gland (left-hand side of figure). This form of negative feedback has been compellingly demonstrated in primates and sheep. Testosterone may act directly on the pituitary gland to inhibit (-) the secretion of LH (right-hand side of figure).

Testosterone also causes the formation of the penis and scrotum into which the testes descend. Testosterone is produced in the fetal testis by Leydig cells and Müllerian inhibiting hormone is produced by the fetal Sertoli cells.

The stimulus for the fetal Leydig cells to produce testosterone cannot be the fetal pituitary since the secretion of testosterone precedes the effective secretion of LH by the fetal pituitary. In the case of higher primates and equines, the placental chorionic gonadotropin may cause the fetal testis to form fetal Leydig cells as well as stimulate those cells to secrete testosterone in response. The situation in the other mammalian genera, however, must be different because these species do not produce a placental gonadotropin. In rodents, the fetal Leydig cells seem to be autonomous; that is, they synthesize testosterone without the stimulus of a gonadotropin. In all mammalian species, the fetal Leydig cells cease producing

androgens soon after birth and seem to disappear in the interstitium of the testes of newborns.

During sexual maturation at the time of puberty, the adult Leydig cells form from undifferentiated cells, called mesenchymal-like cells, in the interstitial spaces between the seminiferous tubules. In rats, these cells actively proliferate from 2 to 4 weeks after birth, but their numbers diminish, suggesting differentiation into a new type of cell. The interstitial cells that give rise to the adult Leydig cell population have been posited to be part of the population of mesenchymal-like cells that during uterine life produced the fetal Leydig cells. Nonetheless, these mesenchymal cells have a very high mitotic index of rapid and multiple cell divisions. The next generation of differentiated cells express the proteins of the adult Leydig cell, 3β -hydroxyl dehydrogenase and LH receptors. These latter cells have been called immature Leydig cells and divide once and produce the adult Leydig cell.

Liddle's Syndrome

see Mineralocorticoids and Mineralocorticoid Excess Syndromes

reducing arterial tissue cholesterol levels that contribute to such atherosclerosis by facilitating reverse cholesterol transport, HDL inhibits oxidation and aggregation of LDL in the arterial wall. Lower HDL cholesterol may be associated with genetic disorders, nutritional habits (high carbohydrate intake), obesity, hypertriglyceridemia, cigarette smoking, and lack of exercise, whereas HDL levels are increased with alcohol ingestion and estrogens or in familial hyperalphalipoproteinemia, another “longevity” syndrome.

VLDL is a triglyceride-rich lipoprotein synthesized and secreted by the liver. Hypertriglyceridemia is associated with genetic disorders, obesity, diabetes mellitus, renal failure, heavy alcohol intake, and drugs such as estrogens.

The measurement of fasting levels of LDL cholesterol, HDL cholesterol, and triglycerides in the serum is obtained as part of comprehensive assessment of the risk of atherosclerotic vascular disease that is commonly estimated according to the following formula: $\text{total cholesterol} = \text{LDL cholesterol} + \text{HDL cholesterol} + \text{triglycerides} / 5$. Hypercholesterolemia is defined as serum total cholesterol of 200 mg/dl or more, according to the National Cholesterol Education Program (NCEP) III guidelines. These guidelines recommend reducing the serum LDL cholesterol to less than 100 mg/dl in persons with coronary artery disease (CAD), peripheral arterial disease (PAD), stroke or transient cerebral ischemic attack, carotid arterial disease, or diabetes mellitus as well as in persons with two or more risk factors (many of whom have the so-called “metabolic syndrome”) who have a 10-year risk of CAD of more than 20% calculated from Framingham Heart Study tables. The NCEP III guidelines further state that persons with two or more risk factors and a 10-year risk of CAD of 10 to 20% should have their serum LDL cholesterol reduced to less than 130 mg/dl. The NCEP III guidelines also state that persons with no risk factors or with one risk factor should have their serum LDL cholesterol reduced to less than 160 mg/dl. A decreased serum HDL cholesterol level of less than 40 mg/dl represents a CAD risk factor. A normal serum triglyceride level, according to NCEP-ATP III guidelines, is less than 150 mg/dl.

The NCEP III guidelines state that other CAD risk factors to tally in a patient’s risk assessment, other than increased serum LDL cholesterol and decreased serum HDL cholesterol, are the following: (1) age (45 years or over for men and 55 years or older for women), (2) cigarette smoking, (3) hypertension (systolic blood pressure of 140 mm Hg or higher, diastolic blood pressure of 90 mm Hg or higher, or treated hypertension),

and (4) a history of premature CAD in a first-degree relative (before 55 years of age in a related man and before 65 years of age in a related woman).

Dyslipidemia includes hypercholesterolemia, increased serum LDL cholesterol, decreased serum HDL cholesterol, and hypertriglyceridemia. Elevated serum total cholesterol, elevated serum LDL cholesterol, and a low-serum HDL cholesterol are risk factors for CAD, PAD, stroke, transient cerebral ischemic attack, carotid arterial disease, heart failure, valvular aortic stenosis, and mitral annular calcium in elderly persons. In general, the higher the serum total cholesterol, the higher the serum LDL cholesterol (not infrequently, however, an elevated LDL may be offset by an increased HDL); the lower the serum HDL cholesterol, the greater the risk of atherosclerotic vascular disease.

Elevated serum triglycerides are associated with an increased risk of atherosclerotic vascular disease. However, except for being a weak independent risk factor for new coronary events in elderly women, hypertriglyceridemia is not an independent risk factor for atherosclerotic vascular disease in elderly or younger men and women (confounded by the inverse relationship between HDL cholesterol and triglyceride levels wherein the low HDL is thought to exert the primary atherogenic effect, a subject of continuing controversy that is further complicated by the high prevalence of the metabolic syndrome in persons at increased CAD risk).

METABOLIC SYNDROME

The clustering of high serum triglycerides, small dense LDL particles, low serum HDL cholesterol levels, hypertension, insulin resistance (with or without glucose intolerance), and a prothrombotic state is called the metabolic syndrome. This constellation is extremely common in patients with type 2 diabetes and is thought to be a precursor to diabetes in many others who are at increased risk for developing diabetes with aging and the passage of time. Statin drug therapy alone, or in combination with niacin or gemfibrozil, can be used to treat the atherogenic dyslipidemia of the metabolic syndrome.

DIETARY TREATMENT OF HYPERCHOLESTEROLEMIA

Persons with hypercholesterolemia and CAD or other atherosclerotic vascular disease should be treated with a Step II American Heart Association diet. They should achieve and maintain a desirable weight.

Cholesterol intake should be less than 200 mg/day. Less than 30% of total caloric intake should be fatty acids. Saturated fatty acids should comprise less than 7% of total calories, polyunsaturated fatty acids should account for up to 10% of total calories, and monounsaturated fatty acids should comprise 10 to 15% of total calories. Protein intake should account for 10 to 20% of total calories. Carbohydrates should comprise 50 to 60% of total calories. In addition to loss of weight in obese persons, long-term aerobic exercise, and dietary treatment of hypercholesterolemia, cigarette smoking should be stopped, hypertension should be treated, and diabetes mellitus should be well controlled.

STATINS

The most effective lipid-lowering drugs in reducing cardiovascular morbidity and mortality in elderly and younger persons are the 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors or statin drugs. Statins reduce serum total cholesterol, LDL cholesterol, and triglycerides, and they increase serum HDL cholesterol. The statin drugs include simvastatin, pravastatin, atorvastatin, lovastatin, fluvastatin, and rosuvastatin. Statin drugs suppress cholesterol biosynthesis by competitively inhibiting HMG-CoA reductase, the enzyme that catalyzes the conversion of HMG-CoA to mevalonate, a precursor of sterols (including cholesterol). This action induces up-regulation of LDL receptors in the liver and increased clearance of LDL from the plasma, thereby decreasing plasma cholesterol levels.

Double-blind, randomized, placebo-controlled studies that have included substantial numbers of individuals age 65 years or over have demonstrated that persons with and without CAD treated with statins have a significant reduction in all-cause mortality, nonfatal and fatal coronary events, new or worsening angina pectoris, coronary or noncoronary revascularization, stroke or transient cerebral ischemic attack, intermittent claudication, heart failure, new carotid bruits, one or more new bruits, and hospitalization for cardiovascular events. Individuals both with and without CAD, with PAD, with prior stroke or transient cerebral ischemic attack, with carotid arterial disease, with diabetes mellitus, with heart failure, with treated hypertension, and with valvular aortic stenosis with dyslipidemia have benefited from treatment with statins.

In the Heart Protection Study, where 5806 of the 20,536 men and women randomized to simvastatin or

double-blind placebo were 70 to 80 years of age at study entry and were 75 to 85 years of age at follow-up, 5 years of simvastatin therapy prevented myocardial infarction, stroke, and revascularization in 70 to 100 persons per 1000 treated persons regardless of age, gender, or initial levels of serum lipids. Reduction of serum LDL cholesterol levels by statins to less than 100 mg/dl in elderly persons is more effective at reducing new coronary events and stroke than is reducing serum LDL cholesterol to higher levels in elderly persons.

OTHER LIPID-LOWERING DRUGS

Other lipid-lowering drugs include the cholesterol absorption inhibitor ezetimibe; bile acid sequestrants such as colestevam, cholestyramine, and colestipol; nicotinic acid; and fibric acid derivatives such as gemfibrozil and fenofibrate. Gemfibrozil may be useful at reducing the incidence of new coronary events and stroke in persons with CAD whose primary serum lipid abnormality is a low-serum HDL cholesterol level. Persons with serum triglycerides of 500 mg/dl or more should be treated with a fibric acid derivative such as gemfibrozil to prevent the development of pancreatitis.

COMBINATION LIPID-LOWERING DRUG THERAPY

If statin drug therapy at maximal safe and tolerated doses does not lower the LDL cholesterol level to less than 100 mg/dl in persons with CAD, PAD, prior stroke or transient cerebral ischemic attack, carotid arterial disease, abdominal aortic aneurysm, diabetes mellitus, or two or more risk factors with a 10-year risk of CAD of more than 20%, ezetimibe or a bile acid sequestrant such as colestevam should be added to the therapeutic regimen. A combination lovastatin-nicotinic acid formulation also has been approved for clinical use.

SPECIAL CONSIDERATIONS IN THE MANAGEMENT OF DYSLIPIDEMIA IN THE ELDERLY

The degree to which NCEP III guidelines and the results of clinical trials designed principally to assess the efficacy and safety of hypolipidemic therapy in predominantly younger patients are applicable to the heterogeneous populations of elderly patients (especially those age 75 years or over) remains a subject of controversy and ongoing research. This was noted in

the acknowledgment in the NCEP III guidelines that individualized clinical judgment, with due attention to comorbidities and other medical and social issues, was especially appropriate in the decision-making process in such patients.

Figure 1 Illustration of phosphatidylcholine and sphingomyelin, the major precursors of lipid second messengers. (A) Phosphatidylcholine: glyceride backbone bound to nonpolar tails containing (1) long chain fatty acyl groups and (2) polar head consisting of negatively charged phosphate group esterified to choline that forms the head alcohol group. (B) Sphingomyelin: (1) polar head group of phosphocholine bound to (2) N-acylated fatty acid linked to (3) sphingosine. R_1 and R_2 , long chain fatty acyl groups.

within the cell (Fig. 2). All of the previously described second messengers derived from the glycerolipid or sphingolipid backbone are discussed individually in the following sections.

GLYCEROLIPID-DERIVED SECOND MESSENGERS

Diacylglycerol

Generation of DAG occurs in two phases depending on the source from which it is produced. DAG generated from the breakdown of PIP_2 by the action of

phosphatidylinositol-specific phospholipase C (PI-PLC) is rapid, and the increases in DAG last about 1 min and are accompanied by the release of IP_3 . The latter causes the release of Ca^{2+} from intracellular stores and increases the cytosolic concentration of these cations. As a second messenger, DAG is limited mainly to the activation of protein kinase C. The simultaneous generation of DAG and Ca^{2+} leads to the activation of protein kinase C isoforms α , β , and γ . The second phase of DAG production is more sustained, takes place without the accompanying release of Ca^{2+} , and might be related to the activation of Ca^{2+} -independent isoforms of protein kinase C. This increase of DAG results directly from PC by the activation of PC-specific phospholipase C (PC-PLC) or indirectly from PC by the sequential activation of phospholipase D (PLD) and phosphatidate phosphohydrolase to generate PA and DAG, respectively. Recent evidence suggests that there is a distinction in the fatty acid composition between the DAG derived directly or indirectly from PC. PC-PLC activation primarily generates polyunsaturated DAG species, whereas activation of PLD results in the generation of saturated/monounsaturated DAG species.

Phosphatidic Acid

PA is a bioactive lipid second messenger generated mainly from PC by the stimulation of PLD in response to the activation of receptor tyrosine kinases by protein growth factors. PA has been shown to be involved in the formation of hydrogen peroxide in neutrophils and in activation of the protein kinase that regulates the neutrophil respiratory burst. Regulation of a variety of biological actions of Ras is also mediated by PA as it binds to and inhibits $\text{p}21^{\text{ras}}$ GTPase-activating protein, effectively increasing the GTP-bound form of Ras and enhancing Ras activity. PA also binds to Raf and translocates it to the membrane where it becomes physiologically active.

Platelet-Activating Factor

Inflammatory cells rapidly synthesize PAF in response to cell-specific stimuli. PAF is a potent biological second messenger and elicits its significant biological responses at nanomolar concentrations *in vitro* and *in vivo*. PAF-dependent activation of extracellular signal-regulated kinase (ERK) has been demonstrated in Chinese hamster ovary (CHO) cells, human vascular endothelial cells, human neutrophils,

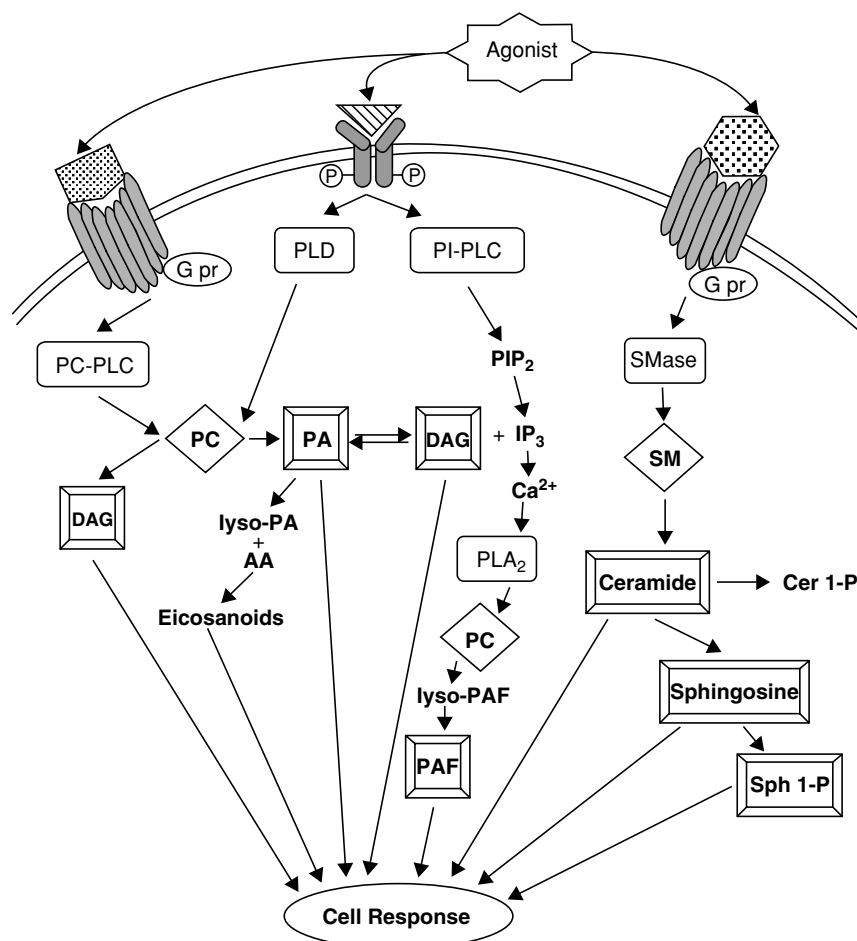

Figure 2 Illustration of lipid second messengers being generated on agonist-stimulated activation of specific enzymes. Agonist stimulation of G protein-coupled receptors activates PC-PLC, which hydrolyzes PC to DAG. Agonist-mediated activation of receptor tyrosine kinase stimulates PLD, which hydrolyzes PC to PA. PA can be further hydrolyzed by PLA₂ to lyso-PA and AA or can be converted to DAG by phosphatidate phosphohydrolase. PI-PLC that is activated by receptor tyrosine kinase hydrolyzes PIP₂ to IP₃ and DAG. IP₃ induces the release of Ca²⁺ ions from internal stores and stimulates PLA₂ to hydrolyze PC to lyso-PAF, which is further acetylated to PAF. Agonist-induced activation of SMase hydrolyzes SM to ceramide, which is further metabolized to Cer 1-P or sphingosine and Sph 1-P. AA, arachidonic acid; DAG, diacylglycerol; G pr, G protein; IP₃, inositol 1,4,5-triphosphate; lyso-PA, lyso-phosphatidic acid; PA, phosphatidic acid; PAF, platelet-activating factor; PC, phosphatidylcholine; PC-PLC, phosphatidylcholine-specific phospholipase C; PI-PLC, phosphatidylinositol-specific phospholipase C; PIP₂, phosphatidylinositol 4,5-bisphosphate; PLA₂, phospholipase A₂; PLD, phospholipase D; SM, sphingomyelin; SMase, sphingomyelinase; Sph 1-P, sphingosine 1-phosphate; Cer 1-P, ceramide 1-phosphate.

and primary hippocampal neurons. Our laboratory has demonstrated that bFGF-mediated phosphorylation and activation of ERK is regulated by PAF in human umbilical vein endothelial cells (HUVECs). We have also shown that stimulation of the PAF receptor by PAF leads to the time-dependent activation of the signal transducers and activators of transcription-3 (STAT-3) protein via Janus kinase-2 (JAK-2) and Src. Our observation that PAF regulates the synthesis of matrix metalloproteinase in HUVECs suggests its importance in regulating

migration and invasion of endothelial cells during an inflammatory response. Activation of focal adhesion kinase (FAK) by PAF has been observed in endothelial cells, suggesting its involvement in cell motility and adhesion. PAF caused phosphorylation of c-Src and PLC γ in rabbit platelets and human epidermoid carcinoma cells. In rat basophilic cells, PAF activated PLC β via pertussis toxin-insensitive G proteins. Both PLC γ and PLC β are important in the further synthesis of PAF within the cell.

SPHINGOLIPID-DERIVED SECOND MESSENGERS

Ceramide

Ceramides are generated from SM by the activation of sphingomyelinase, which is itself stimulated by several agonists, including tumor necrosis factor- α (TNF- α), interleukin-1 (IL-1), nerve growth factor (NGF), 1,25-dihydroxy-vitamin D₃, γ -interferon, chemotherapeutic agents, ionizing radiation, and ligands that engage Fas or CD28 receptors. Ceramides participate as second messengers in signal transduction by the activation of specific serine/threonine kinases or by the stimulation of protein phosphatases. Ceramide appears to be the primary mediator of inflammation in response to TNF- α by activating a protein kinase that stimulates Raf-1, which initiates signaling through the mitogen-activated protein kinase (MAPK) cascade, leading to the activation of PLA₂ and the release of arachidonic acid. TNF- α -induced ceramide has also been suggested to be required for activation of stress-activated protein kinase (SAPK), leading to NF- κ B-dependent gene transcription and apoptosis. Ceramides induce the transcription of cyclooxygenase-1 and -2 as well as a heat shock protein, α B-crystallin. Ceramides have also been shown to interfere with insulin-induced tyrosine phosphorylation of the insulin receptor substrate-1 and cause insulin resistance by inactivation of MAPK cascade via stimulation of protein phosphatases-2A. Regulation of tyrosine kinase cascades involving FAK and paxillin have been implicated to involve ceramide. PKC- ξ , an atypical PKC that is insensitive to phorbol ester and DAG, may be a direct target for ceramide stimulation, leading to rapid induction of NF- κ B. Other potential targets for ceramide-mediated signaling include P23 tyrosine phosphorylation, retinoblastoma gene product (pRb), interleukin-converting enzyme, phospholipase D, and a nuclear phosphoprotein that modulates cell cycle progression.

Sphingosine and Sphingosine 1-Phosphate

The cellular levels of sphingosine and Sph 1-P are determined by their rate of formation from hydrolysis of ceramide by ceramidase and by phosphorylation involving specific kinases. They can also be generated intracellularly by the action of platelet-derived growth factor, which stimulates cells to release the stored Sph 1-P into the bloodstream, stimulating platelet aggregation and thrombosis. The effects of Sph 1-P may involve a previous interaction with Gi/Go-coupled

receptors, with the subsequent activation of MAPK cascade and the transcription factor activator protein-1 (AP-1). Sphingosine and Sph 1-P have also been shown to decrease the cyclic AMP (cAMP) levels in some cell lines and to mobilize Ca²⁺ from internal sources via an inositol-triphosphate independent pathway. A sphingosine-phosphorylcholine-gated Ca²⁺ channel has been characterized and may represent the Sph 1-P-gated Ca²⁺ channel. Sphingosine has been demonstrated to decrease the formation of DAG by inhibiting both Mg²⁺-dependent and -independent phosphatidate phosphohydrolase activity or by stimulating the activity of DAG-kinase with the subsequent generation of PA. This increase in PA can be further enhanced by sphingosine by rapidly activating phospholipase D in some cell types. Sphingosine and Sph 1-P appear to be involved in cytoskeletal dynamics because they induce actin stress fiber formation and stimulate FAK in Swiss 3T3 cells. One of the most important effects of sphingosine is its ability to inhibit PKC and so attenuate cell growth. Indeed, it even acts as an endogenous mediator of apoptosis.

CROSS-TALK AMONG DIFFERENT LIPID SECOND MESSENGERS

Glycerolipid- and sphingolipid-derived second messengers can interact with each other at several sites to control signaling within the cell. Ceramides can stimulate the degradation of PA and PAF and the dephosphorylation of Sph 1-P, decreasing the mitogenic signal of these phospholipids within the cell. These changes are related to the increased activity of phosphatidate phosphohydrolase, effectively decreasing the concentration of these mitogenic lipids relative to ceramide. Activation of phosphatidate phosphohydrolase may terminate the signal from PA, PAF, and Sph 1-P but will also generate DAG, ceramide, and sphingosine, which are also bioactive and so are important for cell signaling by modifying the balance of the bioactive lipids that are implicated in cell activation and in controlling cell growth.

Sphingosine can inhibit the phosphatidate phosphohydrolase activities, causing PA to accumulate and thereby decreasing the production of DAG. This would explain the inhibiting effect of sphingosine on PKC, which is the intracellular target of DAG. Sphingosine can also increase the PA:DAG ratio by stimulating DAG kinase and PLD activities. The DNA-binding activity of AP-1 is stimulated by sphingosine and Sph 1-P. Thus, AP-1 may be the convergent point at which there is integration of the

second messengers derived from the sphingolipid or glycerolipid signals.

Control of PLD activity may be critical for the regulation of cellular activities. PLD activity that is stimulated by PA, PAF, and Sph 1-P is inhibited by ceramide. Thus, ceramide inhibits the formation of DAG by the PLD pathway. Senescent cells lack PLD activity, possibly due to the high concentration of ceramide found in these cells.

The apoptotic and antiapoptotic properties of ceramide and DAG, respectively, are well documented. An increase in ceramide levels induces cell death, which can be overcome by the presence of DAG. DAG might abrogate the ceramide-induced signals leading to apoptosis while allowing signals for other events to proceed. Thus, when DAG and ceramide are combined, cell proliferation prevails over cell death. DAG generated from PC by the action of PC-PLC can stimulate acidic sphingomyelinase activity, leading to generation of intracellular ceramides and activation of the transcription factor NF- κ B.

PKC isoforms are involved in regulation of diverse cellular functions. Both Ca^{2+} -dependent and -independent isoforms of PKC require DAG to be activated. In contrast, the atypical PKC isoforms ξ and λ are independent of Ca^{2+} and not activated by DAG but are regulated by ceramide. Ceramide has also been shown to regulate PKC isoforms α , δ , and ϵ and to induce their translocation from the membrane to the cytosol, suggesting their role in ceramide-mediated apoptosis.

Stimulation of DNA synthesis and cell proliferation by the bioactive lipid phosphates PA, PAF, and Sph 1-P was antagonized by ceramide, which is a potent inhibitor of cell division. It has also been observed that sphingosine, a by-product of ceramide metabolism, increased the DNA synthesis further in the presence of PA and PAF, although the mechanism used is distinct from that used by PA or PAF, suggesting that inhibition of DNA synthesis by ceramide does not depend on its metabolic products.

RECEPTORS OF LIPID SECOND MESSENGERS

Lipid second messengers generated by agonist stimulation exist as gradients and are regionally localized in the plasma membrane or are enriched in smaller microdomains known as rafts or detergent-insoluble glycoprotein-enriched domains (DIGs). The action of these lipids depends on their binding to discrete

protein domains located within the signaling proteins. Because the generation of lipid second messengers is selectively regulated within a particular membrane on a time scale of seconds to minutes, the binding of these lipids to the protein domains is generally of low affinity and is rapidly reversible, allowing the signaling proteins to undergo random diffusion in the cytosol, interspersed with membrane binding and dissociation.

Hydrolysis of PIP_2 by PLC generates DAG and IP_3 , stimulating the release of Ca^{2+} ions from internal stores. This induces Ca^{2+} -dependent PKC translocation to the membrane and binding of DAG to its unique protein kinase C homology-1 (C1) domain, increasing its affinity for acidic phospholipids. In contrast, increased Ca^{2+} ions induce cPLA_2 translocation to the cytosolic leaflet of the endoplasmic reticulum (and possibly other internal membranes) and binding to the neutral lipids through its protein kinase C homology-2 (C2) domain. It has been shown that PA-mediated translocation of Raf to the plasma and endosomal membrane is mediated by a 4-kDa region of Raf and does not activate kinase activity but facilitates its activation by GTP-Ras.

Many cell surface receptors signal through phosphoinositide 3-kinase (PI3K), which can phosphorylate PIP_2 and PIP_3 . These membrane lipids further transmit signals by virtue of their specific interactions with pleckstrin homology (PH) domain-containing signaling proteins. These include the PH domains of kinases Akt, PDK1, and Btk as well as Arf GTP exchange factors ARNO and Grp1, which interact with the inositol phosphate head group.

A lipid that is more important for direction of endosomal traffic than for receptor-linked signaling is phosphatidylinositol 3-phosphate (PI3P). This lipid does not interact with the PH domain-containing proteins but interacts with the early endosomal antigen protein-1 (EEA1) possessing the small Zn^{2+} -containing Fab1-YOTP-Vac1-EEA1 (FYVE) domain. This interaction gives a certain degree of directionality to the endocytic membrane traffic.

The intracellular actions of PAF are mediated through a G protein-linked seven-transmembrane receptor that is expressed on the surface of a variety of cell types. PAF can activate its receptor in both an autocrine and a juxtacrine fashion by binding to the PAF-binding pocket within the membrane, effectively amplifying its biological response. The levels of PAF are regulated by both the desensitization of the receptor and rapid degradation of PAF by PAF acetylhydrolase.

BIOLOGICAL FUNCTIONS OF LIPID SECOND MESSENGERS

Lipid second messengers regulate a variety of biological functions and intracellular signaling events, resulting in diverse cellular functions. Ceramide generated by degradation of sphingomyelin or from sphingosine is known to trigger apoptosis in several cell systems by activation of caspases, down-regulation of PI3K activity, or induction of dephosphorylation and inactivation of antiapoptotic factor Bcl-2, thereby turning off the survival signal leading to apoptosis. Ceramide can also mimic vitamin D₃ or TNF α -induced differentiation of HL-60 cells to monocytes. Sphingosine has been shown to act as a mitogen to increase cell proliferation in a PKC-independent manner. Sphingosine can also mediate cell growth arrest by dephosphorylation of the Rb protein, which is essential for a cell to enter the subsequent S phase. Sph 1-P increases intracellular Ca²⁺ mobilization and cell proliferation but reduces apoptosis and cell migration.

PAF elicits diverse biological responses in various systems. PAF has a profound effect on airways in asymptomatic individuals by evoking bronchoconstriction, airway hyperresponsiveness, plasma exudation, and mucus hypersecretion. PAF can also mimic anaphylactic symptoms in experimental animals. PAF is involved in inflammatory and immune responses and is capable of eliciting many symptoms associated with endotoxic shock-like hypotension or tissue injury as well as activation of platelets, neutrophils, and macrophages. The elevated plasma PAF levels in patients with psoriasis suggest involvement of PAF. PAF can induce proliferation of human endothelial cells, bone marrow cells, and lung fibroblast cells *in vitro*, whereas hyperplasia of guinea pig and rat airways goblet cells has been observed in response to PAF *in vivo*. The reproductive involvement of PAF has been suggested in sperm motility, ovulation, fetal lung maturation, implantation, and initiation/maintenance of parturition during early pregnancy.

CONCLUSION

PC and SM are the primary phospholipid precursors of bioactive lipids that take part in regulation of critical signal transduction pathways involved in cell survival and cell death. Existence of lipid gradients in the plasma membrane on agonist stimulation, and translocation of specific cytosolic proteins to enable binding to the lipid metabolites thereby generated, suggests the involvement of lipid-protein complexes

in transferring the agonist-stimulated signal within the cell. Although the PC- and SM-derived bioactive lipids have specific signaling pathways, their ability to tightly regulate each other's levels allows a balance to be maintained, controlling the mitogenic signals of these phospholipids within the cell. Domain-specific interaction of lipid second messengers with specific proteins is reversible and has low affinity, allowing the signaling protein to undergo rapid dissociation and diffusion in the cytosol. The biological functions of these bioactive lipids are diverse, ranging from inducing the cell to undergo apoptosis and cell death to stimulating the cell toward proliferation and cell survival. It can be concluded that a better understanding of the interaction between various lipid second messengers and their downstream signaling events will be essential for elucidation of mechanisms that regulate cell functions.

Table I Characteristics of Lp(a) and Apo(a)

- Particle consisting of one LDL and one disulfide-linked apo(a) glycoprotein
- High homology between apo(a) and plasminogen
- Synthesis of apo(a) in the liver, assembly of Lp(a) at cell surface
- Site and mechanism of catabolism discussed controversially
- Size polymorphism of apo(a) gene and protein: > 30 alleles and isoforms
- *LPA* gene located on chromosome 6q26–q27: apo(a) alleles differ by K-IV-2 repeat number
- Lp(a) plasma concentrations: 1000-fold interindividual range (from <0.1 to >300 mg/dl) with skewed distribution (most individuals have concentrations of less than 10 mg/dl)
- Inverse relation between K-IV-2 repeats/molecular weight of apo(a) and Lp(a) concentration
- K-IV-2 polymorphism of apo(a) explaining 30 to 70% of the variability of Lp(a) concentrations; this polymorphism and other sequence variations of the apo(a) gene explain 70 to 90% of the variability of Lp(a) concentrations
- Lp(a) concentrations relatively independent of age and gender

Note. Lp(a), lipoprotein(a); apo(a), apolipoprotein (a); K-IV, kringle-IV.

Figure 1 Model of Lp(a) and reported interactions of Lp(a)/apo(a) with components of the fibrinolytic system, cell receptors, and other binding proteins. The central LDL particle, with its core of neutral lipids and the apo B-100 molecule, is attached to one molecule of apo(a) by a single disulfide bond between one of the K-IV repeats (K-IV-9) in apo(a) and the C-terminal region of apo B. The exact spacial orientation of the components is unknown, and the regularity of carbohydrate chains is a simplification. tTPA, tissue-type plasminogen activator; PLG, plasminogen; β_2 GP-1, β_2 glycoprotein-1; PAI-1, plasminogen activator inhibitor-1; MCA, monocyte chemotactic activity; VCAM-1, vascular cell adhesion molecule-1; TGF β , transforming growth factor β ; SMC, smooth muscle cells. Used with permission from Utermann, G. (2000). Lipoprotein(a). In "The Metabolic and Molecular Bases of Inherited Disease" (C. R. Scriver, A. L. Beaudet, W. S. Sly, and D. Valle, eds.), 8th ed., pp. 2753–2787. McGraw-Hill, New York.

Lipoprotein(a) Plasma Concentrations

The mean and median concentrations of Lp(a) in Caucasians are about 15 and 8 mg/dl, respectively, with an extremely broad range from less than 0.1 to more than 300 mg/dl. The distribution of Lp(a) plasma concentrations in the general Caucasian population is skewed, and most of the people express low concentrations (Fig. 2). However, there are large differences in concentrations among various ethnic groups. Individuals of African descent have two- to fourfold higher median plasma levels of Lp(a) than do Caucasians, whereas some Asian populations have significantly lower levels. The distribution of Lp(a) levels in some African populations (e.g., Khoi San) is nearly Gaussian (Fig. 2). The reason for these differences among populations is the subject of speculation.

Genetics of Lipoprotein(a)

Population and family studies demonstrated that Lp(a) plasma concentrations are highly heritable and are, to a large extent, determined by the apo(a) gene locus. Additionally, two minor loci have recently been identified but are not yet confirmed. Other genes, such as the LDL receptor locus, play a role in patients with rare disease. The apo(a) gene is located in the telomeric region of chromosome 6 (6q26–q27). This gene locus determines a size polymorphism as described in 1987 by Utermann and co-workers. The molecular weight of apo(a) isoforms ranges from 300 to more than 800 kDa. Analyses of genomic DNA have shown that the protein size polymorphism is

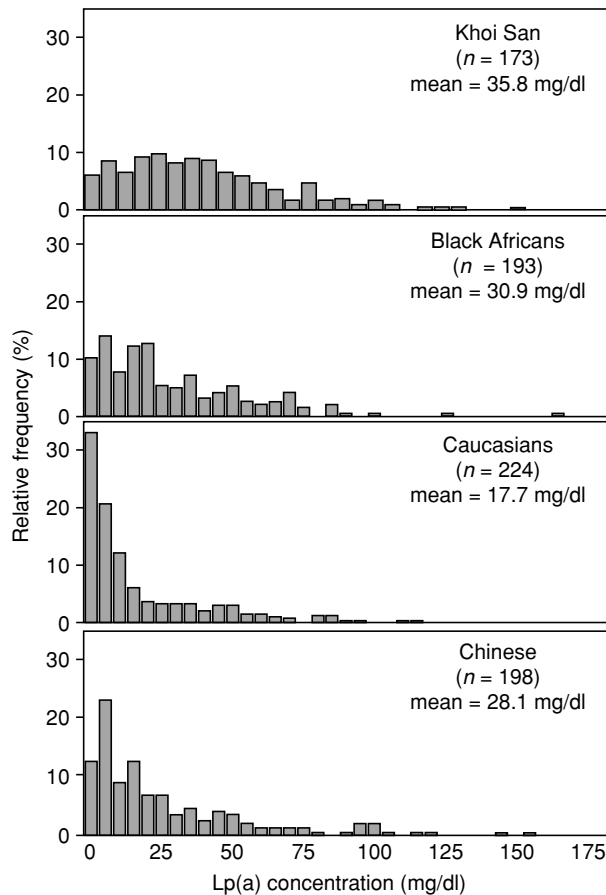

Figure 2 Histograms of the distribution of Lp(a) concentrations in four populations. Used and modified with permission from Kraft, H. G., Lingenhel, A., Pang, R. W. J. Hum. Genet.* **4**, 74–87. Karger, Basel.

caused by a varying number of K-IV-2 repeats in the apo(a) gene (from 1 to >30).

A negative correlation exists between the molecular weight of apo(a) (corresponding to number of K-IV-2 repeats) and the Lp(a) plasma concentrations. Individuals with low molecular weight (i.e., short) isoforms (up to 22 K-IV repeats) on average have high Lp(a) concentrations, whereas those with high molecular weight (i.e., long) isoforms (>22 K-IV repeats) usually express low Lp(a) values (Fig. 3). Depending on the population, approximately 30 to 70% of the broad variability of Lp(a) plasma concentrations can be explained by this size polymorphism. Several further sequence variations at or near the apo(a) gene exist that increase the within-population variance in Lp(a) levels explained by the apo(a) gene to 70 to 90%. This makes

Figure 3 Graphic demonstration of the association of apo(a) alleles with Lp(a) plasma concentrations in a Caucasian population. Lp(a) to a lipoprotein with an exceptionally high genetic heritability and control. This high genetic heritability, in combination with the wide interindividual variation of Lp(a), makes it very difficult to investigate nongenetic influences on Lp(a) concentrations. Depending on the study design, it may be mandatory to consider the genetic polymorphism of Lp(a) as a potential confounder in studies aimed to identify environmental and/or other genetic factors.

LIPOPROTEIN(a) AND ATHEROSCLEROSIS

Numerous retrospective studies, and more recently a remarkable number of prospective case-control studies, have reported significantly higher Lp(a) levels in patients with coronary artery disease, cerebrovascular disease, and peripheral atherosclerosis when compared with those in controls. Many of these studies proposed Lp(a) levels above 30 mg/dl to be associated with an increased risk. However, this threshold depends on the assay used for the measurement of Lp(a). Many studies showed that the risk for atherothrombotic disease associated with Lp(a) increases significantly if other risk factors, such as high LDL or low high-density lipoprotein (HDL) cholesterol concentrations, are also present. Apparently, an interaction of Lp(a) with other lipoproteins changes its atherothrombotic properties.

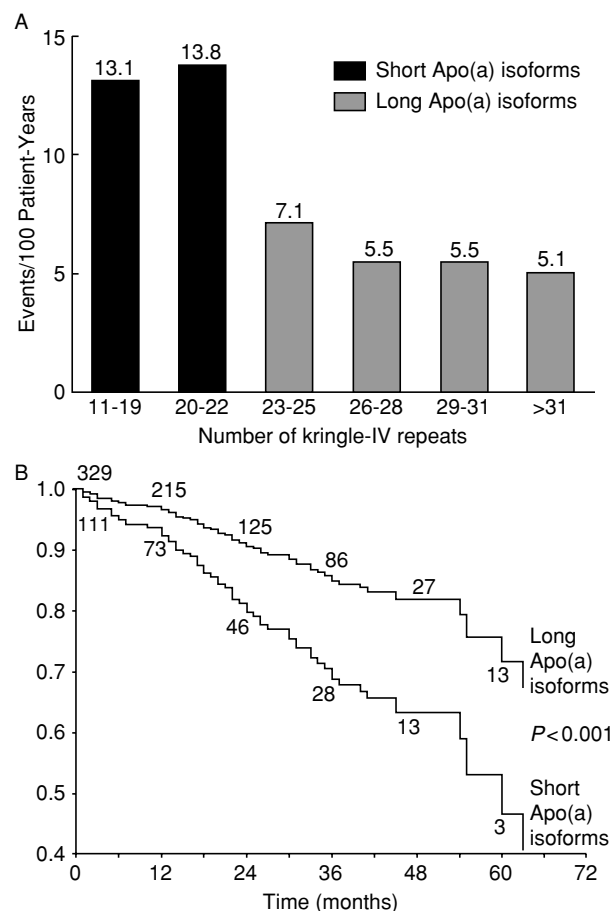

Figure 4 Association between the apo(a) size polymorphism and coronary artery disease (CAD) events in a cohort of 440 unselected hemodialysis patients prospectively followed for a period of 5 years. Of the 440 patients, 66 (15%) suffered a CAD event during follow-up. Panel A shows the number of CAD events per 100 patient-years in relation to the number of kringle-IV repeats of apo(a). Panel B shows the CAD event-free survival in patients with only long apo(a) isoforms (>22 kringle-IV repeats) and with at least one short apo(a) isoform (up to 22 kringle-IV repeats). Adjusted results were obtained from a multiple Cox proportional hazards regression analysis. Numbers near the survival curves represent the number of patients at risk within the two apo(a) isoform groups at 0, 12, 24, 36, 48, and 60 months. Used and modified with permission from Kronenberg, F., Neyer, U., Lhotta, K., Trenkwalder, E., Auinger, M., Pribasnik, A., Meisl, T., König, P., and Dieplinger, H. (1999). The low molecular weight apo(a) phenotype is an independent predictor for coronary artery disease in hemodialysis patients: A prospective follow-up. *J. Am. Soc. Nephrol.* **10**, 1027–1036, Lippincott, Williams & Wilkins.

Studies that considered the apo(a) K-IV-2 repeat polymorphism observed that short apo(a) alleles/isoforms were significantly more frequent in patients with coronary artery disease or other forms of atherosclerosis than in controls (Fig. 4). This suggests that

the apo(a) gene locus determines the risk of atherothrombosis through its control of Lp(a) plasma concentrations. Therefore, the association of genetic variation at the apo(a) gene locus with atherothrombosis supports the notion that Lp(a) is a primary genetic risk factor for atherothrombosis. Recently, this association has also been supported by prospective data (e.g., results presented in Fig. 4).

Several mechanisms by which Lp(a) promotes atherosclerosis have been proposed. High Lp(a) concentrations impair activation of transforming growth factor- β by down-regulation of plasmin generation, contributing to smooth muscle cell proliferation. Experiments in rabbit arteries indicate that oxidized Lp(a) impairs endothelium-dependent dilation more profoundly than does oxidized LDL. Recent studies demonstrated that Lp(a) induces chemotactic activity to human monocytes in a dose-dependent fashion. Lp(a) enhances the expression of intercellular adhesion molecule-1 (ICAM-1) implicit to the adhesion and transendothelial migration of monocytes. Because Lp(a) accumulates in the subendothelial space of the vessel wall, it may act as a potent chemoattractant for these cells in human atherosclerosis. Others observed that the apo(a) size polymorphism influences the effect of Lp(a) on fibrinolysis in that only Lp(a) with short apo(a) isoforms showed high-affinity binding to fibrin surfaces, thereby acting as a prominent competitive antagonist to plasminogen. These *in vitro* findings suggest that high concentrations of Lp(a) with short apo(a) isoforms should have the most pronounced influence on fibrinolysis. In other words, the same Lp(a) concentrations may be associated with a markedly different atherothrombotic risk, depending on the apo(a) isoform. There is some evidence from population studies that this is indeed the case, although heterogeneity may exist among populations.

CONDITIONS OF HIGH LIPOPROTEIN(a) LEVELS

Genetic Influences

The apo(a) gene locus has the strongest influence on Lp(a) levels with usually high Lp(a) levels if the person is a carrier of at least one short apo(a) allele. Approximately 25% of Caucasians are carriers of a short allele. However, there are exceptions to this rule, meaning that some individuals with short apo(a) alleles can express low concentrations and a small fraction of individuals with long alleles may also exhibit high Lp(a) concentrations. In addition, the

relation between apo(a) alleles and Lp(a) concentrations is heterogeneous between populations.

Some conditions are known to influence Lp(a) concentrations (Table II). An inherited disease associated with elevated Lp(a) levels is dominant familial hypercholesterolemia. Heterozygous patients have decreased LDL receptor activities. Some studies did not confirm this observation but might be biased by small sample size combined with the difficulty of detecting a minor gene effect in the presence of a major one. Large family studies demonstrated convincingly that familial hypercholesterolemia affects Lp(a) concentration and that there is a gene dose effect, with homozygous familial hypercholesterolemia having the highest average Lp(a) concentrations. This conclusion was supported by a large sib-pair analysis in Dutch families with familial defective apolipoprotein B-100 (FDB). FDB-affected sibs revealed higher Lp(a) levels than did nonaffected ones with the same apo(a) genotype, demonstrating an effect of the FDB mutation on Lp(a) concentrations. However, neither study provides evidence that Lp(a) is cleared by the LDL receptor given that the effect of the respective mutations on the Lp(a) concentrations could be an indirect one.

Table II Conditions Influencing Lp(a) Concentrations

| |
|--|
| Conditions increasing Lp(a) levels |
| • Familial hypercholesterolemia |
| • Familial defective apolipoprotein B-100 |
| • Renal disease |
| • Systemic lupus erythematosus |
| • Hypothyroidism |
| • Growth hormone therapy |
| • Primary gout |
| • Pregnancy |
| • Postmenopause |
| • Diet: high amounts of elaidic acid or other trans-fatty acids from vegetables and marine sources |
| • Strenuous physical exercise |
| Conditions decreasing Lp(a) levels |
| • Abetalipoproteinemia |
| • Lecithin-cholesterol acyltransferase deficiency |
| • Low-density lipoprotein deficiency |
| • Severe hypertriglyceridemia/type I hyperlipidemia |
| • Hepatic disorders associated with decreased liver function |
| • Alcoholism |
| • Hyperthyroidism |
| • Sex hormones (female and male) |
| • Anabolic steroids |
| • Diet: palm oil and n-3 polyunsaturated acids |

Nongenetic Influences

Kidney Disease

There is clear evidence that Lp(a) is secondarily elevated in kidney disease. It starts to increase during the earliest stages of disease, already before functional impairment of the kidney can be recognized by an increased serum creatinine concentration. With decreasing kidney function, Lp(a) increases further. The levels are elevated severalfold when the disease is accompanied by severe proteinuria and nephrotic syndrome. The Lp(a) levels during stages of kidney replacement therapy depend strongly on the modality of treatment. Peritoneal dialysis patients have markedly higher levels of Lp(a) than do hemodialysis patients; this might be caused by the tremendous loss of proteins by dialysate and a compensatory increase in protein production, including apo(a) in the liver. Lp(a) levels clearly decrease following kidney transplantation in both treatment groups.

It is an interesting but unexplained phenomenon that the increase of Lp(a) in hemodialysis patients and in patients with mild or moderate (nephrotic) impairment of kidney function is restricted to long apo(a) isoforms when compared with isoform-matched controls. Patients with at least one short apo(a) isoform had nearly identical Lp(a) levels when compared with matched controls. This is in line with the observation that Lp(a) in hemodialysis decreases following kidney transplantation only in patients with long apo(a) isoforms and not in those with at least one short isoform.

Lifestyle Factors (Diet and Exercise)

Dietary intervention studies have shown that elaidic acid or other trans-fatty acids from vegetables and marine sources elevate Lp(a) levels if they are consumed in great amounts. Trans-fatty acids produced by industrial hydrogenation of edible oils and fats also increase Lp(a). In contrast, palm oil and n-3 polyunsaturated acids lower Lp(a) concentrations.

The effect of exercise on Lp(a) levels is dose dependent. Moderate exercise does not affect Lp(a) levels, strenuous exercise on a daily basis results in higher Lp(a) concentrations.

INFLUENCE OF THE ENDOCRINE SYSTEM ON LIPOPROTEIN(a) CONCENTRATIONS

Sex Hormones

On average, there are only small differences in Lp(a) concentrations between men and women. Lp(a) is

Table III Pooled Analysis of Studies of Hormonal Replacement Therapy and Its Influence on Lp(a) Concentrations, Performed by Godsland

| Regimen | Number of studies | Percentage change of Lp(a) | | |
|--|-------------------|----------------------------|----------------|------------|
| | | Mean | 95% CI | Range |
| Conjugate equine estrogens (0.625 mg/day) | 13 | -23.9 | -27.8 to -20.0 | -48 to 35 |
| Conjugate equine estrogens (0.625 mg/day plus) Medroxyprogesterone acetate (2.5-5.0 mg/day) | 4 | -20.7 | -25.4 to -16.0 | -24 to 16 |
| Estradiol 17- β (2.0 mg/day) | 5 | -12.9 | -17.6 to -8.2 | -20 to -10 |
| Estradiol 17- β (2.0 mg/day plus) Norethindrone acetate (1.0 mg/day) | 3 | -34.4 | -40.6 to -28.2 | -39 to -31 |
| Transdermal estradiol 17- β (0.05-0.10 mg/day) | 2 | 5.3 | -2.7 to 13.3 | -5 to 6 |
| Transdermal estradiol 17- β (0.05 mg/day plus) Dihydrogesterone (10-20 mg/day) | 3 | -6.0 | -12.4 to 0.4 | -13 to 0 |
| Tibolone (2.5 mg/day) | 7 | -39.2 | -44.7 to -33.7 | -83 to 3 |
| Raloxifene (60-150 mg/day) | 2 | -6.9 | -10.2 to -3.6 | -8 to -5 |
| Placebo controls | 6 | -1.0 | -4.9 to 2.9 | -15 to 3 |
| Untreated controls | 5 | 7.1 | 2.3 to 11.9 | -4 to 14 |

Source. Data according to Godsland, I. F. (2001). Effects of postmenopausal hormone replacement therapy on lipid, lipoprotein, and apolipoprotein(a) concentrations: Analysis of studies published from 1974-2000. *Fertil. Steril.* 75, 898-915, with permission from the American Society for Reproductive Medicine.

elevated during pregnancy and menopause. This increase is clearly counterbalanced by hormonal replacement therapy. Table III shows the percentage changes of Lp(a) levels by various therapy regimens from a pooled analysis of prospective studies performed by Godsland. Conjugated equine estrogens alone were associated with a strong reduction in Lp(a) (-24%). Transdermal administration of estradiol 17- β was accompanied by less of a decrease in Lp(a) than was oral administration. The addition of progestogen to estradiol 17- β had a further strong decreasing effect on Lp(a) (-35%). The strongest effect, with nearly -40%, was seen for tibolone. The higher the baseline levels of Lp(a), the greater the absolute therapy-induced reduction. This is of special interest in light of the Heart Estrogen/Progestin Replacement Study, which detected a protective effect among those with high baseline Lp(a) levels, although otherwise the study did not reveal a protective effect of estrogen replacement therapy in the secondary prevention group as a whole.

Selective estrogen receptor modulators, such as tamoxifen and structural analogues (e.g., raloxifene), seem to have antiestrogenic effects on the endometrium and breast but estrogenic effects on bone and lipid metabolism. Studies applying this treatment in healthy postmenopausal women or in women with breast cancer showed an Lp(a)-lowering effect that was less pronounced than with hormonal replacement

therapy. Tamoxifen has shown even an Lp(a)-lowering effect in men.

There is strong evidence that testosterone decreases Lp(a) levels. This was shown by exogenous testosterone application as well as indirectly by suppression of endogenous testosterone production either by surgical or pharmacological castration using a gonadotropin-releasing hormone agonist. The effect of endogenous suppression of testosterone production was shown not only in prostatic cancer patients but also in young healthy men. A recent double-blind randomized controlled study using transdermal testosterone application in healthy elderly men over 65 years of age did not affect any of the lipid or apolipoprotein parameters, including Lp(a). Whether this is caused by the transdermal application of testosterone has yet to be investigated.

These data suggest that Lp(a) concentrations are under sex hormone control, but the precise mechanism is not yet defined. Hormone-responsive elements have been identified in the apo(a) 5'-flanking region. The significance of this influence under physiological (nontherapeutic and nonpathological) conditions has yet to be determined.

Hypothyreosis and Hyperthyreosis

Several studies investigated Lp(a) in hypothyroidisms and hyperthyroidisms. These studies suggest that

Lp(a) is elevated in the hypothyroid state. However, therapy by thyroid hormones did not always show an Lp(a)-lowering effect, a result that might also depend on whether patients showed overt or subclinical hypothyroidism. A recent double-blind placebo-controlled study in 66 women with subclinical hypothyroidism did not show significant changes in Lp(a) by L-thyroxine replacement therapy. Similar observations were made in another placebo-controlled trial.

Studies that investigated hyperthyroid patients generally showed decreased Lp(a) levels in the hyperthyroid state and increased Lp(a) following therapeutic intervention by thyreostatic medications or radioactive iodine therapy.

In conclusion, thyroid hormones seem to have an Lp(a) level-modulating effect. Again, the mechanism of this effect is unknown.

Influence of Growth Hormone

A large number of studies, including several placebo-controlled double-blind studies, investigated the effect of growth hormone substitution on Lp(a) levels in patients with congenital or acquired growth hormone deficiency. Many of these studies demonstrated a strong Lp(a)-increasing effect of growth hormone. This has raised some concerns about this therapy. However, there is strong evidence from studies in the general population that the atherogenic potential of Lp(a) increases mainly above a threshold of 20 to 30 mg/dl. Because most of the patients have Lp(a) concentrations below 10 mg/dl, the majority of patients receiving growth hormone treatment will not change their atherogenic potential related to Lp(a). Furthermore, the treatment by growth hormone is accompanied by a significant reduction in LDL cholesterol caused by increased LDL receptor activity and by lower triglyceride levels. Therefore, these changes may counterbalance the potential negative effects of an Lp(a) increase.

Diabetes Mellitus

The epidemiological literature on Lp(a) in diabetes mellitus (DM) is conflicting. Numerous case-control studies are clearly biased by the small number of patients investigated. Lp(a) is not elevated in patients with type 2 DM when only large case-control studies are considered.

The situation is less clear in patients with type 1 DM. Elevated and similar concentrations, as compared with controls, were reported. Most large-scale studies in adult patients described nearly identical

Lp(a) values in patients and controls, whereas some studies in children showed higher concentrations in patients. The Diabetes Control and Complications Trial (DCCT) compared the Lp(a) plasma concentrations of 1299 patients with type 1 DM with those of 2158 controls. The researchers observed nearly identical Lp(a) values in the group with intensive insulin therapy ($n = 646$) as compared with controls (mean 18.5 vs 18.2 mg/dl, n.s.) and slightly but significantly higher values in 653 patients with conventional insulin therapy (22.0 mg/dl, $P < 0.05$). This is in line with the observation in some small but longitudinal studies in type 1 DM patients that showed a decrease in Lp(a) with improvement of glycemic control. A further large prospective study in 105 metabolically poorly controlled patients showed absolutely no changes in Lp(a) concentrations after 3 months of intensive therapy with multiple insulin doses, although the profile of other lipoproteins as well as triglyceride concentrations improved significantly.

A further argument against the conclusion that Lp(a) concentrations are elevated in type 1 diabetic patients came from a study of identical twins that found very similar Lp(a) concentrations in diabetic patients and their healthy co-twins. However, this observation rules out diabetes as a secondary cause of high Lp(a) in type 1 diabetic patients. It cannot exclude that a primary elevation of Lp(a) is associated with type 1 diabetes. Because identical twins share apo(a) alleles identical by descent, a genetic cause for the elevation of Lp(a) in type 1 diabetic patients could not be detected by such a study design. Only few studies were originally designed to investigate whether an elevation of Lp(a) in these patients, if present, is genetically determined. These studies included apo(a) phenotype analysis, and most of them came to the conclusion that apo(a) is not associated with type 1 DM. However, the investigated patient groups were heterogeneous in terms of patients' ages and duration of diabetes. A recent case-control study observed higher Lp(a) concentrations in patients with short diabetes duration and a frequency of short apo(a) isoforms nearly twice as high as in controls matched for sex and age. This preferential association of short apo(a) isoforms with diabetes indicates that the apo(a) gene, or a gene very close to the apo(a) gene, may be a susceptibility gene for type 1 DM. In the latter case, the apo(a) gene must be in linkage disequilibrium with the actual susceptibility gene. This is in line with several studies showing linkage of this chromosomal region with type 1 DM. The difference in apo(a) allele frequencies between patients and controls was found only when the

investigated patients were stratified into groups according to diabetes duration. This might be of considerable importance given that Lp(a) plasma concentrations and the apo(a) size polymorphism are possibly related to survival due to the association with atherosclerotic complications. With increasing duration of diabetes, a pronounced and nearly linear decrease in the frequency of patients with short apo(a) isoforms was observed.

Several studies investigated microalbuminuria, macroalbuminuria, and nephrotic-range proteinuria as confounders that increase Lp(a) in type 1 and type 2 diabetic patients. Studies on microalbuminuria were too inconsistent to draw a final conclusion. The concentrations of Lp(a) increase with increasing albuminuria and proteinuria. A longitudinal study recently showed that Lp(a) decreases significantly with decreasing proteinuria in these patients after starting the dialysis treatment. This is in line with the observation that Lp(a) levels in dialysis patients with diabetes or other causes of kidney disease are similar.

Some small case-control and prospective studies found an association between high Lp(a) plasma concentrations and coronary heart disease or peripheral arterial disease in diabetic patients that was not confirmed by others. A large case-control study ($n = 500$) described significantly higher Lp(a) concentrations in diabetic patients with ischemic heart disease or macroangiopathy as compared with those without these conditions. In this study, a 15 to 30% higher probability of developing macroangiopathy was calculated for patients with hypertension, 10 to 20 years duration of diabetes, and Lp(a) levels greater than 30 mg/dl as compared with those with Lp(a) levels less than 30 mg/dl. Large studies described an association between high Lp(a) levels and diabetic retinopathy.

In conclusion, there is evidence that Lp(a) is an emerging risk factor for atherosclerosis and early death in type 1 and type 2 diabetes but not that Lp(a) is elevated secondarily to the disease. However, the Lp(a) levels are modified when the disease comes along with albuminuria or nephrotic syndrome.

WHEN SHOULD LIPOPROTEIN (A) BE MEASURED?

Table IV lists groups of individuals in whom routine screening for elevated Lp(a) levels should be considered. These are mainly groups in which other strong atherosclerosis risk factors operate.

It is recommended that Lp(a) be measured for an individualized assessment of atherosclerosis risk for the planning of therapeutic interventions. Because an acceptable Lp(a)-lowering therapy is still lacking, attention should be directed to other risk factors that can be treated in patients with high Lp(a) plasma concentrations. These include high LDL cholesterol, hypertension, DM, and smoking. Besides the measurement of Lp(a), apo(a) phenotyping might be considered in special patient groups such as patients with end-stage kidney disease.

TREATMENT OF HIGH LIPOPROTEIN(A) LEVELS

Lowering Lp(a) is a frustrating task. No simple and satisfying method or medication is available that can be used in large patient groups and that decreases Lp(a) without major side effects. We do not even know whether therapeutic lowering of high Lp(a) levels alone would be beneficial.

Lp(a) remains unchanged after treatment with widely used lipid-lowering drugs such as hydroxymethylglutaryl coenzyme A (HMG CoA) reductase inhibitors. There is growing evidence that nicotinic acid, and especially its derivative niceritrol, has an interesting Lp(a)-lowering potential. Neomycin has been reported to interfere with the assembly of Lp(a) and to lower Lp(a) moderately. This effect was increased by a combination with nicotinic acid. Lp(a)-lowering steroid hormones are not indicated because of their side effects. Promising specific Lp(a)-lowering effects were described for the antiestrogen tamoxifen. The synthetic steroid tibolone showed a reduction in Lp(a) ranging from 26 to 39% but was accompanied by a decrease in HDL cholesterol between 18 and

Table IV Patient Groups Suggested for Screening for High Lp(a) Levels

-
- Patients with elevated low-density lipoprotein cholesterol concentrations or other forms of dyslipoproteinemia
 - Young patients with atherosclerotic cardiovascular and cerebrovascular disease
 - Individuals from families with a strong history of early cardiovascular or cerebrovascular disease
 - Patients with renal failure
-

23%. Adrenocorticotropin hormone (ACTH) demonstrated a pronounced Lp(a)-lowering effect (up to -65%). Experimental studies observed that tranexamic acid, which blocks the assembly of apo(a), had only a small Lp(a)-lowering effect.

The successful lowering of LDL cholesterol and Lp(a) by LDL apheresis and plasmapheresis in patients with severe hypercholesterolemia and/or high Lp(a) has been demonstrated in several studies, but it is available for only a small number of high-risk patients (e.g., those with drug-resistant hypercholesterolemia). Furthermore, it has to be shown in clinical studies that lowering Lp(a) is beneficial to the patients.

There is no consensus that lithium causes this hyperthyroidism immunologically or in any other way.

LITHIUM AND CALCIUM

Lithium alters the calciostat and renders the parathyroid cell less sensitive to calcium. Some patients develop parathyroid adenomas accompanied by an increase in serum calcium and immunoreactive parathyroid hormone.

OTHER ENDOCRINE EFFECTS

Diabetes insipidus (DI) occurs in up to 40% of patients within a few days of beginning lithium therapy. DI is usually nephrogenic, with high circulating concentrations of arginine vasopressin and an impairment of the renal response to this hormone. Lithium may also inhibit antidiuretic hormone release from the posterior pituitary, leading to central DI.

The clinical effect of lithium on adrenal function is minimal, although urinary aldosterone concentration increases soon after starting the drug. An increase in body weight is commonly seen in patients

receiving lithium. The effects of the drug on glucose metabolism are not thought to be of clinical significance.

RCT in these conditions are discussed. Due to space limitations, many data on genetically engineered mice, which have altered levels of plasma HDL-C, are not discussed.

REGULATORY FACTORS FOR PLASMA HDL CHOLESTEROL LEVELS

HDL particles consist of heterogeneous subclasses. They have higher density (> 1.063 g/ml) and smaller in size (Stoke's diameter 5 to 17 nm) and consist of about 50% lipids and 50% proteins. They can be classified by density (HDL2 or HDL3 fraction), electrophoretic mobility (α - and pre- β -electrophoretic mobility), and apolipoprotein composition (Lp A-I or Lp A-II). The quantity and quality of HDLs are regulated by many factors, such as plasma enzymes, transfer proteins, and cell surface receptors (Fig. 1).

Synthesis and Secretion of the Components of HDL

One of the major constituents of HDL particles is apo AI, which is synthesized in the liver and small intestine. ABCA1, a defect of which causes some HDL deficiency including Tangier disease, is thought to interact with apo AI and phospholipid on the plasma membrane and generate "nascent HDL" particles, which is a discoidal form. Other receptors and

molecules may be involved, although ABCA1 is requisite for the production of HDL particles. Free cholesterol on the nascent HDL is esterified by the action of lecithin:cholesterol acyltransferase (LCAT). LCAT plays a pivotal role in making HDL particles spherical and mature in form in plasma.

Modification of HDL Particles in Plasma

In plasma, several enzymes affect the quality and quantity of HDL particles. Intravascular movement of lipids and apolipoproteins is one of the important sources for HDL particles. Two lipases, lipoprotein lipase and hepatic triglyceride lipase (HTGL), are thought to be involved. The hydrolysis of triglyceride-rich lipoproteins (TRLs) by these lipases releases apolipoproteins and phospholipids in plasma, and these constituents can be used for the formation of new HDL particles. HTGL, located on the liver sinusoid, is thought to remodel large and triglyceride-rich HDLs into smaller ones. Cholesteryl ester transfer protein (CETP) is a plasma glycoprotein that facilitates neutral lipids transfer between lipoproteins. CETP transfers cholesteryl ester from HDL to apo B-containing lipoproteins and, conversely, triglyceride from apo B-containing lipoproteins to HDL. Complete lack of CETP causes marked elevation of HDL-C levels in plasma. Phospholipid transfer

Figure 1 Metabolic map of the generation and regulation of HDL and HDL-mediated cholesterol transport in humans. Arrows denote cholesterol transport in the human body mediated by lipoproteins, plasma lipid transfer proteins, and cell surface receptors. Enzymes and transfer proteins and receptors are shown as red and blue letters, respectively. Cholesterol efflux from peripheral cells is thought to be very diverse. There are some candidates for cell surface receptors, such as ABCA1 and SR-BI.

protein (PLTP) transfers phospholipid and cholesterol from apo B-containing lipoproteins to HDL.

Hepatic Uptake of HDL and HDL Lipid

In the last step of RCT, there are believed to be at least two distinct pathways available to take up cholesterol from plasma. One is the LDL receptor-mediated pathway, illustrated by human CETP deficiency. The other pathway is the HDL receptor(s)-mediated pathway. Although the impact and significance of this pathway are not completely understood in humans, scavenger receptor class B type I (SR-BI) is the physiologically relevant HDL receptor established in mice. This receptor mediates selective uptake of HDL lipid. There is another possible pathway, in which whole particles of HDL may be taken up and catabolized.

Degradation of Apo AI or HDL

In the kidney, apo AI is catabolized by a size-dependent filtration process. Cubilin is thought to mediate reabsorption of apo AI from the proximal tubule lumen.

LOW HDL SYNDROMES

Primary Low HDL Syndromes

Table I shows the comparison of clinical and biochemical characteristics of primary low HDL syndromes.

Tangier Disease and Familial HDL Deficiency with Mutations in the ATP-Binding Cassette Transporter-1 Gene

Tangier disease (TD) is a familial HDL deficiency (FHD) originally described by Frederickson *et al.* in 1961 (Table I). Twin brothers living on Tangier Island, Chesapeake Bay, Virginia, suffered from yellow-orange tonsils, hepatosplenomegaly, and neuropathy. In homozygotes, plasma HDL is virtually absent and triglyceride levels are often elevated. Patients suffer from symptoms caused by the accumulation of cholesteryl ester in many tissues throughout the body (Fig. 2). Thrombocytopenia and hemolytic anemia are sometimes observed. Plasma apo AI concentration is extremely low, with a relative increase in precursors of apo AI. Fibroblasts and macrophages from Tangier patients are characterized by defective lipid, cholesterol, and phospholipid efflux. These cells

Table I Comparison of Clinical and Biochemical Characteristics of Primary Low HDL Syndromes

| | Tangier disease | Familial HDL deficiency without Tangier disease phenotype | Familial LCAT deficiency | Fish eye disease | ApoAI deficiency |
|--|----------------------|---|--------------------------|------------------|------------------|
| Affected gene | ABCA1 | ABCA1 (some cases) | LCAT | LCAT | apoAI |
| Clinical signs and symptoms | | | | | |
| Typical Tangier phenotype (orange tonsils, hepatosplenomegaly, neuropathy) | + | – | – | – | – |
| Corneal opacity | + | + | +++ | +++ | ++ |
| Nephropathy | – | – | + | – | – |
| Risk for coronary heart disease | Moderately increased | Moderately increased | Normal/increased | Normal/increased | Increased |
| Biochemical data | | | | | |
| Plasma total cholesterol | Low | Low | Low | Low | Normal |
| LDL cholesterol | Low | Normal | Normal | Normal | Normal |
| HDL cholesterol | None | None | Very low | Very low | None |
| Plasma triglyceride | Increased | Normal | Increased | Increased | Normal |
| % Cholesterol ester | Normal | Normal | Low | Low | Normal |
| Apolipoprotein (apo)-AI | Very low | Very low | Very low | Very low | None |
| Relative increase in apoAI precursor | + | + | – | – | – |
| α -LCAT activity | Normal | Normal | Very low | Very low | Normal |
| Cell biological data | | | | | |
| Cholesterol efflux from the cells (apoAI mediated) | Absent | Absent | Normal | Normal | Normal |

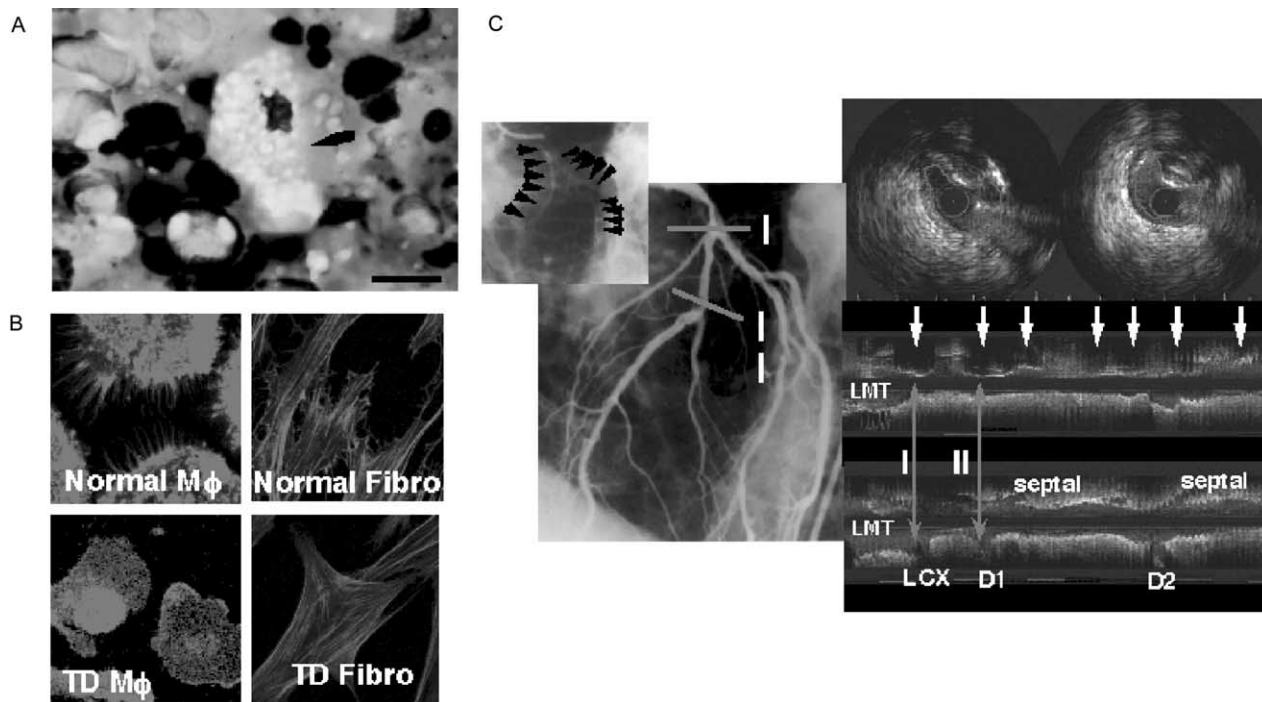

Figure 2 Clinical manifestations in patients with Tangier disease. (A) Foam cells observed in bone marrow. Reproduced with permission from Komuro, R., *et al.* (2000). *Circulation* **101**, 2446–2448. (B) Altered actin cytoskeletons observed in fibroblasts and macrophages from TD patients. Reproduced with permission from Hirano, K., *et al.* (2000). *FEBS Lett.* **484**, 275–279. (C) Severe coronary atherosclerosis demonstrated by intravascular ultrasonography. Reproduced with permission from Komuro, R., *et al.* (2000). *Circulation* **101**, 2446–2448.

have abnormal actin cytoskeletons in association with decreased expression of Cdc42, a member of the RhoGTPases family. Obligatory heterozygotes have half the normal plasma HDL-C and apo AI levels. This disorder is caused by mutations in the *ABCA1* gene, which is located on the long arm of chromosome 9. In some patients with FHD who do not show the typical Tangier phenotype, such as orange tonsils and hepatosplenomegaly, this is also reported to be associated with mutations in the *ABCA1* gene. The molecular mechanism for the phenotypic differences between TD and FHD remain to be investigated, even though they carry mutations in the same gene. Patients with *ABCA1* mutations are thought to have moderately increased risk for CHD.

Familial LCAT Deficiency and Fish Eye Disease

Both familial LCAT deficiency (FLD) and fish eye disease (FED) are caused by the mutations in the LCAT gene. Both disorder lead to a marked reduction in plasma HDL-C. The major clinical symptoms in FLD are corneal opacification, anemia, and proteinuria, which may progress to renal failure. Foam cells accumulate in various tissues, including cornea,

kidney, liver, spleen, and arteries. The ratio of esterified to free cholesterol is extremely low. Lipoproteins are morphologically abnormal, with the appearance of multilamellar vesicles, rouleaux, LpX-like particles.

FED is characterized by the presence of corneal opacities and absence of nephropathy. The molecular mechanism for the phenotypic differences between FLD and FED remains to be investigated.

Apo AI Genetic Mutations and Variations Affecting HDL Levels

Apo AI is the major apolipoprotein in HDL particles. The *apo AI* gene is located on chromosome 11 in a cluster with two other apolipoprotein genes, *apo CIII* and *apo AIV*. Various disruptions and mutations of the *apo AI* gene have been reported. Certain mutations cause complete deficiency of plasma HDL-C levels, also observed for *ABCA1* mutants or LCAT mutants. HDL-deficient patients with *apo AI* mutation do not usually show anemia, proteinuria, orange tonsils, or hepatosplenomegaly. Some mutations or variations in the *apo AI* gene are related to the phenotypic expression of amyloidosis.

Secondary Low HDL Syndromes

Metabolic Syndromes (e.g., Visceral Fat Syndrome, CD36 Deficiency, and Insulin-Resistance Syndromes)

Low HDL-C is often observed in patients with metabolic syndromes, including visceral fat syndrome, CD36 deficiency, and other insulin-resistance syndromes. Hypertriglyceridemia appears to stimulate the lipid exchange and accelerated catabolism of HDL protein. Reduced activities of plasma lipolytic enzymes cause loss of catabolism of TRL, which leads to a reduction of the source for generating new HDL particles. Patients with low HDL-C have a higher risk for CHD.

Inflammations

It is thought that HDL-C may be a negative marker for systemic or local inflammations. In some pathological conditions with chronic or acute systemic inflammation (e.g., severe infections and some hematological malignancy), HDL-C is reduced in association with an increase in serum amyloid A proteins. Some studies have indicated that low HDL-C may be a marker for cardiac events during short-term follow-up, associated with the increase in C-reactive protein.

Cholestatic Disorders

In obstructive liver diseases, plasma HDL-C levels may be markedly reduced to the same extent as in primary HDL deficiency. Plasma total cholesterol levels are usually increased in these states.

Medicines and Drugs

Some drugs, such as thiazides or probucol, are known to decrease plasma HDL-C levels. ProbucoL is a potent hypolipidemic drug that inhibits xanthoma formation even in patients homozygous for familial hypercholesterolemia and in Watanabe heritable hyperlipidemic rabbits.

HIGH HDL SYNDROMES

Primary High HDL Syndromes

Etiologies for high HDL syndrome are listed in [Table II](#).

Cholesteryl Ester Transfer Protein Deficiency

Patients with complete deficiency of CETP activity were found in Japan in the late 1980s. Homozygotes had extremely high plasma HDL-C levels (three to six times normal levels). Plasma levels of apo AI and AII

were increased. Plasma apo B and apo B-containing lipoproteins were relatively decreased. LDL and HDL from the homozygotes are abnormal biochemically and biologically. The HDL particles are large and cholesterol and apo E rich. The LDL particles are small, polydisperse, and apo B rich. The LDLs have reduced affinity for LDL receptors on the fibroblasts, and the HDL have reduced ability to mediate cholesterol efflux from the cells.

The first identified CETP gene mutation was an intron 14 splicing defect (*IN14*), which is a null mutation with a dominant effect on plasma CETP and HDL-C levels. A second CETP gene mutation was a missense mutation in exon 15 (*D442:G*). Both mutations are very common in the Japanese population. The effect of *D442:G* on plasma lipoproteins is less severe than that of *IN14*. Homozygotes for *D442:G* have moderately increased HDL levels. In other countries, some genetic variations have been reported to affect CETP mass and HDL-C levels.

There has been heated discussion about the atherogenicity of the genetic deficiency of CETP. We found a unique area (Omagari, Japan) where *IN14* accumulated. A population-based study in this area showed that there was a U-shaped relationship between HDL-C and the incidence of ischemic electrocardiographic changes. An evaluation of the relationship between CETP gene mutations and CHD in Japanese American men in the Honolulu Heart Program cohort also showed that the men, most of whom had a *D442:G* mutation, had increased risk of CHD. However, the atherogenic effect of CETP deficiency was observed in subjects with moderately

Table II Primary and Secondary High HDL Syndromes

Primary high HDL syndromes

- Cholesteryl ester transfer protein deficiency
- Familial hepatic triglyceride lipase deficiency
- Familial hyper-alpha lipoproteinemia with premature corneal opacity
- Familial hyper-alpha lipoproteinemia with overproduction of apoAI

Secondary high HDL syndromes

- Chronic massive alcohol intake
- Primary biliary cirrhosis
- Multiple lipomatosis
- Drugs
 - Estrogen
 - Corticosteroid
 - Fibrates
 - Nicotinic acid and its derivatives
 - HMG-CoA reductase inhibitor

increased HDL-C levels but not in subjects with marked hyperalphalipoproteinemia (HALP). Overall, CETP plays a crucial role in the reverse cholesterol transport to transfer cholesterol from HDL to apo B-containing lipoproteins. The transferred cholesterol is taken up by the liver via the LDL receptor-mediated pathway in humans.

Hepatic Triglyceride Lipase Deficiency

HTGL plays a role in the conversion of very low-density lipoprotein into intermediate-density lipoprotein (IDL) and LDL by its triglyceride lipase activity. This enzyme also has the function for the remodeling of large, triglyceride-rich HDLs into smaller ones. HTGL is reported to enhance the hepatic uptake of HDL lipid. There are several mutations in the HTGL gene. General features of human HTGL deficiency are increased IDL levels and increased large and TG-rich HDL particles. Some patients with HTGL deficiency are reported to have premature atherosclerosis.

Combined Reduction of CETP and HTGL

Several patients with a combined reduction in CETP and HTGL have been reported to suffer from CHD and corneal arcus. The impact of the combined reduction on atherosclerosis appears to be stronger than that of CETP deficiency alone. One of the possible mechanisms is that both CETP and HTGL play important roles in the remodeling of HDL particles from large to small particles, which are active for cholesterol efflux (Fig. 1). The combined reduction of these two proteins leads to the marked elevation of HDL-C, with the appearance of very large HDL particles, which are not active for cholesterol efflux from the cells.

Hyperalphalipoproteinemia with Increased Production of HDL

A family with marked hyperalphalipoproteinemia was reported to have overproduction of apo AI. The primary cause(s) is not known.

Secondary High HDL Syndromes

Chronic Alcohol Intake

It is well-known that chronic alcohol intake increases plasma HDL-C levels. Some enzymes and transfer proteins, such as CETP and HTGL, are altered in patients with massive chronic alcohol intake. The association between alcohol intake and mortality is U-shaped, suggesting that the beneficial effect of

alcohol intake is only observed in mild to moderate drinkers.

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is a primary cholestatic liver disease for which the primary defect is not known. In the end stage of this disorder, patients have very low HDL-C with the appearance of Lp X, similar to other obstructive or cholestatic liver diseases. In the early stage, patients with PBC often demonstrate high HDL syndrome. In some, HDL-C is markedly increased to the same extent as that in patients with genetic CETP deficiency. In contrast to CETP deficiency, both activities and protein mass of CETP are markedly increased, whereas HTGL is reduced in patients with PBC.

Medicines and Drugs

Some drugs, such as estrogen derivatives, fibrates, and statins, are reported to increase plasma HDL-C levels. Prospective studies using the fibrate gemfibrozil demonstrated that increases in HDL-C during treatment were correlated with the prevention of cardiac events.

SUMMARY

Prospective studies using fibrates have provided evidence that HDL-modifying treatments can reduce the incidence of atherosclerotic cardiovascular diseases. The enhancement of RCT has great potential as an antiatherosclerotic treatment and has been further supported by the identification of the novel molecular targets. On the other hand, the association between HDL-C levels and the incidence of cardiovascular disease is U-shaped but not linear, showing that neither an increase nor a decrease in HDL-C always indicate the atherogenicity in individuals. Methods to measure the number of active HDL particles, evaluate the efficiency and dynamics of RCT, and assess the stability of atherosclerotic lesions are required in order to pursue the previously discussed therapeutic approaches.

Luteinizing Hormone

see LH

potentially have significant effects on many processes involved in the pathophysiology of diseases such as diabetes, hypertension, myocardial infarction, and hypercholesterolemia. Magnesium also influences properties of cell membranes; this process is thought to occur by means of calcium channels and ion transport mechanisms. Calcium flux is inhibited by magnesium from sarcolemmal membranes, through competition for binding sites on actin, and via changes in the adenylate cyclase–cyclic AMP system. The calcium-antagonizing effects of magnesium are well known, and it is for this reason that magnesium has been described as the “nature’s calcium antagonist.” Magnesium is also responsible for the maintenance of transmembrane gradients of sodium and potassium. This is why patients with refractory hypokalemia will not respond to potassium supplementation until magnesium deficiency is corrected.

PATHOPHYSIOLOGY

There are three different biological mechanisms that explain the physiological effects of magnesium in hypertension, diabetes, and hyperlipidemia. First, dysregulation of Na^+ -dependent Mg^{2+} transport is associated with decreased intracellular Mg^{2+} and increased intracellular Na^+ , which may be important in the pathophysiology of hypertension. Second, a relatively low magnesium level creates an intracellular imbalance between calcium and magnesium that results in increased vascular tone in the smooth muscle of the artery and, therefore, in increased blood pressure. Third, magnesium deficiency causes insulin resistance, which in turn causes hyperinsulinemia, resulting in hypertension, diabetes, hyperlipidemia, and atherosclerosis.

MEASUREMENT OF MAGNESIUM

The easiest and most common way in which to assess magnesium status in the clinic is by the serum magnesium. This measures extracellular magnesium only and so has limited clinical usefulness. If a person has low serum magnesium, also known as hypomagnesemia, the person is definitely magnesium deficient, but many people with normal serum levels may be magnesium deficient. Total serum magnesium concentration in adults is between 0.75 and 0.96 mmol/L. This level, which constitutes a small fraction (0.3%) of body magnesium, is kept remarkably stable, even in the presence of intracellular magnesium depletion or overload. Accordingly, the serum magnesium level is not merely in equilibrium with intracellular

magnesium concentration, and it might not reflect intracellular magnesium status. Most cytosolic magnesium is bound to proteins and nucleotides or is sequestered into intracellular organelles. Only a small fraction is present in the free form, which is responsible for the biological actions of magnesium. Until recently, techniques used to determine intracellular magnesium (Mg^{2+}) included metallochromic indicator dyes, nuclear magnetic resonance, and Mg^{2+} -selective microelectrodes. Today, fluorescent probes that accurately measure cellular magnesium are available. Although this fluorescent approach is not used as a routine clinical tool, it has facilitated and enhanced understanding of magnesium regulation and homeostasis in health and disease.

CAUSES AND PREVALENCE OF MAGNESIUM DEFICIENCY

There are three main causes of magnesium deficiency and hypomagnesemia: decreased dietary intake and lack of magnesium in the water supply, alcoholism, and the use of thiazide diuretics.

The prevalence of hypomagnesemia has been found to vary widely, depending on the patient’s clinical condition. In a general population, 6.9% of patients were shown to be hypomagnesemic. In hospital inpatients on a medical–surgical floor, there was a prevalence of 11%, whereas in the intensive care unit (ICU), it was found to be 20%. In a postoperative ICU setting, the prevalence was 60%. A study of diabetic patients established a prevalence of 25%. Another prevalence study of magnesium levels for 120 patients in an urban minority clinic found that 24% of hypertensive patients and 25% of diabetic patients were hypomagnesemic.

EPIDEMIOLOGY

Numerous epidemiological studies have found an inverse relationship between magnesium in the drinking water and cardiovascular mortality. This association between magnesium in drinking water and ischemic heart disease was reconfirmed in a major review of the literature done by epidemiologists at Johns Hopkins University.

The largest epidemiological study of magnesium status was the Atherosclerosis Risk in Communities (ARIC) study. This was a 5-year longitudinal study that examined 15,000 patients and compared dietary magnesium, serum magnesium, and race with the prevalence of hypertension, diabetes, and atherosclerosis. The study controlled for the potential

confounding variables of age and body mass index (BMI). The results showed that African Americans had lower dietary magnesium intake along with lower serum magnesium levels, which significantly correlated with a higher prevalence of hypertension, diabetes, and atherosclerosis.

In a 10-year study, 400 high-risk individuals predisposed to coronary heart disease were divided into one group that received a magnesium-rich diet and another group that was placed on a “usual” diet. Increased dietary magnesium was shown to correlate with less sudden death, less total mortality, and lower incidence of hypokalemia and hypomagnesemia.

MAGNESIUM AND ETHNICITY

An extremely important unanswered question is whether magnesium deficiency, which is more prevalent in the African American community, is a contributing factor to the increased atherosclerosis and mortality rate in this population. Magnesium deficiency has been shown to be a cause of insulin resistance in numerous studies of rigorous methodology. Insulin resistance has been intimately linked to metabolic syndrome X, which is hypertension, diabetes, and hyperlipidemia.

The evidence that there is both an increased incidence of magnesium deficiency and insulin resistance in African Americans comes from various sources. The ARIC study was cited previously. In addition, Ford analyzed the data from the National Health and Nutrition Examination Survey (NHANES) and found that lower dietary magnesium was associated with increased hypertension. Humphries found in young black males that decreased intake of magnesium was associated with insulin resistance even in patients who were not diabetic. In a large study of African Americans, Manolio found an inverse relationship between serum magnesium and fasting insulin levels. As noted previously, African Americans with hypertension or diabetes have a 24 to 25% prevalence of hypomagnesemia.

CLINICAL SIGNS AND SYMPTOMS

Magnesium deficiency is almost always asymptomatic. There are no pathognomonic signs and symptoms of the magnesium-deficient state. The situation must be severe if clinical manifestations are to occur. This would also always be accompanied by low serum magnesium. Symptoms, when they do occur, generally fall into the categories of cardiac effects, metabolic effects, and neurological effects (Table I).

THERAPEUTIC USES OF MAGNESIUM

Intravenous magnesium remains the mainstay of the treatment of preeclampsia and eclampsia. It is also the drug of choice in the treatment of torsades de pointes. It is part of the Advanced Cardiac Life Support (ACLS) protocol to use magnesium for this condition.

Table I Clinical Manifestations of Severe Magnesium Deficiency

| |
|---------------------------------|
| Cardiac effects |
| Atrial fibrillation |
| Atrial flutter |
| Supraventricular tachycardia |
| Ventricular tachycardia |
| Torsades de pointes |
| Coronary artery spasm |
| Hypertension |
| EKG changes: |
| Prolonged PR interval |
| Widened QRS complex |
| Prolonged QT interval |
| Atherosclerosis |
| Metabolic effects |
| Hypokalemia |
| Hypocalcemia |
| Increased intracellular calcium |
| Hyponatremia |
| Increased intracellular sodium |
| Hypophosphatemia |
| Metabolic alkalosis |
| Hyperglycemia |
| Hypercholesterolemia |
| Neurological effects |
| Grand mal seizures |
| Focal seizures |
| Paresthesias |
| Dizziness |
| Vertigo |
| Ataxia |
| Nystagmus |
| Tremor |
| Myopathy |
| Dysphagia |
| Esophageal spasm |
| Delirium |
| Personality changes |
| Depression |
| Headaches |
| Migraines |
| Coma |

There are a number of epidemiological studies showing that low intake of magnesium is associated with decreased lung function. Therefore, it was thought that a bolus of intravenous magnesium would be helpful during moderate to severe asthmatic exacerbations. When this has been tested clinically, it showed only mild and short-lived symptom improvement and did not show a significant effect on pulmonary function.

While some small randomized controlled trials showed that intravenous magnesium was effective in reducing mortality in the immediate postinfarction period, the Magnesium in Coronary Artery Disease or MAGIC trial proved that it was ineffective for this purpose. The MAGIC trial was a large five-year multicenter randomized controlled trial sponsored by the National Institutes of Health in the United States. It showed that there was no difference in mortality or morbidity at 30 days whether or not intravenous magnesium was used.

There are a number of potential benefits of magnesium supplementation for patients with risk factors for atherosclerosis. In patients who are deficient, magnesium could reduce insulin resistance and have a major impact in decreasing morbidity and mortality. Magnesium is both safe and inexpensive. The most common side effect is gastrointestinal distress. The one clinical condition where magnesium should not be used is in patients with renal insufficiency; because magnesium is excreted through the kidney, there is the threat of magnesium overload in these patients.

Although a number of studies show an inverse relationship between magnesium in the water supply and coronary artery disease, the studies that have looked at oral magnesium supplementation for the treatment of various diseases show inconsistent results. When both magnesium and potassium were used together in patients with congestive heart failure and ventricular ectopy, there was a statistically significant reduction in ventricular arrhythmias.

There have been at least 11 randomized controlled trials looking at magnesium supplementation in hypertension. The largest of these studies, the Trial of Hypertension Prevention (TOHP), studied 698 patients for 6 months and found no benefit. This was a primary prevention trial rather than a therapeutic trial. It is possible that many of the patients were not magnesium deficient. Of the randomized controlled treatment trials, 7 showed a positive effect on blood pressure and 3 showed no effect. It was noted that the higher the dose of magnesium, the greater the likelihood of success. No trials that used less than 20 mmol of magnesium showed an effect,

whereas all trials using 40 mmol of magnesium were positive.

There have been two recent randomized controlled trials using magnesium supplementation in the treatment of diabetes. One used 15 mmol of magnesium per day. It found that many diabetics were intracellularly depleted of magnesium supply. Although this was corrected during the trial, there was no improvement in glycemic control. The trial lasted only 8 weeks long. Another trial that used varying doses of magnesium found no effect on glycemic control at the 20-mmol level but found a statistically significant effect at the 40-mmol level.

There has been only one major trial looking at the effect of magnesium on hyperlipidemia. It showed a statistically significant decrease in triglycerides and in the ratio of low-density lipoprotein (LDL) to high-density lipoprotein (HDL).

There have been two major dietary studies looking at high-magnesium diets. One of these was a 10-year cohort study with more than 400 patients comparing a high-magnesium diet to a low-magnesium diet. It showed a marked decrease in overall mortality, a marked decrease in cardiovascular disease, and a 50% reduction in sudden death. The other study was of the Dietary Approaches to Stop Hypertension (DASH) diet. This diet consists mainly of fruits, vegetables, low-fat dairy products, lean meats, fish, and whole grains. It is a diet that is high in potassium, magnesium, and calcium but that is low in sodium. It has been shown to effectively reduce blood pressure in both African Americans and Caucasians.

High magnesium in both the water supply and the diet has shown value in the prevention of cardiovascular disease and in the treatment of hypertension. The results of magnesium supplementation trials have been inconclusive because measuring intracellular magnesium is difficult and because the magnesium dose has been low and the studies have been of short duration.

CONCLUSIONS

Magnesium is a critical cofactor in numerous enzymatic reactions in the body, including the whole energy production cycle. It is an intracellular ion that is difficult to measure in a clinically useful way. Intravenous magnesium is the treatment of choice for pre-eclampsia and torsades de pointes. Contrary to this, randomized clinical trials have proven that intravenous magnesium is ineffective in the treatment of an acute myocardial infarction, and in an asthmatic

attack. A combination of potassium and magnesium does suppress ventricular arrhythmias in patients with congestive heart failure. Magnesium deficiency has been linked to insulin resistance, which is known to cause hypertension, diabetes, hyperlipidemia, and atherosclerosis. African Americans have a higher prevalence of magnesium deficiency than do Caucasians. High-magnesium diets, such as the DASH diet, should be recommended for the entire population for the prevention of cardiovascular disease. This diet has also been shown to reduce blood pressure regardless of a patient's ethnicity. Clinical trials with magnesium supplements in the treatment of hypertension, diabetes, and hyperlipidemia have been inconclusive. The reason is that intracellular magnesium is difficult to measure in a clinically useful way, and previous studies have had doses of magnesium that were too low and for too short a duration. Further studies with higher doses of magnesium for a longer period of time need to be done before it can be determined definitively whether magnesium is useful in the treatment of hypertension, diabetes, and hyperlipidemia.

coordinated fashion during intracellular signal transduction. Acting as a second messenger system, the G protein complex is activated when a ligand binds to its receptor, stimulating an exchange of bound guanosine diphosphate (GDP) for guanosine triphosphate (GTP) on the surface of the $G\alpha$ -subunit. The $G\alpha$ portion subsequently stimulates adenylate cyclase, leading to intracellular cyclic AMP (cAMP) accumulation and downstream gene transcription. Intrinsic GTPase activity within the $G\alpha$ -subunit serves to hydrolyze GTP, allowing for a restoration of bound GDP and completion of the signaling cycle. In McCune–Albright syndrome, the completion phase of this cycle is destabilized, resulting in a signaling pathway that becomes and remains “turned on” in an unregulated and autonomous fashion, as shown in Fig. 2. This phenomenon, known as “constitutive activation,” leads to hyperfunction and proliferation of affected cells. G protein-mediated cell signaling is ubiquitous within endocrine glands as well as in many additional cell types, including those found in bone, liver, skin, and heart. Thus, patients with McCune–Albright syndrome may exhibit a myriad of endocrinopathies and other forms of systemic involvement in addition to the classic triad of features that are most commonly present. Therefore, it is important to conceptualize the disorder as existing within a broad spectrum of potential phenotypic manifestations. Both classic and variant forms of McCune–Albright syndrome are reviewed in the next section.

CLINICAL FEATURES

The precise incidence of McCune–Albright syndrome is unknown, but it is quite rare. At any given time, pediatric endocrine groups in large academic medical centers around the country typically report that they are caring for anywhere from zero to four patients with the disorder. Manifestations of the disease may arise during the neonatal period or at any time during childhood and adolescence. Failure to recognize

features of the disease resulting in a delay in diagnosis is a common problem. Although the true sex ratio is unknown, McCune–Albright syndrome has been reported far more frequently in girls than in boys.

Classic McCune–Albright Syndrome

The combination of precocious puberty, café au lait pigmentation, and fibrous bone dysplasia constitutes the enduring hallmarks of this disease. However, a significant percentage of patients will develop endocrinopathies above and beyond precocious puberty. Therefore, these additional endocrine problems will be considered in conjunction with the other classic features.

Precocious Puberty

The diagnosis of McCune–Albright syndrome is most commonly made following the appearance of precocious puberty. Typically described in girls, a sudden onset of vaginal bleeding is heralded or accompanied by acute breast enlargement. These physical changes are due to autonomous ovarian function characterized by the development of large cysts producing high serum levels of estrogen. Once these cysts resolve, the estrogen withdrawal results in a shedding of the endometrial lining and spontaneous bleeding. The first such episode in girls with McCune–Albright syndrome usually occurs between 1 and 6 years of age, although it may become apparent as early as 4 months of age. The frequency with which subsequent episodes arise is unpredictable and quite varied. Whereas some girls experience extended intervals of ovarian quiescence, others go on to develop recurrent episodes of ovarian hyperfunction with frequent menses. In these cases, additional manifestations of precocious puberty include the appearance of pubic and axillary hair, accelerated growth, and skeletal maturation. Ultimately, untreated progressive precocious puberty results in premature closure of growth plates with significant short stature during adulthood. The precocious puberty observed in boys with McCune–Albright syndrome originates from an analogous hyperfunction of the testes, leading to episodic elevations in serum testosterone levels and the early appearance of secondary sexual characteristics. In both sexes, this premature production of sex steroids is categorized as a form of “peripheral precocious puberty,” indicating that it represents a physiological process outside of the central nervous system pathways through which pubertal development is normally mediated.

Reports of ovarian function during the postpubertal period in McCune–Albright syndrome are

Figure 2 G protein-mediated signal transduction. Panel A depicts the heterotrimeric G protein in the quiescent state, with GDP complexed with the G α -subunit. On ligand binding (B), GDP is exchanged for GTP and the α -subunit dissociates from $\beta\gamma$. Activation of adenylate cyclase (C) results in cAMP formation, leading to downstream gene transcription. In McCune–Albright syndrome, intrinsic GTPase activity within G α is defective (D), rendering the cell cycle turned “on” independent of ligand binding.

inconsistent. Although regular menstrual cycles and normal fertility have been reported in some women, there is also evidence that episodic autonomous ovarian activity persists in many patients. Thus, adolescent and adult women with the disorder may experience irregular periods and occasional prolonged vaginal bleeding.

Other Endocrinopathies

The propensity to additional endocrine abnormalities is a feature of McCune–Albright syndrome. In each of these cases, the underlying mechanism relates to excessive cellular function from increased intracellular cAMP formation. Affected endocrine glands exhibit a surplus of hormone production and evidence of cell

proliferation. The most frequently encountered endocrinopathy (after precocious puberty) is hyperthyroidism, usually accompanied by an enlargement of the thyroid gland. Somewhat less common is the development of pituitary growth hormone excess, which may also be associated with increased prolactin and causes gigantism if it arises prior to closure of the skeletal growth plates. Rarely, an excess of the adrenal steroid hormone cortisol may occur, resulting in a disorder known as “Cushing syndrome.” Other infrequently reported endocrine problems include hyperparathyroidism and hypophosphatemic rickets. Therefore, periodic testing of blood hormone levels for the early detection of endocrinopathies is a routine part of ongoing follow-up for affected patients. The

Table 1 Additional Endocrine Problems Described in Patients with Classic McCune–Albright Syndrome

| Endocrine abnormality | Estimated incidence | Clinical features | Laboratory features |
|--------------------------|---------------------|--|---|
| Hyperthyroidism | 30–40% | Multinodular goiter | Elevated serum thyroxine and triiodothyronine with suppressed thyroid-stimulating hormone |
| Growth hormone excess | 15–20% | Pituitary hyperplasia or adenoma, resulting in gigantism or acromegaly | Elevated serum growth hormone and insulin-like growth factor I |
| Cushing syndrome | 2–5% | Nodular adrenal hyperplasia | Elevated serum cortisol with low adrenocorticotrophic hormone |
| Hypophosphatemic rickets | 2–5% | Rachitic bone changes | Low serum phosphorous |
| Hyperparathyroidism | Very rare | Parathyroid adenoma or hyperplasia | Elevated serum and urine calcium |

incidence and clinical features of the endocrine manifestations of McCune–Albright syndrome above and beyond precocious puberty are summarized in Table 1.

Café au Lait Pigmentation

The spectrum of the skin pigmentation exhibited by an affected patient ranges from small discreet birthmarks to dramatic involvement of an entire limb or side of the body. These flat areas are usually faint at birth and become darker and more obvious over time. As implied by the name, the color of these regions is often similar to that of “coffee with milk,” although they may be darker, depending on the baseline skin tone. Often ending abruptly at the midline, the areas of increased pigmentation follow the outgrowth of distinct cell populations during early embryological development, a pattern designated as the “lines of Blaschko.” Another consistent finding is an irregular border configuration reminiscent of a rocky shore and described as the “coast of Maine,” in contrast to the “coast of California” café au lait birthmarks featured in other disorders such as neurofibromatosis. Investigation of biopsied skin cells from these areas has confirmed that the pigmentation is due to increased melanin production within melanocytes containing the activating $Gs\alpha$ mutation. Figure 3 illustrates the typical appearance of café au lait pigmentation in a patient with McCune–Albright syndrome.

Fibrous Dysplasia of Bone

Of the triad of clinical features observed in McCune–Albright syndrome, the bone disease carries the greatest potential for morbidity. Fibrous bone dysplasia consists of skeletal lesions in which normal tissue has been replaced by abnormal fibrous bone that may take a variety of forms, depending on the location. These abnormal areas may arise anywhere within the body but are most commonly found in the long bones and skull, with multiple sites of involvement being

typical. The destruction of normal bone that occurs in the limbs leads to an increased rate of fracture, potentially severe deformities, bone pain, and decreased mobility. Also debilitating are areas of bony overgrowth involving the face that may even result in hearing loss or blindness from impingement of nerve fibers that traverse the skull. As expected, the fibrous dysplasia is caused by the presence of the $Gs\alpha$ mutation within bone-forming cells. With time, both the number and the severity of bone lesions in McCune–Albright syndrome tend to progress, rendering many affected patients confined to wheelchairs by middle adulthood.

Nonclassic McCune–Albright Syndrome

Nonclassic varieties of the disease may be thought of as those in which the prototypical activating mutation is present in an atypical distribution. This may take the form of an isolated tissue bearing the abnormal $Gs\alpha$ protein, an unusual combination or subset of the classic triad, or extremely widespread involvement with multisystemic consequences. Each of these possibilities is described in the following subsections.

Figure 3 Characteristic appearance of a café au lait spot in a patient with McCune–Albright syndrome.

Isolated $G\alpha$ Mutation

It has now been recognized that the same mutation that causes McCune–Albright syndrome also has an important role in the genesis of a number of sporadic tumors that may arise within endocrine glands. In this context, the activating $G\alpha$ mutation is referred to as *Gsp*, an “oncogene,” in view of its action as a genetic switch resulting in abnormal cellular growth and neoplastic transformation. Rare tumors of the thyroid gland, anterior pituitary, testes, and adrenal glands in which this mutation has been found have all been described.

Forme Fruste McCune–Albright Syndrome

Another context in which an isolated $G\alpha$ mutation is known to occur is in patients exhibiting an apparent isolated feature of the syndrome. Thus, individuals with isolated fibrous bone dysplasia, isolated recurrent ovarian cysts, and isolated café au lait pigmentation all have been demonstrated to harbor the same activating mutation as that found in the classic form of the disease. In a related scenario, cases have been described in which only one or two of the three classic manifestations are present, a situation recognized as a forme fruste variant of the disorder. Similarly, variations on the theme of the classic triad in which a slightly different cell type or endocrine gland is involved are also possible. Given the multitude of tissues in which the mutation may occur, the numbers of possible “faces” of McCune–Albright syndrome are seemingly endless.

Multisystemic Involvement

In a few rare cases, widespread distribution of the $G\alpha$ mutation has resulted in a devastating, multisystemic form of the disorder. In these patients, the presentation occurs during the neonatal period. Because the classic features are often lacking, however, there is usually a delay in making the diagnosis. Clinical findings in these infants have included severe liver disease, multiple endocrinopathies, heart failure, and even sudden death. It is assumed that these cases represent instances in which the activating mutation occurred very early in embryological life, leading to numerous involved areas within the body. A germline mutation, in which every cell would be expected to have the abnormality, has never been described and would presumably be lethal.

TREATMENT OF MCCUNE–ALBRIGHT SYNDROME

The development of effective and safe therapeutic interventions for the various aspects of McCune–Albright syndrome is an ongoing and evolving

challenge. Only with the remote possibility of gene therapy could a cure for the disease ever be envisioned. A number of established palliative treatment options exist, and several novel approaches that may significantly improve the prognosis and quality of life for patients with McCune–Albright syndrome are under investigation. Historic and potential new therapeutic modalities for each of the classic features of the disease are reviewed in this section.

Treatment of Precocious Puberty

Treatment of precocious puberty is typically reserved for patients with evidence of the progressive form of the condition. Thus, a period of observation is obligatory in all children following the initial episode. In girls with a clinical course for which intervention is indicated, the mainstay of treatment is pharmacological, although surgical removal of the ovaries or ovarian cysts has been performed in some cases. The goals of therapy are to halt progression of pubertal development, prevent vaginal bleeding, and retard the advanced rate of skeletal maturation that will compromise a child’s ability to achieve a normal adult height. Until recently, the greatest success had been obtained with the use of the aromatase inhibitor, testolactone, typically at a dose of 40 mg/kg/day. By decreasing the aromatization of androgens to estrogens, the physiological effect of the autonomous ovarian activity was attenuated in some patients receiving this therapy. However, recent evidence has indicated that improved efficacy may be achieved with the use of tamoxifen (10–30 mg/day), an antiestrogen with tissue-specific stimulatory and inhibitory actions at the level of the estrogen receptor. As experience with the use of this medication for the treatment of precocious puberty in McCune–Albright syndrome continues to grow worldwide, in some cases it is becoming first-line therapy for the disorder. Also under development at this time are a number of additional drugs, including more potent aromatase inhibitors, pure antiestrogens, and pure antiandrogens. It remains to be seen whether any of these agents will ultimately prove to be beneficial in the treatment of children with precocious puberty and McCune–Albright syndrome.

Treatment of Café au Lait Pigmentation

Because the impact of the skin pigmentation in McCune–Albright syndrome is essentially cosmetic, this feature of the disorder is typically the least of

the patient's and parents' concerns. However, in cases where extensive involvement of frequently exposed skin is present, therapeutic options primarily revolve around the use of laser technologies.

Treatment of Fibrous Bone Dysplasia

Historically, the only therapeutic approach available for the treatment of fibrous bone dysplasia was surgical. Internal rod placement, bone grafting, and curettage have traditionally been reserved for the most severely affected individuals. However, the outlook for patients with McCune–Albright syndrome suffering from symptomatic fibrous dysplasia has brightened considerably during recent years. This is due to the emergence of the bisphosphonates as a promising medical therapy for the disease. In studies conducted previously, short-term administration of the bisphosphonate pamidronate in both children and adults with fibrous dysplasia resulted in a significant decrease in fracture rate and bone pain as well as a concurrent increase in bone mineral density without apparent side effects. If substantiated over time, these results represent a truly remarkable therapeutic breakthrough with the potential to substantially improve the quality of life for many patients with McCune–Albright syndrome.

CONCLUSION

Wonderful strides have been made in the knowledge and understanding of McCune–Albright syndrome. The identification of an activating G_{α} mutation has afforded valuable insights into normal and abnormal human cellular function, and the development of new therapies continues to improve clinical management. Future collaborative efforts will focus on a determination of the natural history of disease, clarification of remaining enigmas regarding molecular genetics, and designation of optimal treatment strategies for all aspects of McCune–Albright syndrome.

Figure 1 Schematic presentation of the origin of medullary thyroid carcinoma. (A) C cells are located below the basal membrane (arrow). (B) The diagnosis of C-cell hyperplasia is based on the presence of an increased number of C cells (i.e., ≥ 7 cells per follicle). (C) In medullary thyroid carcinoma, proliferating C cells are growing through the basal membrane.

11 (11p15.3–15.5). The primary transcript (pre-mRNA) of this gene is subject to tissue-specific alternative splicing (see Fig. 3). In the thyroid C cells, CT-mRNA of approximately 1000 nucleotides (exons 1–3 and 4) encodes the CT precursor (prepro-CT) of 141 amino acids. In neuronal cells, exons 1 to 3 are coupled to exons 5 and 6, generating an mRNA of approximately 1100 nucleotides encoding the 128-amino acid precursor for calcitonin gene-related peptide-I (CGRP-I). CGRP-I is widely distributed in the nervous system and particularly in the primary sensory neurons, where it functions as a neurotransmitter.

In 1985, a related gene was identified that encodes a polypeptide highly homologous to CGRP-I, named CGRP-II, but not encoding a CT-like molecule. These two CALC genes (CALC for calcitonin complex) and a pseudogene (CALC-III) all are located in the same region of chromosome 11, suggesting that local duplication of a common ancestral gene is the mechanism of their origin. In 1988, a fourth member of the CALC gene family was identified encoding the constituent protein of amyloid fibrils present in pancreatic islets of patients with diabetes mellitus type 2; therefore, it was named islet amyloid polypeptide (IAPP).

Another member of the CT superfamily was discovered in the medulla of adrenal glands and was named adrenomedullin (ADM). This protein functions as a vasorelaxant, and the ADM gene can be considered as the fifth member of the CALC gene family (see Fig. 4).

The members of the CT superfamily act via heterotrimeric G protein-linked, seven-transmembrane domain receptors coupled to cyclic AMP (cAMP) formation and phospholipase C activation. Two isoforms of the human CT receptor have been identified, named hCTR1 and hCTR2. The CGRP receptor

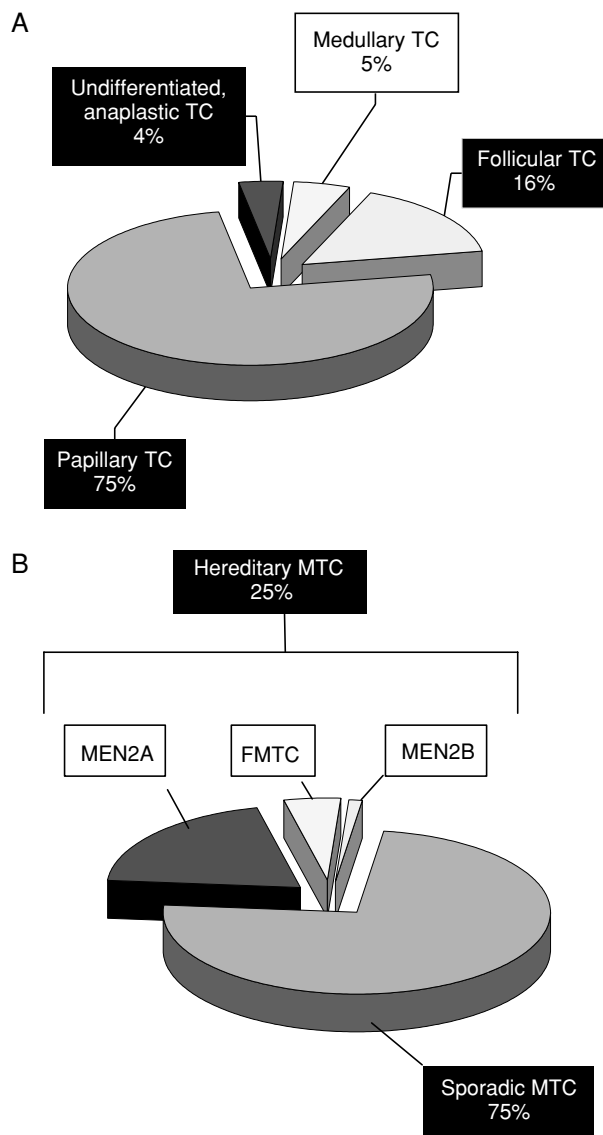

Figure 2 (A) Classification and relative frequency of thyroid carcinoma (TC). (B) Sporadic versus hereditary medullary thyroid carcinoma (MTC).

has approximately 55% homology with hCTR2 and was named CT-receptor-like receptor (CRLR). Recently, receptor activity-modifying proteins (RAMPs) have been identified; these are single-transmembrane domain proteins acting as coreceptors that specify selectivity of hCTR2 for CT or IAPP and selectivity of CRLR for CGRP or ADM.

MTC AND THE RET PROTO-ONCOGENE

MEN 2 is an autosomal-dominantly inherited disease caused by activating missense mutations in the RET

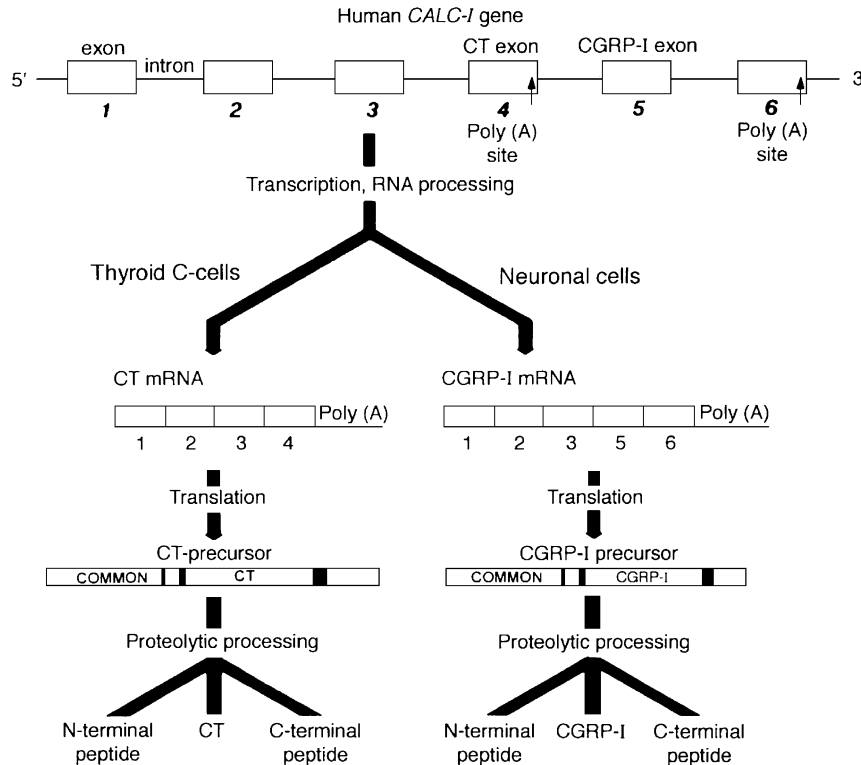

Figure 3 Alternative expression of the *CALC-I* gene. Schematic representation (not drawn to scale) depicts the human *CALC-I* gene, consisting of six exons and five introns and illustrating the generation of calcitonin (CT) mRNA, calcitonin gene-related peptide-I (CGRP-I) mRNA, and their encoded polypeptides. Exons 1 and 6 are noncoding, exons 2 and 3 encode the amino-terminal polypeptide common to the CT precursor (pro-CT) and CGRP-I precursor, and exons 4 and 5 contain the sequences encoding CT and CGRP-I, respectively, plus the carboxy-terminal polypeptides of the CT- and CGRP-I precursors. In thyroid C cells, exons 1 to 3 are coupled to exon 4, generating CT mRNA, whereas in neuronal cells, exons 1 to 3 are coupled to exons 5 and 6, generating CGRP-I mRNA.

proto-oncogene. The RET protein is a member of the family of receptor tyrosine kinases, which are cell surface glycoprotein receptors that transduce signals for cell growth and differentiation. The RET protein consists of an extracellular part with a ligand-binding domain, a cadherin (Ca^{2+} -dependent cell adhesion)-like domain, and a cysteine-rich domain close to the cell membrane. It has a single-transmembrane domain and an intracellular part with two tyrosine kinase subdomains: TK1 and TK2. Activation of RET occurs by the binding of one of its four ligands: glial cell line-derived neurotrophic factor (GDNF), neurturin (NTN), artemin (ARTN), or persephin (PSPN), each of which requires its specific coreceptor GDNF family receptor- α -1,-2,-3, or-4 (GFR- α -1, GFR- α -2, GFR- α -3, or GFR- α -4), respectively (Fig. 5). Interaction of these molecules results in dimerization of RET, cross-autophosphorylation, and subsequent phosphorylation of intracellular substrates. RET is expressed in many cell types, including the C cells of

the thyroid gland and adrenal medulla, and in neurons.

The MEN 2 phenotype is caused by missense mutations affecting cysteine codon 609, 611, 618, or 620 in exon 10 or cysteine codon 630 or 634 in exon 11 of the RET gene (Fig. 6). Mutations in the cysteine codons in exon 10 can also result in FMTC. If cysteine codon 634 in exon 11 is mutated, all organ manifestations of MEN 2A occur, that is, MTC, pheochromocytoma, and hyperparathyroidism. These extracellular MEN 2A/FMTC cysteine mutations lead to a ligand-independent dimerization of receptor molecules and constitutive activation of intracellular signaling pathways. The MEN 2B-associated tumors are caused by mutations in the intracellular TK2 domain (in 95% of the cases involving amino acid 918 and in 5% of those involving amino acid 883 or 922). In more than 50% of cases of MEN 2B with RET codon 918 affected, mutations occur as new (*de novo*) germline mutations.

Figure 4 The CALC family. Schematic comparison depicts the structure of the CALC-I to -III genes, the islet amyloid polypeptide (IAPP) gene, and the adrenomedullin (ADM) gene. Exons are represented by numbered boxes, with the hatched parts indicating the protein-encoding parts. Shown in black are the parts encoding mature calcitonin (CT), calcitonin gene-related peptide (CGRP), IAPP, and ADM molecules. Spotted boxes indicate "pseudo-exons" with homology to exon 2, 3, or 4 of the CALC-I gene. Percentages of identity in amino acid sequences with those of polypeptides derived from the corresponding regions of the CALC-II gene are indicated.

Approximately 75% of all MTCs are sporadic and solitary in origin (Fig. 2B). In approximately 40% of such tumors, a somatic mutation at codon 918 of the RET gene is present. In 15% of sporadic MTCs, a specific germline variant ($-193C > G$) in the gene encoding the RET coreceptor GFR- α -1 was present, and this was associated with increased expression of GFR- α -1.

NATURAL HISTORY OF MTC, GENOTYPE-PHENOTYPE CORRELATION, AND CLINICAL COURSE OF THE DISEASE IN FAMILIES UNDER SURVEILLANCE

C-cell hyperplasia is generally considered as a precursor to MTC in patients with hereditary MTC. The diagnosis of C-cell hyperplasia is based on microscopy criteria: the presence of an increased number of diffusely scattered C cells (≥ 7 per thyroid follicle), clusters of C cells, or 20 or more C cells per (visual) field at a magnification of $\times 200$. MTC is diagnosed when nests of C cells appear to extend beyond the basement membrane and to infiltrate and destroy thyroid follicles.

In investigating the natural history of the disease, large MEN 2 families have to be studied over six or

seven generations retrospectively, so that members who were obligate disease gene carriers and who had no intervention can be identified. Extensive studies on large families reveal that there is a clear genotype-phenotype correlation. In four large MEN 2A families with a RET codon 634 mutation, before clinical screening started, the average life span of obligate disease gene carriers (who died of extensive MTC metastases) was 48 years, compared with 60 years in FMTC families with a cysteine codon 618 mutation of the RET gene. Pheochromocytomas and parathyroid gland adenoma do occur in apparent FMTC families, but they occur less often than in MEN 2 families. Thus, although the distinct clinical course of the disease in a family (frequency of pheochromocytoma and parathyroid gland adenoma and life expectancy) depends primarily on the specific RET gene germline mutation that is present, screening for other endocrinopathies is mandatory in all families with MTC.

Periodic examination of family members revealed that the age of conversion from normal to elevated plasma CT levels during a C-cell stimulation test was 18 to 31 years (mean 23 years) in FMTC families, compared with 6 to 33 years (mean 16 years) in MEN 2 families.

Although the course of disease in FMTC families with a cysteine codon 618 mutation in the RET proto-oncogene is milder than that in MEN 2A families with a cysteine codon 634 mutation, patients with extensive metastases and an aggressive and unfavorable course of the disease may occur in all such families, irrespective of the nature of the RET mutation. Progression of the disease probably depends on additional somatic mutations in other proto-oncogenes and/or tumor suppressor genes. Individual habits, such as diet and smoking as well as the environment and pollution, may promote the occurrence of these additional mutations.

There is greater morbidity and mortality in MEN 2B than in MEN 2A. The survival curves of patients with MEN 2B are similar to those of patients with sporadic MTC who have somatic RET mutations identical with the most common germline mutations causing MEN 2B.

CT MEASUREMENT IN PATIENTS WHERE C-CELL HYPERPLASIA AND/OR MTC ARE SUSPECTED

The main secretory product of MTC is CT; therefore, CT can be used as a tumor marker. In all patients with

Figure 5 Model for the function of the normal (A, B) and MEN 2-mutated (C, D) RET tyrosine kinase receptor-protein complex. (A) In the absence of a ligand (L), both tyrosine kinase receptor RET and coreceptor GFR α are present in a nondimerized form. Activation of the RET protein and of the tyrosine kinase signal transduction pathway does not occur. (B) If a ligand (a member of the GDNF family of neurotropic peptides) is available, interaction with its specific coreceptor will occur. Consequently, the coreceptor will interact with the RET protein. Subsequently dimerization and autophosphorylation of the RET protein occurs, and the tyrosine kinase signal transduction pathway will be activated. As a result, signals for cell growth and differentiation are transduced to the nucleus. (C) Specific mutations (e.g., Cys634Arg in the extracellular cysteine-rich domain of the RET protein) may promote dimerization of the RET protein, independent of the binding of a ligand with its coreceptor. The RET mutation results in continuous autophosphorylation and activation of the tyrosine kinase signal transduction pathway. (D) Other specific mutations (e.g., Met918Thr in the intracellular tyrosine kinase domain of the RET protein) cause autophosphorylation and activation of the tyrosine kinase signal transduction without dimerization of the RET protein. GDNF, glial cell line-derived neurotropic factor; GFR α , GDNF family receptor α ; P, phosphate residue.

progressive disease, both basal and stimulated plasma CT levels are elevated, whereas in patients with early MTC, CT levels may be elevated only after stimulation of CT release from the C cells. The calcium sensor is expressed in normal C cells; therefore, calcium may regulate secretion of CT. Other CT secretagogues include glucocorticoids, CGRP, glucagon, enteroglucagon, gastrin, pancreaticozym, and beta-adrenergic agents. There is a wide range of C-cell

stimulation test procedures. Results depend on the stimulus used (calcium and/or pentagastrin [PG], the dose, the period of infusion, and the time point of sampling). The standard provocative tests use PG (0.5 μ g/kg body weight intravenously over 5 s) or a rapid infusion of calcium gluconate (2.5 mg/kg over 30 s). Blood samples are obtained at baseline and 1, 2, and 5 min after the stimulus. Some experts believe that the two tests should be combined for maximal

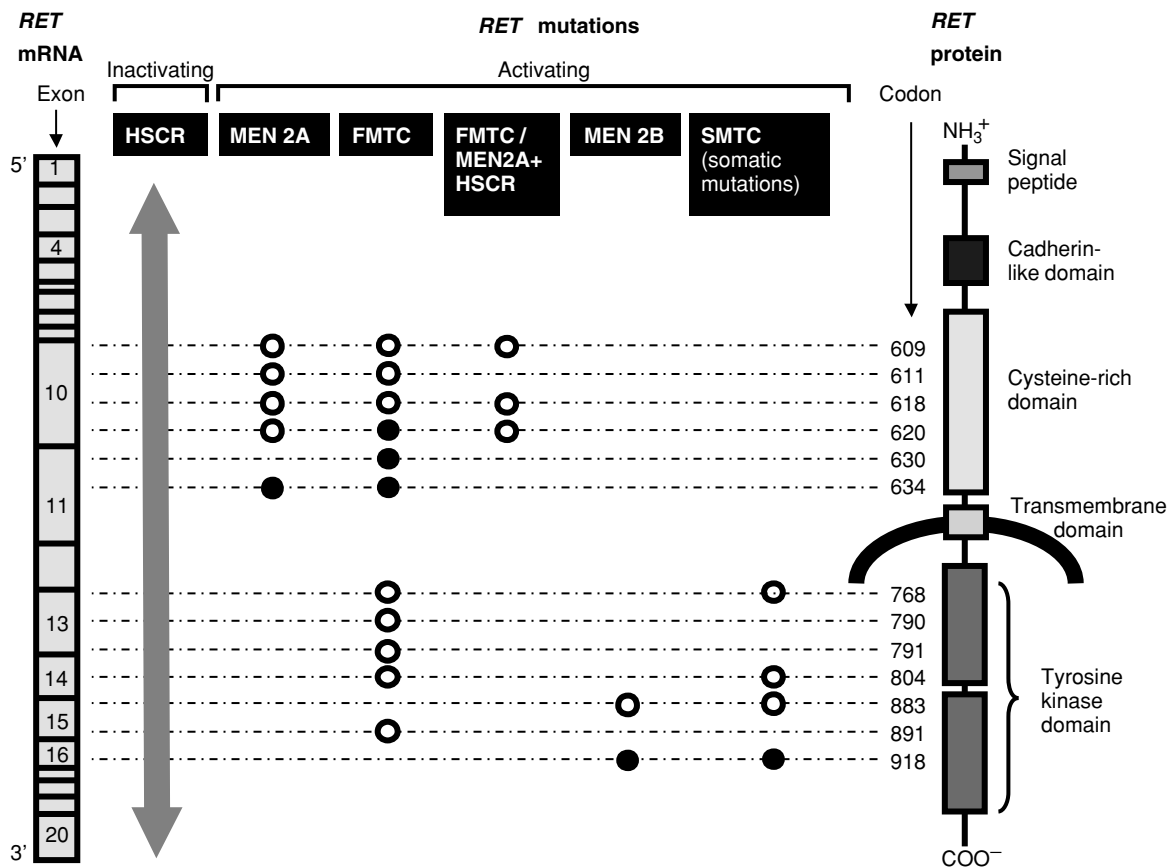

Figure 6 Genotype–phenotype correlations in MTC associated with mutations in the RET proto-oncogene. Figure depicts an overview of mutations in the RET proto-oncogene and associated diseases. Structure of the RET mRNA (left) and the RET protein (right) are depicted schematically (exons and domains are not to scale). For each disease, the responsible mutations and their locations are depicted. Closed circles represent the most frequently observed mutations, whereas open circles represent mutations that are less frequently observed.

sensitivity. In addition, the test results depend on the age, sex, and condition of the research participant tested (fasting state). All infusion procedures may give false-negative results, and with none of the procedures is it possible to recognize very early MTCs, that is, to discriminate between C-cell hyperplasia and micro-MTC. False-positive results (i.e., of research participants without MTC but only C-cell hyperplasia) also occur. In progressive disease, anaplastic dedifferentiation of MTC may decrease CT production and, as such, the utility of CT as a tumor marker.

OTHER TUMOR MARKERS FOR MTC

Besides CT, a number of other substances may be produced by MTC (e.g., carcinoembryonic antigen [CEA], katalcalcin [PDN-21, the carboxy-terminal peptide of the CT precursor], CGRP, IAPP, chromogranin

A, neuron-specific enolase [NSE], somatostatin, adrenocorticotrophic hormone [ACTH], ghrelin), but they are of little value in the diagnosis of MTC. Some MTC metastases do not produce either CT or CEA.

CT MEASUREMENT COMPARED WITH DNA ANALYSIS IN FAMILIES WITH MTC

DNA analysis for the detection of mutations in the RET gene (e.g., by direct nucleotide sequence analysis or mutation-scanning techniques such as single-strand conformation polymorphism [SSCP] analysis) is a highly specific method for the identification of individuals with familial MTC. Because of the high specificity and sensitivity of mutation detection in the RET gene, therapeutic decisions can be based on the results of

Table I Criteria for DNA Analysis of the RET Gene

DNA analysis even in asymptomatic family members with negative C-cell stimulation test results. RET mutation analysis is very useful as a means of excluding genetic susceptibility to the development of MTC and, therefore, as a means of ensuring unaffected family members that further screening with biochemical tests can be abandoned safely (see [Table I](#)).

The use of the DNA test has revealed the limitations of the C-cell stimulation test. DNA analysis can identify patients who have MTC but who do not (yet) have elevated plasma CT levels in C-cell stimulation tests. We have identified a number of young MEN 2 gene carriers with MTC, and not just C-cell hyperplasia, who had normal CT levels. On the other hand, some family members who were later proved not to be disease gene carriers had positive C-cell stimulation tests and so underwent total thyroidectomy. They had C-cell hyperplasia, which occurs in normal individuals at a frequency of approximately 5% (i.e., false-positive C-cell test results). Thus, this plasma CT response to C-cell stimulation does not always distinguish physiological C-cell hyperplasia from pathological micro-MTC, a finding that limits the value of the C-cell stimulation test so far as detecting the presence of MTC is concerned (see [Table II](#)).

PREOPERATIVE SCREENING FOR MTC

In the assessment of at-risk individuals, the DNA test is the gold standard, and a positive result is a sufficient indication for recommending surgery. If an asymptomatic carrier rejects preventive treatment, periodic C-cell stimulation tests are indicated. However, the latter cannot discriminate between C-cell hyperplasia and micro-MTC. Waiting for conversion of stimulation test results from a normal plasma CT level to an elevated level involves the risk of residual carcinoma and/or metastases after surgery and recurrence of the disease.

SURGERY OF MTC

The treatment for a patient with MTC is surgery. The appropriate procedure is total thyroidectomy and careful lymph node dissection of the central compartment of the neck. Disease gene carriers may be divided into three risk groups, depending on the nature of the predisposition to familial MTC. The highest risk concerns children with a predisposition to MEN 2B, most commonly associated with a germline RET mutation in codon 883, 918, or 922. Total thyroidectomy and central neck dissection during the first year of life are advocated by some because early metastasis of MTC has been reported, but others prefer to delay surgery until these children are older (approximately 5 years of age). The second highest risk group includes carriers in kindreds with a mutation in codon 611, 618, 620, 634, or 891. Such family members should undergo a total thyroidectomy, as well as a central node dissection, before 6 years of age. A lower risk is involved in carriers with a codon 609, 768, 790, 791, or 804 germline mutation. In general, MTCs in these patients develop at a later age, grow more slowly, and behave less aggressively. In this group, surgery may be postponed until an abnormal response to a calcium or PG stimulation test is observed (see [Table III](#)).

Table II Dependence of Periodic Clinical Examination Recommended to MEN 2 Disease Gene Carriers on the Specific DNA Mutation in the RET Gene

| Type of tumor | Clinical test |
|--|---|
| MTC | |
| Prior to and after total thyroidectomy | Annually plasma CT levels |
| Pheochromocytoma | |
| RET codon 634 or 918 | • From the age of 5 years: Annually metanephrines in 24-h urine |
| 609, 611, 768, 804 or 891 | • From the age of 10 years: Every 2 years metanephrines in 24-h urine |
| Hyperparathyroidism | |
| RET codon 634 | • Annually Ca, chloride, phosphate |
| 609, 611, 618, 620, 790 or 791 | • From the age of 10 years: Every 2 years Ca, chloride, phosphate |

Table III Dependence of Indication for Total Presymptomatic Thyroidectomy in MEN 2 or Familial MTC on the Specific DNA Mutation in the RET Gene

| Degree of malignancy | Mutated RET codon | Age at surgery |
|----------------------|----------------------------|---|
| 1 | 883, 918, or 922 | Early in the first year of life |
| 2 | 611, 618, 620, 634, or 891 | Before 6 years of age |
| 3 | 609, 768, 790, 791, or 804 | After abnormal C-cell stimulation test result |

Classification of MTC is based on the pathological tumor, node, metastases system (pTNM). Patients with stage I (tumor restricted to the thyroid gland and diameter <1 cm) or II (tumor locally invasive and >1 cm) and complete tumor resection have the best prognosis and are at minimal risk for death from MTC. However, MTC readily invades the intraglandular lymphatics and spreads to other parts of the gland as well as to pericapsular and regional lymph nodes (stage III). Patients with nodal metastases have a high risk of recurrence of the disease. Patients with stage IV have distant metastases (lungs, liver, and bones) and a high risk of death from MTC (see Table IV).

POSTOPERATIVE FOLLOW-UP

What degree of increase in plasma CT concentration must be considered as indicating metastases in patients after thyroidectomy? In MTC patients, preoperative CT levels appear to be predictive of tumor size and postoperative CT normalization. When preoperative CT peak levels after C-cell stimulation were less than 50 ng/L, only 1 of 45 patients had increased plasma CT levels after surgery. Interestingly, a correlation also was found between plasma CT peak levels and tumor size, defined as the largest diameter of the largest tumor, in hereditary MTC. Patients with undetectable basal and stimulated plasma CT levels within 24 h after surgery are those having the best prognosis, and they require no further treatment. Even after satisfactory postoperative results, all patients need lifelong follow-up, at least annually, for

monitoring thyroxin replacement therapy and measuring fasting (basal) CT levels. The question arises as to whether C-cell stimulation tests have to be performed lifelong. Despite a normal basal level, there may be an abnormal peak level after stimulation. On the one hand, it is evidence-based medicine that stimulated CT levels are a more sensitive indicator than are basal values. On the other hand, the burden of periodic stimulation tests and the limited clinical consequences of pathological results justify measuring only basal levels. In many patients, it appears that the basal CT levels become positive several years after surgery. Suspicion about residual or metastatic disease arises if basal CT levels exceed 1 ng/L. Over time, during follow-up, patients are their own controls. Patients with persistently elevated or rising plasma CT levels after adequate surgery should be thoroughly evaluated to define the extent of any local or distant disease. Ultrasound computed tomography or magnetic resonance imaging (MRI) can locate metastases. In addition, other imaging methods, such as [^{99m}Tc]penta-mercaptosuccinic acid (V-DMSA), [¹²³I]meta-iodobenzylguanidine (MIBG), and [¹¹¹In]pentetreotide (related to octreotide) scintigraphy, may be helpful. If local disease in the neck region and/or mediastinum is found and there is no evidence of distant metastases, repeat operation is advocated despite the risk of injury to the nervus recurrence and vocal cord paralysis. Our criteria for reexploration of the neck region are as follows. First, basal plasma CT levels are clearly increased (i.e., >15 ng/L). Second, basal plasma CT levels increase over time. Third, suspected local neck or mediastinal lymph nodes are found, but no distant metastases are detectable by MRI, positron emission tomography (PET), or ultrasonography of the liver, and cytology results of liver specimens are negative.

In patients with evidence of surgically incurable disease (stage IV), monitoring of plasma CT and radiological examination are required. Many such patients show a remarkable stabilization of the disease, and so no further treatment is recommended. A restraint policy (i.e., a “wait and see” approach) is advocated. In patients whose disease shows rapid progress,

Table IV Staging of Medullary Thyroid Carcinoma

| Stage | Characteristic features |
|-------|--|
| I | Tumor < 1 cm and restricted to thyroid gland |
| II | Tumor > 1 cm and/or local invasion |
| III | Regional lymph node(s) positive |
| IV | Metastases at distance |

Note. The highest stage always is applied (e.g., primary tumor <1 cm and regional lymph nodes positive means stage III) Tumors larger than 1 cm are almost always locally invasive.

intervention with cytostatic therapy may be considered. Inhibitors of receptor tyrosine kinase signaling are being developed. These drugs are called “tyrphostins” because they inhibit phosphorylation on tyrosine residues by competition with a tyrosine kinase for substrate and adenosine triphosphate (ATP) binding. Specific inhibition of the RET receptor tyrosine kinase by such drugs might constitute a novel therapeutic approach for MTC that should be investigated.

GENETIC TESTING OF FIRST-DEGREE RELATIVES OF PATIENTS WITH HEREDITARY MTC

If a RET gene germline mutation is identified in a family, testing of young children is appropriate at any time after birth provided that it is preceded by counseling of the parents. Antenatal testing is technically possible. Would-be mothers should be referred to a clinical genetics center before they are pregnant. Options such as *in vitro* fertilization and preimplantation genetic diagnosis may be considered. However, because early treatment and cure are possible, one may question whether this is advisable and ethically acceptable.

If a RET mutation has not been identified in a family and no affected family member is available to give blood for RET testing, stored histological specimens of affected family members should be sought to provide tissue for DNA extraction and analysis. If suspicion of hereditary disease arises and even this alternative is not available, testing of asymptomatic family members may be considered to reveal a germline RET mutation. If no RET germline mutation can be identified in a MEN 2 family, this negative result cannot be accepted unless all exons of the RET gene are examined by nucleotide sequence analysis. In addition, one has to review the clinical evidence for MEN 2. If this evidence is strong, mutation analysis on a new blood sample has to be repeated. In an extensive family, it makes sense to consider genetic linkage analysis. If positive for the chromosome 10 region harboring the RET gene, all RET exons have to be sequenced again.

APPARENTLY SPORADIC MTC AND SCREENING OF FAMILY MEMBERS OF PATIENTS WITH APPARENTLY SPORADIC MTC

Indications for testing for hereditary MTC among patients with apparently sporadic MTC are age at diagnosis of less than 35 years, bilateral or multicentric

involvement, and a family history that is positive or suspected. All patients with MTC for whom there is clinical suspicion of familial disease should be tested for germline RET gene mutations in blood DNA. All exons should be sequenced, starting with exons 10, 11, 13, 14, 15, and 16. If no mutation is found, only a small risk of hereditary MTC remains. In this case, tumor DNA can be analyzed. In sporadic MTC, somatic mutations in codon 883 or 918 occur relatively frequently and identification of one of these mutations argues against, but does not exclude, hereditary disease. Conversely, mutations in cysteine codons in exon 10 or 11 are uncommon in sporadic MTC and are suggestive of hereditary disease.

Before blood samples are taken for DNA analysis, detailed information about the consequences of DNA analysis must be provided to the patient. Psychological support may well be needed before DNA test results are disclosed and during follow-up after diagnosis. Written consent must be obtained.

SUMMARY AND CONCLUSIONS

All individuals with apparently sporadic MTC, but in whom there is suspicion of familial disease, should have mutation analysis of the RET gene. A negative DNA result practically excludes the possibility of hereditary MTC in families where an index case has been investigated and obviates the need for further biochemical evaluation. In families with hereditary MTC, RET gene mutation analysis has superseded measurement of plasma CT in the detection of asymptomatic disease gene carriers. Disease gene carriers may be divided into three distinct risk groups depending on the specific RET gene mutation in the family. The age at which presymptomatic surgery has to be performed depends on the risk group to which the patient belongs. Compared with the results of DNA analysis, the results of CT stimulation tests have become less important in the assessment of the time point of surgery. During follow-up of patients who underwent surgery, measurement of basal plasma CT is still useful. The high sensitivity of measuring stimulated CT levels does not outweigh the burden of lifelong periodic stimulation tests and the limited clinical consequences of slightly elevated levels. Stimulation tests are inevitable for persons at risk who do not want genetic testing.

Figure 1 Melatonin synthesis and the principal neural pathways innervating the pineal gland. SCN, suprachiasmatic nucleus; PVN, paraventricular nucleus; SCG, superior cervical ganglion. Left panel reproduced from Tamarkin, K., Baird, C. J., and Almeida, O. F. X. (1985). Melatonin: A coordinating signal for mammalian reproduction. *Science* **227**, 714–720.

most circumstances, the rate-limiting step in synthesis (Fig. 1) is the activity of serotonin-N-acetyltransferase (arylalkylamine N-acetyl transferase, AA-NAT), with a major increase (7 to 150-fold) in the activity during the dark phase. Serotonin availability may also play a role. The rhythm of melatonin production is endogenous, being generated by clock genes in the suprachiasmatic nuclei (SCN), the major central rhythm-generating system or “clock” in mammals. (The pineal gland itself and the retina are self-sustaining “clocks” in some if not all lower vertebrates.) The rhythm is synchronized to 24 h primarily by the light–dark cycle acting via the retina and the retinohypothalamic projection to the SCN (Fig. 2).

The cDNAs encoding both AA-NAT and the O-methylating enzyme hydroxyindole-O-methyltransferase (HIOMT) (Fig. 1) have been cloned. It is likely that the human enzyme is regulated primarily at a posttranscriptional level, whereas in rodents the key event appears to be cyclic AMP (cAMP)-dependent phosphorylation of a transcription factor that binds to the AA-NAT promoter. Rapid decline in activity with light treatment at night appears to depend on proteasomal proteolysis.

In humans and rodents, melatonin is metabolized to 6-sulphatoxymelatonin (aMT6s), primarily within the liver, by 6-hydroxylation followed by sulphate conjugation. A number of minor metabolites are also formed, including the glucuronide conjugate. Exogenous oral (fast release) or intravenous melatonin

has a short metabolic half-life (20 to 60 min, depending on author and species), with a large hepatic first-pass effect and a biphasic elimination pattern.

Very large interindividual variations in melatonin and aMT6s production are seen with intraindividual stability of both amplitude and timing. This stability leads to the extensive use of melatonin in plasma or saliva and of aMT6s in urine as marker rhythms for circadian phase, for example, in investigating sleep disorders and evaluating adaptation to abrupt phase shifts as in shift work and jet lag. The large individual variations have been ascribed to the size of the pineal gland rather than to variations in enzymic activity.

PHYSIOLOGICAL ROLE OF THE PINEAL GLAND

The pineal is essentially part of the visual system. Probably the most famous of ancient texts on the pineal is that of the influential French philosopher Descartes. In 1662, Descartes considered that, by movements, the pineal controlled the flow of “animal spirits” into motor nerves and so influenced movements of the body. He thought that the stimulus for pineal function came from visual input to the retina (Fig. 2). The latter is a most remarkable insight given that this is effectively true today. The concept of the pineal as the seat of the soul is usually attributed to Descartes, although this idea probably derives from Herophilus. In lower vertebrates, the pineal is directly

Figure 2 The French philosopher Descartes considered, during the 17th century, that the pineal was controlled by light input from the eyes, and today we know that light does indeed regulate the timing of the pineal melatonin rhythm by its synchronizing effects on the activity of the central circadian clock in the suprachiasmatic nucleus (SCN). Light (daylength) also regulates the duration of melatonin secretion at night. In many lower vertebrates, the pineal is effectively a “third eye,” registering overall illuminance and acting itself as a central circadian clock.

photoreceptive and often functions as a “third eye” measuring overall illuminance in the environment for the organization of circadian and seasonal functions. Pineal glands of lower vertebrates are innervated by both afferent and efferent fibers. In reptiles and birds, the gland has a mixed photoreceptor and secretory function. Direct neural connections to the brain exist in mammals, but the sympathetic nervous system provides the main input (Fig. 1). Mammalian pineals consist largely of pinealocytes and glia.

The mammalian pineal is secretory and has lost its capacity for direct photoreception. Remnants of its ancient visual role remain in the presence of, for example, opsins in pinealocytes. However, light indirectly controls mammalian melatonin production via the retino-hypothalamic projection (RHT) and the SCN.

MELATONIN SECRETION CHARACTERISTICS

In the absence of time cues (e.g., light–dark alternation), the melatonin rhythm, like all circadian rhythms, “free runs”; that is, it assumes a period that

is individually variable and genetically determined, usually somewhat longer than 24 h (on average about 24.3 h). Time cues synchronize or “entrain” the rhythm to 24 h. The most potent time cue is the light–dark cycle, and many blind people with no light perception at all show “free-running” melatonin and other rhythms (e.g., sleep, cortisol, core temperature) in a normal environment (Fig. 3).

In addition to entraining the rhythm, daylength (photoperiod) determines the duration of nighttime secretion both by direct suppression of melatonin and by determining the length of the signal emitted by the SCN. Light of suitable intensity, duration, and spectral quality suppresses melatonin production at night; short wavelengths (approximately 465 nm) are most effective. It is likely that short wavelengths are also most effective for entrainment of the rhythm to 24 h.

In mammals, melatonin is secreted into the bloodstream and also probably into the cerebrospinal fluid (CSF). CSF concentrations are reported to be higher than those of plasma in some species. In humans, the evening melatonin onset is usually around 2100 to 2200 h, it peaks around 0300 to 0500 h, and it declines to daytime values by around 0800 to 0900 h (Fig. 4).

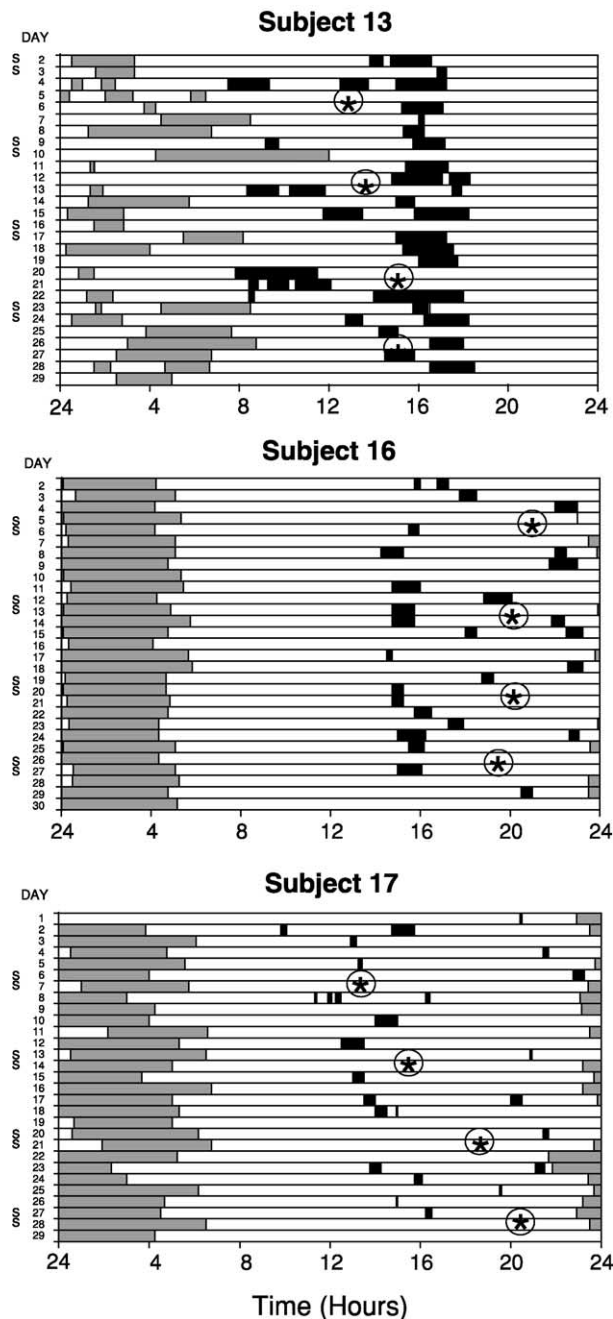

Figure 3 Three blind subjects (no perception of light) showing abnormal sleep and melatonin rhythms. Subjectively recorded sleep is shown by the gray bars, and naps (classified as such by the subjects) are shown by the black bars. Melatonin was assessed as 6-sulphatoxymelatonin (aMT6s) in sequential urine collections for 48 h weekly, and the asterisks indicate the calculated peak times (acrophase) of the aMT6s rhythms. Note the abnormal timing of aMT6s, which normally peaks between 2400 and 0600 h, and the association of naps with daytime melatonin production. Subject 17 is clearly “free running” (i.e., showing endogenous periodicity), with a steady daily delay of the aMT6s rhythm. All blind subjects with no eyes have shown this phenomenon. Subject 16 is synchronized to 24 h but with an abnormal phase position. Cortisol and core

Figure 4 Average concentrations of melatonin in plasma (dashed line, average $N=133$), saliva (dotted line, average $N=28$), and 6-sulphatoxymelatonin (aMT6s) in urine (solid line, average $N=88$), with all measurements done by radioimmunoassay. Diagrammatic representation of mean normal values (healthy men and women over 18 years of age) from the author’s laboratory.

The effective cessation of secretion is earlier, according to various models of the secretion characteristics. The melatonin onset and offset correspond to a number of important events related to biological dawn and dusk, including the evening increase in sleep propensity and decline in core body temperature. During winter, particularly in polar regions, the timing of the rhythm may be delayed compared with summer, and this has been attributed to the weaker light–dark cycle during winter.

MELATONIN RECEPTORS

Melatonin receptors have now been cloned, and three subtypes were initially named Mel-1a, Mel-1b, and Mel-1c. The Mel-1a receptor gene has been mapped to human chromosome 4q35.1. Its primary expression is in the pars tuberalis of the pituitary and the SCN. Mel-1b has been mapped to chromosome 11q21–22, and its expression is in the retina and the brain. Mel-1c is not found in mammals. Two cloned mammalian receptors (Mel-1a and Mel-1b) have recently been

body temperature rhythms show abnormalities similar to those of melatonin. These and other observations in the blind underline the importance of light for synchronizing rhythms and the association of daytime melatonin production with poor nighttime sleep and daytime naps. Reproduced with permission from Lockley, S. A., Tabandeh, H., Skene, D. J., Buttery, R., Bird, A. C., DeFrance, R., and Arendt, J. (1995). Daytime naps and melatonin rhythms in blind people. *Lancet* 346, 1491.

renamed MT1 and MT2. They are a new family of G protein-coupled receptors, have high affinity (K_d 20–160 pmol), and inhibit forskolin-stimulated cAMP formation. Using gene knockout technology and pharmacological manipulations, the results suggest that the phase-shifting receptor is MT2, whereas MT1 is associated with acute suppression of SCN electrical activity in addition to its actions within the pars tuberalis. Several other physiological responses have been ascribed to MT1 and MT2 receptors, including (MT1) melatonin-mediated potentiation of adrenergic vasoconstriction and (MT2) modulation of dopamine release in the retina.

MELATONIN AGONISTS AND ANTAGONISTS

Large numbers of putative and actual melatonin agonists, together with some antagonists, have now been described. The most interesting have effects similar to those of melatonin on rhythm physiology in both rodents and humans. Moreover, a possible therapeutic role for the agonist S20098 in depression is emerging. A recent review summarized melatonin receptor pharmacology to that point.

PHYSIOLOGICAL ROLE OF MELATONIN IN MAMMALS

Photoperiodism

In all species studied, melatonin appears to act as a timekeeping hormone. It has receptors both within and without the central nervous system and can modify gene expression in certain target organs. Pinealectomy abolishes the ability to respond to changing daylength in photoperiodic seasonal breeders. In mammals, the primary role of melatonin is to provide information about photoperiod for the timing of seasonal functions in daylength-dependent (photoperiodic) seasonal species. These functions include timing of breeding, timing of pubertal development, and seasonal changes in coat growth, behavior, and body weight. The critical signal for the timing of photoperiodic events is the changing duration of melatonin secretion according to daylength, together with previous photoperiodic history (Fig. 5). Artificial generation of winter (long night) melatonin profiles during summer is equipotent with artificial long nights in changing the timing of seasonal functions. Melatonin implants (which are “read” as long nights) are used in agriculture to time the season of birth of,

Figure 5 The duration of melatonin secretion changes with daylength, providing an internal time cue for the organization of daylength-dependent seasonal functions in photoperiodic species. This changing duration can be seen in humans if they are maintained in different durations of total darkness. However, domestic intensity light at night is sufficient to greatly diminish or eliminate this photoperiodic response.

for example, lambs and the growth of winter coat of cashmere goats and mink.

Melatonin influences production of gonadotropins and gonadal hormones via actions within the hypothalamus. The precise receptors have not been fully defined. However, melatonin controls seasonal variations in prolactin by a direct action on the pars tuberalis of the pituitary. This structure is the major site of melatonin receptors (MT1) in most species. Photoperiod-dependent gene expression in the pars tuberalis is directly modified by melatonin.

Role in the Mammalian Circadian System

Pinealectomy in mammals leads to subtle effects on circadian rhythms. The speed of adaptation to forced phase shift is enhanced and the activity–rest cycle becomes fragmented in continuous light in rodents. There is good evidence for the importance of the maternal melatonin rhythm in setting circadian phase in neonatal rodents. This may be the most important role for melatonin in the mammalian circadian system given that an essential physiological role in adult mammals remains to be defined. The effects of pinealectomy in humans remain to be clarified; confounding factors are the possible concomitant damage of surrounding structures during surgery. However, suppression of melatonin by the beta-adrenergic antagonist atenolol leads to an enhanced rate of phase shift to applied light.

The peak nighttime levels of melatonin are temporally associated with the nadir in core body temperature (cBT), maximum sleepiness/fatigue, lowest alertness, increased blood lipid (triacylglycerol), glucose, and possibly insulin (Fig. 6). These are correlative associations; however, in the case of cBT and sleep propensity, there is good evidence that melatonin contributes to the nighttime decline and increase, respectively. Light suppression of melatonin at night leads to an increase in cBT and alertness. The increase in alertness correlates to the degree of melatonin

Figure 6 Relationship of plasma melatonin to other major circadian rhythms. Note the close correspondence between the core temperature nadir and the melatonin peak. Reproduced with permission from Rajaratnam, S. M. W., and Arendt, J. (2001). *Lancet* 358, 999–1005.

suppression, but evidence for the quantitative contribution of endogenous melatonin to these effects is lacking. Exogenous melatonin clearly influences sleep. Possibly, the best evidence for a causal role of melatonin in human sleep comes from studies in free-running blind subjects. When they are out of phase (i.e., when melatonin is secreted during the daytime), the peak levels are strongly associated with an increase in daytime napping (Fig. 3). In general, melatonin reinforces functions associated with darkness. In nocturnal animals, its production is associated with activity rather than sleep.

MELATONIN AND HUMAN REPRODUCTION

Melatonin declines during development, peaking at 3 to 4 years, with a plateau circa 18 to 35 years, followed by a decline into old age (although it should be noted that very healthy elderly subjects have not shown this decline). Early work suggested that melatonin might have a role in the timing of human puberty, acting in an inhibitory capacity. Certainly, exogenous melatonin is able to delay pubertal development in rats.

Pineal tumors are frequently associated with precocious/delayed puberty, but melatonin production has not been firmly implicated in normal or abnormal pubertal development in humans. Pineal tumors are heterogeneous and may arise from germ cells (teratomas, germinomas, choriocarcinomas, endodermal sinus tumors, and mixed germ cell tumors), pineal parenchymal cells (pineoblastoma and pineocytoma), and the supporting stroma (gliomas). All are rare (less than 1% of intracranial space-occupying lesions) and tend to occur in individuals under 20 years of age with the exception of parenchymal cell tumors, which occur equally in adults and children. Most of the evidence now suggests that precocious puberty is due to the production of human chorionic gonadotropin (beta-hCG) by germ cell tumors of the pineal. Precocious puberty is associated with abnormally low melatonin levels, whereas in delayed puberty and in hypothalamic amenorrhea, melatonin levels are high compared with those in age-matched normal individuals.

There is no doubt that suitable administration of melatonin can modify human reproductive function, generally speaking, in an inhibitory capacity. It is able to suppress the ovulatory luteinizing hormone (LH) peak and to potentiate testosterone-induced LH suppression in very large doses. It can modulate the ultradian properties of LH and follicle-stimulating hormone (FSH) secretion, and it acutely increases

prolactin (although chronic administration lowers prolactin in animals, corresponding to the effects of long nights). A series of studies in males with and without hypogonadism has reinforced the perception that melatonin is essentially inhibitory to human reproductive function. An (unsuccessful) attempt has been made to develop it as an oral contraceptive in combination with a progestin minipill, with very large daily doses (80 mg). These observations fuel worries concerning the possible reproductive side effects of over-the-counter availability of melatonin as a sleep aid in some countries.

GENERAL HUMAN PATHOLOGY

Numerous reports exist of variations in melatonin secretion as a function of endocrine and other diseases. A problem with many publications is the possible influence of ambient light conditions and posture, together with sleep-wake characteristics of the subjects, especially when a hospitalized group is compared with a nonhospitalized control population. Liver disease such as cirrhosis, which impairs metabolic function, leads to higher than normal plasma concentrations of melatonin. Drugs that stimulate or suppress hydroxylation and conjugation mechanisms, or that compete for metabolic pathways, can be expected to affect circulating melatonin. There is little evidence for a disturbance of melatonin secretion in major sleep disorders such as narcolepsy and Klein-Levine syndrome (intermittent sleeping for days at a time). One very interesting genetic disorder, Smith-Magenis syndrome, is caused by a deletion in chromosome 17p11.2. The syndrome is associated with various physical, developmental, and behavioral disabilities, but it is not fully understood. It is associated with daytime melatonin production and poor nighttime sleep, but with normal cortisol rhythms. Pharmacological suppression of the daytime melatonin leads to improved daytime alertness and nighttime sleep.

Numerous attempts have been made to relate melatonin suppression to exposure to electromagnetic fields, with no consistent data in humans.

Melatonin has been investigated extensively in psychiatric disorders, particularly winter depression and seasonal affective disorder (SAD), in which a causal role has been proposed. No firm conclusions can be drawn yet. Many antidepressant drugs acting on serotonergic or catecholaminergic systems will acutely increase or otherwise modify melatonin production.

There is recent evidence for an involvement of melatonin and the pineal gland in vasopressin production.

POSSIBLE ROLE OF MELATONIN IN CANCER

Melatonin suppression has been linked to infertility and increased incidence of certain cancers. There is evidence of low levels of melatonin in hormone-dependent cancer (estrogen receptor-positive breast cancer and prostate cancer). Some cancers are photo-period dependent in rodents, and melatonin may have a role there. Pinealectomy in rats leads to a shortened survival time in dimethylbenzanthracene-induced mammary cancer; melatonin administration reverses this effect. There is good evidence of melatonin inhibition of growth of some hormone-dependent cancer cell lines and also evidence for stimulation of immune function. Combined melatonin therapy with tamoxifen for breast cancer is being investigated in humans.

MELATONIN AS ANTIOXIDANT/FREE RADICAL SCAVENGER

The melatonin molecule is easily oxidized; therefore, it is not particularly surprising that it demonstrates antioxidant/free radical scavenging effects. The concentrations required are generally orders of magnitude higher than physiological levels. However, there is evidence that endogenous circulating melatonin may be responsible for some of the antioxidant status of blood.
