In addition to chondrodystrophies associated with mutations in the sulfate transporter gene, growth disorders caused by defects in the biosynthetic pathway responsible for synthesis of the high-energy sulfate donor phosphoadenosylphosphosulfate (PAPS) have been identified in humans and mice. In particular, studies in a murine model revealed that there are at least two PAPS synthetase genes. Unlike the aggrecan core protein mutations that have no counterpart in humans, the identification of the PAPS synthetase 2 (*Papss2*) isoform mutation in the *bm* mouse was followed by the elucidation of a *Papss2* mutation in

human spondyloepimetaphyseal dysplasia (Table I). This disorder is characterized by short and bowed lower limbs, enlarged knee joints, and early onset of degenerative joint disease in the hands and knees.

The elucidation of the human PAPS synthetase disorder was facilitated by the extensive previous work on the *bm* mouse. The nonlethal growth disorder brachymorphism is characterized by a dome-shaped skull, short thick tail, and shortened but not widened limbs. The phenotype is inherited as an autosomal recessive and *bm* homozygotes breed normally, have normal life spans, and are of average size at birth, but then exhibit a 50% reduction in limb length over the first month of development. Biochemical analysis showed that *bm* cartilage contains normal levels of glycosaminoglycans that are significantly undersulfated, due to a defect in PAPS synthetase activity. Genetic linkage studies localized two murine members of the PAPS synthetase family, *Papss1* and *Papss2*, to chromosomes 3 and 19, respectively; *Papss2* is tightly linked with the marker for the *bm* locus in chromosome 19. Sequence analysis of *Papss2^{bm}* cDNA revealed a missense mutation in a highly conserved portion of the APS kinase domain and expressed *bm* *Papss2* failed to catalyze the adenosine 5'-phosphosulfate (APS) kinase reaction or to synthesize PAPS. These human and murine PAPS synthetase defects underscore the importance of proper sulfate metabolism for cartilage development and skeletal growth and the multiplicity of genes that might be affected in chondrodysplasias.

REGULATORY MOLECULES

FGFR3

Some of the most common forms of human chondrodysplasias are due to mutations in the fibroblast growth factor receptor 3 (FGFR3). FGF signaling is carried out through the dimerization of four membrane-spanning tyrosine kinase receptors. The formation of dimers is developmentally and tissue-specifically regulated and plays an important role in skeletal differentiation. Mutations in three of these receptors are responsible for a variety of human skeletal dysplasias and craniosynostosis syndromes. Different mutations in FGFR3 are responsible for all four phenotypes in the achondrodysplasia family of skeletal dysplasia: achondrodysplasia, hypochondrodysplasia, thanatophoric dysplasia, and severe achondrodysplasia with developmental delay and acanthosis nigricans (SADDAN). Achondrodysplasia is characterized by relatively short limbs and macrocephaly with frontal bossing and midface hypoplasia. In most of the

reported cases, mutations that result in amino acid substitutions in the transmembrane domain of FGFR3 are responsible for the achondrodysplasia phenotype. Hypochondrodysplasia is very similar to achondrodysplasia but is milder as the rhizomelic dwarfism and craniofacial manifestations are not as pronounced. More than 80% of hypochondrodysplasia cases are due to mutations resulting in substitutions in the intracellular domain of FGFR3. The two forms of the neonatally lethal thanatophoric dysplasias I and II are characterized by very severe rhizomelic dwarfism, strong midface hypoplasia, and extremely small thorax. The type I form has curved femurs with a cloverleaf skull and is associated with a variety of mutations in different domains of FGFR3; in contrast, type II exhibits straight femurs with or without a cloverleaf skull and is always caused by mutations resulting in a specific amino acid substitution in the intracellular tyrosine kinase domain of the FGFR3. The SAADAN disorder results from a different substitution at the same residue that is affected in thanatophoric dysplasia type II. Evidence from mouse models indicates that FGFR3, the expression of which is restricted to proliferating and hypertrophic chondrocytes, is a negative regulator of cell proliferation in the growth plate. Thus, the pathological mechanism through which mutations in FGFR3 are manifested involves gain of function, whereby mutated receptors provide a relatively ligand-independent, constitutively active receptor form. The study of FGFR mutations in human skeletal dysplasia syndromes has provided significant information about these signaling pathways and their involvement in skeletal development.

PTHrP–Ihh Loop

Further insights into growth regulation are provided by mutations that affect the PTHrP receptor. A constitutively active receptor is observed in patients with Jansen metaphyseal chondrodysplasia, an autosomal-dominant disorder characterized by severe hypercalcemia, hypophosphatemia, and short-limb dwarfism (Table I). Blomstrand chondrodysplasia, an autosomal-recessive lethal disorder caused by mutations that generate inactive receptors, is characterized by extremely accelerated chondrocyte differentiation and thus premature ossification. PTHrP receptors belong to the G protein-coupled receptor family and mediate the action of two hormones, parathyroid hormone and PTHrP. Studies in animal models indicate that PTHrP facilitates the proliferation of chondrocytes in the growth plate and negatively regulates

their differentiation to hypertrophic chondrocytes and ensuing programmed cell death. Also, it has been proposed that the PTHrP receptor indirectly mediates the action of Ihh in delaying hypertrophy in the growth plate through a negative feedback loop. How these two rare genetic disorders characterized by activation and inactivation of PTHrP receptor lead to abnormal growth plate development is not clear, but these findings suggest that bone growth and elongation are regulated through a complicated autocrine/paracrine system involving at least PTHrP, its receptor, and Ihh.

Transcription Factors

As more transcription factors and growth modulators that control growth plate development are identified, it is expected that mutations in the genes for these regulatory factors will be associated with additional skeletal abnormalities. One example is campomelic dysplasia, a congenital skeletal dysplasia in humans that exhibits shortening and bowing of the long bones and abnormal facial features including macrocephaly, micrognathia, cleft palate, and flat nasal bridge, as well as male-to-female sex reversal (Table I). Affected babies usually die in the neonatal period or in early infancy of respiratory distress. Chromosomal rearrangements that affect transcription regulatory elements of the SOX9 transcription factor gene promoter or loss-of-function mutations in the coding region of the gene are responsible for this disorder. SOX9 is expressed in mesenchymal condensations and during chondrogenesis and has been proposed to be involved in the regulation of the expression of a number of extracellular matrix molecules, such as type II collagen and aggrecan. Thus, it is not surprising that campomelic dysplasia phenotypic characteristics resemble the human and animal disorders that involve extreme defects in these two ECM molecules.

SUMMARY

As illustrated by the presentation of these representative examples, the chondrodysplasias are a genetically, biochemically, and clinically heterogeneous group of vertebrate disorders. They nonetheless all share the common hallmark of disproportionately short stature owing to abnormal bone growth. The basis for this major phenotypic feature involves disruptions in the normal program of endochondral development due to gene mutations at different levels of the process.

Consequently, the study of diseases that affect skeletal development and growth is providing valuable insights into the role not only of individual genes, but of broader regulatory pathways.

Chronic Fatigue Syndrome and Fibromyalgia

D. J. Torpy

University of Queensland, Greenslopes Private Hospital, Brisbane, Queensland, Australia

Glossary

chronic fatigue syndrome Unexplained debilitating fatigue (>6 months) in association with at least four of the following eight features: sore throat, tender cervical or axillary lymph nodes, impaired hearing and concentration, headaches of a new type, joint pains, muscles pains, prolonged or severe postexertional fatigue exacerbation, and unrefreshing sleep.

fibromyalgia Widespread chronic (>3 months) pain and specific tender points (>11 of 18) on examination.

stress Any external or internal factor that threatens homeostasis, or the stable internal environment.

stress system The biological response system to stress comprising the hypothalamic–pituitary–adrenal axis, with its main product, cortisol, and the sympathetic nervous system, which produces norepinephrine at sympathetic nerve endings (sympathoneural) and epinephrine from the adrenal medulla (sympathoadrenal).

Chronic fatigue syndrome and fibromyalgia are relatively common clinical syndromes. There are syndromal diagnostic criteria for each condition, although fatigue and chronic pain are frequent in both conditions, suggesting possible overlap in their etiopathogenesis. The cause of these conditions remains unknown, and specific, highly successful therapies are not available. Many possible causative theories have been offered, mainly involving infectious agents and psychological factors. The frequency and heterogeneity of these conditions suggest that the causes are likely multifactorial. Evidence suggests that these disorders may represent disorders of the stress system, comprising the hypothalamic–pituitary–adrenal (HPA) axis and the sympathetic nervous system (Table I).

CHRONIC FATIGUE SYNDROME AND FIBROMYALGIA: CLINICAL CONCEPTS

Fatigue may be regarded as pathological when pervasive and unrelated exclusively to exertion. Fatigue, as a sense of tiredness or lack of energy,

may be appreciated centrally in terms of concentration, memory, and motivation or appreciated peripherally, where symptoms are often referred to the muscles.

Unexplained and chronic (>6 months) fatigue has been classified as idiopathic chronic fatigue. The clinical diagnosis and definition of chronic fatigue syndrome (CFS) are based on symptoms such as chronic (>6 months) unexplained fatigue with associated disability and at least four of eight of the following symptoms: impaired short-term memory or concentration; sore throat; tender cervical or axillary lymph nodes; muscle pain; multijoint pain without arthritis; headaches of a new type, pattern, or severity; unrefreshing sleep; and prolonged or severe postexertional fatigue exacerbation. CFS is more common in young adults, with a peak age of onset between 20 and 40 years, and it is more common among women, typically occurring at a ratio of 2 or 3:1. The prevalence of CFS is approximately 0.2–0.7%. Idiopathic chronic fatigue has a prevalence of 2%. Fibromyalgia is characterized by widespread pain and at least 11 of 18 specific tender points on examination. The prevalence of fibromyalgia is thought to be approximately 1–4% of the general population. Diagnosis of CFS or fibromyalgia is based on symptoms and exclusion of other diseases that may present with similar symptoms.

No specific treatment is widely successful; however, a positive diagnosis and reassurance that many patients recover can help affected patients. Cognitive-behavioral therapy may assist and involves the provision of information and counseling to reduce the psychological impediments to recovery as well as encouraging the patient to participate at an appropriate level of social and occupational activity.

On the basis of the tendency for abrupt onset and the observation that many patients experience postinfectious fatigue, it has been proposed that CFS results from an infection. Initial attention focused on the Epstein–Barr virus in CFS, but many CFS patients lack Epstein–Barr virus seropositivity, and many others have antibody titers to other viruses.

Moreover, global increases in humoral immune responses are seen in a number of chronic stress states, and neurohormonal changes may account for these immune aberrations.

CFS is generally not considered to be a psychiatric disorder. Although depression is frequently seen in CFS and fibromyalgia, most patients do not exhibit the characteristic self-reproach or biological features of endogenous depression. Hence, depression may be reactive. Personality attributes such as achievement orientation have also been associated with CFS.

CHRONIC FATIGUE SYNDROME AND FIBROMYALGIA AS STRESS SYSTEM DISORDERS

Stress is defined in biology as any threat to homeostasis and may involve injury, sepsis, or psychic disturbance. To respond to stressors, the body has two neuro-humoral effectors: the hypothalamic–pituitary–adrenal axis, with cortisol as its principal hormonal product, and the catecholamines norepinephrine and epinephrine, produced by sympathetic nerve endings or the adrenal medulla, respectively. Cortisol secretion by the human adrenocortical zona fasciculata is regulated by pituitary adrenocorticotropin (ACTH) and, in turn, by hypothalamic corticotropin-releasing hormone (CRH) and arginine vasopressin. ACTH secretion is influenced by stress, a light-entrained circadian rhythm, and negative feedback at the hypothalamus and inhibitory brain centers. Basal (unstressed) cortisol secretion acts to prevent arterial hypotension by augmenting the effects of catecholamines and to maintain normoglycemia through insulin counter-regulation. Stress-induced cortisol secretion activates the central nervous system, increases blood pressure, elevates blood glucose, and suppresses the inflammatory/immune response to prevent tissue damage. Many of the circulatory and metabolic effects of catecholamines are synergistic with those of cortisol.

A total of 90 to 95% of circulating cortisol is bound to a 383-amino acid glycosylated transport protein, corticosteroid-binding globulin (CBG). Cortisol diffuses through cell membranes and binds the 777-amino acid glucocorticoid receptor- α , which stimulates glucocorticoid response elements of many genes via central “zinc fingers” and largely inhibitory effects through inhibition of the action of *c-fos*, *c-jun*, NF- κ B, and other transcription factors on the activated protein-1 and other DNA binding sites.

Several studies have examined basal and stimulated pituitary–adrenal gland function in CFS. Studies in

the broader CFS patient group have generally detected relative hypocortisolism and altered dynamic responses, providing indirect evidence of a central nervous system understimulation of pituitary–adrenal function. Two different types of heritable disorders of this axis have been described, in which fatigue is the principal symptom: (i) glucocorticoid resistance due to glucocorticoid receptor abnormalities and (ii) mutations of the corticosteroid-binding globulin gene, the main cortisol transport protein. These disorders are probably rare, but they reinforce the notion that primary pituitary–adrenal abnormalities may produce chronic fatigue symptoms. Evidence for stress system dysfunction in CFS and fibromyalgia is summarized in [Table I](#).

Plasma basal morning and evening cortisol measurements, salivary cortisol, and 24-h urine free cortisol levels have been found to be reduced in CFS. Reduced plasma cortisol diurnal variation has been reported, with lower AM cortisol and elevated PM cortisol levels. Although the levels were not significantly different from those of controls, the extent of diurnal variation reached clinical significance. DHEA and its long half-life sulfated metabolite, DHEA-S, are major adrenal gland products in terms of mass. They are important contributors to circulating androgen activity, particularly in women. DHEA and DHEA-S levels were lower in 15 CFS patients compared to 11 controls; furthermore, CFS patients did not display the usual decrease in DHEA:cortisol ratio with ACTH stimulation. A preliminary study of 8

Table I Evidence of Stress System Dysfunction in Chronic Fatigue Syndrome and Fibromyalgia

| |

| Syndromal |
| Onset after prolonged stress |
| Symptoms exacerbated by adoption of hypo- or hyperstressful environments |

selected CFS patients with a subnormal 1 μg ACTH stimulation test showed a 50% reduction in adrenal gland volume on computed tomography scan.

One study of pituitary–adrenal function in CFS patients is notable for its size and use of several complementary methods to assess different components of the axis. This study of 30 patients and 72 normal volunteers found reduced basal evening cortisol, low 24-h urine free cortisol, reduced maximal cortisol response to ACTH, and reduced integrated ACTH response to CRH. These findings were interpreted as suggesting a mild central adrenal insufficiency, perhaps involving endogenous hypothalamic CRH release, as the main regulator of HPA axis function. A reduced ACTH response to arginine vasopressin in 19 CFS patients compared to controls was interpreted as evidence of reduced hypothalamic CRH tone since CRH and vasopressin act synergistically in ACTH release. Although cerebrospinal fluid CRH levels were normal, it has been suggested that CSF–CRH may not reflect hypothalamic CRH secretion.

Relative hypocortisolism, along with the coexistence of fatigue, low blood pressure, and mood alterations in both Addison's disease and CFS, has led to trials of hydrocortisone therapy in CFS. One positive therapeutic study was conducted on 32 CFS patients with disease duration <100 months and a lack of evidence of major depression or other comorbid psychiatric disorder. Five or 10 mg of hydrocortisone was administered for 28 days in a placebo-controlled design. Approximately 28% of patients experienced a reduction in fatigue scores, such that their scores were comparable to those of controls. Only 9% of CFS patients taking placebo experienced similar symptom resolution. A study of full-replacement hydrocortisone (16 mg/m² per day in divided doses, approximately 25–35 mg hydrocortisone daily) in 70 CFS patients for 3 months showed slight improvement on symptom scales, particularly in wellness score, but there was evidence of suppressed adrenocortical responsiveness on the basis of basal and ACTH-stimulated cortisol levels in 12 patients. Patients in this study had a rapid evolution of initial CFS symptoms (<6 weeks).

To further examine the endocrine axes, stimulation testing is a classic endocrine paradigm, in which subtle hypofunction may become more evident through the administration of stimulatory hormones or neuroactive agents. Nevertheless, because central control of endocrine axes cannot be directly assessed due to the lack of accessibility of the hypothalamic–pituitary circulation and brain *in vivo*, interpretation of the findings tends to be presumptive.

Dynamic endocrine testing with human CRH (pituitary stimulus) and D-fenfluramine (central serotonergic stimulus) in CFS patients revealed a trend toward lower cortisol responses, which became statistically significant when ACTH responses were analyzed as a covariate. Reduced ACTH responses to the 5-HT-1a receptor agonist ipsapirone were noted in CFS patients, although there was no difference in cortisol response. On the other hand, reduced ACTH responses to CRH have been reported. Another study showed no difference in cortisol responses to D-fenfluramine. Treadmill exercise produced a blunted ACTH response in CFS.

Insulin hypoglycemia is a profound stimulus of ACTH/cortisol release because it likely induces release of many hypothalamic ACTH secretagogues. Studies in CFS have revealed increased ACTH but normal cortisol responses after insulin hypoglycemia. This finding could be interpreted as indicating low CRH tone, with chronic CRH hyposecretion despite an intact CRH neuron, and secondary adrenal atrophy. Similar findings have been reported for the related disorder, fibromyalgia, after insulin hypoglycemia.

Naloxone is thought to stimulate ACTH and cortisol secretion by blocking tonic opioidergic inhibition of the CRH neuron. Naloxone-mediated activation is blunted in CFS, suggesting that the CRH neuron or pathways inhibitory to this neuron lead to HPA axis hypofunction in CFS, rather than increased opioidergic tone.

Stress system alterations in fibromyalgia include reduced urine free cortisol, altered circadian cortisol rhythmicity, an exaggerated response to CRH, and a paradoxical decline in cortisol levels with exercise. Increased norepinephrine excretion and a hyper-response of norepinephrine to exogenous interleukin-6 have been reported, although muscle sympathetic activity was reduced.

Familial clustering has been noted in CFS and fibromyalgia. Moreover, an epidemiological study of 1004 adult twin pairs from the Australian NH&MRC Twin Registry revealed that fatigue, as measured with the Schedule of Fatigue and Anergia (SOFA) questionnaire, likely has a genetic factor, based on multivariate genetic modeling and a monozygotic:dizygotic concordance ratio of 2.69:1.

Corticosteroid-binding globulin, a key cortisol transport protein, participates in the stress response. CBG levels decline during stress, in part due to interleukin-6-induced inhibition of CBG gene transcription. Two inherited mutations of the CBG gene, leading to lack of synthesis (null mutation) or fourfold reduced CBG:cortisol binding (Lyon mutation), have

been associated with chronic fatigue and mild hypotension. Plasma cortisol levels are low in patients with these CBG mutations, but urine free cortisol is normal.

Glucocorticoid resistance implies reduced tissue effect of circulating cortisol. Fatigue as an isolated symptom has been described in a 55-year-old woman with glucocorticoid resistance. The patient's son, in his 20s, also experienced fatigue but her seven sisters were healthy. Interestingly, fatigue was intermittent in this patient but blood pressure was constantly in the low-normal range, despite hypertension in the patient's mother. The patient did not have postural hypotension. Urinary cortisol was elevated (400–800 nmol/24 h; reference range, <300 nmol/24 h), as were plasma cortisol levels. A thermolabile glucocorticoid receptor was noted, specifically a temperature-induced reduction in [³H]dexamethasone, although a specific glucocorticoid receptor mutation was not reported. Fatigue has also been reported in other cases of glucocorticoid resistance. It is likely that these mutations are rare, but it is interesting that the two mutations leading to a disorder similar to CFS both relate to the HPA axis. It is possible that less severe mutations of these and other genes may contribute to the etiology of chronic fatigue syndrome and fibromyalgia. Since these mutations often have opposing effects on cortisol levels, such as high cortisol levels in glucocorticoid resistance and low cortisol levels in CBG gene mutations, they may contribute to the heterogeneity of findings observed in classic neuroendocrine testing.

CONCLUSION

Chronic fatigue syndrome and fibromyalgia are common idiopathic syndromes. It has been argued that these disorders should be considered together rather than separate on organ-based nomenclature. There is a clinical impression that these disorders can be exacerbated during times of physical or psychic stress. Data indicate relative hypocortisolism, which may explain the fatigue and tendency to low blood pressure, a proposition reinforced by the therapeutic response to supplemental doses of hydrocortisone in a subset of patients. Dynamic studies of the HPA axis suggest that this hypocortisolism is of central origin. Sympathetic nervous system dysregulation may result from the hypocortisolism, particularly elevated catecholamine excretion. An underlying genetic tendency to develop these disorders, suggested by twin studies and familial clustering, may be based on inherited variations in key regulatory peptides of the stress system, as has been shown in rare kindreds

with mutations of the glucocorticoid receptor and corticosteroid-binding globulin genes. Further biochemical and molecular studies of the stress system may integrate these concepts into a coherent model to help explain the variability in neuroendocrine findings, which may be based on patient selection or variable etiology.

Circadian Rhythms: Hormonal Facets

Johannes D. Veldhuis

Mayo Clinic, Rochester, Minnesota, United States

Ali Iranmanesh

VA Medical Center, Salem, Virginia, United States

Steven Pincus

Guilford, Connecticut, United States

Daniel Keenan

University of Virginia, Charlottesville, Virginia, United States

Glossary

circadian Recurring approximately daily or every 24 h.

feedback Repression of a driving stimulus by a downstream product.

feedforward A stimulatory signal upstream of a target cell.

homeostasis Maintenance of stable biochemical conditions.

multivalent Determined by three or more signaling factors.

pulsatile Burst-like or episodic.

Hormonal homeostasis is subject to multivalent control by chemical signals operating remotely via time-delayed feedback and feedforward. The ensemble of interactions mediates short-term (pulsatile) and longer term (circadian) control of the endocrine milieu. Precise orchestration of multihormonal adaptations is critical across the human life span: *in utero*, infancy, puberty, adulthood, and aging. The ensemble concept of coalescent pulsatile and circadian secretory control provides a unifying platform for investigating regulatory pathophysiology.

INTRODUCTION

Circadian rhythmicity abounds in the natural world but is surprisingly difficult to affirm unambiguously in clinical settings. A primary feature is recurrence of measured epochs at a consistent interval (periodicity) of approximately 24 h (Fig. 1A). Second, circadian activity (e.g., cortisol secretion) exhibits a free-running 24-h periodicity, wherein cyclical activity

persists in the absence of external cues such as exercise, food intake, and socially directed behavior. This unique facet is explored in clinical isolation experiments such as extended cave dwelling. Third, the 24-h rhythm is temperature compensated, whereby a change in habitat temperature does not abolish periodicity. Fourth, zeitgeber (or time-given) cues operate that harmonize the rhythmic phase (acrophase or timing of the 24-h maximum) to environmental demands.

The suprachiasmatic nucleus (SCN) is a prime locus of circadian rhythm generation and attendant integration of zeitgeber inputs. In many species, including the human, brief exposure to bright light acts via retinohypothalamic pathways to trigger SCN resetting of the phase of sleep, activity, and hormonal rhythms. Unshielded astronauts orbiting the earth are exposed to sesquihoural (90-min) light–dark cycles and, thereby, potential phase resetting.

Few neuroendocrine rhythms in the human, other than cortisol, satisfy the forgoing strict criteria of circadian drive. In this regard, the body temperature rhythm provides a corollary marker of circadian endocrine activity. When the strict circadian definition is not satisfied, terms such as nycthemeral, 24-h cyclic, diurnally varying, and food- or sleep-modulated variations are more apt.

THE CORTICOTROPIC AXIS

In initial clinical studies, day–night rhythmicity of adrenal secretory control was inferred by a morning elevation and an evening decline in urinary adrenal glucocorticoid metabolites (e.g., 17-hydroxycorticosteroids). Frequent sampling and determination of

Figure 1 (A) Terms applied in monitoring circadian rhythms. (B) Time scales of hypothalamic neuronal outflow and attendant pituitary hormone secretion.

plasma cortisol and adrenocorticotrophic hormone (ACTH) concentrations by immunoassay corroborated nycthemeral adaptations of this stress-adaptive axis. Further analyses disclosed prominent (three- to fivefold) short-term pulsatile ultradian fluctuations (occurring briefly and repeatedly over 24 h).

From a physiological perspective, circadian and pulsatile secretion of ACTH and cortisol arise by way of neuroglandular interfaces linking the central nervous system (CNS), anterior pituitary gland, adrenal cortex, and splanchnic plexus. The hypothalamo-pituitary unit is remarkable in transducing regulatory signals that span time scales of milliseconds, seconds, and minutes (Fig. 1B). Release of hypothalamic stress effectors occurs in brief bursts, each lasting just a few minutes. However, a cascade of subsequent events prolongs the effectual stress response; these include the latency of ACTH drive of adrenal steroidogenesis, slow dissociation of secreted cortisol from a cognate high affinity-binding globulin (CBG) in the circulation, and persistence of target tissue transcriptional and translational events initiated by cortisol exposure. For example, in the human, the plasma corticotropin-releasing hormone (CRH) half-life is 2 to 5 min, the ACTH half-life is 14 to 18 min, ACTH stimulates cortisol secretion over 5 to 30 min, the cortisol half-life is 50 to 85 min, and the cellular effects of glucocorticoids unfold over and persist for several hours.

Ensemble control is achieved via time- and concentration-dependent dynamic interactions among CNS sites, the anterior pituitary gland, adrenal cortex, autonomic neurons and peripheral target organs. Fig. 2 illustrates a simplified biomathematical construct that encapsulates this network-like notion. The two primary hypothalamic agonists are CRH and arginine vasopressin (AVP). Both neuropeptides

are released in short (1- to 3-min) secretory bursts. Terminal nerve fields from paraventricular and supraoptic nuclei, respectively, abut fenestrated and valveless portal microvessels in the median eminence. The portal microvasculature allows protein-peptide exchange between the CNS and the anterior and posterior lobes of the pituitary gland. Pulsatile signaling by CRH and AVP drives prominent ACTH secretory bursts, which are conspicuous in hypothalamo-pituitary portal blood in the conscious horse and sheep.

CRH and AVP trigger exocytotic release of ACTH and promote *de novo* biosynthesis and storage of corticotrophic hormone in pituitary cells. Blood-borne ACTH stimulates adrenal biosynthesis of cortisol by activating a complex series of intracellular second messengers and convergent nuclear transcriptional signals. Activation culminates in the transcription, translation, and phosphorylation of pivotal sterol-transport proteins and cytochrome P450-enriched steroidogenic enzymes. Secreted cortisol is transported in blood as free steroid and (predominantly) in association with high-affinity CBG and low-affinity albumin. Important targets of cortisol action include the liver, lymphoid tissue, muscle, fat cells, the pituitary gland, the hypothalamus, and hippocampal neurons. Central glucocorticoid actions mediate repression of CRH, AVP, and ACTH outflow.

The mechanisms that amalgamate pulsatile (ultradian) and 24-h rhythmic activity are not well understood. However, in an integrative context, circadian rhythms in corticotropin and glucocorticoid concentrations arise from three- to fourfold daily variations in the amplitude of underlying ultradian bursts with lesser (if any) change in frequency. The fundamental basis for such amplitude-mediated control is not established. In the experimental animal, hypothalamic

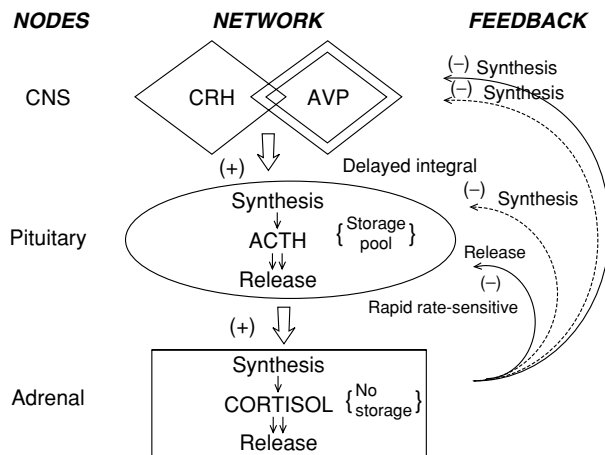

Figure 2 Fundamental feedforward (positive) and feedback (negative) connections that interlink anatomic loci in the CRH/AVP-ACTH/cortisol stress-adaptive axis. Time-delayed, nonlinear, dose-responsive interactions endow circadian, pulsatile and entropic (pattern-regularity) dynamics. Adapted from Keenan, D. M., *et al.* (2001). *Proc. Natl. Acad. Sci. USA* **98**, 4028–4033.

genes encoding CRH and AVP exhibit 24-h rhythmic variations. There is both synergy and redundancy in CRH and AVP actions. In particular, their combined effect is supra-additive, and the genetically CRH-depleted state still maintains a diurnal pattern of ACTH secretion. Glucocorticoid feedback varies across 24 h. Adrenal steroidogenic responsiveness to ACTH also changes over the day and night. The latter depends on splanchnic neuronal drive in the rodent. Thus, nycthemeral mechanisms arise in each of four loci: the hypothalamus, anterior pituitary gland, adrenal cortex, and peripheral autonomic nervous system.

The engineering notion of a servocontrol system (regulated by time-delayed and autoadaptive mechanisms) applies broadly to homeostatic adjustments within the hippocampo–hypothalamo–pituitary–adrenal–splanchnic axis. Feedforward encompasses CRH and AVP’s stimulation of ACTH production and ACTH-specific activation of cortisol secretion, and feedback includes cortisol-mediated inhibition of CRH, AVP, and ACTH output. Ensemble interactions, rather than any single regulatory locus, supervise ultradian and circadian secretion patterns. Greater understanding of such network-level adaptive control should enhance clinical facility in visualizing the mechanistic basis of corticotropic-axis pathophysiology.

Ensemble regulation of complex neuroendocrine systems such as the corticotropic axis is difficult to quantitate precisely. One useful metric is the approximate entropy (ApEn) statistic. This measure

monitors serial subpattern regularity or reproducibility. Changes in this more subtle (subpulsatile) dynamic denote alterations in strength and/or number of signaling connections. Network-like disruption is common in endocrine pathophysiology. For example, ApEn quantitates marked loss of orderly ACTH and cortisol output in patients with corticotropinomas (Cushing’s disease) and identifies significant erosion of hormone pattern regularity in aging. Analogously, growth hormone (GH) and prolactin secretion patterns deteriorate in patients with somatotropinomas (acromegaly) and prolactinomas. Randomness of the hormone release process also increases in aging GH, luteinizing hormone (LH), and insulin.

THE SOMATOTROPIC AXIS

The somatotropic axis embraces (minimally) CNS agonistic and antagonistic neurotransmitter inputs to hypothalamic peptidergic neurons; stimulatory, inhibitory, and synergistic hypothalamic signals to pituitary somatotrope cells; complex actions of GH on diverse target tissues; and insulin-like growth factor type 1 (IGF-1) production and reception. GH secretion is under the control of nycthemeral, pulsatile, and entropic (feedback-sensitive) mechanisms (Fig. 3). Ultrasensitive assays of this protein hormone unveiled 20-fold lifetime variations and 300-fold daily excursions in serum GH concentrations in healthy individuals. Such extrema reflect nocturnal amplification and daytime suppression of GH secretory-burst amplitude (and, in smaller measure, event frequency).

Figure 3 Fluctuations in GH concentrations in a healthy young adult. GH release was monitored by chemiluminescence assay. The profile illustrates tripartite patterns; viz., 24-hour rhythmic (putatively partially circadian) [continuous curve], pulsatile [interrupted line], and entropic (feedback-sensitive orderliness of the release process).

Clinical isolation experiments that establish circadian properties of GH release (e.g., free running, temperature compensated, zeitgeber-dependent control) are not available. However, sleep–wake reversal studies under constant enteral nutrition unmask a significant (35–40%) day–night rhythm in young men. Such assessments are difficult inasmuch as numerous factors govern GH secretion (e.g., fasting, food intake, sleep, exercise, gender, age). Fasting elevates GH concentrations to 10 to 30 $\mu\text{g/L}$, whereas food ingestion suppresses values to less than 0.07 $\mu\text{g/L}$ in men and less than 0.7 $\mu\text{g/L}$ in women. Entry into deep sleep (stages III and IV) amplifies GH release by three- to sixfold within 2.5 min in young men. Conversely, two keynote GH secretagogues, gonadotropin hormone-releasing hormone (GHRH) and gonadotropin hormone-releasing peptide (GHRP), exert somnifacient effects. However, the physiological role of either effector in triggering natural sleep is not defined. Sleep onset also appears to repress hypothalamic somatostatin outflow. Somatostatin is a potent inhibitory tetradecapeptide that restrains pituitary GH release and hypothalamic GHRH secretion. Muting of somatostatinergic inhibition during deep sleep would predictably heighten somatotrope responsiveness and prompt GHRH secretion. The latter concept of somatostatin withdrawal nocturnally could account for diurnal GH rhythmicity in the face of unvarying infusions of GHRH and/or GHRP-2. Exercise promotes GH release acutely in a gender- and exercise intensity-dependent manner, and physical endurance training elevates the daily mean GH concentration by approximately twofold compared with sedentary controls. Each of the forgoing dominant regulators drive GH secretory pulse amplitude without detectably altering frequency or the timing of nycthemeral rhythmicity.

NYCTHEMERAL RHYTHMS IN THYROTROPIN, PROLACTIN, AND LUTEINIZING HORMONE SECRETION

Less is known about the genesis of day–night variations in thyrotropin (TSH), prolactin, LH, and follicle-stimulating hormone (FSH) concentrations in the human. True circadian regulation is not established for these hormones. The amplitude and (less vividly) frequency of TSH and prolactin secretory bursts rise significantly during the late evening (e.g., 2030–2200 h) well before sleep onset. Approximately 35 to 50% of TSH and prolactin secretion may be nonpulsatile (basal), as compared with only 5 to 15% for other anterior and posterior pituitary hormones.

An unresolved physiological issue is whether the nonpulsatile mode of hormone production is regulated over the day and night.

LH concentrations vary by 5 to 15%, and testosterone concentrations vary by 20 to 30%, in healthy young men over 24 h, with maxima occurring at 0430 to 0900 h. The matutinal rise in FSH is minimal and variable. Diurnal rhythmicity of LH and testosterone secretion is evident before adolescence, increases markedly as puberty unfolds, and declines (sometimes to an undetectable level) in older men and women. Continuous EEG recording and frequent (2.5-min) monitoring of reproductive hormone outflow during sleep have unveiled multivalent linkages among sleep stage transitions; LH, FSH, prolactin, and testosterone secretion; and cyclic nocturnal penile tumescence (NPT), which mirrors autonomic neuronal outflow. The forgoing inferred interrelationships are illustrated in Fig. 4A. For example, rapid eye movement (REM) sleep predicts a concomitant surge in NPT activity, whereas non-REM forecasts idiosyncratically time-delayed secretion of LH, testosterone, and prolactin (Fig. 4B).

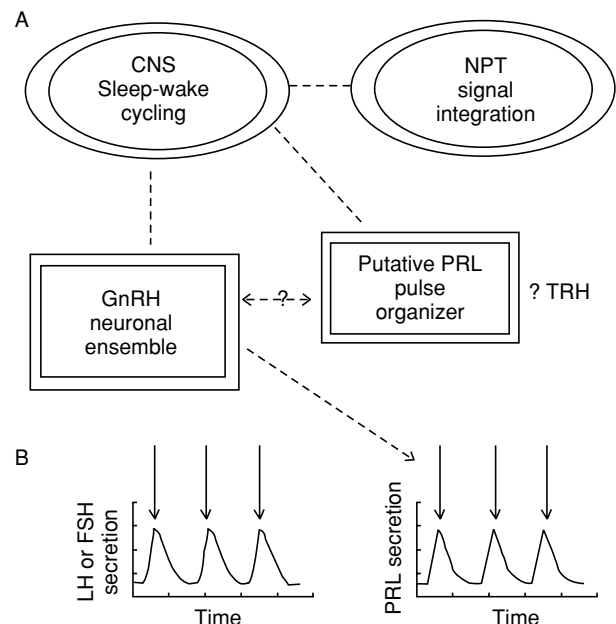

Figure 4 (A) Inferred interconnections among sleep-wake activity centers, autonomic neuronal outflow, and hypothalamic neuropeptide signaling in men. Autonomic traffic triggers oscillations in nocturnal penile tumescence (NPT). The latter activity correlates with rapid-eye-movement (REM) sleep. Episodic release of gonadotropin-releasing hormone (GnRH) drives pulsatile secretion of LH during non-REM sleep. Hypothalamic GnRH stimulates, dopamine inhibits, and additional (diverse) signals modulate pulsatile prolactin (PRL) secretion. (B) Nominal time delays among NPT, REM sleep, LH pulses, and testosterone secretion in young men.

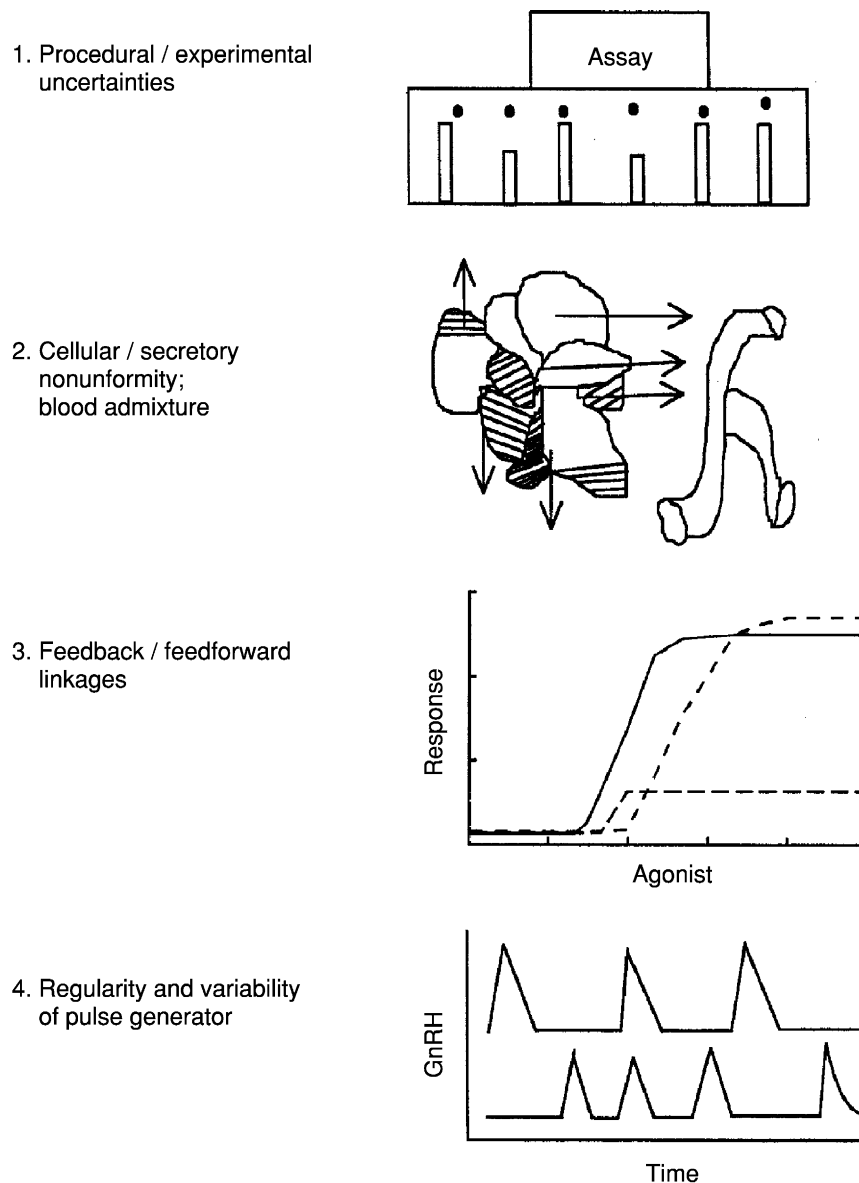

Figure 5 Sources of random (stochastic) variations that impact neurohormone outflow. Adapted from Veldhuis, J. D., *et al.* (1999). *J. Clin. Endocrinol. Metab.* **84**, 3498–3505.

Sleep–wake reversal studies, albeit limited in scope, are consistent with partially sleep-independent modulation of pituitary–gonadal rhythms. The origins and mechanisms of such regulation are unknown. Plausible (but unproven) mechanisms are diurnally cyclic neural signals from the hypothalamus to the pituitary gland and from the spinal cord to the testis.

The frequency of LH pulses declines at night in young men and women (especially during the midfollicular and luteal phases of the menstrual cycle). Nycthemeral frequency adaptations virtually vanish

in older men and postmenopausal women. The latter observation points to a dependency of diurnally varying gonadotropin-releasing hormone (GnRH)/LH pulse generator frequency on gonadal or adrenal sex steroids and/or age. Estrogen and progesterone govern SCN-directed gonadotropin secretion in the female rat.

Epinephrine (adrenalin), insulin, renin, aldosterone, adrenal androgen, leptin, antidiuretic hormone (ADH), oxytocin, and parathyroid hormone concentrations vary over 24 h. Rhythms in these cases arise from multiple (nonexclusive) mechanisms such as

nycthemeral oscillations in autonomic neuronal outflow, diurnal differences in caloric and fluid intake, the sleep–wake cycle, and day–night contrasts in physical activity. For example, aldosterone secretion increases on arising in the morning due to heightened circadian ACTH stimulation, accentuated renin–angiotensin stimulation due to upright posture, increased adrenergic drive associated with nocturnal diuresis, and posturally mediated volumetric adjustments.

STOCHASTIC ELEMENTS

From a clinical and experimental perspective, facile assessment of hormone release is confounded by several important sources of random (stochastic) variability. System uncertainty arises from technical and biological nonuniformities (Fig. 5). Technical factors include variations among (and within) individuals, sample acquisition, processing and assay, and data reduction (e.g., radioactive particle and photon counting, regression fitting, measurement interpolation). Biological factors originate from inconstant hormone synthesis, secretion, and exocytosis by single cells, clusters of cells, and an entire gland; random molecular admixture within, distribution throughout, and elimination from the circulation; time-varying dose–response coupling; and unpredictable pulse timing.

CONCLUSION

The SCN supervises circadian activity of the CRH/AVP–ACTH–cortisol axis. Circadian control is less evident in the GH axis, wherein fasting, food intake, sleep, and exercise act dominantly. LH, FSH, TSH, and prolactin rhythms do not satisfy strict circadian criteria. Prominent 24-h variations in pulse amplitude (and, to some degree, frequency) build diurnal rhythms. Kinetic (elimination) processes delay protein removal from plasma, thereby stabilizing effector concentrations. Homeostasis is coordinated via time-delayed, dose-dependent, nonlinear feedback and feedforward interactions within (and among) neuroendocrine axes. Stochastic variability arises jointly from technical and biological sources. The forgoing ensemble of control mechanisms stabilizes hormone secretion within physiological bounds.

glycation The adventitious reaction of glucose with long-lived proteins resulting in a reduced optimal function.

metabolism The remodeling of collagen by controlled enzymic degradation and synthesis.

turnover The rate at which collagen is replaced.

Collagen is the major supporting protein of the mammalian body—from bone, skin, and tendon to the transparent lens capsule, capillary basement membranes, and renal filtration membranes. It is rapidly remodeled during embryonic development and growth, a process that continues more slowly throughout life. The tissues are also capable of specific repair of the collagen. Therefore, the control mechanisms of collagen metabolism must be extremely specific and consequently very complex. With increasing age, its optimal function is lost due to adverse reactions with body metabolites such as glucose.

INTRODUCTION

The old perception of collagen as a metabolically inert supporting structure has changed dramatically over the past two decades. Approximately 27 different collagen types have been identified, and their biological properties are extremely diverse in addition to their role as a supporting scaffold for various tissues. Collagen acts as a substrate for cell adhesion, regulates fibril formation, and serves as a linker to other matrix components. In addition, it is involved in cell recognition during development and the transduction of extracellular signals. Collagen is also capable of generating peptide factors responsible for the autocrine regulation of collagen metabolism. For example, the terminal domain of type IV collagen has

been reported to inhibit angiogenesis and tumor growth, and other functions for these domains are likely to be identified in the future. As new members of the collagen protein family are being identified, even more functions are being added. The collagen family clearly plays a major role in embryonic development, remodeling of tissues, repair, and aging. The remodeling of collagenous tissues during growth and development clearly must be a very carefully controlled series of processes.

Remodeling is slower following maturation, and recent studies have demonstrated that collagenous tissues are susceptible to adventitious reaction with glucose, a series of reactions now referred to as non-enzymic glycosylation or, more generally, as glycation. These complex reactions lead to advanced glycation end products (AGEs); some of these modify the amino acid side chains, whereas others cross-link the fibrils, resulting in tissue malfunction and increased resistance to remodeling. The mechanism of synthesis and degradation of collagen during these processes is basically understood, but the regulation that maintains the balance between the two has only recently begun to be unraveled. A detailed understanding of the regulation and specific interactions of matrix collagen is central to our knowledge of growth and development, understanding certain disease etiologies, and generating new therapeutic strategies.

COLLAGEN STRUCTURE

The collagens are a closely related group of extracellular matrix molecules (ECMs) that adopt very distinct supramolecular organization (Fig. 1). In addition, the collagens exhibit diverse biophysical properties. The characteristic factor of this family of proteins is the unique triple helical domain composed of three polypeptide chains in which glycine occurs every third residue in the repeating sequence Gly–X–Y, where X and Y are often proline and hydroxyproline, respectively. Consequently, these so-called α -chains are left-handed polyproline helices rather than the

Figure 1 Diagrammatic representation of the major triple helical collagen molecules and their various modes of extracellular aggregation to form supra-macromolecular supporting structures. (A) Types I, II, III, V, and XI are long, rod-like molecules that aggregate in a parallel fashion to form quarter-staggered end overlap fibers. (B) Type IV is a longer, more flexible molecule that aggregates with the procollagen peptides still intact in an antiparallel fashion to form a network structure that is the basis for basement membranes. (C) Types IX and XIV are FACIT molecules possessing interrupted triple helices that decorate the surface of existing fibers, for example, type IX on type II fibers in articular cartilage.

usual protein α -helices. Three of these polyproline helices are bound together into a super right-handed triple helix. The triple helix is stabilized by hydrogen bonding, and the glycine side chain (hydrogen) is small enough to be integrated within the triple helix, allowing tight interchain hydrogen bonding between the NH and the CO of the adjacent peptide chains. This tight structure renders the triple helix particularly resistant to proteolysis. More than 20 different collagen molecules, made up of 38 different α -chains (either as homotrimers or heterotrimers) with two or three different chains, have been identified. The triple helix is not unique to collagen, but other proteins containing the helix are not classified as collagens because they do not aggregate to form ECM assemblies.

Fibrillar Collagens

Type I, II, III, V, and XI collagens aggregate in a quarter-staggered parallel array to form tightly packed fibrils possessing the characteristic 65-nm axial periodicity when viewed in the electron microscope. Type I is the predominant collagen of skin, tendon, and bone and confers strength to the tissue. Type III exists as narrow fibrils and tends to confer flexibility to tissues comprised of type I fibrils. Type II is the major supporting collagen of articular cartilage. The other fibrillar collagens are present in minor quantities and may play a role in regulating fiber size and the interaction with proteoglycans.

Nonfibrillar or Network Collagens

Type IV collagen is the major structural scaffold of basement membranes and exists as an open three-dimensional network that is ideally suited for the close incorporation of laminin and heparan sulfates. These membranes act as cell supports and molecular sieves but can also play a role in cell migration and differentiation. Type VII collagen molecules aggregate as dimers in an antiparallel fashion and act as an anchoring fibril of the basement membrane to the underlying matrix. Types VIII and X appear to form hexagonal arrays in Descemet's membrane of the eye and growth plate cartilage, respectively.

Filamentous Collagens

Type VI collagen aggregates as a loosely packed filamentous structure formed by end-to-end alignment of the tetramers with a repeat period of 100 nm. They occur in many tissues, and it has been suggested that they may align the larger type I fibrils.

FACIT Collagens

The fibril-associated collagens with interrupted triple helices (FACIT) do not form fibrils but associate with other collagen fibrils. Type IX decorates the surface of type II collagen fibrils and may act to limit the size of the type II fibrils or act as a link between the type II

fibrils to form a stabilizing network within the cartilage. Types XII and XIV are similar minor collagens. Type XII has been shown to interact strongly with dermatan sulfate, suggesting that it may act as a molecular cross-link stabilizing the matrix.

Other Minor Collagens

The collagens identified recently, largely by cDNA sequencing, have not all been isolated from tissue, nor have their molecular and supramolecular structures been determined.

The aggregated macromolecular assemblies are often heterogeneous. For example, type I may contain small amounts of types III and XII on the surface and type X in the fibril core. Cartilage type II fibrils are decorated with type IX and possess a core of type XI. The six different type IV chains can form different molecules, for example, $(\alpha 1)2\alpha 2$ in most basement membranes and $\alpha 3, \alpha 4, \alpha 5$ in glomerula basement membrane.

Gene Structure

Each of the known 38 procollagen α -chains is encoded by a separate gene, although some differences in collagens may arise from alternative splicing of primary pre-mRNA transcripts, particularly in the case of type XIII. The genes encoded for these collagen polypeptide chains are widely dispersed among 15 chromosomes and are characterized by high concentrations of guanine and cytosine due to the repeated coding for proline. The type IV genes are located in pairs in head-to-head orientation on chromosome 13 and their promoter regions overlap, but generally the other collagen genes are not closely linked. Most of the exons for the fibrillar collagens have a conserved 54 base-pair repeat but do not appear to be repeated in the nonfibrillar collagens.

COLLAGEN SYNTHESIS

Intracellular Events

The fibroblast is the predominant cell type responsible for the production of collagen, although several other cell types (e.g., endothelial cells, osteoblasts, chondrocytes, muscle cells) are also capable of synthesizing collagen. The processes are now well understood and have been well reviewed (Fig 1).

The major steps can be described as follows. Collagen DNA is transcribed in the nucleus, and the primary RNA is spliced to mRNA and translated in

the cytoplasm. The N-terminal signal sequence peptide is cleaved at the rough endoplasmic reticulum to provide a single procollagen chain that interacts with two other procollagen chains to form the triple helical procollagen molecules.

The procollagen α -chain undergoes a number of posttranslational modifications that include hydroxylation of proline and lysine by prolyl-hydroxylase and lysyl-hydroxylase, respectively, and these reactions involve the cofactors ferrous iron, ascorbate, α -ketoglutarate, and oxygen (Table I). Hydroxylation occurs on the nascent α -chain and proceeds until all of the prolines in the Y position are hydroxylated. This process is crucial to the subsequent stability of the triple helix. The hydroxyproline content determines its thermal stability, and underhydroxylated collagen is unstable and denatures at body temperature. Some of the hydroxylysines may then be glycosylated by galactosyl and glucosyl transferases. These modifications take place only on the nascent α -chains and cease as the triple helix is formed following nucleation of the C propeptides and the subsequent winding together of the polyproline helices into the triple helix. The procollagen molecules are then transported from the rough endoplasmic reticulum to the Golgi apparatus, where they are secreted from the cell.

Extracellular Processing

The N and C propeptides are released from the procollagen molecules on secretion from the cells. This step results in the formation of fibrils. The C propeptide enters the circulation and, unlike the N terminal, is not degraded until it reaches the liver. Therefore, the quantitation of the C propeptide can be used as an accurate stoichiometric determinant of synthesis in which one intact collagen molecule is produced per procollagen molecule (Fig. 2).

Cleavage of the N and C propeptides by specific endopeptidases occurs during secretion from the cell, but the collagen molecule retains short residual non-triple helical regions at the N (16 residues) and C (20 residues) termini. Each of these telopeptides contains a lysine or hydroxylysine residue that is subsequently involved in stabilizing the newly formed fibers through the formation of intermolecular cross-links within the fibril. This is achieved by the oxidative deamination of these residues by lysyl oxidase to form the corresponding aldehydes that then react with specific lysine and hydroxylysine residues in the triple helix. These initial divalent cross-links are predominant during rapid growth and remodeling of the

Regulation of Synthesis

Regulation of procollagen synthesis occurs at several levels: transcription in the nucleus, translation in the cytosol, degradation within the cell and in the extracellular space, and modulation of the concentration of connective tissue-synthesizing cells (Table II). Clearly, under normal physiological conditions, the overall synthesis of collagen has to be in balance with the overall degradation of the collagen fibrils.

Transcriptional Regulation

Synthesis can initially be controlled at the transcriptional level by the activation of particular genes, and recent evidence suggests that the genes must be coordinated. Therefore, the regulation of expression of procollagen genes is clearly a complex process: coordinating genes for the various collagens. The control mechanism is believed to involve both specific DNA sequences (*cis* elements) in the promoter region

collagenous tissues. However, as turnover decreases, they react further to form trivalent stable cross-links. It has been proposed that these trivalent bonds stabilize the mature fibril by forming interfibrillar cross-links.

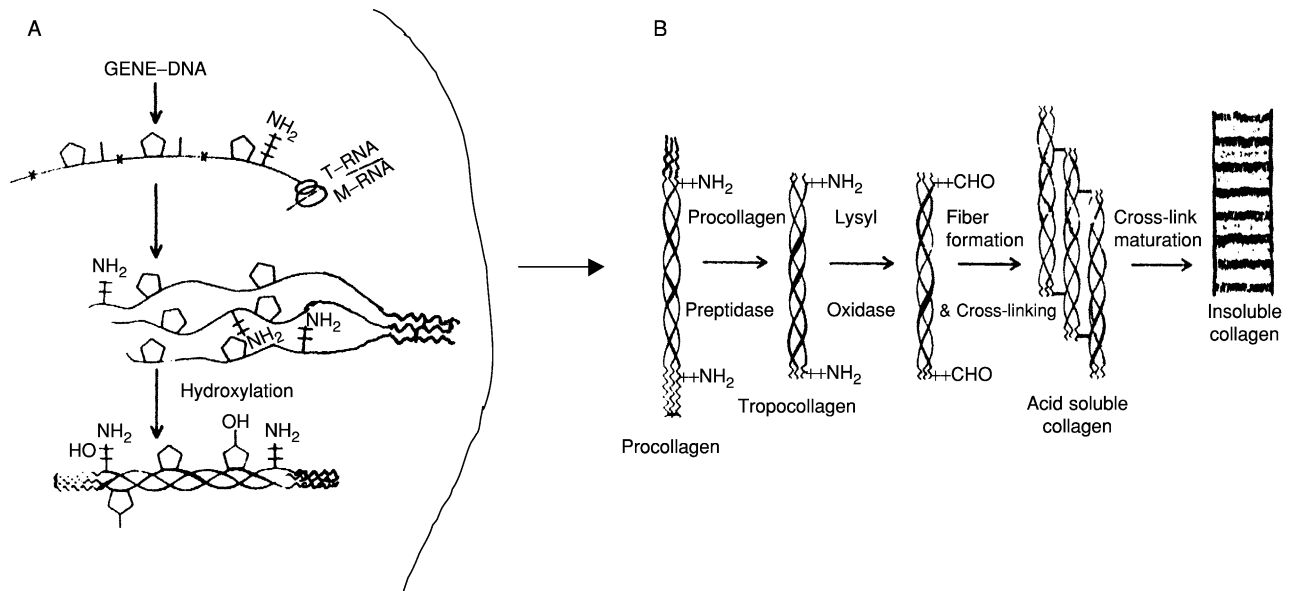

Figure 2 Schematic representation of intracellular (A) and extracellular (B) events in the synthesis of collagen and the formation of the collagen fiber.

that are required for efficient transcription and the promoter sequence required for cell and tissue expression; cell-specific (*trans*-acting) factors are involved in the regulation of collagen gene expression. Any modification of these regulatory elements would result in loss of control and, subsequently, in fibrosis or resorption. Several *cis*-acting regulatory elements and *trans*-acting protein factors have now been identified. The absolute quantitation may be modulated, for example, by cytokines mediated at the transcription level, although posttranslational regulation must also be taken into account.

C and N propeptides of procollagen have been reported to be down-regulators of collagen synthesis by a feedback mechanism, and it has been proposed that they may act either by blocking DNA transcription, by decreasing the half-life of procollagen mRNA, or by altering the rate of mRNA translation.

The rate of collagen synthesis will be determined by the equilibrium between the synthesis of mRNA (i.e., the rate of transcription) and the degradation of mRNA. Protein kinase C, cyclic AMP (cAMP), and various cytokines such as interleukin-1 (IL-1) may affect this equilibrium. Growth factors have also been shown to affect collagen production by altering the steady-state levels of mRNA for procollagen; for example, TGF- β acts at more than one regulatory level by increasing the rate of transcription of procollagen genes, increasing mRNA stability, and decreasing the degradation of the newly synthesized procollagen. There are several TGF- β signaling pathways leading to the activation of collagen genes, one of which is linked directly to the TGF- β receptor at the cell surface and involves proteins known as Smads. TGF- β also activates the connective tissue growth factor (CTGF).

Posttranslational Regulation

The rate of translation of procollagen mRNA is generally not considered to be rate limiting in collagen synthesis. However, the posttranslational modifications, the most important of which is hydroxylation of proline, may be a rate-limiting step.

A second determinant of collagen formation is the rate of the intracellular degradation of newly synthesized procollagen when as much as 30% of the procollagen is degraded. The final step in the deposition of collagen is the proteolytic degradation of the fibrous collagen in a process that is highly regulated, with many cytokines and growth factors affecting the activity of the enzymes involved.

Table III Collagen-Degrading Enzymes: Matrix Metalloproteinases and Cathepsins

| Matrix metalloproteinase | Optimal pH | Major substrate |
|--------------------------------|------------|----------------------|
| Interstitial collagenases | | |
| MMP-1, MMP-8, MMP-13 | 7-8 | Triple helix |
| Gelatinases | | |

| Aspartic proteinases | | |
| Cathepsin D | 3-6 | Telopeptides/Gelatin |

RESORPTION

Degradation

The degradation of collagen is a highly controlled process, as several functionally related proteinases with diverse substrate specificities coordinate to control the degradation and resorption (Fig. 3). The intact triple helical molecules are very resistant to proteolytic degradation, but a specific group of zinc-dependent endopeptidases, known as the metalloproteinases, are capable of degrading collagen (Table III). There are now more than 20 members of this proteinase family. Degradation is initiated by interstitial collagenase (MMP-1) or neutrophil collagenase (MMP-8), both of which cleave the triple helical region into two fragments at a point three-quarters along the length of the molecule at a specific site (Gly-Ileu) near the C-terminal end. The two fragments are thermally unstable and denature at body temperature to random chains of gelatin, which are then susceptible to most proteolytic enzymes, including the gelatinases MMP-2 and MMP-9, which are present in the ECMs.

An alternative route to initial fragmentation/solubilization of the fiber, prior to denaturation and degradation by the gelatinases, is the specific cleavage of the N- and C-terminal peptides on the triple helical side of the cross-links. This can be achieved by the acid cathepsins following phagocytosis by the intracellular lysosomes, but cathepsins can also exist in the extracellular matrix and so can digest the intact fibrils.

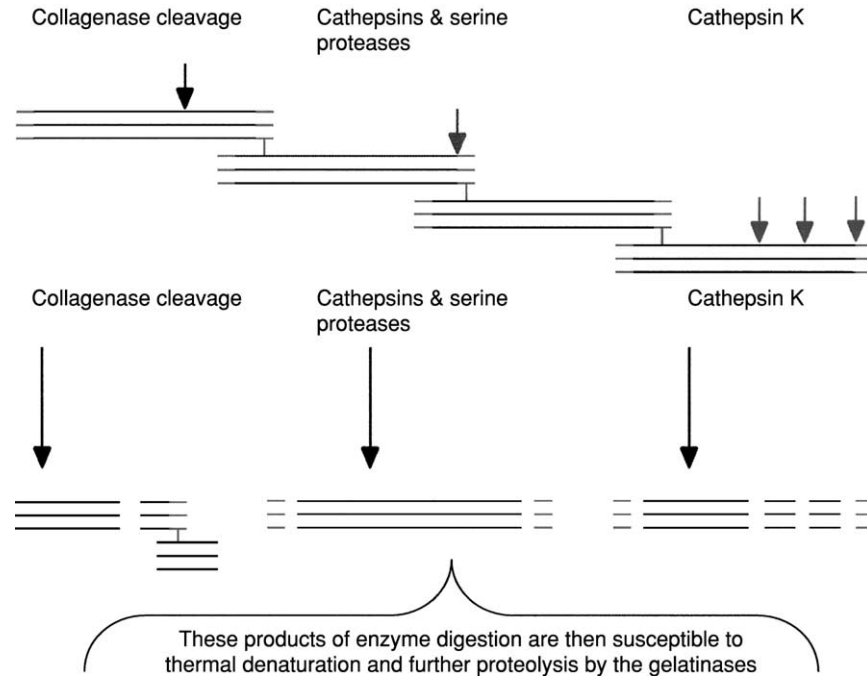

Figure 3 Representation of the various mechanisms involved in the degradation of cross-linked collagen fibers. Mammalian collagenase cleaves the triple helix at a single location to give two fragments three-quarters and one-quarter the length of the molecule. Extracellular cathepsins and serine proteinases cleave the telopeptide region between the triple helix and the cross-links, thereby releasing the molecule into solution. Cathepsin K has been shown to cleave the triple helix at several locations (multiple arrows). The released fragments thermally denature under physiological conditions and are then digested by the gelatinases to small peptides and amino acids. In addition to extracellular degradation of the fiber, damaged fibers are phagocytosed and digested intracellularly within lysosomes by the cathepsins.

Indeed, cathepsin K has recently been reported to be capable of digesting the triple helical region of the type I collagen fibril in bone. The importance of this enzyme in bone metabolism is highlighted in pycnodysostosis, where the congenital deficiency of cathepsin K results in an abnormal skeletal phenotype such as unfused cranial sutures and sclerosis.

Collagenase (MMP-1) is secreted as a proenzyme at 55 kDa or at 57 kDa in the glycosylated form. Collagenase is expressed by most connective tissue cells, and although it has several substrates, its predominant activity is against intact collagen. A novel human collagenase, homologous to rodent collagenase I, has been identified in breast carcinoma and designated MMP-13. Its principal substrates are the interstitial collagens, primarily type II. Guinea pigs possess both MMP-1 and MMP-13; guinea pigs resemble rabbits more closely than they do rodents.

The MMPs share common structural and functional features and can consist of seven defined domains of biological activity; for example, MMP-9 exhibits all seven domains, whereas most others lack at least one of these domains. At the N terminal, the

prepeptide directs the proenzyme to the extracellular matrix and is cleaved during secretion. The second domain contains the "cysteine switch" sequence motif maintaining the proenzyme in its latent state, but this is also lost on activation. The third domain is the catalytic region containing the fibronectin domain to bind gelatinases (MMP-2 and -9) and the zinc-binding domain that is coordinated with three histidine residues at the active site. The fifth short domain contains the type V collagen linker that is proline rich and is probably the recognition site for collagen, followed by the hemopexin domain (hemopexin is a blood glycoprotein with a high affinity for heme) that binds the tissue inhibitors of metalloproteinases (TIMPs). The seventh domain of the membrane MMPs contains a transmembrane domain. A furin-serine proteinase activates the MT-MMPs in the Golgi complex; consequently, these enzymes complex with the plasma membrane in their active form.

Regulation

The MMPs have the capacity to completely degrade the extracellular matrix; therefore, they need to be

strictly controlled. This may occur at three stages: (1) transcriptional regulation by cytokines and growth factors via cell-signaling pathways, (2) extracellular activation of the proenzyme by plasmin or other MMPs, and (3) inhibition by specific TIMPs that are coordinately expressed with the MMPs.

Transcriptional Regulation

The genes that encode the MMPs (except MMP-2) are inducible by cytokines and growth factors; consequently, they have multiple regions in their promoters AP-1, TPA, and SP-1. Therefore, a complex system exists for regulation at the transcriptional level, allowing a subtle interplay between the members of the MMP family and gene control of remodeling in response to physiological and pathological stimuli.

Activation Control

The MMPs (except MT-MMP) are secreted as proenzymes and remain in their latent state until required. Therefore, activation can occur locally at a required site of action. The proenzyme is activated by cleavage of the 77- to 87-N-terminal amino acid sequence by plasmin or one of the other activated MMPs. This activation, known as the cysteine switch, involves water entering the active site and initiating irreversible autolytic cleavage of the propeptide motif PRCG (V/W) PD (V/L). Plasmin is thought to be the most significant activator of MMPs. (*In vitro* activation can be achieved by aminophenyl-mercuric-acetate (APMA), a compound that disrupts the cysteine-zinc interaction.) Activation of MMP-2 occurs by a different route in that it does not possess a plasmin cleavage site and *in vivo* may be activated via MT-MMP or via a pro-MMP-2/TIMP-2 complex. It can also be activated *in vitro* by APMA.

Inhibition Control

The last line of regulation to control matrix degradation is inhibition of the MMPs by the TIMPs, which bind to MMPs with a 1:1 stoichiometry. They are also inhibited by the general serine proteinase inhibitor α -2 macroglobulin, but its action is predominantly restricted to the body fluids. The TIMPs can complex with the latent form of MMPs. There are four structurally related TIMPs: TIMP-1, -2, -3, and -4. TIMP-1 and -2 have a molecular weight of approximately 24 kDa and so are readily diffusible in tissue. TIMP-3 is bound to the plasma membrane. The TIMPs are stabilized by disulfide bonds, with one domain being responsible for enzyme recognition and the other being responsible for inhibition.

Gelatinases

The gelatinases MMP-2 and -9 will degrade collagen following its denaturation to gelatin but will also cleave native type IV collagen because of its numerous short disorganized helical regions due to the absence of the strict Gly-X-Y sequence. MMP-9 expression can be induced by cytokines and growth factors and is associated mainly with the inflammation process and particularly following the ingress of neutrophils. MMP-2 is expressed constitutively and is found in all tissues, particularly during remodeling. Pro-MMP-2 is secreted as a 72-kDa zymogen but can exist in a higher molecular weight glycosylated form, particularly in rodents. The gelatinase recognizes gelatin by the affinity for three fibronectin-like repeat sequences and specifically cleaves Gly-Ileu at the sequence Pro-Gln-Gly-Ileu-Ala-Gln-Glu.

COLLAGEN TURNOVER RATE

The amount of collagen finally deposited obviously continues to increase during mammalian growth. However, collagen synthesis rates decrease with age but do not terminate; collagen is continuously synthesized and degraded slowly throughout life. The rate of this turnover differs considerably among the tissues of the body. For example, the collagen of articular cartilage has a biological half-life of more than 100 years, compared with a half-life of 2 days for the periodontal ligament. Unfortunately, accurate determination of the rate of turnover has been fraught with technical difficulties. The early studies involved following the incorporation of ^{14}C -proline into collagen and determined as ^{14}C -hydroxyproline indicated a very low turnover of collagen; indeed, it was considered virtually metabolically inert. Further studies revealed the surprising finding that up to 30% of the newly synthesized procollagen was degraded before secretion from the cell. Presumably, this involved the removal of aberrant collagen; for example, underhydroxylated collagen is thermally unstable and would denature and hence be readily degraded. Later studies using a flooding dose of ^{14}C -proline suggested a similar rapid degradation of the newly formed extracellular fibers. These studies also suggested that the extent of degradation increased with age and that up to 80% of the total synthesis is degraded before formation of stable fibers in adult rats and rabbits. Furthermore, calculation of the rate of turnover of lung collagen was estimated at 10% per day, a surprisingly high figure.

Alternative techniques have been attempted, e.g., the determination of ^{18}O by mass spectrometry. The

recent identification of isomerization and racemization of L- to D-aspartic acid has been shown to be linearly related to age and hence used to calculate turnover. Based on the rate of D-aspartic acid accumulation in the tissue as determined by high-performance liquid chromatography (HPLC) of the derivitized racemic mixture following hydrolysis, the turnover of human collagen has been estimated at 14 years for skin, 100 years for articular cartilage, and 500 years for dentine. The transformation of D-aspartic acid appears to provide a means of determining the rate of turnover of collagen, and further studies on other collagenous tissues would be valuable. It also needs to be assessed whether the transformation reaches equilibrium at a certain proportion of D-aspartic acid formation.

The glycation cross-link pentosidine has been shown to increase linearly with the age of skin and cartilage and so can be an additional marker of the metabolism of these tissues.

AGING

Glycation

The turnover of collagen decreases following maturation, and this leads to long-term exposure to reducing sugars and the consequent nonenzymic glycation of collagen (Fig. 4). Glycation is a posttranslational modification that is of singular importance in long-lived proteins such as collagen. These Maillard-type reactions can result in random cross-linking, thereby changing the physical and chemical properties, alterations that include reduced turnover to such an extent that they are believed to play a fundamental role in the aging process.

The initial reaction is between the aldehydic group of the open chain form of glucose with either the ϵ -amino group of lysine residues or the ϵ -guanidino group of arginine to form a Schiff base. The resulting Schiff base is then stabilized by undergoing an Amadori rearrangement. The Amadori product undergoes further oxidative reactions, resulting in the formation of stable AGEs. Other pathways to the formation of AGEs may involve metal catalyzed oxidation products of glucose, reaction with lipid oxidation products such as malondialdehyde, and the reaction with natural active metabolites such as methylglyoxal. The many different pathways depend on the conditions available and lead to a diverse range of AGEs. Some have been identified, but these probably represent only the tip of the iceberg in terms of products yet to be identified.

The AGEs may be stable modifications of the amino acid side chains of lysine and arginine (e.g., carboxymethyl-lysine, argpyrimidine, imidazolones of arginine), and these modifications may affect important cell-collagen interactions. Other AGEs may form intermolecular cross-links at random between collagen molecules, thereby stiffening the fiber and reducing its optimal function and turnover. The formation of these AGE cross-links is believed to be responsible for the stiffening of the aorta, thickening of the glomerula basement membranes, cataract formation, and reduction of renal and pulmonary function. The AGE cross-links have also been implicated in the amyloid plaques in neurodegenerative diseases. These changes generally occur slowly with age but are accelerated in diabetes where the glucose levels are much higher, a process often referred to as "accelerated aging." The involvement of AGEs in these deleterious processes is strongly supported by similar changes occurring following the administration of a mixture of AGEs prepared *in vitro* to normal mice.

There are many cell-mediated effects of AGEs on collagen turnover, possibly through the AGE receptors that, when bound, activate key signaling molecules, such as NF- κ B, that alter gene expression. Fibroblast cell lines exposed to glycated albumin can exhibit reduced synthesis of type I collagen and MMP-2 production. In addition, there is a decrease in the adhesion of cells to the matrix, possibly through modifications in the RGD (Arg-Gly-Asp) recognition sequence for the integrins.

The extent of glycation depends on the rate of collagen turnover for a particular tissue; thus, greater glycation has been reported in articular cartilage where turnover is very low, whereas matrix glycation is lower in bone because of the higher metabolic rate.

Glycation may be inhibited by several compounds that compete during the initial stages of the reaction such as aminoguanidine, aspirin, and pyridoxine. Studies have reported a reversal of the effects of glycation in terms of an impressive return of the elasticity of various tissues, including the vascular system by the use of phenyl-dimethyl-thiazolium chloride. Although this type of compound seems to be effective, its proposed mode of action to cleave the glycation cross-links is controversial and may simply involve the removal of specific reaction metabolites. It has also been proposed that the effects of AGEs may be reduced *in vivo* by the presence of AGE-binding scavenger receptors such as those found on a variety of cell types, including macrophages, monocytes, and endothelial cells. Therefore, there does appear to be the

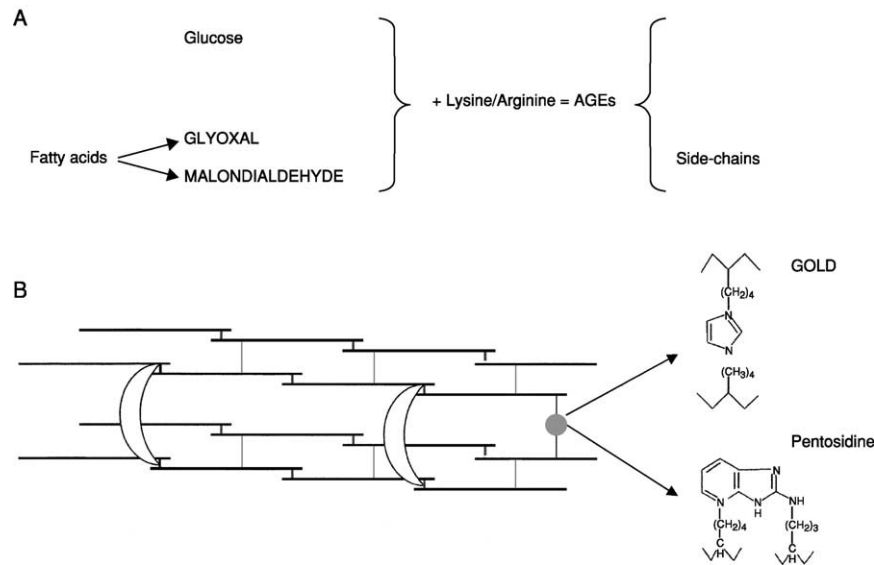

Figure 4 (A) Schematic diagram of the nonenzymic glycosylation (glycation) of collagen by reaction with glyoxal (derived from glucose or fatty acids) and malondialdehyde (derived from fatty acids) to form AGEs. These products may be glycation cross-links or side chain modifications. (B) The proposed location of inter-fibrillar glycation cross-links (double arrows) and the structure of two glycation cross-links: pentosidine and a lysyl-imidazolium product (GOLD). The proposed locations of the lysyl-oxidase-derived immature cross-links (up and down arrowheads) and mature cross-links (crescent symbols) are also shown.

potential for an in-built control mechanism to reduce the damaging effects of glycation *in vivo*.

The accumulation of glycation products certainly correlates with aging, and the glycation products do affect the optimal functioning of vital tissues, but do they cause aging? Inhibition would slow down the loss of function in the cardiovascular and renal tissues and so would lead to better health during old age, but if it is the cause of aging, it would lead to an extension of maximum life span. It is highly unlikely that glycation controls aging.

Isomerization and Racemization

Amino acids exist in proteins in the L form, but isomerization and racemization of these residues in long-lived proteins have been known for some time. Aspartic acid has one of the fastest rates of racemization, and determination of the rare D-aspartic acid form in tissue has been shown to be age related and so can be used as a measure of turnover of the particular protein. Type I collagen undergoes β -isomerization of the Asp-Gly bond within the non-helical C-terminal peptide, and the extent of the transformation increases linearly with age. There are two spontaneous transformations: the racemization of the L-enantiomeric form to the D form and the

isomerization of the peptide backbone by transfer from the α -carboxyl to the β -carboxyl of the peptide-bound aspartic acid. However, the nature of the structural change within the telopeptide, in contrast to glycation, is unlikely to affect the rate of turnover of the modified collagen.

Other chemical modifications accumulate with age, deamidation, oxidation of methionines, *cis-trans* isomerization of prolines, and β -elimination of serine and cysteine, but glycation appears to have the most profound effect on the metabolism of collagen.

collagen A family of extracellular supporting proteins comprising 25% of total body protein.

metabolism The ratio of synthesis to degradation.

turnover The rate at which collagen is replaced.

The health and maintenance of collagenous structures involve the delicate balance between the synthesis of collagen types and their degradation and removal. Disruption in either of these processes can have serious consequences for the performance of the affected tissues.

INTRODUCTION

The turnover and maintenance of functionally competent collagenous tissues involve a delicate balance between synthesis and degradation. An imbalance would lead to either a loss of collagen (i.e., resorption) or an excess of collagen (i.e., fibrosis). The loss or resorption of collagen is probably best exemplified by the fragility of bone in osteoporosis, but loss does occur in other tissues. In pathological fibrosis, the excess synthesis continues unabated, disrupting the normal tissue architecture and function. Fibrosis can occur in nearly any organ of the body, with the most frequently affected being the lung, liver, kidney, heart, and skin.

The initiating factors resulting in a metabolic imbalance, as well as factors initiating the resorption of collagenous tissues, may well be different in the fibrosis of various tissues. However, there are common cellular and molecular events underlying progression of fibrosis; hence, there is a common basis on which therapeutic strategies could be developed. To provide a basis for any therapy, an understanding of the cellular and molecular events is crucial. The metabolism of collagen in terms of the mechanisms of synthesis and degradation has been discussed previously, and the inhibition or stimulation of any of these stages that

are rate limiting could be used to prevent fibrosis or resorption.

We have classified a number of examples of collagen metabolism diseases involving an imbalance in both synthesis and resorption. The latter is best exemplified by bone collagen, and the former is best exemplified by soft tissue collagen. Therefore, it is worth briefly summarizing the properties of collagen in bone. Approximately 90% of the organic matrix of bone tissue consists of collagen. Bone tissue is a composite material consisting mostly of type I collagen, which provides a template for mineralization by hydroxyapatite crystals. The function of the small amount of type V collagen (~3%) is uncertain, but based on the retention of its amino-terminal propeptide, it may be involved in the regulation of type I collagen fiber size. The collagen is synthesized and mineralized by the osteoblasts and is removed primarily by the bone-resorbing osteoclasts. In addition to its important supportive role, collagen provides a means of cellular communication, most notably to the entombed osteocytes, a main function of which is believed to be the transduction of mechanical stimuli that has important consequences for the regulation of bone mass.

Bone loss, or osteopenia, and the subsequent development of osteoporosis are known to occur as a consequence of changes in the circulating levels of some systemic hormones. The reduction in serum estrogen postmenopause and its impact on bone metabolism have probably gained the greatest global interest, but bone loss in response to raised prolactin, parathyroid hormone (PTH), thyroxine (T₄), and glucocorticoids, as well as to reduced insulin, has also been studied.

METABOLIC DISORDERS DUE TO EXCESSIVE DEGRADATION

Estrogen Deficiency

The study of bone tissue in response to reduced estrogen has been the subject of intense academic

and clinical interest because osteoporosis is a leading cause of morbidity, mortality, and social costs. Fracture of the femoral neck exerts the greatest impression on the health services. Indeed, of those who present with this type of fracture, nearly a fifth will die within the first 6 months, and of the remainder, approximately 50% will lose their independence. It has been predicted that the number of individuals over 60 years of age will increase to 700 million by 2025, so clearly the financial burden on the health services is a major concern.

When the circulating levels of estrogen fall with the onset of menopause, bone collagen turnover increases (i.e., the indexes of resorption and formation both are elevated) but the rate of collagen catabolism outweighs collagen synthesis. In addition, this rate of turnover is greater in cancellous sites due to their larger surface area. This increased rate of synthesis of collagen results in a change in quality, for example, higher hydroxylation of the lysine residues and modified cross-linking, both of which lead to a more fragile fibril. The change in quality accelerates the probability of bone fracture and almost certainly accounts for the absence of a correlation of bone mineral density (BMD) and bone fracture observed in clinical practice. Clearly, the quality of the collagen needs to be taken into account.

It has also been demonstrated that osteoblasts mobilize a number of very potent bone-resorbing stimuli in response to diminished estrogen; these include prostaglandins, macrophage colony-stimulating factor (MCSF), interleukins-1 and -6, and tumor necrosis factor- α (TNF- α). It has also been found that the bone tissue levels of transforming growth factor- β (TGF- β) are reduced following estrogen deficiency, and this in turn may lead to greater osteoblast losses through programmed cell death and/or reduced collagen synthesis. The sensitivity of bone to PTH has also been reported to be greater with estrogen deficiency.

Estrogen replacement is a well-established treatment for osteoporosis. Estrogen reduces the rapid phase of bone loss, but the mechanism is unknown, although estrogen receptors are known to be present in both osteoblasts and osteoclasts. The inhibition of bone collagen turnover by estrogen allows the collagen to stabilize by normal enzymic cross-link maturation. However, we found that in the long term (>5 years), the estrogen had an anabolic effect, with the synthesis of new collagen being stimulated. These results indicate that long-term high doses of estrogen have a therapeutic role in postmenopausal women with osteoporosis.

Bisphosphonates are also used in osteoporosis and are believed to inhibit osteoclast activity, but the precise mechanism is unknown.

Cushing's Disease

Since it was first described by Harvey Cushing in 1932, the syndrome of glucocorticoid excess has been recognized as one of the most important causes of bone loss. Indeed, osteoporosis features significantly in the morbidity associated with Cushing's syndrome. What of the mechanism of bone loss in Cushing's syndrome? Osteoblast-like cells and calvarial bone cultures on receipt of glucocorticoids have reduced mRNA levels of α 1(I) collagen (COL1A1). This reduction in type I collagen synthesis is attributed to both a reduction in COL1A1 transcription and a decrease in the stability of the actual mRNA. It has been proposed that glucocorticoids act at a TGF- β -responsive site to block COL1A1 transcription. Because the ability of osteoblasts to produce type I collagen is reduced during periods of raised serum cortisol, there is a reduction in bone collagen synthesis and mineralization. However, the resorption of bone with prolonged glucocorticoid exposure is increased in response to raised serum PTH and decreased estrogen.

Hyperparathyroidism and Hyperthyroidism

Hyperparathyroidism is a common endocrine disease and is due to an excessive production of PTH by the parathyroid gland. It is characterized clinically by hypercalcemia and osteopenia. Albright and Reifenstein referred to it as a "disease of the bones and stones and abdominal groans occasionally complicated by psychological moans."

It is generally agreed that the actions of PTH on bone are via the osteoblast, although binding of iodinated PTH (residues 1–84) has been described for osteoclasts. PTH results in the catabolism of collagen (by stimulating the synthesis of collagenase) as well as in the inhibition of type I collagen synthesis. It has been demonstrated that PTH, by acting through the cyclic AMP (cAMP)–protein kinase A pathway, inhibits the promoter region for type I collagen, possibly through the generation of a protein that binds to the COL1A1 promoter. Another possible mechanism is thought to include the PTH-induced autocrine feedback by prostaglandin E₂ on osteoblasts, resulting in the suppression of COL1A1 gene transcription.

Hyperparathyroidism results in significant bone losses because of heightened bone matrix resorption coupled with reduced type I collagen synthesis. Primary disease results from either parathyroid gland hyperplasia or a single adenoma, whereas secondary hyperparathyroidism is most commonly a consequence of chronic renal failure. A hormone strikingly similar to PTH, PTH-related protein, is the known causal factor for the hypercalcemia associated with malignancy.

More than a century has passed since von Recklinghausen first described bone loss in thyrotoxicosis. Since this initial observation, there has been compelling evidence of a role for thyroid hormones in bone metabolism. Bone loss as a consequence of hyperthyroidism is the result of an imbalance between bone formation and resorption. Cultured rat and human osteoblasts display heightened proliferation and reduced collagen synthesis when treated with triiodothyronine (T₃). The ability of cells to mineralize a collagenous matrix *in vitro* is also reduced when osteoblasts are treated with T₃ and T₄.

Prolapse

As an example of an imbalance in a soft connective tissue turnover, genitourinary prolapse is a very common problem, the precise pathophysiology of which is unknown. However, recent studies have demonstrated that the disorder may be due to a change in the metabolism of the uterine collagen in favor of excessive resorption. This results in a decrease in the mechanical strength of both the uterine tissues and the supporting ligaments.

METABOLIC DISORDERS DUE TO EXCESSIVE COLLAGEN SYNTHESIS

Osteoarthritis

Osteoarthritis (OA) represents the most common form of joint disease. This cruelly debilitating disease is characterized by local and systemic increases in BMD, bony outgrowths (osteophytes), thickening of bone tissue (sclerosis), bone cysts, loss of articular cartilage, and joint space narrowing. However, it has generally been considered to be a disorder of articular cartilage degradation. Although both Radin and Dequeker proposed several decades ago that OA is a whole "joint disease," it is only during the past few years that researchers have looked beyond the degradation of the articular surface in attempting to understand the etiology of the disease. Besides the characteristic local joint changes, another example of

bone tissue abnormality in OA is the striking systemic increases in BMD for nonsynovial sites such as the lumbar spine. The factor(s) responsible for this rise in BMD has not yet been defined.

It was proposed many years ago that increased bone stiffness, attributable to altered collagen metabolism and/or composition, was responsible for placing the increase in shear stresses at the joint surface, with catastrophic consequences for joint function. Such changes in bone collagen stiffness below the articular cartilage would have a significant bearing on the integrity of cartilage tissue; the replacement of bone tissue with the stiffer methacrylate composite produces demonstrable articular cartilage splitting and losses. Like the human, the guinea pig and macaque also develop spontaneous OA. In addition, both of these species display marked morphological changes in bone tissue prior to cartilage tissue involvement (Fig. 1), findings that support earlier claims of an inherent problem of bone collagen metabolism and/or composition in OA. One of the first direct studies that aimed to address bone collagen metabolism in OA reported an increase in the excretion of the mature bone collagen cross-link, lysyl pyridinoline. Subsequent technetium-labeled bisphosphonate studies in

Figure 1 Skeletal tissue changes in an animal model of spontaneous osteoarthritis. (A) Articular cartilage losses and disruption in response to thickened subchondral bone tissue in the Dunkin-Hartley guinea pig. Note the reduced staining for proteoglycan in the articular cartilage (black arrow) and the marked increase in subchondral bone tissue (white arrow). (B) Typical appearance of healthy joint structures in an age-matched guinea pig strain that does not develop osteoarthritis. There is considerably more bone marrow occupying the spaces between the bone trabeculae, and the matrix proteoglycan in the cartilage layer is clearly visible on staining with hematoxylin and eosin (black arrow).

Table I Metabolic Changes That Have Been Reported to Occur within the Trabecular Bone Compartment of Osteoarthritic Femoral Heads (Means \pm SEM)

| Parameter | Healthy bone tissue | Osteoarthritic bone |
|--|---------------------|---------------------|
| Collagen content ($\mu\text{g}/\text{mg}$ tissue) | 79 \pm 7 | 140 \pm 3 |
| Collagen calcification (mmol calcium/mol collagen) | 8.4 \pm 0.14 | 6.2 \pm 0.25 |
| C-terminal propeptide of type I collagen (ng/mg protein) | 11 \pm 6 | 288 \pm 22 |
| Alkaline phosphatase activity (mUnits/mg protein) | 40 \pm 10 | 370 \pm 30 |
| Change in latent MMP-2 | | Two-fold increase |
| Change in active MMP-2 | | Four-fold increase |
| TGF- β (ng/mg protein) | 32.9 \pm 24 | 123.4 \pm 13 |

affected patients identified potential changes in mineral metabolism and hence the possibility of altered collagen calcification in osteoarthritic bone. Taken together, these preliminary findings started to point toward bone abnormalities in a disease that was largely thought to center around a defect in articular cartilage biology.

A comprehensive investigation of bone collagen turnover and composition was conducted by Mansell and Bailey (Table I), who addressed the question of whether changes in collagen metabolism could occur at sites other than those juxtaposed to cartilage damage but at regions nearer the existing head-neck boundary of diseased femoral heads. The overall findings supported altered bone collagen composition and metabolism in OA. Although collagen turnover was affected most profoundly nearest the existing articular surface (subchondral bone), there were clear increases in bone collagen metabolism in the cancellous bone at more distant sites. The synthesis of type I collagen, as determined by the tissue levels of the carboxy-terminal propeptide (PICP), was markedly elevated in osteoarthritic bone, and increased degradation was determined by metalloproteinase levels. The levels of alkaline phosphatase were also greatly elevated, supporting a general up-regulation in collagen synthesis and potential for calcification. However, the extent of collagen mineralization was significantly lower in OA specimens than in age-matched controls, indicating a greater proportion of immature matrix. Additional microscopic investigations revealed disorganized collagen fibrils in diseased bone tissue. The latter may be related to a change in the phenotypic expression of collagen. Under these conditions, bone collagen contains an increasing proportion of the new type I homotrimer $[(\alpha 1)_3]$, as compared with the normal one $[(\alpha 1)_2\alpha 2]$, and an increased level of lysine hydroxylation. Both of these effects actually lead to a weaker collagen fiber in the thickened subchondral bone.

Together with the finding that osteoblasts from OA bone are capable of degrading cartilage, this suggests that a mechanical basis for OA is debatable.

The factor(s) responsible for driving the increase in bone collagen turnover has yet to be identified. Interestingly, two studies have reported raised bone tissue levels of TGF- β , and one of these found an increase in this factor at a nonsynovial joint site (iliac crest). The significance of these findings is reflected in the ability of this agent to stimulate type I collagen synthesis by osteoblasts, and because the collagen content in OA bone tissue is significantly elevated, TGF- β may represent the candidate molecule responsible for the changes observed.

Paget's Disease

Another common bone disease of the elderly involving a change in the metabolism of collagen is Paget's disease, characterized by excessive collagen production and disorganized bone remodeling. The rates of collagen turnover can be increased up to 20-fold. The newly synthesized collagen fibers are disorganized in structure, producing both woven and lamellar bone. This lack of alignment is probably the cause of the most common complication, that is, fracture after trivial injury.

The nature of the biochemical changes in the collagen apparently has not been studied, but clearly the increased metabolism could lead to a high lysine hydroxylation, thereby affecting the fiber size and the cross-linking, both of which lead to increased fragility. Whether there is a change in the genetic type of collagen has not been investigated, but it is probable that the type I homotrimer levels are increased.

The disease is inhibited by antiosteoclastic drugs, suggesting that the primary abnormality is in the osteoclast, but the precise mechanism is unknown.

Calcitonin and bisphosphonates appear to be the preferred treatments.

Cardiac Disease

Cardiac tissue contains collagen types I, III, IV, V, and VI. The most abundant of these is type I collagen, accounting for approximately 80% of the total collagen. Type III collagen forms a further 10%, and the remainder is comprised of the other collagen types. It is the presence of type I collagen that accounts for the diastolic stiffness of the heart.

The accumulation of additional collagen in the heart, or cardiac fibrosis, is known to occur in response to raised levels of the mineralocorticoid aldosterone. Although endothelial cells, myocytes, and fibroblasts have been found to express high-affinity mineralocorticoid receptors, the mechanism of aldosterone-induced cardiac fibrosis is thought to involve angiotensin II. In addition, rodent models indicate that the effect of aldosterone on cardiac fibrosis is critically dependent on salt status; animals infused with aldosterone on a restricted salt diet do not have a fibrosis of the heart. Although mechanical loading has a pivotal role to play in collagen metabolism, the hypertension resulting from raised aldosterone and salt intake is not responsible for the fibrosis. Rather, the reactive interstitial fibrosis that occurs is the result of altered endocrine signaling. Specifically, the myocardium expresses greater levels of the angiotensin receptor (AT1) to which angiotensin II will bind. This ligand, in turn, is known to stimulate the production of TGF- β 1 by fibroblasts, and this stimulates collagen synthesis by these cells. Also, raised bradykinin levels in aldosterone-salt excess may also stimulate increased collagen deposition in the heart. Finally, aldosterone will increase the expression of endothelin receptors, and endothelins are potent stimulators of collagen synthesis. The application of the endothelin antagonist bosentan reduces cardiac fibrosis in response to elevated aldosterone-salt intake. The cardiac fibrosis occurring in response to raised aldosterone, as would take place, for example, with adrenal adenoma, involves the complex interplay between systemic factors and local signaling pathways.

Pulmonary Disease

Pulmonary fibrosis involves the deposition of collagen within the expanded interstitium. Inflammation, fibroblast proliferation, and deposition of collagen occur during the development of pulmonary fibrosis.

No genetic mutations that can be directly associated with pulmonary disease have been established for collagen or elastin. A large number of cytokines could be involved, but the emphasis has been on TGF- β , which has been localized at active sites of collagen production.

The collagen synthesis rate decreases with age, as in other tissues, but does not terminate. In fact, the turnover rates of lung collagen in rats and rabbits have been estimated at 10% per day using a flooding dose of labeled radioactive proline. However, turnover values are notoriously difficult to determine, and several methods are generally required for confirmation.

Dupuytren's Disease and Peyronnie's Disease

Dupuytren's disease (DD) involves the progressive and irreversible deposition of excess fibrous collagen, resulting in contraction of the fingers. The apocryphal story of DD is that Count Dupuytren thought that his coachmen developed DD from the action of pulling on the horses' reins and so released the tension by slashing their fingers with his sword. Surgery is still the only treatment. However, there is no evidence of a mechanical initiation of the disease.

The lesion primarily occurs in the palmar aponeurosis, that is, the collagen that separates the flexor tendon from the overlying fibro-fatty layer. The major questions yet to be answered are what stimuli are responsible for excess collagen synthesis, how this can be controlled, and what the mechanism of contraction is. The stimuli that activate these processes are not known, but considerable progress has been made in detailing the metabolism and biochemical changes in DD.

Structurally, the aponeurosis in DD exhibits highly cellular nodules and fibrous cords. Analysis of the aponeurosis reveals striking increases in the extent of lysine hydroxylation; the level rises from approximately 5 residues per 1000 to 13 per 1000 in DD. There is also a corresponding increase in the proportion of lysine glycosylation that maintains the ratio of hydroxylysine to glycosylated hydroxylysines. Type III collagen is more abundant in the nodules of DD (10–15%), as compared with normal individuals (1–3%), and the concentration of this collagen type is even greater in the fibrous cords (30–40%). In addition, there is a higher level of immature collagen cross-links, indicating greater turnover in DD, a feature that is also observed in the granulation tissue of dermal wounds. However, in the latter case, the

Figure 2 Type III collagen organization in the palmar aponeurosis in both healthy individuals (A) and those with Dupuytren's contracture (B). (A) Fluorescence immunolocalization of type III collagen (white arrows) molecules surrounding the type I collagen fibers in the normal aponeurosis. (B) Diffuse type III collagen distribution (white arrow) in Dupuytren's contracture. This breakdown in collagen organization and loss of the fascicular structure is a typical feature of the aponeurosis in Dupuytren's contracture.

immature cross-links decrease with healing, whereas in DD, the levels remain high even after 10 to 15 years, indicating a failure of the lesion to mature due to the constant remodeling. The high metabolic rate of collagen was confirmed by high PICP levels for synthesis, and high concentrations of the metalloproteinases and cathepsins for degradation, in the long-term (15–20 years) DD tissues.

Normally, the aponeurosis possesses a fascicular structure, with the type I fibers being surrounded by a thin sheath of type III fibers (Fig. 2A). In DD, immunohistology reveals a thickening of the type III fibrous sheath, and the nodules have a disintegrating fascicular lining and an overall increase in type III fiber distribution (Fig. 2B). In the cords, the type I and III fibers are tightly packed, and there is complete

loss of the fascicular sheath (Fig. 3D). The disease is clearly evident in the apparently unaffected aponeurosis, consistent with the observation that DD often recurs within the same aponeurosis following surgery, presumably due to failure of a complete removal of affected tissue. We have suggested that the disease can be initiated and/or propagated by myofibroblast cells migrating along the fascicular sheaths. The initial stimulation for fibrosis remains unknown but appears to be retained in the tissue, as evidenced by continued collagen turnover. A candidate for triggering this response is the superoxide free radical. TGF- β is also thought to play a role in DD due to its reported actions on collagen metabolism and its influence on fibroblast proliferation and myofibroblast differentiation.

The mechanism of palmar contraction remains elusive, but the myofibroblast is critical in this process. Modified fibroblasts certainly have the ability to contract fibrous gels and do so through architectural changes in intracellular actin filaments. These filaments attach to the cell membrane through integrins, and fibronectin in turn is thought to act as a link between the collagen fiber and the integrin molecule. Contraction is largely restricted to the highly cellular nodular regions, whereas collagen accumulation is greatest in the resulting cords.

5-Fluoro-uracil has been shown to suppress myofibroblast differentiation, and the use of γ -interferon was shown to inhibit the transcription of collagen mRNA. Both of these might be useful in blocking the excess deposition of collagen in DD.

DD is often linked to Peyronnie's disease. In Peyronnie's disease, the fibrosis results in curvature of the penis. Unlike DD, the fibrotic plaque of the tunica albuginea tends to harden and even mineralize, suggesting plaque maturation rather than a continuing turnover as in DD. The nature of the collagen in

Figure 3 Schematic representation of the development of Dupuytren's disease. (A) Normal aponeurosis: fascicular structure with type I fibers sheathed in type III collagen. (B) Apparently uninvolved: thickening of the fascicular sheath. (C) Nodules: loss of fascicular structure and formation of new fine type III collagen fibers. (D) Bands or cords: tightly packed fibrils of types I and III collagen but no fascicular structure. Reproduced from Bailey (1994), with permission.

Peyronnie's disease has not been determined, but confirmation of its maturity would indicate a therapeutic approach different from that applied for DD.

Keloids and Hypertrophic Scars

Keloids and hypertrophic scars involve the proliferation of collagen in the dermis, producing a dense collagenous network. Type I collagen mRNA levels have been reported to correlate with increased collagen production, and there is the usual increase in TGF- β . Both of these conditions are similar to DD in that the turnover of collagen is maintained at a high level and does not return to the basal level of the normal dermis, as is the case in healing cutaneous wounds following the initial fibrosis. The stimulus is clearly present throughout these scars, but its nature is unknown.

Scleroderma

Altered collagen metabolism resulting in the hardening of the skin and internal organs gives rise to a group of conditions generally referred to as scleroderma. Patients generally present with the disease when the processes of altered collagen metabolism are well established. Consequently, most studies have concentrated on established lesions, and the initiating factors in scleroderma remain unknown. The earliest lesions appear to be vascular and inflammatory, leading to heightened collagen synthesis in the affected areas akin to wound healing. Fibroblasts from the deep dermis display raised collagen synthesis, so the accumulation of matrix collagen is attributed to the synthetic rate rather than an increase in cell proliferation. Scleroderma fibroblasts appear to have lost their ability to regulate collagen metabolism, which would otherwise be exquisitely controlled during remodeling. Unlike DD, which is highly localized, scleroderma is progressive and spreads across the dermis and into other tissues, for example, extensive fibrosis of the heart, lung, and kidney, all of which can lead to death.

There are temporal changes in the expression of type III collagen in scleroderma. The initial stages of the disease are characterized by raised levels of this collagen type, but as the condition advances, there is a reduction in type III collagen to levels comparable to those of normal skin. This initial increase in type III collagen is also observed in the kidney, heart, and lung. Of additional significance in the case of the kidney is the increased expression of type IV collagen

in the glomerular basement membrane and capillaries, resulting in membrane duplication. In contrast to DD, which maintains a high metabolic rate, scleroderma lesions mature in a manner to that of wounds, that is, a reduction in type III collagen, increased concentrations of mature collagen cross-links, and an overall decline in turnover. Collectively, these metabolic changes result in a thickened hardened skin.

The capillaries are a potential initiating site, and attempts to improve the microcirculation through the application of vasodilators and the use of anti-inflammatory drugs have been considered. The use of agents that regulate collagen synthesis is also being investigated.

REDUCED OVERALL METABOLISM

Diabetes Mellitus

The metabolism of collagen is reduced in diabetes mellitus, allowing the collagen to mature and making it even less susceptible to turnover. It has been suggested that this represents "accelerated aging" of the tissues. This suggestion is supported by the high levels of glycation cross-links formed such as pentosidine and imidazolone cross-links described previously. These cross-links render the tissues stiffer, reducing their optimal function and metabolism.

Animal models that have been made diabetic (plasma glucose concentration of 300–400 mg/dl) through the application of streptozotocin or alloxan, or the diabetic BB rat, exhibit decreased bone formation. Reduced bone matrix formation has been reported for endocortical, periosteal, and trabecular–endosteal surfaces. The actual resorption of bone collagen is also reduced in these animal models. Taken together, the overall turnover of bone collagen is at a standstill in situations of severe diabetes.

Physical measurements of bone toughness support the presence of a more brittle bone tissue in diabetic rat models. This change in matrix quality may be attributed to the hypermineralization of the collagen and/or collagen glycation.

POTENTIAL THERAPEUTIC STRATEGIES

The major questions that are being addressed are as follows. First, what are the stimuli responsible for the initiation of excess collagen synthesis or excess collagen catabolism? Second, what are the factors controlling the subsequent imbalance in metabolism? Little progress has been made on the initiating factors,

so studies have concentrated on the mechanisms of regulation.

The current fundamental research emphasis is to control the expression of the collagen genes. It is generally believed that the expression of collagen genes is coordinated under normal physiological conditions. A loss of this coordination could result in fibrosis or resorption; therefore, attempts have been made to identify these controlling factors. The control may involve several *cis* elements (specific DNA sequences in the promoter region or within the 5' end of the region required for efficient transcription) and the *trans*-acting factors (cell specific). Cells studied *in vitro* demonstrated that synthesis could be inhibited by nucleotides and by antisense genes, but the results are highly variable and delivery would be difficult. The absolute quantitation of collagen production appears to be modulated by growth factors, with these changes being mediated at the transcriptional level. Therefore, attention has focused on the many cytokines and growth factors that have been localized and identified at sites exhibiting heightened collagen synthesis.

Control at the translational level has been under study for several decades. The many specific enzymic stages in the synthesis of collagen could theoretically be inhibited to control overproduction. Prolyl 4-hydroxylase inhibition would prevent the formation of a stable triple helix, C- and N-protease inhibition would prevent fiber formation, and lysyl oxidase inhibition would result in the formation of readily

degradable non-cross-linked fibers. The inhibition of the isomers of prolyl 4-hydroxylase and its cofactors has been investigated extensively and currently appears to be the most likely candidate for the development of an antifibrotic drug.

Congenital Adrenal Hyperplasia, Prenatal Diagnosis and Therapy

Maguelone G. Forest
Hôpital Debrousse, Lyon, France

Glossary

allele Any of two or more alternative forms of a gene occupying the same chromosomal locus.

glucocorticoid Any of a group of adrenocortical steroid hormones whose metabolic effects include stimulation of gluconeogenesis, increased catabolism of proteins, and mobilization of free fatty acids; also a potent inhibitor of the inflammatory response (allergic response).

mineralocorticoid A hormone secreted by the adrenal cortex, such as aldosterone, that maintains normal blood volume, promotes sodium and water retention, and increases urinary excretion of potassium and hydrogen ions.

mutation The process by which a gene or some other DNA sequence undergoes a change in structure.

The biosynthesis of cortisol, a hormone necessary for survival, occurs in the adrenal glands under the stimulus of adrenocorticotrophic hormone (ACTH). The biosynthesis of all adrenal steroids is regulated by a negative feedback, but cortisol is the only adrenal steroid to exert a significant feedback control on ACTH secretion. Thus, when cortisol secretion is insufficient, the feedback loop opens and ACTH rises. A defect in any of the five enzymes necessary for the biosynthesis of cortisol from cholesterol results in congenital adrenal hyperplasia (CAH). These disorders are so named because the adrenal glands are hyperplastic at birth due to unrestrained ACTH stimulation already in fetal life.

INTRODUCTION

Steroid 21-hydroxylase (21-OH) deficiency (Fig. 1) is by far the most frequent cause (>90%) of congenital adrenal hyperplasia (CAH) and is the only cause of CAH discussed in this article. The disorder has two

major consequences: a state of cortisol deficiency and a hyperproduction of adrenal androgens due to adrenocorticotrophic hormone (ACTH) overstimulation. Steroid 21-OH deficiency has a wide spectrum of clinical variants that are not different diseases but represent points of a spectrum of disease severity. Clinical forms of 21-OH deficiency are divided into classic (severe, excongenital) and nonclassic (NC) (less severe, either symptomatic or asymptomatic, termed “cryptic”), which do not present any virilization at birth (Fig. 2).

Steroid 21-OH deficiency is one of the most common autosomal recessive genetic disorders. The classic forms occur in approximately 1 in 14,500 live newborns, whereas the NC forms occur in approximately 1% of the general population. In the classic forms, whether salt-wasting (SW) or simple virilizing (SV) type, the excessive amount of Δ^4 -androstenedione produced by the fetal adrenals is transformed into testosterone in peripheral tissues, including the genital tubercle of the growing embryo, and is responsible for the virilization of affected female fetuses, whereas the affected males have normal genitalia. However, virilization of the females does not correlate with salt loss and ranges from clitoromegaly to a fully masculinized urethra (classified in five Prader stages). The diagnosis is easy by measuring the plasma level of 17-hydroxyprogesterone (17-OHP) in antenatal and perinatal/postnatal samples. The NC presentations are less severe and are clinically expressed later during life by nonspecific hyperandrogenic symptoms, and their diagnosis requires an ACTH test.

Sexual ambiguity is a major complication of the disease, bearing the risk of sex misassignment, requiring difficult reconstructive surgery, and eventually leading to impaired long-term quality of life. This is why prenatal therapy has been proposed for preventing the *in utero* virilization of CAH females. The concept was that of David and Forest, who realized

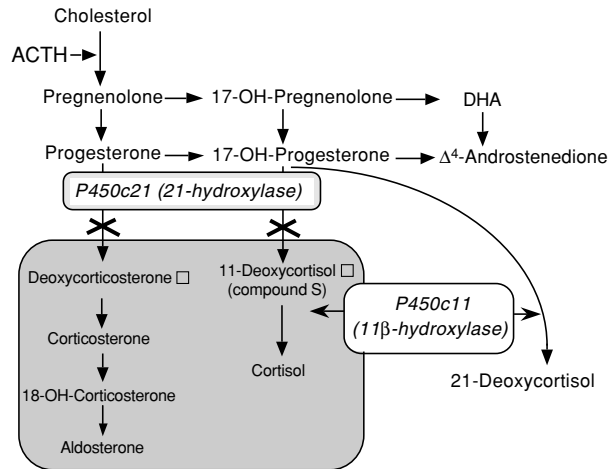

Figure 1 Steroid 21-OH deficiency. Steroids above the enzymatic block are produced in high amounts, whereas those below the block are abnormally low (in the dotted box). The pathway of 21-deoxycortisol is illustrated.

their first prenatal treatment of CAH females in 1979 (published in 1984). Several pediatric centers have followed their protocols, which have been used throughout the world progressively. In any cases, the responsible mutations on the gene CYP21 are now well known and could be identified easily by molecular biology techniques. By combining hormonal and molecular tests, it is now possible to predict the clinical form of the disease in the context of a prenatal diagnosis, which can lead to a prenatal treatment.

GENETIC BACKGROUND

Steroid 21-OH deficiency is a monogenic autosomal recessive condition manifested as heterogeneous phenotypes, all caused by mutations in the CYP21 gene on chromosome 6p21.3, which lies in the class III

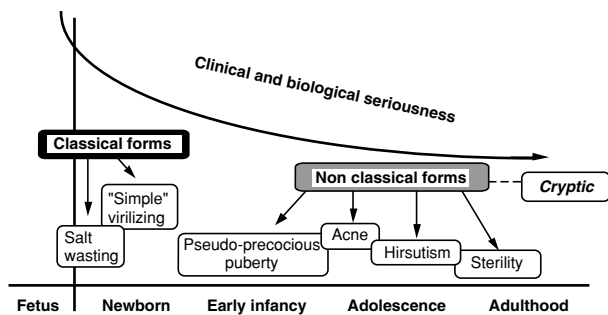

Figure 2 Clinical forms of 21-OH deficiency. Severity and onset of symptoms are classified into two main groups: classic and non-classic.

human leukocyte antigen (HLA) region, a very peculiar region of the genome containing several duplicated genes. Indeed, there are two 21-OH genes 30 kb apart: a pseudogene 21-OHA (now called CYP21P) and the active gene 21-OHB (now called CYP21). The genes encoding the fourth component of the complement (C4A and C4B) and the 21-OH genes form a tandem of duplicated genes that are sometimes repeated more than twice.

The wide range of CAH phenotypes is associated with multiple mutations known to affect 21-OH enzyme activity. As of 2003, 56 different CYP21 mutations have been reported (and nearly 98 new ones were described in a recent thesis); these are mostly point mutations, but small deletions or insertions have been described too, as have complete gene deletions. A total of 15 mutations, constituting 90 to 95% of alleles, are derived from intergenic recombination of DNA sequences between the CYP21 gene and the highly homologous CYP21P pseudogene, whereas the remaining ones are spontaneous mutations. A reliable and accurate detection of CYP21 mutations is important not only for clinical diagnosis but also for carrier detection because there is no significant difference in 17-OHP basal levels between normal and heterozygous individuals. Several strategies based on polymerase chain reaction (PCR)-driven amplification with allele-specific oligonucleotides to the CYP21 gene have been developed. It has been demonstrated that one reaction for PCR amplification of the CYP21 gene and the chimeric CYP21P/CYP21 gene using mixed primers in combination with nested PCR and single-strand conformation polymorphism is considered highly efficient and accurate for molecular diagnosis of CAH due to 21-OH deficiency.

Gross abnormalities (e.g., 30-kb or larger gene deletions, gene conversions) are found in some patients. These rearrangements (gene conversion or deletion) producing new alleles with no enzyme activity (null alleles) account for 20 to 25 of classic 21-OH alleles, whereas small deletions and point mutations make up the rest, even if some rearrangement is associated (e.g., deletion of C4A, deletion of the pseudogene with or without a deletion of C4B). Most of them (9–12 of the 15 more frequent mutations) do normally occur in the pseudogene. The others are very rare mutations and/or are found only in certain ethnicities.

The important finding was the association between given mutations and the clinical forms of the disease. Severe mutation produces null alleles, whereas alleles carrying mild mutation have some 21-OH activity (20 to 50%).

Figure 3 Pedigrees found in CAH families. Severe mutations are illustrated in black, whereas mild mutations are depicted by hatched areas. The classic forms of the disease are due to the combination of severe/severe mutations, whereas the combination of mild/severe mutations is associated with nonclassic forms. If a partner is known to have a severe mutation, a couple is at risk for having a child with a classic form of CAH if the other partner has at least one severe mutation, whether heterozygote (A), CAH affected with a nonclassic form of the disease, (B), or CAH affected with a classic form (C). In contrast, when one partner is known to be heterozygote for a mild mutation, there is no risk for the couple having a child affected with a classic CAH regardless of the genotype of the other partner, whether heterozygote for severe (D) or mild mutation (E), CAH affected with a nonclassic form (F, G), or even CAH affected with a classic form (H).

The clinical form of the disease is dictated by the least severe mutation carried on one allele. Patients with two alleles carrying a severe mutation (null allele), either identical (homozygous) or different (heterozygous), do have a classic SW form of the disease, whereas patients with a severe mutation on one allele and a mild mutation on the other (compound heterozygote) have an NC CAH (Fig. 3). The mutation A (or C) to G near the end of intron 2, causing premature splicing of the intron and a shift in the translational reading frame, is the single most frequent mutation in classic forms. There is a remarkable association between the mutation V281L, either in the homozygous or heterozygous condition, with NC forms. Also, the mutation I172N (either homozygous or compound heterozygous with a null allele) is associated with the SV form. Although this form is not so frequent, it is rather typical (sexual ambiguity in affected girls or early pseudo-precocious puberty in affected boys but no clinical salt loss). Concordance between genotype and phenotype is sufficiently robust to be of significant value in the diagnosis and management of the disorder. Knowledge of the genotype is essential in planning a strategy for prenatal diagnosis and treatment.

GENETIC COUNSELING

When considering prenatal diagnosis and/or treatment, the first step is to offer genetic counseling. The role of genetic counseling is to give the parents

all available information about the disease, the clinical forms and their consequences, and the possibility of prenatal diagnosis and prenatal treatment.

In the past, the genetics of the disease was thought to be “simple” autosomal recessive, with each parent carrying one affected and one normal allele (heterozygote). Then it became difficult to understand a misdiagnosis when prenatal diagnosis did rely on HLA typing because pedigrees were at times more complex than one thought and the parents were not always simple heterozygotes. As illustrated in Fig. 3, when individuals are compound heterozygotes (combination of mild and severe mutations), they can transmit a severe form of the disease even though they are affected with an NC or a cryptic form of the disease (couple G in Fig. 3). In contrast, one CAH-affected parent with a classic form might not transmit the severe form of the disease if the other parent carries one or two mild mutations (couple H in Fig. 3). Thus, prediction of the clinical form of the disease in a couple at risk is possible nowadays provided that the complete genotype of the future parents is available.

PRENATAL DIAGNOSIS

In the past, prenatal diagnosis has been first possible by measuring 17-OHP and other steroid hormones (e.g., Δ^4 -androstenedione, testosterone, 21-deoxycortisol) in the amniotic fluid (AF). The rise in 17-OHP and Δ^4 -androstenedione in CAH fetuses is clear-cut (Fig. 4). The procedure is simple and reliable and does not require the study of the index case, but it permits picking up only the classic forms, not the NC forms. One could argue that the aim of a prenatal diagnosis is to identify the classic forms of the disease, not the NC forms. However, prenatal diagnosis based on steroid analysis is still valuable when there is no other alternative provided that reliable techniques (including chromatographic purification) are available.

When HLA was found to be in closed linkage with CAH, prenatal diagnosis was made by HLA typing (associated or not with the measurement of 17-OHP). The procedure required the study of a previously affected sibling (index case). Unfortunately, the method resulted in many wrong diagnoses due to recombination, haplotype sharing, or complex pedigrees.

Nowadays, prenatal diagnosis is performed during the first trimester and relies almost exclusively on DNA analysis of mutant 21-OH alleles on tissue obtained by chorionic villus sampling (CVS) at 10 to 11 weeks of amenorrhea (WA) providing a complete

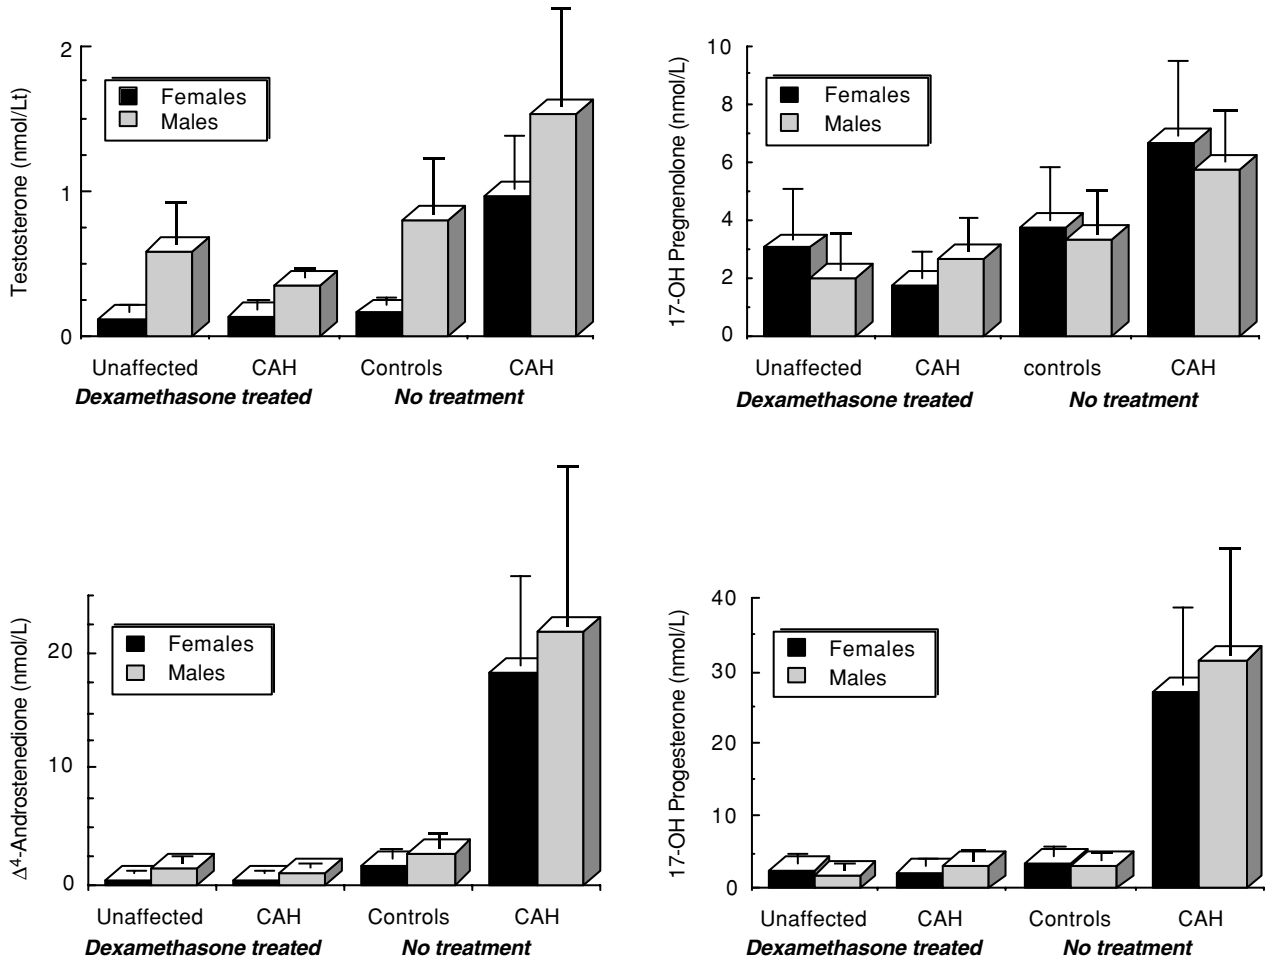

Figure 4 Amniotic fluid (AF) steroid levels. Diagnosis of CAH is made on the high levels of 17-OHP, Δ^4 -androstenedione in both sexes, and high levels of testosterone in female fetuses. In treated pregnancies, AF steroid levels are normalized in the case of CAH-affected fetuses of both sexes.

genotype of the parents. In addition, prenatal diagnosis includes fetal sexing, which can be performed either by karyotyping on fetal cells obtained by CVS or by searching the sex-determining region of the Y chromosome (SRY) on the same cells.

In the past, prenatal diagnosis of CAH was made exclusively in couples having an affected child, but many new situations are emerging in couples where one partner is a relative of CAH patients and also when the index case is one of the parents. Therefore, if the genotype of the CAH-affected partner (presenting with either a classic form or an NC form) is known, the genetic counseling has to determine the risk for the couple to have a fetus affected with classic CAH. The prediction is based on the investigation of the other partner, in whom it is important to detect a possible heterozygotism. In our experience, this can be done in two steps. The first step involves hormonal

studies, that is, measuring 21-deoxycortisol during an ACTH test. Steroid 21-deoxycortisol is a bypass product of the hydroxylation of 17-OHP by the enzyme 11 β -hydroxylase, which is normal (Fig. 1). This compound, normally produced in minute amounts, increases significantly during the ACTH stimulation test (which uses supraphysiological doses). In heterozygote individuals, the increase is significantly greater than that in homozygous normal individuals. In our experience of testing more than 500 people, the accuracy of the prediction of heterozygotism is 90 to 95%, and more than half of them have a normal 17-OHP response. There were fewer than 5% false-negatives, including *de novo* mutations in one parent. The algorithm is outlined in Fig. 5.

Things are not always as simple as the theory. There may be two or more mutations on the same allele (double or triple heterozygote), and when one

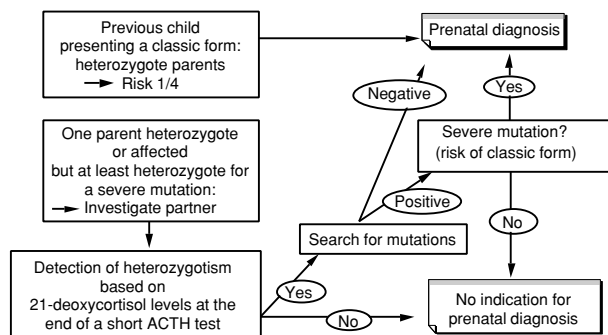

Figure 5 Flow chart of prenatal diagnosis in a couple where one partner is known to have a severe mutation in the CYP21 gene on at least one allele.

mild mutation is found, one has to make sure that the same allele does not carry another mutation. Indeed, two or more mild mutations on the same chromosome result in a null allele. This implies that both parents should be genotyped to identify the genotype correctly. Performing clear-cut informative molecular studies of this disease might require hard work (e.g., Southern blot, sequencing to identify rare mutations). In some cases (< 5%), no mutation is found. Thus, when the search for mutations is negative, a prenatal diagnosis is still performed because one does not want to risk making a wrong prediction.

PRENATAL TREATMENT

This treatment has been proposed for preventing the *in utero* virilization of CAH females. It does not cure the disease itself. After birth, there is still a need for glucocorticoid (and mineralocorticoid) replacement therapy. The rationale of the treatment involves providing the fetus with sufficient glucocorticoid levels to suppress the excessive ACTH stimulation, being mindful that the mechanism that makes the baby become virilized after birth is the same.

Protocols for prenatal treatment used by all groups is based on the work of David and Forest. The latter chose dexamethasone because it has a long half-life, crosses the placenta efficiently because it is not corticosteroid binding globulin (CBG) bound, and is not metabolized by the placental 11 β -hydroxysteroid dehydrogenase (11 β -HSD). The optimal dose was established by Forest and colleagues, who compared the results of various doses (fixed and then related to maternal size). The dose of 20 μ g/kg of maternal weight at the start of treatment was found to be efficacious to

bring down AF levels of 17-OHP back to normal (Fig. 4). We advise using a dose of no more than 20 μ g/kg/day, given in three divided doses to ensure a constant level in the fetus. In the French multicentric study, dexamethasone acetate has been used in all but two cases (associated with an unaffected fetus), whereas dexamethasone is more generally used elsewhere.

The second most important parameter is to start treatment early, that is, before the eighth week of pregnancy, when the fetal anlage is sensitive to the virilizing action of testosterone. If the fetus is found to be a male by karyotype or is found to be an unaffected female by DNA analysis, treatment is discontinued. Otherwise, dexamethasone treatment is continued to term.

The third important part of our protocol is not to stop treatment abruptly but rather progressively by tapered doses (half the dose every 5–6 days).

Finally, our protocol includes the treated mothers a low-salt diet and asking them to pay careful attention to their weight gain.

The current protocol combines prenatal treatment with an early prenatal diagnosis and stopping maternal treatment as soon as possible if it is unnecessary. Our algorithm (Fig. 6) is very close to that proposed by New and colleagues. Treatment is started when pregnancy is diagnosed, and prenatal diagnosis is usually performed during the first trimester. However, if CVS is not available or is refused by the parents, amniocentesis can still be performed and be helpful.

It is important to monitor the compliance of the mother and the efficacy of treatment. Measuring maternal levels of cortisol and dehydroepiandrosterone sulfate (DHEA-S), which should be suppressed, can follow this. Fetal adrenal suppression is also attested by a normalization of 17-OHP levels in the AF of pregnancy associated with CAH fetuses (Fig. 4). Another way in which to look at fetal adrenal secretions is to measure maternal estriol levels, but because this metabolite rises significantly only during the second half of pregnancy, it is useful only when treatment is continued to term in case of an affected female fetus. At that time, suppressed maternal estriol levels are the best indicator of both fetal suppression and maternal compliance (Fig. 7).

The personnel involved with prenatal treatment include an obstetrician to treat the mother taking dexamethasone. Throughout the pregnancy, the mother should be monitored for weight gain, blood glucose, blood pressure, and any other complications. Treatment is discontinued if toxemia occurs. A genetic counselor with expertise in CAH must be available for the family prior to initiating prenatal diagnosis

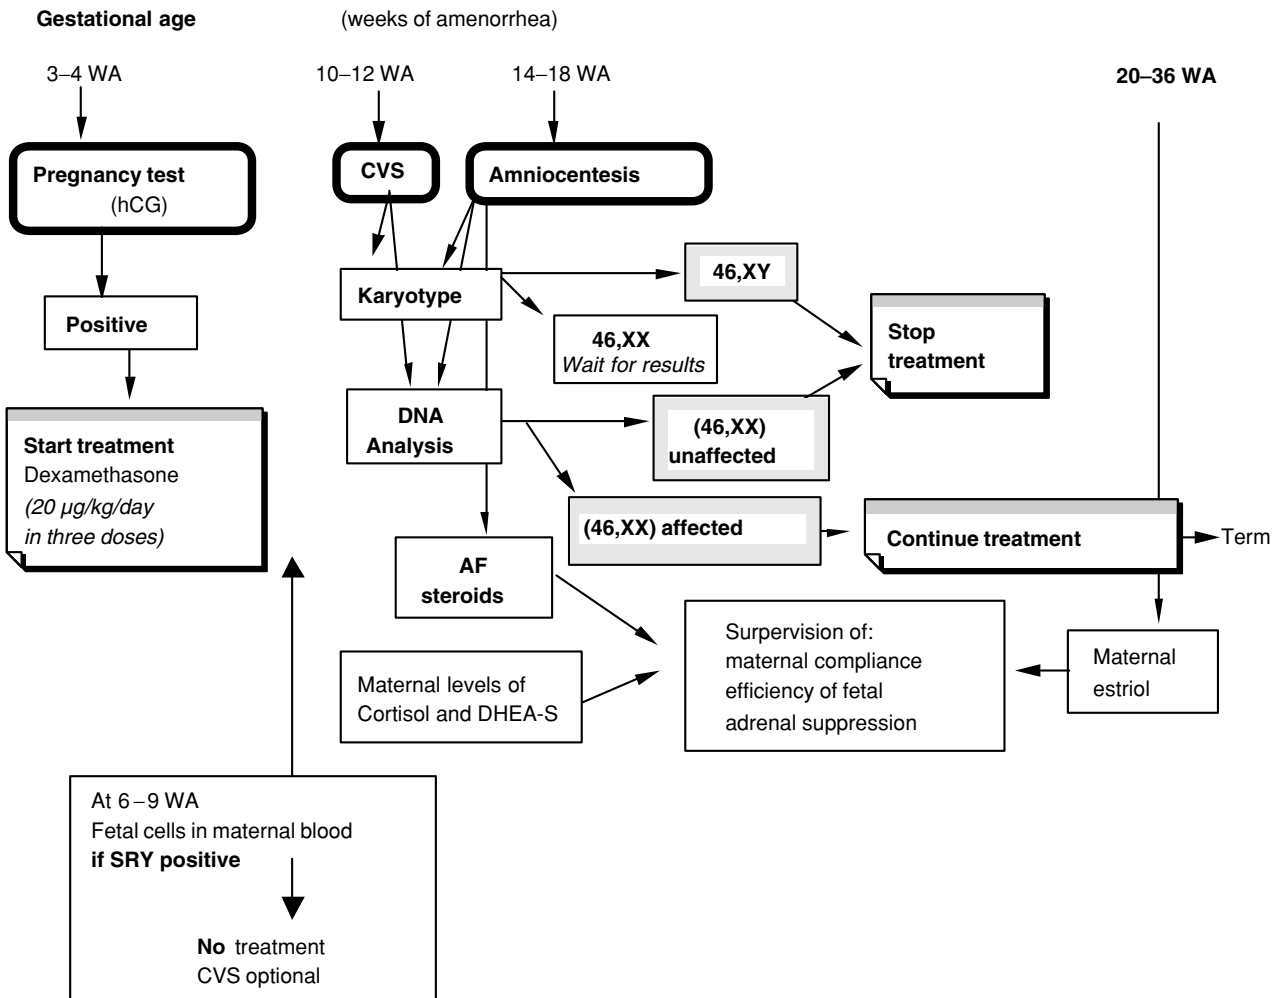

Figure 6 Flow chart of prenatal treatment in a couple at risk for CAH due to 21-OH deficiency. Note the hope of nontreating male CAH-affected fetuses by early fetal sexing on fetal cells taken in maternal blood.

and treatment. A pediatric endocrinologist who will treat the newborn if he or she is affected should be consulted at the initiation of prenatal treatment, and a psychoendocrinologist should be integral to the follow-up of an affected child.

After the birth of a full-term or partially treated newborn, the birthweight, length, head circumference, and any pertinent physical findings (including degree of genital ambiguity and Prader score) should be recorded. At day 3 of life, measurements of serum 17-OHP levels, electrolytes, and plasma renin activity should be taken in affected infants. A blood sample for a repeat DNA analysis also is suggested. In addition, the protocol for prenatal therapy should include the requirement of developmental and psychological follow-up for affected and unaffected individuals who were prenatally treated.

Indications of Prenatal Treatment

This treatment is indicated only in mothers at risk for having a fetus with a classic form of the disease (not with an NC form) and who are willing to continue pregnancy regardless of whether the fetus is affected. Prediction of the clinical form of the disease is now possible because, as mentioned previously, the phenotype is dictated by the least severe mutation carried by one allele. A fetus is at risk for classic CAH if a severe gene lesion (deletion, macroconversion, or point mutation that abolishes 21-OH activity) is present on at least one allele of each parent. This is the case for a couple of heterozygotes carrying a severe mutation on both the maternal and paternal sides (couple A in Fig. 3) or if one partner is heterozygote for a severe mutation and the other partner is CAH affected with

Figure 7 Example of prenatal treatment efficacy (and/or maternal compliance) by measuring maternal estriol (here unconjugated plasma levels) during the second semester of pregnancy.

an NC/compound heterozygote (couple B in Fig. 3). When the mother (or the father) is affected with a classic form of CAH, the couple is at risk for having a child with the same disease only if the partner is heterozygote for a severe mutation (couple C in Fig. 3) but never if the partner has a mild mutation (couple H in Fig. 3).

When the mother is CAH affected, the treatment protocol is a somewhat different situation in that she undergoes a substitutive treatment involving glucocorticoids (hydrocortisone or dexamethasone) and mineralocorticoids most of the time. It is important to determine the risk for the fetus in the couple. If the couple is found to be at risk for the classic form, maternal treatment is adapted or changed for the current protocol of prenatal treatment (total daily dose of 20 $\mu\text{g}/\text{kg}$ body weight of dexamethasone divided into two or three doses) with no change in mineralocorticoids. However, if the couple is at risk only for an NC form, maternal treatment does not need to be changed.

Informed Consent

Informed consent must be obtained from mothers participating in prenatal treatment with dexamethasone. Parents are asked to give informed consent for both treatment and protocols. Yet is their consent really informed? Informed consent, as it relates to the ethical principle of respect for autonomy, presents nurses' perceptions of informed consent, and there are variations in national rules about prenatal diagnosis and/or treatment. For example, in the United States,

the function of the institutional review board (IRB) for CAH is vital in research centers that conduct prenatal treatment for 21-OH deficiency. In France, informed consent should also by law include signed documents by centers that are empowered conduct both genetic counseling and prenatal diagnosis as well as prenatal treatment.

However, it seems reasonable to say that the basis of informed consent includes the following:

- Parents must be appropriately and adequately informed in lay language.
- The scope and detail of the information supplied should be based on a reasonable parent's need to know rather than on the actions of a reasonable doctor.
- The doctor must take care to ensure that the information is understood by the parents and must use a proper method (explaining the "medical word" used by the "doctors") to present information.
- The benefit/risk ratio should be clearly explained in the only situation where beneficence is appropriate (CAH-affected female), as should the lack of benefit to males and unaffected females.
- The risk of complications with CVS and amniocentesis (0.6–0.8%) should also be included, although most institutions will have separate consent forms for those procedures.

A request by an individual to withdraw from the study must be honored, and participants should come from diverse socioeconomic and ethnic backgrounds. However, if prenatal treatment is started and the mother decides to interrupt pregnancy, this can be viewed as a failure of prenatal counseling.

The parents also have rights to confidentiality, and after they are informed, they have the right to freely exercise their choice and to opt not have prenatal treatment and to have only prenatal diagnosis.

HAVE PRENATAL DIAGNOSIS AND TREATMENT ACCOMPLISHED THEIR GOAL?

It is possible to answer this question after many years of experience in the field. Prenatal diagnosis is accurate, and prenatal treatment is effective. Approximately 70% of prenatally treated females are born with normal or only slightly virilized genitalia. The degree of success is variable according to the series (60–85%), but it is linked to maternal compliance and the rationale in the protocol used (e.g., divided daily doses). Treatment failures (i.e., affected females requiring genital reconstruction) have been attributed to late

onset of treatment, cessation of therapy during mid-gestation, noncompliance, and/or suboptimal dosing, whereas others had no ready explanation.

No teratogenic effect has been reported. The infants in large series are born at term with normal length, weight, and head circumference. However, there has been controversy concerning the efficiency of treatment, the estimation of fetal adrenal suppression, and the safety of treatment for the mother and child.

Therapeutic Risks to the Mother

The incidence of maternal complications has varied among investigators. Overall, it is about 10%. In evaluating such data, it is important to correlate the types of adverse side effects observed and the duration of therapy. Both American and European investigators have found a higher incidence of side effects in women treated from the first through third trimesters. In the larger American study, no statistical difference between treated and nontreated women was noted except for weight gain, edema, and striae, which were greater in the treated groups and most often resolved with discontinuation of treatment. In the Scandinavian study, a significant increase in weight gain was observed during early pregnancy when treatment was initiated, but this initial rapid weight gain declined during late pregnancy or when treatment was terminated. Similar findings were observed in the largest European study except in three women, as in a small three-case American study in which severe side effects were reported: Cushingoid features, excessive weight gain, severe striae, hypertension, and hyperglycemia. Most of these women were overweight, prediabetic, and at risk for glucocorticoid exposure. In fact, when considering some of the side effects that have been related to glucocorticoid treatment, one might remember that during pregnancy there is a hypercortisolism state. Many pregnant women with no glucocorticoid treatment do have side effects that include marked weight gain, Cushing's signs, striae, edema, pre-eclampsia, and fatigue. In any event, weight, blood pressure, and glucose tolerance should be monitored closely in all treated women to term. These side effects notwithstanding, many parents of affected girls still opt for prenatal medical treatment due to the severe psychological impact of ambiguous genitalia on the children and families, and in the European study several mothers opted for two or three successive treated pregnancies.

Maternal urinary estriol measurements have also been suggested as a guide to adjusting maternal treatment (Fig. 7). A gradual decrease in the dose of

dexamethasone later during gestation might decrease the incidence of maternal side effects, but there are only little data suggesting the possible efficacy of such a regimen.

In the American study, fetal wastage was not statistically different between dexamethasone-treated and untreated patients. In the large European study, the incidence of miscarriages according to age was less than in the general population and was less than in the same mothers who had miscarriages previously during untreated pregnancies. In addition, there were no maternal side effects at delivery or during the postpartum period. All babies were full term.

These findings reinforce our position as to the contraindication to prenatal treatment in mothers at risk for diabetes or having diabetes, hypertension, obesity, insulin resistance, or cardiovascular disease. Most of the time, these are not good conditions for having babies because all of these situations are aggravated by glucocorticoids.

Therapeutic Risks to the Fetus

In the European study, there were no side effects in most of the fetuses. Intrauterine growth retardation (IUGR) and unexplained fetal death (several months after stopping treatment) have been observed in less than 2% of treated pregnancies, a figure similar to that in the general population. IUGR was seen in only two of the children, and three neonates experienced failure to thrive, although they did catch up in growth after a while. Observed congenital malformations, such as cardiac septal hypertrophy, hydrometrocolpos, and hydrocephalus, were seen in 3 instances among 600 to 800 treated pregnancies; it is difficult to ascertain whether these were due to the treatment.

Therapeutic Risks to the Neonates

In all studies, the dexamethasone-treated fetuses demonstrated normal pre- and postnatal growth compared with matched controls. However, in the Swedish study, several adverse events, such as failure to thrive and delayed psychomotor development, were reported among the treated infants. The three neonates who experienced failure to thrive did catch up in growth after a while.

On the whole, the short-term outcome appears to be rather successful. However, the doses used are thought to be suprphysiological given that dexamethasone is not metabolized rapidly by the placenta, as is cortisol into cortisone (11 β -HSD). Also, the mechanism of

dexamethasone action in the fetus is unclear, and no long-term follow-up studies have been done.

OTHER EFFECTS OF PRENATAL TREATMENT

We believe that prenatal treatment has other beneficial effects as well. In CAH-affected females, prenatal treatment not only prevents sexual ambiguity but also may prevent the consequences of the *in utero* exposure to androgens that might be deleterious for brain programming and induce polycystic ovary syndrome (PCOS). In both sexes, prenatal treatment prevents adrenal hypertrophy. Thus, the postnatal treatment with hydrocortisone is easier and more rapid to adjust at smaller doses.

Is prenatal treatment susceptible to long-term effects in unaffected fetuses? To be effective, the treatment would need to be started by week 6 of gestation, but the genetic diagnosis cannot be made until week 11 or 12. If the mother has had a previous CAH child, only one of four pregnancies will be affected and only female fetuses would benefit from treatment; thus, seven of eight fetuses will be treated needlessly.

In view of these and other concerns, the prenatal treatment of CAH remains an experimental therapy; hence, it must be done only with fully informed consent in controlled prospective trials approved by human experimentation committees at centers that see enough of these patients to collect meaningful data.

From reports of animal studies in the literature, risks for growth retardation, brain abnormalities, and/or hypertension during adulthood are questionable. The question of whether there are long-term side effects in unaffected human infants who were submitted to shorter prenatal treatment nowadays is more difficult to answer. A preliminary study did not show any side effects, but again, it is very difficult to conduct such a study because a control group is not easily available. At this time, we cannot answer such questions because we have to follow these patients or these individuals for at least 20 years. This is why it is believed that a registry should be open for those treatments. Others emphatically disagree with a recent suggestion that prenatal treatment is so experimental as to require approval by institutional review boards.

NEW HOPES IN EARLY FETAL SEXING

It has been known for at least a decade that fetal cells are found in maternal blood. Fetal sex prediction can be achieved using PCR targeted at the SRY gene by

analyzing cell-free fetal DNA in maternal serum. Unfortunately, the results reported show a lack of sensitivity, especially during the first trimester of pregnancy. A new, highly sensitive, real-time PCR was developed to detect an SRY gene sequence in maternal serum during the first trimester (6–11 weeks pregnancy). No false-negative results were observed. Furthermore, no false-positive results occurred, although 27 women who carried a female fetus during their current pregnancies had at least one previous male-bearing pregnancy. Thus, analysis of cell-free fetal DNA in maternal plasma for fetal sex determination would abolish the need for corticosteroid administration and CVS in women with a male fetus at risk for 21-OH deficiency. Then, only three of eight fetuses at risk would undergo unnecessary treatment.

LONG-TERM SIDE EFFECTS OF CAH FEMALES AT RISK

In Lyon, France, we have started a small long-term study with regular follow-up and found normal fundi, normal head circumference (as a testimony of brain development), normal growth, and normal school performance. A control group is very difficult to establish because CAH females are treated with glucocorticoids after birth anyway.

CONCLUSION

Prenatal treatment is efficient in preventing sexual ambiguity in the female CAH-affected individuals. All cases treated should be followed closely and reported. It is of utmost importance that prenatal treatments be in the hands of very specialized teams of clinicians, biologists, and geneticists.

The main benefit of prenatal therapy is to ameliorate potential genital ambiguity in affected females, and it does so successfully. The risks of unnecessarily treating unaffected pregnancies, which seem small at this time, might not be fully elucidated for many years. Prenatal treatment must be done under careful, centralized, and (ideally) long-term medical supervision.

A long-term European study (PREDEX), piloted by the Swedish group, has been started, and we will have some answers in a couple of decades or so.

Congenital Adrenal Hypoplasia Syndromes

Constantine Tsigos

Hellenic National Diabetes Center, Athens, Greece

Glossary

hormone insensitivity Inability of the body to respond to the physiological action of a hormone.

hypothalamic–pituitary–adrenal axis The hormonal axis that regulates the production of adrenal steroid hormones, including glucocorticoids, androgens, and mineralocorticoids.

hypoplasia Atrophy; lack of normal development of an organ or a tissue.

orphan receptor A receptor for which no endogenous ligand has been identified as yet.

The adrenal cortex secretes steroid hormones, including glucocorticoids, mineralocorticoids, and androgens. The glucocorticoid cortisol is secreted by the cells of the intermediate zona fasciculata and its secretion is tightly regulated in a cascade that is called the hypothalamic–pituitary–adrenal axis. Glucocorticoids are crucial for the maintenance of metabolic, cardiovascular, and immune homeostasis. The mineralocorticoid aldosterone is produced by the outer adrenal zona fasciculata. This steroid helps to maintain water and electrolyte homeostasis and its secretion is under the principal control of the renin–angiotensin axis and is only weakly influenced by adrenocorticotrophic hormone (ACTH). Adrenal androgens with 19 carbon atoms, such as dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione, are secreted by the inner zona reticularis and are under the control of ACTH.

ADRENOCORTICOTROPIN INSENSITIVITY SYNDROMES

Familial isolated glucocorticoid deficiency is a form of potentially lethal hereditary unresponsiveness to ACTH that manifests as primary adrenal insufficiency, usually without mineralocorticoid deficiency. Affected children commonly present within the first 2 years of life with hyperpigmentation, recurrent hypoglycemia, chronic asthenia, and failure to thrive.

Typically, they have deficient production of cortisol and adrenal androgens, in the presence of markedly elevated ACTH levels, whereas renin and aldosterone levels are usually normal and responsive to activation of the renin–angiotensin axis. In some cases, the isolated glucocorticoid deficiency is accompanied by alacrima (lack of tears) and achalasia of the esophagus, a triad called the triple A syndrome.

Isolated Glucocorticoid Deficiency

Familial isolated glucocorticoid deficiency is a rare autosomal-recessive disorder that manifests as primary adrenal insufficiency, usually without mineralocorticoid deficiency. From the first description of the syndrome in 1959, it became apparent that affected individuals suffer from a form of hereditary unresponsiveness to ACTH. Indeed, affected children commonly present within the first 2 to 3 years of life with hyperpigmentation, recurrent hypoglycemia that can lead to convulsions or coma, chronic asthenia, and failure to thrive or even death, if it remains undiagnosed. Biochemically, they have deficient production of cortisol and adrenal androgens, in the presence of markedly elevated ACTH levels. Circulating cortisol levels, which are undetectable in the majority of cases, do not increase with short or prolonged stimulation with pharmacological doses of ACTH. Aldosterone and adrenal androgen responses to ACTH are also lost in these patients, suggesting that the underlying unresponsiveness to ACTH is generalized. Renin and aldosterone levels are usually normal, however, and respond appropriately to activation of the renin–angiotensin axis by orthostasis, salt restriction, or furosemide-induced diuresis. Treatment of hereditary isolated glucocorticoid deficiency consists of glucocorticoid replacement therapy. Affected subjects achieve normal growth and development with steroid replacement and live an otherwise normal life.

Histological postmortem studies of the adrenal glands in affected patients have revealed that the

ACTH-dependent zonae fasciculata and reticularis are extremely atrophic, reduced to a narrow band of fibrous tissue. In contrast, the angiotensin II-dependent zona glomerulosa is relatively well preserved, suggesting that the defect is limited to the ACTH-dependent zonae of the adrenal cortex. The etiological involvement of the ACTH receptor gene in familial glucocorticoid deficiency has been proposed since the first description of the syndrome in the late 1950s, but it was only after the cloning of the ACTH receptor gene in 1992 that this hypothesis could be tested. The ACTH receptor [melanocortin receptor 2 (MC2)] consists of 297 amino acids and is encoded by an intronless gene mapped to the distal end of chromosome 18. It belongs to the distinct melanocortin subfamily of the G protein-coupled receptors that couple to G_s and adenyl cyclase to generate cyclic AMP as a second messenger. More than 15 point mutations and frameshift mutations have been reported as homozygote or compound heterozygote mutations in different pedigrees with isolated glucocorticoid deficiency. These mutations are scattered throughout the ACTH receptor molecule and affect all aspects of receptor function.

Mutations within the coding region of the ACTH receptor gene have not been found in all clinically defined cases of hereditary isolated glucocorticoid deficiency. Furthermore, using pairs of polymorphic dinucleotide repeats that are localized in the same region of chromosome 18, to which the human ACTH receptor gene has been mapped, no apparent linkage was demonstrated between the disease and the ACTH receptor gene in the majority of these families. These findings suggest that the etiology of isolated glucocorticoid deficiency might be heterogeneous and that a gene(s) other than the ACTH receptor gene might produce the same phenotype. Reverse genetics and linkage analysis might provide the means to localize the putative gene(s).

Triple A Syndrome

A subset of the patients with hereditary unresponsiveness to ACTH, in addition to hypocortisolism, develop alacrima (lack of tears) and achalasia of the esophagus (leading to difficulty in swallowing). This constellation of symptoms is referred to as triple A syndrome, first described in 1978. Low tear production, usually present from early infancy on, may be confirmed by the Shirmer test, whereas esophageal dysmotility can be demonstrated by barium swallow and/or endoscopic examination. In some cases, the

diagnosis of achalasia may precede the diagnosis of cortisol deficiency. Occasional patients may also develop a variable degree of mineralocorticoid deficiency. It has become apparent that progressive and variable neurologic impairment that involves both central and peripheral neurons is also frequently associated with the triple A syndrome. Neurological defects may include autonomic and peripheral neuropathy, ataxia, and mental retardation and may thus result in a severely disabling disease.

It had been originally proposed that the ACTH receptor may also be defective in the triple A syndrome, but no mutations were found in the entire coding region of this gene in several families with the triple A syndrome. Homozygote or compound heterozygote mutations were found in the AAAS gene on 12q13 in families with the triple A syndrome. AAAS codes for the WD repeat-containing protein ALADIN (alacrima–achalasia–adrenal insufficiency–neurologic disorder). It is of note that no AAAS mutations have been found in testing of several families with isolated glucocorticoid deficiency with a normal ACTH receptor gene, suggesting that isolated glucocorticoid deficiency without MC2 receptor gene mutations is not a *forme fruste* of the triple A syndrome. The function of the AAAS gene must be clarified before further information on the effect of the individual genetic defects can be acquired. ALADIN is postulated to be involved either in cytoplasmic trafficking, like other proteins with WD repeats, or in peroxisomal activities.

X-LINKED CONGENITAL ADRENAL HYPOPLASIA

Congenital X-linked adrenal hypoplasia is a rare disorder that is characterized by primary adrenal insufficiency and hypogonadotropic hypogonadism. The gene responsible for this disorder, DAX-1 (for dosage-sensitive sex reversal critical region at the adrenal hypoplasia locus on the X chromosome), was localized on the short arm of the X chromosome (Xp21). DAX-1 gene encodes a 470-amino-acid member of the nuclear receptor superfamily with an unknown ligand (orphan receptor). This orphan nuclear hormone receptor has a novel DNA-binding domain that has a unique structure that does not resemble the classic zinc-finger DNA-binding domain of these receptors. The DAX-1 gene is expressed not only in the adrenal gland but also in most of the reproductive tissues, such as the hypothalamus, the pituitary gonadotropic cells, and the gonads, and it plays an

important role in the development and functions of both the adrenal glands and the gonads.

More than 60 different mutations in DAX-1 have been reported in patients with X-linked congenital adrenal hypoplasia. Missense mutations in the DAX-1 gene have been identified in the C-terminal ligand-binding domain, whereas frameshift or nonsense mutations have been described in the N-terminal domain, the majority being frameshift or nonsense mutations resulting in premature truncation of the DAX-1 protein.

Patients with DAX-1 mutations develop primary, complete adrenal insufficiency, presenting as salt-wasting and hypoglycemic convulsions in infancy or childhood, as a result of a failure of formation of the adrenal cortex. Plasma cortisol and aldosterone are at a low level and do not respond to exogenous ACTH administration. Because of early diagnosis and treatment of adrenal failure, an increasing number of patients with X-linked congenital adrenal hypoplasia survive. In these patients, hypogonadotropic hypogonadism arises later in life and is recognized as a universal feature of this syndrome. It presents as pubertal delay, possibly due to defective production of hypothalamic gonadotropin-releasing hormone (GnRH) and impaired responsiveness of pituitary gonadotropes to GnRH. Indeed, pulsatile GnRH has proved ineffective at inducing puberty in these patients. Nevertheless, spontaneous onset of puberty, but with incomplete pubertal development, has been reported. More than 10% of patients have bilaterally undescended testes at birth.

Administration of human chorionic gonadotropin (HCG) stimulates testosterone concentrations into the normal range in most patients. However, exogenous gonadotropins are ineffective at inducing spermatogenesis, probably reflecting a direct effect of DAX-1 mutations on Sertoli cell function. Interestingly, an I496S missense mutation in DAX-1 was found in a man who presented with incomplete hypogonadotropic hypogonadism in his twenties and mild adrenal failure. Functional studies showed that this mutation caused a partial loss of DAX-1 function, suggesting that partial loss-of-function mutations in DAX-1 can present with hypogonadotropic hypogonadism and covert adrenal failure in adulthood.

A remarkable discrepancy indeed exists in genotype-phenotype relationships. Thus, the same mutation resulted in two brothers with the complete syndrome, an unaffected grandfather, and a homozygote aunt with only hypogonadotropic hypogonadism and normal adrenal function. It is of note that female heterozygotes for DAX-1 mutations may present with delayed puberty but normal fertility.

PRIMARY ADRENAL INSUFFICIENCY CAUSED BY STEROIDOGENIC FACTOR-1 MUTATIONS

Steroidogenic factor-1 (SF-1) is an orphan nuclear receptor, formally isolated as a pivotal factor in the tissue-specific expression of cytochrome P450 steroid hydroxylases, which are essential for the synthesis of steroid hormones. SF-1 is expressed in the adrenal glands and gonads and is essential for the development and function of these organs and for normal sexual differentiation. In the adrenal glands, SF-1 not only regulates the levels of cytochrome P450 steroid hydroxylases, but also modulates the expression of 3β -hydroxysteroid dehydrogenase, steroidogenic acute regulatory protein (StAR), and the ACTH receptor. SF-1 is also expressed in the pituitary gland and hypothalamus, contributing to the differentiation of pituitary primordial cells into gonadotropes.

Two cases of SF-1 gene mutations have been described. The first mutation was reported in a 46,XY phenotypic female, who presented with primary adrenal failure during the first weeks of life with low circulating cortisol and aldosterone and high ACTH. Although the karyotype of the patient was 46,XY, she retained normal Müllerian structures and streak-like gonads, containing poorly differentiated seminiferous tubules and connective tissue. The patient had a heterozygote two-codon replacement in exon 3 of one of the SF-1 genes, causing substitution of glycine at amino acid 35 by glutamate in the DNA-binding domain of the protein, abolishing its DNA-binding activity. Pituitary gonadotropins responded to GnRH but testosterone did not respond to exogenous HCG administration, suggesting defective gonadal function. After introduction of estrogen and progesterone, the uterus grew and regular menstruation occurred. Based on this case, it seems that SF-1 is essential for sex determination, steroidogenesis, and reproduction. The second heterozygote SF-1 mutation was described in a 27-month-old 46,XX female with normal external genitalia and adrenal failure. Her pubertal development remains to be observed in future years. However, impaired ovarian development and/or steroidogenesis would be expected for this patient.

Congenital Lipoid Adrenal Hyperplasia

Delphine Mallet and Yves Morel
Hôpital Debrousse, Lyon, France

Glossary

congenital lipoid adrenal hyperplasia One of the rarest forms of congenital adrenal hyperplasia (CAH). Adrenal hyperplasia is due to adrenocorticotropin hypersecretion, which is common to all defects of cortisol biosynthesis. The term lipoid refers to the accumulation of lipids in adrenal cells, specific to this form of CAH.

CYP11A Gene encoding the cytochrome P450_{scc}, a steroidogenic enzyme member of a large family of cytochromes.

cytochromes Heme-containing enzymes responsible for protein oxidation, involved in either biosynthesis or degradation. All steroidogenic enzymes belong to the cytochrome family, except for 3 β -hydroxysteroid dehydrogenase and 17 β -hydroxysteroid dehydrogenase.

male pseudohermaphroditism Defect of virilization of external genitalia in 46,XY individuals with well-differentiated testes.

StAR steroidogenic acute regulatory protein: protein implicated in mitochondrial cholesterol transfer, whose gene is mutated in most cases of congenital lipoid adrenal hyperplasia.

Congenital lipoid adrenal hyperplasia is a rare autosomal recessive disease caused by defective production of all adrenal and gonadal steroids, responsible for severe adrenal insufficiency and female phenotype in both sexes. Impairment of steroidogenesis is due to the inability of affected cells to convert cholesterol into pregnenolone.

BIOLOGICAL AND CLINICAL DATA FOR CONGENITAL LIPOID ADRENAL HYPERPLASIA

Congenital lipoid adrenal hyperplasia was first described by Andrea Prader in 1955 and is characterized by severe adrenal failure and female phenotype in both sexes (Fig. 1). Production of all adrenal and

gonadal steroids is severely impaired and can not be stimulated by adrenocorticotropin (ACTH) or human choriogonadotrophic hormone. Mineralocorticoid and glucocorticoid defects are potentially lethal within the first days or weeks after birth in the absence of hormonal replacement therapy because of severe salt loss, vomiting, and dehydration. 46,XY patients present with male pseudohermaphroditism (female phenotype) due to defective testosterone production. Because testicular differentiation is normal, anti-Müllerian hormone is physiologically secreted, which explains the absence of Müllerian-derived structures, such as the uterus or fallopian tubes, in these patients. Skin hyperpigmentation at birth, which occurs in a large number of patients, is due to ACTH hypersecretion during fetal life.

Adrenal enlargement due to the accumulation of lipid droplets is not systematically present or detected by imaging studies. Some symptoms vary, such as age at apparition of first symptoms and degree of hyponatremia. Respiratory distress and hypoglycemia have also been described.

FIRST STEP OF STEROIDOGENESIS

Steroids are all produced from a common precursor, cholesterol. The first enzymatic step of steroidogenesis produces pregnenolone by cleaving the cholesterol side chain (Fig. 2). Cytosolic cholesterol migrates from the outer to the inner mitochondrial membrane, where an enzymatic complex achieves cholesterol hydroxylation and side chain cleavage by transferring electrons and H⁺ ions from P450_{scc} to cholesterol.

This complex is an electron-transfer chain in which NADPH gives electrons to a flavoprotein called adrenodoxin reductase, which transfers them to an iron-sulfur protein called adrenodoxin. Finally, adrenodoxin transfers electrons to P450_{scc} (Fig. 3). Cholesterol has different origins: One part is endogenously synthesized from acetyl-CoA, another part derives from the low-density lipoproteins, and the last

Figure 1 The adrenals and the urogenital tract of a 46,XY individual with congenital lipoid adrenal hyperplasia. Note adrenal enlargement and circumvolutions due to lipid accumulation and the weak virilization of the internal genitalia, vas deferens, and epididymis. From Prader (1955).

part derives from lipid droplets in which cholesterol is stored as cholesterol esters.

SEARCHING FOR CANDIDATE GENES

For a long time, it was thought that congenital lipoid adrenal hyperplasia was due to an enzymatic defect, like other forms of CAH. Cytochrome P450_{scc} was first suspected, but no mutation of the *CYP11A* gene encoding P450_{scc} was identified in several patients studied. This hypothesis was discarded, although it has been demonstrated that in rabbit congenital lipoid adrenal hyperplasia is due to a deletion of the *CYP11A* gene. Furthermore, it was demonstrated that progesterone production is essential for maintaining mammalian pregnancy and avoiding spontaneous abortion.

During pregnancy, progesterone can be produced either by the corpus luteum of the mother's ovary or by the placenta. In rabbit, the female's ovary assumes progesterone production throughout pregnancy, whereas in humans, it produces progesterone only during the first trimester. Therefore, placental progesterone production is necessary to maintain pregnancy in humans. Because the placenta is a fetal

tissue, a fetus homozygous for a mutation abolishing all P450_{scc} activity would abort. In contrast, in rabbit, a female's ovary would continue to produce progesterone, avoiding abortion. Thus, it was determined that the *CYP11A* gene defect could not be responsible for congenital lipoid adrenal hyperplasia in humans, and that the candidate gene is not expressed in the placenta.

Genes encoding adrenodoxin and adrenodoxin reductase were also candidates, but no mutations were found in several patients. This result was not surprising because these proteins are implicated in other enzymatic systems. Therefore, research has been focused on proteins implicated in cholesterol transfer from the cytosol to the mitochondria.

Genes encoding sterol carrier protein-2, its precursor, a 78-amino acid peptide produced from the C-terminal end of the glucose-related protein called GRP-78, the protein presumably implicated in mitochondrial transport of cholesterol, and the benzodiazepine receptor and its presumed ligand, endozepine, became good candidate genes. Unfortunately, no mutation of these genes was detected. Finally, in 1994, Stocco and colleagues identified a protein in mouse Leydig MA-10 cells that was specifically expressed in gonads and adrenals but not in placenta. Its synthesis was rapidly induced by ACTH via cAMP, and this protein was able to increase steroidogenesis when it was transfected in MA-10 cells, accounting for the acute steroid production in response to hormonal stimulation. Therefore, this protein was named the steroidogenic acute regulatory protein (StAR). This protein seemed to be a good candidate to explain the pathogenesis of congenital lipoid adrenal hyperplasia, which has been further confirmed by the detection of mutations of StAR genes in several patients.

STRUCTURE AND FUNCTION OF THE StAR PROTEIN

The StAR protein is 285 amino acids long. The first 26 amino acids of the N-terminal end are presumably implicated in mitochondrial signaling. StAR is expressed in adrenal and gonads but not in the placenta. The mechanism by which StAR allows cholesterol transfer is not clearly understood. Two models exist. The first model was deduced from the study of StAR deletion mutants. StAR lacking the 62 N-terminal amino acids has been shown to be active, whereas it could not enter the mitochondria due to the lack of the signaling sequence. On the other hand, mutants deleted in the C-terminal end lose activity. Recently, a protein

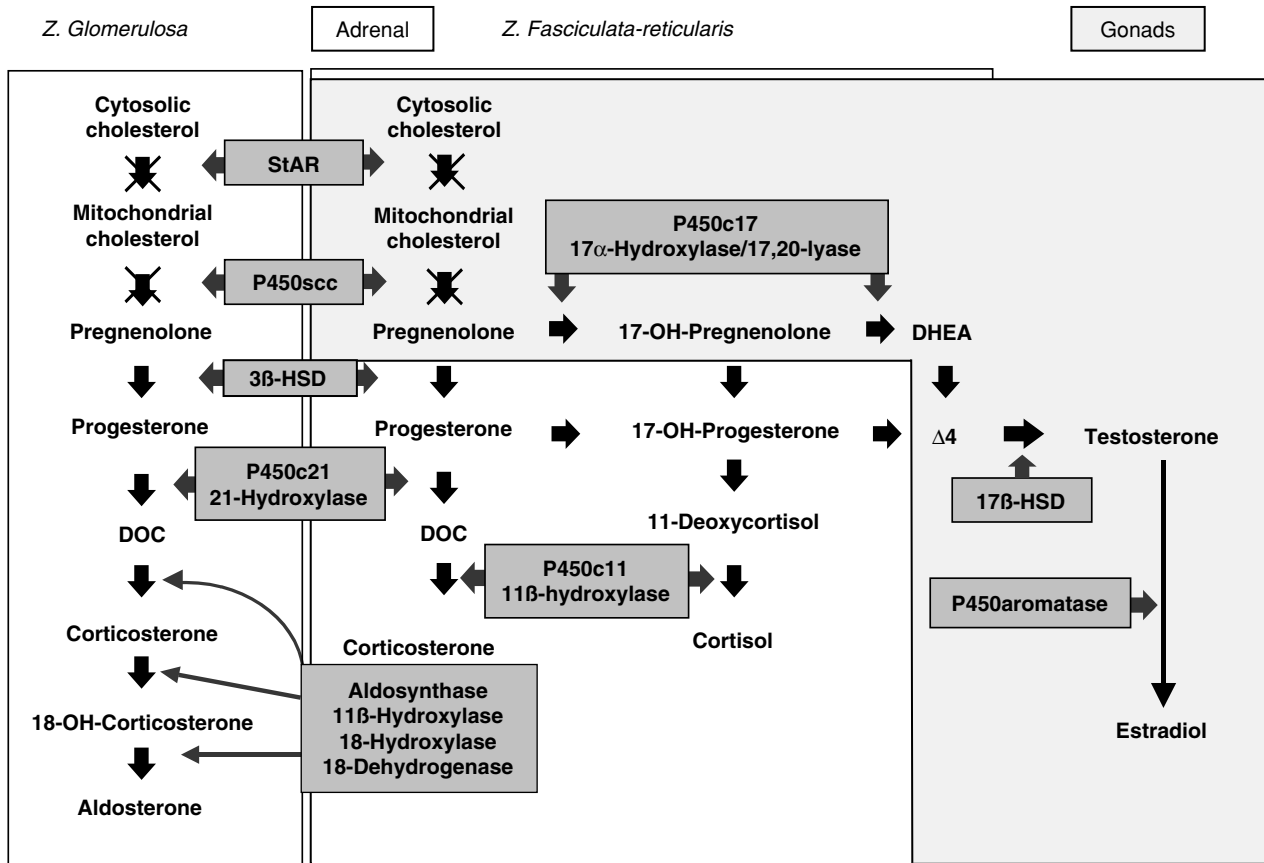

Figure 2 Adrenal and gonadal steroidogenesis. The adrenal contains two zones—the zona glomerulosa, which produces mineralocorticoids, and the zona fasciculata-reticularis, which produces glucocorticoids. Gonads make only sex steroids, using preferentially the $\Delta 5$ pathway.

called MLN64, with an amino acid sequence similar to that of the C-terminal end of StAR, has been identified in placenta. This protein is able to enhance steroidogenesis *in vitro*. Therefore, MLN64 seems to play the StAR role in the placenta, according to the hypothesis that the defective protein in congenital lipoid adrenal hyperplasia is not expressed in this tissue. Similarities between StAR and MLN64 C-terminal ends support the importance of this region. Sequences homologous to the StAR C-terminal region were determined to be a new domain called START (StAR-related lipid transfer domains) because they are able to bind lipids. Study of the tertiary structure of this domain has shown that it forms a hydrophobic tunnel, to which a molecule of cholesterol can bind. Therefore, the first model proposes that cholesterol enters the mitochondria through this hydrophobic tunnel.

The second model was deduced from observations that StAR could form a structure called molten globule at pH 3.5–4. Molten globules consist of proteins that lose some of their tertiary structure but retain their

secondary structure. This model hypothesizes that a StAR conformational change induces a modification of the outer mitochondrial membrane structure, allowing cholesterol transfer.

Figure 3 Schematic representation of the first step of steroidogenesis. StAR transfers cholesterol from the outer to the inner mitochondrial membranes and to the side chain cleavage complex—adrenodoxin reductase, adrenodoxin, and cytochrome P450scc. The cholesterol side chain is then cleaved to form pregnenolone.

Figure 4 StAR gene and pseudogene.

Some issues remain unresolved. For example, only one molecule of cholesterol can pass through the hydrophobic tunnel at a time, which seems inconsistent with the acute steroidogenic response to stimulation. Concerning the molten globule hypothesis, it is not clear how the pH around StAR becomes acidic. Nevertheless, these two models are at the present time the most relevant.

CONGENITAL LIPOID ADRENAL HYPERPLASIA AND THE StAR GENE

Congenital lipoid adrenal hyperplasia has an autosomal recessive mode of inheritance and is essentially due to StAR gene mutations. The gene encoding StAR is located on chromosome 8p, 8 kb long, and composed of seven exons. Amplification of the StAR gene requires the use of primers located in introns due to the existence of a pseudogene on chromosome 13 that does not have introns and contains a large number of rearrangements (Fig. 4). Approximately 30 StAR gene mutations have been described in 57 patients (Table I). Two mutations are more frequent in specific ethnic groups: the *Q258X* mutation in the Japanese population and the *R182L* mutation in the Palestinian population. By studying the clinical data of the 57 patients described as having StAR gene mutations, it appears that there are variations in age at onset of first symptoms. Adrenal insufficiency usually occurs in the first few days after birth, but some patients underwent adrenal insufficiency later and survived without substitutive hormonal treatment for several weeks or months. Differences also exist in gonadal lesions between sexes. Testicular lesions appear early in the development of the fetal testis, as demonstrated by the existence at birth of female phenotype in 46,XY patients.

In contrast, ovarian damage seems to be less severe until puberty since spontaneous breast development at puberty has been observed in some affected girls. A model describing the consequences of StAR gene mutations has been proposed to explain these differences:

the two-hit model. The absence of cholesterol transfer from the outer to the inner mitochondrial membrane results in no response of StAR-dependent steroidogenesis to stimulation, causing the first hit. However, a system exists that allows production of small amounts of steroids by a StAR-independent mechanism that is not clearly understood. Second, accumulation of unmetabolized cholesterol becomes toxic for cellular metabolism, leading to cell death. Because testes are highly stimulated early in fetal life to induce testosterone biosynthesis, engorgement of testicular cells by unmetabolized cholesterol occurs rapidly and leads to cell destruction, which explains the absence of virilization in 46,XY fetus. In contrast, the ovary is not really stimulated before puberty. During the short period preceding engorgement, affected cells are able to synthesize small amounts of estrogens, allowing some degree of feminization at puberty.

Also interesting with regard to congenital lipoid adrenal hyperplasia is the discrepancy between the weak virilization of the vas deferens and epididymis and the absence of virilization of external genitalia described in some 46,XY patients (Fig. 1) and in StAR knockout mice. This suggests that the testicular StAR-independent synthesis of steroids should be sufficient to weakly virilize and develop the nearest internal genitalia by a mechanism of local diffusion. External genitalia, which are more distant from the testes, do not receive enough androgens to be virilized. This dissociated action of androgens has also been described in 17 β -hydroxysteroid dehydrogenase deficiency, but in this case the testosterone derives from the local conversion of precursors achieved by a peripheral isoenzyme.

Although StAR gene mutations have been identified in most patients with congenital lipoid adrenal hyperplasia, 1 patient has been reported without a StAR gene mutation and 2 patients have been reported to be heterozygous. We were unable to identify any StAR gene mutations in 5 of 13 Caucasian patients studied. Research on new candidate genes had been unfruitful until recent reports of *CYP11A* gene mutations in 2 unrelated patients.

CONGENITAL LIPOID ADRENAL HYPERPLASIA AND THE CYP11A GENE

In 2001, the role of the *CYP11A* gene was revisited after the identification of *CYP11A* gene mutations in two patients. One patient is heterozygous for a *de novo* 6-base pair insertion. *In vitro* study showed that mutant protein is totally inactive, suggesting that

ND, no StAR gene mutation detected.

^aMissing were not provided in original publications.

[¶], [‡], [°], ^{*}, [#], [§]Patients with the same symbol are related.

^cNa and K values are from Bose *et al.* (1996). Confirmation of these low Na values at day 1 was not provided in the original report.

this patient suffers from congenital lipoid adrenal hyperplasia because of *CYP11A* haploinsufficiency. The other patient is compound heterozygous for a missense mutation and a *de novo* splicing mutation. The mutant protein bearing the missense mutation retains some enzymatic activity, whereas the splicing mutation abolishes all activity. Thus, in these two cases, a residual activity during fetal life produced enough progesterone to avoid spontaneous abortion. We have also identified *CYP11A* gene mutations in three of five patients affected by congenital lipoid adrenal hyperplasia without StAR gene mutations. Studies of other patients with *CYP11A* gene mutations would help to determine the relationship between genotype and phenotype. Particularly, is the

detection of a heterozygous *CYP11A* gene mutation in a patient enough to explain this disease?

CONCLUSION

The pathogenesis of congenital lipoid adrenal hyperplasia is more complex than that of other steroidogenic enzyme defects. This disorder is an enzymatic disease but also a storage disease, which explains the various phenotypic aspects. The majority of mutations do not affect the *CYP11A* gene encoding P450scc responsible for the enzymatic step, but they do affect the StAR protein, which is involved in cholesterol transport. The study of StAR in the pathogenesis of congenital lipoid adrenal hyperplasia has resulted in a better understanding

of some fundamental aspects of steroidogenesis: its role in transport of cholesterol, the existence of two mechanisms of steroids biosynthesis (one independent of StAR and the other StAR dependent) and the relationship between these two mechanisms, and the phenotype of affected patients. Recently, *CYP11A* gene mutations have been described in two patients with congenital lipoid adrenal hyperplasia, indicating that this disease may be due to either a StAR or a P450scc defect.

The predominance of StAR gene mutations versus *CYP11A* gene mutations may be explained by the fact that complete abolition of StAR activity is compatible with pregnancy, whereas complete P450scc inactivation is lethal for the fetus.

Conn's Syndrome

Franco Mantero and Oliver Bedendo
University of Padua, Padua, Italy

Glossary

aldosterone-producing adenoma A benign adrenal tumor that produces aldosterone in excess; it is usually small (0.5–2.0 cm) and solitary.

hypertension This condition, when due to an excess of aldosterone, is characterized by water retention and an expansion in extracellular volume, resulting in low or suppressed plasma renin activity values and high absolute or relative plasma aldosterone levels.

hypokalemia The excessive preservation of sodium at the expense of potassium loss, as occurs in hyperaldosteronism; however, only < 40% of patients affected by primary aldosteronism are hypokalemic.

primary aldosteronism The most common cause of mineralocorticoid-based hypertension. It is due to an excess of aldosterone, usually caused by an aldosterone-producing adenoma (Conn's syndrome) or bilateral adrenal hyperplasia (idiopathic hyperaldosteronism).

First described in 1955 by Jerome Conn, Conn's syndrome is a clinical syndrome characterized by hypertension and hypokalemia, with low or suppressed plasma renin activity and increased aldosterone excretion, due to a circulating excess of aldosterone, autonomously produced by a benign adrenal tumor.

EPIDEMIOLOGY

Idiopathic hyperaldosteronism due to bilateral adrenal hyperplasia and Conn's syndrome are the most common forms of primary aldosteronism. Conn's syndrome itself accounts for more than 50% of cases of primary aldosteronism.

Primary aldosteronism is the most common cause of mineralocorticoid-based hypertension; initial studies reported prevalence rates of less than 1% among hypertensive patients, but these were largely based on detection of unexplained hypokalemia. Since measurement of the plasma aldosterone concentration

to plasma renin activity ratio was introduced as a screening test and became widely used, higher prevalence rates of 2–12% have been reported, with normokalemic patients representing up to 60% of cases.

PATHOPHYSIOLOGY

Elevated plasma aldosterone levels promote excessive preservation of sodium at the expense of hydrogen and potassium loss in the distal nephron. Sodium retention promotes water retention and an expansion in extracellular volume, resulting in hypertension and suppression of plasma renin.

In patients with an aldosterone-producing adenoma, hypokalemia can be absent or can be present in different grades, sometimes with metabolic alkalosis, mostly depending on the degree and duration of aldosterone excess.

CAUSES

Conn's syndrome usually derives from a small (0.5–2.0 cm), solitary, aldosterone-producing adrenal adenoma. However, more rarely, the adenoma can be multiple or bilateral.

The etiology of Conn's syndrome is still unknown, even if there are rare cases with a genetic basis, as a component of multiple endocrine neoplasia type 1 or manifested in a glucocorticoid- or nonglucocorticoid-remediable form of familial hyperaldosteronism (familial hyperaldosteronism types I and II).

Typically, the tumor is yellow in color due to its high cholesterol content. Based on morphological and biochemical patterns, aldosterone-producing adenomas can be divided into two groups, as follows:

Angiotensin II-Unresponsive Aldosterone-Producing Adenomas

Angiotensin II-unresponsive aldosterone-producing adenomas are predominantly composed of fasciculated-like cells. Aldosterone production is increased

when adrenocorticotropic hormone is administered, but does not respond to low-dose angiotensin II infusion or to a change from a supine to an upright position (postural test). The so-called “hybrid” steroids, 18-oxocortisol and 18-hydroxycortisol, are produced in excess. These tumors are more common among females.

Angiotensin II-Responsive Aldosterone-Producing Adenomas

Angiotensin II-responsive aldosterone-producing adenomas are composed predominantly of glomerulosa-like cells. Aldosterone secretion is increased when low doses of angiotensin II are infused or after a change from a supine to an upright position (postural test). Expression of renin mRNA is typically increased in these adenomas.

CLINICAL FEATURES

Clinical features (and laboratory findings) are usually more severe in Conn's syndrome than in other forms of primary aldosteronism. Moreover, patients are usually younger, with age at presentation typically being less than 50 years.

Hypertension

Similar to other forms of primary aldosteronism, hypertension is often resistant to antihypertensive drugs; however, patients with an aldosterone-secreting adenoma may have more severe hypertension.

Hypokalemia

In Conn's syndrome, hypokalemia may be more profound, with values of less than 3 mEq/liter, compared to all forms of primary aldosteronism.

If hypokalemia is severe, symptoms or signs related to metabolic alkalosis, such as tetany or positivity of Chvostek or Trousseau sign, symptoms or signs related to myopathy, such as weakness, or symptoms or signs related to nephrogenic diabetes insipidus, such as polyuria and nocturia, can be present.

The presence of an aldosterone-producing adenoma is possible even in normokalemic patients.

INVESTIGATIONS

In patients affected by Conn's syndrome, plasma and urinary aldosterone levels are usually higher than in other forms of primary aldosteronism.

Diagnosis is made based on clinical suspicions (hypokalemia, refractory hypertension, young age) in a hypertensive patient, a screening test to reveal low or suppressed plasma renin activity and inappropriately high plasma aldosterone levels, a test to confirm autonomous aldosterone secretion with nonsuppressible plasma aldosterone levels after salt or water loading, and adrenal imaging to reveal the presence of the tumor.

Adrenal vein sampling is indicated to assess lateralized aldosterone excess from solitary adenoma. There remains a debate as to whether adrenal vein sampling should be performed in all cases of primary aldosteronism or only when all previous diagnostic studies are inconclusive.

TREATMENT

Unilateral adrenalectomy is the treatment of choice for patients with an aldosterone-secreting adenoma, resulting in normalization of the serum potassium concentration in 100% of cases, a decrease in blood pressure values in the majority of cases, and a return to normal blood pressure values in 30–35% of cases, after successful excision. Laparoscopic adrenalectomy is as effective as open adrenalectomy, but with lower intra- and postoperative risks.

If surgical therapy is declined or if the patient is not an appropriate candidate for surgery, long-term medical therapy with mineralocorticoid receptor antagonists or epithelial sodium-channel blockers can be successfully undertaken.

Conn's Syndrome, Diagnosis of

Franco Mantero and Oliver Bedendo
University of Padua, Padua, Italy

Glossary

adrenal computed tomography Noninvasive radiological investigation providing morphological data on the adrenals. A high-resolution scan with contiguous <5 mm cuts is usually sensitive enough to detect Conn's adenoma.

adrenal vein sampling Invasive radiological investigation consisting of cannulation of the adrenal veins and subsequent sampling with measurement of plasma cortisol and plasma aldosterone concentrations. It is considered the gold standard test to assess, or to exclude as a diagnosis, a lateralized excess of aldosterone from the adrenals.

fludrocortisone (9 α -fluorohydrocortisone) suppression test This investigation assesses whether suppression of plasma aldosterone by mineralocorticoids and sodium loading is present ("essential" hypertension) or absent (primary aldosteronism). It is considered the gold standard test to confirm primary aldosteronism when the plasma aldosterone concentration to plasma renin activity ratio is increased.

plasma aldosterone concentration to plasma renin activity ratio Screening test to select (when the ratio is increased) hypertensive patients that should undergo further investigations for primary aldosteronism. Plasma aldosterone concentration and plasma renin activity are measured when the patient is in an upright position.

Diagnosis of Conn's syndrome includes a screening test and a confirmatory test to assess inappropriately high and non-suppressible plasma aldosterone levels, radiological imaging to localize the adrenal tumor, and sometimes adrenal vein sampling to assess lateralization of aldosterone excess.

SCREENING

All hypertensive patients with refractory hypertension or hypokalemia or who are younger than 50 years of age should be screened for Conn's syndrome.

Measurements of serum potassium or plasma or urinary aldosterone concentration can be useful, but they are not sensitive enough to confirm the diagnosis, as patients affected by primary aldosteronism may sometimes exhibit levels that are in the normal range. However, when an aldosterone-producing adenoma is present, plasma aldosterone and urinary aldosterone are usually higher than in other forms of primary aldosteronism, with values greater than 25 ng/dl and 30 μ g/24 h, respectively. The isolated measurement of plasma renin activity is also inadequate for screening, as it can show low values even in "essential" hypertensives or in patients with chronic renal failure.

A widely accepted, valid screening test is the measurement of the plasma aldosterone concentration to plasma renin activity ratio taken when the patient is in an upright position; the ratio is typically increased in primary aldosteronism.

Due to their influence on the renin-angiotensin system, antihypertensive medications should be discontinued for 2 weeks before the test is taken and anti-aldosterone drugs should be discontinued for at least 6 weeks prior to testing; in hypokalemic patients, potassium stores must be replenished for 2 weeks prior to the test. However, when complete cessation of medications may not be safe, the ratio seems to be a valid screening test even in patients still taking antihypertensive drugs, except for anti-aldosterone antagonists and beta-blockers.

Although the plasma aldosterone concentration to plasma renin activity ratio has a high level of sensitivity, specificity is poor, as renin levels are sometimes low simply due to ethnicity, age, or kidney disease. A suppression dynamic test to confirm an inappropriate and autonomous aldosterone secretion is thus needed.

CONFIRMATION

A confirmatory test is usually performed after a positive screening test. The fludrocortisone suppression test, saline infusion test, and oral salt-loading test are

widely used to confirm inappropriately high plasma aldosterone levels, which are typically not suppressed by volume or salt loading in Conn's syndrome.

The fludrocortisone suppression test, possibly associated with oral salt loading, has been proposed as the gold standard, as it has the highest level of sensitivity of the available tests, but the patient may require hospitalization when the test is performed.

LOCALIZATION

Radiological investigation is required to detect the adenoma. High-resolution adrenal computed tomography (CT) scanning with contiguous <5 mm cuts seems to be more sensitive than adrenal magnetic resonance imaging (MRI).

Adrenal scintigraphy with iodo-cholesterol and under dexamethasone suppression provides both morphological information and functional information, but sensitivity is poor for tumors smaller than 1.5 cm.

Despite the high degree of sensitivity of CT and MRI, a very small (less than 5 mm) adenoma could escape radiological detection. If the studies are inconclusive, with dubious adrenal imaging features, but there is a high suspicion of adenoma, patients should be considered for adrenal vein sampling.

LATERALIZATION

Despite technical difficulties, such as cannulation of the right adrenal vein, and risks, such as adrenal vein hemorrhage or thrombosis, adrenal vein sampling is the only reliable test to assess lateralization of aldosterone excess.

Cortisol from each adrenal is measured to confirm the correct location of the cannula and the aldosterone to cortisol ratio of the two adrenal veins is compared to assess lateralization. If lateralization is present, contralateral adrenal aldosterone secretion is typically inhibited.

Due to the high prevalence of adrenal incidentalomas, it is still a matter of debate as to whether sampling should be performed in all cases of confirmed primary aldosteronism.

DIFFERENTIAL DIAGNOSIS

Conn's syndrome should always be differentiated from other forms of primary aldosteronism, as this has important therapeutic implications.

Conn's Syndrome versus Idiopathic Hyperaldosteronism

Since angiotensin II-responsive aldosterone-producing adenomas have been recognized, a postural test cannot be used to distinguish between adenoma and bilateral adrenal hyperplasia. Angiotensin II-unresponsive aldosterone-producing adenomas do not respond to a change from a supine to an upright position in terms of aldosterone production, whereas both bilateral adrenal hyperplasia and angiotensin II-responsive adenomas respond (resulting in an increase in plasma aldosterone of greater than 30%)

Negative imaging and lack of lateralization of adrenal vein sampling indicate a diagnosis of idiopathic hyperaldosteronism.

Conn's Syndrome versus Unilateral Adrenal Hyperplasia

Unilateral adrenal hyperplasia, a rare case of primary aldosteronism with a lateralized aldosterone excess, shares the adrenal vein sampling result and therapeutic approach with Conn's syndrome. Radiological imaging can help in the differential diagnosis.

Constitutional Delay of Growth and Puberty (CDGP)

Joost Rotteveel and Henriette A. Delemarre-Van de Waal
Vrije University Medical Center, Amsterdam, The Netherlands

Glossary

central intrinsic restraint Inhibition of gonadotropin-releasing hormone generator by structures above the hypothalamic level.

follicle-stimulating hormone (FSH) A gonadotropin produced by the pituitary that stimulates the testicular Sertoli cells to produce semen in men.

gonadotropin-releasing hormone (GnRH) A hypothalamic hormone that stimulates the pituitary to produce the gonadotropins LH and FSH.

luteinizing hormone (LH) A gonadotropin produced by the pituitary that stimulates the testicular Leydig cells to produce testosterone in men.

puberty GnRH generator activity leading to the development of sexual characteristics.

target height range A zone of ± 1.3 standard deviation score (SDS) from target height in which a person is expected to grow; an estimation of the genetic potential for growth.

Children with constitutionally delayed puberty and maturation present with height standard deviation scores below the target height range, reduced height velocity, and delayed bone age in combination with late onset of puberty. The first manifestation of sexual maturation occurs after 13 years for girls and 14 years for boys.

CHARACTERISTICS OF PUBERTY

Puberty is a maturational process of the hypothalamus–pituitary–gonadal axis resulting in the pubertal growth spurt and development of sex characteristics. At birth, gonadotropin levels are low. This is followed by a transient increase in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels during the first months—the postnatal peak. During childhood, the gonadotropin-releasing hormone (GnRH) generator is suppressed by a central intrinsic restraint

system until puberty begins with pulsatile GnRH and subsequent pulsatile gonadotropin secretion. Pituitary gonadotropins stimulate gonadal growth and activity. Subsequently, the gonads start to produce sex steroids, which are responsible for the pubertal growth spurt and development of sex characteristics. By the end of this process, reproductive function is attained and major psychological changes have occurred.

Prior to the 1990s, there was a trend toward earlier onset of puberty and increased final height. A halt in this trend has been described in Western countries. However, an unconfirmed trend in children in the United States toward earlier onset has been described.

At the population level, there is a large variation in the timing of onset of puberty most commonly due to differences in the maturational program of GnRH secretion. The onset of puberty takes place at the age of 11.5 years (range, 9–14 years) in boys and 10.7 years (range, 8–13 years) in girls. Onset of puberty after these ranges is considered abnormal. The duration of puberty varies considerably. By definition, an equal number of males and females have delayed puberty. However, boys are overrepresented as patients with delayed puberty who seek the help of a clinician. Male puberty occurs later than female puberty. Furthermore, boys with delayed puberty are smaller than their peers due to their prepubertal growth dip. Boys are often extremely distressed about their short stature and absence of puberty.

PUBERTAL DELAY

Delayed puberty is a failure to manifest the initial characteristics of sexual maturation by an age that is more than two standard deviations above the mean for the population. In girls, this is breast development after 13 years of age or menarche after 16 years of age. In boys, this is testicular volume > 4 ml after 14 years of age. Pubic hair development, dependent on the secretion of adrenal and testicular androgens, is often delayed in the constitutional delay of growth and puberty (CDGP) syndrome. However, staging of

pubic hair provides no information about the onset of central puberty: The timing of gonadarche and adrenarche is only loosely related.

CAUSES OF PUBERTAL DELAY

Delayed Puberty without Underlying Abnormality: CDGP

The vast majority of children presenting with delayed puberty have no underlying pathology, and CDGP is the most frequent diagnosis. The fact that other diagnoses have to be excluded does not mean that it is a vague diagnosis. In fact, growth, history, and physical examination reveal a characteristic pattern supporting the diagnosis.

Often, one or both parents had delayed puberty. Growth charts from patients show a low height velocity from childhood that is often lower than the target height range. Boys often present to the clinician when height velocity declines even more during their prepubertal growth dip. Bone age is often delayed but within the target height range.

Hypogonadotropic Hypogonadism

Ruling out hypogonadotropic hypogonadism is the main diagnostic challenge in patients with pubertal delay. Hypogonadotropic hypogonadism is characterized by low levels of gonadotropins. Impaired secretion of GnRH can be functional, such as in CDGP, hypothyroidism, hyperprolactinemia, chronic illness, anorexia nervosa, or malnutrition. In other conditions, GnRH is truly defective. This may be congenital, as in septo-optic dysplasia and Kallmann's syndrome alone or in combination with congenital adrenal hypoplasia (DAX gene mutation), or it may be caused by local factors, such as tumors at the hypothalamus–pituitary level, especially craniopharyngioma. Pituitary defects can be congenital, such as in panhypopituitarism or partial gonadotropin deficiency, caused by local factors such as tumors, or occur after radiation. In partial gonadotropin deficiency, there is a wide degree of hormone deficiency: Pubertal onset may be timely but the progression of sexual maturation incomplete (Fig. 1).

Hypergonadotropic Hypogonadism

If basal concentrations of LH and FSH are raised, the diagnosis is primary gonadal failure. Radiotherapy and chemotherapy can result in gonadal failure.

Figure 1 Patterns of gonadotropin production. In CDGP, normal levels of gonadotropins are reached at a later stage. Partial gonadotropin deficiency may result in late onset or incomplete progression of the expected gonadotropin increments. Therefore, follow-up includes repeated measurements of gonadotropin levels. From Kulin (1996). *J. Clin. Endocrinol. Metab.* **81**, 3460–3464. © The Endocrine Society.

Gonadal insufficiency in girls may be caused by chromosomal abnormalities, such as in Turner's syndrome or variants of gonadal dysgenesis, or by autoimmune ovarian failure. Gonadal failure in boys can be caused by chromosomal abnormalities (Klinefelter's syndrome), anorchia, undescended testes, infections, trauma, or steroid enzymatic deficiencies.

DIAGNOSIS

The main diagnostic concern is not only whether puberty has begun or will begin but also whether puberty will progress. Sequential follow-up over years may be required for a correct diagnosis.

History

Patients with constitutional delay of puberty typically present with delayed linear growth and sexual development. A characteristic growth pattern may be recognized in all three phases of human growth: infancy, childhood, and puberty (Fig. 2).

Height and weight are usually normal at birth. During infancy, children with CDGP often show a decrease in height standard deviation score (SDS), which may result in growth below their target height range. Height SDS will remain low during childhood. The pattern of childhood will continue until puberty starts.

Height velocity will not increase again unless puberty progresses (Fig. 3). Growth during puberty is determined by both sex steroids and growth hormone.

Figure 2 The infancy–childhood–puberty (ICP) model of growth for boys comprises three components. The first 2 or 3 years during infancy are characterized by rapid growth. Thereafter, during the growth hormone-dependent childhood component, growth velocity decreases to a prepubertal rate of 4 or 5 cm/year. Finally, growth velocity during puberty increases again due to growth hormone augmentation by sex hormones. Data are the mean values for age. From Karlberg, J., *et al.* (1987). Analyses of linear growth using a mathematical method. *Acta Paediatr. Scand.* 76(Suppl.), 478–488.

Therefore, delay in the production of sex steroids results in declining height velocity, and patients often present with short stature at an age when puberty can be expected. This is called the prepubertal growth dip (Fig. 4). The magnitude of the growth spurt is determined by the timing of puberty. In CDGP, the growth spurt is decreased (Fig. 5). Final heights may be comparable with those of early maturers due to the longer period of prepubertal growth, and final height is usually within the target height range. However, some researchers have reported that a proportion of these boys may not achieve full final height appropriate to their parental percentiles, probably because of detrimental effects of late puberty on spinal growth.

The main focus of the history should be the pattern of growth. If possible, old growth charts should be obtained. History should also focus on the start and progression of pubertal development. In 75% of cases, family history reveals a pattern of slow maturation in parents or siblings. Often, parents were short statured as children, and after a late onset of puberty attained normal final height. Women should be asked about menarche and men about first spontaneous ejaculation or the age of first shaving. Some parents have been treated for late puberty. The absence of a

Figure 3 Velocity chart from the ICP model showing the contribution of the pubertal component. From Karlberg, J., *et al.* (1987). Longitudinal analysis of infantile growth in an urban area of Lahore, Pakistan. In “Modelling of Human Growth” (J. Karlberg, ed.). University of Goteborg, Goteborg, Sweden.

positive family history makes it important for other diagnostic possibilities to be excluded.

One should specifically ask about nutritional habits. Malnutrition, especially anorexia nervosa, is an important cause of maturational delay in girls. Exercise intensity is important in athletes and ballet dancers. Regarding prior medical illness, one should ask about congenital defects. Signs of diseases such as hypothyroidism, growth hormone deficiency, inflammatory bowel disease, Noonan syndrome, and Turner syndrome should be sought for actively.

Physical Examination

Important in the physical examination is the measurement of height. Short stature, well below target height range, is a common finding. If possible, height velocity should be calculated. Typically, sitting height is low in comparison to leg length due to the inhibitory effect of delayed puberty on spinal growth. This may result in a disproportionate adult stature. Disproportion due to low sitting height is a very reliable sign. Its absence points to an alternate diagnosis. Weight for height should be recorded to evaluate nutritional status. One should search for signs of congenital conditions (midline defects) and chronic illnesses.

Figure 4 Prepubertal loss of height velocity (prepubertal dip) in a boy with CDGP. He was successfully treated with oxandrolone, a weak nonaromatizable androgen.

Sexual development should be recorded as Tanner stage. Stage B2 in girls is breast budding. In boys, stage G2 or a testicular volume of more than 4 ml indicates onset of puberty. Asymmetrical testes are found in tumors that may accompany intersex disorders presenting at puberty.

Bone Age

An X-ray of the left hand and wrist should be obtained at the first visit. During follow-up, this can be repeated. Bone age will usually be delayed more than 2 years. The predicted final height should fall within the parental target height range. Bone age at presentation is often 12 or 13 years. Without the influence of sex steroids, bone age is unlikely to progress beyond the age at presentation. Bone age may be delayed from childhood on. In contrast, bone age in hypogonadotropic hypogonadism can progress beyond 13 years. Therefore, a bone age of more than 13 years indicates the latter diagnosis in a boy with an absence of pubertal development.

Figure 5 Timing of the pubertal growth spurt for early and late male maturers. Note the relatively slow height velocity (<5 cm per year) for the slow maturer from 11 to 14 years of age. This is the period of most concern for the slow maturer, during which the physical discrepancy from his peers becomes more dramatic. Note also that the peak height velocity of the slow maturer is similar to those of the fast and the average maturers. Final height attainment was achieved by the fast maturers by 18 years, whereas the slow maturers were still growing at this age. Thus, although the slow maturer is smaller as a boy, and especially as a young teenager, the adult stature is usually normal. Adapted from Hammar, S. L., and Eddy, J. A. K. (1968). "Nursing Care of the Adolescent." Heinemann Medical, London.

Laboratory Findings

Random measurement of gonadotropins and estrogens should be done initially. As in pubertal failure, gonadotropin levels are low in CGDP. Follow-up will show an increase in gonadotropin levels in CDGP but not in hypogonadotropic hypogonadism. Therefore, it is not possible to differentiate CDGP from hypogonadotropic hypogonadism during puberty. Even in adulthood, a major diagnostic difficulty is partial gonadotropin deficiency.

No single test can reliably discriminate CGDP from hypogonadotropic hypogonadism. Several investigators have tried to develop a test that can differentiate between CDGP and gonadotropin deficiency. Although in general GnRH agonists cause higher levels of gonadotropins in patients with CDGP than in patients with hypogonadotropic hypogonadism, children with hypogonadotropic hypogonadism may respond and children with CDGP may not. Therefore, there may be no advantage in performing a GnRH test. In a sleep test, increased LH levels can be measured for CDGP but not for hypogonadotropic hypogonadism. However, no single test seems to be

completely reliable. Therefore, clinical symptoms are far more important. Establishing the diagnosis depends mainly on the growth curve, testicular volume, and bone age

Hyperprolactinemia should be excluded since this condition may induce late onset of puberty or a halt in pubertal progress. Prolactin levels can be measured randomly. Hypothyroidism needs to be excluded by measuring thyrotropin and thyroxine levels.

Additional Tests

In the case of hypergonadotrophic hypogonadism, a karyotype should be performed to rule out Klinefelter's syndrome in boys and Turner's syndrome in girls.

The spontaneous growth hormone secretion of insulin-like growth factor-1 (IGF-1) and IGFBP-3 is diminished in many boys with CDGP. Also, during growth hormone stimulation tests, stimulated levels of growth hormone may be in the deficient range. However, a diagnosis of growth hormone deficiency cannot be established on these grounds. Boys older than age 10 should be primed with testosterone 5 days before the growth hormone stimulation test; otherwise, growth hormone deficiency will be falsely diagnosed. Furthermore, there is no need to investigate the growth hormone axis when the diagnosis of CDGP is considered. When puberty begins or testosterone therapy is initiated, growth hormone secretion normalizes completely.

TREATMENT

The treatment of CDGP should be aimed at the different problems that these boys encounter. Reassurance that puberty will eventually occur is usually not enough. Boys with pubertal delay are often extremely distressed and feel uncomfortable with their peers. School performance and psychosocial well-being may be seriously affected. Depression, oppositional behavior, low self-esteem, reduced peer contact, aggression toward peers, and general social immaturity can all be presenting signs. Other problems to consider are the deleterious effects of excessively delayed puberty on spinal growth, leading to a disproportionate stature in adulthood. Furthermore, a delay in onset of puberty may lead to a delay in peak bone mineral density and herald an increased risk of osteoporosis in later life. This has not been confirmed, and normal volumetric bone mineral density and bone turnover in young men with histories of constitutional delay of puberty have been reported.

Testosterone Treatment

Short-Term Low-Dose Testosterone

Treatment with sex steroids is logical for CDGP. Treatment at a normal pubertal age (≤ 13 years) provides a better chance of preventing segmental body disproportion, and short-term testosterone therapy in boys may increase bone mineral density. Self-confidence may return even after a short period of low-dose testosterone therapy.

Short-term low-dose therapy in most boys accelerates growth (Fig. 6). Final height is not diminished since bone maturation does not advance with this treatment regimen. However, final height is not improved either.

The optimum time to begin testosterone therapy is probably the normal pubertal age, but bone age maturation may be equally important. Testosterone therapy in boys with a bone age < 10 years should be avoided. Dosage is 25–100 mg/month intramuscularly

Figure 6 Induction of puberty with testosterone. This boy presented with no signs of puberty at 16 years and was treated with testosterone. Virilization and a normal pubertal growth spurt were induced. Testicular volume did not increase to > 6 ml, and testosterone levels decreased when treatment was stopped. The diagnosis was hypogonadotrophic hypogonadism. From Brook, C. D. G. (1998). "Clinical Paediatric Endocrinology." Blackwell, Oxford, UK.

for 3 months. Testosterone is usually injected at intervals of 2–4 weeks. Monthly intramuscular treatment provides 2-week periods of action. In between, testicular growth stimulated by LH and FSH can be assessed, indicating when testosterone therapy can be discontinued. Although this treatment regimen has been proven to be safe, the progression of bone age during testosterone therapy should be monitored. A second short-term low-dose course of testosterone may be given if puberty does not proceed as expected after the first course. However, the diagnosis should be reconsidered if puberty does not progress at all.

Longer Term Courses of Testosterone

Longer term courses or higher dosages of testosterone have been associated with major advances in bone age, resulting in final heights below the genetic potential. However, the optimum dose and duration of a testosterone course that provides a good balance between virilization, growth, and bone age resulting in a normal final height are not known. Until course duration and dosages can be compared, we advise short-term low-dose courses only.

Oxandrolone

The synthetic androgen oxandrolone is not aromatizable. Theoretically, this offers the possibility to exert an androgen-mediated, growth-promoting effect without increasing bone age, thereby improving final height. In clinical practice, however, little or no difference is seen between oxandrolone and short-term low-dose testosterone in terms of growth stimulation and bone age. Both treatments result in little or no increase in final height. However, oxandrolone may have a positive effect on the prepubertal growth dip (Fig. 4). If the main goal is to achieve height gain during this phase, then oxandrolone may actually improve final height. If virilization is the main goal, then testosterone should be used.

The best time to start oxandrolone therapy is when height velocity starts to decline (i.e., at the time of the prepubertal growth dip). Oxandrolone can be given once daily in a dosage of 1.25–2.5 mg. Testicular volume should be followed until the volume is 10–12 ml. The endogenous production of testosterone is capable of inducing the pubertal growth spurt. Testosterone levels should be checked before discontinuing oxandrolone to prevent loss of height velocity due to relatively low levels of testosterone. If levels are low, oxandrolone therapy should be continued until

testosterone levels reach the adult reference range. The progression of bone age should be followed during therapy on a 6-month basis.

Aromatase Inhibitors

Estrogen causes epiphyseal closure in both sexes. In males, estrogen is derived from testosterone via the aromatase system. When testosterone is combined with an aromatase inhibitor, the former causes virilization and a growth spurt, whereas the latter delays epiphyseal closure. A significantly higher predicted adult height has been reported with the use of aromatase inhibitors. However, clinical trials are still under way, only small groups of patients have been studied, and actual final heights have not been reported.

Growth Hormone Therapy

There is no indication for the use of growth hormone in boys with delayed puberty. No studies have found a positive effect on growth. Short-term use can cause a transient acceleration in growth velocity, but long-term use has not been found to improve growth or adult height.

FOLLOW-UP

During therapy, the progress of puberty should be followed carefully by repeated measurement of testicular volume. An increase in gonadotropin levels provides additional information. Especially when treating with androgens, X rays of the left hand and wrist for bone age estimations should be obtained regularly.

Before discharging the patient, the clinician must be sure that the endpoints of puberty have been reached. For boys, the endpoint is an adult level of testosterone, and for girls it is the onset of a normal menstrual cycle. Adult-sized testes is not a sufficient endpoint since the bulk of gonadal constituents are of germinal cell origins.

Contraception, Male

C. Hay and F. C. W. Wu

University of Manchester, Manchester, United Kingdom

Glossary

azoospermia The absence of sperm in the ejaculate.

gonadotropins The pituitary hormones luteinizing hormone and follicle-stimulating hormone.

oligozoospermia The presence of <3 million sperm/ml in the ejaculate.

severe oligozoospermia The presence of ≤ 1 million sperm/ml in the ejaculate.

Development of a male hormonal contraceptive would ideally provide a safe, effective, and alternative birth control method for couples. One-third of couples worldwide choose a male contraceptive method; only two effective options are available. Vasectomy is very effective but essentially irreversible. Condoms as long-term contraception have a relatively high failure rate. In addition to the impact on the contraceptive choice for individual couples, at a global level there is a need for population control. The world population in 1999 reached 6 billion people for the first time, representing an increase in population of 4.4 billion since 1900. If the current birth rate is maintained, the world population will approach 19 billion by the year 2100. Such a population size would be unsustainable and result in immense poverty, overcrowding, resource depletion, and increased pollution.

MECHANISM OF ACTION

The aim of a male hormonal contraceptive is to suppress spermatogenesis and therefore prevent pregnancies. Spermatogenesis is dependent on the pituitary gonadotropins both directly and via intratesticular testosterone (T) production (see Fig. 1). The intratesticular T concentration in the seminiferous tubules is critical to the maintenance of spermatogenesis. The drive for T production is provided by luteinizing hormone action on Leydig cells in the testis. Gonadotropin secretion requires pulsatile gonadotropin-releasing hormone (GnRH) secretion from the hypothalamus; therefore, either GnRH deficiency or

nonpulsatile stimulation inhibits the pituitary–gonadal axis. Inhibitors of the hypothalamic–pituitary–gonadal axis are shown in Fig. 1. With the resultant inhibition of intratesticular testosterone production, systemic levels will also fall. Symptoms and signs of hypogonadism would therefore result if systemic testosterone were not administered in any treatment regimen. Successful treatments used for suppression of spermatogenesis have included androgen-only regimens and androgen combinations with other agents, i.e., progestogens.

CONTRACEPTIVE REGIMENS

Androgen Only

Testosterone is rapidly degraded by first-pass metabolism in the liver following oral or systemic administration. Chemical modification of androgen preparations is therefore necessary to reduce hepatic breakdown and prolong the duration of therapeutic action. The oral preparations that are available have a relatively short half-life and frequent dosage is required. Prolongation of the half-life is achieved by the formulation of T esters in lipid vehicles that are administered by intramuscular (im) injection.

Testosterone Enanthate

Studies using im testosterone enanthate (TE) have confirmed that supraphysiological doses of testosterone induced azoospermia in 40–70% of Caucasian males. Efficacy studies subsequently demonstrated a relationship between the extent of spermatogenesis suppression (sperm concentration) and contraceptive failure (pregnancy) rate. The pregnancy rate for azoospermia was only 0.8 per 100 person years (comparable to female injectables) and 8.1 per 100 person years for oligozoospermia. The combined failure rate was 1.4 pregnancies per 100 person years, which is comparable to the female oral contraceptive pill and is better than the typical first-year failure rate of condoms (12%). These studies demonstrated that

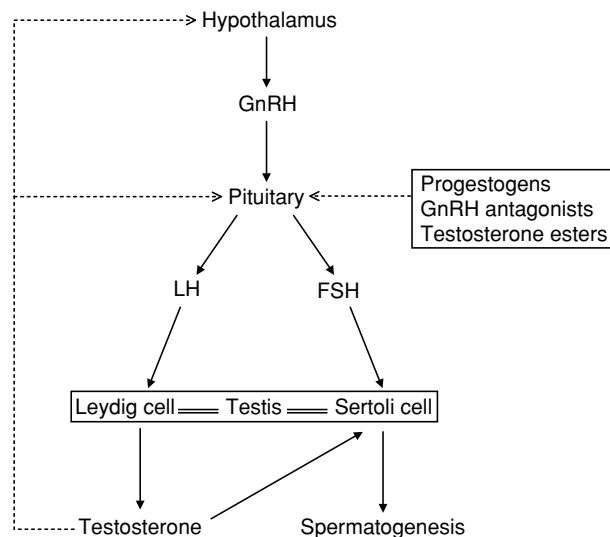

Figure 1 The hypothalamic–pituitary–gonadal axis. Solid arrows show the pathway of spermatogenesis promotion and the dashed arrows show inhibitory influences. Endogenous testosterone acts via negative feedback pathways to inhibit both GnRH release from the hypothalamus and gonadotropin release from the pituitary. Exogenous sex steroids and GnRH analogues reversibly manipulate this physiological response. LH, luteinizing hormone; FSH, follicle-stimulating hormone.

hormonal suppression of spermatogenesis can be an efficacious and reversible contraceptive for men. They also demonstrate that targets of suppression to ensure effective contraceptive protection are azoospermia and severe oligozoospermia (<1 million sperm/ml).

This approach had two drawbacks: (1) unsatisfactory pharmacokinetics of TE resulted in widely fluctuating levels of testosterone and frequent weekly injections and (2) high doses (causing supraphysiological T levels) were required to induce and maintain adequate suppression of spermatogenesis. Side effects encountered in these studies were androgen-related effects including acne, weight gain, behavioral effects, lowered high-density lipoprotein cholesterol (HDL-C), and increased hematopoiesis. For these reasons, longer acting testosterone esters and alternative strategies were sought.

Testosterone Undecanoate

Testosterone undecanoate (TU) is an unsaturated, aliphatic, fatty acid ester of T that is partially absorbed from the gut lymphatics following oral administration. The only available oral TU (Restandol) has low bioavailability and requires twice or thrice daily dosing.

The formulation of TU in tea seed oil (in China) and castor oil (in Germany) for intramuscular use has yielded longer acting testosterone depots with more

favorable pharmacokinetics. TU alone (tea seed oil) was found to induce azoospermia in 96% (23/24) of Asian men (500 or 1000 mg in tea seed oil every 4 weeks) and in 57% (8/14) of Caucasian men (1000 mg in castor oil every 6 weeks) studied. Phase III contraceptive efficacy trials using TU alone are in progress in China. A combination of TU with a progestogen has been studied in Caucasian subjects (see [Table I](#)).

Alternative Androgen Preparations

Testosterone Implants

Testosterone implants are small cylindrical pellets that are inserted into the subcutaneous tissue of the lower abdominal wall. Insertion requires a minor surgical procedure under local anesthesia. In Australia, a dose of 1200 mg (six pellets) has been shown to cause spermatogenic suppression equal to that for TE alone with similar or fewer metabolic side effects.

Testosterone Patches

Testosterone patches provide noninvasive, transdermal, self-administered delivery of testosterone when applied daily to the body or scrotal skin. The main limitations include a high incidence (40–60% of subjects) of skin irritation related to the alcoholic excipients employed, the frequent shaving of the scrotum, and poor adhesiveness, particularly in hot weather. Two studies have used a body patch in combination with a progestogen (oral levonorgestrel and desogestrel).

19-Nortestosterone

19-Nortestosterone (19-NT) and its derivative 7 α -methyl-19-nortestosterone (MENT) have both been studied in healthy men, with encouraging results. 19-NT alone was studied in Indonesian men and rates of sperm suppression were equal to those for TE. Subdermal MENT implants have also been shown to suppress to azoospermia in 70% of cases.

Testosterone Buciclate

Testosterone buciclate is a long-acting ester. Due to problems with the formulation, few data are available.

Testosterone Microspheres

Testosterone microspheres are biodegradable polyacrylate–glycolide spheres containing testosterone and they exhibit first-order absorption kinetics. They have been studied in hypogonadal men via both intramuscular and subcutaneous administration. The results are encouraging and application in a hormonal contraceptive is feasible in the future.

Note. DMPA (depot medroxyprogesterone acetate) was administered by a single im injection. T implants (testosterone implants) were administered once (800 mg dose) or at weeks 0 and 12 (400 mg). CPA (cyproterone acetate) was administered orally once daily. TE (testosterone enanthate) at 100 mg was administered by im injection once weekly. LNG (levonorgestrel) was administered orally once daily. TU (testosterone undecanoate) was administered either orally (80 mg) twice daily or im (1000 mg) every 6 weeks. T patch (testosterone patch) delivers 5 mg every 24 h. DSG (desogestrel) was administered orally once daily. NETE (norethisterone enanthate) was administered im every 6 weeks.

^aSevere oligozoospermia in this report was defined as <3 million/ml.

^bOne subject was azoospermic at week 12 but had a count of 0.1 million/ml at week 16.

^cSubjects were commenced on 250 µg daily until week 12. If they had not suppressed to azoospermia at week 12, the dose was increased to 500 µg daily.

^dOne subject dropped out of the trial.

^eTwo subjects dropped out of the trial for personal reasons.

^fOnly one dose group of the three in the study is included.

^gThree Chinese men maintained sperm counts >3 million/ml.

^hTwo men withdrew at weeks 12 and 16 (counts <1 million/ml).

GnRH Antagonists

GnRH antagonists cause suppression of gonadotropins, which is rapidly achieved within hours. Studies have shown spermatogenic suppression at least equal to that for TE. Furthermore, when the GnRH antagonist Nal-Glu was used to initiate suppression, this suppression could then be maintained with TE alone. Although these synthetic peptide compounds clearly have contraceptive potential, the disadvantages are their expense, their short half life, and the need for subcutaneous injection to avoid intestinal breakdown. Side effects encountered have included local skin reactions and pruritis at the site of injection. New long-acting depot preparations of potent GnRH

antagonists may have a place in male contraception where rapid induction of spermatogenic suppression can subsequently be maintained by testosterone alone.

Progesterone/Androgen Combinations

Exogenous progestogens can inhibit gonadotropin secretion, reduce systemic testosterone levels, and suppress spermatogenesis in men. Combining a progestogen with testosterone exploits the synergistic actions of the two steroids that can be used at lower doses for spermatogenesis suppression. A number of different progestogen/androgen combinations have been studied (see Table I).

Depot Medroxyprogesterone Acetate

Depot medroxyprogesterone acetate (DMPA) has been combined with 19-NT, TE, and T implants. Trials with 19-NT in combination with DMPA in Indonesian men resulted in an azoospermia rate of 98% compared to 96% for TE alone. In Caucasian men, the combination of DMPA with T implants achieved azoospermia rates exceeding those for TE alone. No significant weight gain or metabolic effects (e.g., on lipid parameters) resulted. The main limitation with DMPA use is the prolonged period (up to 6 months) that is often necessary for sperm recovery following cessation of treatment.

Cyproterone Acetate

Cyproterone acetate (CPA) has been combined with im TE and oral TU. The anti-androgenic properties of CPA are effected by the blockade of T and DHT at the receptor level. There is also gonadotropin inhibition at the pituitary. The combination of two oral preparations in a true male pill was assessed with oral CPA and TU. Unfortunately, azoospermia occurred in less than 20% of subjects. The reason for this is most likely related to the inadequate androgen replacement provided by oral TU. CPA at a higher dose (25–100 mg) with TE did result in azoospermia in 100% of men. Furthermore, the time to azoospermia was half that of the TE-alone group (49 days versus 98 days). Though encouraging, dose-dependent decreases in hemoglobin and body weight were observed in those subjects receiving CPA. These side effects are very likely anti-androgen related. These effects may limit future application of this combination.

Levonorgestrel

Levonorgestrel (LNG) has been extensively studied with a variety of androgens. Initially, a dose of 500 µg daily with TE confirmed greater sperm suppression than with TE alone (azoospermia in 67% versus 33% of subjects). Further study with lower doses of LNG (250 and 125 µg) did not compromise sperm suppression rates. Adverse effects were dose dependent and included lowered HDL-C and weight gain. A combination of TU/LNG was compared to TU alone. There was no difference in suppression to azoospermia (50%). Testosterone patches have been studied with oral LNG (250 µg daily) and with long-acting LNG implants. Relatively poor sperm suppression (severe oligozoospermia in <60% of subjects) was observed in both studies. A likely reason for the relatively disappointing results may relate to the unreliable administration or absorption of T so that

circulating levels in only the low-normal range can be achieved. This highlights the critical role of testosterone in achieving efficient spermatogenesis suppression: a sufficient but not supraphysiological amount of T conveniently delivered with kinetics that can sustain stable plasma levels is required. The transdermal preparations that are available fall short of these requirements.

Desogestrel and Etonogestrel

Desogestrel (DSG) is an oral third-generation progestogen with potent progestational activity and lower androgenicity. These potentially favorable properties led to the study of DSG in combination with TE. Oral DSG in combination with various TE doses produced 100% azoospermia (Table I). These results demonstrate the synergistic action of this steroid combination. A lowering of HDL-C of 20–25% was observed in these studies. A cross-cultural study assessed DSG in combination with 400 mg testosterone implants. At 24 weeks, there was a significant difference between dose groups with 100% (300 µg group) versus 71% (150 µg group; 11/13 Caucasian men, 11/18 Chinese men) azoospermia. A significant decline in HDL-C independent of dose was observed in the Caucasian men only. DSG has been combined with a T patch but similar to the LNG/patch study, sperm suppression was inferior to that seen with other regimens.

Etonogestrel (ENG) is the active metabolite of DSG and has been formulated as a subdermal implant for female contraception (Implanon, NV Organon). One study has assessed ENG rods (68 mg ENG per rod) in combination with T implants. Azoospermia was achieved in 9/14 men in both groups. However, suppression was inconsistent in the lower dose group. Further study of this promising progestogen implant is planned for the future.

Norethisterone Enanthate

Norethisterone enanthate (NETE) is a depot progestogen administered by intramuscular injection converting to the metabolically active norethisterone. NETE and TU have been combined in a 6-week regimen. The results have been very encouraging (see Table I), with azoospermia occurring in 93% of men. Adverse effects of the TU/NETE combination have included moderate increases in hemoglobin (within the normal range) and decreases in HDL-C.

ETHNIC DIFFERENCES

There are clear differences in the rates of azoospermia achieved in Asian populations compared to Caucasian

populations. In studies using androgens alone (TE and TU), azoospermia was achieved in 90 and 96% of Asian men versus 74.3 and 57% of European or American men. The possible explanations for these differences include genetic and environmental influences that are not yet fully understood. Intraethnic variation is also seen within Caucasian populations. Suppression to azoospermia occurred in 40–70% of men in the World Health Organization trials using TE alone. No correlations were found to explain this. A possible explanation is intraethnic heterogeneity in the biological response to androgens.

SUMMARY AND CONCLUSIONS

There is evidence to support couple dissatisfaction with available contraceptive methods. A cross-cultural survey found that women felt the contraceptive burden too frequently falls to them and they welcomed the idea of a male contraceptive pill. An important aspect of any male hormonal method is that from the start of treatment there is a time lag until sperm suppression is sufficient for contraceptive efficacy. This lag time occurs because sperm production takes 2–3 months and therefore following gonadotropin suppression a similar period of time is necessary to reach severe oligozoospermia. However, a similar lag time also applies to vasectomy (irreversible) and a lag time of 1 month applies to the female oral contraceptive pill. An important point is that hormonal methods for either the male or female should be suggested as sole contraception only when the user is in a stable relationship. In this situation, the choice of contraceptive is often planned and a lag time is unlikely to deter users.

Public-funded research has reached a stage where realization of male hormonal contraception is within reach. The beginnings of participation by the pharmaceutical industry are encouraging and a necessary step leading to product development. A progestogen/androgen combination is most likely to be the first product to be marketed. Further development of long-acting depot formulations or oral and nonsteroidal compounds will provide a variety of contraceptive formulations that will allow men to have a widened choice and encourage acceptability and usage.

Corticotropin-Releasing Hormone (CRH) and Inflammation

George Mastorakos and Ioannis Ilias

University of Athens Medical School and Aretaieion Hospital, Athens, Greece

Glossary

antalarmin A pyrrolopyrimidine nonpeptide compound {*N*-butyl-*N*-ethyl[2,5,6-trimethyl-7-(2,4,6-trimethylphenyl)pyrrolo[2,3-*d*]pyrimidin-4-yl]amine(1)}, acting as a selective corticotropin-releasing hormone receptor type I antagonist.

corticotropin-releasing hormone (CRH) A 41-amino-acid peptide, secreted principally by the parvocellular neurons of the paraventricular hypothalamic nuclei. CRH is the major physiological corticotropin secretagogue.

immune/inflammatory (I/I) response Septic or nonseptic injurious agents lead to the immune system's reaction by means of the I/I response. The result of this response is the destruction or walling-off of the attacking microorganism or the destroyed tissue. This response is microscopically characterized at the local level by dilation and increased permeability of microvessels, both leading to increased blood flow, exudation of plasma, and migration and accumulation of leukocytes.

The immune/inflammatory (I/I) response is influenced by the brain through regulation of peripheral nervous system functions and endocrine responses. Cells of the immune system have receptors for a number of hormones, neuropeptides, and neurotransmitters. Therefore, the responses of these cells may be modulated by changes in neuroendocrine and/or autonomic activity.

INTRODUCTION

The hypothalamic–pituitary–adrenal (HPA) axis is activated during stress and represents one of the major pathways through which the brain regulates the I/I response. Conversely, products of the I/I response influence brain function. In addition, immune cells produce a number of hormones and neuropeptides, such as corticotropin-releasing hormone (CRH) and

α -melanocyte-stimulating hormone, which probably act locally as autacoids during both the early and late stages of the I/I process. This locally produced CRH, hereafter called “peripheral CRH,” has been also implicated in other physiological functions, such as reproduction.

CENTRAL CRH AND THE HPA AXIS—PERIPHERAL CRH

Sauvagine, urotensin I, urocortin, and CRH belong to a family of peptides with similar activities. In humans, the CRH and urocortin genes are located on chromosomes 8 and 2, respectively. Initially, CRH is synthesized as a larger precursor molecule (spanning 191 amino acids in humans) from which it is cleaved at flanking basic amino acid pairs. CRH is secreted—along with other adrenocorticotrophic hormone (ACTH) secretagogues, such as arginine vasopressin (AVP), cholecystokinin, met-enkephalin, and dynorphin—into the hypophyseal portal blood via projecting axons to the median eminence. The plasma half-life of CRH in humans is 4 min. The secretion of CRH is regulated by inputs from higher centers integrating the effects of the circadian pacemaker, stress, and glucocorticoid negative feedback (acting at pituitary, hypothalamic, and higher levels, such as the hippocampus). ACTH released by CRH leads to the secretion of cortisol and other adrenal steroids.

Most of the plasma CRH is apparently of nonhypothalamic origin since hypothalamic CRH is rapidly enzymatically decomposed at the pituitary level. Although the contribution of hypothalamic CRH to the total plasma CRH is small, in certain circumstances, such as insulin-induced hypoglycemia, hypothalamic CRH release leads to increments in plasma CRH concentration.

Peripheral CRH has been found in the adrenal medulla, the testes, the ovaries, the gastrointestinal tract, the pancreas, the myometrium, the endometrium, and the placenta as well as diverse inflammatory

sites. The epithelial cells of human and rodent endometrium produce CRH throughout the menstrual cycle, whereas the stroma needs to undergo decidualization in order to produce CRH. The placenta secretes CRH, leading to an increased maternal plasma CRH concentration during the third trimester of pregnancy. Only in humans, plasma CRH is bound to a high-affinity binding protein, with a concomitant reduction in its bioactivity.

Two types of G protein-coupled CRH receptors, types 1 and 2 (CRH-R1 and CRH-R2, respectively), with seven transmembrane domains each, have been described. Their genes are located on chromosome 17q12. Alternatively spliced isoforms α , β , γ , and δ have been identified for CRH-R1, whereas isoforms α , β , and γ , plus a stomach variant, have been identified for CRH-R2. CRH-R1 is most abundant in neocortical, cerebellar, and sensory relay structures, whereas CRH-R2 is predominantly localized in specific subcortical areas and peripheral tissues. CRH-R1 α is present on both epithelial and stromal cells of the human endometrium. CRH binds to type CRH-R1 of the anterior pituitary corticotrophs, resulting in adenylyl cyclase activation and increased intracellular cyclic AMP (cAMP) concentration, cAMP-dependent protein kinase A activation, increased influx of extracellular calcium via L-type calcium channels, and the production of lipoxygenase metabolites of arachidonic acid. The net result is the secretion of ACTH and other proopiomelanocortin (POMC)-derived peptides within a few seconds, whereas increased POMC gene transcription and POMC biosynthesis ensue. The number of CRH-R in corticotroph cells may modulate the ACTH response.

THE I/I RESPONSE

The cellular components of the I/I response consist of circulating nonlymphoid leukocytes and lymphocytes and local immune accessory cells. Nonlymphoid leukocytes include the monocytes/macrophages, neutrophils, basophils, and eosinophils. Local immune accessory cells include the endothelial cells, tissue fibroblasts, resident macrophages, and macrophage-related cells, such as liver Kupffer cells, type A synovial-lining cells, and central nervous system (CNS) glial cells, as well as the basophil-related mast cells. Many substances secreted locally in the inflammatory area by the above-mentioned cells act as autocrine or paracrine regulators and/or mediators of the inflammatory response, as well as endocrine messengers between the inflammatory process and other systems

such as the CNS, HPA axis, and peripheral nervous system. These substances include the vasoactive amines, histamine and serotonin, the kallikrein/kinin system, the Hageman factor and other clotting factors, the fibrinolytic system, several components of the complement system, and eosinophil and platelet activators. They also include cytokines [such as tumor necrosis factor α (TNF α), TNF β , interferon- α , interferon- β , and interferon- γ], interleukin-1 (IL-1) through IL-14 (as well as their binding proteins and natural antagonists), many lipid and glucolipid products of triglyceride metabolism (such as several active products of arachidonic acid, including the endoperoxides, the thromboxanes, prostacyclin, and leukotrienes), and platelet-activating factor. In addition, active oxygen radicals, including nitric oxide and lysosomal constituents such as neutral proteases, participate in the inflammatory response.

CRH AND THE I/I RESPONSE

Hypothalamic (central) CRH has been considered to act indirectly in an anti-inflammatory fashion, since the end product of the HPA axis' stimulation is cortisol, which has thoroughly studied anti-inflammatory actions. Moreover, it is known that among the pro-inflammatory cytokines, IL-6 is a potent stimulator of the human HPA axis, and a secretagogue of magnocellular AVP. The administration of IL-6 subcutaneously provokes considerable elevations in plasma ACTH, cortisol, and AVP. It has been shown that IL-6, in patients with head trauma (an aseptic inflammatory state) and the syndrome of inappropriate secretion of antidiuretic hormone, is quantitatively correlated with AVP. The latter is also known to be a potent activator of the HPA axis.

Since CRH is the main stimulator of POMC production from the pituitary, and certain POMC products (like ACTH and β -endorphin) can directly affect the I/I response, it has been hypothesized that CRH itself might be directly involved with the I/I response. The putative role of CRH in the I/I response was further suggested by the presence of CRH-specific binding sites in human lymphocytes secreting POMC-derived peptides (ACTH and β -endorphin). By employing the rat air-pouch model of acute aseptic chemical inflammation, immunoreactive CRH (IrCRH) was localized in the inflammatory tissue by immunohistochemistry. IrCRH was also found in the cytoplasm of immune accessory cells such as macrophages, endothelial cells surrounding vessels, and tissue fibroblasts. Immunoneutralization

studies *in vivo* with a highly specific anti-CRH polyclonal antiserum resulted in a significant suppression of the inflammatory response, suggesting that peripheral CRH promotes inflammation. The decrease in inflammation by anti-CRH antiserum was similar to that caused by immunoneutralization of TNF α (a well-known mediator of the I/I response that was used as a positive control). The effects of the combined administration of anti-CRH and anti-TNF α were not additive, indicating that the two antisera might interfere with a common pathway of the inflammatory response. Furthermore, locally produced somatostatin mediates the glucocorticoid anti-inflammatory effects at the inflammatory sites, whereas CRH levels at inflammatory sites are lowered in the presence of somatostatin analogues.

The mobility of this "immune" peripheral CRH is similar, as assessed by high-performance liquid chromatography, to that of r/hCRH 1–41 (the form produced by the rat and human hypothalamus as well as by the human placenta). The presence of CRH at peripheral inflammatory sites has also been demonstrated in other animal models of both acute and chronic inflammation. IrCRH was present in inflammatory cells of rat joint tissue with streptococcal cell wall- and adjuvant-induced arthritis. CRH mRNA was present in the inflamed synovia from arthritic rat joints that expressed specific CRH-binding sites. Furthermore, IrCRH was seen in the synovial-lining cell layers and blood vessels from the joints of patients with rheumatoid arthritis (RA) and osteoarthritis, whereas high levels of CRH immunoreactivity were found in the synovial fluids of patients with RA. IrCRH was also found in immune accessory cells from uveitic retinas and corpora vitrea from Lewis rats with experimentally induced autoimmune uveitis. Additionally, the local presence of CRH appears to be of pivotal importance in the process of experimental autoimmune uveoretinitis in rodents, since retinas from immunized B10.A mice treated with anti-CRH antibody showed significantly lower apoptosis and Fas and Fas ligand (FasL) expression than placebo-treated animals. Thus, CRH at inflammatory sites seems to be involved in the activation of the Fas/FasL system.

Whereas central CRH participates in the systemic endocrine inhibition of the I/I reaction, peripheral immune CRH may participate in autocrine/paracrine stimulation of inflammation. The mechanisms of the peripheral CRH-mediated component of the I/I response are still unclear, although these may be mediated by local POMC gene products with known pro-inflammatory activity and/or by inflammatory cytokines. Another possible source of peripheral

immune CRH and other neuropeptides thought to be important in inflammation (such as substance P and SMS) other than the accessory immune cells is the primary afferent (sensory) nerves as well as the sympathetic postganglionic neurons. CRH and substance P are depleted in the rat spinal cord and dorsal root ganglia in response to capsaicin, which is toxic to the sensory afferent fibers. Also, IrCRH is present in the interomedialateral sympathetic column as well as the ganglia of the sympathetic chain and, therefore, could contribute to the inflammatory process through the sympathetic postganglionic fibers. Thus, CRH is involved in opposing, and site-specific, pro- and anti-inflammatory actions.

CRH IN THE I/I PHENOMENA OF THE FEMALE REPRODUCTIVE SYSTEM

Physiological phenomena taking place in the female reproductive tract (such as decidualization and luteolysis) bear characteristics of an aseptic inflammation. In addition, pregnancy has been explored from the immunological point of view since it can be considered a semiallograft situation.

CRH and CRH-R have been localized in the ovary in rat and in the ovary, endometrium, myometrium, and placenta in human. Further tentative actions of CRH on the female reproductive system have been suggested. CRH was shown to have an inhibitory effect on ovarian steroidogenesis, mediated through CRH and interleukin-1 receptors, and possibly linked to the processes of follicular atresia and luteolysis. Locally produced embryonic and endometrial CRH plays a role in both the aseptic inflammatory process of implantation and the anti-rejection process that protects the fetus from the maternal immune system. Early in pregnancy, the implantation sites in rat endometrium contain 3.5-fold higher concentrations of CRH than the interimplantation regions. It has been suggested that CRH of fetal and maternal origin regulates FasL production, thus affecting the invasion process through a local autocrine/paracrine regulatory loop of cytotrophoblast cells and regulating their own apoptosis. CRH decreases FasL expression in embryonic trophoblast and maternal decidua and promotes apoptosis of activated T lymphocytes. Abnormalities of maternal immune tolerance to the fetal semiallograft, and of fetal tolerance to the maternal semiallograft, have been implicated in pathological conditions of pregnancy, such as recurrent early miscarriage, preeclampsia, and eclampsia. These conditions are characterized by inflammation in the

fetal–maternal interface and/or systemic manifestations. More specifically, it has been proposed that inadequate, CRH-mediated, self-induction of FasL in extravillous trophoblasts might be involved in the pathophysiology of infertility and recurrent fetal resorption or miscarriage.

PERSPECTIVES

Pyrolopyrimidine compounds have been developed as CRH receptor antagonists. Antalarmin has been used in investigations of the physiologic central and peripheral roles of CRH in the I/I response and reproductive function. The binding kinetics of antalarmin were determined in competitive displacement binding experiments with homogenates prepared from tissues differentially expressing CRH-R subtypes. In experiments in rats, the *in vivo* administration of antalarmin significantly antagonized both central and peripheral actions of CRH. In these experiments, the prior administration of antalarmin or neutralizing anti-CRH antibody blocked pituitary CRH receptors and the exogenous or endogenous CRH-induced ACTH release. Confirming the peripheral pro-inflammatory actions of CRH, antalarmin also suppressed the subcutaneous inflammation induced by carrageenan. Leukocyte concentrations of subcutaneous exudate were reduced by antalarmin compared to vehicle controls. This effect was dose-dependent and was comparable to that of CRH antibody, where suppression of the leukocyte concentration was observed.

In some experiments, antalarmin was administered in rats from day 1 of pregnancy and for the following 10 days. A 50% reduction was observed in the number of implantation sites in animals that received the lower dose and a 70% reduction in those that received the higher dose of antalarmin. Additionally, female rats treated with antalarmin showed diminished endometrial FasL expression. Hence, implantation in rats was prevented by antalarmin, which blocked CRH-R1. Antalarmin reduced the inflammatory-like reaction of the endometrium to the invading blastocyst. Consequently, antalarmin and analogous compounds might represent a new class of nonsteroidal inhibitors of pregnancy at its very early stages.

In sheep, hypothalamic CRH stimulates the fetal production of ACTH, which in turn leads to a surge of fetal cortisol secretion that precipitates parturition. A 10-day intravenous infusion of antalarmin in sheep fetuses significantly prolonged gestation. Thus, CRH receptor antagonism in the fetus can also delay parturition.

The therapeutic potential of pyrrolopyrimidine compounds in some forms of inflammation directly mediated by CRH-R1 is evident and hopefully will enhance the understanding of the multitude of roles that CRH plays in I/I reactions. Although the systemic toxicity of this class of compounds has not yet been fully determined, preliminary studies in rats and nonhuman primates have indicated that they are relatively safe.

Corticotropin-Releasing Hormone, Family of

Robert J. Denver

University of Michigan, Ann Arbor, Michigan, United States

Glossary

corticotropin-releasing hormone (CRH)-binding protein A secreted protein that binds CRH-like peptides with affinity that is equal to or higher than that for the CRH receptors.

G protein-linked receptor A polypeptide containing seven-transmembrane spanning domains. The ligand-binding domain is found on the extracellular side of the plasma membrane. These receptors influence the activity of intracellular second messenger systems by interacting with G proteins in the plasma membrane.

hypophysiotropin A hormone produced in the hypothalamus and transported to the anterior pituitary that modifies pituitary hormone secretion.

neurosecretion Release of neurohormones from modified nerve terminals directly into a vascular supply. Organs capable of neurosecretion are referred to as neurohemal organs.

prohormone Precursor polypeptide that is processed by proteolytic cleavage to biologically active peptides or hormones.

stress Physical or emotional strain or tension capable of disrupting homeostasis. Immediate endocrine responses to stress are characterized by increased plasma concentrations of glucocorticoids. Behavioral responses to stress include increased arousal, escape behavior, anxiety-like behavior, and decreased sexual behavior.

Corticotropin-releasing hormone [CRH; also referred to as corticotropin-releasing factor (CRF)] is a member of a family of related peptides in vertebrates that includes the fish urotensins-I, frog sauvagine, and the urocortin/stresscopin peptides. CRF was first named for its stimulatory effect on corticotropin [also known as adrenocorticotrophic hormone (ACTH)] secretion from the anterior pituitary gland. ACTH is the primary pituitary regulator of adrenal glucocorticoid biosynthesis and secretion. Members of the CRH family of peptides play central roles in the regulation of neuroendocrine, autonomic, and behavioral responses to physical and emotional stress.

THE CRH FAMILY OF PEPTIDES

The chemical nature of the corticotropin-releasing factor activity present in the vertebrate hypothalamus remained elusive until 1981, when Wylie Vale and colleagues isolated a 41-amino acid (aa) peptide from porcine hypothalamus that was capable of stimulating pituitary adrenocorticotrophic hormone (ACTH) secretion. Concurrently, Karl Lederis and colleagues isolated a 41-aa peptide with sequence similarity to corticotropin-releasing hormone (CRH) from the caudal neurosecretory organ (the urophysis) of the teleost fish, the common sucker (*Catostomus commersoni*), that they named urotensin-I (UI) based on its tissue of origin (urophysis) and its vasopressive activity. Since the early 1980s, several other CRH-like peptides have been isolated and some of their diverse physiological roles have been elucidated.

The vertebrate CRH family of peptides is composed of at least two distinct paralogous lineages, designated the CRH lineage and the UI/urocortin (UCN) lineage. CRH molecules, which are 41 aa in length, have been isolated from the brains of fishes, an amphibian, and mammals. Additional CRH-like peptides represented by the paralogous UI/UCN lineage were first identified in fishes; these peptides share approximately 50% sequence similarity with the CRHs. UCN, a 40-aa peptide, was isolated from the brains of rodents and human and shown to have 53–63% sequence similarity with fish UIs. Subsequently, two other UCN-like peptides that are 38 aa in length were predicted based on cDNA sequences isolated in mammals. These UCN-like sequences isolated from human were given the names stresscopin (SCP) and stresscopin-related peptide (SRP). Similar sequences were simultaneously isolated from mouse and designated urocortin-II (UCN-II) and urocortin-III (UCN-III). The human SCP and mouse UCN-III are homologous, as are the human SRP and the mouse UCN-II. The UCN-II and UCN-III peptides and similar sequences from pufferfishes (*Fugu rubripes* and *Tetraodon nigroviridis*) may

represent a separate, closely related lineage of the CRH family.

A 40-aa peptide that appears to be related to the UI/UCN lineage is sauvagine (SV), which was isolated from the skin of the frog *Phyllomedusa sauvagei*. Because this peptide has only been isolated from one frog species, and other UI/UCN-like peptides have not been identified in amphibians, the precise phylogenetic relationship of SV to the UI/UCN lineage is uncertain.

All CRH-like peptides are initially synthesized as a larger prohormone that is cleaved by prohormone convertases at dibasic residues to form the mature peptide; mature CRH-like peptides range from 38 to 41 aa residues. The cryptic peptide (N-terminal region of the prohormone) is cosecreted with CRH but has no known biological function. It is hypothesized that the cryptic peptide of the prohormone plays a role in intracellular protein folding and perhaps targeting to the secretory pathway.

MECHANISMS OF ACTION OF CRH-LIKE PEPTIDES: CRH RECEPTORS AND BINDING PROTEIN

The actions of CRH are mediated by specific receptors expressed in target cells and localized to the plasma membrane. In mammals, a number of distinct CRH receptor isoforms deriving from two paralogous genes and one secreted binding protein (CRH-BP) have been identified. The receptors are seven-transmembrane domain G-linked proteins that transduce extracellular signals by stimulating intracellular cAMP production. The receptors exhibit differential rank order affinities for CRH peptides and tissue-specific patterns of expression. The first CRH receptor isolated in mammals, designated CRHR₁, is a 415-aa protein and was originally thought to not discriminate among the CRH or UI/UCN lineages (i.e., it possessed high affinity for all). However, findings show that CRHR₁ exhibits very low affinity for SRP/UCN-II and no measurable affinity for SCP/UCN-III (these peptides are selectively bound by CRHR₂). CRHR₁ is expressed in the anterior and intermediate lobes of the pituitary and in numerous sites throughout the brain.

A second CRH receptor subtype, CRHR₂, shares 70% sequence similarity with CRHR₁. The CRHR₂ has two splicing variants in rodents and three splicing variants in humans (humans: CRHR_{2α}, 411 aa;

CRHR_{2β}, 431 aa; CRHR_{2γ}, 397 aa). The CRHR₂ proteins possess significantly higher affinity for UI/UCN-like peptides than for CRHs. Significantly, SRP/UCN-II and SCP/UCN-III are selectively bound by the CRHR₂ proteins. In rodents, CRHR_{2α} is expressed in the brain within the lateral septal nuclei and regions of the hypothalamus, whereas CRHR_{2β} is expressed in peripheral tissues (e.g., lung, skeletal muscle, ovary, cardiac myocytes, and gastrointestinal tract). In humans, all three CRHR₂ splicing variants are expressed in the brain, but only CRH-R_{2α} is expressed in peripheral tissues.

Studies of transgenic mice that lack one of the two CRH receptor genes support the hypothesis that the molecules subserve different physiological functions. Compared with wild type, CRHR₁ knockout (ko) mice exhibit lower plasma corticosterone concentrations, blunted ACTH responses to stress, altered adrenal morphology, and decreased anxiety-like behavior. CRHR₂ ko mice show altered adaptation to stress, increased anxiety-like behavior, and impaired cardiovascular function. Further advances in our understanding of CRH receptor biology have been possible due to the development of selective, nonpeptide CRHR₁ antagonists. For example, several pyrolopyrimidine compounds (e.g., antalarmin) have been found to selectively block CRH binding to CRHR₁ in a noncompetitive manner; this compound does not affect binding to CRHR₂ or the binding of other ligands to other G protein-linked receptors. Work on peptide-based CRHR₂-specific antagonists shows that this receptor can also be specifically targeted using pharmacological approaches.

A secreted CRH-binding protein (CRH-BP) was first isolated from human blood plasma. The structure of this protein has been elucidated in several mammalian species and in the frog *Xenopus laevis*. The protein ranges from 321 to 324 aa and exhibits a high degree of sequence similarity among species. Biochemical evidence indicates the presence of a CRH-BP in the brains of representatives of each vertebrate class. It is hypothesized that the CRH-BP modulates the bioavailability of CRH-like peptides. The CRH-BPs that have been characterized bind CRH-like peptides with affinities that are equal to or higher than those for the CRH receptors. This and other findings have led to the hypothesis that the primary function of the CRH-BP is to neutralize CRH activity by binding the peptide and making it unavailable to bind to receptors. It is also possible that the CRH-BP could function in targeting the peptide for clearance. Alternatively, the CRHBP could function to maintain

high levels of CRH in the blood or within tissues, thus facilitating the action of the peptide. The CRH-BP is expressed at different sites depending on the species (i.e., brain, liver, pituitary, intestine, and placenta), but all species studied express the protein in the pituitary and brain. Placental expression of the CRH-BP in humans has been implicated in regulating CRH bioavailability during late gestation; CRH is thought to play a critical role in the timing of parturition in mammals. Finally, studies of transgenic mice that either overexpress the CRH-BP or lack the CRH-BP gene indicate an important role for this binding protein in modulating CRH bioavailability.

EXPRESSION AND PHYSIOLOGICAL ACTIONS OF CRH-LIKE PEPTIDES

The expression of vertebrate CRH-like peptides in various brain regions and in peripheral tissues is consistent with their primary role in physiological and behavioral responses to stress. The synthesis and release of CRH increases in response to stress, and the peptide is implicated in the rapid increase in glucocorticoid biosynthesis by the adrenal glands, suppression of feeding, suppression of immune function, and enhanced locomotion, among others. The expression of CRH in neurosecretory neurons in the hypothalamus and the stimulatory action of CRH on pituitary ACTH secretion are common to all vertebrates. CRH is synthesized in hypothalamic nuclei (parvocellular neurons of the paraventricular nucleus in mammals) and is released at modified nerve terminals in the median eminence into the pituitary portal circulation. CRH is transported to the anterior pituitary gland, where it binds to its receptors and controls the secretion of pituitary hormones. CRH is also a potent releasing factor for thyroid-stimulating hormone in nonmammalian species. This thyroid stimulatory role for CRH has been implicated in the control of amphibian metamorphosis, which is a thyroid-dependent process. CRH also regulates α -melanocyte-stimulating hormone secretion in lower vertebrates, thus playing a role in skin pigmentary changes associated with background adaptation.

CRH-like peptides are expressed in brain regions outside of the neurosecretory cells of the hypothalamus, including the cortex, limbic system, and brainstem nuclei that are associated with autonomic function. Although there are differences in expression patterns among species, the basic brain region-specific patterns of expression are conserved among vertebrates. Prominent expression of CRH in mammals

is observed in the cerebral cortex, tegmentum, amygdala/hippocampus (important for stress adaptation), brainstem (locus coeruleus), and spinal cord. Peripheral sites of CRH expression include the gut, spleen, thymus, skin, adrenal gland, and placenta. Expression of UCN tends to be more restricted than that of CRH, being found in the Edinger–Westphal nucleus of the tegmentum, the hypothalamus, and a small group of neurons in the telencephalon. Mouse UCN-II is expressed in stress-related cell groups in the hypothalamus and brainstem, and UCN-III is expressed in the hypothalamus and the medial amygdala.

The expression of CRH-like peptides in extrahypothalamic neural circuits has been implicated in their behavioral effects, where they are thought to function as neurotransmitters/neuromodulators, thus integrating behavioral and physiological responses to stress. In mammals, the actions of CRH peptides, in addition to their hypophysiotropic role, include control of appetite (to decrease food intake), behavioral responses to stress (arousal, escape, anxiety-like behavior, and diminished sexual behavior), enhancement of learning, alterations in cardiovascular function, and modulation of immune responses. Thus, in addition to their central role in the endocrine stress response through activation of the hypothalamic–pituitary–adrenal axis, CRH-like peptides also serve to integrate the autonomic and behavioral responses to stress via their actions in the central nervous system. CRH-like peptides are potent anxiogenic and anorectic agents, and their aberrant expression has been implicated in depressive, anxiety-related, and eating disorders.

Corticotropin-Releasing Hormone, Placenta

Katia P. Karalis and Joseph A. Majzoub
Children's Hospital, Boston, Massachusetts, United States

Glossary

cytotrophoblast, syncytiotrophoblast Placenta-specific cell types. The former refers to single cells that constitute the predominant trophoblast cell in the first part of pregnancy and are replaced by syncytiotrophoblast as pregnancy advances. Syncytiotrophoblast is the main secretory trophoblast cell.

hypothalamic–pituitary–adrenal (HPA) axis The main endocrine axis mediating the stress response. Activation of the HPA axis leads to stimulation of hypothalamic corticotropin-releasing hormone, which stimulates pituitary ACTH secretion, leading to glucocorticoid secretion from the adrenal.

Corticotropin-releasing hormone (CRH) is a 41-amino acid neuropeptide identified in the central nervous system as well as in several peripheral tissues. CRH has been found in the placenta of different primates. In humans, CRH can be measured in the maternal circulation, with very high levels as labor approaches, suggesting its usefulness as a marker of the timing of parturition. In this article, the regulation of placental CRH during human pregnancy, its maternal effects, and its putative significance for the fetus are discussed.

INTRODUCTION

Corticotropin-releasing hormone (CRH), first identified in the hypothalamus as one of the major regulators of the hypothalamic–pituitary–adrenal (HPA) axis activation in response to stress, is also found in a variety of extrahypothalamic sites, including placenta. Among mammals, CRH is expressed only in primate placenta. However, the gorilla and chimpanzee are the only primates in which the pattern of secretion of placental CRH during pregnancy resembles that of humans. In humans, CRH is detectable in maternal circulation at the end of the first trimester of pregnancy, with levels increasing up to 100-fold during the last month of pregnancy and declining to nondetectable levels postpartum. The pattern of

secretion of placental CRH into maternal blood is pulsatile, with a constant pulse frequency throughout gestation and increasing pulse amplitude as pregnancy advances. What stimulates the expression of placental CRH in primates but not in other mammals, as well as the basis for the differential expression and secretion patterns among primates, remains unclear.

HUMAN PLACENTAL CRH: EXPRESSION AND REGULATION

Hypothalamic and placental CRH are products of the same gene, which is well conserved among different vertebrates. CRH has been identified in cytotrophoblasts in placentae from first- and second-trimester pregnancies. During the third trimester of pregnancy, placental CRH expression is abundant in the syncytiotrophoblast cells, compatible with the high levels of circulating CRH during that gestational period. In humans, significant CRH expression has been found in other tissues of the maternal–fetal unit, including the amnion, chorion, and decidua.

A variety of factors shown to regulate hypothalamic CRH gene expression have similar effects on the placental CRH gene. Thus, interleukin-1, prostaglandins, and catecholamines stimulate, whereas sodium nitroprusside inhibits, its release. Glucocorticoid, an inhibitor of hypothalamic CRH synthesis and secretion, paradoxically stimulates placental CRH mRNA and peptide expression. Progesterone, a steroid synthesized by trophoblasts, also inhibits placental CRH gene expression. Progesterone and glucocorticoid are antagonistic steroids based on their competition for binding on the glucocorticoid receptor. The stimulatory effect of glucocorticoid on placental CRH may be explained by the reversal of the inhibitory effect of progesterone in trophoblasts, which express glucocorticoid receptor but not progesterone receptor. Furthermore, mifepristone (RU 486), another antiprogesterin, also stimulated placental CRH gene expression.

In humans, increased placental CRH expression parallels the increasing level of cortisol in late gestation, suggestive of a positive feedback relationship between placental CRH and glucocorticoid, unlike the negative feedback loop operating between the latter and hypothalamic CRH. Administration of β -methasone, a potent glucocorticoid analog resistant to placental inactivation, in pregnancies less than 32 weeks' gestational age, results in suppression of placental CRH secretion, whereas in more advanced pregnancies suppression is not found and stimulation may occur. The change in the response of placental CRH to glucocorticoid during gestation might be related to the relative level of progesterone associated with the gestational age, consistent with *in vitro* findings.

PARADIGMS OF ABNORMAL PLACENTAL CRH EXPRESSION IN HUMANS

The highest expression of CRH is achieved as labor approaches, and it decreases to prepartum levels within 24 h following delivery, supporting the placental origin of circulating CRH during pregnancy. Inappropriately high CRH levels, compared to those in gestational age-matched normal pregnancies, have been described in pregnant women with pregnancy-induced hypertension or in intrauterine growth retardation. In several cases of complicated pregnancies, such as pregnancy-induced hypertension, increased glucocorticoid levels coexisted with inappropriately high for the gestational age placental CRH levels. In preterm labor, both high and normal levels of CRH have been reported; this discrepancy is most likely attributed to the wide spectrum of pathology associated with this condition.

MATERNAL EFFECTS OF PLACENTAL CRH

CRH made in the placenta is secreted into both the fetal and the maternal circulation. Biological actions of CRH in humans may be limited by its binding to a high-affinity binding protein, CRH-binding protein (CRH-BP), an approximately 40-kDa glycoprotein expressed in the brain of all species studied. The presence of high amounts of CRH-BP in human maternal plasma up to the last weeks of gestation may serve to protect the maternal pituitary from the increased circulating CRH levels and thus to prevent development of Cushingoid features. The mild Cushingoid appearance of pregnant women might

result from the escape of CRH from binding by the CRH-BP, which could thereby stimulate maternal pituitary ACTH release and cortisol secretion and contribute to pregnancy-associated hypercortisolemia. In further support of a biological effect of placental CRH in maternal physiology is the suggestion that the postpartum decline in maternal HPA axis activity might result from the withdrawal of placental CRH and possibly account for the occurrence of postpartum mood changes.

In addition to its synthesis in placenta, CRH is expressed in the decidua and the fetal membranes. CRH has been reported to have synergistic effects with oxytocin or prostaglandin on the induction of myometrial contractility. It has also been shown to cause vasodilation of the uterine vasculature through a direct effect on smooth muscle contractility. Thus, CRH may directly affect the mechanical component of parturition, in addition to its regulatory effect on the hormonal pathways related to the initiation of labor.

PUTATIVE SIGNIFICANCE OF PLACENTAL CRH

Unlike the placentae of nonprimate mammals such as the sheep, the human placenta does not express P450 17,20-lyase; thus, the increased fetal cortisol production in late human pregnancy is unable to inhibit the production of placental progesterone. Since the human placenta cannot directly synthesize estradiol, the fetal adrenal zone is the predominant source of its precursor, dehydroepiandrosterone (DHEA). Fetal adrenal DHEAS secretion, leading to placental estradiol production, likely plays a major role in the initiation of labor via stimulation of oxytocin, oxytocin receptor, gap junction, and prostaglandin synthesis. Placental CRH may have evolved in primates to stimulate fetal adrenal activity and possibly ACTH secretion, thereby satisfying the high demand for DHEA synthesis.

The increase in fetal cortisol secretion is necessary for the maturation of the fetal lung and other systems required for extrauterine survival. Consistent with the hypothesis that placental CRH stimulates the fetal pituitary-adrenal axis is the parallel increase in placental CRH and fetal cortisol levels in the last weeks of gestation. It is possible that placental CRH acts directly on fetal adrenals, in addition to its stimulatory effect on fetal pituitary. This hypothesis is supported by a report describing the expression of CRH-R1 mRNA in early midgestation human fetal adrenal tissue as well as *in vitro* evidence for direct stimulation of steroidogenesis by CRH.

CONCLUSION

CRH is expressed in the primate placenta. In humans, its expression is significantly increased in the last trimester of pregnancy. Placental CRH expression is further stimulated in pregnancies associated with preterm labor, such as when complicated by intrauterine growth retardation or pregnancy-induced hypertension, or in twin pregnancies. Placental CRH may be important for both the maturation of the fetus and the completion of gestation.

Craniopharyngiomas

David Anthony Price

Royal Manchester Children's Hospital, Manchester, United Kingdom

Glossary

chondrification The formation of cartilage or a conversion into cartilage.

fossa A trench or channel.

papilloedema Swelling of the optic disk, often due to increased intracranial pressure.

Craniopharyngiomas are intracranial tumors derived from remnants of Rathke's pouch, an embryological structure formed as a diverticulum of the stomodeum. These tumors produce clinical symptoms that are caused by increased intracranial pressure, damage to contiguous neural structures, and destruction of the pituitary gland. Although nonmalignant in nature, they are locally invasive, recurrent, and frequently a mixture of solid and cystic components. Cushing introduced the term craniopharyngioma in 1932.

EMBRYOLOGY

In the fourth week of embryological life, a diverticulum is formed in the roof of the primitive mouth cavity and meets a downgrowth from the floor of the forebrain. The diverticulum is termed the hypophysial pouch, ectodermal in origin, and the precursor of the anterior pituitary gland. The forebrain derivative is the neurohypophysial bud, neuroectodermal in origin, and will form the posterior pituitary gland, the infundibular stem, and the median eminence.

The ectodermal diverticulum is also known as Rathke's pouch and its stalk passes between the chondrification centers of the presphenoid and basisphenoid bones. The connection between Rathke's pouch and the pharynx degenerates in the sixth week, although a remnant, the basipharyngeal canal, may be detected in the sphenoid bone at birth. During the formation of the pituitary, there is an apparent rotation resulting in other remnants of Rathke's pouch lying above the gland and pituitary fossa.

It is from these remnants that craniopharyngiomas are considered to arise.

INCIDENCE

The incidence of new cases of craniopharyngioma is 1 to 2 per 1 million per year, and they account for 1–5% of all intracranial tumors. They occur more commonly in children and adolescents than in adults. No consistent sex bias has been reported, but some studies have shown a slight male preponderance.

CLINICAL PRESENTATION

Symptoms and signs of increased intracranial pressure, such as headache, vomiting, and papilloedema, may be the presenting features. Visual disturbances, especially visual field defects, and features of endocrine dysfunction are common. Children are more prone to endocrine problems, for example, poor growth and delayed or arrested puberty. Symptoms of diabetes insipidus can present but may be obscured by concomitant adrenal insufficiency. There may be cognitive dysfunction and behavioral and personality changes. Owing to the subtle and insidious nature of endocrine and cognitive changes, there is often a protracted period of symptomatology that can last for years before diagnosis.

RADIOLOGICAL FEATURES

Children are very likely to have abnormalities detected on plain skull radiographs that include enlargement, erosion, and destruction of the sella turcica and tumor calcification. Adults also show abnormalities of the sella and tumor calcification but to a lesser extent, which probably reflects the relative preponderance of adamantinomatous and papillary types of tumor. Computed tomography (CT) and magnetic resonance (MR) scans demonstrate localization and characteristics of these tumors. Most are suprasellar

Figure 1 MR scan with gadolinium (T_1 weighted) of craniopharyngioma in a child. Solid components are white. The tumor is mainly above the sella and extends behind the clivus, invading the hypothalamus above and displacing the pons behind. Tumor extends into the sella.

with intrasellar elements. CT scans show any calcification and, with contrast, the solid component and capsule of the cystic component. MR scans (Fig. 1) also allow distinction between the solid and cystic components.

HISTOLOGY

In the World Health Organization's "International Histological Classification of Tumors," craniopharyngiomas are grade I. Two histological types are described, adamantinomatous and papillary.

Adamantinomatous craniopharyngiomas have a solid component that is a loosely structured, multi-layered squamous epithelium and has some similarity with developing enamel cells or adamantoblasts. Nodular wet keratin is typical and has a tendency to calcify. The cystic element is usually multilocular but can be singular, and it is mostly lined by a stratified squamous epithelium. Cysts contain cholesterol,

and the viscous yellow or brown fluid is variously described as motor oil or engine oil.

Papillary craniopharyngiomas consist of epithelial strands forming papillae and lack calcification and the oily fluid. This histological type is rarely seen in children.

TUMOR MANAGEMENT

Surgery and irradiation are the main forms of treatment; the role of chemotherapy is not established. Surgical interventions are dependent on localization and size of the tumor. Resection may be partial or radical, and ventricular shunting is needed if there is secondary hydrocephalus. Recurrence can occur after apparent total resection. Irradiation may be given if there is residual tumor after operation. The role of postoperative irradiation is debatable; there are strong advocates for its use to prevent or delay recurrence. Of major concern is the severe morbidity following hypothalamic damage after surgery, and many authorities prefer more limited resection of large tumors invading the hypothalamus followed by irradiation.

MEDICAL MANAGEMENT

Frequently, there are endocrine deficiencies before primary tumor treatment, and they are almost universal afterwards. Therefore, hormone replacement treatment (thyroxin, glucocorticoid, sex steroids, growth hormone, and vasopressin analog) is needed for hypopituitarism. Postoperative fluid balance must be maintained. Introduction of growth hormone treatment in children is often delayed until postoperative growth can be assessed. Some children grow quickly after operation even though they are deficient of growth hormone, and this phenomenon is usually associated with hyperphagia and weight gain. There is no evidence that hormonal replacement causes earlier or more frequent recurrence.

Educational and other assistance for the visually impaired may be needed. Cognitive dysfunction, especially memory impairment, needs to be addressed using psychological strategies.

PROGNOSIS

Ten-year survival rates have been reported by several centers and vary from 60 to 93%. Although these rates may seem to be good, the underlying tumor is non-malignant and quality of life in survivors can be seriously impaired. Excluding endocrine dysfunction,

approximately two-thirds of childhood craniopharyngioma survivors have major morbidity, often visual. Hypothalamic damage in children is particularly debilitating. Extensive resection of large tumors is a bad prognostic factor for survival and for good quality of life.

Standardized mortality rates (SMRs) are increased 5-fold, with a higher risk for females (11-fold), and there is a 3-fold increase in cardiovascular and cerebrovascular mortality. When compared with other pituitary tumors causing hypopituitarism, those with craniopharyngioma had higher SMRs.

Cytokine Actions, Cellular Mechanism of

Michael David

University of California, San Diego, California, United States

Glossary

cytokines (also known as lymphokines and monokines) Low-molecular-weight, pharmacologically active ligands with diverse functions secreted by one cell for the purpose of altering either its own functions (autocrine effect) or those of adjacent cells (paracrine effect).

inflammation A potentially harmful process involving diverse cell types and soluble mediators, including cytokines, by which an organism counteracts potentially injurious insults, such as bacteria, viruses, and other pathogens.

signal transduction The perpetuation of ligand-receptor interaction-derived instructions through intracellular second messenger molecules or enzyme cascades.

Cytokines represent a group of transiently expressed, low-molecular-weight molecules that play a vital role in intercellular communication and regulate numerous physiological and pathological events, such as lymphocyte development and activation, inflammatory processes, and programmed cell death.

INTRODUCTION

Research during the past decade has led to the discovery of many new cytokines, their sources, and respective cell surface receptors. The elucidation of their signaling pathways has facilitated a better understanding of cytokine receptor-mediated gene induction. In addition to their complex biological effects, cytokine-induced transcriptional activation is the product of an intricate network of multiple signaling cascades.

This article presents an overview of cytokine-mediated transcriptional responses mediated through STAT proteins, NF- κ B, and the MAPK/SAPK cascades, signaling pathways widely used among cytokine receptors.

OVERVIEW OF CYTOKINE SIGNALING

Two fundamental concepts are crucial for understanding the complexity of cellular responses to cytokine stimulation. First, the generation of opposing signals through multiple pathways emanating from the same receptor is common in cytokine-initiated signal transduction. This concept is illustrated by the conversion of the antiproliferative actions of interferon- γ (IFN- γ) into a mitogenic response in the absence of STAT1 or by the simultaneous activation of the caspase cascade as well as the antiapoptotic NF- κ B pathway by the tumor necrosis factor- α (TNF- α) receptor. Second, every cell encounters a myriad of stimuli simultaneously *in vivo*, and it is the integration of the signaling events initiated by each individual receptor that ultimately determines the final cellular response. Synergistic amplification or antagonistic suppression of the biological effects of two simultaneously acting cytokines are exemplified by the augmenting effect of IFN- γ on the IFN- γ response or attenuating consequences of IFN- γ on TGF- α stimulation, respectively.

THE JAK/STAT PATHWAY

The discovery of the Jak/STAT pathway was the result of investigations on the mechanism by which interferons activate immediate-early response genes. Although research during the past decade has demonstrated that the Jak/STAT pathway is activated by a diverse group of cytokine and growth factor receptors, it is predominantly members of the hematopoietin subfamily of cytokines acting through class I and class II receptors that use this signaling cascade.

Jak/STAT Family Members

The first STAT proteins were identified as the regulatory cytoplasmic components of the IFN- γ -induced transcription factor complex, interferon-stimulated response element-3 (ISGF3). Two splice variants of STAT1, STAT2 and the DNA-binding subunit p48,

were found to bind the ISRE enhancer as a multiprotein complex in response to IFN- γ . Alternatively, STAT1 homodimers activated via the IFN- γ receptor can bind a distinct element called GAS (IFN- γ -activated sequence). Several other cytokines and growth factors were reported to activate STAT-like DNA-binding proteins (Table I), and subsequent identification of these proteins resulted in the cloning of five additional mammalian STAT genes (*STAT3*, *STAT4*, *STAT5A*, *STAT5B*, and *STAT6*). Several of the STAT proteins are represented by various splice variants; however, *STAT5A* and *STAT5B* are encoded by two distinct genes. In contrast to the more restricted expression of *STAT4* in spleen, heart, brain, peripheral blood cells, and testis, most STAT proteins are rather ubiquitous. Several conserved structural and functional domains characterize all seven mammalian STAT proteins as well as their *Drosophila* and *Dictyostelium* orthologs. A carboxy-terminal tyrosine residue, which serves as the target for ligand-induced phosphorylation, is crucial for dimerization, nuclear translocation, and DNA binding of STAT molecules. The src-homology 2 (SH2) domain of STAT proteins facilitates homo- or heterodimerization via reciprocal interaction with the

phosphorylated tyrosine residue. In addition, the SH2 domain facilitates the specific recruitment of STAT molecules to activated, tyrosine phosphorylated cytokine and growth factor receptors as well as Jak tyrosine kinases. Dimerization of STAT proteins allows the centrally located DNA-binding domains to interact with consensus palindromic sequences that differ only in their core nucleotide sequence. In several STAT proteins, the region C terminal to the tyrosine phosphorylation site harbors the transactivation domain (TAD), whose posttranslational modification through serine phosphorylation, presumably by members of the ERK/SAPK kinase family, accounts for the regulated interaction of the STAT-TAD domains with transcriptional coactivators such as CBP/p300 or MCM5.

Mechanism of Activation

It was again the paradigm of the interferon signaling cascade that led to the discovery of the participation of the Janus tyrosine kinases in STAT-mediated gene transcription. Disrupted expression of Tyk2 or Jak1 resulted in IFN- γ unresponsive cells, whereas similar

abrogation of Jak1 and Jak2 expression caused the loss of IFN- γ responsiveness. Contrary to the ubiquitous expression of these kinases, a fourth family member, Jak3, was identified whose expression is restricted to cells of hematopoietic origin. The most striking feature in the structure of Jak family members is the presence of a kinase-like domain and the absence of any SH2- or SH3-like structures that are commonly found in cytoplasmic tyrosine kinases. The relatively large (120–140 kDa) Jak kinases are constitutively associated with many cytokine and growth factor receptors. Nevertheless, this association can be increased after cytokine stimulation.

The general outline of the sequential events that led to STAT-mediated gene transcription has been derived mostly from evidence obtained from the interferon signaling paradigm (Fig. 1). It is believed that engagement of ligands to their respective receptors results in an increased local concentration of Jak proteins due to receptor aggregation and increased affinity of the receptors for Jak kinases. Subsequent transphosphorylation of the Jaks results in the activation of their kinase activity, such that they can phosphorylate tyrosine residues in the receptor chains. These phosphotyrosine moieties provide the docking sites for the STAT proteins via their SH2 domains, leading to their tyrosine phosphorylation, dimerization, and nuclear translocation. Parallel signaling

events, presumably involving ERK/SAPK family members, are responsible for further phosphorylation of the serine residues in the C terminus of the STAT proteins, which are required for efficient transcriptional response. For some receptors, the intrinsic tyrosine kinase activity of the receptor, and not the presence of Jak kinases, is required for the tyrosine phosphorylation of STAT proteins. In addition to these phosphorylation events, STAT arginine methylation has been determined to be a crucial requirement for IFN- γ -induced transcriptional responses. Of equal importance to the activation of a signaling pathway is its spatially and temporally coordinated attenuation. Several independent mechanisms are responsible for the negative regulatory control over the Jak/STAT pathway. The tyrosine phosphatase SHP1 acts on activated receptors and the Jak kinases, whereas the tyrosine phosphatase TcPTP dephosphorylates several STAT proteins in the nucleus. The SH2 domain-containing SOCS proteins have been identified as a family of cytokine-inducible inhibitors of Jak kinase activity, thus acting in a classical negative feedback loop. In contrast, the constitutively expressed nuclear PIAS proteins do not prevent the phosphorylation of STAT proteins but exert their negative regulatory role by associating with tyrosine phosphorylated STAT dimers and preventing them from binding DNA. As is the case with other signaling pathways, much of our understanding of the diverse functions of Jak and STAT proteins and their regulation *in vivo* has been further clarified through the generation of transgenic or knockout animals.

Figure 1 The Jak/STAT pathway exemplified by the IFN signal transduction cascade: Ligand binding triggers the activation of the Jak kinases and subsequent phosphorylation of STAT proteins. STAT1/2 heterodimers use IRF9 as an adapter to bind to the ISRE, whereas STAT1/1, STAT3/3, and STAT5/5 homodimers and STAT1/3 heterodimers bind GRR/GAS-like enhancer elements directly.

SIGNAL TRANSDUCTION VIA THE SAPK CASCADE AND NF- κ B

Components or products of infectious microorganisms (e.g., LPS) evoke an inflammatory response characterized by the expression of proinflammatory cytokines, such as interleukin-1 (IL-1) and TNF- α . The binding of these cytokines to class III and class IV cytokine receptors rapidly induces a genetic program to respond to cellular stress and to generate inflammatory mediators (e.g., chemokines, acute phase proteins, proteases, adhesion molecules, and prostaglandins).

The signaling events triggered by the IL-1 receptors closely resemble those initiated by the Toll-like receptors (TLRs), which are responsible for the cellular recognition of pathogen-characteristic molecular patterns. Indeed, a region called the TIR (Toll/IL-1 receptor) domain is highly conserved between the TLRs and the IL-1 receptor. Although the

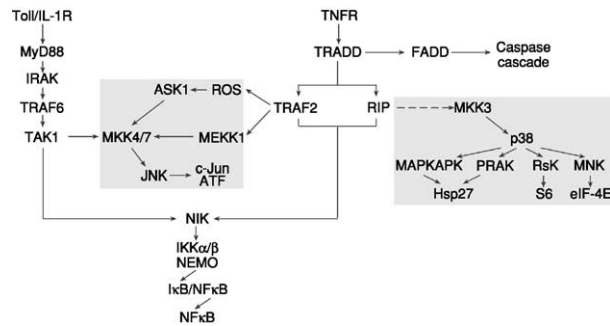

Figure 2 Toll/IL-1R- and TNFR-mediated activation of the NF- κ B and SAPK pathways: Signals originating from the Toll/IL-1R and TNFR converge on NIK to activate NF- κ B. The pathways leading to the activation of the SAPKs p38 and JNK are shaded.

TNF receptors are structurally distinct from their TIR-containing counterparts, they share numerous signaling components in order to promote ligand-induced transcriptional responses (Fig. 2). Activation of the transcription factor NF- κ B represents a point of convergence for the signaling cascades originating from TLR/IL-1R and TNFR. Although a key mediator in the inflammatory response, NF- κ B was first isolated in B cells as a factor necessary for immunoglobulin kappa light-chain transcription. NF- κ B binding sites have since been identified in a number of genes encoding cytokines and chemokines, adhesion molecules, acute phase proteins, antiapoptotic genes, or transcription factors. Thus, NF- κ B was implicated in innate immunity as well as in the adaptive immune response. NF- κ B exists as a homo- or heterodimer of any of the five isolated subunits: RelA (p65), RelB, c-Rel, p50, and p52. The p50 and p52 subunits are first generated as the longer p105 and p100 forms, respectively, which are then proteolytically processed into the shorter, active forms. All members contain a conserved rel homology domain (RHD) within their N terminus that contains the dimerization, I κ B-binding, and nuclear localization signal (NLS) regions. Additionally, RelA, RelB, and c-Rel contain a C-terminal transactivation domain that is absent in p50 and p52. Hence, p50 and p52 homodimers are transcriptionally repressive.

Activation of NF- κ B occurs through the protein synthesis-independent degradation of inhibitors of NF- κ B (I κ B), freeing NF- κ B proteins from the cytosolic tether and exposing the NLS. Once in the nucleus, NF- κ B negatively regulates its own activity by inducing transcription of I κ B, which enters the nucleus and chaperones NF- κ B molecules out through an active export pathway involving the I κ B nuclear export sequence.

The I κ B family members (I κ B α , I κ B β , I κ B ϵ , I κ B γ , and Bcl-3) contain ankyrin repeats that bind the NF- κ B RHD, an N-terminal regulatory domain, and a C-terminal PEST motif for proteolytic degradation. Activators of the NF- κ B pathway trigger serine phosphorylation of I κ B proteins that targets them for ubiquitin-mediated destruction by the 26S proteasome. Two closely related proteins with I κ B kinase (IKK) activity, IKK α and IKK β , and a scaffolding subunit IKK γ (NEMO) assemble into a large-molecular-weight complex capable of phosphorylating I κ B proteins. Upon stimulation by TNF and IL-1, the IKK subunits are activated by phosphorylation on serine residues by the MAPKKK family member NIK.

A number of adapter proteins assemble into a signaling scaffold and link the Toll/IL-1 and TNF receptors to IKK activation and consequently NF- κ B activation. The adapter protein MyD88 (myeloid differentiation factor 88) binds to TLR and IL-1R. Interacting through its death domain, MyD88 binds the serine/threonine kinase IRAK (IL-1R-associated kinase), which in turn recruits TRAF6 to the complex. Additionally, the MAPKKK TAK1 (TGF- β -activated kinase) associates with TRAF6 and activates NIK in an IL-1-dependent manner. Similarly, the death domain containing TNFR promotes the formation of a large signaling complex by interacting with the death domain of TRADD. TRADD links the TNFR to FADD, thereby initiating proapoptotic signals via the caspase cascade, but also induces the antiapoptotic NF- κ B pathway by recruiting TRAF2. Although TRAF2 is sufficient to recruit the IKK complex to the TNFR, the RIP kinase is required for full activation of IKK kinase activity.

The nonapoptotic TRAF2-dependent cascade also leads to the activation of the SAPKs p38 and JNK via two distinct pathways. Activation of MKK3 in a RIP-dependent manner triggers p38 phosphorylation, whereas the pathway leading to JNK activation involves MEKK1 and MKK4/7. Furthermore, a role for ASK1 in supporting sustained JNK activity was observed under apoptotic conditions. In the case of IL-1R, the events leading to ERK, p38, and JNK activation are less well documented. Nevertheless, it appears that the pathways leading to p38 and JNK activation diverge from the NF- κ B activation cascade at the level of TAK1, which facilitates activation of MKK4/7 in addition to NIK.

CONCLUSION

The discovery of the Jak/STAT pathway and the identification of numerous crucial elements in the NF- κ B

and SAPK activation cascade have provided new momentum for research on cytokine responses. It is important to note, however, that many additional signaling molecules contribute to the cellular responses toward cytokine exposure. The raf–MEK–ERK cascade, the PI3 kinase/Akt pathway, the small GTP-binding proteins Rac/Rho/Cdc42, and the caspase cascade are significant contributors to many cytokine responses. The continuous exploration of the multitude of specific, overlapping, and redundant activities of individual cytokines within a larger signaling network remains an extraordinary challenge for the future.

or interferon- γ (IFN- γ), cytokine production is one of the many functions of the producing cells. Hormones are released in the circulation and act at distant sites. On the other hand, cytokine production is transient; they act over short distances and are not found in substantial amounts in the circulation. Polypeptide hormones are frequently restricted in their action to a limited set of cellular targets, with the notable exception of insulin. In contrast, many cytokines are pleiotropic, affecting a variety of cells and tissues. Also unlike hormones, structurally different cytokines have overlapping actions, as illustrated by IL-1 and tumor necrosis factor (TNF).

None of these distinguishing features are absolute. For instance, transforming growth factor- β (TGF- β) and M-CSF are present in substantial amounts in the circulation under normal conditions, and IL-6 is produced in response to local inflammatory signals and acts distantly on the liver, contributing to the acute phase response.

RECEPTORS OF THE IMMUNOGLOBULIN SUPERFAMILY

Receptors of the immunoglobulin (Ig) superfamily include those for the inflammatory cytokines IL-1 and IL-18 and a series of structurally similar orphan receptors whose function is only partly known.

IL-1 is a group of related cytokines including two agonist proteins (IL-1 α and IL-1 β) and an antagonist protein (IL-1ra). IL-1 plays a key role in the onset and development of the host reaction to invasion, being an important factor in the initiation of the inflammatory response and in the triggering of immune functions. IL-1 has a pivotal role in the regulation of the hypothalamic-pituitary-adrenal axis and in the modulation of thyroid functions, ovulation and pregnancy, and the brain-endocrine-immune axis in general. Receptors for IL-1 are expressed ubiquitously; thus, most of the cells and tissues of the body are responsive to IL-1 effects.

IL-18, a molecule structurally very similar to IL-1, is a very potent inducer of IFN- γ production and activation of Th1 cells and natural killer (NK) cells. IL-18 is produced by several immune and nonimmune cells and tissues, including the zona reticularis and zona fasciculata of the adrenal cortex, that produce glucocorticoids. In Cushing's syndrome, the increased levels of IL-18 correlate with those of serum cortisol. IL-18 has been associated with other endocrine disorders, such as autoimmune thyroiditis of the obese chicken (a model of Hashimoto's thyroiditis) and

type 1 autoimmune diabetes. Physiologically, like IL-1, IL-18 is apparently involved in the regulation of ovary functions, ovulation, and pregnancy. Six other proteins belonging to the IL-1 family have been identified (IL-1F5-F10), whose receptor specificity and functional characteristics have yet to be determined.

Due to the high potency of its inflammatory effects, IL-1 activity is tightly regulated in the body by a complex network of control systems, which include two types of inhibitors—the receptor antagonist IL-1ra and the second type of IL-1 receptor (IL-1RII), which is a natural scavenger of IL-1 (decoy receptor). Regulation of IL-1 activity is attained by a strict hierarchy of binding affinity of the two receptors (the activating IL-1RI and the decoy IL-1RII) for the various members of the IL-1 family. The presence of a third receptor chain, the accessory protein IL-1RAcP, adds a further level of regulation since this chain is required for IL-1RI-mediated activation but it can be sequestered into an inactive complex by IL-1RII. A schematic representation of the mechanism of IL-1 binding to its receptor complex and of the IL-1-triggered pathway of signal transduction is shown in Fig. 1.

The IL-18 receptor system largely resembles that of IL-1. The IL-18 receptor is composed of two chains, IL-18R α and IL-18R β , that are structurally very similar to IL-1RI and IL-1RAcP and initiate the

Figure 1 IL-1 receptor complex and signal transduction pathway.

Table I Ig-like Receptor Family: IL-1R/IL-18R Molecules

| Receptor | Ligand | Function |
|-----------------|--|---|
| IL-1RI | Agonist IL-1 α and IL-1 β , antagonist IL-1ra, IL-1F10 (to soluble receptor form) | Initiates and amplifies the immune and inflammatory response activated by agonist ligands; inhibited upon binding the antagonist ligand |
| IL-1RII | IL-1 β , less efficiently IL-1 α and IL-1ra | Decoy receptor, unable to initiate signal transduction |
| IL-1RAcP | Coreceptor for IL-1RI bound to agonist ligands IL-1 α and IL-1 β | Responsible for signaling together with ligand-bound IL-1RI; can form inactive complexes with IL-1RII bound to IL-1 |
| IL-18R α | IL-18, IL-1F7 | Initiates IL-18-dependent activation of Th1 and NK cells; function upon binding of IL-1F7 unknown |
| IL-18R β | Coreceptor for IL-18R α bound to IL-18 | Responsible for signaling together with ligand-bound IL-18R α |
| T1/ST2 | Orphan receptor | Unknown; possible role in the activation of Th2 responses |
| TIGIRR | Orphan receptor | Unknown |
| IL-1RAPL | Orphan receptor | Deletions in the gene are associated with X-linked mental retardation |
| IL-1Rrp2 | Binds IL-1F5 (antagonist of IL-1F9) and IL-1F9 | Unknown |
| SIGIRR | Orphan receptor | Unknown |

same signal transduction pathway. In addition to the receptor chains for the inflammatory cytokines IL-1 and IL-18, the family of IL-1 receptors includes a series of IL-1R-like orphan receptors. The gene coding for one of these receptors (IL1RAPL, expressed in the hippocampus) is a strong candidate for X-linked nonsyndromic mental retardation locus, suggesting that molecules resembling IL-1 and IL-18 may play a role in the development or function of the central nervous system. The 10 known members of the IL-1R/IL-18R family are shown in [Table I](#).

TNF RECEPTORS

The TNF receptor family includes more than 20 members that are involved in a variety of functions. [Figure 2](#) shows the two TNF receptors (RI and RII), which serve as paradigms for members of the family acting primarily as death receptors. Ligands of members of the TNF-R family generally have a long-chain β -sheet structure. When membrane-associated as a type II integral membrane protein or when released, TNF forms a trimer. TNF release involves a member of the matrix metalloprotease family (TNF- α -converting enzyme). Receptor engagement and oligomerization in the case of TNF-RI and related receptors (fas) lead to cell death via activation of the caspase cascade. Members of this group of TNF receptors have as first enzymatic activity a protease (caspase 8). TNF-RII and related receptors activate NF- κ B, via adapter proteins and promote survival.

Receptors of the TNF family serve diverse functions in pathophysiology, ranging from induction of apoptosis (fas and TNF-RI) to ontogeny of the lymphoid system (TNF and lymphotoxin receptor), bone remodeling (RANK and its decoy receptor osteoprotegerin), innate immunity, and inflammation. Blocking TNF with soluble TNF-RII or antibodies has proven useful in human rheumatoid arthritis and Chron's disease.

Figure 2 TNF receptors. TACE, TNF- α -converting enzyme.

COMMON γ -CHAIN RECEPTORS

The common cytokine receptor γ -chain (γ_c) is the signaling chain in the receptor complexes of the cytokines IL-2, IL-4, IL-7, IL-9, and IL-15. Mutation in the gene that encodes γ_c results in severe combined immunodeficiency in humans and mice. Signals that are dependent on γ_c have been shown to be important for T cell differentiation, activation, expansion, and survival.

IL-2 is the prototypic T cell growth factor. The biologic effects of IL-2R signals influence T cell growth and can also promote cell survival, effector function, and apoptosis. IL-2 and IL-2R are also expressed by cells other than lymphocytes (e.g., pituitary and adrenal cells), suggesting a role for this cytokine in the autocrine and paracrine regulation of the hypothalamic–pituitary–adrenal axis. The IL-2 receptor complex is composed of three chains. IL-2R α binds IL-2 with low affinity. IL-2R β increases the affinity of the IL-2/IL-2R α complex. The γ_c associates with the IL-2/IL-2R α /IL-2R β complex and initiates signaling.

IL-7, a product of stromal cells, induces potent B cell lymphopoiesis, followed by bone loss, resembling estrogen deficiency. The IL-7 receptor is composed of two chains, IL-7R α and γ_c . Following receptor cross-linking, rapid activation of several classes of kinases occurs, including members of the Janus and Src families and PI3-kinase. A number of transcription factors are subsequently activated, including STATs, c-myc, NFAT, and AP-1.

IL-9 is a Th2 cytokine with major involvement in malignant proliferation (e.g., T cell lymphomas and leukemias and Hodgkin's disease). The IL-9 receptor is heterodimeric, formed by the specific IL-9-binding chain IL-9R α and by the signaling γ_c .

The heterotrimeric IL-15R complex is very similar to that for IL-2 and comprises the unique IL-15R α subunit, IL-2R β (CD122), and the γ_c . The γ_c and β subunits are responsible for transducing intracellular signals and the α subunit mediates specific, high-affinity binding of IL-15. The production of IL-15 and IL-2 by essentially different cell types suggests that these cytokines mediate similar functions in distinct sets of tissues and/or organs. IL-2R β knockout mice, as well as IL-15R α knockout mice, are deficient in both NK cells and NK-T cells (i.e., cells implicated in so-called "innate immunity").

IL-4 is a Th2 cytokine that acts on both hematopoietic and nonhematopoietic cells through different types of receptor complexes. There are two different forms of IL-4R. Type I IL-4R is predominantly expressed in hematopoietic cells and consists of IL-4R

p140 (IL-4R α) and the γ_c . The type II form of IL-4R is predominantly expressed in nonhematopoietic cells, which do not express the γ_c , and consists of IL-4R α and IL-13R α_1 chains. This alternative form of IL-4R is also used as a functional component in the IL-13R complex.

IFN RECEPTORS AND RELATED MOLECULES

Interferons are potently active proteins synthesized by somatic cells of all mammalian species. Broadly, IFNs are clustered into two subfamilies, type I and type II. The type I IFN family includes IFN- α , IFN- β , IFN- ω , and IFN- τ . These molecules use the same cell surface receptors, IFN- α R1 and IFN- α R2 (belonging to the type 2 cytokine receptor family for α -helical cytokines), and have similar functions (antiproliferative, immunomodulatory, and antiviral effects). Type II IFN is the cytokine IFN- γ , which has lower antiviral activity than type I IFN but has a major immunomodulatory role. Cellular responses to IFN- γ are mediated by its heterodimeric cell surface receptor (IFN- γ R1/IFN- γ R2).

The family of IL-10-related cytokines comprises a series of members, including IL-19, IL-20, IL-22, IL-24, and IL-26. Although the predicted helical structure of these homodimeric molecules is conserved, certain receptor-binding residues are variable and define the interaction with specific heterodimers of different members of type 2 cytokine receptors. This leads, through the activation of signal transducer and activator of transcription (STAT) factors, to diverse biological effects. For example, whereas IL-10 is a well-known immunomodulatory cytokine, IL-22 mediates acute phase response signals in hepatocytes and IL-20 induces the hyperproliferation of keratinocytes, one of the possible pathogenic mechanisms of psoriasis.

Receptors for INFs, IL-10, and its related cytokines are all members of the cytokine receptor family type 2 (CRF2). The family also includes tissue factor (TF), the membrane-binding chain for FVII/FVIIa. CRF2 members are present in the extracellular part of fibronectin III domains and have conserved intracellular regions involved in the interaction with downstream signaling molecules. As a prototype, the IL-10 receptor consists of a long chain (IL-10R1), the major signaling component, and an additional receptor chain (IL-10R2) with a short intracellular segment. Similarly, all the other receptor heterodimers of this family combine a long chain with a large intracellular

Table II CRF2 Receptors and Their Ligands

| Receptor complex | Ligand | Function |
|-----------------------------------|---------------|--|
| IFN- α R1/IFN- α R2 | IFN type I | Antiviral, antiproliferative, immunomodulatory effects |
| IFN- γ R1/IFN- γ R2 | IFN- γ | Immunomodulatory, inflammatory, antiviral effects |
| IL-10R1/IL-10R2 | IL-10 | Down-regulation Th1 activities, antiinflammatory |
| IL-20R1/IL-20R2 | IL-19 | Unknown |
| IL-20R1/IL-20R2 | IL-20 | Keratinocyte activation, keratin expression, synergistic with IL-1 |
| IL-20R1/IL-20R2 | IL-24 | Tumor growth inhibition |
| IL-22R/IL-10R2 | IL-22 | Induction of acute phase proteins in hepatic cells, activation of pancreatic acinar cells; no IL-10-like activity, no inhibition of IL-10 activity |
| IL-22R/IL-20R2 | IL-20 | Unknown |
| IL-22R/IL-20R2 | IL-24 | Tumor growth inhibition |

domain and a smaller accessory chain. Signaling through the heterodimeric CRF2 complexes for the individual IL-10-like cytokines involves the activation of JAK kinases and the phosphorylation of STAT factors, which induce γ -activated sequence-dependent or STAT-dependent transcription of target genes. Because STAT3 seems to be a common major transcription factor mediating stimulatory effects, the tissue-specific surface expression of the specific combination of CRF2 subunits likely plays the key role in determining the function of the respective IFN/IL-10 family member. A summary of the CRF2 receptors and their ligands is provided in [Table II](#).

CHEMOKINE RECEPTORS

Chemokines are a superfamily of small proteins vital for immune and inflammatory reactions and viral infection. Most chemokines cause chemotactic migration of leukocytes, but they also affect angiogenesis, collagen production, and the proliferation of hematopoietic precursors. Based on a cysteine motif, CXC, CC, C, and CX3C families have been identified. The chemokine scaffold consists of an N-terminal loop connected by Cys bonds to the more structured core of the molecule (three β -sheets) with a C-terminal α -helix. Approximately 50 human chemokines have been identified.

Chemokines interact with seven-transmembrane domain, G protein-coupled receptors. Eight CC (CCR1–8), five CXC (CXCR1–5), and one CX3C (CX3CR1) receptor have been identified.

The chemokines' main function is chemotaxis for leukocytes. Chemokines are redundant in their action on target cells. No chemokine is active on only one leukocyte population, and usually a given leukocyte population has receptors for and responds to different

chemokine molecules. The chemokines' interactions with their receptors show considerable promiscuity. Most known receptors have been reported to interact with multiple ligands, and most ligands interact with more than one receptor. G protein-coupled receptors are a classic target in pharmacology. Likewise, given the role of chemokines in various human diseases, ranging from HIV infection to allergies, their receptors' pharmacology is a prime target for research. Although redundancy is a formidable problem, blocking one agonist or one receptor may be beneficial in certain disease models. Therefore, simple chemicals with chemokine antagonistic properties or with selective inhibitory activity on chemokine production are a holy grail in cytokine pharmacology.

gp130 USING RECEPTORS

Receptors for IL-6 and related cytokines (oncostatin M, leukemia inhibitory factor, ciliary neurotrophic factor, and cardiotrophin) share a common gp130 chain, which activates a JAK/STAT signaling cascade. Ligands for these receptors share a four- α -helical bundle, long-chain structure. The IL-6R β chain binds the ligand and forms a signaling receptor complex in membrane-bound and soluble form (trans-signaling). The liver is a prime target for IL-6, which activates the production of acute phase proteins (e.g., C-reactive protein). In addition, IL-6 amplifies inflammation in tissues.

Cytokines, Constitutive Secretion

Nobuyuki Tanaka and Kazuo Sugamura
Tohoku University Graduate School of Medicine, Sendai, Japan

Glossary

human T-cell leukemia virus type I (HTLV-I) A causative agent for adult T-cell leukemia.

interleukin-2 (IL-2) A cytokine that regulates lymphocyte proliferation via the IL-2 receptor (IL-2R).

interleukin-4 (IL-4) A cytokine that regulates B-lymphocyte activation and differentiation into antibody-secreting cells.

tumor necrosis factor- α (TNF- α) An inflammatory cytokine, secreted mainly by macrophages, that provokes increased vascular permeability, inflammation, and apoptosis.

Cytokines are potent protein messengers participating in cell-to-cell communication with a variety of biological activities. Their constitutive secretions may lead to autoimmunity, allergy, and cancers.

INTRODUCTION

The identification of a number of cytokines has shed light on our understanding of the regulation of homeostasis. In the immune system, accumulating evidence has revealed roles of cytokines in cell fate determination such as development, proliferation, differentiation, and cell death. In addition to the “favorable” roles of cytokines to maintain homeostasis in a healthy condition, uncontrolled secretion of potent cytokines may provoke autoimmune diseases, allergies, and cancers. This article discusses some examples of human diseases as well as lessons learned from model animals, including transgenic mice.

CYTOKINE CONSTITUTIVE SECRETION POSSIBLY INVOLVED IN LEUKEMOGENESIS

Interleukin-2 (IL-2) is a cytokine first identified as a T-cell growth factor. Constitutive expression of IL-2 and its receptor (IL-2R) has been suggested to be related

to development of adult T-cell leukemia (ATL). ATL is caused by infection with human T-cell leukemia virus type I (HTLV-I). HTLV-I-infected T cells derived from healthy individuals as well as ATL patients constitutively express IL-2R and are easily immortalized in the presence of IL-2. The functional IL-2R consists of three subunits: α -, β -, and γ -chains. The γ -chain is constitutively expressed on every hematopoietic cell population, including T cells, but expression of the α - and β -chains and production of IL-2 are inducible after antigen stimulation in normal T cells. HTLV-I-infected T cells constitutively express all three IL-2R subunits. Furthermore, the HTLV-I genome contains a pX region coding for a transactivator protein named p40^{tax}, which has been demonstrated to transactivate transcription of at least IL-2 and IL-2R α genes. Hence, it can be speculated that HTLV-I-infected T cells are stimulated to proliferate constitutively by IL-2 in an autocrine or paracrine manner, and this may result in further malignant transformation of the cells. Such a mechanism of HTLV-I-induced leukemogenesis favors the notion that ATL cells are derived from CD4⁺ T cells with potentiality for IL-2 production.

Another example of autocrine-related lymphoid malignancy is Hodgkin's lymphoma (HL). HL is a unique lymphoma characterized by the appearance of Reed-Sternberg cell and multiple cytokine secretion. One report suggests that most Hodgkin's lymphoma cells secrete IL-13 and express IL-13R α -chain, leading to their proliferation in an IL-13 autocrine manner. Because IL-13 shares the γ c-chain as a receptor subunit with IL-2, it is of note that constitutive signaling by the cytokines sharing the γ c-chain may relate to leukemogenesis.

EXCESSIVE INFLAMMATORY CYTOKINE SECRETION AS A PATHOGENESIS FOR AUTOIMMUNE DISEASES

IL-6 was originally identified as a B-cell differentiation factor, and it is now known to be multifunctional in

regulation of the immune system, hematopoiesis, acute phase reaction, and inflammation. The first clue to suggest its role in autoimmunity came from the finding that cardiac myxoma cells produce IL-6 and patients suffering from this disease frequently manifest autoimmune symptoms such as hypergammaglobulinemia and production of autoreactive antibodies. Because surgical removal of the cardiac myxoma induces the disappearance of the autoimmune conditions, myxoma cells that contain a high level of IL-6 mRNA expression seemingly contribute to the autoimmune pathogenesis. Among the autoantibodies, anti-DNA and antichromatin antibodies are shown to be dependent on IL-6. Systemic lupus erythematosus (SLE), a systemic autoimmune disease, also has been suggested to be related to IL-6. Serum IL-6 levels of SLE patients are usually normal, but SLE patients with serositis or SLE patients during disease exacerbations show increased IL-6 levels in sera. In addition to IL-6, B cells in patients with active SLE express IL-6R as well as IL-2R, suggesting the competency of these cells toward IL-6-induced reaction. Alternatively, an anti-IL-6R mAb inhibits the spontaneous production of anti-DNA antibodies, indicating that B cells are activated by IL-6R-mediated signals in SLE. Transgenic mice expressing IL-6 develop a massive polyclonal plasmacytosis with autoantibodies and mesangial cell proliferative glomerulonephritis (MPGN). Dysregulated expression of IL-6 can trigger polyclonal plasmacyte proliferation, resulting in generation of a malignant monoclonal plasmacytoma.

Another possible pathogenesis in relation with IL-6 is an inflammatory bowel disease, Crohn's disease (CD). CD activity indexes correlate well with serum IL-6 levels, and steroid therapy reduces IL-6 levels to induce remission of CD. In fact, soluble IL-6R, which can signal in the absence of membrane-bound IL-6R, is significantly high in sera of CD patients.

Another inflammatory and autoimmune disease possibly related to IL-6 is rheumatoid arthritis (RA), which is a heterogeneous and chronic joint disease. In RA patients, affected joints are invaded by leukocytes and synoviocytes are activated; thus, destructive arthritis occurs, resulting in cartilage destruction, bone resorption, and deformity. Although proinflammatory cytokines produced by macrophages and dendritic cells, such as TNF- α and IL-1 β , also are detectable in RA-affected synovial fluids, high levels of IL-6 affect B cells to produce autoantibodies such as rheumatoid factor (RF). Involvement of IL-6 is also suggested in juvenile chronic arthritis (JCA). Serum IL-6 levels of patients with JCA are increased during active status, correlating with a severity of the joint.

Because osteoclasts are stimulated by IL-6, bone destruction and resorption may also be activated by IL-6. Mice deficient in IL-6 result in delayed onset and reduced severity of an experimentally induced autoimmune disease called collagen-induced arthritis (CIA). These findings imply that excessive secretion of IL-6 is associated with the destructive phenotype of RA, although IL-6 is not the only factor responsible for the pathogenesis.

In addition to IL-6, autoimmune RA is associated with constitutive secretion of TNF- α . High-affinity anti-TNF- α mAbs, neutralizing its function, have been used successfully for clinical therapy in moderate to severe RA patients with appreciable effects. In *in vitro* studies, anti-TNF- α mAb profoundly decreased IL-1 secretion from synovial cells derived from RA patients. As expected, IL-1R antagonist or soluble IL-1R type II is also under way for clinical trials, either alone or in combination with anti-TNF- α mAb.

SKEWED CYTOKINE SECRETION FOR THE PATHOGENESIS OF ALLERGY

Allergic inflammatory reactions are induced by T-helper 2 (Th2) cells secreting the "Th2 cytokines" such as IL-4, IL-5, and IL-13. IL-4, first identified as a B-cell-stimulating factor, activates and differentiates B cells and, therefore, enhances antibody production. Immunoglobulin E (IgE)-class antibodies secreted by B cells are bound to the Fc receptor on the surface of the mast cells, which react to the specific antigens to release chemical mediators such as histamine. In mice, such Th2 reactions are surprisingly different between strains. For example, on antigen challenge, CD4+ T cells from BALB/c mice overproduce IL-4, whereas those from C57/BL6 mice produce much less IL-4. On pathogen challenge such as *Leishmania major*, BALB/c mice show a lethal phenotype, whereas C57/BL6 mice may survive with the same pathogenic burden. Because IL-4 knockout mice manifest reduced Th2 response, IL-4 should play a pivotal role in the pathogenesis of allergic disorders, although a certain genetic background definitely contributes to the susceptibility.

EXCESSIVE CYTOKINE SECRETION DURING INFECTION

Toll-like receptors (TLRs) are now well known for pathogen recognition during the early phase of infection. For example, lipopolysaccharides (LPSs) are recognized by TLR4 along with other association

molecules, resulting in macrophage and dendritic cell activation. An immediate outcome of LPS-induced activation is a secretion of proinflammatory cytokines such as TNF- α , IL-1 β , and IL-6. These cytokines favor elimination of the pathogen; they work locally at the site of infection to initiate inflammation with intravascular mononuclear cell recruitment, leading to protection against the pathogens. However, if massive and systemic secretion occurs, the host will face systemic and fatal reaction with circulation insufficiency, referred to as endotoxin shock or sepsis. Oversecretion of TNF- α is considered to be paramount in the development of shock given that injection of TNF- α into mice leads to septic-like shock, whereas TNFR type II knockout mice do not fall into septic shock. Because an initial response to the pathogen is important to activate acquired immunity, proinflammatory cytokines may be necessary to activate lymphocytes as well as to provoke inflammation.

Another example of excessive innate immune response is familial Mediterranean fever (FMF), an inherited disease characterized by recurrent episodes of fever and inflammation. Most patients with FMF carry missense mutations in the C-terminal region of PYRIN protein, and this induces a hyperreaction to a small amount of LPS. Recurrent and continuous secretion of IL-1 β then results in recurrent fever in patients.

CONCLUSION

Over the past two decades, great progress has been achieved in our knowledge of cytokines both *in vitro* and *in vivo*. Identification of a causative gene for

immune-deficient diseases and inflammatory diseases has facilitated further understanding of the roles of cytokines themselves as well as of their signaling mechanisms. In addition, animal models, including transgenic and gene-targeted mice, have facilitated and continue to facilitate our insight into the pathogenesis of diseases as well as development of new clinical interventions. Although we need to pay attention to their side effects, anti-cytokine therapies would be an important measure for controlling immune disease, infection, and cancers.

immunological innate response, recognition of “foreignness” is one of the first responses of phagocytes (monocytes or macrophages). One of the most important roles of the phagocyte is to alert the rest of the immune system of an attack. The phagocyte has many secreted proteins in its arsenal, some of the most important being the cytokines.

CYTOKINES

Cytokines are soluble low-molecular-weight proteins (≈ 20 kDa) secreted by immune cells and they are the intracellular messenger molecules of the immune system. Cytokines determine the scope and type of an immune response that is generated after infection. Cytokine is a word that is derived from *cyto-*, meaning cell, and *-kinin*, a combining form used in naming hormones, usually peptide hormones (e.g., bradykinin). The term tends to be used as generic shorthand for several related signaling molecules (Table I). Cytokine is an imprecise term, but it is in very common usage. The categorization of cytokines has always been a problem because they were originally named for the activity that they described. Generally, growth factors are not classified as cytokines.

The cytokine pathway is akin to the endocrine system, with the cytokines being analogous to hormones in that cytokines serve as the intracellular messengers of the immune system. All the actions of cytokines are receptor mediated with binding to high-affinity receptors on target cells so they are active at picomolar (10^{-12} M) concentrations. Cytokines are not stored as preformed molecules within the cell; their synthesis is initiated by new gene transcription. This transcriptional activity is usually brief, ensuring that cytokine synthesis and release are transient. Cytokine actions can be autocrine (binding to its receptor and then activating the same cell that secreted it), paracrine

(binding to its receptor on a target cell in close proximity to the cell that released it), or systemic, which is also sometimes called endocrine (binding to its receptors on a target cell in a distant part of the body). Cytokines are not used exclusively by the immune system, as cells of the endocrine and nervous system will respond to the actions of cytokines. The attributes of cytokines include pleiotropy (one cytokine with different biological effects on different target cell types), redundancy (two or more cytokines with the same biological effects on a target cell), synergy (combined effect of two cytokines on a target cell), and antagonism (one cytokine blocking the effect of another cytokine on a given target cell).

Cytokines mediate many of the fundamental functions of the innate immune response. They are also involved in all aspects of the inflammatory response (e.g., fever, tissue remodeling). Table II lists just a few of the myriad actions of cytokines. Just as with innate immunity, many of the critical activities of the effector cells involved in acquired immunity are mediated by cytokines. For example, during the activation phase of specific immune responses, cytokines are involved in the growth and differentiation of lymphocytes.

In general terms, the database of cytokine sequences continues to be confined to human cytokines, laboratory model species, and economically significant domestic animals. The accumulation of primary sequence data on a wider range of species will be a valuable addition to researchers' knowledge of this medically and scientifically important group of molecules.

CYTOKINE EVOLUTION

More than 200 different cytokines, mostly from humans and mice, have been described. Evidence suggesting that protein molecules with cytokine-like activities could be isolated from other vertebrate

Table I Nomenclature of Cytokines

| Synonym | Simple definition |
|----------------------------|--|
| Interleukins | Macrophage-derived stimulatory/inhibitory molecules |
| Monokines | Stimulatory/inhibitory molecules secreted by mononuclear phagocytes |
| Lymphokines | Stimulatory/inhibitory molecules secreted by activated T lymphocytes |
| Colony-stimulating factors | Stimulatory/inhibitory molecules involved in the growth and differentiation of immature leukocytes in the bone marrow |
| Interferons | Stimulatory/inhibitory molecules that generally protect against viral infections |
| Chemokines | A family of molecules, related to interleukin-8, that function mainly as leukocyte chemoattractants |
| Tumor necrosis factor | A potent mediator of inflammatory and immune functions, released by leukocytes, that is selectively cytotoxic for many transformed cells |

Table II Some Examples of the Actions of Cytokines

| | |
|--|---------------------------------------|
| T cell proliferation | B cell activation and proliferation |
| Cell growth and proliferation | Production of fever |
| Stimulation of neutrophil development | Acute-phase protein production |
| Stimulation of eosinophil growth and differentiation | Stimulation of mast cells |
| Lymph node development | Stimulation of apoptosis |
| Stimulation of cytokine production | Stimulation of B cell class-switching |
| Natural killer cell activation | Mononuclear cell chemoattractant |
| Increases in major histocompatibility complex class I expression | Cytotoxicity of transformed cells |
| Stimulation of intestinal epithelium | Macrophage activation |
| Inhibition of macrophage migration | Stimulation of bone resorption |
| Stimulation of immunoglobulin secretion | Endothelial cell activation |
| Stimulation of bone marrow cell progenitors | Suppression of macrophage functions |
| Stimulation of serum cation concentrations | |

animals has accumulated. This biological activity was based on cross-reactivity with antibodies and substitution of active molecules in mammalian-based assay systems. Primary sequence data from numerous vertebrate species have been reported. Most of these cytokines have been cloned using polymerase chain reaction-based techniques based on primers derived from existing sequence homologies principally between humans and mice.

Interleukin-1 (IL-1) is recognized in vertebrates as being a major cytokine of innate immune responses. In addition to IL-1, IL-6 and tumor necrosis factor α (TNF α) make up a collection of cytokines with overlapping biological properties; these proteins are known as the pro-inflammatory cytokines. The majority of cytokines isolated and sequenced from non-mammalian vertebrates have been pro-inflammatory cytokines.

In 1985, two distinct, but distantly related cDNAs encoding proteins sharing human IL-1 biological activity (termed IL-1 α and IL-1 β) were isolated from a macrophage cDNA library. A third member of the IL-1 family is an antagonist protein that shares sequence similarity with IL-1 α and IL-1 β , the IL-1 receptor antagonist (IL-1ra). With the sequencing of the human and mouse genomes and subsequent database searches, other mammalian members of the interleukin-1 family (IL-1F) have been identified. One of those molecules is a homologue of IL-1ra. IL-1F5 (IL-1 δ) shows 52% amino acid homology to IL-1ra. Even though IL-1F5 is similar to IL-1ra, it is not yet known whether it behaves like IL-1ra in regulating the response of IL-1 α and IL-1 β via competitive inhibition. Along with IL-1F5, three other molecules were identified and cloned: IL-1F6 (IL-1 ϵ), IL-1F7 (IL-1 ζ), and IL-1F8 (IL-1 η). The novel genes demonstrate

significant sequence similarity to IL-1 α , IL-1 β , IL-1ra, and IL-18, and in addition they maintain a conserved intron-exon composition that is shared with the other members of the family. One of the newest members of the family is IL-1 θ (IL-1F10), which may also be an IL-1ra homologue.

Cytokines have been isolated from other vertebrates as well. The following paragraphs give a quick summation of some studies, all of which would be too numerous to describe here. For example, IL-1 α , IL-1 β , IL-4, IL-5, IL-6, IL-8, IL-10, IL-15, granulocyte/macrophage colony-stimulating factor, interferon- γ (IFN- γ), and TNF α have all been cloned and characterized from nonhuman primates [e.g., rhesus monkey (*Macaca mulatta*) and pigtailed monkey (*Macaca nemestrina*)]. These cytokines share 93 to 99% homology at the nucleic acid and protein levels with their human equivalents.

IL-1 β , IL-10, TNF α , and TNF β have been isolated from marsupials [Virginia opossum (*Trichosurus vulpecula*) and wallaby (*Macropus eugenii*)]. When compared to human and mouse amino acid sequences, identities average > 60% for both species.

IL-2, a cytokine produced by activated T lymphocytes, which is a T cell-stimulatory factor, has been cloned from beluga whale (*Delphinapterus leucas*) and gray seal (*Halichoerus grypus*) T cells. The deduced amino acid sequence of IL-2 from beluga whale shared 61–93% identity with the sequences from 12 other mammalian species and that from gray seal shared 59–88% identity with the mammalian sequences. In addition, IL-6 was cloned and sequenced from harbor seal (*Phoca vitulina*), killer whale (*Orcinus orca*), and Southern sea otter (*Enhydra lutris nereis*). When these amino acid sequences were compared with those from 10 other mammalian species, the

sequence identities ranged from 41 to 84%, 42 to 80%, and 37 to 89%, respectively.

Cytokines have been found in lower vertebrates as well. The frog (*Xenopus laevis*) IL-1 β amino acid sequence shares >35% identity with the human IL-1 β sequence. An important negative regulatory cytokine, transforming growth factor- β (TGF- β), has also been cloned from *Xenopus*. The *Xenopus* TGF- β amino acid sequence is >75% identical to its human counterpart.

In studies of lower vertebrate cytokines, the cytokines from birds and fish have been among the best characterized. The potential of avian cytokines as natural mediators and regulators of the immune response is thought to offer exciting alternatives to conventional antibiotic therapeutics. IL-1 β , IL-2, IL-15, IFN- α , IFN- β , and IFN- γ have all been cloned from chickens (*Gallus gallus domesticus*), turkeys (*Meleagris gallopava*), or ducks (*Anas platyrhynchos domesticus*). The chicken IL-1 β amino acid sequence is 25% identical to the human sequence. Surprisingly, analysis of the chicken IL-2 amino acid sequence shows that it is ancestral to both mammalian IL-2 and IL-15. This finding suggests that the chicken gene duplicated and mutated before the evolutionary separation of mammals and birds.

Fish cytokines have been extensively studied and molecularly characterized. The therapeutic use of cytokines as adjuvants in aquaculture has been driving the research. TNF α from flounder (*Paralichthys olivaceus*) and rainbow trout (*Oncorhynchus mykiss*) has been cloned. The amino acid sequence of the flounder cytokine displayed 20–35% identity with mammalian cytokines, whereas the trout sequence displayed 31–36% similarity to mammalian TNF α . Rainbow trout, carp (*Cyprinus carpio*), seabass (*Dicentrarchus labrax*), seabream (*Sparus aurata*), turbot (*Scophthalmus maximus*), and dogfish (*Scyliorhinus caniculus*) IL-1 β genes have all been characterized. In general, they all share approximately 25% amino acid sequence identity with the human gene. A second distinct IL-1 β gene has been identified in rainbow trout and carp. The significance and function of this second IL-1 β gene in fish immune responses have yet to be determined. Numerous IL-8-like molecules have also been sequenced in fish.

FUNCTIONS OF CYTOKINES IN VERTEBRATE SPECIES

Cytokines are involved in orchestrating the immune and inflammatory responses in all vertebrates

(Table II). The biological activity of an individual cytokine is almost indistinguishable when its activity is observed in any vertebrate's immune system. For example, the function of IL-1 in the human immune system is the same as it is in fish, chicken, or frog. Similarly, levels of IL-2 in stressed seals are reported to be elevated, whereas levels of IL-6 in seals with inflammatory disorders are also elevated, just as would be observed in birds, fish, or any other vertebrate animal. Cytokines are important, ancient, and functionally conserved molecules.

INVERTEBRATE CYTOKINE-LIKE MOLECULES?

Since invertebrate defense is only innate in nature, it is reasonable to assume that an IL-1-like molecule (or other pro-inflammatory cytokines) could be a part of the invertebrate immune response. Evidence of this possibility came in 1986 when an IL-1-like activity was isolated and characterized in an invertebrate (the echinoderm *Asterias forbesi*). The echinoderm IL-1-like molecule stimulated the proliferation of murine thymocytes and fibroblasts, which are standard assay systems for mammalian IL-1. In addition, an antibody to human IL-1 inhibited the activity of the echinoderm IL-1-like molecule in these assays. This finding gave credence to the hypothesis that there is an evolutionary continuity of IL-1. Other studies have shown that this result was not an isolated finding. Proteins with IL-1-like properties have been found in other invertebrates, such as tunicates, insects, and other echinoderms.

Other cytokine-like molecules have been identified in numerous invertebrates ranging from mussels (*Mytilus galloprovincialis* Lmk) to snails (*Biomphalaria glabrata*). These molecules include TNF α , IL-2, IL-6, and IL-8. All of these studies relied on functional assays that indicated a likeness to vertebrate cytokine activities. The significance and rationale of searching for cytokines that are involved in immunity in invertebrates is the assumption that these molecules will serve a similar function in the invertebrate immune response. There may be a central role for such molecules. Even though several invertebrate genomes have been sequenced, no cytokine-like proteins have been identified. The search for the gene sequences associated with these molecules continues.

Another line of evidence suggests that cytokine molecules could be found in invertebrates. The Toll receptor (TLR) proteins in *Drosophila* are involved in establishing the dorsal–ventral axis during

embryogenesis and also participate in the innate immune response. The molecule shows striking similarities in plants, invertebrates, and vertebrates. Twelve mammalian/human TLRs have thus far been described. The TLRs respond to different microbial products through a shared IL-1 receptor (IL-1R) signaling pathway. The TLRs share the IL-1R cytoplasmic signaling cascade. Both type I IL-1 receptor and TLRs are highly homologous in their cytosolic domains. This complex signaling pathway activates both the IL-1R and the Toll-like receptors in vertebrates.

Sheddases are also known to process cytokine receptors such as TNF family receptors, IL-1 receptors, and IL-6 receptor α chain. Theoretically, the importance of the regulation of cytokine activity by shedded cytokine receptors is twofold. First, sheddase inactivates receptors by removing the ligand-binding domain from the cell surface. Because this is a very quick process to inactivate receptors, this mechanism may be critical for shutting off cytokine signals. Second, soluble ligand-binding domains of receptors bind to their ligands and sequester the ligands from functioning. It has also been reported that some soluble cytokine receptors can stabilize cytokines when they are at low concentration. However, the physiological or pathological importance of the shedded cytokine receptors *in vivo* has to be elucidated further. Interestingly, the soluble binding protein for the inflammatory cytokine IL-18, IL-18-binding protein (IL-18BP), was identified. This protein is encoded by a unique gene and functions as an inhibitor for IL-18. Besides soluble receptor molecules, soluble cytokine-binding proteins can be another mechanism to regulate cytokine activities. This article summarizes the most extensively studied cytokine-processing proteases of the ADAM family and the caspase family.

CYTOKINE PROCESSING BY THE ADAM FAMILY OF PROTEASES

Sheddase for TNF Family

Identification of Sheddase of TNF Family

Phorbol ester, a well-known activator of protein kinase C, induces shedding of various cytokines, such as the TNF family, and cytokine receptors, such as TNF receptors, IL-1 receptors, and IL-2 and IL-6 receptor α chains, from the plasma membrane. Other stimuli, such as bacterial toxins and C-reactive proteins, can induce shedding of some of these proteins as well. The shedding of these proteins by PMA is inhibited by hydroxamate compounds known as inhibitors for metalloproteases. TNF α is first produced as a 26-kD, membrane-bound form. TNF α -converting enzyme (TACE) sheds membrane-bound TNF α to yield a 17-kD mature soluble form. The activity of TACE is up-regulated by PMA and inhibited by hydroxamate compounds such as TNF α protease inhibitor (TAPI), indicating that TACE belongs to the metalloprotease family. TACE was biochemically purified, and the gene encoding TACE was cloned. It encodes 824 amino acids. TACE turned out to be one of the ADAM family proteases and was designated as ADAM17.

Structure of ADAM

ADAM family proteases are also known as metalloprotease disintegrin cysteine rich (MDC). The first ADAM family member was identified as protease expressed on the sperm membrane and is crucial for the sperm-egg fusion. So far, there are 34 identified members in the mammalian ADAM family. In addition to the shedding of ectodomain of cytokines and cytokine receptors, some of the family members are involved in sperm-egg fusion, neural development, myoblast fusion, and many other developmental processes. ADAM family protease is a multidomain, type I transmembrane protein (Fig. 1). It consists of an N-terminal signal sequence, a pro-domain, a catalytic domain of metalloprotease that harbors a Zn²⁺ binding site, a disintegrin cysteine-rich region, an epidermal growth factor (EGF) repeats cysteine-rich region, a transmembrane region, and a cytoplasmic tail of variable length. The domain structures are highly preserved; however, the function of each domain needs to be elucidated.

The disintegrin and EGF repeats domains of ADAMs play some roles in cell-cell interaction. These cysteine-rich domains of ADAM1 are required for the sperm-egg binding. The same region of ADAM12 mediates adhesion and cell spreading by binding to syndecans. The disintegrin domain of sheddase, ADAM17, is partly required for the susceptibility of the metalloprotease activity to hydroxamate.

Pro-domain is processed at the amino acid sequence "RVKR" by fulin-like convertases in the trans-Golgi network. Because the pro-domain is blocking the catalytically active site, the removal of the pro-domain is necessary for ADAMs to become active metalloproteases.

The catalytic domain of some ADAMs contains a consensus sequence "HEXXHXXGXXH(D)" that is highly conserved in Zn²⁺-dependent metalloproteases. Three histidine residues in the motif are involved in binding the catalytically essential Zn ion.

Figure 1 Domain structure of the ADAM family. ADAM family protein consists of a signal peptide (SP), a pro domain (Pro), a metalloprotease catalytic domain with a Zn²⁺ binding site (Cat), a disintegrin cysteine-rich region (Disintegrin), an EGF repeats cysteine-rich region (EGF), a transmembrane domain (TM), and a cytoplasmic domain (Cyt).

Anchoring ADAM17 to the membrane is essential for this enzyme to shed various cell surface proteins. The function of the cytoplasmic tail is unknown. The cytoplasmic domain of ADAM17 is not required for shedding various substrates, including TNF α .

ADAM17-Disrupted Mice

R. A. Black and colleagues created mice harboring the deletion of the Zn²⁺-binding domain of ADAM17, thereby inactivating the metalloprotease activity. They also established immortalized fibroblast cell lines from these mutant mice. By using the mutant mice as well as the cell lines, they showed that ADAM17 is the major sheddase not only for TNF α but also for p75 tumor necrosis factor receptor (p75TNFR), IL-1 receptor-II (IL-1R-II), p66TNFR, tumor growth factor- α (TGF α), and colony-stimulating factor-1(CSF-1). The essential role of ADAM17 in development was also revealed. The majority of ADAM17 mutant mice die between embryonic day 17.5 and the first day after birth. The mutant mice show failure of eyelid fusion as well as defects in epithelial cell maturation and organization observed in skin, intestine, lung, stomach, and the airway branching. The phenotypes of eye, hair, and skin are similar to those of mice disrupted with EGFR or EGFR ligands such as EGF and TGF α , suggesting that shedding of these cytokines by ADAM17 is critical for their function in the development of skin. There are six members of the EGFR ligand: EGF, heparin-binding EGF (HB-EGF), TGF α , amphiregulin, betacellulin, and epiregulin. Presumably, ADAM17 is required for the shedding of all of those EGFR ligand proteins.

G Protein-Coupled Receptor and HB-EGF Shedding

It is well known that activators of G protein-coupled receptor (GPCR) induces transient low-level signaling through EGFR, a process termed "transactivation." Transactivation is observed in various signaling pathways of different types of cells. In the heart, vasoactive molecules such as phenylephrine (PE), angiotensin II (AngII), and endothelin-1 (ET-1) use GPCR and induce cardiac hypertrophy. The signal through GPCR activates sheddase that sheds HB-EGF, a member of the EGFR ligand family. Among the various metalloprotease inhibitors, KB-R7785 showed selectivity to HB-EGF shedding. In two-hybrid screening of the human heart cDNA library by protein kinase C- δ (PKC δ) as a bait,

ADAM12 was isolated. KB-R7785 inhibited pressure overload-induced or vasoactive molecule-induced hypertrophy in mice. Furthermore, in ADAM12-deficient mice, the shedding of HB-EGF from mouse embryonic fibroblasts was severely impaired. These results suggest that ADAM12 is a specific sheddase for HB-EGF, especially for cardiomyocyte. HB-EGF shedding activity of ADAM9 was shown by the over-expression of the wild type and mutant form of this ADAM family member *in vitro*. However, ADAM9-deficient mice did not show the impairment of the shedding of HB-EGF. The target specificity of the ADAM family *in vivo* might be regulated not only by the substrate specificity of ADAM itself but also by the association with other molecules required for the interaction with the substrates.

REGULATION OF INFLAMMATORY CYTOKINES, IL-1 β AND IL-18

Regulatory Mechanism of the Processing of IL-1 β and IL-18

Biological Activities of IL-1 β and IL-18

IL-1 β and IL-18 are two important pro-inflammatory cytokines produced by various cell types, including macrophages and dendritic cells. IL-1 β stimulates inflammatory responses such as fever, hypotension, lymphocyte activation, recruitment of leukocytes to the site of inflammation, anorexia, hypoglycemia, and induction of acute phase proteins by activating the production of pro-inflammatory cytokines, including itself, IL-6, IL-8, and TNF α . IL-18 plays an important role in inflammatory responses, especially in the induction of pro-inflammatory cytokine IFN γ and in the enhancement of T-helper subset Th1 differentiation with IL-12.

Processing of IL-1 β and IL-18

Both cytokines are produced as pro-form (31 kDa for IL-1 β and 24 kDa for IL-18) that have very weak biological activities and no signal peptides. Therefore, they are not produced in the regular secretory pathway but rather are produced in cytoplasm. Pro-form of these cytokines is converted to active form on the processing by caspase-1, also known as the IL-1 β -converting enzyme (ICE), one of the members of inflammatory caspases. Human caspases-1, -4, and -5 and mouse caspases-1, -11, and -12 are grouped as inflammatory caspases, whereas other caspases play roles in apoptosis. Caspase-11 collaborates with caspase-1 for the processing of these cytokines in mice. This has been clearly shown by the defect of the active

Figure 2 Structure of the large protein complex of inflammatory caspases caspase-1/ASC/NALP-1/caspase-5 and caspase-1/Ipaf. CARD domain, ■; caspase catalytic domain, ■; PYD domain, □; NACHT domain, ■; LRR domain, ▨; FIIND domain, ▨.

form of IL-1 β or IL-18 production in mice deficient in either caspase-1 or caspase-11. The human counterpart of mouse caspase-11 is presumably caspase-5. These caspases are produced with N-terminal pro-domain that needs to be removed for the protease activity and caspase recruitment domain (CARD) in addition to the C-terminal protease domain.

Regulation of IL-1 β and IL-18 Activities

Both IL-1 β and IL-18 are regulated at the transcriptional level. These cytokine genes are induced by the signaling pathway from IL-1Rs, TNFRs, toll-like receptors (TLR), or other inflammatory cytokine receptors. Transcription factors such as NF- κ B, IFN consensus sequence-binding protein (ICSBP), Pu.1, and AP-1 have been shown to be important for the transcriptional activation of these cytokine genes. Another mechanism for the regulation of this cytokine activity is the processing of pro-domain. Stimuli such as bacterial toxins, hypotonic stress, nigericin, antimicrobial peptides, and LPS can facilitate the processing of IL-1 β . Pro-IL-18 has been shown to be processed on bacterial or viral infection. In addition, the majority of these stimuli can induce apoptosis of the cytokine-producing cells.

The mechanism that regulates the activity of inflammatory caspases is unknown; however, those caspases are shown to form large-molecular-weight complexes (approximately 1 mDa) of multiple adaptor proteins involved in inflammatory responses (Fig. 2). These complexes of various inflammatory proteins are termed “inflammasome.” One inflammasome consists of adaptor proteins, NALP-1 (nacth, LRR, and PYD containing protein 1) and ASC (apoptosis-associated, speck-like protein containing a CARD), and two inflammatory caspases, caspase-1 and caspase-5. Both caspase-1 and caspase-5 harbor the CARD domain to interact with the CARD domain of ASC and

NALP-1, respectively, in homophilic fashion. ASC associated with caspase-1 binds to NALP-1 through the homophilic binding of the PYD (pyrin) domain. NALP-1 self-associates and presumably forms a multisubunit complex with caspase-1 and caspase-5. Caspase-1 associates with another adaptor protein, Ipaf (ICE protease-activating factor/CARD12), by the homophilic interaction of the CARD domain. The activation mechanism of pro-apoptotic caspase, caspase-9, has been proposed. Cytochrome C released from mitochondria induces the assembly of adaptor protein, Apaf-1 (apoptotic protease-activating factor-1), to form apoptosome. Then, pro-caspase-9 binds to each Apaf-1 through the homophilic interaction of the CARD domain, resulting in the multimerization of pro-caspase-9. This assembly of pro-caspase-9 leads to the intermolecular processing and activation. This model might be applicable to the caspase-1 combined with Ipaf or NALP-1, pycard, and caspase-5. However, the ligand equivalent to cytochrome C for the inflammasome has not yet been identified.

Proteins carrying only the CARD domain, pseudo-ICE or ICEBER, inhibit caspase-1 activation by blocking the assembly of caspases with adaptor protein complex through the CARD–CARD interaction. In addition, activated inflammatory caspases are released from cells rapidly. This could be the mechanism to cease continuous activation of the inflammatory cytokines. Activation of inflammatory cytokines could be very harmful to the host; thus, the activity must be strictly regulated.

IL-18-Binding Protein

Besides the shedded cytokine receptors, cytokine-binding protein has been reported. IL-18-binding protein (IL-18BP) was identified from both mouse and human. IL-18BP carries signal peptide but no

transmembrane domain. Its molecular weight is approximately 40 kDa. It binds to IL-18 and prevents it from binding to the receptor. Thus, this protein can inhibit the IL-18-dependent IFN γ production both *in vitro* and *in vivo*. Administration of IL-18BP into mice ameliorates colitis in the mouse model. However in patients with Crohn's disease, both IL-18 and IL-18BP are increased in the intestinal tissue. Its physiological and pathological functions need to be further elucidated. A creation of gene-targeted mice is especially necessary. A search for such binding proteins for other cytokines is also required.

or developmental defects of the hypothalamus or by destructive lesions such as tumors, inflammatory processes, vascular lesion, and trauma. Usually, patients with isolated gonadotropin deficiency have normal height for their age during the prepubertal period, in contrast to patients with constitutional delay, who are short. In hypogonadotropic hypogonadism, gonadotropin responses to GnRH stimulation may be subnormal, but because of the functional hypogonadotropism in constitutional delay, the differential diagnosis between these two conditions may be difficult.

Temporary Gonadotropin Deficiencies

Anorexia Nervosa

Anorexia nervosa is usually associated with severe or even fatal weight loss, which is due to distorted body image, obsessive fear of obesity, and avoidance of food. Virtually all patients have primary or secondary amenorrhea. Functional hypogonadotropic hypogonadism is at least partly due to severe weight loss, but amenorrhea may also precede the onset of weight loss. The underlying pathophysiology of amenorrhea is due to GnRH deficiency because the luteinizing hormone (LH) secretory pattern in pubertal-aged girls with anorexia is similar to that seen in girls during prepuberty: low or absent LH pulses and blunted LH response to exogenous GnRH. Pulsatile administration of GnRH has been shown to restore a pubertal pattern of LH secretion, confirming the hypothalamic location of the defect. Recovery of normal weight will normalize most endocrine and metabolic functions, but amenorrhea may persist for years.

Athletic Training

Overly intensive exercise may inhibit GnRH secretion, arrest pubertal development, and cause amenorrhea. These disorders are common especially among long-distance runners, gymnasts, and ballerinas. Hypogonadotropic hypogonadism may develop even when the female athletes have normal weight but have less fat and more muscle than do nonathletic girls. In female athletes with delayed or arrested pubertal development, adrenarche usually takes place at the normal age. The mechanism of delayed puberty is unclear, but interruption of intensive training advances puberty and menarche before any change in body composition or weight, suggesting a direct effect physical activity on GnRH secretion.

Malnutrition and Chronic Diseases

In malnutrition and chronic diseases, weight loss below the level of 80% of ideal body weight can cause delayed or arrested pubertal development. Nutrition plays an important yet uncharacterized role in the control of GnRH secretions. For example, in regional enteritis, gonadotropin secretion remains normal if nutrition is optimally balanced, but a non-optimal nutritional status will result in a hypogonadotropic state and arrested pubertal maturation. Chronic renal insufficiency delays pubertal development, but after successful renal transplantation, gonadotropin secretion is usually restored.

Central Nervous System Tumors

Tumors causing delayed puberty most commonly interfere with GnRH synthesis or secretion. Deficiency of other pituitary hormones is common. Associated posterior pituitary hormone deficiencies are often manifested by diabetes insipidus.

Craniopharyngioma

The most common neoplasm causing hypothalamic-pituitary dysfunction and hypogonadotropic hypogonadism is craniopharyngioma. It is actually a congenital tumor that most commonly becomes symptomatic between 6 and 14 years of age. At presentation, the most common symptoms are headache, visual disturbances, short stature, delayed puberty, polyuria, and polydipsia. Skull radiographs may show suprasellar or intrasellar calcification or an abnormality in sella turcica. CT scans may reveal fine calcifications that are not apparent on routine skull radiographs. The structure of the tumor varies from solid to cystic. Treatment consists of surgery and radiotherapy, but the recurrence rate is high even when complete surgical removal is attempted.

Langerhans' Cell Histiocytosis

Langerhans' cell histiocytosis (LCH), also called Hand-Schüller-Christian disease or histiocytosis X, is characterized by infiltration of lipid-containing histiocytic cells in the skin, bone, and viscera. Cyst-like areas can be found in flat bones of the skull, pelvis, dorsolumbar spine, scapula, and long bones of the arms and legs by X ray. CNS involvement and, in particular, hypothalamic-pituitary involvement are well-described features of LCH. The precise incidence of CNS-LCH disease is unknown, and the natural history is poorly understood. Diabetes insipidus (DI) is reported to be the most common and

well-described manifestation of hypothalamic–pituitary involvement (up to 50%). Anterior pituitary dysfunction has been reported in up to 20% of patients with LCH and occurs almost exclusively concurrently with DI. Although histiocytosis is not a tumor, it can be treated with chemotherapeutic agents, especially vinblastine. However, the natural course of the disease is fluctuating, making evaluation of treatment effect difficult. Endocrine function is not improved following medical treatment of LCH with chemotherapy and glucocorticoids. All LCH patients should undergo a thorough endocrine evaluation periodically.

Germinomas

Germinomas are the extrasellar tumors that often cause delayed puberty, although these tumors are a rarity among primary CNS tumors. Polydipsia, polyuria, and visual disturbances are the most common symptoms associated with these tumors, followed by arrested growth and delayed puberty. Germinomas are commonly located in the pituitary stalk, in the suprasellar region of the hypothalamus, or in the proximity of the pineal gland. Seeding of the tumor to the cerebrospinal fluid is common, and this can also be used in the diagnosis, where examination of tumor markers (hCG β and alphafetoprotein) or germ cells (with positive placental alkaline phosphatase staining) in the cerebrospinal fluid may be helpful. These laboratory findings, together with clinical features and an excellent response to radiation therapy, are so characteristic that surgery is rarely indicated except for biopsy to establish histological diagnosis.

Other Central Nervous System Disorders

Defects in Development

Various malformations affecting the development of the prosencephalon may cause hypogonadotropic hypogonadism combined with deficiency of any or all other pituitary hormones. Midline malformations are often associated with optic dysplasia, and absent septum pellucidum is often found by imaging techniques (septo-optic dysplasia). Other congenital midline defects, which may range from holoprosencephaly to cleft lip and palate, may also be associated with variable hypothalamic–pituitary dysfunction.

Genetic defects affect development of the anterior pituitary cause hypopituitarism, including hypogonadotropic hypogonadism in some cases. During fetal development of the anterior pituitary gland, a number

of sequential processes occur that affect cell differentiation and proliferation. Recent advances in molecular biology have revealed several steps that are required for pituitary cell line specification, and several genes have been identified to play a role in control of these steps. Mutations in the DAX-1 gene cause X-linked adrenal hypoplasia congenita and mutations in the DAX-1-related orphan nuclear receptor, steroidogenic factor-1, and leptin and prohormone convertase-1 may influence GnRH release and processing of the GnRH receptor. The pituitary transcription factors, HESX-1, LHX-3, and PROP-1, are important for the development of gonadotropin-secreting cells. Depending on the condition, different approaches for counseling are needed. Despite recent advances, the pathophysiological basis of hypogonadotropic hypogonadism in the majority of individuals remains unclear. Recently, compound heterozygote mutations in the GnRH receptor gene were described in both males and females, and hormonal resistance was confirmed *in vitro*.

Because of different causes, there is a wide spectrum of phenotypes, ranging from complete hypogonadotropic hypogonadism with lack of pubertal development to a partial hypogonadism with an arrest of pubertal development. In complete GnRH resistance, endogenous LH secretory patterns are abnormal, either apulsatile or characterized by a low to normal pulse frequency with small pulses or erratic pulses of low amplitude. In patients with partial resistance, basal LH plasma concentrations are low, but follicle-stimulating hormone (FSH) levels are in the normal range.

Kallmann Syndrome

Kallmann syndrome is the most common form of isolated hypogonadotropic hypogonadism. Hypogonadism is due to GnRH deficiency, and the other components of the syndrome include anosmia or hyposmia due to hypoplasia of the olfactory lobes and occasionally cleft lip and palate, unilateral renal agenesis, short metacarpals, sensorineural hearing loss, and color-blindness. About half of Kallmann syndrome patients have mutations in the KAL gene on chromosome Xp22.3. This gene encodes an extracellular matrix protein that regulates axonal path finding and cellular adhesion. Defect in this gene causes failure of fetal GnRH neurosecretory neurons to migrate from the olfactory placode to the medio–basal hypothalamus, causing hypoplasia of the olfactory sulci. Autosomal disorders (dominant or recessive) may also cause Kallmann syndrome, but the gene defects of the forms have not yet been characterized.

Because about half of the patients have X-linked disorder, the syndrome is more common in boys than in girls.

Iatrogenic Gonadotropin Deficiencies

Treatment of CNS tumors, leukemia, or neoplasms with cranial irradiation may result in gradual development of hypothalamic–pituitary failure. GH deficiency is the most common component of the radiation-induced hormone disorder, but gonadotropin deficiency also occurs when the radiation dose is high enough. Development of radiation-induced hypothalamic–pituitary failure usually takes from 1 year to several years to develop.

HYPERGONADOTROPIC HYPOGONADISM

Gonadal Dysgenesis Syndromes

Turner Syndrome

The syndrome of gonadal dysgenesis (Turner syndrome) is the most common form of hypergonadotropic hypogonadism, affecting about 1 in 2500 live-born girls. About half of girls with Turner syndrome have the 45,X karyotype, but about 99% of fetuses with this karyotype abort spontaneously, and in 1 of 15 spontaneous abortions the fetus has the 45,X karyotype. Turner syndrome may be regarded as a continuum ranging from the typical 45,X phenotype to a normal male or female phenotype. Chromosomal mosaicism and structural abnormalities of the sex chromosomes modify the clinical features. Typical features include short stature (which may be apparent already at birth), lymphedema of the extremities and loose posterior cervical skinfolds during the newborn period, low-set or deformed ears, epicanthal folds, ptosis, micrognathia, high arched palate, dental abnormalities, wide-spaced nipples caused by shield-like chest, hypoplastic areolae, short neck with low hairline, and cubitus valgus. Abnormalities of the left side of the heart include coarctation of the aorta, aortic stenosis, and bicuspid aortic valves. Renal anomalies include abnormal position or alignment (horseshoe kidney) and various anomalies on the collecting system. Patients with Turner syndrome have increased incidence of inflammatory bowel disease, autoimmune thyroiditis, Graves' disease, and insulin resistance. Intelligence is usually normal, but spatiotemporal processing, visuomotor coordination, and mathematical skills performance may be impaired.

Ovarian insufficiency is also apparent at birth, as evidenced by high gonadotropin concentrations during the neonatal period. During childhood, with the development of the CNS-mediated inhibition of GnRH secretion, gonadotropin levels decrease to near normal levels, but by 10 years of age they usually are elevated again. The Müllerian structure (uterus and fallopian tubes) is present but remains infantile if the ovarian failure is not adequately treated with hormone replacement therapy. Histologically, the ovaries are streaks of connective tissue, with a decreased number of primordial follicles and oocytes for age. Spontaneous oocyte death is accelerated, resulting in complete loss of the oocyte pool in most cases.

Sexual infantilism is one of the most common clinical findings in girls with Turner syndrome. More than 90% have gonadal failure. It is important to remember, however, that up to 30% of girls will undergo spontaneous pubertal development and that 2 to 5% will have spontaneous menses and may have the potential to achieve pregnancy without medical intervention. Pubertal development may be delayed and, in most patients, is followed by progressive ovarian failure.

Most patients are small for their gestational age at birth, and the slow growth rate is apparent after 3 years of age. Most girls fail to have a pubertal growth spurt due to insufficient estrogen production in the ovaries. The mean adult height is approximately 143 to 146 cm, depending on both parental heights and the overall height of the same genetic population.

Pure Gonadal Dysgenesis

The term “pure gonadal dysgenesis” refers to phenotypic females with no pubertal development and the 46,XX or 46,XY karyotype without detectable chromosomal abnormalities. Patients with 46,XX gonadal dysgenesis have normal stature, bilateral streak gonads, normal female internal and external genitalia, and (sometimes) sensorineural deafness. Malignant transformation of the streak gonad is rare. Most cases are sporadic, but autosomal-recessive form has also been described. Patients with familial or sporadic 46,XY gonadal dysgenesis have normal female internal and external genitalia with occasional clitoral enlargement due to increased testosterone production by the gonad, bilateral streak gonads, and normal or tall stature with eunuchoid body proportions. The dysgenetic gonads may undergo neoplastic transformation, so gonadectomy is indicated.

Other Causes of Primary Ovarian Failure

Irradiation and Chemotherapies

Damage to the gonads by irradiation or chemotherapy depends on the patient's gender, age at the time of treatment, radiation dose and fractionation schedule, and total dose and nature of chemotherapy delivered. Most chemotherapy protocols use multiple agents whose effects may be synergistic. Biochemical detection of gonadal damage is rarely possible before puberty, so treatment-induced gonadal damage during childhood may present with infertility or premature menopause during adulthood. Abdominal, pelvic, and total body irradiation may result in ovarian and uterine damage. The human oocyte is sensitive to radiation, with an estimated LD50 of less than 4 Gy. Less than 2% of children receiving total body irradiation subsequently became pregnant, although there may be some protection of ovarian function in prepubertal girls. Uterine radiation increases the incidence of nulliparity, fetal loss, and small-for-dates infants, and it reduces the success of assisted reproduction. Suppression of the pituitary–gonadal axis with gonadal steroids or GnRH agonists does not protect the ovary from the damage induced by irradiation or chemotherapy.

Hypergonadotropic Ovarian Failure

Hypergonadotropic ovarian failure, also termed the “resistant ovary syndrome,” is a heterogeneous disorder with unknown etiology in most cases. Approximately 40% of patients have a point mutation, causing a single amino acid substitution in the extracellular domain of the FSH receptor and subsequent inactivation of the receptor function. Patients with and without the receptor mutation have amenorrhea with variable development of secondary sex characteristics and have high serum levels of gonadotropins. Histological examinations of ovary biopsies show the presence of follicles in all patients with the receptor defect, whereas only 1 in 4 of those with unknown etiology has follicles. Hence, whereas the receptor defect causes a specific arrest in follicular maturation, most patients with hypergonadotropic ovarian failure have true ovarian dysgenesis. The ovarian phenotype in patients with inactivating FSH receptor mutation is informative in regard to the role of FSH in the regulation of follicular development: the early phases of follicular maturation (up to the preantral stage) are independent of FSH, but for the final maturation of the follicle, this gonadotropin is absolutely necessary.

Autoimmune Ovarian Failure

Autoimmune ovarian failure is often one of the components of autoimmune polyendocrinopathies. Autoimmune polyglandular syndrome type I is an autosomal recessive disorder caused by mutation in the autoimmune regulator (AIRE) gene, which maps to 21q22.3. It is characterized by two of the three major clinical symptoms that may be present: Addison disease, hypoparathyroidism, and chronic mucocutaneous candidiasis. Moniliasis often precedes symptoms and signs of endocrinopathy. Furthermore, hypoparathyroidism usually reveals itself before adrenal insufficiency.

Ahonen and colleagues reported data from a 10-month to 31-year follow-up of 68 patients from 54 families, ages 10 months to 53 years at the time of report. Hypoplasia of the dental enamel and keratopathy were frequent and were not attributable to hypoparathyroidism. Some of the manifestations of the disorder did not appear until the fifth decade. Thus, all patients need lifelong follow-up for the detection of new components of the disease. Candidiasis was the initial manifestation in 60% of the patients and was present in all patients at some time. Hypoparathyroidism was present in 79%, adrenocortical failure in 72%, and gonadal failure in 60% of female patients over 13 years of age.

DIAGNOSIS

The cutoff age for identifying girls who need evaluation for delayed puberty may vary in different ethnic groups, but in most populations early signs of secondary sexual development should be present by 13 years of age.

A thorough history should note the signs of anorexia, the intensity of athletic training, and the timing of puberty of both parents (Fig. 1). In constitutional delay of puberty, often either one of the parents developed late. A history of chronic illnesses, such as celiac disease and inflammatory bowel disease, will suggest a temporary or secondary delay of puberty. Stature and height velocity should be evaluated using appropriate growth charts. Height velocity is usually slow in patients with constitutional delay and is usually normal in patients with hypogonadotropic hypogonadism, but especially hypogonadotropic states cannot be ruled out by short stature and slow growth rate. Likewise, bone age (X-ray film of left hand and wrist read according to standards such as Greulich and Pyle) delay provides useful information

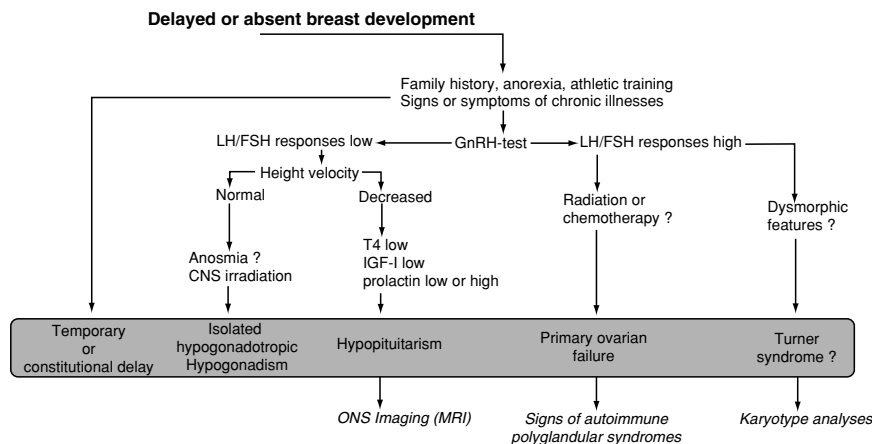

Figure 1 Differential diagnosis of delayed puberty.

in the growth analysis, but it contributes little to the differential diagnosis.

Gonadotropin levels assessed by a single basal LH and FSH determination are often increased in primary ovarian failure or in Turner syndrome, but the basal gonadotropin values are not useful in the differential diagnosis of constitutional delay and hypogonadotropic hypogonadism. Dynamic testing, such as administration of synthetic GnRH, may provide information for the differential diagnosis. In some girls with constitutional delay, a pubertal pattern of response (post-GnRH maximum LH higher than maximum FSH) may be observed, but a low prepubertal response to GnRH can be found in some girls with constitutional delay and typically in hypogonadotropic hypogonadism. Follow-up is often warranted before a definitive diagnosis can be made.

MANAGEMENT OF DELAYED PUBERTY

When estrogen therapy is required to induce pubertal development, the dosing and timing should be aimed at mimicking normal pubertal development, taking account of the individual's desire to begin puberty and also of the family history of age at onset of puberty. Doses should be adjusted to the responses of individual patients, who may be monitored in terms of the development of secondary sex characteristics, bone maturation, and/or uterine volume.

In hypopituitary girls and in girls with Turner syndrome, estrogen therapy should be coordinated with the use of GH. This should be individualized for each patient to optimize both growth and pubertal development. When growth promotion is a priority,

consideration should be given to delaying estrogen therapy to avoid compromising final height.

Before initiation of estrogen therapy in girls with Turner syndrome, serum gonadotropin levels should be determined to exclude the possibility of delayed spontaneous pubertal development. If gonadotropin levels are normal, a sonographic examination should be undertaken to determine the status of the gonads. Hormonal induction of feminization should be initiated and carried out in a manner that simulates the normal growth and development of secondary sex characteristics as closely as possible. Estrogen therapy needs to be initiated and adjusted according to the needs and priorities of the individual. Thus, if growth promotion is a priority, estrogen therapy should not be initiated before 12 years of age unless height has already been maximized. In girls with Turner syndrome, estrogen therapy should ideally be started by 15 years of age. Estrogen therapy should be initiated at a low dose (one-sixth to one-quarter of the adult dose) and increased gradually (at intervals of 3–6 months). Doses can then be adjusted to the response (Tanner stage, bone age, or uterine growth), with the aim of completing feminization gradually over a period of 2 to 3 years.

A progestin such as medroxyprogesterone should be added either when vaginal bleeding first occurs or after 12 to 24 months of estrogen therapy to establish monthly menstrual cycles.

Individuals with Turner syndrome who have functioning ovaries and who progress through puberty spontaneously should receive contraceptive and genetic counseling. However, ovulatory function should be documented (FSH and LH measurements) because a perimenopausal pattern of anovulation can lead to endometrial hyperplasia.

reflecting maturation of the hypothalamic–pituitary system. Alternatively, an 8 AM serum testosterone value of 0.7 nmol/liter (20 ng/dl) heralds the development of puberty in boys within 12–15 months according to one study. However, although these indicators are helpful, no single test reliably distinguishes a constitutional delay in growth and puberty from hypogonadotropic hypogonadism. All indices in constitutional delay before the onset of puberty are identical to endocrine measurements in a child of the same delayed skeletal age, which are, in turn, similar to those found in hypogonadotropic hypogonadism.

Growth rate before the physical changes of the onset of puberty in these boys is often suboptimal for chronological age but growth velocity usually increases to normal levels after puberty begins. Growth hormone (GH) release to GH secretagogues may be decreased in children with constitutional delay before puberty begins although the amplitude of GH secretion and the GH response to GH-releasing hormone increase after the administration of exogenous aromatizable androgens or estrogens or after the onset of puberty. Thus, affected boys have functional, temporary GH insufficiency for chronological age but not for bone age; this does not constitute a rationale for

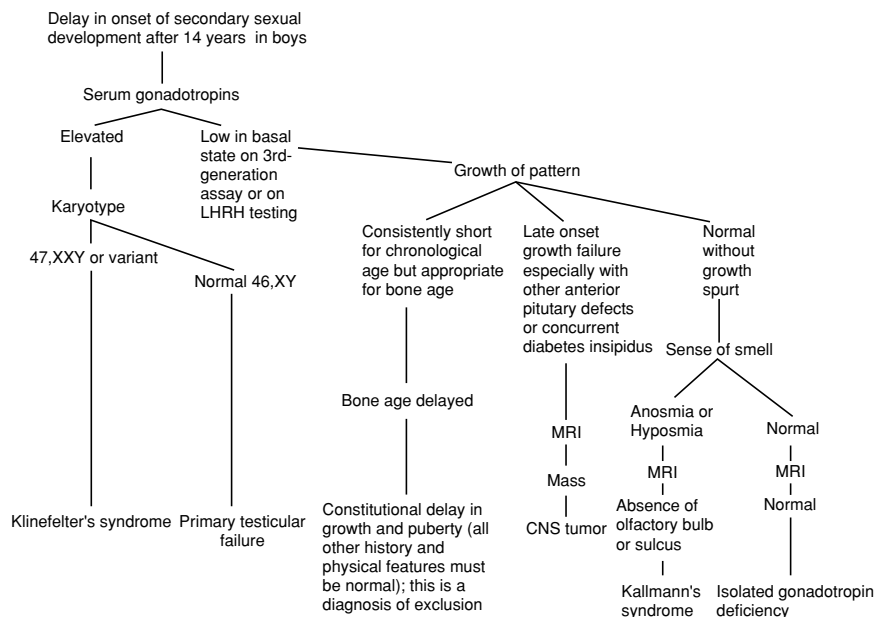

Figure 1 The diagnosis of delayed puberty. Modified from Grumbach, M. M., and Styne, D. M. (2003).

treatment of constitutional delay with growth hormone, as growth hormone therapy does not improve adult height in customary constitutional delay although it may increase growth rate.

The discovery of the critical role of estradiol in skeletal maturation in boys as well as girls led to the suggestion that in boys with constitutional delayed growth and puberty, treatment with an aromatase inhibitor would improve adult height by inhibiting skeletal maturation. In a double-blind, randomized, placebo-controlled study, this proved to be true, suggesting future possibilities for such a plan.

Normal volumetric (but not areal) bone density is described in young men previously affected by constitutional delay in contrast to the decreased peak bone mass due to hypergonadotropic or hypogonadotropic hypogonadism.

HYPOGONADOTROPIC HYPOGONADISM

Gonadotropin deficiency is due to insufficient pulsatile secretion of LHRH and the resulting follicle-stimulating hormone (FSH) and LH deficiencies lead to delayed sexual maturation. The magnitude of the LHRH deficiency may be quantitative—either absolute or relative—or qualitative; it may involve abnormalities in the amplitude or frequency of LHRH pulses or in both components and hence the phenotype

can vary from severe sexual infantilism to instances in which the separation from constitutional delay of puberty is difficult. LHRH deficiency may be congenital or acquired. With associated GH deficiency, decreased growth velocity, especially during the expected pubertal growth spurt, and short stature result. Patients with isolated FSH and LH deficiencies are usually of normal height for age by the middle adolescent years, in contrast to boys with constitutional delay in puberty who are usually short for chronological age throughout their growing period.

Central Nervous System Disorders

Central nervous system (CNS) disorders, including tumors that cause delayed puberty, are usually extra-sellar masses that interfere with LHRH synthesis, secretion, or stimulation of pituitary gonadotropes. Most of these classes of patients with gonadotropin deficiency also have a deficiency of one or more additional pituitary hormones (or an increased concentration of plasma prolactin) and those with GH deficiency have a late onset of growth failure compared with congenital hypopituitarism where there is growth failure early in life. The presence of both anterior and posterior pituitary deficiencies developing after infancy suggests an expanding lesion, whereas this combination manifesting in infancy suggests a midline developmental defect.

Craniopharyngioma

Craniopharyngioma is the most common brain neoplasm associated with hypothalamic–pituitary dysfunction and sexual infantilism; symptoms usually arise before the age of 20 years and the peak incidence occurs between the ages of 6 and 14 years. This tumor of Rathke's pouch originates from epithelial rests along the pituitary stalk that extend superiorly to the hypothalamus; craniopharyngiomas stay within the sella turcica or, more rarely, may be found in the nasopharynx and CNS. Signs develop as the tumor encroaches on surrounding structures. Symptoms include headache, visual disturbances, short stature, polyuria and polydipsia of diabetes insipidus, and weakness of one or more limbs. Signs include visual defects (including bilateral temporal field deficits), optic atrophy or papilledema, and the poor growth of GH deficiency, delayed puberty, and hypothyroidism. Most subjects are already below the mean in height and height velocity at the time of diagnosis. Laboratory findings include deficiencies in one or more anterior and posterior pituitary hormones. The plasma concentration of prolactin may be normal or increased. Bone age is usually delayed. Approximately 70% of patients with craniopharyngioma have an abnormal sella as well as suprasellar or intrasellar calcification and less than 1% of normal individuals have such calcification. Computed tomographic (CT) scans [but not magnetic resonance imaging (MRI) scans] reveal fine calcifications that are not apparent on routine roentgenograms, and CT or MRI scans with contrast (the diagnostic procedure of choice) can determine whether the tumor is cystic or solid and indicate the presence of hydrocephalus.

Smaller, intrasellar craniopharyngiomas can be resected or decompressed by transsphenoidal microsurgery, but larger or suprasellar masses usually require craniotomy. The recurrence rate is high for complete surgical removal. The combination of limited tumor removal and radiation therapy leads to at least as satisfactory a neurological prognosis and better cognitive outcome as attempts at complete surgical extirpation and to a better endocrinological outcome. Virtually all subjects with radical removal of craniopharyngioma require replacement with gonadal steroids and growth hormone. Postoperative hyperphagia and obesity may develop and correlate with the magnitude of the hypothalamic damage, probably due to injury to the hypothalamic ventromedial nuclei (associated with increased parasympathetic activity and hyperinsulinemia) and/or the paraventricular nuclei.

Rathke-Cleft Cyst

A Rathke-cleft cyst can produce symptoms and signs indistinguishable from those of a craniopharyngioma but the usual treatment for this condition is surgical drainage and excision of the cyst wall.

Other Extrasellar Tumors

Other extrasellar tumors may cause other extrasellar tumors that arise in or encroach on the hypothalamus.

Germinomas

Germinomas (previously termed pinealomas, ectopic pinealomas, atypical teratomas, or dysgerminomas) or other germ cell tumors of the CNS are the extrasellar tumors that most commonly cause sexual infantilism, although these are rare considering all primary CNS tumors. They usually present during the second decade and polydipsia and polyuria are among the most common symptoms, followed by visual difficulties and abnormalities in growth and puberty. The most common endocrine deficiencies involve vasopressin and GH, but other anterior pituitary hormone deficiencies (including gonadotropin deficiency) and elevated serum prolactin levels are frequent. These germ cell tumors secrete human chorionic gonadotropin (hCG), as well as α -fetoprotein, into spinal fluid and serum. Germ cell tumors in boys may delay puberty or may cause isosexual precocity by secretion of hCG, which stimulates the Leydig cells of the testes.

A germ cell tumor may arise in the suprasellar hypothalamic region, in the pineal region, or in another area of the CNS. Subependymal spread along the lining of the third ventricle is common and seeding may lead to involvement of the lower spinal cord and *corda equina*. MRI scans with contrast enhancement are useful in the diagnosis of tumors more than 0.5 cm in diameter and for the detection of isolated enlargement of the pituitary stalk, an early finding on MRI scans, which must periodically be monitored by MRI for further development of a tumor. Although the pituitary gland increases 100% in size between year 1 and 15, the pineal gland does not change after age 1; any enlargement after 1 year should indicate suspicion of a mass lesion. Pure germ cell tumors (germinomas) are radiosensitive and radiation is the preferred treatment; the clinical features and the response to radiation therapy are so characteristic that surgery is usually indicated only for biopsy to establish a tissue diagnosis. However, a mixed germ cell tumor may require both radiation therapy and chemotherapy.

Hypothalamic and Optic Gliomas or Astrocytomas

Hypothalamic and optic gliomas or astrocytomas may cause sexual infantilism as a component of neurofibromatosis (von Recklinghausen's disease) or independently.

Pituitary Tumors

Only 2–6% of all pituitary adenomas occur in childhood and adolescence. Most pituitary adenomas occurring before adulthood are prolactinomas, with GH-secreting adenomas and chromophobe adenomas being the next most common. Hyperprolactinemia due to micro- or macroprolactinomas of the pituitary is uncommon in childhood and adolescence and is a rare cause of delayed puberty in both boys and girls, although removal or diminution of the tumor allows resumption of pubertal development. Galactorrhea may be absent by history but it is often demonstrable by manual manipulation of the nipples (serum prolactin rises after manipulation of the nipples, so samples should be obtained before examination or many hours later). Transsphenoidal resection of microprolactinomas in children and adolescents is an effective treatment. The dopamine agonist bromergocryptine can decrease serum prolactin concentrations and decrease the size of the tumors; this may be used when resection of the adenoma is incomplete or to reduce the size of the tumor in large macroprolactinomas before attempted surgical removal.

Other CNS Disorders Leading to Delayed Puberty*Langerhans' Cell Histiocytosis*

Langerhans' cell histiocytosis (Hand-Schüller-Christian disease, or histiocytosis X) is a clonal proliferative disorder of Langerhans' histiocytes or their precursors and is characterized by the infiltration of lipid-laden histiocytic cells or foam cells in the skin, viscera, and bone. Diabetes insipidus usually results from infiltration of the hypothalamus and/or the pituitary stalk and is the most common endocrine manifestation, although GH deficiency and delayed puberty may occur. There may be visceral involvement including the lung, liver, and spleen and cyst-like areas in flat bones of the skull, the ribs, the pelvis, and the scapula, in the long bones of the arms and legs, and in the dorsolumbar spine. Lesions of the mandible lead to the radiographic impression of "floating teeth" within rarefied bone and the clinical finding of absent or loose teeth. Infiltration of the orbit may lead to exophthalmos, and mastoid or temporal bone involvement may lead to chronic otitis media. Treatment with glucocorticoids, anti-neoplas-

tic agents, and radiation is promising in terms of survival but more than 50% of patients have late sequelae or progression and the natural waxing and waning course of this disease makes evaluation of therapy difficult.

Postinfectious Inflammatory Lesions of the CNS, Vascular Abnormalities, and Head Trauma

Postinfectious inflammatory lesions of the CNS, vascular abnormalities, and head trauma rarely cause hypogonadotropic hypogonadism. Tuberculous or sarcoid granulomas of the CNS are the rare causes. When hydrocephalus or a subarachnoid cyst causes delayed puberty, decompression will often reverse this result.

Radiation of the Head

Treatment of CNS tumors, leukemia, or neoplasms of the head and the face may result in the gradual onset of hypothalamic-pituitary failure. GH deficiency is the most common but gonadotropin deficiency also occurs. Decreased growth due to GH deficiency with precocious puberty can lead to a decrease in the final height of children with acute lymphocytic leukemia treated with CNS radiation.

Developmental Defects

Developmental defects, mainly midline malformations of the head and the CNS, cause a variety of endocrine deficiencies. Septo-optic dysplasia or optic dysplasia is due to abnormal development of the prosencephalon with the optic nerve usually affected, leading to small, dysplastic, pale optic discs, pendular (evenly moving side to side) nystagmus, and possibly blindness. There may be GH deficiency and diabetes insipidus as well as adrenocorticotrophic hormone (ACTH), thyroid-stimulating hormone (TSH), and gonadotropin deficiencies. Short stature and delayed puberty may result, although true precocious puberty is an alternative outcome. The septum pellucidum is often absent in association with optic hypoplasia or dysplasia, leading to septo-optic dysplasia. The pituitary gland may be hypoplastic and some patients may have an ectopic location of the neurohypophysis on MRI. A mutation in the HESX1 is a rare cause of septo-optic dysplasia.

Other developmental defects of the anterior pituitary gland are caused by mutations in encoding transcription factors involved in the early aspects of pituitary development. Mutations in the LHX3 and PROP-1 homeobox genes may cause autosomal-recessive hypogonadotropic hypogonadism and other pituitary hormone deficiencies. PROP-1 mutations cause GH and TSH deficiencies but may be associated

with delayed puberty or the late onset of secondary hypogonadism in adulthood and may also cause ACTH deficiency. Other congenital midline defects ranging from complete dysraphism and holoprosencephaly to cleft palate or lip are also associated with hypothalamic–pituitary dysfunction. Homozygous mutations in the *LHX3* gene are associated with multiple pituitary hormone deficiencies including LH and FSH and severe restriction of head rotation.

Individuals with myelomeningocele (myelodysplasia) have an increased frequency of endocrine abnormalities, including hypothalamic hypothyroidism, hyperprolactinemia, and elevated gonadotropin concentrations, whereas some patients demonstrate true precocious puberty.

Isolated Gonadotropin Deficiency

Isolated gonadotropin deficiency is due to a defect in the hypothalamus involving the LHRH pulse generator and/or the pituitary gonadotropes without an anatomic lesion. Puberty is delayed or pubertal maturation is incomplete. The testes, if palpable, are small and the concentration of serum inhibin B, an estimate of seminiferous tubule function, is low. Micropenis or undescended testes or both signs are evidence of a fetal testosterone deficiency.

Isolated gonadotropin deficiency may be sporadic or occur in families in an autosomal-dominant, autosomal-recessive, or X-linked recessive pattern. Whereas patients with CNS tumors usually have associated GH deficiency and growth failure, and those with constitutional delay in growth and adolescence are short for chronological age, patients with isolated gonadotropin deficiency are usually of appropriate height for their age. Due to delayed bone age and epiphyseal fusion, these patients develop increased arm span for height and decreased upper/lower ratios (eunuchoid body proportions) and usually become tall adults.

Kallmann's Syndrome

Kallmann's syndrome is the most common form of isolated hypogonadotropic hypogonadism with delayed puberty, in which anosmia or hyposmia resulting from agenesis or hypoplasia of the olfactory lobes and/or sulci is associated with LHRH deficiency. Affected individuals may not notice impaired olfaction; testing with graded dilutions of pure scents is useful to discriminate the magnitude of the deficit. Undescended testes and gynecomastia are common

in this and all types of hypogonadotropic hypogonadism in boys. Approximately one-half of males with Kallmann's syndrome are born with a micropenis. Associated defects inconstantly present are cleft lip and/or palate, imperfect facial fusion, seizure disorders, short metacarpals, pes cavus, neurosensory hearing loss, cerebellar ataxia and nystagmus, ocular motor abnormalities, and, limited to the X-linked form, unilateral, or rarely bilateral, renal aplasia or dysplasia and mirror movements of the upper extremities (synkinesia). All of these structures and organs are sites of expression of the *KAL* gene in the human fetus.

There may be bilateral agenesis of the olfactory bulbs on coronal and axial cranial MRI scans and absent or abnormal olfactory sulci bilaterally. Over 90% of those with Kallmann's syndrome have an abnormal cranial MRI. Kallmann's syndrome can be transmitted as an X-linked, autosomal-dominant, or autosomal-recessive trait. The majority of cases of Kallmann's syndrome do not have mutations in the *KAL* gene on the X chromosome, but these cases are more likely to have a complete absence of gonadotropin secretion pulses and have an absence of migration of GnRH neurons to the hypothalamus.

The Xp22.3 locus is the site of the *KAL-1* gene, an X-linked gene that escapes X inactivation and encodes a glycoprotein, termed anosmin-1, with characteristics of an extracellular neural adhesion molecule, which could function as a pathfinder in the guidance of LHRH neurons from the olfactory placode of the fetus to the medial basal hypothalamus. A variety of deletions and mutations of the *KAL* gene have been described including large and small (exon) deletions, point mutations, and a variety of nonsense mutations leading to frameshift and premature stop codons. Contiguous gene deletions in this region of the X chromosome can lead to an association of Kallmann's syndrome with X-linked ichthyosis caused by steroid sulfatase deficiency, mental retardation, and chondroplasia punctata. The fetal LHRH-containing cells and neurites are arrested in their migration to the brain and end in a tangle around the cribiform plate and in the dural layers adjacent to the meninges beneath the forebrain.

Hypogonadotropic hypogonadism may be transmitted by autosomal-recessive inheritance with none of the other features of Kallmann's syndrome. Males with cerebellar ataxia and deficient gonadotropin production have been reported in kindreds with X-linked inheritance (possibly a variant form of Kallmann's syndrome) and hypogonadotropic hypogonadism may be associated with the multiple lentigenes and basal cell nevus syndromes.

LHRH Receptor Mutations

LHRH receptor mutations are reported in familial and sporadic patients and lead to various degrees of hypogonadotropic hypogonadism with normosmia. In the autosomal-recessive form, there are heterozygous or homozygous mutations in the LHRH receptor. The patients may present with severe features of isolated hypogonadotropic hypogonadism, sexual infantilism, ranging to delayed puberty, or relatively mild hypogonadism and infertility. The clinical variants include the fertile eunuch variant. In all types of congenital gonadotropin deficiency, male patients are likely to manifest micropenis due to a lack of fetal gonadotropin stimulation of fetal testes during the last half of gestation. Micropenis may also occur in boys with congenital growth hormone deficiency.

No mutations of the LHRH genes have been reported.

X-linked Congenital Adrenal Hypoplasia and Hypogonadotropic Hypogonadism

X-linked congenital adrenal hypoplasia and hypogonadotropic hypogonadism are due to a deletion or mutation in the DAX-1 gene (dosage-sensitive sex reversal-A adrenal hypoplasia congenita gene on the X chromosome gene 1). The DAX-1 gene, a member of the nuclear receptor superfamily, encodes an orphan receptor that is a putative transcriptional repressor. The DAX-1 locus undergoes X inactivation. It maps to the DSS (dosage-sensitive sex reversal) locus (Xp21); a double dose of DAX-1 is associated with a female phenotype or ambiguous genitalia in 46,XY males. DAX1 has a steroidogenic factor 1 (SF1) response element in the 5' promoter region. SF1 is another orphan member of the nuclear hormone receptor superfamily; both DAX-1 and SF1 are expressed in the adrenal glands, gonads, pituitary, and hypothalamus, which raises the possibility of an important interaction between these two genes and their products. Abnormalities of the DAX-1 gene are characterized by severe glucocorticoid deficiency, mineralocorticoid deficiency, and, at puberty, androgen deficiency. A mature adrenal cortex is lacking and the abnormal structure of the adrenal cortex resembles that of the fetal zone made up of disorganized vacuolated cytomegalic cells. In the majority of affected boys, the severe primary adrenal insufficiency with hyponatremia, hyperkalemia, acidosis, and hypoglycemia (failure to thrive, vomiting, poor feeding, dehydration, circulatory collapse, increased pigmentation) is lethal if untreated early in life. The concentration of plasma ACTH is high and plasma

cortisol and aldosterone levels are low. The testes are undescended in less than one-half of the patients; micropenis is rare, but occasionally urogenital abnormalities and hearing loss are present. Most commonly, signs of sexual maturation at the age of puberty, including the absence of pubic and axillary hair and testicular enlargement, are lacking; the concentrations of serum FSH, LH, and testosterone are low.

Contiguous gene syndromes are not uncommon in association with X-linked congenital adrenal hypoplasia, as the gene maps to Xp21, distal to the glycerol kinase gene and the Duchenne muscular dystrophy gene and proximal to the gene associated with mental retardation. Rare patients have defects in all of these areas.

Isolated LH Deficiency

Isolated LH deficiency or the fertile eunuch syndrome is associated with deficient testosterone production (which responds to administration of hCG) in the presence of variable spermatogenesis. In most instances, it is an incomplete form of isolated gonadotropin deficiency; the disorder may be idiopathic or secondary to a hypothalamic pituitary neoplasm.

Isolated FSH Deficiency

Isolated FSH deficiency is rarely due to mutations in the FSH β -subunit, either homozygous or compound heterozygous. Females are mostly affected but two affected men have been described; both had azoospermia, small, soft testes, and an absence of serum FSH; some patients have delayed puberty.

Idiopathic Hypopituitary Dwarfism

Idiopathic hypopituitary dwarfism is usually caused by a deficiency of hypothalamic releasing factors. In the untreated state, patients with deficient LHRH have delayed or absent puberty and, in contrast, patients with isolated GH deficiency ultimately undergo spontaneous, if delayed, pubertal development, without exogenous gonadal steroids, when the bone age reaches the pubertal stage of 11 to 13 years, usually during GH therapy. Common to many patients with idiopathic hypopituitary dwarfism is early onset of growth failure; late onset of diminished growth suggests the presence of a CNS tumor or other serious problems. Breech delivery, especially in males, perinatal distress, idiopathic hypopituitarism, and malformations of the pituitary stalk demonstrable by MRI are common in such patients. Familial forms of multiple pituitary hormone deficiencies with either

autosomal-recessive or X-linked inheritance are less common.

Treatment of prepubertal children with isolated growth hormone deficiency with growth hormone can increase the rate of pubertal development. Alternatively, if GH treatment is instituted in children already in puberty who have a limited height potential, limitation of the amount of growth attained with GH treatment often results; in these instances, the use of LHRH agonists to suppress pubertal development in addition to the use of GH is useful in increasing final height. The judicious use of low-dose testosterone in affected boys of pubertal age with associated gonadotropin deficiency does not seem to impair growth achieved by growth hormone replacement.

Miscellaneous Conditions

Prader-Willi Syndrome

Prader-Willi syndrome is a syndrome of early onset childhood hyperphagia, pathological obesity and carbohydrate intolerance, infantile central hypotonia and lethargy, delayed onset and poor fetal activity, a tendency for intrauterine growth retardation, short stature by 15 years of age, small hands and feet, mild to moderate mental retardation, emotional instability including perseveration, obsessions, and compulsions, and characteristic facies with almond-shaped eyes, triangular mouth, and narrow bifrontal diameter. Delayed puberty is usually related to hypogonadotropic hypogonadism caused by hypothalamic dysfunction. Affected boys often have micropenis and cryptorchidism. The frequency is approximately 1 in 20,000. It is very rarely familial and is caused by abnormalities involving the long arm of chromosome 15 in the region q11–q13. Most patients with Prader-Willi syndrome have a paternal deletion of 15q11–q13; a minority of cases have maternal uniparental disomy (either isodisomy or heterodisomy), where both chromosomes 15 are derived from the mother, possibly by non-disjunction during maternal meiosis, and represent a striking example of genomic imprinting. Rarely, an imprinting center defect has been detected. One candidate-imprinted gene that maps to this region, SNRPN (small nuclear ribonucleoprotein-associated polypeptide SmN), implicated in splicing pre-mRNA, is expressed in the brain and hypothalamus and is one explanation of the syndrome.

Plasma GH responses to provocative stimuli and to sleep are usually low due to obesity but may be normal. In June 2000, the U.S. Food and Drug

Administration approved rhGH treatment as an indication for children with Prader-Willi syndrome without a requirement for assessing growth hormone secretion; however, genetic testing is required to confirm the clinical diagnosis. GH treatment decreases body fat, fat utilization, lean body mass, linear growth, energy expenditure in the syndrome with a possible improvement in physical strength, and motor development.

Laurence-Moon and the Bardet-Biedl Syndromes

The Laurence-Moon and Bardet-Biedl syndromes are rare autosomal-recessive traits that both combine retinitis pigmentosa and hypogonadism of various etiologies; many Bardet-Biedl patients have developmental delay as do all of the Laurence-Moon patients. Laurence-Moon syndrome, however, demonstrates spastic paraplegia, whereas the Bardet-Biedl syndrome has postaxial polydactyly, onset of obesity usually in early infancy, renal dysplasia, and a relatively high prevalence among the Bedouin of the Middle East. Similar findings are present in Biemond's syndrome II with iris coloboma, hypogenitalism, obesity, polydactyly, and developmental delay, but it too is a distinct entity. The genetically and phenotypically heterogeneous Bardet-Biedl syndrome is linked to six loci that map to chromosomes 2, 3, 11, 15, 16, and 20; in most cases, three mutant genes are required for the phenotype to develop.

Functional Gonadotropin Deficiencies

Severe systemic and chronic disorders and malnutrition are associated with delayed puberty or failure to progress through puberty. In general, weight loss of any cause to less than 80% of ideal weight for height can lead to gonadotropin deficiency and low serum leptin levels; weight regain usually restores hypothalamic-pituitary gonadal function over a variable period. If adequate nutrition and body weight are maintained in patients with regional enteritis or chronic pulmonary disease, gonadotropin secretion is usually adequate. The weight loss of anorexia nervosa is classically found in girls, but boys may develop this psychiatric disease as well.

Cystic fibrosis also delays puberty, in large part through malnutrition, but even with normal pubertal progression, boys with cystic fibrosis almost universally have oligospermia caused by obstruction of the spermatic ducts unrelated to their nutritional status. The greater prevalence of reproductive difficulties in male patients with cystic fibrosis compared

with female patients may be due to the greater prevalence of the cystic fibrosis transmembrane regulator in male reproductive tissues, such as the epididymis and vas deferens, and as a consequence more viscid luminal contents, which ultimately damage the testes. Alternatively, the epididymides may be deficient and the vas differentia absent.

Sickle-cell disease may cause a delay of the pubertal growth spurt and peak height velocity although adult height may be normal; Leydig cell function is often impaired due to ischemia of the testes, gonadotropin deficiency, or both factors. Thalassemia major leads to abnormal sexual maturation in a majority of boys and many experience growth failure due to hypothyroidism or gonadotropin deficiency. Thalassemia carries the risk of hemochromatosis, which causes multiple endocrine abnormalities, and the desferioxamine therapy itself may cause skeletal dysplasia and compromise pubertal growth; GH secretion is usually not affected.

Chronic gastrointestinal diseases, such as Crohn's or celiac diseases, are often accompanied by delayed puberty; successful therapy to restore nutrition enables puberty to progress. Chronic renal disease has been associated with delayed pubertal development and decreased pulsatile gonadotropin secretion; successful renal transplantation usually restores gonadotropin secretion. Patients with nephrotic syndrome or glomerulonephritis treated with alternate-day glucocorticoid therapy have poor pubertal growth, poor secondary sexual development, and deficient gonadotropin secretion in a pattern resembling constitutional delay in puberty.

Advances in the treatment of leukemia have improved the prognosis; children with early onset and long-term remission experience puberty at an appropriate age or with only slight delay, whereas patients with initial symptoms of leukemia in late childhood may have considerable delay of pubertal development. Further CNS radiation may cause hypogonadotropic hypogonadism and/or growth hormone deficiency, and radiation to the abdomen or pelvis and certain types of chemotherapy, especially if administered during puberty, may impair gonadal function and cause primary hypogonadism. The adult height in boys may be reduced less with a dose of 1800 cGy rather than 2400 cGy.

If hypothyroidism delays the onset of puberty, treatment with levothyroxine will allow progression. Poorly controlled diabetes mellitus can lead to poor growth, fatty infiltration of the liver, and sexual infantilism (Mauriac's syndrome), probably related to poor nutritional status. Prepubertal children with

diabetes mellitus are most vulnerable to poor glyce-mic control, whereas pubertal subjects exhibit normal growth unless severe hyperglycemia occurs; adolescents with even moderately poor control frequently have some degree of growth impairment and delayed puberty. Cushing's disease can cause delayed onset or arrest of gonadarche, which is corrected by removal of the ACTH-secreting pituitary adenoma.

Although men are less often affected than women, males may also be affected by rigorous physical training, with decreased LH response to LHRH and decreased spontaneous LH pulse frequency and amplitude resulting; the serum testosterone is normal or low.

HYPERGONADOTROPIC HYPOGONADISM: SEXUAL INFANTILISM CAUSED BY PRIMARY GONADAL DISORDERS

Primary gonadal failure and the impaired secretion of gonadal steroids lead to decreased negative feedback and elevated LH and FSH levels. The most common forms in boys are associated with Klinefelter's syndrome and its variants.

Klinefelter's Syndrome

In Klinefelter's syndrome (syndrome of seminiferous tubular dysgenesis), elevated gonadotropin levels are found postpubertally; before the age of 12 years, gonadotropin concentrations are in the prepubertal range. Rarely, low gonadotropin concentrations occur when hypogonadotropic hypogonadism is associated with 47,XXY Klinefelter's syndrome. Prepubertally, patients can be detected by the disproportionate length of the extremities and decreased upper/lower body ratio without an increase in arm span. There is variation in Leydig cell function, but the plasma concentration of testosterone tends to be in the normal range until approximately the age of 14 years, after which it may fail to rise to normal adult levels. Thus, the onset of puberty may not be delayed, but impaired Leydig cell reserve and low testosterone levels may cause slow progression or arrest of pubertal changes. Serum estradiol/testosterone ratios and TeBG levels are higher than those in normal males, which indicates an increased estrogen effect and a decreased testosterone effect. These factors probably account, at least in part, for the gynecomastia characteristic of Klinefelter's syndrome during adolescence.

Neurobehavioral abnormalities, primarily in language and frontal executive functions, are frequent,

and some say universal, in Klinefelter's syndrome. These problems may be severe enough to lead to evaluation in childhood and the prepubertal diagnosis. The global IQ in unselected populations of Klinefelter's syndrome is normal or near normal but verbal IQ is usually lower than performance IQ. Patients with clinical or psychological problems are referred more often for evaluation, so some studies suggest more significant deficits than found in an unselected population of XXY individuals.

Approximately 20% of mediastinal germ cell tumors are associated with Klinefelter's syndrome and they occur at a younger age than the mediastinal germ cell tumors that are not associated with Klinefelter's syndrome (average ages of 16 years versus 27 years in one study). These germ cell tumors, which may be located in the midline anywhere from the CNS to the pelvis, secrete hCG and can induce sexual precocity in young boys. Klinefelter's syndrome must be considered in boys with hCG-secreting germ cell tumors, especially if the tumor is located in the mediastinum or CNS.

Other Forms of Primary Testicular Failure

Much cancer therapy affects testicular function, and as more children survive with effective therapy for cancer, adult infertility may result. Chemotherapeutic agents used in the treatment of nephrotic syndrome, leukemia, or Hodgkin's disease, such as chlorambucil, vinblastin, Mustargen, Oncovin, and procarbazine, have led to Sertoli cell, Leydig cell, and germ cell damage (sometimes reversible) in prepubertal patients. Even if spontaneous progression through puberty occurs, serum FSH and LH concentrations may be elevated and the inhibin B concentrations decreased during puberty, indicative of gonadal damage. COPP/MOPP therapy for Hodgkin's disease can cause severe damage to germinal cells apparently without much effect on Leydig cells even if therapy occurred in the prepubertal period. In addition, adriamycin, bleomycin, vinblastine, and dacarbazine also can cause germ cell depletion. Gonadal damage can occur earlier as a result of therapy in the prepubertal period but may not be demonstrable until the age of puberty.

Radiation to the gonads can cause primary testicular failure, usually resulting in azoospermia, although normal testosterone secretion may be associated with elevated LH and FSH values (compensated Leydig cell failure); the gonads must be shielded from the treatment, if possible. Although doses of 0.35 Gy to the testes may lead to temporary aspermia, doses over

2 Gy lead to permanent aspermia and over 15 Gy may cause Leydig cell dysfunction.

LH resistance caused by Leydig cell LH receptor abnormalities are reported in rare boys with a male phenotype and lack of pubertal development along with gynecomastia, elevated plasma LH levels, and early pubertal plasma testosterone concentrations that did not increase after hCG administration. Several different mutations may be at fault.

DIAGNOSIS OF DELAYED PUBERTY AND SEXUAL INFANTILISM

When prepubertal boys present at age 14, the physician must make a clinical judgment as to which are variants of the norm and which require extensive evaluation and treatment. Lack of progression through the stages of puberty, even if the age at onset is normal, may also require evaluation; a boy who has not completed secondary sexual maturation within 4.5 years after onset of puberty may have a hypothalamic, pituitary, or gonadal disorder. The diagnosis of hypergonadotropic hypogonadism is readily established by elevation of random plasma LH and FSH concentrations. However, the differential diagnosis of hypogonadotropic hypogonadism versus constitutional delay in growth and adolescence is more difficult because of the overlap in physical and laboratory findings in the two conditions and no single test consistently makes this distinction.

The medical history must elicit all symptoms of chronic or intermittent illnesses and all details pertaining to growth and development as well as the patient's sense of smell and nutritional status. Disorders of pregnancy and abnormalities of labor and delivery, if present, suggest that a congenital or neonatal event may be related to the delay in puberty. Poor linear growth and poor nutritional status during the neonatal period and childhood may reflect longstanding abnormalities of development. A growth chart is plotted to represent graphically the increase in stature and to assess growth velocity from birth. Late onset of growth failure usually indicates a serious condition. Family history may reveal disorders of puberty or infertility, anosmia, or hyposmia in relatives as well as delay in the age at onset of puberty in parents or siblings. Recalled age of pubertal onset is relatively reliable in women but less often accurate in men. A history of consanguinity is important in the detection of autosomal-recessive disorders.

The physical examination includes determination of height and weight; the upper/lower segment ratio

or sitting height is calculated and the arm span is measured and compared with the height to determine whether there is a lack of spine growth from, e.g., radiation, or whether eunuchoid proportions are present. The height velocity should be documented over a period of at least 3 months, preferably 6 months. The signs of puberty are noted and the stage of secondary sexual development is determined according to the "Tanner" standards. The length and width of the testes are recorded or the volume is assessed using an orchidometer. The length and diameter of the stretched penis are determined. Obese boys often appear to have a small penis because of excessive adipose tissue surrounding the phallus; only when the fat is retracted can the full extent of phallic development be assessed. (This feature is among the most common causes of inappropriate referral for hypogonadism.) The extent of axillary hair is noted, as is the degree of acne. The possibility of cryptorchidism, anorchia, or retractile testes should be differentiated if no testes are palpated in the scrotum. Neurological examination, including examination of the optic discs and visual fields by frontal confrontation perimetry and evaluation of olfaction, may reveal findings suggesting the presence of a CNS neoplasm or a developmental defect (Kallmann's syndrome). The small testes and gynecomastia of Klinefelter's syndrome may suggest this diagnosis. Complete physical examination is important in the search for a chronic disorder that may delay puberty.

Laboratory studies include determination of serum LH and FSH concentrations by "third-generation" assays, measurement of the rise in LH levels after LHRH administration, determination of testosterone concentrations, and measurements of thyroxine and prolactin concentrations if the clinical features warrant. It is important to use one of the few national endocrine laboratories for the determinations of the hormones of puberty as most local laboratories are interested only in differentiating normal, higher, adult values from inappropriately low levels and not the low concentrations characteristic of the early stage of pubertal development. Radiographic examination includes bone age determination and, if the diagnosis is at all consistent with a CNS lesion, an MRI of the brain with specific attention to the pituitary and hypothalamic area using contrast; only advanced pituitary tumors or significantly calcified craniopharyngiomas will appear on lateral skull films and, though a positive result is useful, a negative radiograph cannot rule out a CNS defect. CT scanning can detect calcification, in contrast to MRI scans. Assessment of chromosomal karyotype should be considered in boys with

suspected Klinefelter's stigmata or behavior. A presumptive diagnosis of constitutional delay in growth and adolescence is made if the history is normal and the growth chart reveals a history of short stature but consistent growth rate for skeletal age (and no signs or symptoms of hypothalamic lesions), if the family history includes parents or siblings with delayed puberty, if the physical examination (including assessment of the olfactory threshold) is normal, if optic discs and visual fields are normal, or if the bone age is significantly delayed. In classic cases, an MRI of the hypothalamic-pituitary region may not be necessary but constitutional delay is a diagnosis of exclusion. The rate of growth in these patients is usually appropriate for bone age. A decrease in growth velocity occurs in some normal children just before the appearance of secondary sexual characteristics and may awaken concerns if such a pattern occurs in these subjects; if the decrease is significant, another diagnosis may be warranted.

Measurement of 8 AM serum testosterone is proposed to be an accurate indication of impending pubertal development; a value of greater than 0.7 nmol/liter (20 ng/dl) predicts enlargement of the testes to greater than 4 ml by 12 months in 77% of cases and in 15 months in 100% of cases, whereas in those with a value less than 0.7 nmol/liter only 12% entered puberty in 12 months and only 25% entered puberty in 15 months. Failing progression into puberty, there does not appear to be a practical and reliable endocrine test for indisputably differentiating between constitutional delay in growth and adolescence and hypogonadotropic hypogonadism. Watchful waiting remains the procedure of choice.

Patients with deficiency of gonadotropins combined with deficiency of other pituitary hormones require careful evaluation for a CNS neoplasm. Visual field or optic disc abnormalities support the diagnosis of a CNS tumor; even if these tests are normal, a cranial MRI should be performed to evaluate the pituitary gland and stalk and the hypothalamic region. CT scans, but especially MRI of the head, are valuable in detecting mass lesions and developmental abnormalities of the hypothalamic-pituitary region. Late onset of hypothalamic-pituitary defect is an ominous sign requiring evaluation.

TREATMENT OF DELAYED PUBERTY AND SEXUAL INFANTILISM

Patients with constitutional delay in growth and adolescence ultimately have spontaneous onset and

progression through puberty so that reassurance and continued observation are sufficient. However, psychological stress may occur due to the immature appearance and school work may suffer due to the child's poor self-image. Thus, for psychological reasons, prepubertal boys of age 14 years or older may receive a 3- to 6-month course of testosterone enanthate; cyprionate or cyclopropionate may be helpful or transdermal testosterone may be applied according to the doses and provisos given below. If spontaneous puberty does not ensue or the concentrations of plasma gonadotropins and plasma testosterone in boys do not increase, the treatment may be repeated once. When treatment is discontinued after bone age has advanced to 13 or 14 years in boys, patients with constitutional delay usually continue pubertal development on their own, whereas those with gonadotropin deficiency do not progress and may, in fact, regress.

A fourth-generation aromatase inhibitor, letrozole, administered along with testosterone in a randomized controlled trial in boys with constitutional delay in puberty and growth decreased the advancement in bone age, an effect that will presumably lead to a greater adult height by strikingly decreasing the synthesis of estradiol from testosterone. This treatment is experimental; it may improve the decreased adult height in some boys with constitutional delay compared to their predicted genetic potential, a decrease that testosterone cannot overcome.

Functional hypogonadotropic hypogonadism associated with chronic disease is treated by alleviating the underlying problem or improving nutrition.

Congenital or acquired gonadotropin deficiency as a result of a lesion or surgery requires replacement therapy with gonadal steroids at an age approximating the normal age of onset of puberty. If untreated GH deficiency and shorts stature coexist with gonadotropin deficiency, testosterone treatment may be delayed; if bone age advancement and epiphyseal fusion are brought about by testosterone replacement before therapy with GH causes adequate linear growth, adult height will be compromised. Alternatively, if puberty is not initiated early enough, the patient may suffer psychological damage. Generally, puberty in such patients can be initiated with low-dose gonadal steroids by the age of 14 years in boys, regardless of the definitive diagnosis of gonadotropin deficiency. Isolated growth hormone-deficient patients may have a delayed onset of puberty; with growth hormone administration, puberty usually occurs at an appropriate age but may progress faster than in normal individuals. Clinical trials are in progress to

determine the effects of artificially delaying puberty with an LHRH analogue to attempt to achieve a greater final height in patients with isolated GH deficiency treated with hGH.

Klinefelter's syndrome is compatible with varying degrees of masculinization at puberty, but some patients require testosterone replacement. The concentration of plasma testosterone and LH should be monitored every 6 months during puberty and yearly thereafter. If the LH level rises more than 2.5 SD above the mean value or the testosterone level decreases below the normal range for age, testosterone replacement therapy is indicated. There is a growing feeling among parents that testosterone treatment in the early pubertal period improves language skills, reading ability, and behavior in boys with Klinefelter's syndrome, and well-controlled studies supporting this contention are available.

Hypogonadotropic hypogonadism or hypergonadotropic hypogonadism are both treated with gonadal steroid replacement. Alkylated testosterone preparations are not used because of the risk of peliosis hepatitis (hemorrhagic liver cysts); progression to liver failure can occur. Boys may receive testosterone enanthate, propionate, or cyprionate, 50–100 mg every 4 weeks intramuscularly at the start; later the dosage is gradually increased to 200 to 300 mg every 2 to 3 weeks. Testosterone may also be administered by a cutaneous patch on scrotal skin or on nonsexual skin or by new testosterone gel preparations, usually rubbed onto the forearms; both methods have been approved for adults but have not yet been approved for boys under the age of 16 years.

Secondary Sexual Characteristics

The timing and tempo of pubertal development are linked to alterations in the HPG and GH/IGF-I axes. There may be great variability in the onset of pubertal development, but once entrained, there is less variability in progress through the pubertal stages. Still, there is significant variability in the progression of puberty (tempo) that may be very relevant to the boy with delayed adolescence. The external signs of pubertal development have been summarized into relatively easily discernible stages. In general, scrotal thinning and reddening occur concomitantly with an increase in testicular volume to 4 ml or greater. As testis size increases and the levels of the male hormone testosterone increase, there is lengthening of the phallus followed by an increase in its circumference as it further lengthens. Pubic hair increases in area from just above the phallus to growth in all directions, including the medial thigh. The quality of the hair becomes more coarse and curly. With delayed pubertal development, the chronological age differs from the “biological” age. The various stages of growth noted previously—take-off and PHV—and the endocrinological changes noted in what follows are more tightly correlated to the biological age than to the chronological age.

THE ENDOCRINE SYSTEM AND PUBERTAL DEVELOPMENT

Gonadotropins

After peaks of activity during fetal life and within the first few months of extrauterine life, the HPG axis becomes quiescent, only to reawaken at puberty. Gonadotropin release is pulsatile at all ages. Puberty is anticipated by an increase in the amplitude of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion that may be detected several years before the external signs of pubertal development are present. Initially, biologically relevant surges (“pulses”) of LH occur only after the onset of deep sleep. These permit the testis to increase the production of the potent androgen testosterone. However, the hypothalamic-pituitary axis for LH remains exquisitely sensitive to the negative feedback actions of testosterone or one of its metabolites, estradiol, such that the minor increases in testosterone are able to dampen LH release. As puberty unfolds, the small increments in testosterone levels are no longer able to maintain suppressed levels of LH. The increases in LH continue for longer and longer periods

during the day, pushing testosterone levels even higher. Concomitantly, the feedback sensitivity of the HPG axis diminishes and the ambient levels of testosterone are no longer sufficient to suppress the surges of LH. At the end of the pubertal process, the pulsatile release of LH occurs every 1 or 2 h during the day and night.

Gonadal Steroid Hormones

Nighttime increases in circulating levels of testosterone are often detectable even before the external signs of puberty develop. The daytime levels rise later as the testis volume increases. The circulating levels of testosterone are substrate for at least two important enzymes, 5 α -reductase (converts testosterone to dihydrotestosterone, DHT) and aromatase (converts testosterone to estradiol). The effects on the lean body mass are in part due directly to testosterone and indirectly to estradiol because the latter leads to the marked increases in GH and IGF-I due to an action of estradiol on the hypothalamus and pituitary. Circulating estradiol levels cause maturation and eventually closure of the epiphyses of the long bones, signaling the virtual cessation of linear growth. Diminished bone mass is present in boys with delayed pubertal development, including severe constitutional delay of growth and puberty (CDGP).

Growth Hormone and Insulin-like Growth Factor-I

Growth hormone levels increase throughout the first stages of pubertal development to reach a maximum at the time of PHV. The levels of IGF-I also rise, denoting a switch to positive feedback or at least an absence of negative feedback action of IGF-I on GH release. Although serum testosterone levels increase markedly by PHV, it is likely that the conversion to estradiol is responsible for the alteration in pulsatile GH release.

Summary and Integration

During pubertal development, there is an intricate interplay between the increased activation of the HPG and the GH/IGF-I axes. Both contribute to the pubertal spurt in linear growth and to the marked alterations in body composition and the regional distribution of body fat. They have independent and at least additive, if not synergistic, actions at puberty.

CAUSES OF DELAYED PUBERTAL DEVELOPMENT IN BOYS

Delayed pubertal development has many causes, both physiological (functional) and pathological. It usually occurs because of inadequate secretion of the gonadal steroid hormones, especially that of testosterone in boys. The causes may be conveniently separated into hypogonadotropic (central) and hypergonadotropic causes, depending on primary hypothalamic–pituitary dysfunction or primary gonadal failure.

Of these categories, the physiological causes are by far the most common, especially in 14- to 16-year-old boys. As the second decade of life ends, the likelihood of finding a pathological cause rises sharply (see Table I).

EVALUATION OF DELAYED PUBERTY IN BOYS

As with any evaluation that includes growth and development, one begins with the growth curve. Normal

Table I Causes of Delayed Pubertal Development in Boys

| |
|--|
| Hypergonadotropic (primary) hypogonadism |
| Congenital |
| Chromosomal abnormality |
| Klinefelter syndrome 47 XXY and variants |
| Anorchia (vanishing testis syndrome) |
| Acquired |
| Trauma (or surgery) |
| Chemo or radiation therapy |
| Post infectious (e.g., mumps orchitis) |
| Hypogonadotropic (secondary) hypogonadism |
| Congenital |
| Various forms of hypothalamic–pituitary disease |
| Gonadotropin-releasing hormone deficiency |
| Multiple pituitary hormone deficiencies |
| Congenital malformations as part of holoprosencephalic anomalies |
| Acquired |
| Tumors, particularly craniopharyngioma |
| Pituitary apoplexy |
| Malnutrition and acute and chronic systemic disease |
| Endocrine deficiencies |
| Hypothyroidism |
| Hyperprolactinemia |
| Head trauma |
| Physiological |
| Constitutional delay of growth and puberty |

growth over an extended period of time speaks to the overall general good health of the individual. The childhood growth rate is relatively constant, usually between 5 and 7 cm per year. In boys who undergo puberty at the usual time, there is an almost imperceptible slowing of growth (the take-off point). This is followed by rapid acceleration to PHV and then deceleration toward zero velocity as the epiphyses of the long bones close. The greater the delay in pubertal development, the greater the slowing of growth before take off—often called the preadolescent “dip.” This occurs at the time that one’s peers are undergoing their most rapid growth, highlighting the differences among likely normal individuals. However, this knowledge does not mitigate the distress of the smaller, and often slighter, individual.

The evaluation is no different from any other medical evaluation in that the history can often give clues as to what to look for in the physical examination or what laboratory tests to order to integrate the information to produce a differential diagnosis. Of particular importance in the history is pattern of growth, not only of the child but also of his siblings and parents. The pubertal development of the siblings and parents can be of help as well because there is some familial patterning.

Although it is not often emphasized, one should take a detailed dietary history because delayed pubertal development may be related to a total energy deficit—caloric deprivation and/or excessive use. Prior medical conditions and some of the medications used to treat them can delay growth and pubertal development. There are many individual organ systems that may be disordered and cause delayed growth and pubertal development. Many are related to the gastrointestinal (GI) system—decreased intake and/or excessive caloric losses. The other major organ systems that can be affected are the endocrine system and central nervous system (CNS). Disorders of the HPG, GH/IGF-I, thyroid, and adrenal axes can lead to delayed growth and sexual maturation. CNS disease may be heralded by headache, visual disturbance, seizures, and nausea and vomiting.

The general physical examination might not be too rewarding unless there are congenital (or acquired) anomalies. The typical boy with delayed pubertal development has a relatively normal physical examination—but for a younger child. The key elements are the measurements of height and weight and the genitalia, including pubic hair. There are convenient stages to mark pubertal progression; noting the Tanner stages can integrate not only the timing but also the tempo of pubertal development.

Laboratory testing that may help to define the diagnosis includes the hemogram and tests of liver, kidney, and GI function. From the endocrine point of view, one seeks evidence for low IGF-I and IGF binding proteins (BP)-3, low thyroxine level, low testosterone level, or high prolactin or cortisol level. The detailed endocrine evaluation is beyond the scope of this article.

Imaging studies may help; an X ray of the left hand and wrist can indicate a bone age (biological age). That is critical as one tries to determine whether the delay is significantly outside of the normal variation. Other imaging, whether CNS or GI or the like, should follow from clues gathered in the history, physical examination, and laboratory evaluations. A karyotype is indicated if Klinefelter syndrome is considered. Boys with this condition often have delayed tempo of puberty but are of normal or slightly increased stature.

The younger the child during his teenage years, the more likely that physiologically delayed puberty (CDGP) is the correct "diagnosis." Treatment depends on the diagnosis.

TREATMENT OF DELAYED PUBERTAL DEVELOPMENT IN BOYS

For most causes of delayed puberty, testosterone administration will form part of the therapeutic plan. It may be exogenous (usual) or may involve merely waiting for the endogenous testosterone to be secreted. By the time most boys with CDGP arrive in the specialist's office, testosterone therapy has already been considered. It is critical to start slowly and increase the dose slowly so as not to cause too rapid epiphyseal closure and shortened adult height. Testosterone therapy can be halted as the testes increase in size, in concert with increasing endogenous testosterone secretion.

For pathological conditions, the treatment of the individual obviously depends on the diagnosis. It may be as simple as adding calories or dampening the activity of inflammatory bowel disease, or it may be as complex as removing a CNS tumor or correcting significant renal failure. Many of the endocrine deficits can be replaced (e.g., GH, thyroxine, testosterone), and some of the excesses can be dampened (e.g., hyperprolactinemia, Cushing syndrome).

Whatever the cause, it is critical to follow the growth and development status over time. The amount of testosterone given should escalate over time to mimic the natural evolution of puberty. Physiologically delayed puberty is very common in 12- to 15-year-old boys. As they become older adolescents, it is less likely that a physiological cause for delayed pubertal development will be found. Often, it is the disease and distress that are the most prominent symptoms, and discussions with the patient and his parents along with short-term therapy with testosterone may be all that is required to help get the boy through pubertal development and toward young adulthood. In addition to growth and genital development, there are remarkable alterations in body composition, including bone mass and fat distribution. Dissatisfaction with his body image is often a cardinal feature of the adolescent boy's distress, and therapy with testosterone has major salutary effects.

have depression. T_3 has been reported to influence the effect of antidepressants either by hastening the onset of response or by converting a nonresponder into a responder. Although it has been given as adjuvant therapy for refractory depression for more than two decades, efficacy has not been definitively established in double-blind control trials and its use for this purpose remains controversial.

CLINICAL MANIFESTATIONS OF DEPRESSION AND THYROID DISEASE

At a given point in time, major depression may affect up to 15% of the general population. The diagnosis is made in those who present with a depressed or irritable mood and who have a lack of interest or pleasure for at least 2 weeks in combination with other symptoms (see Table I). The initial episode of depression most frequently occurs during the fourth or fifth decade of life but may occur at any age. If left untreated, the duration of an episode can vary greatly, from a few months to 1 or more years. Occasionally, it will persist as chronic depression. A family history of mood disorders is common. Recurrence, which can be seen in half of such patients, generally occurs within 2 years of the first episode.

As in thyroid disease, depression occurs more often in women than in men. Although the peak incidence in women occurs between 35 and 45 years of age, the diagnosis is now made more frequently in older women than was the case previously. The prevalence of autoimmune thyroid disease is highest among women more than 40 years of age. Most individuals presenting with depression do not have biochemical evidence of thyroid dysfunction; despite this, depression and thyroid dysfunction share many clinical features (see Table II). In those cases where patients present with depression and findings that suggest thyroid dysfunction, it may be difficult to distinguish clinically which entity is the cause of the symptoms.

REGULATION OF THE HYPOTHALAMIC–PITUITARY–THYROID AXIS

The fundamental actions of the hypothalamus–pituitary–thyroid axis (HPTA) are based on stimulation of the pituitary thyrotrophs balanced by a negative feedback inhibition. The hypothalamus regulates the synthesis and release of thyrotropin (TSH) through the secretion of thyrotropin-releasing hormone (TRH). TRH is produced in the paraventricular nucleus (PVN) of the hypothalamus and then is transported to the specialized nerve terminals in the median eminence before being liberated into the hypophyseal portal blood. The basophilic cells of the anterior pituitary produce TSH in response to TRH. Then, TSH is liberated in the circulation and stimulates the thyrocytes to produce thyroid hormones via the thyrotropin receptor (TSHr). Once thyroxine (T_4) and T_3 are liberated, they exert an inhibitory effect on TSH and TRH secretion (see Fig. 1). Apart from thyroid hormones, there are other inhibitors of TSH secretion. This group includes somatostatin, dopamine, glucocorticoids, and certain cytokines (see Table III). On the other hand, α -adrenergic agonists stimulate the thyrotrophs.

The most abundant thyroid hormone produced by the thyroid gland is T_4 . The monodeiodination of T_4 in extrathyroidal tissues gives rise to 80% of the T_3 in the peripheral circulation, with the remainder being derived from direct thyroid gland secretion. Within the CNS, local deiodination activity in the brain is of great importance because it enables the CNS to maintain an optimal T_3 content. Type II 5'-deiodinase and 5-deiodinase are the major mediators of this process. The former, which is responsible for the conversion of T_4 to T_3 , is found in the cerebral

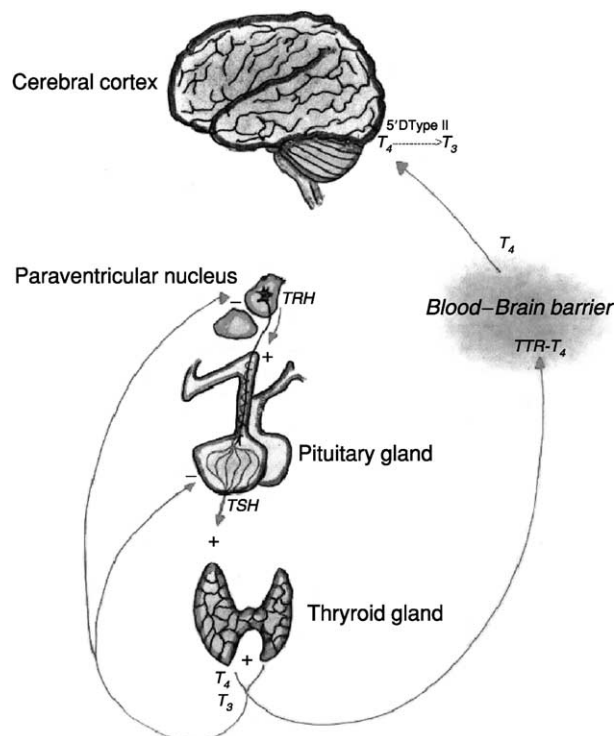

Figure 1 The hypothalamic–pituitary–thyroid axis (HPTA). The fundamental action of the HPTA is based on stimulation of the pituitary thyrotropin by thyrotropin-releasing hormone (TRH). In response to this signal, thyrotropin (TSH) is liberated into the circulation and reaches the thyroid gland, which secretes thyroxine (T_4) and triiodothyronine (T_3), with the former being the most abundant hormone produced by the gland. Through a negative feedback response, both TRH secretion and TSH secretion are inhibited by the thyroid hormone. Other substances can also inhibit TSH secretion to a certain degree. Once T_4 is in the circulation, it crosses the blood–brain barrier with the aid of transthyretin (TTR). Within the cerebral cortex, T_4 is converted into T_3 by 5′-deiodinase type II (5DType II). Finally, T_3 is inactivated by 5-deiodinase (5D) into diiodothyronine (T_2). Triiodothyronine is the active thyroid hormone at the cellular level.

cortex, pituitary, and hypothalamus. The latter is also found in the cerebral cortex but not in the anterior pituitary. It results in degradation of T_3 and inactivates T_4 , yielding reverse triiodothyronine (rT_3). In addition, 5-deiodinase activity predominates in the euthyroid state, and the rT_3 produced plays a role in the regulation of local deiodination (see Fig. 1). The distribution of these enzymes within the various regions of the nervous system varies. The cortex has the highest level of activity, followed by the midbrain, pons, hypothalamus, and brainstem (in that order).

ALTERATIONS OF THE HYPOTHALAMIC–PITUITARY–THYROID AXIS IN DEPRESSION

Patients with depression can present many abnormalities of the HPTA (see Fig. 2). The most widely recognized disturbance is blunting of the TSH response to TRH stimulation. Defined as a TSH rise of less than $5 \mu\text{IU/ml}$, this phenomenon occurs in 25 to 30% of depressed individuals. Normalization of this response is noted once clinical recovery ensues. It differs from thyrotoxicosis in which the TSH response is flat and the circulating T_3 levels are elevated. A blunted TSH response is not unique to depression and may occur in other clinical settings (see Table III). The mechanism of this blunted response is not entirely clear, but one hypothesis proposes that there is TRH hypersecretion with down-regulation of the TRH receptors on the thyrotrophs.

Another common abnormality of the HPTA is held to be an increase in total and/or free thyroxine (FT_4) levels, although still within the conventional normal range, that regress after successful treatment of depression. It has been reported that some patients admitted with acute psychosis, including depression, manifest a transient elevation above normal levels of T_4 and/or FT_4 and occasionally TSH. These findings usually resolve spontaneously within 2 weeks. In a fetal rat hypothalamic culture system, we showed an increase in TRH gene expression on glucocorticoid exposure. This effect is notable because human depression is characterized by hypercortisolemia, which we believe leads to activation of the TRH neuron and, consequently, thyroid function. The hypercortisolemia of depression probably results from impaired function of the hippocampus, a locus for glucocorticoid negative

Figure 2 Alterations of the hypothalamic–pituitary–thyroid axis (HPTA) in depression. In depression, various alterations of the HPTA have been described. (1) Blunted (+/–) thyrotropin (TSH) response to exogenous thyrotropin-releasing hormone (TRH) administration. (2) Elevated cortisol levels activate the TRH neuron, which can lead to down-regulation of the TRH receptor, providing one possible explanation for blunting of the TSH response to exogenous TRH. A spillover of TRH into the cerebrospinal fluid (CSF) can occur. (3) Decreased levels of transthyretin (TTR), a thyroxine (T_4) transport protein, have been found. (4) Circulating T_4 levels have been found to be elevated. (5) Inhibition of 5'-deiodinase type II (5DType II) occurs, possibly due to elevation of cortisol, resulting in decreased triiodothyronine (T_3). (6) T_4 is converted into reverse T_3 (rT_3), resulting in higher rT_3 levels in the CSF.

feedback of the hypothalamic–pituitary–adrenocortical axis. Although glucocorticoids generally inhibit the thyroid axis in humans and rats *in vivo*, a “functional” disconnection of the hypothalamus from the rest of the brain (as is postulated to occur in depression) would remove this inhibitory influence from the hypothalamus. Indeed, a fornical lesion that severs the hypothalamus from hippocampal regulation will increase thyroid function. In many ways, the hypothalamus in culture is analogous to a deafferented hypothalamus *in vivo*. We hypothesize that the direct stimulation of the TRH neuron by glucocorticoids seen *in vitro* is overridden *in vivo* by an inhibitory influence emanating from the hippocampus in the normal human or rat but not in some persons with clinical depression. In these individuals, activation of the TRH neuron could lead to increased hypothalamic TRH secretion with down-regulation of the TRH receptors. This could result in a blunted TSH response to exogenous TRH and spillover of TRH into the cerebrospinal fluid

(CSF), increased levels of which have been reported. In addition, we have explored a direct effect of antidepressants on the TRH neuron to explain the reversal of hyperthyroxinemia with successful treatment of clinical depression. The results showed that the selective serotonin reuptake inhibitors (SSRIs) and the tricyclic antidepressants (TCAs) inhibit TRH secretion. These studies suggest that the fall in circulating T_4 levels seen with antidepressant medication might reflect a direct effect on the TRH neuron and consequent reduced activation of the thyroid axis. Antidepressants may also be clinically efficacious by enhancing T_4 -to- T_3 conversion in the CNS.

As mentioned previously, T_3 is the active thyroid hormone in the brain. It has been hypothesized that depression leads to inhibition of type II deiodinase, possibly due to the elevated cortisol levels in this disorder. Therefore, T_4 is converted to rT_3 by 5-deiodinase. This would explain the elevated levels of rT_3 in the CSF of individuals with unipolar depression.

Transthyretin (TTR), a T_4 transport protein, is synthesized by the choroid plexus and accounts for up to 25% of the protein in the CSF. It has a relative binding affinity of 39.3% for T_4 and of only 1.4% for T_3 ; thus, it is unlikely that TTR plays a significant role in the transport of T_3 across the blood–brain barrier. Interestingly, in a study of eight patients with refractory depression, CSF levels of TTR were much lower when compared with nine patients with neurological disease but without depression. The authors of this study proposed that low levels of TTR could give rise to “brain hypothyroidism” with normal peripheral thyroid hormone concentrations in depression.

Autoimmune thyroiditis is found in at least 15% of depressed patients and is associated with an exaggerated response to TRH stimulation. In rapid cycling bipolar disease (four or more episodes of manic depression per year), the prevalence of autoimmune thyroid disease is even higher, reaching up to 50% in one series. Furthermore, women with postpartum thyroiditis often suffer from depression. In a study of 145 women with presence of antithyroid antibodies, 47% had significant depressive symptoms. When these women were compared with a control group, with negative titers to antithyroid antibodies, only 32% presented with depressive symptoms regardless of the thyroid function abnormalities. Among the antibody-positive individuals, 62 had episodes of thyroid dysfunction; a total of 27 had signs of hypothyroidism, 11 had signs of hyperthyroidism, and 24 showed biochemical evidence of hyperthyroidism followed by hypothyroidism.

Alterations in the circadian rhythm of TSH have been described, including absence of the normal nocturnal TSH surge that may result in an overall diminution of thyroid hormone secretion. This suggests that there may be a degree of central hypothyroidism in some patients with depression. Furthermore, sleep deprivation, which has an antidepressant effect, leads to restoration of the nocturnal TSH rise and an elevation in the levels of T_4 and T_3 .

DEPRESSION IN THYROID DISEASE

Hypothyroidism

Hypothyroidism indicates any degree of thyroid hormone deficiency. The Wickham survey found an incidence of 2% among 2800 individuals. The mean age at diagnosis was 57 years. Female predominance was noted, although in debilitated geriatric populations the prevalence does not have a gender difference. Subclinical hypothyroidism (SCH) is characterized by a mild elevation of the serum TSH, normal circulating levels of thyroid hormones, and absence of the typical symptoms of overt hypothyroidism. The prevalence of SCH is 2 to 8%. It is higher in women than in men (7.5 vs. 2.8%), particularly if the individual is over 60 years of age. In that instance, the prevalence can be as high as 16%. Progression to overt hypothyroidism occurs in 20 to 50% of individuals within a period of 4 to 8 years. Those patients with elevated titers of antithyroid antibodies have a higher incidence of progression (close to 80% within 4 years).

Studies in adult patients with hypothyroidism have demonstrated decreased cerebral blood flow and consumption of oxygen and glucose (27% below normal). Results from positron emission tomography (PET) studies indicate that TSH levels correlate inversely with global and regional blood flow as well as cerebral glucose metabolism. In addition, when PET studies were performed in individuals with severe hypothyroidism of short duration, the brain activity was globally reduced without the regional modifications observed in primary depression. As noted previously, T_3 in the brain is derived from deiodination of T_4 by type II deiodinase. The activity of this enzyme is increased in hypothyroidism. Intracerebral generation of T_3 increases as serum concentrations of T_4 decline. It seems that intracellular T_3 concentrations will remain fairly stable until serum T_4 has been depleted. Depression has been described in all grades of hypothyroidism. The occurrence of depression is believed to be higher in those who have a history of

a first-degree relative with depression. Up to 10% of patients admitted for treatment of depression are found to have subclinical or frank hypothyroidism. Clinical manifestations are indistinguishable from non-thyroid-related depression. Response is usually refractory to antidepressants alone; on certain occasions, it has also been resistant to thyroid hormone replacement.

Hyperthyroidism

Hyperthyroidism can be seen in up to 3% of individuals over 60 years of age. Typically, Graves' disease is still the most common cause of thyrotoxicosis in the elderly, but toxic multinodular goiter or adenomas are more frequent than they are in young people. The classic findings of hyperthyroidism are not seen in the elderly. The term "apathetic thyrotoxicosis" has been used to address such a condition, which may be associated with depressive symptoms (see Table IV), that are relieved by antithyroid treatment. The laboratory data may show a suppressed TSH with or without frank elevation of T_4 and T_3 . In studies of patients with thyrotoxicosis, depression has been documented in up to 30 to 60% of the cases.

THYROID HORMONE SUPPLEMENTATION IN DEPRESSION

In the evaluation of thyroid hormone as adjuvant therapy for depression, there is a need to exclude patients with borderline TSH elevation as well as those with detectable antithyroid antibodies. This population may respond favorably to thyroid hormone supplementation simply because of underlying hypothyroidism. In addition, when parameters of thyroid function are evaluated, the antithyroid peroxidase (anti-TPO) antibody should be included. It is conceivable that patients with evidence of autoimmune thyroid disease might benefit from treatment

with levothyroxine because the treatment corrects a cryptic underlying decrease in thyroid function. Patients with rapid cycling bipolar disease may benefit from pharmacological doses of levothyroxine. Such cases may reflect an aberrant expression of hypothyroidism. In studies involving thyroid hormone as adjuvant therapy in depression, T_3 appears to be superior to T_4 and so is used much more often. Cooke and colleagues reported that T_3 augmented the response to antidepressant therapy in T_4 -replaced hypothyroid patients in a randomized controlled trial during a 3-week period. Joffe found T_3 to be significantly more effective than T_4 in patients with depression who did not respond to TCAs. However, because T_4 equilibrates in tissues more slowly than does T_3 , 6 to 8 weeks of T_4 therapy may be required for adequate comparison of its efficacy with the more rapidly acting T_3 .

Thyroid Hormone Use to Hasten Antidepressant Response

The use of T_3 has been proposed to hasten antidepressant effect. The therapeutic response of TCAs is delayed up to 1 month. Prange and colleagues studied 20 patients with retarded depression, and 10 patients received T_3 sodium (25 μ g daily) in addition to imipramine (150 mg daily). The remaining patients were given imipramine, at equivalent doses, as well as placebo. After 10 days of treatment, they reported a significant improvement in the Hamilton Rating Scale (HRS) for depression. The scores improved by 50%, when compared with the initial value, in those taking the combination of imipramine and T_3 . The patients treated only with imipramine reached the same reduction in the HRS, but not until after the third week of treatment. The benefit of the combination was limited to women. Wilson and colleagues reported a similar benefit from adjuvant T_3 in 20 individuals with nonretarded depression.

Wheatley studied a double-blind comparison of amitriptyline alone and in combination with two doses of T_3 (40 and 20 μ g daily). These patients had been admitted for neurotic depression with minimal anxiety symptoms. A total of 52 patients were enrolled and then divided into three groups. All received amitriptyline (100 mg daily). There was a steady and significant improvement in depression scores for those who received T_3 (40 μ g daily) after 14 days of therapy. Interestingly, the patients who received the lower dose of T_3 did not seem to be that different from the placebo group when the self-rating scores were

reported. Once adjustments were made for gender, there was a significant response in females but not in males, confirming prior findings. There was no significant difference in responses once results were adjusted to age and anxiety score.

Some studies have not found any benefit from the use of thyroid hormone as an accelerator. One of these was a randomized double-blind study of 49 patients with primary depression in which patients were treated with imipramine (200 mg daily) alone or in combination with T_3 (25 μ g daily for 10 days). The researchers were unable to demonstrate at the end of the study period (22 days) that there was a significant difference between the two arms. The authors of the study questioned the efficacy of T_3 in enhancing the antidepressive activity of imipramine.

As Joffe and colleagues pointed out, these and other studies performed more than two decades ago suffered from the major limitations of small sample size and what are currently judged to be inadequate doses of antidepressants. Therefore, T_3 has not been established as a means of accelerating the onset of response to TCAs.

Thyroid Hormone Use to Convert Nonresponders to Antidepressants into Responders

Approximately 25% of patients with depression fail to improve with TCAs alone. As a consequence, there has been much interest in the possibility that augmentation therapy with T_3 could convert a nonresponder into a responder. While investigating the use of thyroid hormone as an augmentation strategy, Goodwin and colleagues treated 12 patients who had failed treatment with TCAs for at least 4 weeks and added T_3 (25–50 μ g daily). After 28 days of treatment, 8 patients experienced a significant improvement in the rating (score <5) that was sufficient to allow discharge from the hospital, whereas 4 reached a significant reduction in the HRS score (decrease of >3 points). Another study, one of the largest published to date, took 51 nonresponders to TCAs and added either T_3 , lithium, or placebo to the antidepressant. There was a significant response in half of those included in the T_3 and lithium groups when compared with those in the placebo group, although no superiority was seen in the use of either medication for augmentation. Thase and colleagues evaluated the efficacy of augmentation with T_3 in a series of 20 outpatients with recurrent unipolar depression who had failed an extended and closely monitored course

(>12 weeks) of imipramine and interpersonal psychotherapy. In their open clinical trial of adjunctive T_3 (25 μg daily) for 4 weeks, the overall response did not differ significantly from that of a matched historical comparison group managed with imipramine alone. Similar findings were noted by Steiner and colleagues, who used a double-blind study to compare the addition of T_3 to imipramine with imipramine and placebo and with electroconvulsive therapy (ECT). At the end of the 5 weeks, 3 of the 4 women with recurrent unipolar endogenous depression in each group responded to the specific regimen administered.

Currently, the most frequent prescribed antidepressants are the SSRIs. There are no controlled trials of T_3 augmentation with these agents. However, we can find case reports of beneficial effects from T_3 after failure to respond to them. An example is a 30-year-old woman with major depression who did not respond to a 10-week trial of fluoxetine (20 mg daily for 4 weeks and 40 mg daily for the remainder). Just 6 days after the addition of T_3 (25 μg daily), she reported improvement in her mood. The HRS score had dropped from 23 to 10. By 4 weeks of treatment, the score was 8, her suicidal ideations had disappeared, and her energy level and motivation had improved.

Moreover, recent studies have focused on whether a relationship can be detected between the swiftness in reaching a clinical remission or the risk of recurrence and the baseline thyroid hormone levels. Cole and colleagues observed that approximately one-third of 65 patients who presented in the depressive phase of bipolar I disorder had a thyroid profile consisting of a normal free thyroxine index and TSH values, although the levels were above the median in the latter. The remaining patients did not present with this profile and had a median time to remission of 1 year, whereas the group just mentioned experienced remission 4 months faster. Thus, the authors questioned whether adjuvant therapy with thyroid hormone may optimize the management of patients presenting in the depressive phase of bipolar disorders. Joffe and colleagues looked at the relationship between basal thyroid hormone levels and the life course of depressive illness in 75 outpatients with unipolar major depressive disorder. The significant positive predictors of recurrence were comorbid anxiety, number of previous episodes of depression, prolonged course of episodes, and level of T_3 . An increase in T_3 was associated with a 22% decrease in the risk of recurrence.

Although T_3 adjuvant therapy may help 25% of TCA nonresponders as some researchers claim, ob-

servers must be cautious about this conclusion for many reasons. First, we do not know with certainty which clinical and/or biochemical parameters determine the subset of depressed patients who will benefit from adjuvant T_3 . Second, the clarification of the thyroid status was not universally reported in the studies that are available, and unrecognized "subclinical" hypothyroidism or autoimmune thyroid disease could have led researchers to overestimate the therapeutic response to T_3 . Third, the relationship between T_3 dose and clinical response is unclear. Fourth, because the longest duration of T_3 administration in studies has been only a few weeks, the extent of treatment remains imprecise, although it has been recommended by some investigators that thyroid augmentation be discontinued 8 to 12 weeks after a response and then reinstated if symptoms recur. Fifth, studies regarding long-term side effects from use of T_3 in depressed patients are not available, and when instituting this form of therapy, the potential effect of thyroid hormone overreplacement on the heart and bones has to be strongly taken into account. Finally, longer and larger randomized, double-blind, placebo-controlled trials are needed, especially with SSRIs given that these are the contemporary antidepressants.

USE OF THYROTROPIN-RELEASING HORMONE IN REFRACTORY DEPRESSION

The therapeutic use of TRH in mood disorders is based on the fact that this hormone has direct effects on the CNS independent of pituitary and thyroid stimulation. High-affinity receptors to TRH are found throughout the brain especially, in the amygdala and the hippocampus, and modulate the effects of serotonin and dopamine. In addition, in some studies the concentrations of TRH in the CSF of untreated individuals with mood disorders were elevated. It remains unclear whether this corresponds to a natural compensatory mechanism or to a pathological occurrence. This elevation could render an explanation for the blunted TSH response after exogenous administration of TRH because if the relatively high endogenous levels of TRH are causing receptor down-regulation, the pituitary might be less responsive to exogenous stimulation. Some treatments for mood disorders, such as carbamazepine, increase endogenous production of TRH, further elevating the CSF levels and favoring the hypothesis that this is a compensatory mechanism possibly trying to overcome

the brain hypothyroidism. Marangell and colleagues administered 500 μg of TRH intrathecally to eight drug-free patients with refractory depression. Identical sham spinal punctures were performed a week apart. The study was carried out in a double-blind fashion. Five patients had a clinically significant, rapid, and robust but short-lived improvement in mood after TRH infusion, but not after the sham puncture. Systemic thyroid function was unaltered. None of the patients showed a worsening of depression after infusing TRH, suggesting that the elevation of TRH in the CSF is likely due to a physiological response. Intrathecal TRH might be a positive modulator of mood and might have a role in the treatment of refractory depression.

CONCLUSIONS

Hypothyroidism predisposes patients to depression that may be wholly reversed by thyroxine replacement. When first seen for depression, most patients have normal circulating TSH, T_3 , and T_4 . However, 15% may have subclinical hypothyroidism and have a TSH hyper-response to TRH stimulation. Another 10 to 15% may show evidence of autoimmune disease. In this setting, thyroxine may alleviate depressive symptoms alone or in combination with antidepressants. Various thyroid axis abnormalities in depression have been described, including a blunted TSH response to exogenous TRH, an increase in circulating T_4 , and elevated TRH levels in the CSF. It is hypothesized that there is enhanced hypothalamic TRH secretion that is triggered by dysfunction in the hypothalamic–pituitary–adrenal axis. The clinical features of depression often resemble those of hypothyroidism and may reflect brain hypothyroidism despite systemic euthyroidism. The mechanism may be related to impaired conversion of T_4 to T_3 in the brain due to inhibition of type II 5'-deiodinase, possibly by increased levels of circulating cortisol and/or reduced transport of T_4 across the blood–brain barrier. Adjuvant therapy with T_3 for patients receiving antidepressant medication has been postulated to augment responsiveness to therapy in about a quarter of cases of refractory depression, possibly by correcting brain hypothyroidism. TCAs and SSRIs have been reported to inhibit TRH gene expression *in vitro*, a fact that might explain the normalization of serum T_4 levels following treatment; TCAs also enhance the

conversion of T_4 to T_3 in the brain, providing another potential explanation for their therapeutic efficacy in depression. In some studies, the concentrations of TRH in the CSF of untreated individuals with mood disorders have been found to be elevated, and it is possible that this corresponds to a natural compensatory mechanism. Intrathecal TRH might be a positive modulator of mood, and its administration in refractory depression might be a reasonable strategy in managing the depression, but further studies are needed.

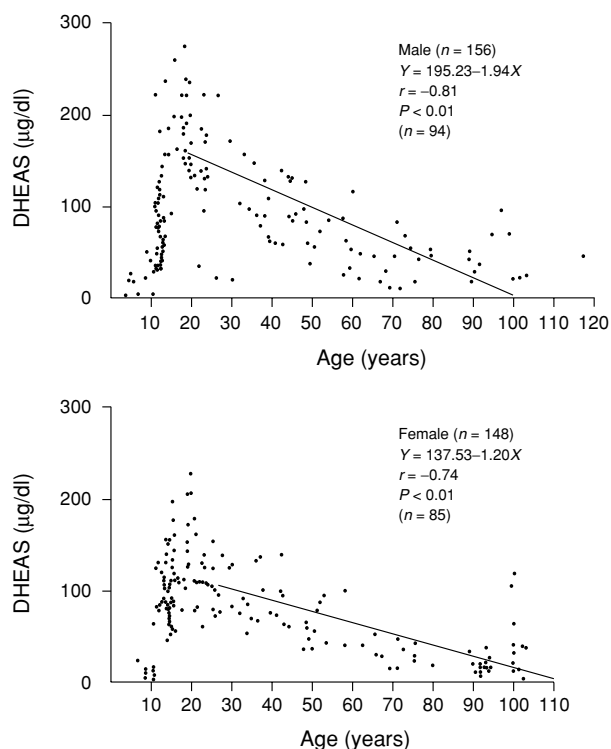

Figure 1 Age-related change in plasma DHEAS in the male and female.

BIOLOGICAL EFFECTS AND MECHANISM OF ACTION OF DHEA

The mechanism of action of DHEA(S) remains unclear, but three possible mechanisms have been hypothesized. The first possible mechanism is a direct action through the specific receptor. Although specific binding sites for DHEA have been reported in various cells and tissues, the receptor has not been successfully cloned as yet. The second possible mechanism is an indirect action, in which DHEA is converted to testosterone, or is further converted to estrogen by aromatase, in peripheral tissues and acts through the androgen receptor or the estrogen receptor. Thus, DHEA can be converted to active sex steroids and function in the same cell. This mechanism is called "intracrine action." The third possibility is that the hydrophobic DHEA molecule may alter cell function by interacting with certain macromolecules, such as enzymes.

Experimental studies have demonstrated that DHEA(S) has various beneficial effects including an anti-diabetic effect, prevention of atherosclerosis,

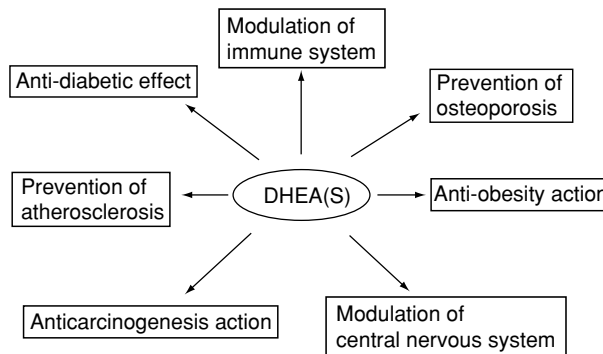

Figure 2 Beneficial effects of DHEA(S).

anti-obesity action, prevention of osteoporosis, and modulation of the immune system (Fig. 2).

Anti-diabetic Effect

It is reported that administration of DHEA improved insulin resistance by suppression of the increased activities of glucose-6-phosphatase and fructose-1,6-bisphosphatase in a non-insulin-dependent diabetes model, db/db mice. DHEA is also reported to improve insulin resistance observed in rats and decrease the serum level of tumor necrosis factor- α in obese Zucker rats. DHEA increases glucose uptake *in vitro* through the activation of protein kinase C or phosphatidylinositol 3-kinase. In human studies, the serum DHEAS level is reported to be lower in non-insulin-dependent diabetic patients than in age-matched normal male subjects.

Anti-obesity Action

An anti-obesity effect of DHEA has been observed in animal studies and may be related to several mechanisms including decreased lipogenesis and increased thermogenesis. In humans, the plasma concentration of DHEA decreases inversely with body mass index.

Prevention of Atherosclerosis

There are many retrospective and cross-sectional human studies demonstrating reciprocal relationships between the serum concentration of DHEA(S) and the incidence of ischemic heart disease. Animal studies also showed that the administration of DHEA

suppressed atherosclerosis induced by intimal injury or a high-cholesterol diet. It has been reported that DHEA suppressed the accumulation of cholesterol esters induced by the addition of acetylated low-density lipoprotein in cultured macrophage cells.

Prevention of Osteoporosis

Postmenopausal osteoporosis is a widespread clinical problem that correlates with low circulating levels of sex steroid hormones. A significant positive correlation between bone mineral density and the serum DHEAS level, but not the serum estradiol level, was observed in postmenopausal women, suggesting a possible role for DHEA(S) in preventing osteoporosis. It has been demonstrated that primary cultured human osteoblasts have aromatase activity, which is enhanced by dexamethasone and 1,25-hydroxyvitamin D₃ (Fig. 3). These results suggest that osteoblasts may utilize the circulating DHEA(S) and convert it to estrogen by aromatase to maintain bone mass after menopause.

REPLACEMENT THERAPY OF DHEA IN HUMANS

The replacement of DHEA has attracted attention in view of both the prevention of age-related diseases and the control of aging. DHEA is commercially available as a food supplement in the United States,

but the purity and content of that DHEA are not clearly specified. Clinical intervention trials of DHEA replacement are essential for establishing the significance of that therapy. Results from three randomized placebo-controlled studies support the concept that oral replacement of DHEA has beneficial effects.

Six months of daily replacement of DHEA (50 mg/day) in healthy adults (13 men and 17 women) restored the level of DHEA and DHEAS to the high levels observed in young people and caused an increase in the serum concentrations of androgen and insulin-like growth factor-I. This result is associated with a remarkable increase in perceived physical and psychological well-being in both sexes without an effect on libido.

The administration of DHEA (50 mg/day) in 24 female patients with adrenal insufficiency normalized serum concentrations of DHEA, DHEAS, androstenedione, and testosterone. DHEA significantly improved overall well-being as well as scores for depression and anxiety, the frequency of sexual thoughts, sexual interests, and satisfaction of both the mental and physical aspects of sexuality.

Two hundred eighty healthy men and women (60–79 years old) were given DHEA (50 mg/day) or placebo orally for 1 year in a double-blind, placebo-controlled study (DHEAge Study). DHEA administration reestablished a “young” concentration of DHEAS and a small increase in testosterone and estradiol with no adverse side effects. A significant increase in most libido parameters was observed in older women. An improvement in skin status in terms of hydration, epidermal thickness, sebum production, and pigmentation was also noted, particularly in women. Bone turnover was improved in women over 70 years of age as assessed by bone mineral density and bone resorption markers.

CLINICAL TRIAL FOR THE TREATMENT OF VARIOUS DISEASES

In a study of 14 postmenopausal women, 12 months of daily administration of DHEA via 10% cream caused a significant increase in bone mineral density accompanied by a 2.1-fold increase in the plasma osteocalcin level with no adverse side effects. Oral replacement of DHEA (50 mg/day) in 18 elderly people also increased bone mineral density and decreased fat mass.

The intravenous administration of DHEAS (200 mg/day for 8 weeks) in 11 patients with myotonic dystrophy led to an improvement in the activities of

daily living, an increase in muscle strength, and a decrease in myotonia.

Oral administration of DHEA (50–200 mg/day for 1 year) in 50 female patients with systemic lupus erythematosus (SLE) induced a decrease in the activity of SLE and led to a decrease in the requisite dose of prednisolone.

CONCLUSION

DHEA is theorized to act as an anti-aging hormone against age-related diseases. However, it is not known whether or not the increase in sex steroid levels in long-term DHEA replacement is safe with regard to the development of steroid-dependent cancers, such as ovarian and prostate cancers. It is necessary to establish the clinical evidence for DHEA replacement therapy in the elderly by conducting prospective long-term randomized studies.

responsible for acquired NDI. In addition to drug treatment, acquired NDI can also occur temporarily or permanently as a result of certain diseases, such as chronic kidney failure, sickle cell disease, amyloidosis, sarcoidosis, and Sjögren syndrome, and infections.

MOLECULAR MECHANISMS OF INHERITED NDI

Water reabsorption by the collecting duct is under hormonal control of AVP. The hormone binds to *AVPR2*s of collecting duct cells and initiates a series of intracellular events (Fig. 1). *AVPR2* is a peptide

Figure 1 Mechanism of AVP-induced increase in water permeability in collecting duct cells. The first step in the antidiuretic action of vasopressin (AVP) is its binding to the V₂ vasopressin receptor (*AVPR2*), which is located on the basolateral membrane of collecting duct cells. The receptor is linked to a heterotrimeric G α s protein, which activates adenylyl cyclases. The cyclases increase the production of cyclic AMP (cAMP). By an unknown process that involves protein kinase A, *aquaporin-2* (*AQP2*)-containing vesicles are translocated to the apical plasma membrane, those increasing water permeability of the collecting duct. Mutation of the *AVPR2* or the *AQP2* gene can cause inherited NDI.

receptor that belongs to the large superfamily of G protein-coupled receptors (GPCRs). The receptor activates adenylyl cyclases by interacting with the heterotrimeric G α s protein. Adenylyl cyclase activation increases the intracellular concentration of cyclic AMP (cAMP). cAMP induces the translocation of *AQP2*-laden vesicles to the apical plasma membrane. Ultimately, an increase in the number of *AQP2* water channels incorporated into the luminal membrane of collecting duct principal cells elevates cellular water permeability. The molecular mechanisms underlying docking and fusion of *AQP2*-bearing vesicles are currently unknown.

Following the identification of the DNA sequences and genomic structures of the *AVPR2* and *AQP2* genes, mutations in both genes were determined to be responsible for inherited NDI forms. Autosomal NDI accounts for approximately 10% and X-linked NDI is responsible for approximately 90% of cases of congenital NDI. However, X-linked NDI is still a rare disorder and occurs with a frequency of 4–8 per 1 million male live births. Identification of the molecular defect underlying inherited NDI is of clinical significance because early diagnosis and treatment of affected infants can prevent physical and mental retardation resulting from repeated episodes of dehydration. Probably because of dehydration and hypernatremia in early infancy, only 11% of untreated patients with inherited NDI have normal intelligence. Therefore, immediate genetic testing and identification of inactivating mutations within the candidate genes followed by adequate treatment of inherited NDI result in almost normal physical and mental development.

Mutations in the *AVPR2* Gene

The *AVPR2* gene is located at the genomic locus Xq28, and more than 170 disease-causing *AVPR2* mutations have been identified in X-linked NDI families. A large variety of genomic alterations have been identified in the *AVPR2* gene, yielding approximately 51% missense mutations, 23% small deletions, 10% nonsense mutations, 8% small insertions, and 6% large or complex deletions with no preference for a distinct receptor portion. The remaining 2% affect proper mRNA splicing.

Mutations within the *AVPR2* gene can affect receptor function at different levels. At the genomic level, partial or complete gene deletion can interfere with gene transcription. Small genomic alterations can lead to nonsense mutation-mediated mRNA decay and splicing errors (mRNA level). Mutation-induced

structural changes in the receptor protein can interfere with proper receptor folding and trafficking (post-translational level), thus promoting protein degradation in endosomes. Finally, mutations can also abolish receptor signaling by disturbing the ligand-binding domain or G-protein interaction sites (functional level). After a GPCR has been synthesized, the receptor polypeptide adopts a structure that enables the receptor to pass through the endoplasmic reticulum (ER) quality control machinery. More than 80% of all missense mutations lead to incompletely folded receptor proteins that are retained intracellularly by the ER quality control system. Some clinically relevant examples of *AVPR2* mutations show that loss of receptor function is mainly caused by reduced affinity for the natural ligand (e.g., F105V and V290G). The impaired ligand binding is indicated by a concentration-response curve that is shifted toward higher vasopressin concentrations. To clearly differentiate between trafficking defects and abolished agonist binding and/or functional coupling, second messenger and radioligand binding assays and immunologic methods are applied in *in vitro* test systems.

Mutations in the *AQP2* Gene

In less than 10% of the NDI families studied, congenital NDI has an autosomal recessive mode of inheritance. Approximately two dozen disease-causing mutations have been identified in the *AQP2* gene, which is located in chromosome region 12q13. Sixty-five percent are missense mutations, 23% frameshift mutations caused by small nucleotide deletions or insertions, 8% nonsense mutations, and 4% splice site mutations. Similar to many *AVPR2* mutations, the majority of mutant *AQP2* proteins underlying autosomal recessive NDI were found to be intracellularly trapped and not expressed at the luminal plasma membrane.

Mutations in the *AQP2* gene are also the basis of the autosomal dominant NDI. Aquaporins form homotetramers containing four water channel molecules. It has been demonstrated that a mutation in only one allele of the *AQP2* gene (e.g., E258K) has a dominant negative effect on the wild-type *AQP2* by interfering with proper membrane targeting of the *AQP2* homotetramer.

Animal Models of NDI

A nonsense mutation known to cause X-linked NDI in humans (E242X) was introduced into the mouse

genome. The mutant male mice died within the first week after birth, apparently due to hypernatremia and dehydration caused by the inability of these animals to concentrate urine. The body weight and the urine osmolality levels of the *AVPR2*-deficient mice were significantly reduced. Interestingly, heterozygous adult female mice showed clear symptoms of NDI, including reduced urine-concentrating ability, polyuria, and polydipsia.

A mouse knock-in model of autosomal NDI (T126M mutation) was generated by a targeted *AQP2* gene replacement strategy. The mutant mice died within 6 days after birth unless given supplemental fluid. Urine/serum analysis showed a urinary concentrating defect with serum hyperosmolality and low urine osmolality that could not be corrected by a *AVPR2* agonist. Immunohistologic and histologic analyses revealed kidney collecting duct dilatation and papillary atrophy.

CLINICAL SYMPTOMS AND DIAGNOSTIC

The primary symptoms of NDI are polyuria and polydipsia. Inherited NDI may appear in the first weeks of life with symptoms that include fever, irritability, constipation, failure to thrive, lack of appetite, vomiting, and high blood levels of sodium chloride. Due to recurrent electrolyte and fluid imbalances, NDI patients can develop mental retardation. In some cases, secondary symptoms of NDI are observed, such as an enlarged urinary bladder, dilated ureters, or nonobstructive hydronephrosis.

If a patient shows the classic symptoms of DI (polyuria and polydipsia), testing includes measurements of urine osmolality and serum/plasma parameters, such as sodium, potassium, chloride, osmolality, and AVP level. To confirm an NDI diagnosis and to help determine the type of NDI, the patient is given a water-deprivation test. Measurement of the patient's response to a synthetic analog of AVP, 1-desamino-8-D-arginine vasopressin (desmopressin, DDAVP) is also required. If the patient shows almost normal urine concentration abilities in response to DDAVP, a pituitary DI is more likely. It has been reported that *AQP2* is detectable in the urine in both soluble and membrane-bound forms. In normal subjects, an infusion of DDAVP increased the urinary excretion of *AQP2*. In patients with central DI, administration of vasopressin in the same form likewise increased urinary excretion of *AQP2*, but there was no increase in patients with X-linked or autosomal NDI.

The expression of AVPR2 is not only restricted to the kidney but also found in extrarenal tissue, such as endothelium cells. Thus, DDAVP stimulates the release of factor VIII-related antigen from vascular epithelium and factor VIII coagulant activity from liver and other unidentified sites in normal subjects, in addition to increasing plasma renin activity and stimulating the release of von Willebrand factor. DDAVP administration also exerts a vasodilatory action, manifested by facial flushing, a decrease in diastolic blood pressure, and an increase in pulse rate. These effects of DDAVP administration were absent in NDI patients and reduced in obligatory carriers. In autosomal recessive NDI patients with a defect in *AQP2*, the defect is limited to the kidney and the extrarenal effects of DDAVP are normal. Extrarenal parameters may be useful to differentiate clinically between the *AVPR2* and *AQP2* gene defects.

Some patients may have a partial form (partial resistance to AVP) of DI. In these cases, diagnosis is more challenging. A significant number of patients who have either the acquired or the inherited forms of NDI can concentrate their urine during standard fluid deprivation and/or DDAVP tests because they have only partial resistance to the antidiuretic effects of vasopressin.

TREATMENT

There is no causal cure for inherited NDI. Affected males should be treated immediately with abundant water intake day and night, a low-sodium diet, and thiazide diuretics. Temperature, urine volume, water intake, appetite, and growth should be monitored closely during the first months. The urinary output is decreased by only 30%, and a normal growth curve is difficult to attain during the first 2 or 3 years of life, despite employing the previously discussed treatments and providing intensive attention.

Thiazide diuretics can reduce polyuria of NDI patients, but they can also deplete the body's potassium stores. To maintain sufficient potassium in the body, combining a thiazide (e.g., hydrochlorothiazide) with a potassium-sparing diuretic (e.g., amiloride) may be more effective than using a thiazide alone. Thiazides can reduce the degree to which the kidney can excrete lithium and should be used with care in

cases of lithium-induced NDI because of a toxic buildup of lithium plasma levels. Amiloride is more widely used in these cases because it inhibits the accumulation of lithium. Sometimes, thiazides are used in combination with indomethacin. Indomethacin inhibits the synthesis of prostaglandin in the kidney, which leads to a reduction of polyuria in cases of both inherited and acquired NDI. Low-sodium diets (300–500 mg sodium per day) are recommended because the improvement of water absorption is negated by a diet heavy in salt.

There are some experimental approaches to rescue the function of mutant *AQP2* and *AVPR2* molecules. It has been demonstrated that small molecules such as glycerol (so-called chemical chaperones) can assist mutant *AQP2s* to exit from the ER and ultimately be transported to the plasma membrane. Similarly, non-peptide antagonists have been successfully used to improve plasma membrane trafficking and function of intracellularly retained AVPRs harboring missense mutations. Based on findings that all *GPCRs* are likely composed of multiple folding units, it was demonstrated that truncated *AVPR2s* can be functionally reconstituted by coexpressing the missing receptor fragments. In the future, these new approaches may provide alternatives for restoring kidney concentration abilities. The therapeutic feasibility of these potential strategies needs to be tested in mouse models for NDI.

components. The AVP is then transported within these vesicles down the neuronal axon to the posterior pituitary, where it awaits an excitatory stimulus for release into the circulatory system.

Secretion

In healthy adults, AVP secretion is regulated primarily by the effective osmotic pressure of extracellular fluid. This pressure is determined by the concentration of solutes that do not readily cross cell membranes, and it results largely from the concentration of serum sodium and its associated anions. Total osmolarity may be determined by direct plasma measurement or estimated by doubling the serum sodium, with minor additions for blood urea nitrogen (BUN) and serum glucose (Glu), as follows:

$$\text{Calculated serum osmolarity} = 2(\text{Na}) + \text{BUN}/2.8 + \text{Glu}/18$$

The influence of osmolarity on AVP secretion is mediated by specialized sensory cells known as osmoreceptors that are thought to be located in the front of the hypothalamus near the supraoptic nucleus. They are capable of detecting minute changes in the plasma concentration of sodium and certain other solutes. The level at which AVP secretion begins is commonly known as the osmotic threshold or setpoint. Below this level of osmolarity, AVP secretion is suppressed to low or undetectable levels. Above it, AVP secretion rises steeply in direct proportion to plasma osmolarity. In healthy adults, the osmotic setpoint for AVP release averages approximately 280 mOsm/liter, corresponding to a serum sodium concentration of approximately 135 mEq/liter, although it may vary appreciably due to genetic influences, pregnancy, and even menstruation. The sensitivity of osmoregulation also varies widely between individuals.

In addition to osmoregulation, nonosmotic stimuli may play a major role in AVP release under pathologic conditions. Major changes in blood pressure or volume may trigger specialized sensors known as baroreceptors, which are located in the atria, aorta, and carotid vessels. This pathway undoubtedly plays an important role under conditions such as hemorrhage or dehydration, but it is not believed to play a major role under normal conditions since major changes on the order of 10–20% are necessary to appreciably increase AVP release. Other nonosmotic stimuli, such as nausea, cortisol deficiency, and low blood sugar, may also effect an increase in AVP release. Notably, nausea is one of the most powerful

stimuli, resulting in a 50- to 100-fold increase in basal AVP levels.

Action

In humans, the primary biologic action of plasma AVP is to fine-tune the urinary excretion of water by selectively increasing its reabsorption from the reduced volume of glomerular filtrate that reaches the collecting ducts. This antidiuretic effect is mediated by binding of AVP to receptors located on cells lining the collecting duct, thereby increasing the number of water channels in these cells. The net result is an increase in water permeability, allowing water to passively diffuse from the tubular fluid into the hyper-tonic milieu of the renal medulla. Resultant urine excretion is marked by low volume and high concentration. Urine concentration, measured as osmolarity or specific gravity, varies as a positive exponential function of plasma AVP concentration (Fig. 1B) and has a curvilinear inverse relationship to urine flow (Fig. 1A). This relationship may be altered in various

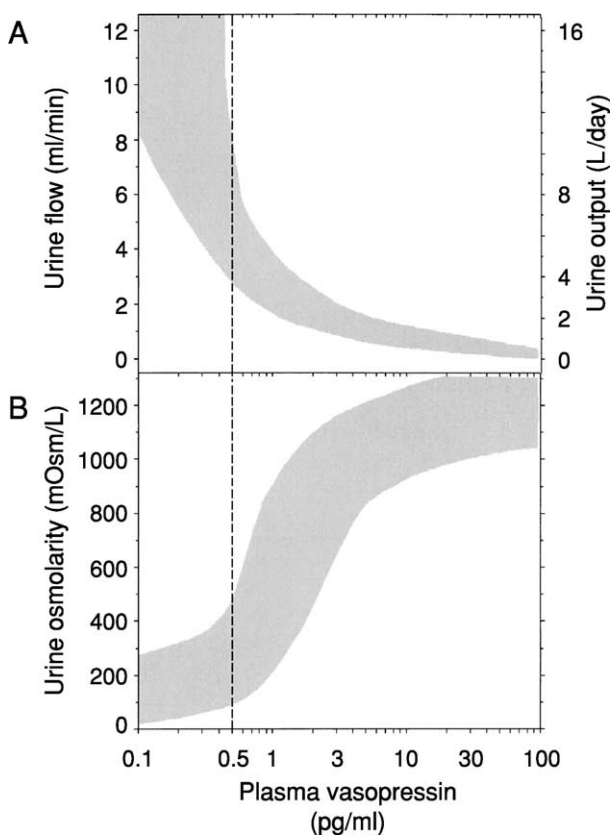

Figure 1 Typical response in normal individuals: (A) inverse curvilinear relation of urine volume and flow rate to plasma vasopressin levels and (B) direct exponential response of urine concentration (expressed in osmolarity) to plasma vasopressin levels.

ways by disorders of the kidney or variations in the amount of sodium, chloride, urea, or other solute necessary for excretion.

Thirst and Satiation

In humans, the regulation of water intake is as important as the control of urine output for maintaining normal water balance. Thirst, defined as a consciously perceived desire for water, is the principal mechanism for ensuring that water intake is always sufficient to replenish losses. It is regulated by hypothalamic osmoreceptors in much the same way as AVP. The only difference seems to be that the osmotic threshold for thirst is “set” slightly higher (5–15 mOsm/liter) than that for AVP release. Thus, in a healthy adult, thirst and polydipsia usually do not begin until plasma osmolarity rises to a level at which AVP secretion is sufficient to produce a maximum antidiuresis. This arrangement ensures that the antidiuretic mechanism will always be utilized initially in the defense against hypertonic dehydration, with provision for an essential backup protection against water losses that threaten to overwhelm the other compensatory mechanisms. Some kind of satiety mechanism for inhibiting water intake may also exist in healthy adults since fixing antidiuresis near the maximum for weeks does not result in overhydration because basal, *ad libitum* fluid intake decreases in proportion to urine output. Thus, the mechanisms for regulating fluid intake not only provide a necessary function but also are able to do so with admirable precision in maintaining a normal water balance under various adverse conditions.

CAUSES

Neurogenic diabetes insipidus (DI) is considered an uncommon disorder, although there are no reliable data regarding incidence or prevalence, and diagnosis may frequently be missed. Approximately 50% of cases can be attributed to destruction of the neurohypophysis by an identifiable genetic, congenital, or acquired disease, including trauma, neoplastic infiltration from either primary or metastatic disease, granulomatous disease, and infection (Table I). The remainder are classified as idiopathic. Of the genetic forms, the most common is a completely penetrant, autosomal dominant form caused by mutations of the AVP gene.

PATHOPHYSIOLOGY

Typically, irreversible destruction of 80–85% of the neurohypophysis is necessary to elicit neurogenic DI.

Table I Causes of Neurogenic Diabetes Insipidus

| |
|--|
| Acquired |
| Head trauma (closed and penetrating) |
| Neoplasms |
| Primary |
| Craniopharyngioma, adenoma, dysgerminoma, meningioma |
| Metastatic (lung, breast) |
| Hematologic (lymphoma, leukemia) |
| Granulomas |
| Sarcoidosis, histiocytosis |
| Infectious |
| Chronic meningitis, viral encephalitis, toxoplasmosis |
| Inflammatory |
| Lymphocytic infundibuloneurohypophysitis, Wegener's granulomatosis, lupus erythematosus, scleroderma |
| Vascular |
| Sheehan's syndrome, aneurysm (internal carotid), infarction |
| Pregnancy (associated with vasopressinase) |
| Idiopathic |
| Congenital malformations (present at birth, regardless of causation) |
| Septo-optic dysplasia |
| Midline craniofacial defects |
| Holoprosencephaly |
| Hypogenesis, ectopia of pituitary |
| Genetic |
| Autosomal dominant |
| Autosomal recessive |
| X-linked recessive |

In adults with normal thirst and access to water, overt signs of dehydration are absent since the polyuria produces only a 1 to 2% decrease in total body water prior to commensurate increases in thirst and fluid consumption. Only when thirst is deficient and/or access to water is limited are patients unable to compensate for the urinary loss, and they can develop significant elevations in serum sodium (hypernatremia) and hyperosmolarity. The AVP deficiency can vary in severity from patient to patient, resulting in large individual differences in the urinary response to fluid deprivation. Many patients with partial AVP deficiency retain the ability to concentrate urine above 300 mOsm/liter.

DIAGNOSIS

The initial step in the evaluation is to establish the presence of DI by obtaining a 24-h urine collection to document that the volume is abnormally high (typically exceeding 45 ml/kg per 24 hours) and the concentration or osmolarity is abnormally low (typically less

than 300 mOsm/liter). A urine creatinine should be obtained simultaneously to confirm an adequate collection.

Once a diagnosis of DI is established, the next step is to determine the type of DI. This is essential because treatment strategies vary markedly and, if misapplied, can have dire consequences. Measurements of basal plasma osmolarity or sodium are rarely, if ever, helpful because they are almost always normal and vary over the same range in all types of DI. Therefore, except in the rare patient with hypertonic dehydration (i.e., hypernatremia) under basal conditions, the first step in the differential diagnosis is to determine whether the patient can concentrate urine in response to fluid restriction. Close monitoring is necessary, with serial determinations of body weight, fluid intake and output, and periodic measurements of plasma and urine for both osmolarity and sodium, in order to define the patient's response. Failure to concentrate urine above 300 mOsm/liter prior to either a 5% decrease in body weight or an increase in plasma osmolarity or sodium above the upper limit of normal excludes partial forms of DI and indicates a severe form of nephrogenic or neurogenic DI. In this instance, further differentiation between nephrogenic and neurogenic DI can be accomplished by determining the response in urinary concentration to antidiuretic hormone by injection of desmopressin acetate in a typical treatment dose. A precipitous decline in urine volume accompanied by an increase in excess of 50% in urinary osmolarity following administration of desmopressin indicates severe neurogenic DI (Fig. 2). However, an absent or attenuated response indicates nephrogenic DI.

If the patient concentrates urine in response to fluid deprivation, severe forms of nephrogenic or neurogenic DI are excluded, but the patient may still have primary polydipsia or partial forms of nephrogenic or neurogenic DI. Further differentiation among these disorders may be performed by measuring plasma AVP when plasma osmolarity and/or sodium are above the normal range (Fig. 3). This requisite of plasma hypertonicity may be difficult to achieve rapidly by fluid deprivation alone in this subset of patients who retain some degree of urinary concentrating ability, and cautious intravenous infusion of hypertonic (3%) saline may be required.

Magnetic resonance imaging (MRI) of the brain may also be helpful in the differential diagnosis of DI as well as in identifying the pathology responsible for the neurogenic and dipsogenic forms. On T1-weighted midsagittal images, the posterior pituitary emits a hyperintense signal (or bright spot) in 85–90%

Figure 2 Characteristic pattern of selected variables observed in individuals with severe neurogenic DI under basal conditions and in response to desmopressin (DDAVP) administration. Note that treatment primarily restores urinary concentration and rapidly reduces thirst and fluid consumption, with normalization of urine volume.

of healthy individuals. This bright spot is almost always present in patients with primary polydipsia but is invariably absent or small in patients with neurogenic DI. However, it is also usually absent in cases of nephrogenic DI. Therefore, a normal posterior pituitary bright spot excludes neurogenic DI, mitigates against nephrogenic DI, and strongly favors dipsogenic DI. The absence of the bright spot is less meaningful but is a strong indication against primary polydipsia and favors the diagnosis of neurogenic or nephrogenic DI.

MANAGEMENT

There are two major aspects in the treatment of neurogenic DI. The first is the elimination of the polyuria, thirst, and polydipsia by treating with desmopressin acetate, a synthetic analogue of the natural hormone that is more resistant to degradation and devoid of smooth muscle effects. It may be given orally (p.o.), intranasally (i.n.), or parenterally [subcutaneously (s.q.) or intravenously (i.v.)], with relative doses between the different routes approximating

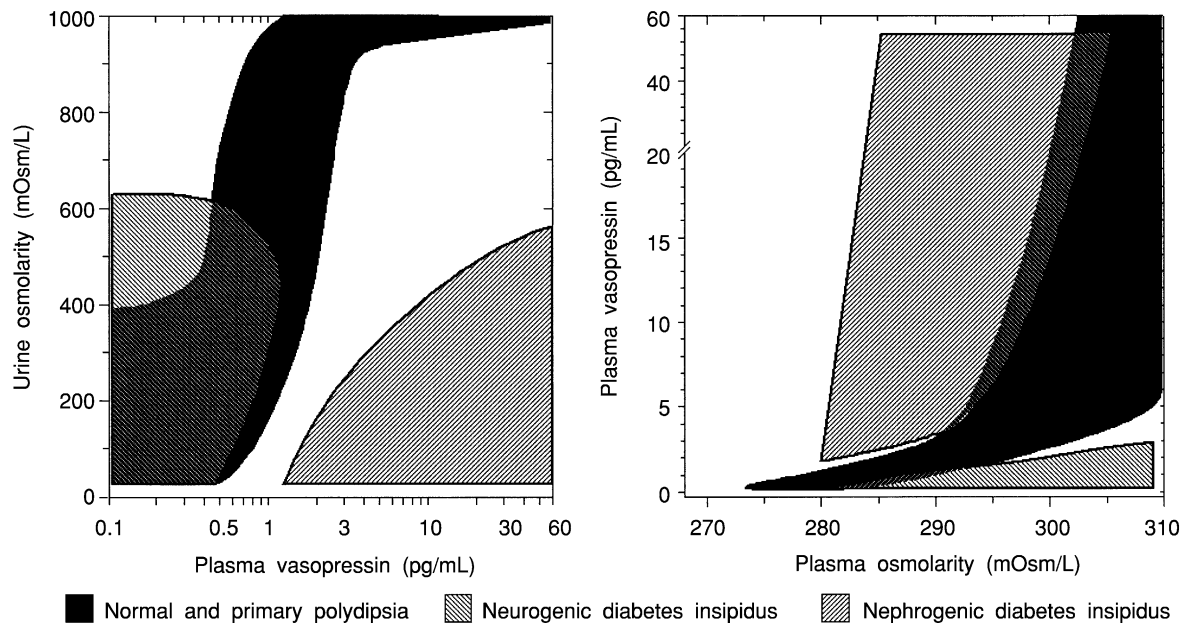

Figure 3 Relationship of plasma vasopressin to urine osmolarity (left) and plasma osmolarity (right). The wide range of values for both plasma osmolarity and AVP levels was generated by fluid deprivation, with hypertonic saline administration as needed. The shaded areas illustrating neurogenic and nephrogenic DI represent both complete and partial forms of each syndrome.

a logarithmic scale. Typical replacement doses for an adult are 50–200 μg p.o., 5–20 μg i.n., or 1 or 2 μg i.v. or s.q. given two or three times per day as needed to maintain the antidiuretic effect. Individual requirements vary widely and must be determined empirically by assessing relief of symptoms and changes in 24-h urine volume.

If the patient with neurogenic DI has a normal thirst mechanism and drinks only when thirsty, administration of desmopressin in doses sufficient to completely normalize urine output will not result in water intoxication because spontaneous fluid intake decreases in exact proportion to urine output and insensible loss. However, if the patient has primary polydipsia or an associated hyperdipsia, the same treatment will rapidly produce water intoxication because fluid intake is not reduced as much as urine output and the excess cannot be excreted due to the antidiuretic effect of desmopressin. This can have a variety of consequences, ranging from mild asymptomatic hyponatremia to mental status changes, seizure, coma, and even death in extreme circumstances. Therefore, in the first 3–7 days following the initiation of desmopressin or a change in dose, patients should be monitored to verify that their thirst and polydipsia cease and serum sodium remains within the normal range. Furthermore, they should be counseled regarding the symptoms and risk of

water intoxication and the paramount importance of drinking only enough to satisfy thirst.

An alternative to desmopressin in the treatment of neurogenic DI is chlorpropamide. This drug, classified as a first-generation sulfonylurea, has typically been used for treatment of diabetes mellitus, although it has been found to be effective in controlling or at least ameliorating signs and symptoms of neurogenic DI. The mechanism of its antidiuretic effect is uncertain, but it is thought to be due to either potentiation of existing plasma AVP or direct receptor activation. Regardless, for the patient with neurogenic DI, the net effect is similar to that achieved with desmopressin, although antidiuresis is typically slower in onset and its maximal effect is less.

The second aspect of treatment is the search for the underlying cause of neurogenic DI. At a minimum, this involves obtaining an MRI of the brain to search for a space-occupying lesion, such as a neoplastic, infectious, or granulomatous process, that might be treated medically or surgically. If the MRI does not show a likely cause and/or there is a history of childhood onset or other affected family members, the possibility of a genetic cause should be investigated by direct genetic testing. It should be remembered, however, that despite a thorough investigation, no cause is found in up to 50% of cases, resulting in a diagnosis of idiopathic neurogenic DI.

PREVALENCE OF DIABETES MELLITUS

The prevalence of diabetes is increasing among the U.S. population across age groups. According to data from the Centers for Disease Control (CDC), diabetes affects 6.2% of the population, which represents approximately 17 million people. In addition, undiagnosed diabetes occurs in more than one-third of this population group, or approximately 5.9 million people. Estimates of the prevalence of the disease among older adults in 2000 indicated that 7 million people, or 20% of all people older than age 65, had diabetes. The prevalence of diabetes was 22 and 19% among elders in the age categories 65–74 and 75+, respectively.

Analyses of annual trends of the prevalence of diabetes among the elderly indicate that in addition to being high, it is also on the rise. In 1990, the prevalence of diagnosed diabetes among the older adult population (aged 45+) ranged from 5.5% among those 45–64 years of age to approximately 10% among people aged 65–74 (Fig. 1). By 1999, the prevalence of diabetes was 8.1 and 14.5% for the same age groups, respectively, with increases from 8.6 to 12.6% among people 75 years of age or older.

Between 1990 and 1999, the largest increase in the prevalence of diabetes was observed among people 65–74 years of age, for whom diagnosed diabetes increased 48% (from 10 to 15 per 100 people) (Fig. 2). Increases of 47 and 46.5% were also observed for older adults in the 45–64 and 75+ age groups, respectively.

People with diabetes are approximately two times more likely to die than those free of the condition, with the most frequent cause of death being cardiovascular disease. In 1999, diabetes was the sixth leading cause of death based on CDC data. Furthermore,

Figure 1 Age-adjusted prevalence of diabetes in the U.S. older adult population (45 years or older) by age group, per 100 population, 1990–1999.

Figure 2 Increases in the prevalence of diabetes in the U.S. older adult population (45 years or older) by age group, 1990–1999.

diabetes imposes a major economic burden on the health sector of most countries. According to estimates from the American Diabetes Association (ADA), in 1997 the total costs in the United States associated with diabetes were \$98 billion, of which 45% represented direct medical costs and the remaining 55% (\$54 billion) was attributed to indirect costs, including disability, work loss, and premature mortality due to the disease.

RISK FACTORS ASSOCIATED WITH DIABETES

There is uncertainty about the specific factors that trigger the development of type 2 diabetes. However, it is known that certain high-risk groups of people are more likely to develop the condition than other groups. Table I summarizes some of the main risk factors for diabetes. Age is an important risk factor, with a positive association beginning after age 30. As previously noted, more than 20% of the U.S. population aged 65 or older has diabetes. It has been reported that Hispanics, African Americans, Native Americans, Pacific Islanders, and other ethnic and racial groups are at a higher risk for diabetes than the general population. Also, evidence shows that approximately 80% of adults with type 2 diabetes are overweight and physically inactive. Those with a family history of diabetes are also at increased risk for the disease. Women who have had gestational diabetes or who have given birth to a baby weighing more than 9 pounds are also at higher risk for developing diabetes later in their lives. Furthermore, there is elevated risk for diabetes among women with polycystic ovary syndrome who are also overweight. The risk is also high for those known to have impaired glucose tolerance (IGT) or impaired

Table I Risk Factors for Type 2 Diabetes

| |
|---------------------------------|
| Older than 45 years of age |
| Obesity |
| Family history of diabetes |
| Ethnicity |
| History of gestational diabetes |
| Hypertension |
| Dyslipidemia |
| Impaired fasting glucose |
| Impaired glucose tolerance |

fasting glycemia (IFG) as well as for those who have high blood pressure or signs of heart disease or poor circulation.

SYMPTOMS OF DIABETES IN THE ELDERLY

Type 2 diabetes has a gradual onset, with signs of the disease developing over years. The classic symptoms, listed in [Table II](#), are usually subdued or even absent in older individuals, and the disease is often diagnosed several years after its onset, when complications are already present. Regular screening for the disease after age 45 is usually the best way to detect early type 2 diabetes and avoid complications associated with the disease.

DIAGNOSIS

The current criteria for diagnosis of diabetes mellitus are based on the 1997 recommendations of an international expert committee from the ADA and the World Health Organization. Based on these recommendations, and according to the 2003 guidelines from the ADA, three diagnosis criteria may be used, with confirmation on a subsequent day. [Table III](#) lists these criteria.

Hyperglycemia between normal and diabetes levels is classified as prediabetes and includes two categories: IFG, which is present with fasting plasma glucose

Table II Symptoms of Type 2 Diabetes

| |
|-----------------------------------|
| Polyuria (frequent urination) |
| Polydipsia (excessive thirst) |
| Weight loss |
| Severe fatigue and/or nausea |
| Blurred vision |
| Frequent and recurrent infections |
| Slow healing of wounds or sores |

Table III Diagnosis of Diabetes Mellitus^a

| Parameter | Criteria for diagnosis |
|---|---|
| Fasting plasma glucose | 7.0 mmol/liter (126 mg/dl) |
| Random plasma glucose ^b and symptoms of diabetes | 11.1 mmol/liter (200 mg/dl) (see Table II) |
| Oral glucose tolerance test | 11.1 mmol/liter (200 mg/dl) 2 h after a glucose load 75 g |

^aAccording to the American Diabetes Association (2003a).

^bRandom or casual refers to any time, independent of meal times.

between 6.1 and 6.9 mmol/liter (110–126 mg/dl), and IGT, which is diagnosed with an oral glucose tolerance test that results in 2-h plasma of 7.8–11.0 mmol/liter (140–199 mg/dl).

Detection of diabetes among older individuals generally occurs late. It is estimated that onset of type 2 diabetes precedes clinical diagnosis by 10–12 years. It has been reported that among people with undiagnosed type 2 diabetes, 10–29% have retinopathy, 10–37% have proteinuria, and 9% have neuropathy at the time of diagnosis. These complications associated with uncontrolled diabetes take 10 or more years to develop in the presence of the disease.

COMPLICATIONS OF TYPE 2 DIABETES

Since the metabolic problems associated with diabetes affect the entire body, elderly people with this condition face multiple potential complications affecting many different organ systems. If the management of the disease is poorly controlled, if the disease is left untreated, or if the diagnosis is made late, serious complications can occur. Moreover, poor glyce-mic control among people with diabetes is a major risk factor for end-stage complications of this condition.

Cardiovascular disease (e.g., coronary heart disease and stroke) is the leading cause of morbidity and mortality among persons with diabetes. Cardiovascular disease is two to four times more common in adults with diabetes. The rate of stroke is 2.5 times higher in this population, and high blood pressure affects 60–65% of those with diabetes.

Diabetes is the leading cause of blindness and visual impairment in adults. Nerve damage combined with peripheral vascular disease make diabetes the most common cause of lower extremity amputation. Between 60 and 70% of persons with diabetes have mild to severe forms of diabetic nerve damage, and more than half of lower limb amputations in the United States occur among diabetics.

There is conclusive evidence that good control of blood glucose levels can substantially reduce the risk of developing complications and slow their progression in all types of diabetes. Results from the Diabetes Control and Complications Trial Research on type 1 diabetes, the U.K. Prospective Diabetes Study on type 2 diabetes, and the Kumamoto study, also on type 2 diabetes, confirm that better glycemic control is associated with reductions in both the incidence and the progression of retinopathy and nephropathy in subjects with type 1 and type 2 diabetes mellitus. Available evidence also links macrovascular disease (cardiovascular, peripheral vascular, and cerebrovascular disease) to glycemic status. Furthermore, subjects with good long-term glycemic control have better survival rates than those with average fasting blood glucose.

CLINICAL MANAGEMENT OF DIABETES IN THE ELDERLY

Initial clinical management of diabetes in the elderly usually consists of medical nutrition therapy and increases in physical activity. However, few elderly people can adhere strictly to the required changes in diet and physical activity, and controlling hyperglycemia becomes a challenge. Therefore, in the vast majority of cases, drug therapy is needed soon after the disease is detected. Currently, drug options include second-generation oral sulfonylureas, metformin, troglitazone, acarbose, insulin, insulin analogs, and combinations of these drugs. These drugs have demonstrated efficacy in increasing insulin availability, decreasing insulin requirements, or both. Careful planning and adherence to the clinical management designed for the elderly with diabetes can provide good glycemic control. Self-monitoring of blood glucose by the elder diabetic, along with clinical diabetes monitoring of hemoglobin A1c, which informs the medical team about glucose control during the past 3 or 4 months, are good parameters for monitoring the disease. A hemoglobin A1c level lower than 7% is usually the goal for achieving good control.

Evidence is lacking about the benefits of tight glycemic control in older adults (older than 65 years of age). However, elderly diabetic patients with a prognosis for extended life and who are able to manage their disease should have the same goals for glycemic control as younger adults (Table IV). For elders with advanced diabetes, disease complications, advanced cognitive or physical impairment, or comorbidities that may reduce their life expectancy, less intensive goals can be pursued. In any case, it is advisable to

Table IV Goals for Glycemic Control of Adults^a

| Goal | Criteria |
|--|---|
| For glycemic control | |
| Hemoglobin A1c | <7% |
| Preprandial plasma glucose | 5.0–7.2 mmol/liter (90–130 mg/dl) |
| Postprandial plasma glucose | <10.0 mmol/liter (180 mg/dl) |
| For cardiovascular health control | |
| Blood pressure | Systolic <130 mmHg and/or diastolic <80 mmHg |
| Lipid profile | |
| High-density lipoprotein cholesterol | >1.1 mmol/liter (40 mg/dl) |
| Low-density lipoprotein cholesterol | <2.6 mmol/liter (100 mg/dl) |
| Triglycerides | <1.7 mmol/liter (150 mg/dl) |

^aBased on the American Diabetes Association (2003b).

individualize the clinical management of diabetes among elderly individuals.

Proper clinical and self-management of elderly people with diabetes is often difficult and costly due to circumstances associated with aging and comorbidities. Physical ailments, affective or cognitive disorders, psychosocial problems such as depression, functional impairment, and living situation can all interfere with proper management of diabetes in the elderly and potentially exacerbate problems associated with noncompliance with medications, poor eating, the absence of glucose monitoring, and lack of adequate physical activity.

Furthermore, the impact of cardiovascular risk factors is significant among people with diabetes. Therefore, the management of diabetes requires control of cardiovascular risk factors, including hyperglycemia, hypertension, and dyslipidemia. Diabetes needs to be viewed and treated as part of the metabolic syndrome, keeping in mind that the main goals of diabetes management, whenever the circumstances apply, are tight glycemic control and more aggressive management of risk factors associated with cardiovascular disease.

CONCLUSION

The rapidly increasing rates of diabetes among older adults and the tremendous social and economic impact of the disease require that this disease be treated as a high-priority public health problem. Prevention of the disease among the growing elderly population is the best strategy to reduce the burden of diabetes. Results from the Diabetes Prevention Trial showed that lifestyle strategies (healthy eating

and increased physical activity) are more effective than drugs for preventing the development of diabetes, with a 58% reduction in the incidence rate of diabetes among people at high risk. These lifestyle changes were particularly successful for people older than age 60. From this evidence, a strong argument can be made for focusing on the prevention of diabetes in older adults through improvement of the favorable factors associated with diabetes and the metabolic syndrome, particularly lifestyle factors.

DIAGNOSIS

The diagnosis of diabetes is made by the presence of the classical symptoms of diabetes (polyuria, polydipsia, and unexplained weight loss) and unequivocal hyperglycemia documented on two occasions. Hyperglycemia is defined as a random plasma glucose ≥ 200 mg/dl plus symptoms of diabetes, a fasting plasma glucose ≥ 126 mg/dl, or a 2-h plasma glucose ≥ 200 mg/dl following a 75-g oral glucose challenge in adults (1.75 g/kg in children). Between 10 and 40% of patients with new-onset type 1 diabetes have ketoacidosis at presentation. Unlike patients with type 2 diabetes, type 1 patients are typically lean, have had weight loss, and are frankly symptomatic. When the diagnosis is in doubt, type 1 can be confirmed by the finding of islet-related autoantibodies [islet cell antibodies (ICA), antibodies to glutamic acid decarboxylase (GADA), insulin autoantibodies (IAA), and insulinoma-associated antigen-2 (IA-2)]. ICA and GADA are found in approximately 70% of new-onset cases, and if all four are measured, in excess of 90% of new-onset type 1 diabetes patients are positive.

MANAGEMENT

In 1921, Frederick Banting and Charles Best discovered what was thought to be the cure for diabetes—insulin. Prior to the discovery of insulin, type 1 diabetes was a slow but sure death sentence for which the only treatment was a diet low in carbohydrates and sugar and high in fats and protein. Of course, insulin is not the cure for diabetes but is, rather, the vital tool for managing this disease and controlling complications. The Diabetes Control and Complications Trial demonstrated a strong relationship between intensive management and good metabolic control and the rate and progression of complications. Intensive therapy, however, is neither workable nor appropriate for all patients. What is evident, however, is that improved overall blood glucose control should be sought at all ages while avoiding severe hypoglycemia, weight gain, or emotional problems for the patient and the family.

Type 1 diabetes management in children (and adults) is complex, requiring a multidisciplinary medical team, including a diabetologist, a nurse who is a certified diabetes educator, a nutritionist, a psychologist, and, if possible, a social worker. The disease should be approached as affecting not just the individual with diabetes but also the entire family. The team works together to help teach family members and involve them in the decision-making process for the

patient. A successful management program must be consistent and flexible. A balance must be sought between the needs of the medical establishment (insulin, nutrition, exercise, blood glucose testing, HbA1c tests, lipids, and complication surveillance) and the lifestyle demands and desires of the patient. Each patient needs individualized therapy based on age, schedule, social environment, and capabilities. A health care team that knows the patient and the family well will be in a better position to make recommendations that work.

Advances in diabetes management, including the development of newer long- and short-acting insulins and improved blood glucose monitoring and delivery systems, have facilitated the daily management of patients with the disease.

The following are the overall goals of diabetes management:

- Set realistic goals for each child and family: Consider the patient's age, family involvement and social situation, economic factors, and history of hypoglycemia.
- Near normalization of blood glucose levels and HbA1c measurements or, when not possible, improvement on subsequent follow-up.
- Prevention of diabetic ketoacidosis.
- Avoidance of severe hypoglycemia.
- Maintenance of normal quality of life.
- Achievement of normal growth, development, and maturation in children.
- Multidisciplinary support, including nutritional education and psychological support.
- Close surveillance and prevention of microvascular, macrovascular, and neuropathic complications.

A variety of insulin regimens are available for use that must be individualized depending on patient compliance, the patient's level of social support, and various other factors, including dietary and exercise regimens. Possible insulin regimens include subcutaneous injections of a basal (long-acting) insulin with bolus insulin therapy before meals, mixed injections of fast- and intermediate-acting insulin several times per day, and the insulin pump. Inhaled insulin, the insulin patch, and buccal/intranasal insulins are under investigation. In addition to improved insulin therapy, glucose monitoring devices have become simpler to use, allowing for blood testing from sites other than the finger that are less painful, and they have also become faster. Minimally invasive near continuous glucose monitoring devices have been applied to the clinical setting.

GENETICS OF TYPE 1 DIABETES

In the United States, the Caucasian population has a 0.3% risk of developing type 1 diabetes, whereas first-degree relatives of patients with the disease are 15 times more likely to develop the disease. Monozygotic twins have a concordance rate of approximately 50%, whereas dizygotic twins have a reduced concordance rate of 6–10%. The high rate of discordance even in identical twins suggests that environmental factors, not just genetic susceptibility, play a major role in the development of this disease.

Approximately 20 susceptibility gene intervals have been identified for type 1 diabetes. The major susceptibility gene region is the human leukocyte antigen (HLA) region located in the major histocompatibility complex (MHC) on chromosome 6p21, which accounts for up to 65% of genetic susceptibility. The MHC complex spans a 3.5-megabase region of chromosome 6 and is subdivided into three regions (classes I–III). The most important genetic factors in type 1 diabetes are the HLA class II genes. Evidence from animal and human studies has shown that certain loci of class II HLA alleles—HLA-DQA1, HLA-DQB1, and HLA-DRB1—are involved in susceptibility to type 1 diabetes. The majority of patients with type 1 diabetes carry either the HLA-DR3 or HLA-DR4 class II alleles, with approximately 30% being DR3/DR4 heterozygous. In Caucasians, the DR3/DR4 genotype confers the highest risk for development of type 1 diabetes, followed by DR4 and DR3 homozygosity, respectively. Additionally, HLA-DQ alleles have been shown to be a key susceptibility factor in type 1 diabetes. In Caucasians, type 1 diabetes is strongly associated with two combinations of DQA1 and DQB1 alleles: DQA1*0501–DQB*0201, which encodes the DQ2 molecule, and DQA1*0301–DQB1*0302, which encodes the DQ8 molecule. Individuals who are heterozygous for the DQ2 and DQ8 molecules have the highest risk of developing type 1 diabetes, with approximately 30% of individuals affected with type 1 diabetes being heterozygous for DQ2/DQ8. It has been proposed that the degree of susceptibility/protection from the HLA genotype correlates with specific amino acid positions of the DQB1 gene. Position 57 is thought to play a crucial role in determining susceptibility to type 1 diabetes because the residue at position 57 contributes to the shaping of the antigen presenting pocket of the molecule, suggesting that the development of diabetes may depend on events surrounding antigen presentation. However, class II genes do not explain all of the HLA association with type 1 diabetes. Class I genes

have been postulated to influence susceptibility and clinical aspects of the disease, such as age of onset and the rate of beta cell destruction. Other non-HLA susceptibility genes have been mapped, include the IDDM2 insulin gene VNTR (variable number of tandem repeats) locus on chromosome 11p15.5.

ENVIRONMENTAL FACTORS

Environmental factors, such as diet, immunizations, and viruses, may potentially trigger the onset of autoimmunity or hasten progression to disease in patients who already have evidence of autoimmune “prediabetes.” A case for early exposure to viruses in the pathogenesis of type 1 diabetes can be made for congenital rubella. Approximately 30% of children with congenital rubella develop autoimmune diabetes. Viruses could trigger an autoimmune response either by directly damaging the pancreatic beta cells or by invoking molecular mimicry. At least 14 different viruses have been reported to be associated with the development of type 1 diabetes in human or animal models. Viruses suspected to induce autoimmunity to the beta cells via molecular mimicry include retrovirus, mumps, rubella, cytomegalovirus, and Epstein-Barr virus, whereas viruses that are suspected to induce autoimmunity via direct cytolytic damage to the beta cells include coxsackie B and other enteroviruses. The enteroviruses have received attention as a possible trigger of the development of diabetes because observational studies have noted an increase in the incidence of enteroviral infections in individuals with type 1 diabetes preceding the development of the disease, and some studies have demonstrated the presence of the viral genome in diabetic patients.

Immunizations have also been implicated in the pathogenesis of type 1 diabetes. An increase in the incidence of type 1 diabetes in Finland was correlated with the initiation of a mandatory immunization program against diphtheria–pertussis–tetanus. There were also reports of an association between vaccination for hemophilus influenza and an increased incidence of type 1 diabetes. However, in 1998 an expert committee from the National Institutes of Health found no evidence to support these assertions.

Of the putative dietary triggers for diabetes, cow's milk has been the most extensively studied. Epidemiologic, ecologic, and immunological studies suggest a possible link between the early introduction of cow's milk into an infant's diet and/or a decreased period of breast-feeding and the subsequent development of type 1 diabetes. However, this issue is debated

and will likely only be settled with the completion of the Trial to Prevent Diabetes in the Genetically At-Risk study, in which the introduction of cow's milk to high-risk relatives is delayed.

AUTOIMMUNITY

As previously mentioned, islet autoantibodies (ICA, GADA, IAA, and IA-2A) distinguish type 1 diabetes from other types of diabetes. None of the islet cell antibodies have been found to play a role in the pathologic destruction of the beta cells.

Combinations of these autoantibodies have been found to denote significant risk for the subsequent development of diabetes, both in unaffected relatives of individuals with type 1 diabetes and in the general population.

IDENTIFICATION OF AT-RISK SUBJECTS

There are two approaches to identifying individuals genetically susceptible to the development of type 1 diabetes prior to clinical manifestation of the disease: (i) antibody testing followed by quantification of risk by further antibody, genetic, and metabolic testing and (ii) primary genetic screening of newborns with determination of high-risk HLA genes and ensuing quantification of risk by further autoantibody, genetic, and metabolic testing. Primary antibody testing is based on the finding that 60–80% of patients with new-onset type 1 diabetes have islet autoantibodies. Studies have shown that the presence of a single autoantibody imparts an approximate 10–20% risk of subsequently progressing to disease, whereas combinations of autoantibodies carry a 5-year risk of $\geq 50\%$. The presence of metabolic derangements in addition to serologic markers increases the predictability of screening. Persistent loss of first-phase insulin response during an intravenous glucose tolerance test carries a 50–70% 5-year risk in ICA-positive individuals. Changes in glucose tolerance measured during an oral glucose tolerance test generally occur later in the disease process, indicating significant beta cell destruction. Identification of at-risk individuals has led to a multitude of clinical trials in an attempt to prevent the development of this disease.

PREVENTION TRIALS

The ability to identify individuals who will subsequently develop the disease, together with the tremendous and increasing burden of the disease, has

facilitated studies aimed at the prevention of type 1 diabetes. After several pilot studies, three large-scale, adequately powered trials were commenced in the mid-1990s.

Diabetes Prevention Trial—Type 1

The objective of the U.S. Diabetes Prevention Trial—Type 1 (DPT-1) was to determine whether antigen-based (insulin) therapy (either parenteral or oral) in at-risk individuals could prevent or delay the onset of type 1 diabetes. Studies of animal models of type 1 diabetes, as well as encouraging pilot studies of prediabetic relatives of probands, provided strong rationale for this trial. In the DPT-1 trial, more than 100,000 first- and second-degree relatives of patients with diabetes underwent genetic, immunologic, and metabolic assessment to quantify their risk. Patients with a projected 5-year risk $\geq 50\%$ were randomized either to an annual 4- or 5-day intravenous infusion of regular insulin followed by the administration of subcutaneous ultralente insulin twice daily or to a close observation arm. Those with a risk of 25–50% were randomized to oral insulin or placebo. Unfortunately, in neither arm was insulin successful in preventing or delaying the onset of diabetes.

European Nicotinamide Diabetes Intervention Trial

Nicotinamide, the water-soluble amide of nicotinic acid and an oxygen free radical scavenger, was shown to prevent the development of type 1 diabetes in mouse models and showed encouraging results in small studies of at-risk human subjects. A double-blind study was conducted in several European countries in which either nicotinamide or placebo was administered to islet cell antibody-positive, first-degree relatives of patients with type 1 diabetes. Unfortunately, there was no difference in the incidence of diabetes between the two groups after 5 years of follow-up.

Trial to Prevent Diabetes in Genetically At-Risk

The Trial to Prevent Diabetes in Genetically At-Risk was designed to evaluate whether avoidance of cow's milk for at least the first 6 months of life could prevent or delay the onset of type 1 diabetes in high-risk infant relatives of type 1 probands. Mothers of infants enrolled on the basis of high-risk HLA genes breast-feed their infants for at least 6 months. When weaning

occurs, the infants are randomized to either a standard cow's milk-based formula or a casein hydrolyzed formula. The study is ongoing in Scandinavia and North America. The creation of a worldwide multicenter network (TrialNet) will facilitate the conduct of multifaceted approaches to prevent the disease.

SEARCHING FOR A CURE

Advances in both pancreatic and especially islet cell transplantation have led to both enhanced patient and graft survival. Unfortunately, less than 10,000 transplants have been conducted worldwide, and in the United States alone, more than 1 million people have type 1 diabetes. Thus, there is a need to derive an unlimited supply of insulin-producing cells. In addition, patients require lifelong immunosuppression to prevent rejection (alloimmunity) and possibly prevent recurrence (autoimmunity). Potential sources include deriving beta cells from stem cells (pancreatic ducts, bone marrow, liver, cord blood, and embryonic stem cells) and gene therapy approaches. Encouraging results have been obtained in several animal models, although no gene therapy studies have been conducted in humans with type 1 diabetes. It is hoped that the successes in the laboratory and animal models will be emulated in humans.

CONCLUSION

The incidence of type 1 diabetes continues to increase, as does the amount of health care dollars spent on the day-to-day management and long-term complications of this disease. Despite therapeutic advances, the burden to patients in terms of cost to the individual and cost to society remains high. The quest for prevention and cure remains the priority.

| Criteria for diabetes mellitus | Criteria for prediabetic states (i.e., impaired fasting glucose and impaired glucose tolerance) |
|---|---|
| Symptoms of hyperglycemia with random plasma glucose ≥ 200 mg/dl Fasting plasma glucose ≥ 126 mg/dl on at least two occasions 2 h plasma glucose ≥ 200 mg/dl after 75 g oral glucose challenge | Impaired fasting glucose: Fasting plasma glucose ≥ 110 mg/dl and < 126 mg/dl Impaired glucose tolerance: 2 h glucose ≥ 140 mg/dl but < 200 mg/dl after 75 g oral glucose challenge |

deficiency secondary to autoimmune destruction of beta cells or genetic defects.

According to the 1997 ADA proposal, several criteria may be used independently to establish the diagnosis of diabetes: (1) a FPG ≥ 126 mg/dl on more than one occasion; (2) a random plasma glucose of 200 mg/dl or more with typical symptoms of diabetes; or (3) a 2 h value ≥ 200 mg/dl during a 75 g OGTT.

The recommendations of the Expert Committee of the ADA, however, discouraged the routine use of the OGTT in clinical practice. A new entity, impaired fasting glucose (IFG), was created and defined as a FPG between 110 and 125 mg/dl as a more sensitive indicator of impaired glucose homeostasis based on the fasting glucose. The diagnosis of IGT remained essentially unchanged and was defined as a FPG of < 126 mg/dl with a 2 h postchallenge blood glucose between 140 and 199 mg/dl during an OGTT.

In 1999, the WHO revised their previous (1985) diagnostic criteria for the diagnosis and classification of diabetes mellitus and took into account the 1997 ADA criteria. The principal difference between the 1997 ADA and the 1999 WHO criteria is that the ADA discourages the use of the OGTT as a routine diagnostic tool but the WHO does not.

EPIDEMIOLOGY OF TYPE 2 DIABETES MELLITUS

The data from the U.S. Third National Health and Nutrition Examination Survey (NHANES III), conducted between 1988 and 1994, involved 18,825 subjects ≥ 20 years of age and provided a determination of prevalence for T2DM, IFG, and IGT. Using only the FPG of ≥ 126 mg/dl as the diagnostic criterion for T2DM (i.e., the 1997 ADA criteria), diabetes (diagnosed and undiagnosed) affected approximately 7.8% of adults ≥ 20 years of age in the United States. Rates increased with age, reaching 18.8% in individuals ≥ 60 years old, and U.S. minorities were more frequently affected by diabetes. A higher prevalence of undiagnosed T2DM was found using the 2 h OGTT

criterion since 48% of individuals with a post-challenge glucose ≥ 200 mg/dl have FPG levels < 126 mg/dl. IFG was found in 6.9% of those ≥ 20 years of age, whereas IGT was diagnosable in 15.6% of adults between 40 and 74 years of age. The lower prevalence of IFG compared with IGT was due to the fact that 70% of individuals with 2 h plasma glucose 140–199 mg/dl have a FPG < 110 mg/dl.

Irrespective of diagnostic criteria, prevalence rates for T2DM have been increasing in developed countries over the past 3–4 decades and there has been an alarming increase in developing countries over the past 10 years. Thus, the problem of T2DM, which is already a major cause of patient suffering, mortality, and health care costs, is expected to worsen as a worldwide public health burden.

GENETICS OF TYPE 2 DIABETES MELLITUS

T2DM aggregates within families and concordance rates in monozygotic twin pairs (60–90%) are greater than in dizygotic twins (30–40%). This pattern of transmission is consistent with a polygenic form of inheritance. Causal mutations have been identified in rare monogenic forms of diabetes, for example, mutations in the insulin receptor gene in patients with type A severe insulin resistance and acanthosis nigricans and mutations in glucokinase and certain hepatic nuclear factor genes in some families with maturity onset diabetes of the young. Patients with single gene mutations conform to a particular subphenotype of the disease.

The polygenes that contribute to the common form of T2DM have not yet been elucidated. It is likely that T2DM is heterogeneous in that multiple polygenic forms of the disease share many characteristics of a common phenotype. Environmental determinants that predispose to the disease include physical inactivity, obesity, and high-calorie, high-fat diets. The interaction between genes and environment is evident when groups of Africans, Australian Aborigines, or Amerindians, who have a low prevalence of T2DM in

their native cultures, adopt a Western lifestyle and develop diabetes at higher rates than other racial/ethnic groups in the same environment.

PATHOPHYSIOLOGY OF TYPE 2 DIABETES MELLITUS

Although type 2 diabetes may be heterogeneous, several major metabolic defects consistently contribute to hyperglycemia. These major defects include the following: (1) peripheral insulin resistance due to decreased glucose transport activity in skeletal muscle; (2) impaired insulin secretion in response to glucose; and (3) elevated rates of hepatic glucose production. All three of these metabolic defects are present in overt diabetes and contribute significantly to the diabetic state.

Insulin resistance (IR) is considered by some investigators to be a fundamental defect in patients with T2DM. The 1997 recommendations of the Expert Committee of the ADA considered IR to be a necessary aspect of the diagnosis of T2DM. Hence, by definition, all patients with T2DM would be characterized by IR. However, proof for this contention is problematic for two reasons. First, rigorous measurement of insulin resistance requires research methods such as the hyperinsulinemic glucose clamp or the frequently sampled intravenous glucose tolerance test (fsIVGTT). Second, since insulin sensitivity is a continuous variable, there is no established cutoff value below which individuals would be considered to be insulin resistant. In 1997, Haffner and colleagues, using the fsIVGTT to estimate insulin sensitivity in 479 T2DM patients, determined that the majority of subjects were insulin resistant, regardless of race or ethnicity. Other studies have found lower prevalence rates, of approximately 80%, for IR among T2DM patients. Therefore, the prevalence of IR in T2DM depends on the definition and methods employed, ranging from 80 to 100%. In fact, the 1999 WHO proposal for the definition and classification of T2DM, which otherwise agrees with most of the 1997 ADA criteria, did not consider the presence of IR to be a requirement for the diagnosis of T2DM.

Inadequate beta-cell function is also usually considered an essential component of T2DM pathogenesis. The most striking functional defect is a specific loss of first-phase or acute glucose-induced insulin secretion, whereas responses to other secretagogues, such as the amino acid arginine, can be relatively preserved. Defective insulin secretion becomes progressively worse over the course of the disease and this is

associated with the need for combination medical therapy and exogenous insulin for glycemic control. Chronic hyperglycemia contributes to progressive beta-cell failure in a process sometimes known as “glucotoxicity.” Both insulin resistance and defective glucose-mediated insulin secretion can be detected in prediabetic individuals; however, an insulin-resistant individual who maintains full insulin secretory responses will generally not develop T2DM.

INSULIN RESISTANCE SYNDROME

There is a wide variation in insulin sensitivity in normoglycemic individuals. Relative insulin resistance is associated with additional metabolic traits that in combination place these individuals at risk for the future development of T2DM and/or cardiovascular disease. These traits can include hyperinsulinemia; some degree of glucose intolerance; upper body fat distribution or abdominal obesity; dyslipidemia characterized by high triglycerides, low high-density lipoprotein (HDL) cholesterol, and small dense low-density lipoprotein (LDL) particles; elevated blood pressure, elevated c-reactive protein; high plasminogen activator inhibitor-1 levels; and a positive family history for T2DM. The clustering of several of these traits has been linked to insulin resistance in a single individual and referred to as insulin-resistant syndrome (IRS) or metabolic syndrome. IRS/metabolic syndrome represents an important new concept that is critical for improved identification and management of metabolic and cardiovascular risk. For example, institution of lifestyle changes in these individuals resulting in mild weight loss (5–7%) and adherence to a regular exercise program can cut rates of progression to overt T2DM by over 50%, as demonstrated by the Diabetes Prevention Program. Furthermore, patients with IRS/metabolic syndrome should be targeted for more aggressive control of dyslipidemia and blood pressure.

One problem has been the lack of consensus on how to identify or diagnose IRS/metabolic syndrome. To address this problem, the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol (Adult Treatment Panel III) proposed in 2001 that the metabolic syndrome could be defined in individuals who met at least three of five criteria [waist circumference >102 cm in men and >88 cm in women; fasting glucose 110–125 mg/dl; triglycerides \geq 150 mg/dl; HDL cholesterol <40 mg/dl in men and <50 mg/dl in women; blood pressure >130/85].

Additional research is required to determine the adequacy of this scheme in identifying patients at risk.

TREATMENT OF TYPE 2 DIABETES MELLITUS

The most important reason to treat T2DM aggressively is to prevent its chronic complications, both microvascular and macrovascular. It is well known that the degree of chronic hyperglycemia, best reflected in glycosylated hemoglobin measurements, is directly related to microvascular complications (neuropathy, nephropathy, and retinopathy). In addition, the treatment of hyperglycemia, aimed at obtaining near-normoglycemia, prevents or at least slows the progression of these complications independently of the glucose-lowering agent used.

Whereas microvascular complications cause significant morbidity and cost, it is the macrovascular complications (coronary artery disease, cerebrovascular disease, and peripheral vascular disease) that cause most of the excess mortality in patients with T2DM when compared to the rest of the population. The prevention of these macrovascular complications, particularly coronary artery disease, is not as dependent on simple glycemic control as that of the microvascular complications, although there is some evidence suggesting that strict glycemic control may have a beneficial effect in terms of reduction of cardiovascular events. Consequently, the prevention of the macrovascular complications requires aggressive management of the modifiable traditional risk factors for cardiovascular disease frequently present in these patients, namely, dyslipidemia, hypertension, obesity, and smoking. Therefore, the care of T2DM patients must focus on achieving aggressive targets for blood pressure (<130/80) and serum lipids (LDL cholesterol <100 mg/dl, triglycerides <150 mg/dl; HDL cholesterol >40 mg/dl) with drugs such as HMG (3-hydroxy-methyl-glutaryl) coenzyme A reductase inhibitors, fibric acid derivatives, niacin, and blood pressure-lowering preparations.

The cornerstones of anti-diabetic therapy are as follows:

Diet

A very important component of the management of all patients with T2DM is diet. A trained dietician should be involved in assessing dietary history and lifestyle, reviewing dietary principles, and developing and executing the meal plan on an ongoing basis. The diet plan should be tailored to the individual and account

for personal preferences, age, gender, current nutritional and clinical status, cultural practices, degree of obesity, medications, and activity level. Although the recommended caloric distribution has fluctuated over time, the general approach is to limit fat calories, reduce cholesterol and saturated fatty acids, and allow modest protein and complex carbohydrates, with a dietary composition that approximates 50% carbohydrates, 30% fat, and 20% protein.

Weight loss can have a dramatic effect to reduce (or sometimes eliminate) the need for diabetes medications and can also ameliorate dyslipidemia and hypertension, in overweight patients. This is often best accomplished by a moderate caloric reduction of 250–500 calories below the weight maintenance in the context of a nutritionally sound meal plan, proper caloric distribution, and an exercise regimen. Alternatively, a very-low-calorie diet (500–800 kcal/day) can be used in select patients. With either moderate reduction or very-low-calorie diets, weight loss is frequently achieved but is difficult to sustain. However, significant metabolic and cardiovascular benefits can be realized without achieving ideal body weight. Hypoglycemia will improve within a few days, even before measurable weight loss, during the hypocaloric phase. However, at least a 5% weight reduction is required after weight stabilization. A further weight reduction of 10% will significantly improve glycemia, insulin sensitivity, and serum lipid profile if sustained.

Exercise

The vast majority of diabetic patients should be prescribed some form of regular exercise. Exercise is an important adjunct in glycemic control, weight loss, maintenance of weight reduction, management of cardiovascular risk factors, and sense of well-being. Exercise training raises HDL cholesterol, lowers blood pressure, and leads to a 20–40% increase in insulin sensitivity by enhancing insulin action in skeletal muscle. There is evidence that regular physical activity of even modest intensity (e.g., walking three to five times per week) significantly improves insulin sensitivity in individuals at high risk for diabetes.

Pharmacologic Therapy

The treatment of type 2 diabetes has been revolutionized in the past several years by the availability of several new classes of oral hypoglycemic agents, listed in [Table II](#). These agents influence biochemical processes in different organs and differentially ameliorate multiple metabolic defects that cause hyperglycemia.

Sulfonylureas and the two new nonsulfonylurea agents, repaglinide and nateglinide, interact with the sulfonylurea receptor/potassium channel complex on pancreatic beta cells and increase insulin secretion. Metformin's principal site of action is the liver and acts to reduce hepatic glucose production. The new oral agents in the thiazolidinedione class, rosiglitazone and pioglitazone, act as insulin sensitizers. They enhance insulin's ability to stimulate glucose uptake in the skeletal muscle and adipose tissue and also cause a decrease in the levels of circulating free fatty acids, which are usually elevated and are thought to play a pathogenic role in T2DM. Therefore, these classes of oral agents ameliorate deficient insulin

secretion, high hepatic glucose output, or insulin resistance, which are the three major defects that combine to produce hyperglycemia in nearly all patients with type 2 diabetes. In addition, α -glucosidase inhibitors have been introduced, which impede carbohydrate digestion and absorption in the gut, thus reducing the postprandial glycemic rise.

Since multiple classes of effective drugs have become available, oral agents have become the preferred choice for initiating medical therapy in most patients. However, since T2DM is a progressive disease, secondary failure to the first oral agent is the rule. When this occurs, it is generally advantageous to add a second drug that acts on a different metabolic defect (i.e., insulin secretion, hepatic glucose output, or insulin resistance) than the first drug, since the two drugs will interact synergistically to help control glycemia.

However, exogenous insulin remains a mainstay of therapy, especially in patients with longer disease duration who have failed one or more of the oral agents. This often involves the addition of bedtime insulin in combination with an oral agent and, later, multiple daily insulin doses. Although both the liver and skeletal muscle are insulin resistant in T2DM, dose-response differences dictate that, at serum insulin levels produced by exogenous insulin therapy in many patients, hepatic glucose production can be partially or completely inhibited, whereas lesser degrees of glucose uptake stimulation are observed in skeletal muscle. This ability to restrain hepatic glucose production is a key property whereby insulin helps achieve targets for lower glycosylated hemoglobin (e.g., HbA1c) values either as a single agent or in combination with oral agents.

Table II Pharmacologic Classification of Agents Used in the Treatment of Diabetes Mellitus

| |
|---|
| Oral insulin secretagogues |
| <i>First-generation sulfonylureas</i> |
| Tolbutamide |
| Chlorpropamide |
| Tolazamide |
| Acetohexamide |
| <i>Second-generation sulfonylureas</i> |
| Glyburide |
| Glipizide |
| Glimepiride |
| <i>Nonsulfonylurea insulin secretagogues</i> |
| Repaglinide |
| Nateglinide |
| Inhibitors of carbohydrate absorption |
| <i>α-Glucosidase inhibitors</i> |
| Acarbose |
| Miglitol |
| Inhibitors of hepatic glucose output |
| <i>Biguanides</i> |
| Metformin |
| Insulin sensitizers |
| <i>Thiazolidinediones</i> |
| Pioglitazone |
| Rosiglitazone |
| Exogenous insulin |
| <i>Human insulin</i> |
| Regular insulin |
| NPH insulin |
| Lente insulin |
| Ultralente insulin |
| <i>Human insulin analogues</i> |
| Lispro insulin |
| Aspart insulin |
| Glargine insulin |

in reciprocal decreases of myoinositol and taurine. Depletion of these metabolites becomes rate limiting for essential intracellular metabolism. The vascular theory was once considered separate from the metabolic theory. It states that reduced nerve blood flow results in hypoxia/ischemia and causes the development of DPN. It is now clear that the metabolic and vascular theories are linked on many levels. Glucose flux through the polyol pathway causes the depletion of NADPH and NAD⁺. Without sufficient NADPH, cells cannot regenerate the glutathione required to neutralize reactive oxygen species. Consequently, the peripheral nerve sustains oxidative damage that decreases endoneurial blood flow and promotes ischemia. The activity of the potent vasodilator, nitric oxide (NO), is also tightly linked to NADPH. NO, synthesized by NO synthase, is a NADPH-dependent reaction. Therefore, depletion of NADPH limits NO synthesis and in turn causes vasoconstriction and ischemia, which contribute to nerve conduction slowing.

DIAGNOSIS AND TREATMENT

Three treatment strategies are clinically available. Of most importance is the early diagnosis of DPN. Early diagnosis allows for the implementation of the second strategy: good glycemic control and foot care. The third approach is focused on the treatment of painful DPN and is added to good glycemic control and foot care.

The early diagnosis of DPN is imperative. It makes early intervention possible, thereby significantly decreasing patient morbidity. It is important that other causes of neuropathy are excluded prior to DPN being related to diabetes. This is especially important if there are unusual features of the neuropathy, such as rapid progression, marked asymmetry, or more motor than sensory deficits.

In 1988, the San Antonio Consensus Panel recommended five quantifiable measures for the accurate diagnosis of DPN: a symptom questionnaire, a standardized clinical examination, quantitative sensory testing, nerve conduction studies, and autonomic function testing. Patients are classified as having stage I (no symptoms) or stage II (symptoms) neuropathy. Each stage is further divided into grades from A to C depending on the number of positive test results and the severity of clinical impairment. These criteria are being used to study the Rochester Diabetic Cohort. Modified criteria have been implemented in several clinical trials, including the DCCT.

Simpler screening instruments for DPN are also available. These instruments were developed because

patient and physician resources are frequently limited, making completion of the San Antonio criteria difficult. In the United Kingdom, DPN is diagnosed if patients present with mild signs and moderate symptoms or moderate signs alone, in the absence of symptoms. The Michigan Neuropathy Screening Instrument includes inspecting the feet for dry skin, callus, fissure, or ulceration; assessment of vibratory sensation in the great toes; and testing for ankle reflexes. A score of >2 indicates neuropathy with a high sensitivity (80%) and specificity (95%). Because of its simplicity, the Michigan Neuropathy Screening Instrument is also highly reproducible. Another simple method for screening patients for the presence of DPN is the use of a 10-g nylon monofilament. The filament is pressed against the sole of the foot until the filament buckles, indicating a known force has been applied. If a patient is unable to perceive the filament, he or she is at increased risk for complications of DPN.

Glycemic Control and Foot Care

The DCCT clearly demonstrates that improved glycemic control decreases the frequency of DPN in patients with type I diabetes mellitus. Glycemic control requires thorough patient education. Patients are instructed on the importance of diet and regular glucose monitoring. This is achieved with a team consisting of the patient, a diabetes nurse educator, a dietician, and a physician.

Good foot care is also important. Patients are instructed to inspect their feet every night for evidence of dry skin, cracking, or fissuring of the skin. The importance of footwear is also well documented. Shoes must cushion the points of contact between the foot and the shoe and must accommodate any inherent or acquired foot deformities. For patients with mild neuropathy, cushioned socks and high-quality athletic shoes with room for the forefoot and toes are helpful. In severe cases, patients may require customized inserts or molded shoes.

Acute and Chronic Painful DPN

A stepwise treatment protocol is used for patients with painful DPN. Nonsteroidal anti-inflammatory drugs provide relief in many patients with chronic painful DPN. In a double-blind, placebo-controlled trial, both ibuprofen (600 mg four times per day) and sulindac (200 mg two times per day) effectively decreased pain associated with DPN. However, this class of drugs cannot be used in patients with renal impairment.

The tricyclic antidepressants are the best studied class of drugs for the treatment of painful DPN. In double-blind, placebo-controlled trials, amitriptyline, nortriptyline, and imipramine were each effective in the treatment of painful DPN. If a patient continues to experience disabling pain, a second drug, gabapentin, is added to the therapeutic regimen. Patients may also be started on gabapentin as a first-line therapy, with a tricyclic added if a second medication is needed. Carbamazepine is also a good drug to add to either a tricyclic antidepressant or a serotonin uptake inhibitor. Double-blind, placebo-controlled trials have found that it provides symptomatic relief to a large percentage of afflicted patients.

For patients who are on two medications and still experiencing significant discomfort, capsaicin cream may be used. Capsaicin cream is a topical therapy that inhibits the uptake of substance P at sensory endings. Patients are instructed to apply capsaicin cream (0.075%) four times per day, the regimen that was successful in a double-blind, placebo-controlled trial.

If these therapeutic strategies fail, the second drug is discontinued and a new drug is instituted. The first choice is the cardiac antiarrhythmic drug mexiletine, which is effective in patients who otherwise are refractory to treatment. The antiepileptic topiramate can also be used in refractory patients. If a patient remains resistant to these treatment strategies, he or she should be referred to a comprehensive pain clinic. Here, patients frequently receive local nerve blocks, a transcutaneous electrical nerve stimulation (TENS) unit, or, in certain cases, acupuncture. Unfortunately, the prognosis for good pain relief in patients who require a pain clinic referral is low.

CONCLUSION

A systematic, stepwise approach to patients with DPN ensures optimal patient care and decreases the risks

for short- and long-term disability. Future therapies hold promise, particularly those targeted toward ameliorating the metabolic and vascular abnormalities that develop in the peripheral nervous system as a result of continued hyperglycemia.

Down Syndrome

see Short Stature and Chromosomal Abnormalities

thyroid-related effects of cytokines, monoclonal antibodies, heparin, phenytoin, amiodarone, and inhibitors of hormone binding to plasma proteins.

Some of these drug effects can be put to therapeutic use, for example, the use of lithium, cholestyramine, cholecystographic contrast agents, iodide, or glucocorticoids in unusual or complicated cases of thyrotoxicosis. It should also be noted that abnormal thyroid function, either thyrotoxicosis or hypothyroidism, can influence the effect and potential toxicity of a wide range of therapeutic agents, predominantly by altering their metabolism or clearance.

ALTERED SECRETION OF THYROID-STIMULATING HORMONE

Glucocorticoids, either endogenous or exogenous, are potent inhibitors of thyroid-stimulating hormone (TSH) secretion. Dopaminergic drugs, even at doses that do not influence blood pressure, cause profound inhibition of TSH secretion; after cessation of dopamine infusion, there is a rapid reversal of TSH suppression within a few hours.

Cytokines directly affect TSH secretion. For example, infusion of interferon- α in normal volunteers results in a 60–70% decrease in serum TSH within 8–12 h, prior to any significant change in serum thyroid hormone concentrations. In addition, cytokines can induce or aggravate autoimmune thyroid dysfunction.

During long-term amiodarone therapy, TSH tends to be high in relation to serum free thyroxine (T₄), because this drug, or its active metabolite, desethylamiodarone, acts as an antagonist at thyroid hormone receptors. Heavy amphetamine abuse can result in higher than normal levels of serum TSH and may cause TSH-induced hyperthyroxinemia. In general, agents that increase or decrease the basal level of serum TSH have a similar effect on the TSH response to thyrotropin-releasing hormone, whenever the two effects have been directly compared.

ALTERED RELEASE OF THYROID HORMONE FROM THE GLAND

Iodide at a high dosage acutely decreases the release of thyroid hormone from the gland, apparently by inhibition of proteolysis. Glucocorticoids exert a similar effect that was initially attributed to TSH suppression, but the effect also occurs when TSH is suppressed, as in Graves' disease. Lithium inhibits thyroid hormone

release as a result of decreased proteolysis of thyroglobulin. These agents are occasionally used as additional medications in the management of complicated thyrotoxicosis, especially when standard anti-thyroid drugs cannot be used.

INHIBITION OF 5'-(OUTER RING) DEIODINATION OF T₄

The outer ring deiodinase, or 5'-deiodinase, that is present predominantly in liver, kidney, thyroid, and heart, designated type 1, is a selenoprotein that catalyzes the peripheral conversion of T₄ to triiodothyronine (T₃) and reverse T₃ (rT₃) to 3,3'-T₂. This activity is markedly diminished by caloric deprivation and in catabolic states. Activity of this enzyme is also inhibited by numerous drugs (Table I), resulting in decreased T₃ and increased rT₃ serum concentrations. Several iodinated compounds, including amiodarone and oral cholecystographic contrast agents, also inhibit the pituitary 5'-deiodinase type 2, an effect that results in decreased formation of T₃ in the pituitary, leading to a slight increase in serum TSH, generally within the normal reference range.

Beta-blockers differ from one another in their effect on 5'-deiodination. Propranolol in high doses diminishes the production of T₃, an effect due to a quinidine-like membrane stabilizing effect, rather than specific beta-blockade. This T₃-lowering effect is not seen with other beta-blockers, such as atenolol, metoprolol, or labetalol. The symptomatic benefit of beta-blockers in thyrotoxicosis appears to be independent of their influence on serum T₃.

A subnormal serum T₃ concentration is a normal response to illness or caloric deprivation that is potentially beneficial; this acute response should not be interpreted as hormone deficiency. During non-thyroidal illness, or with the use of medications that can lower serum T₃, the possibility of thyrotoxicosis should not be dismissed on the grounds of normal serum T₃, if this diagnosis is supported by T₄ excess and suppression of TSH.

Because of its ability to rapidly lower serum T₃, the oral cholecystographic contrast agent ipodate has been used as an additional agent in the management of thyrotoxicosis.

DISCHARGE OF TISSUE POOLS OF THYROID HORMONE

Isotope studies demonstrate that acute administration of lipid-soluble oral cholecystographic contrast

Table I Principal Medications That Influence Thyroid Hormone or TSH Levels

| |
|---|

agents causes the acute release of tissue T4 stores, mainly from the liver, resulting in a transient increase in the serum T4 concentration of up to 30%. Reported acute transient increases in serum T4 of up to 60% following treatment with the alkylating agents cyclophosphamide and ifosfamide may also be due to hormone displacement from tissues.

ALTERED CONCENTRATION OF PLASMA-BINDING PROTEINS

Estrogens, whether endogenous or exogenous, commonly affect tests of thyroid function by increasing total serum T4 and T3 due to an increase in the serum concentration of thyroxine-binding globulin (TBG), but free T4 and T3 remain normal. Estrogens increase the glycosylation of TBG, which slows its clearance, leading to a higher serum concentration,

or binding capacity, with normal binding affinity. Transdermal estrogens do not show this effect to the same extent, because they have less influence on hepatic proteins. In pregnancy, the mean total serum T4 concentration is increased by approximately 30%, with up to 40% of values falling outside the normal reference range in the second and third trimesters. It is not certain whether other drugs that alter the serum concentration of TBG (Table I) increase the synthesis or retard the clearance of TBG.

At least initially, until a new steady state is established, the dose requirement for T4 replacement can change in response to changes in binding protein. For example, a higher dosage of T4 may be required in women taking estrogens. Conversely, commencement of androgen treatment for breast cancer, which results in a 50% lowering of serum TBG, may result in acute features of thyrotoxicosis in some women maintained on stable replacement dosage of T4. An initial T4 dose reduction by 20–50% is recommended, although the need for permanent dose modification has not been established.

In response to an acute increase in the concentration of binding protein, there will be an initial tendency for the free hormone concentration to decrease, leading to a transient increase in serum TSH; an increase in total hormone concentration then restores the baseline free serum T4 concentration, but the free fraction of T4 is lower. Changes in T3 binding follow a similar pattern. Reverse changes follow a decrease in the concentration of binding protein. The turnover rate of hormone remains unchanged, but the extracellular pool size is altered. A similar sequence occurs if there is altered occupancy of the binding protein by a competitor.

COMPETITION FOR THYROID HORMONE BINDING TO PLASMA PROTEINS

Thyroid hormone-binding proteins show wide cross-reaction with unrelated hydrophobic ligands, such as nonesterified fatty acids (NEFA) and various drugs (Table I). In contrast, the binding proteins for corticosteroids, vitamin D, and the sex hormones are more specific for a single family of ligands. Substances that interfere with T4 and T3 binding are themselves bound to albumin. Because of differences in relevant total therapeutic concentration and albumin binding, the hierarchy of drug competitor potency *in vivo* in undiluted serum differs markedly from the rank order of drug affinity for isolated TBG.

Serum dilution and albumin concentration need to be clearly defined in the interpretation of *in vitro* drug competition studies, because the concentrations of free ligand and competitor(s) and the number of unoccupied binding sites do not maintain the relationship that exists prior to serum dilution. The terms “predilution” and “codilution” describe two contrasting artifacts.

Predilution occurs when the concentration of albumin is decreased by dilution before a competitor is added (Fig. 1). At lower concentrations of albumin, there is a disproportionate increase in free competitor concentration. Hence, predilution before addition of competitor magnifies apparent competition. In contrast, an underestimate of competitor potency occurs with codilution, where total concentrations of binding proteins, hormone, and competitors diminish in parallel. Free ligand concentrations diverge widely with dilution; i.e., the free concentration of a drug with a free fraction in serum of 1:50 decreases markedly at a serum dilution of only 1:10, whereas the free concentration of T4, which has a free fraction of approximately 1:4000 before dilution, will be much better sustained with dilution. Hence, competitor effects will be lost with codilution and free T4 will be underestimated.

Figure 1 Addition of a binding competitor after prior dilution of a serum sample will falsely accentuate hormone displacement, because dilution of serum albumin increases the free competitor concentration (predilution). In contrast, parallel dilution of all serum constituents tends to obscure displacement of T4 and T3 by a competitor that was present in the original serum sample (codilution), because the concentration of free competitor decreases more than the concentration of free hormone (see text).

Figure 2 Effect of furosemide on estimates of serum free T4 by three methods, showing that T4 displacement is progressively lost with increasing sample dilution. The least diluted serum sample most closely reflects the *in vivo* effect. Redrawn from Hawkins *et al.*, 1998.

This type of artifact was shown with therapeutic concentrations of phenytoin and carbamazepine, which increased the free fraction of T4 by 40–50% in undiluted serum, but produced no increase in free T4 when assayed in diluted serum. Similarly, the T4-displacing effect of furosemide is most obvious (Fig. 2) in methods with the least sample dilution.

Kinetics of the competitor will influence its effect on T4 and T3 *in vivo*. A competitor of long half-life will eventually result in a new steady state with normal free hormone and lowered total hormone concentration, i.e., an increased free fraction. In contrast, the effect of short half-life competitors, such as furosemide or salsalate, on serum free T4 and T3 will depend on the time between dosage and sampling.

Any substance that shares albumin-binding sites with a competitor can influence the free concentration of that competitor. Indoles and furans that accumulate in renal failure can displace drugs from albumin and may thus indirectly accentuate drug effects on hormone binding; i.e., the free hormone concentration can be influenced by substances that have little direct effect on hormone binding.

The effect of heparin on increasing the apparent free T4 concentration *in vitro* is an example of spurious competition. Heparin treatment causes the *in vivo* release of lipases, followed by generation of NEFA during sample storage or incubation *in vitro*, leading to much higher NEFA concentrations in the assay tube than were present *in vivo* (see Fig. 3). Heparin doses as low as 10 units can cause this effect after prolonged sample incubation, especially if serum triglyceride is increased. Low-molecular-weight heparin

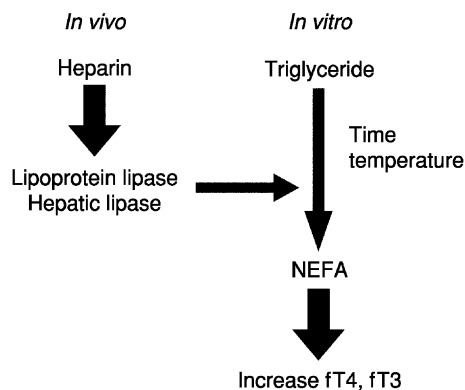

Figure 3 Heparin-induced changes can markedly increase the apparent concentration of serum free T4. Heparin *in vivo* (left) liberates lipoprotein lipase from vascular endothelium. Lipase acts *in vitro* (right) to increase the concentration of free fatty acids to >3 mmol/liter, which displaces T4 and T3 from TBG. Generation of free fatty acids is increased by sample storage or incubation and by high serum triglyceride. The T4-displacing effect is accentuated at low albumin concentrations. Concept from Mendel *et al.*, 1987.

preparations have a similar effect. This artifact may account for reports of method-dependent increases in apparent free T4 concentrations in hospitalized subjects who are often exposed to heparin.

IMPAIRED THYROXINE ABSORPTION

Numerous agents (Table I) can impair the absorption of ingested T4, probably by binding T4 in the bowel lumen. Such agents have little effect if the pituitary–thyroid axis is intact, but they may make fixed oral T4 dosage inadequate in hypothyroid patients who have no capacity to increase T4 production. This effect can generally be minimized by avoiding concurrent ingestion of T4 and potential inhibitors of absorption.

ENHANCED THYROID HORMONE METABOLISM

There is usually little effect from medications that enhance thyroid hormone clearance if the pituitary–thyroid axis is normal, but effects may be profound when an individual is dependent on exogenous T4. Hepatic T4 and T3 metabolism is enhanced by numerous agents that stimulate the cytochrome P450 system. In addition to the known effects of rifampicin, phenytoin, carbamazepine, and barbiturates, other compounds may have this effect, for example, antibiotics, psychotropics, and nontherapeutic xenobiotics.

DRUG INTERACTIONS

Tests of thyroid function may be especially affected when several agents are given together. For example, the concurrent use of high-dose furosemide with dopamine can result in profound hypothyroxinemia. Furosemide at high dosage displaces T4 from TBG, thereby accelerating its clearance, while concurrent dopamine infusion inhibits the normal TSH response to hypothyroxinemia. When dopamine treatment is concluded, serum TSH can rise transiently to supranormal levels that can be misinterpreted as indicating primary hypothyroidism. The combination of rifampicin, which accelerates T4 clearance, with glucocorticoid-induced inhibition of TSH secretion may also cause hypothyroxinemia.

AGENTS THAT MODIFY IMMUNE FUNCTION

Treatment of hepatitis C with interferon- α is frequently associated with thyrotoxicosis or hypothyroidism, sometimes in a sequence that suggests thyroiditis; the abnormalities are often transient, with resolution occurring over several months after treatment is ended. The prevalence of this effect has been estimated at 15–30%, with greater frequency in females and those with positive thyroid peroxidase antibody. In contrast, thyroid dysfunction is less common during interferon- β treatment of neurological disorders, such as multiple sclerosis.

Monoclonal antibody treatment for multiple sclerosis may lead to persistent autoimmune thyroid dysfunction. Six to 30 months after treatment, one-third of previously euthyroid patients who received a 5-day course of the humanized anti-CD52 monoclonal antibody developed antibodies against the TSH receptor, associated with carbimazole-responsive thyrotoxicosis that tended to persist after withdrawal of carbimazole.

Transient primary hypothyroidism for 6 months to 2 years, perhaps of autoimmune origin, has been described in association with hypersensitivity reactions to phenytoin, carbamazepine, and sulfonamides; *in vitro* studies suggested an immune interaction with thyroid peroxidase.

CLINICAL ISSUES WITH PARTICULAR DRUGS

Amiodarone

Amiodarone is the most complex and troublesome of the drugs that can affect thyroid status (Table II).

Table II Medications with Multiple Effects on the Pituitary–Thyroid Axis

| |
|--|
| Glucocorticoids |
| Inhibit TSH secretion |
| Impair thyroid hormone release from the gland |
| Inhibit 5'-deiodination of T4 and rT3 |
| Decrease concentration of TBG |
| Amiodarone |
| Delivers iodine load |
| Iodine-induced thyrotoxicosis (Jod-Basedow) |
| Iodine-induced hypothyroidism |
| Causes unique form of thyrotoxicosis due to thyroiditis |
| Retards T4 clearance |
| Inhibits 5'-deiodination (type 1 and type 2) of T4 and rT3 |
| Thyroid hormone receptor antagonist? |
| Augments TSH secretion |
| Phenytoin |
| Inhibits T4 and T3 binding to TBG |
| Accelerates T4 clearance and metabolism |

Benign euthyroid hyperthyroxinemia, with high total and free T4, normal or subnormal serum T3, and increased serum rT3, occurs in up to one-third of amiodarone-treated subjects. This abnormality requires no treatment—the diagnosis of amiodarone-induced thyrotoxicosis should not be based on T4 excess alone.

In iodine-replete regions, the predominant amiodarone-induced thyroid problem is hypothyroidism, which is especially likely to occur on a background of thyroid autoimmunity. Routine replacement with T4 is effective, but therapy may need to be modified because of associated heart disease.

The most difficult abnormalities that result from amiodarone therapy are two unpredictable forms of thyrotoxicosis, one due to iodine excess and the other attributed to a unique form of persistent thyroiditis with specific intracellular inclusion bodies. Severe life-threatening thyrotoxicosis can occur rapidly, without premonitory abnormalities of thyroid function. Weight loss, deterioration of cardiac function, and severe myopathy are the important clues to this diagnosis. There can be poor correlation between circulating thyroid hormone levels and the clinical features of amiodarone-induced thyrotoxicosis, perhaps because of interaction of this drug, or its active metabolite desethylamiodarone, with thyroid hormone receptors.

A distinction between these two forms of amiodarone-induced thyrotoxicosis by color Doppler flow studies has been reported. If blood flow is increased, the thyrotoxicosis may be directly due to iodine

excess; standard anti-thyroid drugs, with the possible addition of potassium perchlorate, may be appropriate first-line therapy. In contrast, glucocorticoids are generally preferred in the thyroiditis variant that shows markedly decreased thyroid blood flow. Emergency thyroidectomy may be necessary in some cases of severe amiodarone-induced thyrotoxicosis that cannot be controlled medically.

Lithium

This agent, widely used in the management of manic-depressive illness, has several effects on the pituitary–thyroid axis, the most important being the effect of inhibiting thyroglobulin hydrolysis and hormone release. Lithium exacerbates, or may possibly cause, autoimmune thyroid disease of the Hashimoto type, leading to eventual primary hypothyroidism, often with goiter. Women with positive anti-peroxidase antibodies are especially likely to be affected. Among 690 lithium-treated Scottish patients, 14% of women and 4.5% of men developed various grades of thyroid failure. There are also reports of lithium-induced thyrotoxicosis of probable autoimmune origin.

It is generally recommended that TSH, T4, and anti-peroxidase antibodies be assessed before commencement of lithium therapy, with serial evaluation of thyroid status every 6–12 months during treatment or if a goiter develops. Thyroxine replacement is recommended if there is TSH excess or progressive thyroid enlargement, even if TSH remains within the reference range. Doses of T4 sufficient to suppress TSH to subnormal levels probably retard goiter growth, but this point remains unproven.

Phenytoin

This anti-epileptic commonly results in subnormal serum total T4, with an apparent lowering of free T4, not accompanied by the anticipated increase in TSH. Such findings are not easily distinguishable from central hypothyroidism due to pituitary deficiency. The effect on free T4 may be spurious, because the T4-displacing effect of phenytoin is poorly reflected by assays that use diluted serum, leading to an underestimate of the free T4 concentration (see above).

It remains difficult to make an accurate assessment of thyroid status in hypopituitary patients who are taking T4 together with phenytoin or carbamazepine; serum TSH is not useful and free T4 estimates can be misleading. Phenytoin accelerates T4 clearance by induction of cytochrome P450 enzymes, so that

the replacement dose may need to be increased. Treatment with phenytoin or carbamazepine can make previously optimal treatment of primary hypothyroidism inadequate or may unmask diminished thyroid reserve.

EFFECTS OF THYROID STATUS ON DRUG EFFECTS

In general, thyrotoxicosis increases drug clearance, whereas hypothyroidism may markedly retard drug disposal. During thyrotoxicosis, standard drug dosage may be ineffective, as, for example, in the reputed “insensitivity” of thyrotoxic patients to digitalis preparations. A higher than normal dosage may be required, but as the thyrotoxicosis comes under control, digitalis toxicity can occur unless dosage is adjusted.

Severely hypothyroid subjects are abnormally sensitive to narcotics, sedatives, and analgesics, due to diminished clearance of these substances. This may be recognized as prolonged respiratory depression after anesthesia, when hypothyroidism has not been previously recognized.

Anticoagulant therapy is an exception to this rule. Consumption of coagulation factors tends to be more rapid in active thyrotoxicosis, with a tendency toward increased responsiveness and lower coumarin dose requirements. An increase in dosage may be required as control of thyrotoxicosis is achieved.

PATHOPHYSIOLOGY

These diagnostic criteria for type III HLP reflect the prolonged circulation and accumulation of remnant lipoproteins in patients with this disorder. Remnants are lipoproteins at intermediate stages in the catabolism of TG-rich lipoproteins, both chylomicrons of dietary intestinal origin ($d < 0.95$, $S_f > 400$, containing apo B-48 as the structural apolipoprotein) and VLDL of endogenous hepatic origin (containing apo B-100). Remnants are formed by the selective extraction of TG from the chylomicron or VLDL lipoprotein core, lipolysis mediated by lipoprotein lipase (LPL) that is bound by heparan sulfate proteoglycans (HSPG) to capillary endothelial cells (with apo C-II as an essential coenzyme). The remnant lipoproteins generated in this way are reduced in TG (and proportionally increased in cholesterol) and are smaller, denser, and of slower electrophoretic mobility than their precursors. They are normally

efficiently removed by the liver (Fig. 1) after sequestration in the space of Disse, where further lipolysis by LPL and hepatic lipase (HL) takes place prior to their uptake by hepatocytes. This uptake may take place via three alternative mechanisms: (1) the LDL receptor (LDL-r); (2) the LDL receptor-related protein (LRP), with or without bound HSPG; or (3) HSPG alone. Apo E on the remnant surface is critical in this process, serving as the principal ligand for the LDL-r and LRP. Of the various alternative removal mechanisms, the LDL-r is thought to be of primary regulatory importance, with the ontologically more primitive and pluripotential LRP serving in a "backup" role, apparent only when the LDL-r is deficient or defective (as in FH, in which remnants do not accumulate).

The capacity for remnant removal is normally sufficient to fully assimilate these lipoprotein intermediates during an 8- to 12-h overnight fast, even in a circumstance with a high flux of TG-rich lipoproteins

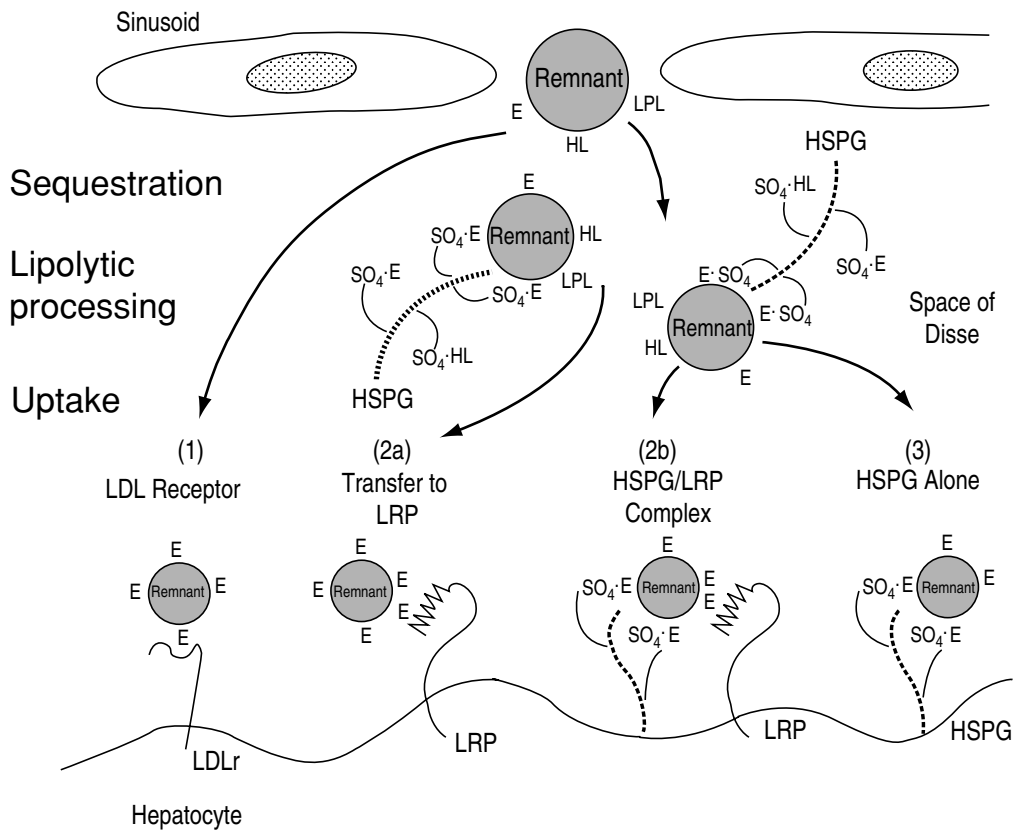

Figure 1 Scheme of hepatic lipoprotein remnant processing in the space of Disse and uptake by hepatocytes, which can take place by three alternative mechanisms: via the LDL receptor (LDL-r) (1); transfer to the LDL receptor-related protein (LRP), either directly (2a) or as a complex with heparan sulfate proteoglycans (HSPG) (2b); or via hepatocyte-bound HSPG alone (3). The relative contributions of the three are affected by lipolytic processing via lipoprotein lipase (LPL) and hepatic lipase (HL) as well as by interactions between apo E and HSPG and the affinities of apo E and apo B for the LDL-r and LRP. Reproduced from *J. Lipid Res.* **40**, 1-16 (1999).

such as following an oral fat load or in the presence of high endogenous VLDL secretion rates (as in diabetes and the “metabolic syndrome” of insulin resistance). However, when remnant removal capacity is limited (as perhaps with hypothyroidism and certain dysglobulinemias), especially in a person whose apo E has reduced affinity for the LDL-r and LRP (i.e., with the apoE_{2,2} genotype or who lacks apo E altogether on an inherited basis), and TG-rich lipoprotein flux is increased, remnants accumulate and acquire the properties of the cholesterol-rich, β -VLDL characteristic of type III HLP, including the persistence in fasting plasma of cholesterol-rich chylomicrons (at TG levels below 300 mg/dl).

The most common molecular basis of dysbetalipoproteinemia is the homozygous inheritance of isoapo E₂, which differs from the wild-type E₃ in a single amino acid substitution (cysteine for arginine at residue 158). (E₄ has an additional arginine for cysteine substitution at residue 112 and, hence, is the most basic of the three.) The cys-arg substitution at residue 158 dramatically diminishes the affinity of E₂ for the LDL-r (by 98–99%) and for LRP (by 60–70%). Even in the hypolipidemic state, TG-rich lipoproteins of intermediate density with an increased C/TG ratio characteristic of dysbetalipoproteinemia predominate and β -VLDL can be detected in fasting plasma, albeit at very low levels. However, lacking a coexisting cause for hyperlipidemia, such persons are actually hypolipidemic, with low levels of LDL. Indeed, the apo E genotype is the most powerful genetic determinant of population plasma cholesterol levels; average LDL cholesterol levels (and cardiovascular risk) increase with increasing numerical apo E genotype: E₂/E₂ < E₂/E₃ < E₃/E₃ \approx E₂/E₄ < E₃/E₄ < E₄/E₄. The gene frequencies of epsilon 2, 3, and 4 vary among populations; on average, the E_{2,2} pattern is present in approximately 1%.

However, as noted earlier, when the E_{2,2} genotype coexists with a cause for hyperlipidemia (genetic or acquired), this otherwise hypolipidemic phenotype is converted to one of the most hyperlipidemic (and atherogenic) of all (type III HLP). The required associated cause of hyperlipidemia is often a second inherited condition, most frequently FCHL (often considered synonymous with hyperapobetalipoproteinemia). FCHL may be present in as much as 1% of the general population (and in 10% of those with premature coronary disease); hence, type III HLP resulting from the coincidence of E_{2,2} with FCHL may have a prevalence as high as 1 in 5000 to 10,000. Alternatively (or in addition to FCHL), insulin resistance may be the precipitating factor for type III HLP.

In a recent population-based Dutch study, the E_{2,2} genotype was present in 0.6% and type III was present in 18% of these. In a referral sample from the same clinic, hyperinsulinemia was present in two-thirds of patients with type III HLP.

The pathophysiological hallmark of FCHL is apo B-100 (and VLDL) overproduction. Hence, in the presence of the E_{2,2} genotype, VLDL apo B overproduction (with consequent increased remnant generation) appears to saturate a reduced remnant removal capacity, one that is attributable to impaired recognition of apo E₂ by the LDL-r and LRP. However, what mediates the efficient removal of E₂-bearing remnants with diminished conversion to LDL in the absence of apo B overproduction remains enigmatic and subject to controversy. The prolonged plasma residence time of the remnants in type III HLP probably accounts for their progressive cholesterol enrichment (through exchange of lipids and apolipoproteins), oxidation, ultimate removal by scavenger receptors (as part of the atherogenic process), and deposition in other extravascular compartments, including the skin as xanthomas over areas subject to trauma.

A related area of concern in lipoprotein physiology is the general issue of the postprandial lipemia common to all forms of hypertriglyceridemia and the special atherogenicity of the remnants that circulate during prolonged alimentary lipemia. In this regard, even a partial limitation in apo E₃- or E₄-mediated remnant removal conferred by heterozygous E₂ status may contribute to accelerated atherogenesis in a person with apo B overproduction. (β -VLDL and premature ASCVD have been reported in persons of E₂/E₃ phenotype in kindreds with FCHL.) Alternatively, diminished LDL-r capacity, whether on an inherited (FH) or acquired (hypothyroidism) basis, may also cause type III HLP in persons with apo E₂/E₂. However, in that circumstance, LDL cholesterol levels may actually be elevated (or at least not diminished) as a reflection of decreased LDL-r activity.

Type III HLP may also rarely be seen in patients lacking apo E altogether, as these patients also accumulate β -VLDL remnants and suffer accelerated atherogenesis. (Apo E knockout mice are favorite models for studying atherosclerosis.) Like their counterparts who are E_{2,2} homozygotes, such persons without apo E demonstrate prolonged circulation of VLDL apo B and reduced conversion to LDL as manifestations of impaired remnant removal. (“Remnant removal disease” is a synonym for type III HLP.)

An even more severe limitation in remnant removal may occur in persons with rare apo E mutants that

produce type III HLP (with accelerated atherogenesis), in this instance genetically transmitted in an autosomal-dominant mode. This can occur from a single amino acid substitution (e.g., arg 136 → ser/cys) or the insertion of a tandem repeat of amino acids 121 to 127 (apo E-Leiden). Such apo E mutants appear to interfere with remnant removal mediated by HSPG, producing a blockade so complete that a coexisting cause of hyperlipidemia is not required for expression of type III HLP. An essential role for HL in remnant removal is also suggested by the presence of type III HLP in persons homozygously lacking HL on an autosomal-recessive genetic basis. However, in this circumstance, HDL levels are increased (and atherogenicity is relatively less than in the E_{2,2} homozygote), presumably reflecting the role of HDL in reverse cholesterol transport (and the role of HL in accelerating HDL catabolism).

A final paradox remains to be resolved: the hypolipidemic effect of estrogen in type III HLP. Suggested clinically by the rare expression of the disorder in women prior to menopause in this autosomal-codominant condition, clinical studies (reproduced in animal models) have repeatedly demonstrated amelioration of type III HLP by estrogen therapy. TG levels decline (in contrast to their usual elevation with estrogen), as does VLDL cholesterol, and β-VLDL may disappear while HDL cholesterol rises; however, LDL levels do not rise, even though VLDL apo B is converted to LDL more readily. Thus, estrogen appears to facilitate remnant removal. Perhaps this may reflect enhanced clearance by LDL-r, LRP, or HSPG. However, it would seem unlikely that this effect would be mediated by enhanced TG lipolysis given that HL declines and LPL does not increase in women treated with estrogen.

Hence, at least a portion of the enigma of type III HLP remains. How does a genetic limitation in remnant removal result in decreased LDL? By what pathway are E₂-bearing remnants removed from the circulation without down-regulating the LDL-r or becoming deposited in extravascular sites given that this would increase—not decrease—atherogenic risk? How does estrogen, which increases VLDL secretion, produce a net reduction in remnant accumulation in E_{2,2} homozygotes with type III HLP?

TREATMENT

As would be deduced from its pathophysiology, treatment of type III HLP begins with lifestyle modifications that reduce atherogenic risk in general and

diminish TG-rich lipoprotein production, especially via limitation of fat and cholesterol in an American Heart Association step II diet, coupled with caloric restriction/enhanced caloric expenditure to achieve ideal body weight. Drug therapy should proceed according to National Cholesterol Education Program-Adult Treatment Panel III (NCEP-ATP III) guidelines, although according to those based on non-HDL cholesterol levels rather than estimated LDL concentrations, which are inaccurate in type III HLP and besides which reduction of VLDL cholesterol is actually a primary therapeutic objective. TG-lowering (and HDL-raising) agents are especially effective (fibric acid derivatives and niacin), although HMG Co-A reductase inhibitors (statins) also appear to be effective and safe. Lipid lowering has been associated with regression of xanthomas in type III HLP, and coronary artery disease risk reduction would appear to be commensurate with non-HDL cholesterol reduction (although no specific study of individuals with type III HLP has been reported using cardiovascular disease end points). Estrogen replacement therapy has a special role in postmenopausal women, possibly alone but perhaps more effectively when combined with a fibrate or a statin.

Bulimia

Persons with bulimia engage in cycles of bingeing and purging and/or other unusual means of controlling weight. These include using enemas and abusing laxatives and diuretics. Gorging cycles may also alternate with periods of severe food restriction and anorexics may also engage in bulimic behavior. In contrast to anorexia, weight often does not fall to critically low levels, although it may fluctuate. This, compounded with the secretive nature of the disorder, makes bulimia difficult to diagnose. Bulimia is most common in young women, especially those in high school and college, and often coincides with other impulsive behaviors and depression.

NORMAL REPRODUCTIVE FUNCTION AND THE MENSTRUAL CYCLE

Reproductive Hormonal Axis

To better understand the effects of eating disorders on the reproductive axis, the normal functioning of the female reproductive system should be considered. The mechanism of the normal menstrual cycle is the result of a number of different endocrine systems working in concert. These include the hypothalamus region of the brain and the adjacent anterior pituitary gland, as well as the ovaries and related organs (see Fig. 1). The hypothalamus secretes gonadotropin-releasing hormone (GnRH), signaling the pituitary gland to release luteinizing hormone (LH) and follicle-stimulating hormone (FSH). These two gonadotropins stimulate the ovaries to produce and secrete the sex hormones. The ovaries secrete primarily estrogens (mostly estradiol), progestins (mostly progesterone), and androgens.

GnRH Pulsatility

The pulse generator in the arcuate nucleus of the hypothalamus controls the secretion of GnRH. Throughout the course of the female reproductive cycle, the hormone is released in varying spurts or pulses. The pulsatility of GnRH release causes subsequent pulses of gonadotropins, which affect the changes in the reproductive tract that characterize the menstrual cycle. GnRH release is regulated in response to changing levels of sex hormones, but the mechanism behind the pulse generator is not entirely understood. It is thought, however, to be highly

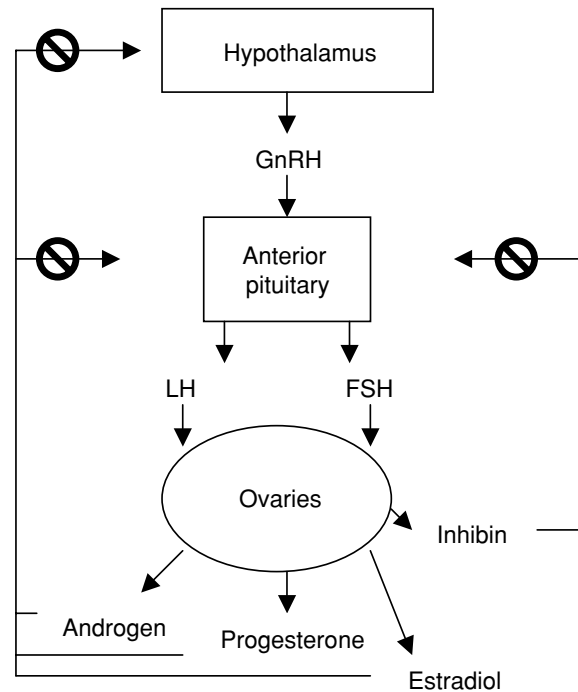

Figure 1 Gonadotropin-releasing hormone (GnRH), secreted from the hypothalamus, induces the release of the gonadotropins [luteinizing hormone (LH) and follicle-stimulating hormone (FSH)] from the anterior pituitary gland. LH and FSH control the production and release of the sex hormones, estradiol, progesterone, and androgen, from the ovaries. These hormones, in turn, inhibit the secretion of GnRH, LH, and FSH. In addition, the ovaries produce inhibin, which exerts a negative feedback effect on the release of FSH.

sensitive to stress and metabolic factors. This may help explain the amenorrhea that often accompanies nutritional disturbances.

INSULTS TO THE REPRODUCTIVE AXIS

Eating Disorders and Reproductive Dysfunction

The physiologic effects of eating disorders on the female reproductive system are not completely understood, but appear to suppress ovulation and favor reproductive economy via a neuroendocrine mechanism.

Anorexia Nervosa

In addition to the characteristic amenorrhea, anorexia produces other effects on the endocrine system, including changes in cortisol and thyroid hormones, which may affect the reproductive system.

Bulimia

Bulimics may also have menstrual irregularities, but reproductive dysfunction is generally less severe than in anorexics. Patients may be anovulatory with adequate estrogen secretion. Although amenorrheic, bulimics may maintain a normal or close to normal weight. However, bulimics have a wide variety of other medical problems that are superimposed on the anorectic syndrome. These include severe tooth decay, parotid enlargement, stomach rupture, metabolic alkalosis, carpopedal spasm, hypercarotenemia, and pancreatitis.

Amenorrhea

Amenorrhea, the lack of menstrual periods, is the primary effect of eating disorders on the reproductive system. It can be classified as primary or secondary, depending on the time of onset. Primary amenorrhea is a delay in menarche beyond the age of 16. Secondary amenorrhea occurs when periods are absent for more than 3 to 6 months in women who previously menstruated regularly. The dysfunctions that lead to amenorrhea are numerous and can result from an endocrine or physical disturbance at various steps along the reproductive axis. However, the type of amenorrhea generally seen in eating disorders is reversible hypothalamic amenorrhea. It can be either primary or secondary in nature, depending on whether or not the eating disorder began before puberty, thus delaying menarche.

The physiologic basis for hypothalamic amenorrhea is the disruption of the hypothalamus' pulsatile secretion of GnRH. A number of studies have shown a depression in GnRH pulsatility associated with starvation. This suggests that the GnRH pulse generator may be affected by metabolic fuels and/or is able to sense a drop in weight below a certain setpoint. When energy expenditure is greater than dietary intake, GnRH inhibition occurs, thereby lowering the release of LH and FSH from the anterior pituitary and shutting down or limiting ovarian stimulation and estradiol production.

Although actual levels of LH and FSH may not appear significantly altered, the 24h patterns of hormonal pulses more closely resemble prepubertal patterns than those of a mature female. Prepubertal LH and FSH patterns are characterized by decreased and low-amplitude pulsations. However, studies have shown that follicular maturation, and even menstruation, can be induced in many patients by the pulsatile administration of exogenous GnRH. Therefore, as is seen in patients who recover their weight, the

amenorrhea can be reversible when normal hormone pulsatility is restored.

Other Types of Hypothalamic Amenorrhea**Athletic**

Hypothalamic amenorrhea is also prevalent among female athletes. In addition to the maintenance of low body weight, it is thought that a combination of other environmental factors, such as heavy exercise and mental stress, may contribute to the large number of amenorrheic women athletes. Some research suggests that women who sustain heavy exercise loads consistently over a period of time suffer an energy deficit that occurs because their daily energy expenditure exceeds their caloric intake. The body may compensate for this loss by decreasing resting metabolic rate and thereby disrupting the menstrual cycle. Because metabolic rate is depressed in these individuals, some are able to maintain normal weight despite a negative energy balance and amenorrhea.

Functional Hypothalamic Amenorrhea

Functional hypothalamic amenorrhea (FHA), a diagnosis of exclusion, occurs in normal weight, non-athletic women and has no apparent cause. Although previously attributed to stress, some evidence suggests that women with FHA may actually be incurring an energy deficit as a result of dieting. This energy deficit produces metabolic and endocrine effects similar to those seen in eating-disordered and athletic amenorrheics. Therefore, although anorexia and bulimia present extreme examples of the effect of nutritional aberrations on the reproductive system, menstrual irregularity and amenorrhea can occur from simple weight loss and dieting-associated weight loss. Understanding this effect may explain the significant number of recovered eating-disordered patients who do not regain menses with weight gain. By continuing disordered eating patterns, metabolic abnormalities may persist despite the return to normal weight.

The exact mechanism by which these adaptive metabolic changes influence the hormone cascade responsible for the maintenance of the menstrual cycle is unknown. However, researchers are pursuing an unknown metabolic signal or signals that may inform the GnRH pulse generator of the low weight and/or negative energy balance. Scientists are studying the roles of dehydroepiandrosterone, insulin-like growth factor, and cortisol, as well as leptin, a protein synthesized by the obesity gene, for possible clues.

Leptin

Leptin is a small polypeptide hormone secreted primarily by adipocytes (fat cells). Leptin levels appear to be regulated by total energy intake and fat stores and correlate significantly with body mass index in humans. Because leptin is a regulator of the basal metabolic rate, it is thought to be a particularly important indicator of nutritional status. Studies have shown this effect in amenorrheic athletes and eating-disordered patients in whom leptin levels and metabolic rate tend to be low.

Studies have shown that leptin may also be a significant mediator of reproductive function. Research indicates that if leptin levels fall below a critical threshold, menstruation will not occur. Although the mechanism by which this occurs is unknown, leptin may affect changes in GnRH pulsatility as leptin receptors have been found on hypothalamic neurons thought to be involved in the control of the pulse generator.

Leptin is also connected to thyroid function and to the onset of puberty. When nutritional status is poor, altered leptin levels are directly correlated with changes in thyroid hormone. Thus, leptin may not only act as a regulator of metabolic rate, but also as a mediator of menstrual status by slowing metabolism and possibly returning a woman to a prepubertal-like state when challenged with starvation.

OSTEOPOROSIS

One of the most permanent and devastating medical effects of hypothalamic amenorrhea in young women is significant osteopenia (reduced bone mass) and severe osteoporosis later in life. Studies suggest that almost half of an individual's bone mass is formed during adolescence and early adulthood, making this period especially critical to a woman's long-term health. Women who do not reach peak bone mass during this window are at a higher risk for osteoporosis once bone mass begins to decline.

Two homeostatic mechanisms act on bone simultaneously: hormones and mechanical stress. In normal circumstances, they maintain skeletal integrity and serum calcium levels. With aging or menstrual disturbance, factors such as diet, hormonal levels, and mechanical strain cause bones to become more vulnerable to fracture and osteoporosis. Studies have also shown that the normal mechanism that causes bones to strengthen in response to weight-bearing exercise is not functional in amenorrheic athletes. Although it

is unclear how this mechanism functions, these women have significantly lower bone mass density than their normally cycling counterparts.

Like amenorrheic athletes, anorexics have significantly decreased bone mass density. Although depressed estrogen levels may be partially responsible for this increased risk of osteoporosis, studies suggest that other mechanisms are also involved. The discovery of leptin receptors on bone may represent one such mechanism that could account for the low bone density and high stress fracture rates seen in women with hypothalamic amenorrhea.

EFFECTS OF EATING DISORDERS ON FERTILITY

As a result of anovulation and hypoestrogenic amenorrhea, infertility may occur. Patients may need induction of ovulation with clomiphene citrate or gonadotropins. However, there is also a high miscarriage rate of 25 to 30% in this population, as well as a high frequency of low-birth-weight babies born to women who are underweight.

TREATMENT

Though there are a variety of approaches used to treat eating disorder-induced and exercise-induced amenorrhea, all treatments are oriented toward a return to normal weight. Treatments include combinations of the following: psychotherapy, psychoanalysis, drug therapy, behavior modification, dietary therapy, and reduction of exercise load. Treatment with hormone replacement therapy or oral contraceptive therapy is controversial and does not appear to be uniformly effective.

Table I Characteristic Features of ECL Cells

| Properties in common with other peptide hormone-producing cells | Unique properties |
|---|---|
| Argyrophil staining | Histamine formation, storage, and secretion |
| Cytoplasmic secretory granules/vesicles | HDC |
| Chromogranins | Stimulation by gastrin (via CCK ₂ receptors) |
| APUD properties | |
| Costorage of amines and peptides | |
| Proteolytic "processing" enzymes in granules/vesicles | |
| Exocytotic proteins | |
| PGP 9.5, Reg protein | |

Note. APUD, amine precursor uptake and decarboxylation; CCK₂, cholecystokinin-2; HDC, histidine decarboxylase; PGP 9.5, protein gene product, molecular weight 9.5 kDa; Reg, regenerating-gene.

that bud off the *trans*-Golgi network. These microvesicles are probably loaded with cargo, such as proteolytic enzymes and secretory peptide precursors (such as chromogranin A and prohormone). As a result of protein condensation (probably induced by low pH), the electron-lucent microvesicles are transformed into dense-cored granules while still in the *trans*-Golgi area. When the Golgi-associated granules embark on their journey toward the periphery of the cell, they start to take up histamine from the cytosol by means of the vesicle monoamine transporter type 2 (VMAT₂), which is located in the granule/vesicle membrane. The continued accumulation of histamine is associated with transformation of the granule into a large electron-lucent (but dense-cored) secretory vesicle. As a consequence of stimulation of the cell

(by, e.g., gastrin), the secretory vesicles will fuse with the cell membrane to release their contents by exocytosis (Fig. 1D). Small electron-lucent microvesicles in the periphery of the ECL cells are thought to be part of the regulated secretory pathway, arising from the process of membrane retrieval (endocytotic vesicles). In the case of exposure to sustained gastrin stimulation, the secretory vesicles in the cytoplasm will fuse with one another to form large vesicles, referred to as vacuoles. The development of vacuoles parallels the development of lipofuscin bodies, which probably arise from the oxidative conversion of native lipids and proteins to a polymerized, nondegradable, and chemically ill-defined material. Both vacuoles and lipofuscin bodies are crinophagic (and/or autophagic) organelles, which may incorporate or be associated with primary lysosomes to form part of the lysosomal compartment. The time-dependent accumulation of vacuoles and lipofuscin bodies is associated with a progressive impairment of ECL cell functions.

FUNCTIONS OF ECL CELL PRODUCTS

Immunocytochemistry has revealed the presence of numerous potentially bioactive substances in the ECL cells (see Table I).

Histidine Decarboxylase

Histidine decarboxylase (HDC) catalyzes the formation of histamine from histidine. Western blot analysis of oxyntic mucosal extracts has revealed the presence of at least three different isoforms of HDC, having molecular masses of approximately 74, 63, and 53 kDa; the 63 kDa form seems to be enzymatically active. ECL cells respond to gastrin with up-regulation of HDC at both the transcriptional and the translational/posttranslational levels and with down-regulation of its degradation.

Histamine

ECL cell histamine plays an important role as mediator for gastrin-induced acid secretion. Gastrin stimulates the ECL cells by acting on cholecystokinin-2 (CCK₂) receptors to mobilize histamine, which in turn stimulates the parietal cells via the histamine H₂ receptor to secrete acid. This pathway is referred to as the gastrin–ECL cell–parietal cell axis.

Chromogranin A

Peptides of the chromogranin family (e.g., chromogranins A, B, and C) occur in endocrine cells through-

out the body. They probably function as chaperones in the packaging of secretory products in granules. It has also been suggested that they might be biologically active messenger molecules. The ECL cells are notably rich in pancreastatin (rat chromogranin A 264–314 amide) and pancreastatin-related products. In fact, the ECL cells contribute 70–90% of the circulating pancreastatin in rats.

Exocytotic Proteins

Several exocytotic proteins and their isoforms, originally identified in the neurons, also occur in endocrine/neuroendocrine cells, including the ECL cells. These proteins include vesicle-associated membrane proteins (also called synaptobrevins), synaptotagmins, synaptosomal-associated protein of 25 kDa, syntaxin, Munc-18, and cysteine string protein. The process of exocytosis depends on these proteins. In the ECL cells, exocytosis is triggered by Ca²⁺ entry, causing a rise in [Ca²⁺]_i.

Reg Protein

Reg protein is thought to be released from the ECL cells to act as a mediator of gastrin-induced growth of the oxyntic mucosa.

REGULATION OF ECL CELL SECRETION

The ECL cells are controlled by a complex regulatory system. They carry the following receptors (preferred ligand is shown in parentheses): CCK₂ receptor (gastrin and CCK), PAC₁ receptor [pituitary adenylate cyclase-activating peptide (PACAP)], VPAC₂ receptor [vasoactive intestinal peptide (VIP)], somatostatin type 2 receptor, galanin receptor, β₂-adrenergic receptor (adrenaline), EGF receptor, neuronal growth factor receptor type 1, fibroblast growth factor receptor type 1, and EP₃ receptor (prostaglandin E₂). The nature of the ligands of these receptors is such that the regulation of ECL cell secretion can be categorized into endocrine, paracrine, and neural control. Briefly, gastrin, PACAP, and VIP stimulate ECL cell secretion, whereas somatostatin, galanin, and prostaglandin E₂ inhibit it. Interestingly, acetylcholine and histamine seem to have no effect on the ECL cells.

REGULATION OF ECL CELL GROWTH

The turnover time of ECL cells in mice and rats is between 20 and 100 days. The ECL cells respond to sustained gastrin stimulation first with hypertrophy and then with general diffuse hyperplasia, which reflects a transient increase in the ECL cell self-replication rate. Potent anti-secretagogues, such as histamine H₂ receptor antagonists and proton pump inhibitors, are widely used clinically to treat acid-related disorders. An increased incidence of gastric carcinoids, later identified as ECL cell tumors or ECLomas, was noted in the murine stomach after long-term treatment with these acid inhibitors. In view of the known trophic effect of gastrin on ECL cells, the stimulus behind the development of ECL cell tumors is hypergastrinemia rather than achlorhydria. Thus, effective inhibition of gastric acid secretion abolishes the luminal acid feedback inhibition of the antral G cells and leads to hypergastrinemia, which in turn stimulates the ECL cells to divide, at first resulting in general diffuse ECL cell

hyperplasia, later resulting in focal hyperplasia with multiple micronodules, and finally resulting in frank tumors (carcinoids).

is needed to release the low-molecular-weight and soluble forms of the peptides. Though it is well known that, for example, EGF can be released as 6, 45, and 200 kDa molecules, little is known concerning the various forms of the EGF ligands and even less is known concerning the biological diversity found in molecular forms derived from the same precursor molecule of the ligand.

It has been questioned whether the membrane-spanning precursors could possibly play a role as receptors themselves. This is most obvious for the EGF precursor, both because it is the largest of all the precursors because of its well-conserved sequence and because it has structural features in common with the low-density lipoprotein (LDL) receptor. Thus far, however, a receptor function has been described only for the precursor of HB-EGF. In human and monkey, the HB-EGF precursor acts as the cellular receptor for diphtheria toxin.

One or more of the EGF-related ligands are present in all the tissues of the body (Table I). EGF has been the most thoroughly examined and its distribution is restricted to a few sites. It is produced in exocrine glands and in the kidney and it is secreted into urine and secretions such as tears and saliva. In contrast, other members of the EGF system, such as TGF- α , are more widely expressed.

The protein level of the peptides was initially determined from rather insensitive receptor-binding assays. Antibodies against the low-molecular-weight forms of all the peptides except for epiregulin have become commercially available and thus it is possible to perform both immunohistochemical studies and measurements employing, e.g., enzyme-linked immunosorbent assay methodologies. A major problem concerning such studies is that relatively little is known concerning the ability of the antibodies to recognize the precursor forms of the EGF ligands.

By and large, the ligands function close to the place of their synthesis. They act as paracrine or even autocrine growth factors and it is doubtful that they have a function as classical hormones produced in one place and transported through the bloodstream to act at other organs.

Many of the ligands are active in both their membrane-bound and soluble forms. Thus, proteolysis of the ligands may regulate whether they act on distant cells or whether they are able to act only on neighboring cells. Some of the proteolytic enzymes responsible for the release of membrane-bound precursors have been identified, such as the metalloproteinases releasing HB-EGF, and they represent yet another mechanism for regulating the activity of the EGF system.

In conclusion, the general picture emerging for the EGF ligands is that of a group of structurally related growth factors synthesized as precursor molecules and most likely able to act as membrane-bound peptides as well as after proteolytic release. The activity is mediated by binding to one or more of the receptors belonging to the EGF system.

MODE OF ACTION

The EGF system promotes a number of actions at the cellular level. The earliest described and the most comprehensively studied function is the stimulation of proliferation. In particular, an increased activity of the EGF system is found associated with the increased proliferation observed in a number of cancer cells. Other functions include cellular migration, chemotaxis, cellular adhesion, and cellular differentiation. Activation of the EGF system may also prevent cells from entering the programmed cell death pathway. Though it is evident that many different signals may be the result of interaction between EGF ligands and their receptors, the exact pathways leading to growth as compared to lack of apoptosis or differentiation have yet to be described.

The activity of the EGF ligands requires the presence of membrane-bound receptors. Four receptors, HER1–4 (human EGF receptor), are known. Three of them (HER1, HER3, and HER4) are recognized by one or more of the EGF ligands, whereas no ligands able to bind to HER2 have been identified. Three of the receptors (HER1, HER2, and HER4) have tyrosine kinase activity and are able to phosphorylate tyrosine residues.

All of the receptors are membrane-spanning single-chain glycoproteins of approximately 200,000 kDa. The ligand-binding site is present in the extracellular part of the molecule, whereas the tyrosine kinase activity is mapped to the intracellular part of the molecule. A protein domain containing several tyrosine phosphorylation sites further characterizes the intracellular portion. Activation of these sites represents the first step in the signal transduction cascade. In addition, the intracellular part contains a number of other phosphorylation sites involved in the regulation of the EGF receptor by other proteins. The intracellular part of the receptor also contains binding sites for tyrosine phosphatases. These enzymes are responsible for down-regulating the number of tyrosine-phosphate residues formed and are thereby able to modify the signal induced by the interaction of the ligand and the receptor.

Binding of the EGF ligands to the EGF receptor induces dimerization either in the form of a homodimer of two receptors, e.g., two HER1 molecules, or in the form of a heterodimer, where, e.g., HER1 dimerizes with HER2. All the ligands described in this article bind to HER1 but some of them also bind to HER4 (HB-EGF, betacellulin, epiregulin) (Table 1). Increased signaling diversity is added to the system by heterodimerization with either HER2 or HER3. HER2 apparently has no activating ligand but potentiates signaling and HER3 increases the signaling diversity of the system although it has no active kinase domain.

The model for transmitting the activity of the EGF ligand present outside the cell into a signal within the cell involves several steps. First, the ligand binds to the preferred receptor. This induces both dimerization and activation of the tyrosine kinase activity of the receptor. The activation induces phosphorylation of tyrosine residues present on the intracellular part of the receptors though a reaction often referred to as autophosphorylation. But in fact, it is thought that one partner of the formed receptor dimer phosphorylates the other and vice versa.

The phosphorylated tyrosines on the intracellular part of the activated receptors generate docking sites for intracellular proteins containing SH2 (Src homology 2) or other phosphotyrosine-binding domains. These activated adapter molecules then activate a series of signaling molecules in the cytoplasm, which results in the activation of many different signal transduction pathways, such as the mitogen-activated protein kinases, phosphoinositol kinase, and protein kinase A. Ultimately, the activation of the signal transduction pathways results in regulation of the expression of specific genes in the nucleus.

One of the immediate results of signaling through the EGF pathway is an up-regulation of the EGF ligands synthesized by the cells, with HB-EGF and amphiregulin being induced earliest. This self-induction is considered to represent a local amplification of the signal.

Thus far, only activation of the EGF system has been discussed, but obviously it is as important to understand how this signal is turned off again. One mechanism is dephosphorylation of the phosphorylated tyrosine residues on the activated receptors by intracellular phosphatases. In fact, it has been discussed whether the phosphatases are the main determinants of the activity of the EGF receptors. In this scenario, a low phosphatase level will result in a high degree of activity, whereas a high phosphatase level will prevent the presence of phosphorylated tyrosines

on the receptors and thereby prevent the initiation of the signaling cascade.

Another mechanism for termination of signaling through the EGF system is internalization of the ligand–receptor complex by endocytosis. After activation of the receptor by a ligand, the ligand–receptor complex is taken up by the cell through the clathrin-coated regions of the cell membrane. In the endosome, the internalized ligand is degraded and the receptors may be either recycled or degraded. A key protein determining whether a receptor is recycled or degraded is Cbl. Cbl binds to the activated receptor after internalization, which results in ubiquitination and degradation of the receptor. In the absence of Cbl, the receptor is transported back to the cell membrane and is able to engage in the signal transduction process again. The stability of the internalized receptor dimers is an important determinant of the recycling pathway controlled by Cbl. Studies on the degradation of the different forms of receptor homodimers and heterodimers have shown that HER1 receptor homodimers have a high level of stability, whereas heterodimers have a lower level of stability. Consequently, the unstable heterodimer complex uncouples before it is bound by Cbl and thereby the receptors are recycled to the cell membrane. This mechanism contributes to the signaling superiority of the heterodimeric receptor complexes.

In summary, the EGF system with its many receptors and ligands represents a complicated alphabet able to transmit a wide variety of messages from outside the cell into the nucleus. The net result of the signaling can be observed, but how to interpret the many possible combinations between ligands and receptors has yet to be determined.

LESSONS FROM GENE-MANIPULATED MICE AND PHARMACOLOGICAL STUDIES

At first it was believed that the majority of EGF was synthesized in the submandibular glands and that deficiency could be studied by removal of these glands. Then the picture emerged of a number of ligands belonging to the EGF system, which were able to replace one another's function and which were synthesized locally in all regions of the body. In this scenario, deficiency of the EGF system can be studied only employing knockout animals and severe effects can be expected only if the common key point, the receptor, is nonfunctioning.

The TGF- α knockout mice have been thoroughly studied. Small but distinct features characterize these animals. They develop changes in the growth of the fur, including curly whiskers, and their eyes do not develop normally. Also, an EGF knockout animal has been developed, but lack of EGF does not impose a characteristic feature on these animals.

Quite a different picture is observed for animals lacking the EGF receptor (HER1). Most of these animals die *in utero* and those that are born display severe defects in the lungs and in the gastrointestinal system. Also, animals lacking HER2 or HER4 die *in utero*. In these animals, the major malformations occur in the heart. In addition, correct development of the brain is dependent on the presence of EGF receptors and here HER2 and HER3 seem to be the key players.

Drugs able to inhibit the activity of HER1 or HER2 have been developed and used for the treatment of cancer. From a physiological point of view, it is interesting that drugs interfering with HER1 result in side effects related to the skin, such as acne, whereas drugs directed toward HER2 may induce cardiac symptoms. Thus, in the adult human organism, the skin seems to be the tissue most sensitive to a lack of HER1 signaling, whereas the heart seems to be the organ most sensitive to signaling through HER2.

An excess supply of EGF ligands has been studied in two ways. In transgenic animals, increased expression of TGF- α leads to premalignant or malignant transformations in, e.g., the skin and the mammary glands. Less dramatic is the result of an overexpression of amphiregulin. It decreases the final maturation of the keratinocytes and leads to a condition similar to psoriasis.

Another path has been to inject large doses of EGF into rats or mini-pigs. Such studies have shown that EGF promotes the growth of the urinary tract in particular. After 3 weeks of treatment, the ureter of the mini-pig more than doubles its size, but after cessation of therapy, the ureter slowly decreases in size toward pretreatment values. It is not known whether the potential role of the EGF ligands in tumor development precludes the use of these ligands in situations where growth of tissue is required. The potential of the EGF ligands in this regard is obvious as judged from the studies performed thus far.

Studies on gene-modified animals have confirmed the notion that the EGF ligands by and large may replace one another and have also stressed the role of the ligands in connection with the development of cancer. The few data available also indicate that even though the ligands may often replace one another, each of them is likely to play a unique role.

EGF LIGANDS AND CANCER

It has already been noted that there is a tight connection between the EGF system and the development and growth of cancer. The EGF receptor is a proto-oncogene and one or more of the receptors are overexpressed in numerous types of cancer, including breast cancer and other cancers of epithelial origin. The activity of the EGF system is regulated both by the expression of the receptors and by the ligands and it is well known that coexpression of both a receptor and a ligand from the EGF system is related to a poor prognosis for the patient. It has been observed that the expression of a subset of the EGF ligands (epiregulin, TGF- α , and HB-EGF) is a stronger predictor for survival in patients with bladder cancer than the expression of the receptors. The precise mechanism behind the increased expression of the EGF ligands is unknown; gene amplification for any of the ligands has not been described. This is in contrast to the situation for HER2, where gene amplification is observed in approximately 20% of breast cancer patients.

Hundreds of papers describe the possible usefulness of measurement of the EGF ligands and their receptors as prognostic factors in patients with cancer, but a far more exciting development has taken place. The first drug able to inhibit signaling through the EGF system (Herceptin or trastuzumab) has now been registered for treatment of patients with breast cancer that overexpresses HER2. Herceptin is a humanized monoclonal antibody able to inhibit HER2. The first clinical phase III trial on breast cancer patients published in 2001 showed a remarkable effect. The time to disease progression increased from 4.6 to 7.4 months in patients receiving Herceptin plus chemotherapy as compared to patients receiving chemotherapy alone. The same drug is also being tested for the treatment of a variety of tumors overexpressing HER2, including pancreatic cancer, colorectal cancer, and bladder cancer. Similarly, monoclonal antibodies against HER1 are currently being tested for the treatment of patients with head and neck cancer.

Another strategy for decreasing signaling through the EGF system is to use drugs that are able to inhibit the tyrosine kinase activity of the receptors. A number of such drugs are being tested for the treatment of non-small-cell lung cancer and head and neck cancer. Other strategies involve the introduction into the tumor of a transcription factor, E1A, that is able to decrease the expression of HER2. Initial experiments on patients with ovarian or breast cancer have shown that this principle may also work.

The role of the EGF system in the development and growth of cancer is well established and data showing that inhibition of the system is a new treatment modality for cancer are rapidly accumulating. The treatment is well accepted and improves the condition of the patient. Thus far, the reported side effects have been limited. In view of the widespread occurrence of the EGF system and in view of its potential role for tissue regeneration, this has been a pleasant surprise.

UPCOMING CHALLENGES

Inhibition of the EGF system seems to be a challenging new treatment modality for cancer. To fully explore this possibility, there is a need to know more about the normal physiology of EGF and the related ligands. The mode of synthesis and release needs to be explored and more must be learned about the differences between normal and diseased tissue. Only with such knowledge at hand will it be possible to ensure a rational way to treat the cancer cells without damaging other tissues of the body. At the same time, it is to be expected that a more profound knowledge of the EGF ligands will allow this system to be modulated in order to promote growth and differentiation in situations such as restoration after tissue damage.

required for differentiation of the fetal gonads into testes, which then produce the hormones necessary for sexual differentiation of other structures. The configuration will be female unless the fetal testis secretes Müllerian-inhibiting substance (MIS) to induce regression of the Müllerian duct and testosterone to both maintain the Wolffian duct and masculinize external genitalia.

This process can be illustrated with a pathological example, testicular feminization mutation (i.e., androgen insensitivity syndrome), in which genetic males have an X-linked mutation that renders their androgen receptors (ARs) insensitive to the actions of their endogenous androgenic hormones. Because they have a functional SRY gene, individuals with this mutation will develop testes that secrete testosterone and MIS; however, their tissues cannot be masculinized without functional ARs, so they will appear to be female at birth. Incomplete androgen insensitivity leads to intermediate sexual differentiation, with hypospadias (displacement of urethral opening from the tip of the phallus) and cryptorchidism (undescended testes) being common outcomes.

Effects Seen in the Laboratory: Purposeful Disruption

Disruption of male sexual differentiation similar to that seen in individuals with incomplete androgen insensitivity syndrome can be mimicked in the laboratory by exposing animals to chemicals that antagonize the action of endogenous androgens at the AR (antiandrogens). Perinatal exposure to flutamide (a powerful pharmaceutical AR antagonist) or to pesticides with antiandrogenic activity (e.g., vinclozolin, linuran) causes female-like anogenital distance, hypospadias, cryptorchidism, decreased weights of sex accessory glands, and retained mammary tissue in male rodents and rabbits, even at low doses. Interestingly, some of the same developmental defects can be induced in males by perinatal exposure to estrogenic pharmaceuticals such as diethylstilbestrol (DES) and ethinyl estradiol. The mechanism of estrogen action is unclear but has been speculated to involve abnormal gene imprinting, interference with androgen production, androgen/estrogen ratio imbalance, and/or interference with testis development. Abnormal testis development potentially can lead to abnormal sexual differentiation (because normal differentiation depends on normally functioning testes) but also can have functional effects that are not apparent until puberty or later (e.g., abnormal sperm production,

testicular cancer). Cryptorchidism itself can lead to abnormal sperm production and increased risk of testicular cancer. In controlled laboratory settings, perinatal exposure to antiandrogens or environmental estrogens also produces functional effects, including changes in basal and luteinizing hormone-releasing hormone (LHRH)-induced gonadotropin release and circulating levels of sex steroids, reduced sperm count, and changes in average testis weight.

THE ENDOCRINE DISRUPTION HYPOTHESIS

Consideration of morphological and functional abnormalities detected in wildlife and epidemiological studies in the context of results from the laboratory studies mentioned previously gave rise to the endocrine disruption hypothesis, that is, that previously unexplained reproductive system abnormalities in wildlife and human populations might be caused by exposure to environmental chemicals shown, under controlled conditions, to disrupt endocrine function.

EVIDENCE

Wildlife and Epidemiological Indicators

Regarding EDC effects on male sexual differentiation, most evidence from studies on wildlife comes from nonmammalian species such as demasculinized/feminized Florida alligators exposed to a pesticide spill and agricultural runoff and feminized fish exposed to estrogenic sewage effluent.

Most scientists agree that testicular cancer rates among humans have been rising. An analysis of sperm count data from 1934 to 1996 confirmed earlier studies indicating that sperm densities have been declining in Western countries, although some scientists have pointed out that methodological factors (e.g., geographical variability) might confound the analysis. Congenital abnormalities, such as hypospadias and cryptorchidism, appear to have increased in frequency in some populations, notably in England and Denmark, but also appear to have increased and then leveled off around 1985 in many populations.

For most studies, there are little or no data on EDC exposure or tissue loads; even for those studies that do have this information, the results are only correlative. Performing prospective double-blind controlled studies on the effects of EDCs on humans is not possible, so the best causal evidence comes from industrial accidents and an unfortunate medical

treatment mistake: the use of DES to prevent miscarriage. Males exposed to DES *in utero* have a higher prevalence of cryptorchid testes, epididymal cysts, hypoplastic testes, and abnormal sperm than do unexposed men, and these effects mimic those seen in rodents exposed to DES *in utero*. Studies on the effects of this potent pharmacological estrogen provide insight to possible mechanisms of EDC action, but typical EDC loads in the general public are unlikely to reach this potency and also might include EDCs with other modes of action (e.g., antiandrogenic). However, the general public is at risk for some exposure; one study found that one-third of routine amniocentesis samples (taken during the second trimester) had detectable levels of EDCs. Possible EDC exposure sources for children *in utero* and/or postnatally include occupational exposure, industrial spills, plasticizers in plastic products, agricultural runoff and overspray, diet (e.g., fish from contaminated waters, meat from animals treated with hormones), and some cosmetic products (e.g., hair care). Proponents of the endocrine disrupter hypothesis warn that laboratory studies on EDC effects, combined with epidemiological evidence of increasing rates of male reproductive disorders, provide cause for concern about EDC exposure, particularly *in utero* during the critical periods for organogenesis and sexual differentiation.

Caveats

The difficulty in establishing EDC causation for abnormal health trends, and in some cases in verifying the trends themselves, has led to criticism of the endocrine disrupter hypothesis. Critics recognize that the hypothesis is biologically plausible but call for stronger evidence than is currently available.

for endometriosis. Many women will present with no physical symptoms, yet endometriosis will be discovered during the course of an infertility evaluation. Other women may present with a pelvic mass on routine annual gynecological examination.

Another common clinical manifestation is that of cyclic symptomatology. With classic pelvic endometriosis, pelvic pain, dysmenorrhea, and dyspareunia may worsen with menses. This is presumed to be due to localized bleeding that causes irritation at the sites of the endometriotic implants. Locally, the bowel may be affected, causing dyschezia or diarrhea with menses. In rare cases, endometriotic foci may be located in other parts of the body, such as a surgical scar (causing cyclical incision bleeding), in the lungs (causing cyclic hemoptysis or pneumothorax), or in the brain (causing catamenial seizures). When unusual, seemingly nongynecological symptoms occur only with menses, endometriosis often becomes part of the differential diagnosis.

DIAGNOSIS

The diagnosis of endometriosis requires direct visualization by laparoscopy or laparotomy, preferably with biopsy for histologic confirmation. However, when the clinician suspects endometriosis, the first step is to obtain a history and perform a physical examination. Abdominal examination may reveal diffuse or focal tenderness in the lower quadrants or occasionally rebound tenderness or guarding. Pelvic examination including rectovaginal examination may reveal cervical motion tenderness, adnexal tenderness, or masses or nodularity of the uterosacral ligaments. Although the above findings are suggestive of endometriosis, they are insufficient to make a definitive diagnosis.

Other less invasive modalities have been studied including CA-125 levels and radiologic imaging studies. CA-125 is a tumor marker for certain types of ovarian tumors and has been studied for use in the diagnosis of endometriosis. Although levels are elevated in advanced disease, the rise is nonspecific and is not seen in minimal or mild disease. Therefore, the test is of limited value except in estimating the risk that a pelvic malignancy exists. Pelvic ultrasonography is useful for evaluating pelvic masses that are suspected to be endometriomas. An ovarian cyst with homogenous low-level internal echoes suggests the presence of an endometrioma. Magnetic resonance imaging may occasionally detect endometriosis, but has a very poor sensitivity.

Table I Locations of Endometriosis

| Common sites | Less common sites |
|-----------------------|-------------------|
| Ovary | Brain |
| Pelvic peritoneum | Lung |
| Uterine serosa | Bowel |
| Fallopian tube | Ureter |
| Posterior cul-de-sac | Kidney |
| Uterosacral ligaments | Appendix |
| Rectovaginal septum | Vulva |
| Anterior cul-de-sac | Incision |

The diagnosis of endometriosis is made by visualization, most often at the time of laparoscopy. Most authors advocate biopsy to confirm the diagnosis, but this is not always carried out. A thorough examination of the pelvis is performed, paying particular attention to sites such as the ovaries, ovarian fossae, uterosacral ligaments, and pouch of Douglas, which are the most common sites for endometriotic lesions. These lesions may have a myriad of appearances including powder burn lesions, fleshy lesions, adhesions, and peritoneal pockets. Some of the sites where endometriosis may be found are shown in [Table I](#).

At this time in the diagnosis, the extent of the disease may be staged. The most commonly used staging system is the American Society for Reproductive Medicine (ASRM) revised classification system. The system involves a point system based on the size, depth, and location of both implants and adhesions. Points are tallied on a form and a stage is assigned based on the number of points. These include stage I (minimal, 1–5 points), stage II (mild, 6–15 points), stage III (moderate, 16–40 points), and stage IV (severe, 40+ points). Although the staging system may be useful for assessment of fertility potential, the ASRM stage does not correlate well with the degree of pelvic pain.

TREATMENT

The treatment of endometriosis depends on the individual patient's presenting symptoms. A woman who is asymptomatic but is diagnosed with endometriosis at the time of an unrelated surgical procedure (e.g., a laparoscopic tubal sterilization) does not necessarily require treatment. In the absence of pain or infertility, the disease may be managed expectantly. When a patient presents with endometriosis-related pain, she may be treated using a myriad of various medical or surgical therapies. On the other hand, a patient who presents with endometriosis and infertility may be

treated using surgical means or other types of infertility treatments that are not directly related to endometriosis.

Medical treatment for endometriosis-related pain involves the use of hormonal therapies to suppress ovulation, as listed in [Table II](#). The rationale for this type of treatment is that the implants of endometriosis are similar to normal eutopic endometrium and will respond to estrogen and progesterone in the same way. Thus, the same hormonal therapies that can induce amenorrhea in women with dysfunctional bleeding would be expected to decrease pain in women with pelvic endometriosis.

Most commonly, a “pseudo-pregnancy-type” regimen is used with oral contraceptives for initial treatment. Due to the benign nature of this therapy, treatment is often initiated prior to obtaining a definitive diagnosis. A standard monophasic 30 or 35 µg birth control pill is taken continuously, with no days off and no placebo pills. This will mimic the hormonal milieu found during pregnancy in which high levels of estrogen and progesterone are observed. In general, pregnant women with endometriosis experience a significant abatement of symptoms during pregnancy. Alternatively, progestational agents may be used. Depot formulations of progestational agents, such as medroxyprogesterone acetate (Depo-Provera), or daily oral progestins, such as medroxyprogesterone acetate (Provera, Cycrin) and norethindrone (Aygestin), may be used.

An even more effective way to treat endometriosis pain involves what is called a “pseudo-menopause” regimen. Various medications can be used to suppress the hypothalamic–pituitary axis, resulting in a hypogonadotropic, hypoestrogenic state. One of the first pseudo-menopausal agents to be widely used was Danazol (Danocrine). Danazol is an orally active androgenic steroid believed to both suppress ovulation

and act directly to cause atrophy of the endometriotic implants. Given in doses of 200 to 400 mg twice daily, it is accompanied by side effects that may include hot flashes, vaginal dryness, muscle aches, deepening of the voice, and hirsutism. Gonadotropin-releasing hormone (GnRH) agonists, such as leuprolide (Lupron), goserilin (Zoladex), nafarelin (Synarel), and buserelin, have become the agents of choice to induce a pseudo-menopause. These medications are all administered parenterally. Some are designed to be used monthly or even at 3-month intervals for prolonged suppression of endogenous gonadotropins. This suppression will create a hypoestrogenic milieu and will cause the involution of the endometriotic implants, which are estrogen-dependent. The side effects of the GnRH agonists include headaches, hot flashes, vaginal dryness, and bone loss. In order to prevent the sequelae of osteoporosis later in life, Danazol and GnRH analogues are limited to 6 to 9 months of use.

The GnRH agonists may also be used on a longer term basis when accompanied by low doses of estrogen plus progestin replacement. This type of regimen is referred to as add-back therapy and its rationale is based on the estrogen threshold hypothesis. This hypothesis states that endometriosis and bone loss respond to different circulating estrogen levels. The goal thus is to attain an estrogen level that is high enough to conserve bone density yet low enough to prevent regrowth of the endometriosis lesions. The patient is started on a long-acting GnRH agonist, and concurrently or at a later date, low-dose estrogen/progestin replacement therapy is added in a dose that is similar to that given to menopausal women. Alternatively, a norethindrone-only regimen may be used. Add-back therapy has been demonstrated to be safe and effective when used for up to 1 year. Although there exists no general consensus on how long a patient may be kept on such a regimen, many clinicians will continue such therapy for a number of years, with intermittent monitoring of bone density by DEXA scan to ensure that there is no significant bone loss.

Treatment with anti-progestins and aromatase inhibitors is considered experimental and will not be reviewed in this article.

Surgical therapy may also be employed for the treatment of endometriosis. Frequently, surgical treatment is performed at the time of the initial laparoscopy when the diagnosis of endometriosis is made. After the diagnosis is established, the lesions discovered may be fulgurated or resected. Various modalities have been used to ablate the implants including various lasers (CO₂, KTP, Nd-YAG), bipolar or monopolar cautery, endocoagulation, the harmonic

scalpel, and sharp resection. Although many physicians have advocated the use of laser for ablation, there are no data that show better outcomes associated with a specific energy source. At the time of surgery, any pelvic adhesions noted may be lysed in order to reduce the pain. Additionally, the uterosacral ligament, which carries sensory nerve fibers from the uterus, may be ablated at this time to assist in pain relief. If an endometrioma or chocolate cyst is encountered, when possible the cyst is opened, the chocolate fluid is aspirated, and the cyst wall is excised.

Other surgical procedures are available for the treatment of endometriosis. The procedures described above for laparoscopy may also be performed at the time of laparotomy. A presacral neurectomy may be performed to interrupt the sympathetic nerves at the level of the superior hypogastric plexus. In some instances, one or both ovaries may be removed and sometimes a hysterectomy may be required. Many patients with intractable endometriosis pain and multiple prior surgeries benefit from a "pelvic clean-out," which involves total abdominal hysterectomy with bilateral salpingoophorectomy. It should be noted that even this most definitive of therapies is only approximately 90% effective in the resolution of pain.

ENDOMETRIOSIS AND INFERTILITY

The incidence of endometriosis in infertility patients undergoing diagnostic laparoscopy is relatively high (38%), yet the association between endometriosis and infertility remains unclear. Advanced cases of endometriosis (stage III and IV disease) are associated with decreased fertility, presumably on the basis of pelvic adhesions and mechanical factors. Less advanced cases (stages I and II) are considered by some authors to be causal of infertility and others as merely coincidental. The suggested mechanisms include interference of peritoneal fluid with sperm function and fertilization and luteal phase dysfunction.

A meta-analysis by Hughes on the treatment of infertility in early stage endometriosis found no benefit of medical treatment on pregnancy rates, but a possible benefit of surgical treatment. Medical treatment appears not to be beneficial and in fact may be detrimental by causing a delay in pregnancy due to suppression of ovulation. The use of laparoscopic surgery to treat early stage endometriosis was evaluated in two randomized controlled trials. A large Canadian multicenter study showed an increase in monthly fecundity in patients in whom endometriosis was ablated compared with those in whom it was left

in situ. A much smaller Italian trial failed to show any benefit. Thus, it appears likely though not certain that early stage endometriosis may benefit from surgical treatment.

Infertility in endometriosis patients can be treated by the same modalities used to treat those with unexplained infertility. Superovulation with gonadotropins accompanied by intrauterine insemination resulted in a significant increase in pregnancy rates in women with unexplained infertility in a large multicenter study. *In vitro* fertilization is also very effective in women with early and advanced stages of endometriosis.

SUMMARY

Endometriosis is an enigmatic disease that is defined by the presence of endometrial tissue in an ectopic location. The etiology remains unknown, though there are certain changes in the immune system as well as an association with abnormal outflow tracts. The symptoms of endometriosis include various manifestations of pelvic pain and infertility and are often temporally related to menses. Diagnosis is made by surgical visualization and treatment may involve hormonal manipulation and/or surgical ablation or resection.

ANATOMY AND PHYSIOLOGY OF PENILE ERECTION

Because of its anatomy, the penis can rapidly engorge with blood, increase dramatically in size, and develop rigidity. Within the penis are two paired corpora cavernosa and a corpus spongiosum. The corpus spongiosum, which surrounds the urethra, terminates in the glans penis. A thick fibrous sheath, the tunica albuginea, encases the sponge-like cavernosal tissue, which consists of interconnecting lacunar spaces lined by vascular endothelium. Trabeculae form the walls of the lacunae and are composed of thick bundles of smooth muscle fibroblasts, collagen, and elastin. This arrangement enables very high intracavernosal pressure generation and penile rigidity when venous outflow is reduced and the lacunae are engorged.

When flaccid, the penile smooth muscle cell, arteries, and corpora cavernosa are in a state of tone (contraction). Relaxation of the smooth muscle (arterial and cavernosal) increases blood flow into the corpora cavernosa. The arterial pressure expands the relaxed trabecular walls, and the venules are compressed against tunica albuginea. This mechanism of veno-occlusion restricts the outflow of blood through these channels. After ejaculation or cessation of the erotic stimuli, the smooth muscle in the arteries and lacunar spaces contracts. Inflow of blood is reduced, venous outflow from the corporeal spaces resumes, and the penis returns to a flaccid state.

Neuromuscular Influence

Increased arterial flow causing the penile erection is controlled by the autonomic nervous system. Peripheral innervation consists of sympathetic nerves arising from the T11 to L2 and parasympathetic and somatic nerves arising from the S2 to S4. They reach the pelvic plexus through hypogastric and pudendal nerves. The glans penis is rich in nerve endings that convey touch, pain, temperature, and vibration. Although neural centers in the lumbosacral spinal cord can cause erection in response to penile stimulation, erections usually are stimulated by olfactory, auditory, visual, and other sensory inputs. These inputs are perceived centrally by the frontal, temporal, parietal, or occipital lobe. Furthermore, they may be stimulated by memory or fantasy. Signals are sent to the visceral brain, to the rhinencephalon, and subsequently to the spinal cord centers.

Several neurotransmitters are involved in penile erection. Histochemical studies indicate that the corpora cavernosa are rich in adrenergic fibers,

acetylcholinesterase-containing (probably cholinergic) nerves, and nerves that are immunoreactive to vasoactive intestinal polypeptide (VIP) and neuropeptide Y. Nitric oxide is the primary endothelium-derived relaxing factor. It causes the smooth muscle in the corpora cavernosa to relax. It is produced from L-arginine by nitric oxide synthase. Nitric oxide activates guanine cyclase, forming intracellular cyclic guanosine monophosphate (cGMP). cGMP decreases intracellular calcium, resulting in smooth muscle relaxation. cGMP is degraded by phosphodiesterase-5, and inhibition of this enzyme potentiates the erectile process.

Endocrine Influence

In humans, testosterone and dihydrotestosterone (DHT) play critical roles during embryogenesis of the testes, epididymis, vas deferens, seminal vesicles, prostate, and external genitalia. Sex steroids are implicated in imprinting gender identification on the central nervous system. Development of accessory glands, testes, external genitalia, and secondary sex characteristics at puberty depends on normal circulating androgen levels and on target androgen tissue responsiveness. In addition, androgen mediates the development and maintenance of libido and erectile function.

Early studies in mixed populations indicate several age-related changes. Serum total testosterone levels fall, sex hormone-binding globulin (SHBG) levels increase, free testosterone levels fall, and estradiol levels tend to remain constant after the fifth decade of life. Health status and age can affect total and free testosterone levels. Androgen deficiency most commonly occurs in men over 60 years of age.

ETIOLOGY OF ERECTILE DYSFUNCTION

Vascular

ED frequently is due to vascular dysfunction. Altered blood flow to and from the penis is thought to be the most frequent organic cause of impotence. Hypogastric-cavernous arterial bed occlusion can occur, but more commonly, penile endothelial dysfunction at the level of the penis decreases blood flow to the lacunar spaces and prevents complete relaxation of the trabecular smooth muscle. This also contributes to a "venous leak," decreasing penile rigidity and increasing the latency to achieve maximal erection. The most common associations with arteriogenic

impotence include diabetes mellitus, hypertension, hyperlipidemia, cigarette smoking, perineal or pelvic trauma, and pelvic irradiation.

Diabetes Mellitus

The prevalence of ED in men with diabetes mellitus is in the range of 50% at 50 years of age, and it increases with age. An individual with diabetes who smokes cigarettes is 1.4 times more likely to have ED than is a nonsmoker. In men with diabetes, ED progresses gradually, and other symptoms and signs of autonomic neuropathy are frequently present. ED is more common in men with severe vascular or neurological complications. Thus, ED in men with diabetes may be caused by vascular disease, neuropathy, or both.

Hypertension

Men with hypertension frequently report difficulty in initiating or maintaining erections that are adequate for sexual intercourse. Clinicians widely believe this to be a side effect of antihypertensive medication. The reported incidence of erectile failure is 14% with propranolol, 9% with hydrochlorothiazide, and 1% to 41% with clonidine. However, untreated hypertension is independently associated with increased ED.

Neurogenic Impotence

Disorders affecting the spinal cord or the peripheral efferent autonomic fibers to the penis cause partial or complete ED. This may be due to afferent limb interruption of reflexogenic erections as well as to interruption of tactile perception, with projections to supraspinal centers that may be important in maintaining psychogenic erections. Although the reflexogenic erectile mechanism is preserved in men with supraspinal lesions, the erections usually are poorly maintained without constant tactile stimulation.

Common neurological disorders associated with ED include spinal cord injury, multiple sclerosis, and peripheral neuropathy due to diabetes mellitus or alcoholism. In addition, surgical procedures (e.g., radical prostatectomy, cystoprostatectomy, proctocolectomy) may disrupt the autonomic nerve supply to the corporal bodies.

In patients with spinal cord injury, preservation of erectile function is largely dependent on the completeness and level of the spinal lesion. Although 75% of patients with spinal cord injury have some capacity to have penile erections, the erections are adequate for penetration in only 25%.

Endocrine Impotence

Androgen Deficiency

Androgen deficiency is a widely recognized cause of sexual dysfunction. Diminished libido, reduced ejaculate volume, and ED commonly accompany androgen deficiency that develops after puberty. ED symptoms usually become manifest when testosterone levels are less than 300 ng/dl. The estimated prevalence of androgen deficiency in unselected men with ED ranges from 2 to 23% but is higher in older men. Many patients with ED and testosterone deficiency have secondary or tertiary hypogonadism. Pituitary and hypothalamic imaging is recommended when the morning testosterone level is less than 150 to 200 ng/dl. On average, older patients are less likely to experience an improvement in erections due to comorbid diseases that cause ED.

Hyperprolactinemia

ED is common in men with pituitary tumors. Fully 76% of patients with a tumor in the region of the sella turcica reported decreased or absent libido or potency. These patients often have subnormal serum testosterone levels. Prolactin levels are more than 50 ng/ml in most patients with prolactinomas. Normalizing minimal hyperprolactinemia does not ameliorate ED. Therefore, prolactin levels less than 50 ng/ml should alert the physician to evaluate medications and thyroid, liver, and renal function. Studies performing routine measurement of serum prolactin found a low yield of prolactinomas (<1% of patients). Measuring the morning prolactin level when the testosterone level is less than 300 ng/dl and luteinizing hormone (LH) is normal or low, when sexual desire is low, or when gynecomastia is present is recommended.

DIAGNOSTIC WORKUP OF ERECTILE DYSFUNCTION

The evaluation of patients with ED begins with a thorough history and physical examination. Initial questions should focus on the onset, progression, and duration of the symptoms. The presence of nocturnal erections and the ability to attain erections with a different partner may help to differentiate psychogenic causes from organic causes. It also is important to assess libido, which may indicate androgen deficiency, depression, or excessive stress. The medical history is essential to assess comorbidities commonly associated with ED (especially diabetes, hypertension, peripheral vascular disease, neurological disorders, and coronary artery disease).

Because the use of certain drugs is associated with ED, a detailed and complete drug history should be taken. Recent changes in social status, alcohol consumption, and cigarette smoking should be noted.

The physical examination is essential. It should focus on the cardiovascular, endocrine, neurological, and genitourinary systems. Blood pressure, palpation of peripheral pulses, and auscultation for abdominal and femoral bruits should be assessed. Special attention to signs of androgen deficiency (e.g., decreased body and facial hair, gynecomastia, testicular atrophy or decreased testicular consistency, regression in prostate size) must be undertaken. The penis should be examined for fibrous plaques (Peyronie's disease), and the rectal exam should assess the sphincter tone and the prostate.

Appropriate laboratory testing should complement the history and physical examination. Patients should be screened for diabetes as well as for liver and renal disease. Routine measurements of serum testosterone are recommended, and thyroid-stimulating hormone (TSH) should be obtained if there are signs suggesting thyroid or pituitary disease.

In refractory patients, nocturnal penile tumescence testing (NPT) and duplex ultrasonography in conjunction with intracavernosal administration of vasoactive agents may be indicated. Patients with ED and normal NPT usually have psychogenic impotence; whereas abnormal NPT in conjunction with normal sleep usually indicates organic cause (vascular or neurological). These tests should be performed in centers where there are facilities and expertise to perform and interpret them.

TREATMENT

There are many treatment considerations and options for men with ED. The goal of treatment is to restore libido and the capacity to acquire and sustain an erection. Treatment should address the cause of ED. Patients should be asked to avoid cigarette smoking, excessive alcohol consumption, and drug abuse. Changes in medication should be tried. Medication may contribute to ED in up to 25% of patients with ED. The major drugs that induce ED are thiazide, beta-blockers, and some antidepressants.

Psychosexual Therapy

When depression and excessive anxiety are associated with ED, psychosexual counseling is indicated. When it is selected appropriately, the success rate for psychosexual therapy can reach 70%. Furthermore, some

patients with organic ED can benefit from sex therapy because it reduces anxiety and sexual inhibition. Yohimbine, an alpha-2-adrenergic receptor-blocker, may be effective in some men with psychogenic ED. In a double-blind, placebo-controlled study that evaluated men with psychogenic ED, it was found that 37% of men treated with yohimbine responded to treatment. However, other studies have not found yohimbine to be beneficial.

Hormonal Therapy

Testosterone replacement therapy is the treatment of choice for men with hypogonadism. Because of the potential complications of testosterone replacement therapy in men over 50 years of age, we suggest that the hematocrit, serum prostate-specific androgen (PSA), and digital rectal examination of the prostate be done at baseline, 3 and 6 months, and then annually. Testosterone should not be provided to eugonadal men with ED or to men with a history of prostate or breast cancer.

Hyperprolactinemia may decrease libido by suppressing gonadotropin-releasing hormone (GnRH), resulting in reduced LH and testosterone levels. Treatment of hyperprolactinemia with a dopamine agonist or surgical removal of the tumor may restore testosterone levels and potency.

Medical Treatment

After excluding conditions treatable with specific therapies, the clinician should consider treatment with a type 5-phosphodiesterase inhibitor. These drugs provide effective oral therapy for a wide range of disorders causing ED. Sildenafil, the first available type 5 inhibitor, acts by inhibiting cGMP phosphodiesterase type 5, resulting in increased intracellular cGMP. cGMP increases nitric oxide-induced smooth muscle relaxation of arteries to the penis and of vascular tissue in the corpora cavernosum. Sildenafil was evaluated in 532 men with ED of organic, psychogenic, and mixed causes, and 69% of all attempts of sexual intercourse were successful for the men receiving sildenafil compared with 22% for those men receiving placebo. For maximum effectiveness, sildenafil should be taken 1 h before planned intercourse and preferably at least 2 h after a meal. It should be started at a 50-mg dose. If tolerated but not fully efficacious, the dose can be increased to 100 mg. Sildenafil is absolutely contraindicated in patients taking nitrates. Some level of exercise tolerance should be documented; otherwise

a treadmill test should be considered for patients at risk for cardiac disease.

Penile self-injections were more popular before the introduction of sildenafil. This treatment involves injecting vasoactive drugs (e.g., alprostadil, papaverine, phentolamine) that induce relaxation of the smooth muscles. Penile self-injections are especially effective in men with neurogenic impairments such as spinal cord injury and diabetes mellitus. The major side effects are penile pain and priapism.

Alprostadil also is available for intraurethral application (Medicated Urethral System for Erection [MUSE]). In a placebo-controlled study, 65% of patients treated with MUSE successfully completed intercourse compared with 19% of men treated with placebo. However, this efficacy rate has not been replicated in unselected populations of men with ED.

Medical Devices

Vacuum devices increase the volume of blood in the penis by creating a vacuum around the penis. After the penis is engorged, a constriction ring is placed at the base of the penis to prevent venous outflow. The induced erection usually is sufficient for vaginal penetration and sexual intercourse. Adverse events include pain, bruising, and retrograde ejaculation. Vacuum constriction devices represent an alternative for patients who cannot tolerate type 5 phosphodiesterase inhibitors or who do not wish to use intracavernosal injection.

Surgery

Surgical therapy is offered to patients who are refractory to other less invasive treatments. Vascular reconstruction is sometimes indicated in young patients with a history of pelvic trauma. Skepticism exists regarding other vascular reconstruction surgeries. Penile prostheses are a viable option for patients who cannot be treated medically. There are two kinds of penile prostheses: the semi-rigid prosthesis and the inflatable prosthesis. The inflatable prosthesis is better accepted but is more expensive. It also is associated with more frequent mechanical failure than are the semi-rigid devices.

ER β is more numerous than ER α in the testis. Within the prostate, ER α is located primarily in the stroma, whereas ER β is present in the epithelial cells. ER α is expressed in both osteoblasts and osteoclasts, and ER β is expressed mostly in osteoblasts.

Pituitary secretion of luteinizing hormone (LH) controls the secretion of E₂ and testosterone from the testis. E₂ and testosterone, in turn, provide negative feedback at the level of the hypothalamus and anterior pituitary to regulate gonadotropin secretion. Testicular E₂ secretion is also stimulated whenever plasma LH/human chorionic gonadotropin (hCG) levels are elevated. Elevated levels of estrogen, either endogenous or exogenous, can reduce testicular testosterone secretion by suppression of LH release. Furthermore, excess estrogen stimulates SHBG synthesis in the liver, resulting in increased bound testosterone with a reduction in plasma-free testosterone.

ROLES OF ESTROGEN IN MALE PHYSIOLOGY

Lessons from Males with Estrogen Deficiency States

Descriptions of a man with estrogen resistance and three men with aromatase deficiency provide insights into our understanding of estrogen action in the male. In 1994, Smith and colleagues described a 28-year-old

man with estrogen resistance due to an autosomal recessive missense mutation in exon 2 of ER α , resulting in a complete loss of protein function. He had eunuchoid skeletal proportions with a height of 204 cm, delayed bone age (15 years), open epiphyses, persistent linear growth, and accelerated bone turnover with marked osteopenia. Biochemical testing revealed normal serum concentration of testosterone and elevated circulating levels of follicle-stimulating hormone (FSH), LH, E₂, and E₁.

Subsequently, from 1995 to 2002, three unrelated men with severe aromatase deficiency secondary to distinct autosomal dominant missense mutations of the CYP19 gene were reported. Like the man with estrogen resistance, the aromatase-deficient men (24–31 years of age) all had a tall stature (height of 187–204 cm) with continued linear growth, delayed skeletal maturation (bone age of 14.0–16.5 years), open epiphyses, and evidence of severe osteopenia. Biochemical studies revealed normal to elevated levels of testosterone, LH, and FSH and showed very low levels of circulating E₂ and E₁. The details of the phenotype and biochemical data of the estrogen-resistant and aromatase-deficient men are summarized in [Table I](#).

When the ER α -negative man was treated with high doses of estrogen, there were no clinical, hormonal, or metabolic changes. In contrast, the aromatase-deficient men responded dramatically to relatively low doses of estrogen, resulting in correction of the

Table I Summary of the Phenotype and Biochemical Data of a Man with ER α Defect and Three Men with Aromatase Deficiency

described hormonal abnormalities without side effects such as gynecomastia.

Observations in estrogen-resistant and aromatase-deficient men have redefined our view of estrogen action and the male skeleton. Other findings from these human models, including the role of estrogen in lipid/carbohydrate metabolism and spermatogenesis, are discussed in subsequent sections of this article.

Estrogen and the Male Skeleton

Despite normal or elevated levels of testosterone, men with impaired estrogen synthesis or action all had delayed epiphyseal closure, severe osteopenia, and evidence of increased bone turnover. Although these men had normal pubertal onset and normal male secondary sexual characteristics, they did not experience the classic growth spurt associated with puberty. Estrogen stimulates pubertal growth spurt in both sexes by enhancing growth hormone secretion during puberty. Contrary to prior belief, epiphyseal fusion in males is not mediated by testosterone; rather, it is mediated by estrogen. With estrogen treatment, despite declining levels of testosterone, all of the men had complete epiphyseal fusion within 6 to 9 months and had a progressive increase in bone mass. In one man, after 3 years of continuous estrogen therapy, bone mass increased by 20.7% in the lumbar spine, 15.7% in the femoral neck, and 12.9% in the distal radius. Thus, androgen alone is clearly not sufficient to promote normal skeletal growth and maturation. Both androgen and estrogen are required for accrual of optimal peak bone mass in men. Estrogen appears to increase bone mass by exerting anabolic as well as antiresorptive effects.

Evidence from mouse knockout models (α -ERKO, β -ERKO, and ArKO mice) has also contributed to our understanding of estrogen and the male skeleton during recent years. Deletion of the ER α or aromatase gene in the male mouse results in osteopenia with increased markers of bone remodeling. In contrast, the skeleton of the ER β knockout male mouse is phenotypically identical to that of the wild type. It appears that estrogen mediates its effects on the bone primarily through ER α , although both ER α and ER β are expressed in the bone.

Estrogen is clearly critical for bone mass acquisition in the growing skeleton. However, the inherited states of impaired estrogen synthesis or action do not clearly reflect the role of estrogen in maintaining bone density in the mature adult skeleton. Additional data from nearly all of the cross-sectional observational

studies looking at the relationships between sex steroid levels and bone mineral density (BMD) show that E₂, especially the non-SHBG-bound E₂, has a better correlation with BMD than do either total or free testosterone levels.

In a prospective study, it was found that the BMD in young men (20–40 years of age), when compared with that in elderly men (60–90 years of age), was most closely correlated with E₂ levels. In particular, the decreased bioavailable E₂ levels in elderly men appear to be a good predictor of age-related bone loss. This relationship was further investigated by giving elderly men physiological hormone replacement after pretreatment with a gonadotropin-releasing hormone (GnRH) agonist and an aromatase inhibitor. Estrogen alone was far more effective than testosterone alone in preventing an increase in bone resorption markers. Estrogen and testosterone combined have positive synergistic effects on bone remodeling. Based on the data, it was estimated that estrogen is responsible for about 70% of the total effect of sex steroids on bone resorption, whereas testosterone (in the absence of conversion to estradiol) accounts for no more than 30% of the effect. Another study reported that when elderly men were treated with an aromatase inhibitor for 9 weeks, they had a significant increase in bone resorption markers and a decrease in bone formation markers when compared with baseline. Therefore, a subset of elderly men with low bioavailable E₂ are the most susceptible to age-related bone loss similar to the increased risk of bone loss seen in postmenopausal women. More studies are needed in this area.

Effects of Estrogen on Lipids and Carbohydrates

Despite differences of total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels in estrogen-resistant and aromatase-deficient men, serum concentrations of high-density lipoprotein (HDL) cholesterol are uniformly low (Table I). The low HDL cholesterol is likely the result of unopposed action of androgen as well as the decreased estrogen. When estrogen therapy was initiated, levels of HDL cholesterol and other lipids improved due to an increase in estrogen with a concomitant decrease in androgen.

There appears to be an association between estrogen deficiency and the propensity of developing insulin resistance (Table I). The estrogen-resistant man had axillary acanthosis nigricans, a cutaneous marker of insulin resistance, in addition to elevated

glycosylated hemoglobin (HbA1C 9.5%). Two of the men with aromatase deficiency also had inappropriately elevated serum insulin levels. When estrogen was given, serum insulin levels were lowered in all except the estrogen-resistant man.

Estrogen and the Prostate

Benign prostatic hypertrophy (BPH) is usually found in men over 50 years of age. Estrogen concentration in the stroma increases with age with contributions from peripheral sources and from aromatization of androgen within the stroma. Estrogen can induce squamous epithelial metaplasia and can stimulate growth of the fibromuscular stroma, resulting in BPH. Estrogen also induces synthesis of insulin-like growth factor-1 (IGF-1), which acts to prime the response of epithelium to androgen. Therefore, estrogen can increase epithelial proliferation indirectly by enhancing androgen action.

By increasing the levels of circulating SHBG, estrogen can exert an inhibitory effect on the prostate by reducing the amount of free testosterone available for the androgenic stimulation of prostate. The decrease in the plasma concentration of testosterone is further mediated by the negative feedback action of estrogen on LH secretion. Therefore, in contrast to its growth-promoting effect in BPH, estrogen in pharmacological amounts can reduce the size and function of the epithelial cells of the prostate and has been a form of therapy in prostate cancer. Alternatively, estrogen may exert antiandrogen effects within the tumor cells, or it may be directly inhibitory to the tumor cells.

Epidemiological studies demonstrate geographical differences in incidence rates of prostate cancer, with a 30-fold greater incidence in the United States than in Japan and a 120-fold greater incidence in the United States than in Shanghai, China. The geographical differences are thought to be due to dietary factors such as soy (phytoestrogens), which may be protective against the development of prostate cancer, in addition to genetic factors.

ESTROGEN-EXCESS STATE IN THE MALE

The major clinical signs of estrogen excess in males are gynecomastia, testicular atrophy, erectile dysfunction, and infertility. Estrogen-secreting tumors and other endogenous or exogenous sources of estrogen can induce inhibition of testicular function by inhibiting gonadotropin secretion (Table II).

Gynecomastia

The crucial factor in the development of gynecomastia from any cause is not the absolute level of estrogen but rather the ratio of estrogen to testosterone; the higher the ratio, the greater the likelihood of developing gynecomastia. Table II summarizes the various causes of gynecomastia.

Physiological gynecomastia occurs during the newborn period, during adolescence, and with advanced age. Breast enlargement occurs in approximately 60 to 90% of newborns due to stimulation by maternal placental estrogen, and it usually resolves within a few weeks. Pubertal gynecomastia usually has an onset of between 10 and 12 years of age and peaks at approximately 13 to 14 years of age. It affects 30 to 40% of adolescent boys, and in the majority of cases it resolves by 17 years of age. The high plasma ratio of E₂ to testosterone in boys with pubertal gynecomastia is likely the result of normal aromatase activity in the testis and the extraglandular tissues before maximum production of testosterone is achieved. The prevalence of gynecomastia in older men ranges from 40 to 70%. With advanced age, the increased ratio of estrogen to testosterone favors feminization. However, in elderly men, it is a diagnosis of exclusion given that many elderly patients take medication or have medical problems that may contribute to breast enlargement.

Pathological gynecomastia can be due to a variety of causes, resulting in an alteration of the estrogen/testosterone ratio (Table II). Gynecomastia can be seen in men with androgen deficiency or resistance. When testosterone production or action is compromised, elevated plasma gonadotropin levels further alter the plasma estrogen/testosterone ratio by stimulating the testis to produce more estrogen. Likewise, men with testicular tumors or bronchogenic carcinoma have increased testicular estrogen production largely from the stimulating affect of hCG produced by the tumor. Liver disease, starvation, thyrotoxicosis, and adrenocortical tumors are conditions where increased amounts of aromatizable androgen (i.e., androstenedione) are produced and gynecomastia can occur due to increased availability of this substrate for extraglandular aromatization.

There are several reports of familial gynecomastia due to excessive extraglandular aromatase activity. The initial description was a boy, age 10 years 7 months, who had accelerated linear growth (height of 157 cm), advanced bone maturation (bone age of 15 years), and severe gynecomastia (Tanner stage IV). The clinical signs of hyperestrogenism occurred at

Table II Causes of Gynecomastia

| |
|---|

| Testicular tumors |
| hCG-secreting tumors (bronchogenic carcinoma) |
| Adrenocortical adenoma or carcinoma |
| Severe liver disease |
| Hyperthyroidism |
| Recovery from malnourishment |
| Excess aromatase activity (hereditary) |
| <i>Drug induced</i> |
| Estrogens or estrogen agonists (digitalis, phytoestrogens, estrogen creams, diethylstilbestrol) |
| Clomiphene, gonadotropins |
| Aromatizable androgens |
| Antiandrogens or inhibitors of androgen synthesis (spironolactone, ketoconazole, flutamide, metronidazole, cimetidine, etomidate, cyproterone) |
| Drugs that cause elevated prolactin (phenothiazines, haloperidol, methyl dopa, reserpine, metoclopramide, tricyclic antidepressants) |
| Others (ranitidine, omeprazole, alkylating agents, cisplatin, busulfan, isoniazid, penicillamine, captopril, enalapril, amiodarone, nifedipine, verapamil, diazepam, phenytoin, amphetamines, heroin, marijuana, alcohol) |
| Idiopathic gynecomastia |

8 years of age, around the time of adrenarche when androstenedione levels began to rise. The conversion of androgens to estrogens in this boy was about 50 times greater than that observed in normal prepubertal boys. Another kindred of five males spanning two generations had a similar condition, resulting in marked prepubertal gynecomastia and accelerated bone maturation (bone age of 14.5 years in a 10-year-old). An autosomal dominant pattern of inheritance was established in another kindred of four affected members. A 9-year-old boy from this kindred had prepubertal gynecomastia, and his 712-year-old sister had precocious puberty. His father and his paternal grandmother had prepubertal gynecomastia and macromastia, respectively. The genetic defect of the aromatase excess syndrome has not been elucidated.

Drugs that alter the ratio of estrogen to androgen at the level of the breast can cause gynecomastia

(Table II). Exposure to estrogen in men, either in the form of a pill or transdermally via ointments or cream, can result in gynecomastia. There also have been reports of gynecomastia in children who ingested dairy or meat products from estrogen-injected cows. Digitalis administration may result in gynecomastia, presumably by the binding of digitalis to the ER. As mentioned previously, gonadotropin-like substance such as hCG may cause gynecomastia by increasing testicular estrogen synthesis. In addition, drugs that impair testosterone synthesis or action can also cause gynecomastia. Approximately 50% of the men who receive high-dose spironolactone (150 mg/day) develop gynecomastia due to inhibition of both testosterone synthesis and testosterone action. Spironolactone at low doses (50 mg/day) may cause gynecomastia, although less commonly, by blocking androgen binding to the receptor, with less effect on testosterone synthesis.

Estrogen and the Male Reproductive System

FSH and androgens are known to be important in the regulation of spermatogenesis. However, emerging evidence suggests that estrogen also plays an important role in spermatogenesis and male fertility. Estrogen appears to play a role in the development and maintenance of the efferent ductules and epididymides. On the cellular level, estrogen may play a role in controlling the proliferation, development, and function of the Leydig, Sertoli, and germ cells.

Men with estrogen deficiency due to a defect in estrogen action or synthesis have abnormal spermatogenesis (Table I). Conversely, men with either exogenous or endogenous estrogen excess can experience azospermia. The ratio of testosterone to E₂ is perhaps more important in spermatogenesis and fertility than is the absolute level of estrogen.

Increased environmental exposure to estrogen in males during fetal development may also have detrimental effects on development and function of the male reproductive system. Pregnant women who took diethylstilbestrol (DES) during pregnancy from 1945 to 1971 had male offspring with a significantly higher incidence of disorders of the reproductive tract, decreased sperm counts, and decreased sperm activity.

Male Breast Cancer

Breast cancer is responsible for less than 1% of all cancer deaths in men. The ratio of female breast cancer to male breast cancer is 100:1 in Caucasians and 70:1 in African Americans. A higher incidence is reported in Jewish men and in men living in a stretch of Bantu-speaking countries in central Africa. Other risk factors include a family history of breast cancer, history of exogenous estrogen exposure, increased circulating endogenous estrogen from chronic liver disease, testicular pathology, and prior chest wall irradiation. The greatest risk factor for developing male breast cancer is Klinefelter's syndrome. The risk in affected men is about 50-fold higher than in men with a normal genotype. The risk of male breast cancer appears to be associated with conditions with relative estrogen excess and/or lack of androgen, resulting in an altered ratio of estrogen to testosterone.

CONCLUSION

During recent years, some of the critical roles played by estrogen in the male have been recognized. We have just begun to understand estrogen action in men. More investigations are needed to clarify the mechanisms by which estrogen mediates its effects in male physiology.

recurrence when the medication is stopped. Vaginal dryness occurs at menopause and is improved by ERT.

Many women experience symptoms that develop long after menopause starts, such as vaginal atrophy, dyspareunia, and urinary tract symptoms, including stress incontinence, urinary tract infections, and increased urinary frequency. ERT, along with Kegel exercises to strengthen the vaginal muscles, improves these symptoms.

Osteoporosis Prevention and Treatment

Estrogen depletion, which occurs at menopause, increases bone resorption. There is a loss of bone mineral density of approximately 3% per year in the first 5 years of menopause. In later years, the rate of bone loss decreases. ERT prevented this bone loss and actually improved bone density in several randomized controlled double-blind studies. However, as soon as ERT is stopped, bone loss resumes at the initial high rate. ERT may be started at any age after menopause to prevent bone loss.

Osteoporotic fractures are reduced in patients on ERT compared to nonusers. The addition of progesterone does not alter these beneficial effects. It is estimated that HRT causes 172 fewer fractures per 100,000 users per year.

Selective estrogen receptor modulators (SERMs), raloxifene and tamoxifen, also have beneficial effects on bone. Raloxifene causes a greater increase in bone mineral density than tamoxifen and has been shown to decrease fracture risk.

POTENTIAL BENEFITS

Cardiovascular

The relative risk of heart disease increases at menopause, coinciding with estrogen depletion. Estrogen has many beneficial effects on the cardiovascular system, including vasodilation, diminished arterial plaque formation, decreased platelet aggregation, improved carbohydrate metabolism, increased fibrinolysis, antioxidant properties, and improved lipid profile. Progesterone may diminish some but not all of these beneficial effects. The lipid profile was examined in a prospective randomized 3-year trial (Postmenopausal Estrogen/Progestin Interventions), which showed a decrease in total cholesterol, an increase in high-density lipoprotein (HDL), and a decrease in low-density lipoprotein in estrogen users. The addition of medroxyprogesterone acetate diminished

the beneficial increase in HDL, whereas micronized progesterone did not alter the beneficial effect.

Oral estrogen (not transdermal estrogen) use also increases triglyceride levels, which are associated with increased cardiovascular risks. Severe familial hypertriglyceridemia is a contraindication to ERT.

Most epidemiologic studies indicate an almost 50% reduction in heart disease with current ERT and HRT. These studies may have a selection bias that overestimates the beneficial effects.

Randomized clinical trials for secondary prevention of heart disease have not shown similar results. Dr. D. M. Herrington performed a 3-year randomized placebo-controlled trial on women with heart disease, which failed to show a beneficial effect of ERT or HRT by quantitative coronary angiography. HERS (Heart and Estrogen/Progestin Replacement Study), a randomized, double-blind trial treating women with preexisting coronary artery disease with HRT found a 50% increase in cardiac events in the first year of the study in the treatment group. By the fourth year, there was a decreased risk in the treatment group. Overall, there was no difference in cardiac events over 4 years. Possible reasons for the increased risk in the first year may be an increase in thromboembolic events and systemic inflammation in HRT users. ERT should not be started in the first year after a cardiovascular event due to the increased risks. If a patient was already on ERT, there were no increased risks in continuing the medication. Randomized clinical trials on the effects of HRT in women without cardiovascular disease are being conducted.

Cognition

Estrogen has been shown to have beneficial effects in the brain, such as increasing synapses, augmenting neuronal growth, antioxidant protection of neurons, and decreasing amyloid P concentrations (found in Alzheimer's neurofibrillary tangles). Estrogen stimulates pathways that have important functions in memory and learning. However, ERT does not improve cognitive function in normal healthy subjects.

Meta-analysis indicates approximately one-third less dementia in estrogen users than in nonusers. Small short-term randomized studies have not shown a benefit of ERT in Alzheimer's patients but it may help to enhance the positive treatment effect of tacrine.

Other Potential Benefits

Meta-analysis indicates that estrogen use may decrease the risk of colon cancer. Studies indicate a

potential benefit for ERT to prevent falls, improve depression, reduce osteoarthritis, preserve teeth, accelerate wound healing, decrease insulin resistance, prevent age-related hearing loss, decrease skin wrinkles, reduce dryness of the skin, improve visual acuity, reduce dryness of the eyes, lower intraocular pressure, and decrease cataract formation. Multiple epidemiologic studies indicate decreased mortality rates but selection bias is a concern. More evidence is needed to assess these claims.

RISKS

Endometrial Hyperplasia and Cancer

Stimulation of the uterine lining with ERT is well documented. This can lead to endometrial hyperplasia and progress to endometrial cancer in women who have not had a hysterectomy. Endometrial hyperplasia can be demonstrated in 20% of women using estrogen alone within 1 year. Women who use unopposed estrogen have a 4 to 15 times increased incidence of uterine cancer. Endometrial hyperplasia and cancer rates increase with higher doses and longer duration of estrogen use. Adequate progesterone supplementation reduces this risk to baseline levels. Women with late-stage estrogen receptor-positive endometrial cancer should not be given HRT until they are in remission for at least 5 years.

Breast Cancer

Women with prolonged high estrogen states, such as early menarche, late menopause, and nulliparity, are known to be at higher risk for breast cancer. Therefore, there is concern about whether ERT increases the risk of breast cancer. There have been over 50 epidemiologic studies, at least five meta-analyses, and a reanalysis of the risk of breast cancer with postmenopausal ERT. The results are inconclusive but it is likely that there is a slight increase in risk. It is estimated that estrogen use may increase breast cancer by approximately 200 cases per 100,000 individuals in the first 5 years of estrogen use. After 15 years of ERT, an increase of 1200 cases is estimated. Progesterone is known to have stimulatory effects on the breast but progesterone supplementation has not been shown to increase the risk of breast cancer.

The breast cancer that develops in women on HRT tends to be diagnosed earlier (perhaps due to increased surveillance with mammography), to be less virulent, and to be less fatal. SERMs may have a better risk profile for women with a personal or family

history of breast cancer. Breast cancer risk needs to be discussed in perspective with the benefits of HRT.

Other Risks

HERS showed a threefold increase in the risk of thromboembolism during the first year of HRT. The risk returns to baseline levels after the first year. Only 1% of the time is venous thrombosis fatal. Screening for thrombotic disorders is appropriate when warranted by patient or family history. Evidence suggests that there is approximately twice the risk of gallbladder disease, a 30% increased risk of ovarian cancer, and twice the risk of systemic lupus erythematosus. There may be exacerbations of asthma, migraines, and seizure disorders.

PREPARATIONS AND USAGE

Estrogen

The estrogen with the highest potency in the body is estradiol. Micronized estradiol can be used for ERT. However, a preparation of daily conjugated equine estrogens (0.625 mg) is most commonly prescribed in the United States. It is mainly estrone but also includes many forms of estrogen derived from pregnant mares. Equivalent dosages for bone of oral estrogens are shown in Table 1. It is unclear whether these products have equivalent actions in all organ systems. Estrogens are also given in transdermal and transvaginal forms.

Phytoestrogens are natural weak estrogens found in soy products, which, in high doses, reduce hot flashes. No research has been performed on other benefits or risks.

Supplemental Progesterone

Progesterone should be used as adjunct treatment with estrogen whenever a woman has a uterus to

Table 1 Equivalent (in Bone) Estrogen Products

| Category | Brand | Dose (mg) |
|--|--------------------------|-----------|
| Conjugated equine estrogen | Premarin | 0.625 |
| Conjugated plant estrogen | Cenestin | 0.625 |
| Esterified estrogens | Menest | 0.625 |
| Piperazine estrone sulfate (estropipate) | Ogen, Ortho-est, generic | 0.625 |
| Micronized estradiol | Estrace, generic | 1 |
| Ethinyl estradiol | Estinyl | 0.05 |

protect against endometrial pathology. It is not necessary when a woman has had a hysterectomy since progesterone does not prevent the risk breast cancer and may adversely affect some of the cardiac benefits of estrogen alone. In the United States, medroxyprogesterone acetate is most commonly used.

Progesterone can be given cyclically for 12 to 14 days of the month (medroxyprogesterone 5–10 mg) or continuously (2.5–5 mg) to protect against endometrial hyperplasia. Using progesterone for less than 12 days or every 3 months is less protective against endometrial hyperplasia.

Medroxyprogesterone acetate can have unpleasant side effects, such as bloating, breast tenderness, irritability, and depression. Other progestins may have a better side effect profile. Micronized progesterone at doses of 200–400 mg administered cyclically or 100–200 mg administered continuously have been shown to minimize endometrial hyperplasia. It has an added benefit of less reduction in the beneficial HDL rise provided by estrogen alone. Norethindrone (0.7 mg cyclic or 0.35 mg continuous administration), norgestimate (0.09 mg), and norethindrone acetate (5 mg daily) are also acceptable alternatives. Progestin can also be given as a vaginal suppository, transdermal patch, intrauterine device, or intramuscular injection.

Treatment Regimens

As suggested above, progesterone supplementation can be given cyclically or continuously to prevent endometrial pathology. Estrogen should be prescribed alone to women who have had a hysterectomy.

Cyclic use of progesterone usually causes cyclic vaginal bleeding in 80–90% of women. Some may have enjoyed years without this inconvenience. However, half of the women who use continuous HRT experience unexpected vaginal bleeding in the first 6 months. After 1 year, 10–50% continue to have this side effect. Bleeding should be investigated if it occurs at unexpected times in the cyclic regimen or after 6 months with the continuous regimen by ultrasound measurement of the endometrial lining and/or by endometrial biopsy.

Some women desire only ERT despite the risks of endometrial cancer due to intolerable side effects from progesterone. These patients must be monitored closely with yearly endometrial biopsy to ensure that no pathology develops.

SERMs

Tamoxifen is prescribed to women who have had estrogen receptor-positive breast cancer to reduce recurrence and to high-risk women to prevent breast cancer. It improves the lipid profile and reduces bone loss. Negative effects include worsening of hot flashes, increasing thromboembolism, and increasing the risk of endometrial polyps, hyperplasia, and cancer. Intrauterine progesterone has been given to prevent endometrial pathology.

Raloxifene (60 mg) improves bone mass, decreases fracture rates, improves the lipid profile, and protects the endometrium. A 3-year trial showed a decrease in breast cancer rates but longer term studies are needed. Unfortunately, hot flashes and thromboembolic disorders are exacerbated. Leg cramps are an unexpected side effect.

Table I Vaginal Compounds Available in the United States

| | Brand name | Pharmaceutical company | Estrogen | Available dosage | Common starting dosage | Maintenance dosage |
|------------------------|-----------------------|------------------------|-----------------------------|--|------------------------|-----------------------|
| Estrace | Estrace | Warner Chilcott | Estradiol | 0.1 mg E ₂ /g | 2–4 g/day | 1 g thrice weekly |
| Estring vaginal ring | Estring | Pharmacia Upjohn | Estradiol | 7.5 µg/24 ^h in 2 mg reservoir | | Stable for 90 days |
| Dinestrol cream | Ortho Dinestrol cream | Ortho-McNeil | Dinestrol | 0.01% cream | 1–2 applicators/day | 1–3 times weekly |
| Premarin vaginal cream | Premarin | Wyeth-Ayerst | Conjugated equine estrogens | 0.625 mg/g | 0.5–2 g/day | 1 g/day |
| Vagifem | Vagifem | Pharmacia Upjohn | Estradiol | 25 µg/tablet | 1 tablet/day | 1 tablet twice weekly |

Changes in endometrial thickness are even larger than those caused by similar oral doses of estradiol. Vaginal estrogen therapy should therefore be no different than other methods of estrogen replacement therapy: unopposed estrogen stimulation should be discouraged in all cases and close follow-up should be maintained on a regular basis.

VAGINAL THERAPY CONSIDERATIONS

Most estrogens are readily absorbed across mucous membranes. Consequently, vaginal absorption can be achieved via creams, saline suspensions, tablets, or hormonally impregnated pessaries and rings. All of these modes of transmission, save the use of saline suspension, have been officially approved for clinical usage (see Table I). Each of these methodologies has its own unique list of advantages and disadvantages. Micronized estradiol suspended in a saline buffer has the swiftest absorption profile, with peak systemic levels occurring at 2 h, compared with 4 h for the same dosage compounded in a vaginal cream. Conversely, vaginal rings impregnated with estradiol produce systemic levels that persist for as long as 3 months. Generally, estrogenic compounds in vaginal creams will achieve approximately one-fourth of the systemic levels gained by an equivalent oral dosage of the same estrogen.

VAGINAL CREAMS

Vaginal creams remain the mainstay of transvaginal estrogen therapy. A variety of estrogenic compounds have been formulated for admixture in a water-soluble base (see Table I). Most commonly initiated for urogenital atrophy and atrophic vaginitis, treatment is generally instituted with higher doses on a daily basis. Therapy should be continued for 1 to 2 weeks at this dosage. A small amount of the cream should be

lightly applied to the vulva simultaneously to assist in restoration of tissue integrity. At that point, dosage should be decreased in a gradual manner to one-half the starting dose for a similar period of time. A maintenance dosage of 1 g (refer to Table I) of either estradiol or conjugated equine estrogens can be given one to three times weekly once restoration of the vaginal mucosa has been achieved. The most common adverse sequelae of therapy remain the same as with other methods of estrogen replacement: changes in the nature of vaginal bleeding patterns, breast tenderness, allergic reactions, and headaches. Close follow-up and addition of an oral or vaginal progestin should be considered in all cases of maintenance therapy.

VAGINAL RINGS/PESSARIES

Vaginal rings consist of crystalline estradiol mixed with a liquid polymer, polydimethylsiloxane. This mixture is then molded into rings similar in shape and size to the contraceptive diaphragm. After an initial burst effect, sustained and reasonably constant levels of estradiol, approximately 60 pg/ml, are seen for 3 months. Such devices have been shown in open, parallel-group, comparative trials to be effective in the treatment of urogenital atrophy in greater than 75% of patients. Due to their similarity to the diaphragm, they can be placed by either a medical professional or the patient herself and are tolerated far better than the relatively stiffer structure of estrogen-containing pessaries. Side effects can include fever, pain, pruritis, urticaria, and a modest foreshortening of the vagina. Ring or pessary systems may be unsuitable for women with narrow, short, or stenosed vaginal canals. Narrowing of the vagina, vaginal stenosis, prolapse of pelvic structures, and active vaginitis make the vagina more susceptible to adverse side effects of these systems. Patients with these limiting factors should be considered for alternative modalities.

does not alter the progression of diabetic retinopathy. All diabetic retinopathy eventually reaches an involuntional stage in which visual loss may relate to macular detachment, ischemia, long-standing macular edema, or optic nerve disease.

The treatment of diabetic retinopathy is focused on the prevention of visual loss. Clinical trials clearly indicate that good control of blood glucose reduces the risk of the onset and progression of retinopathy, with the possibility of transient worsening of retinopathy at the beginning of tight control. Focal or grid laser treatment should be considered when there is clinically significant macular edema regardless of the stage of diabetic retinopathy. Clinically significant macular edema is present when funduscopic findings meet any of the following three criteria: retinal thickening within 500 μm of the center of the macula; hard exudates within 500 μm of the center of the macula associated with thickening of the adjacent retina; or retinal thickening more than one disc area in size, part of which is within one disc diameter of the center of the macula. Panretinal laser photocoagulation, a procedure in which laser burns are applied to the retina outside the macular and optic disc, is indicated for PDR with high-risk characteristics, defined as one of the following three findings: neovascularization of the disc that is more than one-fourth of the disc area in size, any degree of neovascularization of the disc associated with preretinal or vitreous hemorrhage, or neovascularization elsewhere in the retina that is more than one-half of the disc area in size associated with a preretinal or vitreous hemorrhage. Some ophthalmologists also include neovascularization of the iris as a high-risk characteristic. Pars plana vitrectomy for the removal of vitreous and replacement with saline, combined with endolaser therapy with or without cataract extraction and lens implant, may be considered when the ocular media are too hazy for an adequate fundus view for laser therapy. Other conditions suitable for vitrectomy and endolaser include dense, nonclearing vitreous/premacular hemorrhage, tractional retinal detachment involving the macula, severe fibrovascular proliferation or macular epiretinal membrane, retinal neovascularization refractory to laser photocoagulation, and red blood cell-induced glaucoma. Peripheral retinal cryotherapy is used for advanced proliferative diabetic retinopathy with hazy ocular media by some ophthalmologists. Patients with type 1 diabetes have more aggressive proliferative diabetic retinopathy than those with type 2 diabetes and benefit from earlier laser photocoagulation and vitrectomy. Noncompliant patients should be treated early as well.

It is recommended that patients with type 1 diabetes be referred for an eye examination within 5 years after diagnosis and reexamined at least annually. Those with type 2 diabetes should have an eye exam at the time of diagnosis and be reexamined at least annually. Since retinopathy can become more aggressive during pregnancy, these women should have an eye exam before conception or early in the first trimester and at least every 3 months thereafter until parturition. Patients with mild NPDR should have an eye exam every 9 months, those with moderate NPDR every 6 months, those with severe NPDR every 4 months, and those with PDR every 2 or 3 months.

GLAUCOMA AND HYPHEMA

Small isolated tufts of neovascularization at the pupillary border are relatively common in patients with diabetes and can be carefully followed without initial treatment. Patients with contiguous neovascularization of the iris or the anterior chamber angle may develop hyphema (bleeding in the anterior chamber) and glaucoma. They require prompt panretinal photocoagulation regardless of the presence of high-risk characteristics. Patients with diabetes are also at an increased risk for primary open-angle glaucoma as well as pupillary block glaucoma after cataract surgery. Note that topical beta-blockers for glaucoma in diabetic patients may mask the warning symptoms of hypoglycemia, such as sweating, shaking, and restlessness.

CATARACT

Typical nuclear sclerosis, cortical opacities, and especially posterior subcapsular cataract occur earlier and more frequently in patients with diabetes. Rarely, the lens may become completely opaque in several days to weeks in patients with diabetes (true diabetic cataract). Although diabetic retinopathy may progress after cataract surgery, patients enrolled in clinical trials who underwent cataract surgery usually had improved visual acuity postoperatively.

DIABETIC NEUROPATHY

Diabetes affects multiple cranial nerves, including II (optic nerve)–VI, and is thus called diabetic polyneuropathy. Diabetic papillopathy is benign disc edema associated with mild visual loss. It has no correlation with the severity of diabetic retinopathy. Spontaneous

resolution usually occurs after 3 months. The transient nature, frequent bilaterality, benign outcome, and the absence of subsequent disc atrophy are some of the features that help distinguish diabetic papillopathy from ischemic optic neuropathy. Diabetes is a risk factor for ischemic optic neuropathy, which may result in profound visual loss. Characteristic telangiectatic vessels at the optic disc can be observed in some patients with type 1 diabetes who experience sudden visual loss due to ischemic optic neuropathy. No effective treatment has been established for nonarteritic ischemic optic neuropathy.

An isolated third, fourth, or sixth cranial nerve palsy may develop from diabetic microvascular disease, resulting in diplopia, and it may be accompanied by intense periorbital pain. Rarely, two of these cranial nerves are involved simultaneously. Third cranial nerve involvement does not cause dilation of the pupil. A diabetic cranial nerve paralysis usually resolves within 3 months without intervention. Diabetic neuropathy of cranial nerve V may result in neurotrophic keratopathy and nonhealing corneal epithelial defects.

REFRACTIVE CHANGES

Diabetes can affect the clarity of the lens, its refractive index, and its accommodative amplitude. The state of lenticular hydration can be affected by blood glucose level, causing transient changes of the refractive power of the lens, most commonly myopic but occasionally hyperopic. Patients with diabetes have a decreased amplitude of accommodation compared to age-matched controls, and presbyopia may occur at a younger age.

MUCORMYCOSIS

In patients with diabetes, particularly those with ketoacidosis, a rare but life-threatening orbital infection may be caused by the fungus *Mucor*. Decreased vision, pain, proptosis, red-eye, and fever usually occur. Intravenous amphotericin B, surgical debridement of the necrotic tissue, and diabetic control are required to prevent death.

MISCELLANEOUS

Diabetes has nonspecific corneal manifestations, such as punctate epithelial erosions, basement membrane changes leading to delayed epithelial healing, Descemet's folds, and decreased corneal sensation. Tear production is decreased in patients with diabetes.

Figure 1 Eye disease in diabetes.

Glycogen infiltration of the pigment epithelium, sphincter, and dilator muscles of the iris may cause decreased pupillary responses. Autonomic neuropathy of diabetes can also be contributory. Patients with diabetes have a higher incidence of asteroid hyalosis, a condition with minute white opacities composed of calcium-containing phospholipids in the vitreous. Repeated vitreous hemorrhage in diabetic patients may result in cholesterolosis, also called sychysis scintillans, with refractile cholesterol crystals in the inferior vitreous. Partial posterior vitreous detachment, which may cause floaters, flashes of light, vitreous hemorrhage, and retinal breaks, is seen far more commonly in patients with PDR than in individuals without diabetes or with NPDR. Children born to mothers who have diabetes during pregnancy may have superior segmental optic nerve hypoplasia (topless disc), with a matching inferior semialtitudinal visual field defect. Diabetes is also a risk factor for cystoid macular edema after cataract surgery.

CONCLUSION

The eye diseases associated with diabetes are summarized in Fig. 1. Most can be prevented with tight control of blood glucose levels. Modalities have been developed to treat each of these eye diseases in diabetes. Since diabetic retinopathy remains the leading cause of visual loss despite the currently available treatments, clinical trials are under way to test the use of intravitreal steroids, oral and local antivascular endothelial growth factor agents, in preventing macular edema and retinal neovascularization, without the retinal destruction by laser photocoagulation.

assembled in liver from lipids synthesized *de novo* or from dietary lipids stored in liver between meals. Levels of lipoproteins are important predictors of atherosclerotic cardiovascular disease and are also critical in diagnosing disorders of lipoprotein transport, which afflict approximately 20% of the populations of Western societies. The vast majority of those affected have one of several hyperlipoproteinemias, but a number of syndromes afflicting a relatively small number of people exist, characterized by low levels of total cholesterol, either due to low levels of apoA1-containing lipoproteins [e.g., high-density lipoprotein (HDL)] or due to low levels of apoB-containing lipoproteins (e.g., LDL). This article is devoted to low-apoB syndromes, with special emphasis on familial hypobetalipoproteinemia.

GENETICS

Abetalipoproteinemia is due to a set of mutations in the gene for microsomal triglyceride transfer protein (MTP). The MTP protein is crucial to the initial assembly of VLDL and chylomicron particles in liver and intestine, respectively. Early during assembly, apoB is synthesized on polyribosomes and cotranslationally transferred into the lumen of the endoplasmic reticulum (ER). Triglycerides synthesized nearby associate with MTP and are transferred onto apoB to form primary VLDL particles. In a second step, the primary particles “mature” as they acquire more lipids from secondary VLDL particles in the *trans*-ER and Golgi and the mature particles are secreted from hepatocytes (or in the case of chylomicrons, from enterocytes). MTP dysfunction renders assembly ineffective and lipids destined for cellular export accumulate in hepatocytes and enterocytes. Chylomicron retention disease (Anderson’s disease) is similar symptomatically, but its molecular defect is in the Sar 1 GTPase of COPII vesicles that transport lipoproteins from ER to Golgi.

Similarly, the genetic cause(s) is not known for the vast majority of cases of FHBL. Less than 5% of cases are due to mutations of the apoB gene (APOB). Most mutations are insertions or deletions of a few base pairs and produce frameshifts of translation resulting in the introduction of premature stop codons and truncated proteins. The truncations are designated according to a centile nomenclature: the normal protein of 4536 amino acid residues, secreted from liver as part of VLDL particles, is designated apoB100. The normal intestinal variant associated with chylomicrons is apoB48. Over 40 different truncations, some as short as apoB2 and some as long as apoB89,

have been described. Null alleles probably result in untranslated mRNA. A fascinating group of seven families has been identified in which the FHBL trait seemed to segregate in a Mendelian dominant fashion, but in which no truncated forms of apoB were detectable in plasma. A genome scan was performed followed by linkage analysis. The FHBL trait was not linked to any locus on chromosome 2 (the site of APOB). Rather, linkage was established to a susceptibility locus on chromosome 3p21, between markers D3S2407 and D3S1767. In a third group of five families, genome scanning and linkage studies indicated linkage to neither chromosome 2 nor chromosome 3. Thus, FHBL appears to be genetically heterogeneous.

METABOLISM OF ApoB-CONTAINING LIPOPROTEINS IN FHBL

Plasmas of homozygotes bearing mutations specifying apoB truncations longer than apoB48 contain three subfamilies of apoB-containing lipoproteins. For example, the plasmas of subjects heterozygous for the apoB54.8 mutation contain apoB100, apoB48, and apoB54.8 particles. Plasmas of homozygous individuals contain only the truncated form. Lipoproteins bearing truncated forms of apoB vary in size directly with the lengths of the truncations; i.e., apoB89-bearing particles have sizes and densities similar to those of normal apoB100-bearing VLDL and LDL, whereas apoB38.9-bearing particles have sizes intermediate between LDL and HDL and densities similar to those of large HDLs. Furthermore, short truncation-containing particles contain smaller molar amounts of triglycerides per particle than apoB100-containing particles. The presence of various forms of apoB on distinct particles permits the performance of concurrent *in vivo* metabolic studies on the kinetic parameters of apoB100 and apoB truncation-bearing particles, with apoB100 particles serving as internal controls for the truncations. Truncated forms are usually present at <20% of the levels of apoB100 particles, due to reduced production rates and enhanced clearance relative to apoB100 particles. This is due to a combination of low production rates and rapid clearance rates. The relative importance of production and clearance rates in setting the plasma levels of truncation-bearing particles depends on the truncation in question. For example, the production rate of apoB89-containing particles is only 15% lower than normal, but their clearance rate is more than twice normal due to the enhanced affinity of interaction of apoB89 with the LDL receptor. For apoB75,

production is more impaired than for apoB89, but clearance is still rapid due to enhanced interaction with the LDL receptor. The shorter truncations, such as apoB38.9, are cleared very rapidly, mostly by the kidney. Clearance is probably mediated by the megalin/gp330 receptor located in proximal tubule cells. Based on the presence of one normal allele specifying the production of apoB100, the average concentrations of apoB100 in plasmas of heterozygotes would be expected to be $\approx 50\%$ of levels in unaffected controls. In fact, levels are closer to $\sim 30\%$ of normal. This is due to production rates that are $\sim 30\%$ of normal.

HEPATOSTEATOSIS

As a result of low rates of production of the normal lipid transporter protein apoB100 and the impaired capacities particularly of short truncations of apoB to transport triglycerides, the export system for hepatic lipids via VLDL particles is impaired. This would be expected to result in the accumulation of triglycerides in liver. Indeed, several groups have reported cases of hepatic steatosis detected by ultrasound or in rare instances by liver biopsy. Schonfeld *et al.* examined 22 individuals with various truncations of apoB ranging from apoB4 to apoB89 and 13 controls, using magnetic resonance spectroscopy. Results were calculated from energy spectra and represent a precise noninvasive method for quantifying liver fat. The mean value for liver fat in FHBL was five times that of controls. The differences between FHBL and controls could not be accounted for by dietary intake, indexes of total body and abdominal fat, or indexes of glucose tolerance and insulin sensitivity, suggesting that the APOB mutations per se were responsible.

LESSONS FOR FHBL FROM RECOMBINANT MICE AND HEPG2 CELLS

Mice and Cells

Several recombinant mice meant to mimic human FHBL have been produced. The author's group created two types of apoB truncation-harboring mice by targeted homologous recombination in embryonic stem cells, using the Cre-loxP system to excise any extraneous genomic sequences that may have been introduced during recombination. The resulting apoB38.9 and apoB27.6 mice closely resemble their human counterparts with respect to the genomic sites of the mutations. Maeda's group has produced an

apoB81 mouse and Young's group has produced apoB83 and apoB39 mice. The author's group has also produced an apoB82-expressing HepG2 cell line.

Plasma Lipoproteins

In contrast with humans, mouse livers produce not only apoB100 and the apoB truncations, but also apoB48. Thus, apoB48-containing lipoproteins arise from both liver and intestine. The mice exhibit hypobetalipoproteinemia, with low levels of cholesterol and apoB. Similar to human heterozygotes, three sub-families of apoB-containing lipoproteins circulate in plasmas of apoB^{+38.9} and apoB^{+27.6} heterozygous mice: those containing apoB100, apoB48, and the apoB truncation. Plasma levels of apoB100 and apoB48 are approximately equal; plasma levels of the truncations are much lower. In the plasmas of apoB^{38.9/38.9} and apoB^{27.6/apoB27.6} homozygous mice, only apoB truncation-containing lipoproteins circulate and their plasma lipid levels are very low.

Mouse ApoB Lipoprotein Metabolism

Studies performed *in vivo* and in primary cultures of hepatocytes demonstrate that livers of apoB^{+38.9} mice produce apoB100 only in small amounts, that apoB48 is the dominant normal variant, and that apoB38.9 is produced in equimolar amounts with apoB48. In apoB^{+27.6} mice, the relative amounts of apoB100 and apoB48 produced are the same as for apoB38.9 mice, but the relative amount of apoB27.6 produced exceeds that of apoB48 by approximately fivefold. Since plasma levels of both the apoB truncations are less than the levels of apoB48, the truncation-containing lipoproteins must be cleared more rapidly than apoB48 lipoproteins. The more rapid clearance of the mutant apoBs is compatible with previous *in vivo* studies in humans and rabbits. Similarly, although more apoB48 is produced than apoB100, plasma levels of apoB48 lipoproteins are equal or less than levels of apoB100 lipoproteins, confirming older studies that apoB48 is cleared more rapidly than apoB100. The secretion of apoB100 in humans at rates lower than those expected based on the number of normally functioning alleles is due to enhanced intracellular degradation prior to secretion of apoB100 in the presence of the defective apoB81 or apoB82 alleles.

Hepatosteatosis in Mice

The low rate of synthesis and secretion of normal apoBs, the rapid clearance of truncation-containing

lipoproteins, and the limited ability of the apoB38.9 and apoB27.6 truncations to ferry triglycerides led the author's group to predict that just as in humans, the mice would also have fatty livers. Indeed, liver triglycerides were increased 1.5- and 3-fold in apoB^{+38.9} and apoB^{38.9/38.9} mice, respectively, over age- and sex-matched apoB^{+/+} wild-type mice. Similarly, liver triglycerides of apoB^{+27.6} and apoB^{27.6/27.6} were increased 3- and 5-fold. The greater accumulation of triglycerides in the animals bearing the shorter truncation is compatible with the more severe defect in the transport capacity of the shorter truncation.

Feedback Inhibition of Hepatic Triglyceride Synthesis

It is interesting that the APOB defect-induced disturbance of triglyceride transport produces feedback inhibition of fatty acid synthesis in liver in the recombinant mice, in a gene-dose-dependent fashion. This is accompanied by decreases in hepatic mRNA levels for the transcription factor SREBP-1c that regulates enzymes in the fatty acid synthetic pathway and in the mRNA levels for the enzymes fatty acid synthase and steroyl coenzyme A desaturase-1. This feedback would tend to limit the amount of fat accumulated in the face of the APOB mutation-induced defect in the triglyceride export pathway. Thus, the amount of fat accumulated is under the control of several genes; the expression of the genes relative to one another probably sets hepatic triglyceride levels.

The Region between ApoB38.9 and ApoB27.6 Supports Embryogenesis

ApoB-containing lipoproteins appear to be critical in supporting embryogenesis, at least in mice. Heterozygous crosses are expected to produce homozygous wild-type, heterozygous, and homozygous affected offspring in proportions of 25, 50, and 25%. However, crosses between mice heterozygous for null mutations of apob (apoB⁺⁰) yield more than 25% wild-type (apoB^{+/+}) pups, more than the expected 50% heterozygotes, and ~2–3% apoB^{0/0} homozygotes, which is ~10% of the expected number. Thus, the induction of a null mutation in mouse apob results in embryonic lethality for homozygotes. By contrast, apoB^{+38.9} × apoB^{+38.9} crosses yield ~13% apoB^{38.9/38.9} homozygotes, i.e., ~50% of the expected number. By contrast, heterozygous crosses of apoB^{+27.6} yield only 3–4% apoB^{27.6/27.6} homozygous offspring, similar to the yield of null

homozygotes, suggesting that the first 27.6% of the N-terminal region contains very little, if any, apoB sequence (or structure) able to support embryogenesis. In contrast, the next 11.3% (the stretch of sequence between apoB27.6 and apoB38.9) does contain such structures. This hypothesis was verified by making apoB^{+38.9} × apoB^{+27.6} crosses. The yields of compound heterozygotes (apoB^{38.9/27.6}) were nearly identical to the yields of apoB 38.9 homozygotes; i.e., apoB38.9 was able to “rescue” apoB27.6 fetuses.

ApoB38.9-Containing Lipoproteins Can Support Atherogenesis

ApoB-containing lipoproteins are the major atherogenic particles in plasma. After LDL particles enter the subendothelial space, some of the particles interact with proteoglycans and become oxidatively modified. This is an early event in atherogenesis. The interaction with proteoglycans is mediated by binding sites on apoB located near the N-terminal part of the molecule that were identified in studies carried out *in vitro*. The apoB38.9 mouse permitted the translation of these findings to the situation *in vivo*. The apoE^{-/-} knockout mouse is a frequently used model of atherosclerosis. ApoE^{-/-} mice develop florid aortic atherosclerosis even while eating normal low-cholesterol- and low-fat-containing mouse chow. ApoB-containing cholesterol-rich particles are responsible for the atherosclerosis in these animals. To assess whether apoB38.9-containing particles could support the development of aortic lesions, apoB^{38.9/38.9} mice were crossed with apoE^{-/-} mice. The resultant apoB^{38.9/38.9}/apoE^{-/-} mice developed just as much atherosclerosis as the apoB^{+/+}/apoE^{-/-} mice. Thus, the first 38.9% of the N-terminal end of apoB contains sufficient structure for lesion formation.

Therapy

In abetalipoproteinemia, which produces severe symptoms related to malabsorption of fat and fat-soluble vitamins, low-fat diets and replacement therapy are mandatory. Since most subjects with FHBL are asymptomatic, the diagnosis is usually made on routine cholesterol screening. After the serious secondary causes for low cholesterol and apoB levels are ruled out, usually no therapy is needed. However, given the frequency of fatty liver in these subjects, periodic evaluations of liver function may be warranted.

normal development) and position of the urethral meatus (for normal deposition of semen). The prostate exam enables one to assess prostate size, firmness, tenderness, and the presence of cysts (congenital and ejaculatory duct), which may be associated with ejaculatory duct obstruction.

The scrotal exam should be performed in a warm examining room to promote relaxation of the scrotum. It is important to record the position (scrotal and inguinal), volume (normal, ~15–25 ml), and consistency (normally firm) of the testis. Normally, more than 70% of the testis volume is from germ cells alone. Therefore, a soft and/or small testis is indicative of abnormal spermatogenesis. The diagnosis of a varicocele is generally made on physical examination. The detection of a varicocele is greatly facilitated by examining the patient standing. Varicoceles are graded as follows: grade I, palpable only with Valsalva; grade II, palpable without Valsalva; and grade III, visible. The presence or absence of the vas deferens can be confirmed by physical examination.

Semen Analysis

The semen analysis is the cornerstone of male infertility evaluation. Two or three samples collected by masturbation after a minimum of 3 days of abstinence should be examined. Assessment of semen volume is important because it is indicative of seminal vesicle function (~70% of the semen volume is of seminal vesicle origin) and of the patency of the ducts distal to this gland (ejaculatory ducts). In azoospermic men, a low semen volume may be due to a distal obstruction (e.g., ejaculatory duct), seminal vesicle agenesis (associated with congenital absence of the vas deferens), hormonal deficiency, or, rarely, retrograde ejaculation.

Sperm concentration is indicative of quantitative spermatogenesis and the normal cutoff is 20 million sperm per milliliter. However, spontaneous pregnancies are possible for couples in which the man's sperm concentration is less than 20 million sperm/ml. Reports have suggested that a sperm concentration cutoff of 14 million sperm/ml may be more appropriate. Percentage sperm motility and sperm morphology are indicators of qualitative spermatogenesis. Typically, the percentage of sperm motility should be >50% and the percentage of sperm with normal morphology should be >30%. It is generally accepted that sperm morphology is a better predictor of fertility than sperm concentration or sperm motility. Although each of the conventional semen parameters (sperm concentration, motility, and morphology) may

help to differentiate infertile from fertile men, none of these parameters is a powerful discriminator because there is significant overlap between semen parameters of infertile and fertile men. Indeed, some infertile men have normal semen parameters and are said to have unexplained infertility. Moreover, conventional semen parameters exhibit a high degree of variability from sample to sample; as such, there is a need for multiple analyses.

Specialized sperm function tests have been developed in the hope of better discriminating fertile from infertile men. It is also hoped that these tests may help predict fertility potential (*in vivo* and *in vitro*) better than conventional semen parameters. Finally, evaluating sperm function may increase our understanding of spermatogenesis and gamete biology. However, no single specialized sperm function test has been universally accepted.

Hormonal Evaluation

The initial hormonal evaluation should include measurement of serum follicle-stimulating hormone (FSH) and testosterone (T) levels. Abnormal FSH or T levels should prompt further evaluation with serum luteinizing hormone (LH) and prolactin determination.

Typically, most men with spermatogenic failure have an elevated serum FSH, with or without an elevated serum LH and low serum T. Although there is no absolute FSH cutoff above which active spermatogenesis is ruled out, most clinicians agree that men with FSH levels greater than twice the upper limit of normal (generally associated with small, soft testes) probably have nonobstructive azoospermia (with the predominant histology being maturation arrest or Sertoli cell-only pattern), and a confirmatory testis biopsy is not indicated. As such, men with high FSH and small testes are not candidates for surgical reconstruction. However, men with elevated serum FSH may harbor small foci of active spermatogenesis amid a histologic background that is predominantly characterized by maturation arrest or Sertoli cell-only pattern. In these men, a diagnostic biopsy may be useful to predict the presence of sperm for a subsequent therapeutic testis biopsy [used in conjunction with *in vitro* fertilization (IVF) and intracytoplasmic sperm injection (ICSI)].

Low serum FSH, T, and LH is suggestive of hypogonadotropic hypogonadism with secondary spermatogenic failure. In these men, measurement of prolactin level is indicated together with pituitary

imaging to rule out a pituitary lesion. These men often respond to hormonal replacement therapy (in the form of intramuscular human chorionic gonadotropin (hCG) and FSH or pulsatile subcutaneous gonadotropin-releasing hormone). A normal hormonal evaluation is suggestive of normal, active spermatogenesis but does not rule out spermatogenic failure.

Imaging Studies

Further assessment of reproductive tract anatomy is possible with the aid of ultrasonography. A scrotal/testicular ultrasound is used for assessment of testicular volume, epididymal anatomy, and the presence or absence of varicoceles. A transrectal ultrasound (TRUS) is primarily used to assess prostate anatomy. In infertile men, a TRUS is also used to evaluate the seminal vesicles and ejaculatory ducts in order to determine whether there is a genital tract obstruction at this level. Vasography is used (at the time of surgical reconstruction) to confirm and localize a ductal obstruction.

Genetic Evaluation

Many cases of male infertility may be associated with a genetic defect. One concern is that the genetic defect responsible for the man's infertility may be transmitted to his child through assisted reproduction. In many cases, this causes the same problem in the next generation (infertility in a male child), but some genetic defects may cause other diseases, miscarriage, or even early death. As such, appropriate genetic testing and counseling are an essential part of the infertility evaluation. The available clinical genetic tests for male-factor infertility include chromosome analysis, Y microdeletion analysis, and cystic fibrosis mutation analysis.

Chromosomal Analysis or Karyotype

The prevalence of chromosomal abnormalities in the general population is less than 1%. The prevalence of chromosomal abnormalities in men with azoospermia is up to 14%. Klinefelter's syndrome (47,XXY) is the most common abnormality, observed in approximately 10% of azoospermic men. Other chromosome abnormalities described in infertile men include 47,XYY; 46,XX; X-autosome, Y-autosome, and auto-some-autosome translocations; and pericentric inversions. Sex chromosome abnormalities are seen in approximately 12% and autosome abnormalities in

1% of azoospermic men. In men with oligospermia, the prevalence of chromosomal abnormalities is approximately 5%: Sex chromosome abnormalities are seen in 1 or 2% and autosome abnormalities constitute the other 3%. In clinical practice, a karyotype is recommended in infertile men with severe oligospermia (<10 million sperm/ml) and nonobstructive azoospermia. Clearly, the karyotype analysis is important given the serious reproductive consequences of transferring an abnormal chromosomal complement to the offspring (e.g., miscarriage and birth malformations).

Y Microdeletion

In approximately 10% of men with azoospermia or severe oligospermia (<5 million sperm/ml), a portion of the long arm of the Y chromosome is missing. It is speculated that one or more genes important in spermatogenesis reside within this deleted region of the Y chromosome, which explains the observed phenotype associated with Y microdeletions. It does not appear that men with this condition have any other physical problems apart from infertility. There is evidence that men with a Y microdeletion pass on the genetic abnormality to their male offspring through IVF/ICSI. Genetic counseling and Y microdeletion testing are recommended for infertile men with severe oligospermia and nonobstructive azoospermia.

Cystic Fibrosis Gene and Male Infertility

The cystic fibrosis transmembrane conductance regulator (CFTR) gene is located on chromosome 7. More than 800 different mutations of the CF gene have been reported. In the Caucasian population, the carrier frequency of these autosomal recessive mutations is approximately 4%. Mutations of this gene have been associated with CF and male infertility. CF mutations have been associated with congenital bilateral absence of the vas deferens (CBAVD) (80%), epididymal obstruction (30%), and oligospermia (~20%). They have not been associated with testicular failure or nonobstructive azoospermia. CF mutations result in a defective chloride channel and this is associated with production of thick respiratory and gastrointestinal secretions, leading to the CF phenotype. In male infertility, CF generally results in obstruction of the excurrent duct system, resulting in obstructive azoospermia. Genetic counseling and CF mutation testing are recommended for infertile men with CBAVD, idiopathic epididymal obstruction, and oligospermia.

Testicular Biopsy

A testicular biopsy is indicated for men with azoospermia and normal (or slightly elevated) serum FSH to confirm active spermatogenesis on testicular histology and, hence, diagnose obstructive azoospermia. Men with prior vasectomy and men with CBAVD generally have normal spermatogenesis, and a testis biopsy is not usually indicated. Men with elevated serum FSH (at least twice the upper limit of normal) likely have nonobstructive azoospermia, and a testis biopsy is not indicated because it is unlikely to indicate active spermatogenesis. However, with the advent of advanced assisted reproductive technologies, it is possible to harvest sperm from the testis of men with nonobstructive azoospermia because they may harbor rare foci of spermatogenesis and to use the sperm for IVF with ICSI. As such, the indications for testicular biopsy have broadened.

MANAGEMENT

General Recommendations

Prior to initiating therapy (medical or surgical) for the treatment of male infertility, efforts should be made to eliminate any potential gonadotoxins (agents toxic to the gonads or testicles). A number of medications are known to have adverse effects on sperm production, including hormonal agents (e.g., testosterone or its derivatives), antineoplastic agents (chemotherapeutic drugs), and other miscellaneous drugs. Cigarette smoking is associated with decreased sperm counts and sperm function. Similarly, excessive alcohol consumption (binge drinking) has a detrimental effect on sperm production in the testis. Proper nutrition is also important to maintain adequate sperm production. Finally, chronic exposure to excessive heat (hyperthermia) is detrimental to normal sperm production in the testis.

Medical Therapy for Spermatogenic Failure

Specific medical therapy (targeted to specific pathology, e.g., hormonal replacement for hypogonadotropic hypogonadism) is generally effective in improving spermatogenesis and semen quality. On the other hand, nonspecific or empiric therapy (targeted to unknown pathology) is largely ineffective and should remain experimental until studies prove the contrary. As such, men with idiopathic spermatogenic failure are not candidates for empiric medical therapy.

For most men with idiopathic male infertility associated with spermatogenic failure, assisted reproduction (AR) is the treatment of choice.

A small subset (<5%) of infertile men with spermatogenic failure suffer from endocrine infertility. Specific causes of secondary testicular failure include hypogonadotropic hypogonadism, hyperprolactinemia, hypothyroidism, and congenital adrenal hyperplasia.

Hypogonadotropic hypogonadism can be congenital (Kallman's syndrome) or acquired (secondary to a pituitary adenoma, pituitary infarction, radiotherapy, or idiopathic). The standard treatment involves replacement of deficient hormones. Typically, patients are treated with intramuscular human chorionic gonadotropin (hCG, 1000–2000 IU two to three times per week) and human menopausal gonadotropin (100 IU two or three times per week) for at least 1 year. Alternatively, pulsatile GnRH (2–40 μ g every 2 h by pump) can be administered. The newer recombinant gonadotropins have also been used. Generally, this form of treatment results in increased testicular volume and improved semen quality, with many men obtaining normal fertility.

Hyperprolactinemia can be secondary to a pituitary tumor (generally benign), hypothyroidism, liver disease, medication (antidepressants and cimetidine), or idiopathic. Typically, patients are treated with bromocriptine (2.5–10 mg/day), which suppresses growth of prolactin-secreting tumors, or the longer acting form cabergoline (1 mg/week). For large tumors, transphenoidal resection of the pituitary adenoma is recommended.

Hypothyroidism or hyperthyroidism may be associated with depressed sperm production. Treatment consists of thyroid hormone replacement or ablation of the hyperactive thyroid. Generally, this leads to improved sperm production and return of fertility.

Congenital adrenal hyperplasia is a condition caused by a congenital enzyme deficiency leading to depressed steroid levels. These patients are treated with steroid replacement and generally this leads to improved sperm production and return of fertility.

Surgical Therapy for Spermatogenic Failure

Varicocelectomy

Varicocelectomy is the only male infertility surgery specifically designed to improve spermatogenesis. Varicocelectomy is indicated in men with a clinical varicocele, abnormal semen parameters and couple infertility. This is based on the demonstration that varicocele is associated with a progressive decline in

testicular function and that repair of varicocele can improve spermatogenesis. Varicocelectomy is also indicated in men with a clinical varicocele and testicular pain and in the child or adolescent with a clinical varicocele and decreased ipsilateral testicular volume (>2 ml difference between the right and left testis).

Many studies have evaluated the outcome of varicocelectomy on fertility parameters, and most have demonstrated an improvement in semen quality and pregnancy rates. However, because the bulk of the outcome data on varicocelectomy are derived from uncontrolled or poorly designed controlled studies, the value of these results is limited. Overall, varicocelectomy results in significant improvement in semen analysis in 60–80% of men, and pregnancy rates after varicocelectomy vary from 20 to 60%.

Studies indicate that there may be some benefit in repairing varicoceles in infertile men with azoospermia and clinical varicocele. Although significant improvement in semen quality (the appearance of sperm in the semen) is reported in approximately 50% of these men, a clinically significant outcome (with spontaneous pregnancy) is reported in less than 20% of these cases. Preoperative testicular biopsy is predictive of outcome in these cases. Only men with mature spermatids or spermatozoa on testicular biopsy had a good outcome (the appearance of sperm in the semen). Men with maturation arrest or Sertoli cell-only pattern on testicular biopsy remained azoospermic postoperatively.

Surgical Sperm Retrieval

The advent of advanced AR has made it possible for men with spermatogenic failure to father children. In the subset of men with spermatogenic failure and azoospermia, only testicular surgical sperm retrieval coupled with AR will allow these men to father children. Although a standard open testicular biopsy can be used to extract testicular sperm in men with spermatogenic failure, microsurgical testicular sperm extraction (micro-TESE) has been advocated as the gold standard approach for sperm retrieval in men with nonobstructive azoospermia. With the testicle opened, the operating microscope enables the surgeon to identify and extract the most dilated seminiferous tubules (indicative of active spermatogenesis) while thinner tubules (indicative of germ cell aplasia) are spared. As such, micro-TESE allows for maximal sperm recovery and minimal tissue extraction.

Spermatozoa recovered by testicular biopsy can only be used in conjunction with IVF/ICSI (in which a single sperm is injected into the oocyte). Pregnancy rates are in the range of 30–40%.

Assisted Reproduction

Assisted reproduction is indicated for couples in which the man suffers from idiopathic spermatogenic failure. AR is also indicated for couples in which the man has a specific cause of spermatogenic failure but has not responded to conventional therapy (e.g., varicocelectomy for varicocele) or has chosen AR instead of conventional therapy.

In men with a mild degree of spermatogenic failure and borderline semen parameters, three to six cycles of sperm washing with intrauterine insemination (IUI) should be attempted first. IUI is a minimally invasive form of AR; however, pregnancy rates are in the range of 5–15% per cycle and are highly dependent on the concentration of motile sperm (the minimum threshold for effective IUI is 3–5 million motile sperm).

For couples in which the man has severe oligospermia or nonobstructive azoospermia, only the most advanced AR (IVF/ICSI) will allow them to achieve a pregnancy. In men with nonobstructive azoospermia, a surgical testicular sperm retrieval procedure is necessary to obtain spermatozoa. IVF/ICSI is also indicated for couples that have failed to achieve a pregnancy through IUI. However, the pregnancy rates with advanced AR (e.g., IVF/ICSI) remain modest, with most centers reporting IVF/ICSI pregnancy rates of 30–40% when female factors (e.g., advanced female age) are excluded.

the fluidity of the phospholipid bilayer and facilitates the acrosome reaction. As sperm progress through the reproductive tract, cholesterol is removed from the plasma membrane by albumin and high-density lipoproteins found in the female genital tract. Membrane fluidity may also be increased by removal of phospholipids in a second mechanism. In some species, extracellular glycoproteins are stripped from sperm traversing the genital tract. When glycoproteins are removed from the membrane, associated phospholipids are also removed. These modifications of the plasma membrane may expose membrane-bound enzymes and ligands utilized in sperm penetration of the cumulus oophorus and anchoring to the zona pellucida.

Other hallmarks of capacitation are an increase in adenylate cyclase, a subsequent increase in cyclic AMP (cAMP) and cAMP-dependent protein kinases, and an increase in the intracellular calcium concentration. Capacitation is absolutely dependent on an influx of extracellular calcium, which may be at least partially mediated by T-type (voltage-sensitive) calcium channels present in the sperm membrane. The elevation of cAMP affects numerous cellular events and is necessary for the acquisition of hyperactivated motility.

Hyperactivation of the sperm occurs concomitantly with capacitation. Capacitation and hyperactivation have been delineated as separate processes by studies showing that sperm can be hyperactivated but not capacitated by incubation in culture medium containing calcium but not containing serum or albumin. Both events are triggered in part by extracellular calcium, but hyperactivation manifests as changes in motility, whereas capacitation is principally seen as membrane remodeling. Hyperactivated sperm have a distinct figure-eight tail whip and move in a less progressive fashion than nonhyperactivated sperm. The changes in motility associated with hyperactivation are likely requisite for sperm penetration of the oocyte vestments.

Physical and functional barriers to fertilization exist and may serve as selection mechanisms. Prior to capacitation, sperm must have sufficient motility to move to the site of fertilization. Only a minority of ejaculated sperm undergo capacitation. In the human, the cumulus facilitates the selection of both morphologically normal and capacitated sperm. Only capacitated sperm can undergo zona binding and the acrosome reaction, but a premature acrosome reaction will preclude zona binding. Studies have shown that severely infertile patients may have a deficient capacitation ability and increased incidence

of chromosome aneuploidies. Therefore, proper capacitation appears to be one of the key selection processes of fertilization. The significance of the selection process is not well understood and has considerable ramifications in assisted reproductive technologies.

SPERM BINDING TO THE ZONA PELLUCIDA

Following penetration of the cumulus, the sperm cell must bind and penetrate the zona pellucida, which is both a barrier and a facilitator of fertilization. The zona is an integral part of the block to polyspermy, provides species specificity, and is a selective barrier for capacitated sperm. It facilitates fertilization by stimulating the acrosome reaction, which is necessary for binding to the oolemma. In mammals, the zona pellucida is composed of three secreted glycoproteins, ZP1, ZP2, and ZP3. ZP2 and ZP3 are heavily cross-linked by ZP1, the "structural" zona protein, creating a porous matrix around the oocyte.

Glycosylation of ZP3 near the carboxy terminus is slightly varied in different species. Variation of the O-linked oligosaccharides, found at the carboxy terminus, provides species specificity by allowing only complementary sperm to bind and penetrate the zona. Sperm egg-binding proteins (EBPs) bind to the zona pellucida through the O-linked oligosaccharides on ZP3 (Fig. 1A). Several candidate EBPs, such as sp56, p95, and GalTase, likely become available for binding on the surface of the sperm through membrane remodeling as a result of capacitation.

ACROSOME REACTION AND PENETRATION OF THE ZONA PELLUCIDA

The penetration of the zona pellucida is driven by two physiological events, sperm motility in the hyperactive state and the acrosome reaction. Although the acrosome reaction is stimulated by the binding of sperm to O-linked oligosaccharides of ZP3, ZP3 will not induce uncapacitated cells to undergo the acrosome reaction. Binding to ZP3 stimulates two pathways: G protein-linked signal cascades and voltage-sensitive T-type calcium channels. Activated second messengers and T-type channels raise the intracellular calcium concentration and activate phospholipase C, inducing the acrosome reaction.

The acrosome reaction involves the fusion of the outer acrosomal membrane and the plasma

Figure 1 An overview of fertilization. (A) Capacitated sperm penetrate the cumulus cells and bind to ZP3 on the zona pellucida. (B) Following induction of the acrosome reaction by ZP3, ZP2 ligands facilitate zona penetration. (C) The equatorial region of the sperm plasma membrane binds to the oolemma and fuses. (D) Decondensation of the sperm head and formation of the male and female pronuclei.

membrane. The fusion and vesiculation of the membranes cause the release of the enzymes stored within the acrosome. These enzymes include acid glycosylhydrolases, acid phosphatases, aryl sulfatases, esterases, and acrosin. When released, the proteases may disrupt the zona pellucida matrix and facilitate zona penetration. The penetration of the zona is dependent on ZP2, which also has specific sperm surface receptors (Fig. 1B).

The acrosome reaction results in a modification of the phospholipid and protein content of the resulting plasma membrane. Additionally, several transmembrane and membrane-associated proteins are localized to the equatorial region of the sperm head. These proteins create equatorial binding motifs on the sperm recognized by the oolemma.

OOLEMA–SPERM BINDING AND FUSION AND THE BLOCK TO POLYSPERMY

Sperm–oocyte binding is mediated by proteins from the ADAM (a disintegrin and metalloproteinase domain) family. They include fertilin and crytistin. The receptor on the oocyte is thought to be from the

integrin protein family. Once bound to the oocyte, the sperm plasma membrane begins to integrate with the oolemma (Fig. 1C). The fusion of the gametes is dependent on the sperm protein CD9, an integral membrane protein that associates with the integrin proteins of the oocyte.

There are two postulates proposed for the mechanism of gamete fusion, viral-type or SNARE (soluble *N*-ethylmaleimide-sensitive fusion attachment protein receptor)-type fusion. Viral-type fusion relies on the presence of a fusion peptide region found in fertilin- α , formerly PH30. The fusion peptide causes a destabilization of the lipid bilayer and fusion pores are created in a manner similar to the fusion mechanism of viruses. SNARE-type fusion has been proposed but has not been described in gamete fusion. In this mechanism, transport vesicles and subsequent fusion are directed by t- and v-SNAREs located on the target membrane and the vesicle, respectively.

Oocyte activation, in response to sperm–oocyte fusion, is the first step to incorporation of the sperm nucleus and the block to polyspermy. Two pathways are involved in oocyte activation. First, as the sperm fuses with the oocyte, soluble proteins or peptides capable of activating calcium channels in the

membrane are released into the oocyte. Second, G protein activation mobilizes intracellular calcium stores through inositol 1,4,5-triphosphate/diacylglycerol activity. The calcium transients or waves originate from the site of sperm entry and then propagate through the oocyte. Calcium waves signal the onset of oocyte activation and prepare the oocyte cytoplasm to receive the sperm nucleus. The calcium waves continue through pronuclear formation.

The first calcium waves are followed by the release of cortical granules, which remodel the oolemma and modify the zona. In addition, there is an increase in the perivitelline space. These changes preclude further sperm penetration of the zona pellucida or binding of the oolemma, thus blocking polyspermy.

PRONUCLEAR FORMATION AND SYNGAMY

The sperm nucleus is largely inactive at the time it enters the oocyte. During spermiogenesis, nuclear histones are replaced by protamines to increase the chromatin packaging and the sperm becomes transcriptionally repressed. After oocyte penetration, the sperm nucleus and chromatin must be made ready for fusion with its maternal counterpart. This requires decondensation of the sperm nucleus, which is initiated by degradation of the nuclear envelope by oocytic lipases. During decondensation, protamines bound to the DNA are replaced with maternally derived histones. Decondensation results in a swelling of the sperm head and a release of the sperm tail. The sperm pronucleus is completed by addition of a nuclear membrane consisting of oocytic lipid vesicles and nuclear pore complexes (Fig. 1D).

The newly formed pronucleus migrates centrally toward the simultaneously forming female pronucleus (Fig. 2). The migration is regulated by microtubule formation, which is directed by the microtubule organizing center (MTOC). The main component of the MTOC is the centrosome, which is paternally derived in the human. After the pronuclei have aligned centrally in the oocyte, the paternal pronuclear envelope is degraded and the maternal pronuclear envelope encompasses both fractions. Syngamy, the final step of the fertilization process, is completed with the alignment of homologous chromosomes, creating a unique genome for the embryo. During fertilization, the oocyte is in metaphase II; one copy of the maternal chromosomes is extruded in the second polar body and fertilization is complete.

CLINICAL IMPLICATIONS

Any abnormalities in the fertilization process may lead to infertility. The most common abnormality of fertilization is diminished capacitation, which results in a lower probability of a competent sperm binding and penetrating the zona. Although there is limited availability of diagnostic techniques to evaluate the other steps of fertilization, abnormalities of ZP3, the acrosome reaction, oocyte activation pronuclear formation, syngamy, and the block to polyspermy have all been reported.

Polyspermy, fertilization by more than one sperm, is a common fertilization error. The mechanisms to block polyspermy are less efficient in older women undergoing *in vitro* fertilization (IVF) and may be absent in some women. Most dispermic embryos undergo early demise and account for approximately 10% of detected spontaneous abortions. However, most polyspermic embryos will not implant or be detected when occurring *in vivo*. Triploid concepti may also be of maternal origin, as a result of abnormal meiosis in the oocyte. Some cases of triploidy result in hydatidiform moles, concepti with hyperplasia of the trophoblast. Moles are more likely to form if the triploidy is of paternal origin. Complete moles are diploid, but completely androgenic and lacking any fetal tissue.

Figure 2 The male and female pronuclei migrate toward the center of the oocyte through microtubule-assisted movement. The nucleoli are visible and align vertically.

Two techniques have greatly facilitated therapy of some types of fertilization failure. *In vitro* sperm capacitation techniques increase the percentage of capacitated sperm available for artificial insemination or IVF. Sperm capacitation techniques vary from simple washing, which is the removal of sperm from semen and resuspension in culture medium, to more complex preparations, including density gradient isolation of motile sperm and/or incubation in culture medium containing calcium ionophores, phosphodiesterase inhibitors, or a high concentration of albumin. The second therapy, intracytoplasmic sperm injection (ICSI), involves the direct injection of sperm into the cytoplasm of the oocyte during IVF. ICSI will effectively treat defects of capacitation, zona binding, the acrosome reaction, zona penetration, and oolemma-sperm fusion. Future therapies to treat fertilization failure may include such diverse procedures as cloning, oocyte cytoplasmic transfer, and artificial oocyte activation.

third zone, between the definitive and fetal zones of the adrenal, known as the transitional zone. After mid-gestation, transitional zone cells have the capacity to synthesize cortisol, and by 30 weeks gestation in the human, the definitive and transitional zones take on the structural and functional characteristics of the zona glomerulosa and fasciculata, respectively, of the adult adrenal cortex.

FUNCTIONAL DEVELOPMENT OF THE FETAL ADRENAL

During mid-gestation (16–22 weeks), the fetal adrenal lacks the enzyme 3 β -hydroxysteroid dehydrogenase/isomerase (3 β HSD), a critical enzyme for the *de novo* synthesis of glucocorticoid and mineralocorticoid hormones. By 28 weeks gestation, 3 β HSD is expressed within the definitive and transitional zones, and it appears that the fetal adrenal can synthesize and secrete cortisol from at least 30 weeks gestation. Interestingly, it appears that the transitional zone is the major source of cortisol production given that 3 β HSD and CYP17 both are localized within this zone, whereas CYP17 is not expressed in the definitive zone that, therefore, produces aldosterone during late gestation. 3 β HSD is not expressed in the fetal zone of the adrenal cortex throughout gestation. However, there is high level of expression of the enzyme CYP17 in the fetal zone; therefore, this zone produces large quantities of the androgenic C19 steroid dehydroepiandrosterone sulfate (DHEA-S), which is the major steroid produced by the primate adrenal during gestation. There is evidence from a range of experimental studies that adrenocorticotrophic hormone (ACTH) derived from the fetal pituitary plays a key role in the regulation of adrenal growth and in the zone-specific changes in steroid output during mid- and late gestation. For example, treatment with an agent, metyrapone (which increases fetal ACTH concentrations), results in induction of expression of 3 β HSD in the transitional zone of the fetal rhesus monkey adrenal gland. Furthermore stimulation of the hypothalamic–pituitary–adrenal axis results in a premature stimulation of hypertrophic growth and steroidogenesis in both the definitive and transitional zones of the fetal adrenal during late gestation. These data suggest that the ontogenetic changes in fetal pituitary ACTH secretion and in adrenal responsiveness to ACTH play an important role in the induction of 3 β HSD expression in the transitional zone.

ACTH also plays an important role in the marked growth of the fetal zone, which comprises 80 to 90%

of the gland during most of gestation and in the stimulation of DHEA-S secretion from this zone. Disruption of the fetal hypothalamo–pituitary axis in the human fetus results in a failure of the fetal zone to grow after 15 weeks gestation and dexamethasone administration to pregnant rhesus monkeys during late gestation, suppressing fetal hypothalamo–pituitary function and resulting in atrophy of the fetal zone. There is also substantial evidence that the actions of ACTH on fetal adrenal growth may be mediated by intra-adrenal growth factors, including insulin-like growth factor-2 (IGF-2).

After birth, there is a rapid remodeling of the fetal zone of the adrenal cortex; therefore, it has been suggested that the placenta may play a role in the differentiation, maintenance, or growth of this zone. The specific role of placental factors in the regulation of fetal adrenal steroid output is discussed in the next section.

THE FETAL ADRENAL, DHEA, AND THE PLACENTA

The primate placenta does not produce estrogens *de novo* from cholesterol and cannot convert pregnenolone or progesterone into C19 steroids because it lacks CYP17. Therefore, the human placenta produces estrogens by aromatization of the C19 precursors DHEA-S and the 16-hydroxyl form of DHEA-S, which are synthesized predominantly in the fetal adrenal and liver, respectively. In the placenta, sulfatase acts to produce DHEA and 16-hydroxy DHEA, which are then aromatized to estradiol, estrone, and estriol. Therefore, maternal estrogen levels rise in parallel with the increase in the output of DHEA-S from the fetal adrenal during late gestation. It has been demonstrated in the rhesus monkey that infusion of androstenedione at 0.8 of gestation results in an increase in maternal plasma estrogen concentrations and in premature delivery. The coadministration of the aromatase inhibitor 4-hydroxyandrostenedione prevented the androstenedione-induced changes in maternal estrogen concentrations and delivery. Because estrogen infusion alone does not induce premature birth, this suggests that it is the autocrine/paracrine functions of estrogen at its site of production that play critical and central roles in delivery in the primate.

THE FETAL ADRENAL, CORTISOL, AND THE PLACENTA

In most mammalian species, including the primate, there is an increase in fetal plasma glucocorticoid

concentrations during late gestation due to activation of the fetal hypothalamo–pituitary axis. Glucocorticoids play a key role in inducing maturational changes in the fetal lungs, kidneys, liver, and gut—therefore, in a successful transition from intrauterine life to extra-uterine life. Although cortisol is secreted by the fetal adrenal during late gestation, it is also produced locally within the placenta and a range of fetal tissues. The interconversion of biologically active cortisol and inactive cortisone is catalyzed by two isoforms of the enzyme 11 β -hydroxysteroid dehydrogenase (11 β HSD-1 and 11 β HSD-2). It has been proposed that the placenta can regulate fetal adrenal function through the regulation of the amount of maternal cortisol that crosses the placenta to the fetus via regulation of the activity of placental 11 β HSD-2. Studies in the baboon have shown that during mid-gestation there is an increase in the reduction of cortisone to cortisol in the placenta and have proposed that this would result in a decrease in fetal ACTH secretion (via increased negative feedback action of the maternally derived glucocorticoids on the fetal hypothalamo–pituitary axis) and that factors other than ACTH then stimulate the growth and function of the fetal zone. During later pregnancy, there is an increase in the oxidation of cortisol to cortisone in the baboon placenta, and this would allow ACTH concentrations to increase with an associated increase in adrenal growth and DHEA-S production. Interestingly, placental estrogens can stimulate increased conversion of cortisol to cortisone, and this would result in a positive feedback loop leading to an increased secretion of ACTH from the fetal pituitary, DHEA-S from the adrenal, and enhanced placental estrogen production.

During late gestation, there is also an increase in prostaglandin (PG) synthesis by the intrauterine tissues, and administration of PG synthase inhibitors suppress uterine activity and prolong gestation, whereas exogenous PGs stimulate uterine activity. It has been proposed that glucocorticoids may be one of several regulatory factors that stimulate the synthesis and secretion of intrauterine PGs. Although cortisol may be derived from the fetal adrenal, placental 11 β HSD-2 activity is decreased by PGs. Thus, an increase in PG output during late gestation would result in a decrease in the conversion of cortisol to cortisone in the placenta, resulting in a further increase in cortisol stimulation of PG production. **Figure 1** provides an illustration of the steroidogenic pathway.

Corticotropin-releasing hormone (CRH) is present in placental tissue and the decidua in increasing amounts during human pregnancy, and CRH concentrations also increase in umbilical cord blood

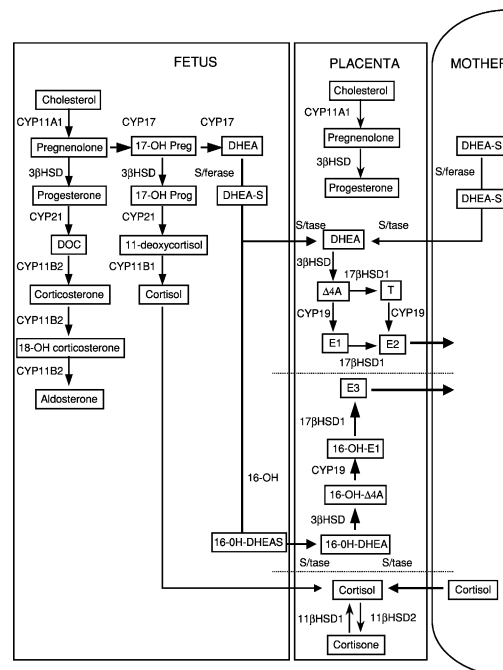

Figure 1 Schematic of the steroidogenic pathway describing the sites of synthesis of the key adrenal and placental steroids in the fetal–placental unit. DOC, deoxycorticosterone; 17-OH-Preg, 17-hydroxy-pregnenolone; 17-OH-Prog, 17-hydroxy-progesterone; DHEA, dehydroepiandrosterone; DHEA-S, dehydroepiandrosterone sulfate; D4A, androstenedione; T, testosterone; E1, estrone; E2, estradiol; E3, estriol; CYP11A1, cytochrome P450 cholesterol side-chain cleavage; CYP17, cytochrome P450 17 α -hydroxylase, CYP21, cytochrome P450 21-hydroxylase; CYP11B1, cytochrome P450 11 β -hydroxylase; CYP11B2, aldol synthase; CYP19, cytochrome P450 aromatase; 3 β HSD, 3 β -hydroxysteroid dehydrogenase; 17 β HSD1, 17 β -hydroxysteroid dehydrogenase type 1; 16-OH, 16-hydroxylase; S/ferase, DHEA sulfotransferase; S/tase, sulfatase.

samples. In addition, it has been shown that maternal plasma CRH concentrations are predictive of the subsequent length of gestation. One proposal is that placental CRH influences fetal adrenal growth and steroidogenesis and that, in turn, fetal cortisol can stimulate placental CRH production, creating a positive feedback loop between the placenta and the fetal hypothalamo–pituitary–adrenal axis. Importantly, it has been shown that CRH can act directly on the fetal zone of the fetal adrenal gland to increase the output of DHEA.

INTRAUTERINE STRESS AND THE FETO-PLACENTAL UNIT

There has been considerable recent interest in the impact of poor maternal nutrition and placental insufficiency on the functional interactions between the

fetal hypothalamic–pituitary–adrenal axis and the placenta. There is extensive epidemiological evidence that a suboptimal intrauterine environment or increased exposure to glucocorticoids *in utero* is associated with poor adult health outcomes. It has been proposed that prolonged maternal or fetal stress may be associated with enhanced exposure of the fetus to glucocorticoids of maternal or fetal origin that results in changes in an array of fetal tissues and the placenta. Experimental animal studies have demonstrated that maternal undernutrition results in increased maternal and fetal cortisol concentrations, but it is not clear whether such increases are sustained in poorly nourished pregnant women and their fetuses. Interestingly, restriction of placental growth and function results in an increase in fetal cortisol concentrations, and it is apparent that the increase in cortisol is not a consequence of activation of the fetal hypothalamo–pituitary axis. Plasma ACTH concentrations are not elevated and CYP17 expression is not up-regulated in the adrenals of growth-restricted fetuses. It has been proposed that placental factors such as PG E₂ may stimulate adrenal glucocorticoid output. This would represent an important mechanism for cross-talk between a failing placenta and the fetal adrenal and could set in motion a series of positive feed-forward

endocrine loops within the feto–placental unit designed to mature key fetal organs in preparation for a preterm delivery.

Table I Chromosomal Localizations of Human FGF Genes

| Gene | Localization |
|---------|--------------|
| FGF1 | 5q31 |
| FGF2 | 4q26-q26 |
| FGF3 | 11q13 |
| FGF4 | 11q13.3 |
| FGF5 | 4q21 |
| FGF6 | 12p13 |
| FGF7 | 15q15-q21.1 |
| FGF8 | 10q24 |
| FGF9 | 13q11-q12 |
| FGF10 | 5p12-p13 |
| FGF11 | 17p31.1 |
| FGF12 | 3q28 |
| FGF13 | X26 |
| FGF14 | 13q34 |
| (FGF15) | |
| FGF16 | — |
| FGF17 | 8p21 |
| FGF18 | 5q34 |
| FGF19 | 11q13.1 |
| FGF20 | 8p21.3-p22 |
| FGF21 | 19q13.1-qter |
| FGF22 | 19p13.3 |
| FGF23 | 12p13.3 |

closely linked to the FGF3 and FGF4 genes in orthologous chromosomal regions. These findings indicate that human FGF19 is the human orthologue of mouse Fgf15.

Human FGFs range in molecular mass from 17 to 34 kDa and have a conserved approximately 120-amino acid residue core with approximately 30 to 60% amino acid identity. Most FGFs (3–8, 10, 15, 17–19, and 21–23) have amino-terminal signal peptides and are readily secreted from cells. FGF9, FGF16, and FGF20 lack obvious amino-terminal signal peptides but are secreted nonetheless. These FGFs have a noncleaved amino-terminal hydrophobic sequence that is required for secretion. FGF1 and FGF2 also lack signal peptides but, unlike FGF9, FGF16, and FGF20, are not secreted. FGF1 and FGF2 may be released from damaged cells or by an exocytotic mechanism that is independent of the endoplasmic reticulum–Golgi pathway. FGF11 through FGF14 lack signal peptides and remain intracellular. It is unknown whether FGF11 through FGF14 interact with known FGFRs or function in a receptor-independent manner within cells.

Figure 1 Apparent evolutionary relationships of human FGF genes.

Most human FGF genes are scattered throughout the genome. The chromosomal locations of all except FGF16 are known (Table I). Several FGF genes are clustered within the genome. FGF3, FGF4, and FGF19 are located at 11q13 and are separated by only 40 and 10 kbp, respectively. FGF6 and FGF23 are located within 55 kbp at 12p13, whereas FGF17 and FGF20 map to 8p21–p22. These gene locations indicate that the FGF gene family was generated both by gene and by chromosomal duplication and translocation during evolution.

The apparently evolutionary relationships of the 22 known human FGFs are shown in Fig. 1. FGFs can be classified into several subgroups or subfamilies. Members of a subgroup share increased sequence similarity and biochemical and developmental properties. For example, members of the FGF8 subfamily (FGF8, FGF17, and FGF18) have 70 to 80% amino acid sequence identity, similar receptor-binding properties, and some overlapping sites of expression. Members of FGF subfamilies are not closely linked in the genome, indicating that the subfamilies were generated by gene translocation or genome duplication events but not by location duplication events.

Table II The Major Phenotypes of Fgf Knockout Mice

| Gene | Survival of null mutant | Phenotype |
|-------|-------------------------|---|
| Fgf1 | Viable | None identified |
| Fgf2 | Viable | Mild cardiovascular, skeletal, neuronal |
| Fgf3 | Viable | Mild inner ear, skeletal (tail) |
| Fgf4 | Lethal, E4–5 | Inner cell mass proliferation |
| Fgf5 | Viable | Long hair, angora mutation |
| Fgf6 | Viable | Subtle, muscle regeneration |
| Fgf7 | Viable | Hair follicle growth, ureteric bud growth |
| Fgf8 | Lethal, E7 | Gastrulation defect, central nervous system development, limb development |
| Fgf9 | Lethal, P0 | Lung branching, XY sex reversal |
| Fgf10 | Lethal, P0 | Multiorgan development, including limb and lung |
| Fgf12 | Viable | Neuromuscular phenotype |
| Fgf14 | Viable | Neurological phenotype |
| Fgf15 | Lethal, E9.5 | Not clear |
| Fgf17 | Viable | Cerebellar development |
| Fgf18 | Lethal, P0 | Skeletal development |

THE FGFR FAMILY

Most FGFs mediate their biological responses by binding to and activating cell surface receptors. The human FGFR gene family consists of four members, FGFR1 through FGFR4. FGFRs, transmembrane receptors, contain three extracellular immunoglobulin-like domains and two intracellular tyrosine kinase domains and share approximately 55 to 70% amino acid sequence identity. Alternative splicing of FGFR1 through FGFR3 generates two isoforms: the “b” and “c” isoforms. The FGFR protein family consists of seven members: FGFR1b, FGFR1c, FGFR2b, FGFR2c, FGFR3b, FGFR3c, and FGFR4. This alternative splicing event is regulated in a tissue-specific manner and dramatically affects ligand–receptor binding specificity. The “b” and “c” isoforms tend to be expressed in epithelial and mesenchymal lineages, respectively.

INTERACTION OF FGFS WITH HEPARIN OR HEPARAN SULFATE

FGFs interact with heparin or heparan sulfate proteoglycan. The interaction stabilizes FGFs, making them more resistant to thermal denaturation and proteolysis, and may severely limit their diffusion and release into interstitial spaces. The interaction also results in the formation of dimers and higher order oligomers. Although the biologically active form of FGF is poorly defined, it has been established that heparin is required for FGF to effectively activate FGFR. Additional studies have shown that heparin and/or

heparan sulfate act to increase the affinity and half-life of the FGF–FGFR complex.

THE FGF SIGNALING

FGFRs transmit extracellular FGF signals to cytoplasmic signal transduction pathways through tyrosine phosphorylation. By binding ligand, FGFRs dimerize and phosphorylate specific tyrosine residues on their own and others' cytoplasmic tails.

The phosphorylation of FGFRs triggers the activation of cytoplasmic signal transduction pathways, including the MAPK signaling pathway, the PLC γ signaling pathway, the Src signaling pathway, the Crk-mediated signaling pathway, and the SNT-1/FRS signaling pathway.

Fgf KNOCKOUT MICE

Many Fgf genes have been disrupted by homologous recombination in mice. The phenotypes range from very early embryonic lethality to subtle phenotypes in adult mice. The major phenotypes observed in Fgf knockout mice are shown in [Table II](#).

HUMAN DISEASES CAUSED BY FGF SIGNALING DISORDERS

Chondrodysplasia Syndromes

Achondroplasia (ACH) is characterized by deduced growth of long bones with proximal elements affected

more severely than distal elements. Hypochondroplasia (HCH) is characterized by mild short stature and shares some clinical features with ACH. Thanatophoric dysplasia (TD) is characterized by a very severe skeletal dysplasia and is clinically similar to homozygous cases of ACH. Most cases of these syndromes originated from amino acid substitutions of FGFR3. These mutations constitutively activate FGFR3.

Craniosynostosis Syndromes

Craniosynostosis is characterized by premature fusion of cranial sutures. Associated phenotypes in some craniosynostosis syndromes include malformations in the appendicular skeleton and nonskeletal phenotypes such as mental retardation. Mutations in FGFR1 through FGFR3 have been associated with craniosynostosis syndromes. However, most craniosynostosis syndromes are associated with mutations in FGFR2. Most of the mutations are missense or small in-frame insertions or deletions. These mutant FGFRs are dominant with gain-of-function mutations.

Tumor-Induced Osteomalacia and Autosomal Dominant Hypophosphatemic Rickets

Tumor-induced osteomalacia (TIO) is a renal phosphate wasting disorder resulting in low serum phosphorus concentration and osteomalacia. Removal of the tumors responsible for TIO normalizes phosphate metabolism. These tumors secrete a heat-sensitive molecule of approximately 25 kDa designated "phosphatonin" that specifically inhibits sodium-dependent phosphate transport in cultured renal proximal epithelial cells. Phosphatonin was found to be FGF23. Autosomal dominant hypophosphatemic rickets (ADHR) is also a renal phosphate wasting disorder resulting in low serum phosphorus concentration, rickets, and osteomalacia. The ADHR gene was also found to be the FGF23 gene with missense mutations.

Borjeson–Forssman–Lehmann Syndrome

The chromosomal location (Xq26) and tissue-specific expression pattern suggest that the FGF13 gene may be a causal gene for Borjeson–Forssman–Lehmann syndrome, an X-linked mental retardation syndrome.

Cancers

The expression of FGFs in human cancers has been documented on numerous occasions, and in many instances overexpression of mRNA and/or protein has been found in conjunction with amplification of the respective FGF genetic locus.

The oncogenicity of FGF3 and FGF4 genes following transfection into NIH 3T3 cells has been documented. These genes are not expressed in adult tissues. Amplification of these genes has been demonstrated in a variety of human cancers, including Kaposi's sarcoma and stomach tumors.

In prostate, bladder, and renal cancers, FGFs regulate the induction of metalloproteinases that degrade extracellular matrix proteins, thereby facilitating tumor metastasis. Probably because of their potent angiogenic properties, aFGF and bFGF have received the most attention. However, there is increasing evidence that other FGFs also play crucial roles in the tumors. The recent identification in transitional cell carcinoma of a high frequency of mutations in FGFR3 predicted to activate the kinase activity of the receptor indicates a potential role as an oncogene in the urothelium.

It has become well accepted that solid tumors must create a vascular system for nutrient delivery and waste removal to grow appreciably. Angiogenesis is critical to the progression of gliomas. A role for vascular endothelial growth factor in glioma angiogenesis has been demonstrated convincingly. However, FGFs are also expected to influence glioma angiogenesis by directly stimulating endothelial cell proliferation and/or by mediating the expression of key proteases on endothelial cells necessary for angiogenesis.

FGFS AND FGFRS AS THERAPEUTIC TARGETS IN HUMAN CANCERS

Because FGFs and/or FGFRs have been identified in tumor vasculature and supporting stromal cells as well as in tumor cells, FGF and FGFR targeting reagents may be useful for targeting tumor vasculature/stroma and tumor cells. A variety of FGF-targeting reagents have been expected to inhibit tumor growth, including antisense FGF oligonucleotides, soluble FGFRs, neutralizing antibodies, peptides corresponding to FGF functional domains, and small molecules such as pentosan polysulfate, suramin, and Suradista. FGFR-targeting reagents, including antisense FGFR oligonucleotides, dominant negative FGFRs, toxin-conjugated anti-FGFR antibodies, and small molecule FGFR protein kinase inhibitors, have also been expected to inhibit tumor growth.

to 46 times greater risk for lower extremity amputation than persons without diabetes. Foot wounds are the proximate cause of 90% of these nontraumatic amputations. In addition to the physical and emotional problems they cause, amputations have been associated with an increased mortality in the subsequent 3 years. By 2025, there will be more than 300 million persons with diabetes worldwide, emphasizing the urgency of this problem.

Financial Cost

As with the clinical morbidity, the financial cost of treating diabetic foot ulcers is substantial. One database of approximately 7 million patients followed over a 2-year period revealed that the total direct cost for treated diabetic foot ulcers was \$16 million or an average of \$4595 per ulcer episode. Another study identified attributable costs for a 40- to 65-year-old male with a new foot ulcer as \$27,987 for the 2 years after its occurrence. Studies of diabetes-related lower extremity amputation in Europe and the United States over the past decade have reported direct related costs ranging from \$20,000 to \$27,000. Indirect costs, such as loss of productivity and long-term care at skilled facilities or by family members, may double the total cost to society.

PATHWAYS TO ULCERATION AND AMPUTATION

Risk Factors for Foot Problems

Many factors, especially poor foot care and inappropriate footwear, increase the risk of foot ulceration. Most studies have shown that foot lesions generally arise from a combination of three factors. Peripheral neuropathy (the insensate foot) is the most important and can be identified by the patient's inability to feel 10 g of pressure applied with a Semmes-Weinstein monofilament. The other two factors are foot deformity, largely related to motor neuropathy, and repetitive moderate pressure or stress. In a case-control model assessing 225 diabetic patients, Lavery and co-workers noted that the presence of neuropathy alone increased the risk of ulceration 1.7-fold, neuropathy and deformity increased the risk 12.1-fold, and neuropathy, deformity, and a history of previous ulcer or amputation increased the risk of developing another ulcer approximately 36-fold. The major precipitating cause of foot amputation is an ulceration that fails to heal. An additional contributing factor is the presence of arterial vasculopathy, most frequently involving the

infrageniculate blood vessels. Accelerated atherosclerosis associated with diabetes can lead to critical foot ischemia that impairs wound healing and infection resolution.

The Role of Infection

All open wounds are colonized by microorganisms, but when the lesion is complicated by clinical signs and symptoms of infection (which occurs in perhaps half the cases), the likelihood of a poor outcome greatly increases. Diabetic foot ulcers with concomitant infection and ischemia are up to 90 times more likely to result in a high-level amputation than wounds without those two additional risk factors. Infection is usually caused by aerobic gram-positive cocci, particularly staphylococci; chronic wounds, especially those previously treated with antibiotics, may become infected with aerobic gram-negative rods and anaerobes. Deep infections, which often involve the underlying bone, can be both limb- and life-threatening. Diagnosing bone infection can be difficult and may require imaging procedures (preferably magnetic resonance studies) or bone biopsy.

TREATING FOOT WOUNDS

Once an ulcer develops, it is critical to get it healed as quickly as possible. This requires attention to local, systemic, and social or psychological issues. The wound must be carefully assessed for neurologic, vascular, and infectious complications. Some patients will need to be hospitalized, whereas others can be safely treated at home. Almost all wounds will require some debridement of necrotic material and callus; some may require further surgical intervention (e.g., incision and drainage, or bone resection). Infected wounds should be cultured (preferably by sending a sample of tissue, not a swab) and empiric antibiotic therapy should carefully selected. If the limb is ischemic, a vascular evaluation may be needed. Appropriate dressings must be selected, based on the type of wound, and the patient or caregiver must be instructed on how to properly change them. Limb edema and dry skin should be treated. Any systemic metabolic problems (e.g., poor glycemic control, malnutrition) should be addressed. The patient should never walk out of the office in the same shoe that caused an ulceration; proper footwear and methods or devices to offload the involved site are crucial to healing the wound. Foot lesions present the provider with a teachable moment to instruct the patient on

the causes of foot problems and how they may be prevented.

HOW ULCERS AND AMPUTATIONS CAN BE PREVENTED

Intervention at any point in the critical pathway to ulceration may prevent the serious foot complications of diabetes. For instance, reducing foot pressure points with appropriate footwear or orthoses and modulating activity should help avoid ulceration. Treating infected wounds with appropriate (and not excessive) antimicrobial therapy should prevent deeper infections. Improving blood flow (e.g., with a distal bypass procedure) to a critically ischemic wound should lessen the likelihood of amputation. Other key preventative factors include the following: regular foot inspection by the patient and health care providers; for patients with risk factors for foot ulcerations, regular foot examination and care by primary care and podiatric providers; wearing appropriate shoe gear; and, in some instances, undergoing judicious surgical interventions to reduce deformity may be helpful. Lower extremity ulcerations and amputations in persons with diabetes take a terrible toll on the individual and on the world's health care systems, but the good news is that they are almost entirely preventable with appropriate care and education.

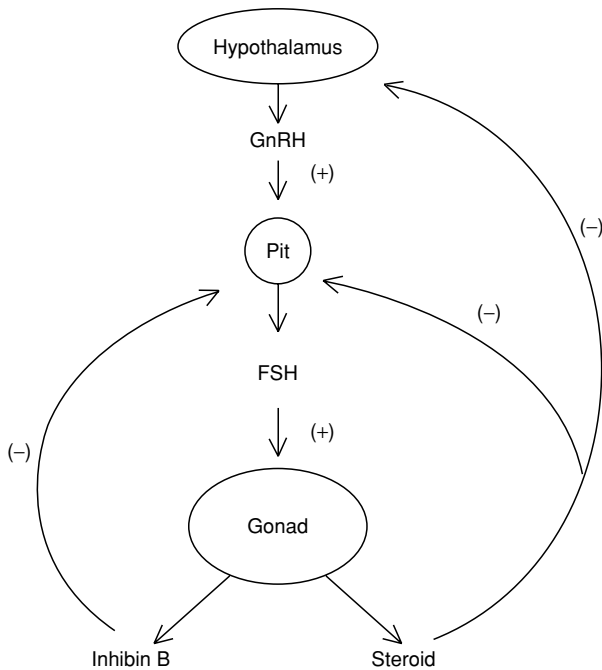

Figure 1 This schematic is a general introduction to the concept of the regulation of FSH secretion and action. The hypothalamus secretes GnRH, which acts on the pituitary gland (Pit) to stimulate the secretion of FSH. FSH stimulates (+) the gonad to secrete steroids that act on the hypothalamus, pituitary gland, or both, to inhibit (-) the secretion of FSH. FSH also stimulates (+) the gonad to synthesize a protein, inhibin B, that inhibits (-) the secretion of FSH by the pituitary gland.

by the hypothalamic polypeptide, GnRH. Only one hypothalamic secretagogue stimulating the synthesis and secretion of both gonadotropins has been identified, although two releasing hormones, one for each gonadotropin, were initially postulated and the designation of GnRH rather than luteinizing hormone-releasing hormone is used throughout this article. The secretion of this hypothalamic secretagogue is episodic and regular. GnRH is released by neurons that terminate on the blood vessels running along the pituitary stalk. These vessels constitute a specialized form of the circulatory system, called a portal system. Portal systems are characterized as special veins that arise in one organ system and terminate in another before returning to the heart. They carry the pulses of GnRH to the gonadotropes in the pituitary gland and stimulate the synthesis and release of FSH. Accordingly, FSH is also released from the pituitary gland in pulses. Changing the pattern of the GnRH pulses results in coincidental changes in the pattern of pulsatile secretion of FSH. GnRH binds to a G protein-coupled membrane receptor on the surface of the gonadotrope, activating the $G_{q/11}$ proteins that, in

turn, stimulate phospholipase C. This enzyme generates inositol-1,4,5-triphosphate and diacylglycerol. The increased levels of these intracellular messengers activate protein kinase C (PKC) and increase intracellular calcium also. PKC and calcium regulate the expression of the β -subunit gene, whereas secretion of FSH is regulated by the increase in intracellular calcium.

RECEPTOR AND RECEPTOR DEFECTS

The receptor for FSH is found only in the gonads and has been described in several mammalian species. The FSH receptor (75–80 kDa) is a member of the family of G protein-coupled receptors. Like all members of this family of receptors, it is composed of three domains, a transmembrane domain, an extracellular domain, and an intracellular domain. The transmembrane domain is composed of seven hydrophobic stretches of 20–25 amino acids that form α -helices traversing the cellular membrane alternating between intracellular and extracellular loops. The extracellular domain of the receptor binds FSH, which, in turn, causes the intracellular domain to activate the G_s protein. This is the first step in an intracellular cascade that continues with activation of the enzyme adenylyl cyclase and production of cyclic AMP (cAMP). In turn, cAMP-dependent protein kinase (PKA) is activated and phosphorylation of the transcription factor CREB (cAMP regulatory element-binding protein) leads to the expression of genes coding for several factors regulating the cellular functions of proliferation, differentiation, and survival. This pathway has been expanded to include various isoforms of adenylyl cyclase, phosphodiesterase, and anchoring proteins of PKA. Other transcription factors, e.g., stimulatory protein 1, upstream stimulatory factor, estrogen receptor- α , and estrogen receptor- β , have been shown to be activated by high intracellular concentrations of cAMP. In addition, CREB can be phosphorylated by kinases other than PKA.

The gene of the FSH receptor has 10 exons, the last encoding both the transmembrane and intracellular domains. Only a few mutations have been identified. A Finnish family has a mutation in the FSH receptor gene that prevents its transport to the cellular membrane. The women of this family have amenorrhea and atrophic ovaries with follicles that do not develop beyond primary follicles. The men homozygous for this mutation are normally virilized and have sufficient testosterone to initiate and maintain spermatogenesis. A second mutation leads to a partially

defective receptor. These women also present with primary amenorrhea and the ovaries are of normal size, but folliculogenesis proceeds only to antral follicles. The larger follicles degenerate. In addition to these mutations in the receptor, mutations in the gene for the FSH β -subunit in two men have been reported. These men had small testes and were azoospermic. The difference in the phenotype of men with inactivating mutations of FSH or its receptor remains an unresolved paradox.

ACTION IN THE OVARY

FSH, as the full name suggests, acts on the ovary by stimulating folliculogenesis. Before the role of FSH in the ovary is discussed, a brief description of the ovarian cycle is necessary. During fetal development of the female mammal, the primitive germ cells in the ovary enter meiosis and arrest in the prophase of meiosis I. Each oocyte is surrounded by a single layer of cells, and soon after formation, these primordial follicles enter a resting phase. During fetal life in primates and ruminants and within the first 2 weeks after birth in rodents, some of the primordial follicles are activated and become primary follicles. The mechanisms that stimulate the primordial follicles to initiate folliculogenesis are unknown, but are clearly independent of gonadotropin action. Two layers of somatic cells develop around the oocyte. The outermost layer is composed of theca cells that are separated from the innermost layer, comprising granulosa cells, by a basement membrane. Both types of cells proliferate, increasing the size of the follicle until a fluid-filled cavity, or antrum, forms in the layers of the granulosa cells. The mature, or antral, follicle ruptures, marking the end of folliculogenesis.

The rupture of the follicle releasing the oocyte and some of the granulosa cells surrounding it is called ovulation. During the periovulatory period, anti-inflammatory factors are produced and appear to aid in rapid healing and vascularization of the ruptured follicle. The theca and granulosa cells remaining in the ruptured follicle differentiate into luteal cells, forming the corpus luteum that characterizes the luteal phase of the ovarian cycle. If no pregnancy occurs, after a finite time specific to each species, the corpus luteum dies, marking the end of the luteal phase. The rapid involution of the corpus luteum is called luteolysis and is regulated by specific factors. Luteolysis is necessary before a subsequent ovarian cycle can begin. The follicular phase, ovulation, luteal phase, and luteolysis constitute the ovarian cycle and

FSH plays an important role only during the first phase of the ovarian cycle, namely, folliculogenesis.

The theca cells of the developing ovary produce androgens in response to LH. FSH stimulates the granulosa cells to produce the enzyme aromatase, which converts the androgens produced by the theca cells into estradiol (Fig. 2). As the number of granulosa cells increases by mitosis, a greater amount of estradiol is produced by the developing follicle. FSH also increases the number of LH receptors on theca cells. Estradiol inhibits the secretion of FSH and LH. With the increase in LH receptors on the theca cells of one or more follicles in the presence of decreased LH, only those follicles with sufficient gonadotropin stimulation will continue folliculogenesis. As the follicle enlarges, a cavity forms around the oocyte so that it is surrounded by a few layers of granulosa cells and fluid, but a peduncle of granulosa cells remains

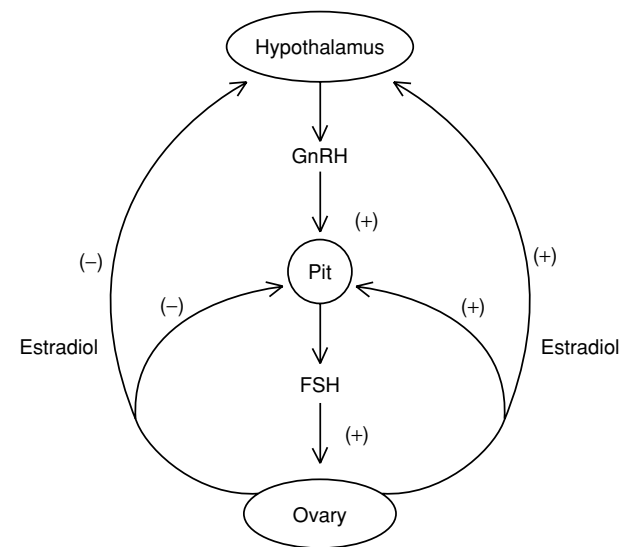

Figure 2 The feedback mechanism regulating FSH in the female mammal. The hypothalamus secretes GnRH, which acts at the pituitary gland (Pit) to stimulate (+) the secretion of FSH. FSH stimulates the granulosa cells of the ovarian follicle to proliferate and synthesize the steroidogenic enzyme aromatase. This enzyme converts androstenedione, produced by the theca cells of the follicle under LH stimulation, into estradiol. During early folliculogenesis, estradiol acts at the hypothalamus, pituitary gland, or both, to inhibit (-) the secretion of FSH (left-hand side of figure). At the end of folliculogenesis, the high concentrations of estradiol in the blood produced by the large graafian follicle cause an abrupt release of LH (not shown) and FSH (right-hand side of figure). The abrupt release of FSH may result from a direct action of the steroid at the pituitary or indirectly at the hypothalamus to increase the secretion of GnRH that, in turn, causes a marked increase in pituitary secretion of the gonadotropins. The former action of the estradiol is an example of positive feedback.

attached to the rest of the follicle. Once the level of circulating estradiol produced by the graafian follicles is elevated, the steroids cause an abrupt release of LH and FSH, which results in ovulation, that is, the extrusion of the oocyte and the granulosa cells immediately surrounding it, which is subsequently referred to as the oophorus cumulus. Once ovulation has occurred, the role of FSH is greatly diminished and the formation of the corpus luteum and maintenance of the endometrium of the uterus are under the influence of LH.

ACTION IN THE TESTIS

The role of FSH in regulating spermatogenesis in adult mammals has been controversial for several decades. FSH appears to have little direct role in regulating spermatogenesis in the testes of adult male rodents. It, however, is the primary determinant of the spermatogenic capacity of the rodent testis. This capacity is defined as the number of sperm potentially produced by the male gonad and intuitively this must directly relate to the number of spermatogenic stem cells and the capacity of the structure of the gonad to nourish and support the progeny of these stem cells. Before further discussion, a brief description of Sertoli cell proliferation and establishment of the seminiferous epithelium is presented.

The Sertoli cells of the mammalian testis are the only somatic cells in the seminiferous epithelium and are known to proliferate only during fetal and peripubertal development in rodents. A third period of Sertoli cell proliferation occurs during infancy in higher primates. After these somatic cells have attained a population size associated with adulthood, proliferation ceases and the cells terminally differentiate. The mature Sertoli cells serve to organize and nourish the germ cells that make up the remainder of the cell types in this epithelium. Moreover, they are the mediators of the action of FSH because they are the only cells in the male that have receptors for FSH. FSH is the hormone that stimulates Sertoli cell proliferation in the rodent testis, but, in primates, both FSH and LH are equally effective in stimulating the proliferation of Sertoli cells. Because the Sertoli cells provide the nutrients and structural support to spermatogenesis, it was immediately recognized that FSH regulates the spermatogenic capacity of the testis. In contrast to this situation in rodents, FSH plays a more direct role in regulating spermatogenesis in higher primates. Before this role is discussed, a brief review of spermatogenesis is presented.

Spermatogenesis is a series of processes comprising three phases: stem cell renewal, germ cell proliferation, and spermiogenesis. Stem cell renewal is the mechanism that guarantees that a large and undiminishing number of undifferentiated germ cells are continually available for the subsequent waves of spermatogenesis. The spermatogenic stem cells are called type A spermatogonia and, depending on the species, several type A spermatogonia have been identified. In addition to renewing their population, the type A spermatogonia also produce more differentiated spermatogonia, often referred to as type B spermatogonia. These latter cells, depending again on species, may produce two or more generations of differentiated spermatogonia. The differentiated spermatogonia in the final generation divide and produce the primary spermatocytes. These germ cells enter prophase of meiosis I, lasting from 1 to 2 weeks, and the primary spermatocytes synthesize fourfold more DNA than is found in a somatic cell. During the remainder of the long prophase, the homologous chromosomes form bivalents and crossing over of the genetic material occurs. The primary spermatocytes rapidly complete meiosis I, producing two haploid secondary spermatocytes each, but with twice the haploid content of DNA. The secondary spermatocytes enter meiosis II and form the haploid spermatids containing the haploid amount of DNA, often referred to as C. The spermatids enter spermiogenesis, during which the nuclear contents condense, the acrosome is formed, a tail is produced, and the amount of cytoplasm is reduced. This process requires approximately 2 to 3 weeks to complete.

The central role of the pituitary to stimulate spermatogenesis in adult rodents and primates was established nearly 60 years ago by Phillip E. Smith. Surgical removal of the pituitary gland, hypophysectomy, of adult rats led to a decrease in testicular weight and the seminiferous epithelium comprised Sertoli cells and germ cells as mature as spermatids. Hypophysectomy of adult rhesus monkeys resulted in a precipitous decline in testicular size associated with the complete regression of the seminiferous epithelium to the extent that the tissue comprised only Sertoli cells and type A spermatogonia, that is, only stem cells. Additional experiments on adult rodents and monkeys have confirmed Dr. Smith's earlier observation. Moreover, his observation was extended by demonstrating that replacement of testosterone in hypogonadotropic hypogonadal rhesus monkeys resulted in a stimulation of testicular growth to approximately 60% of the pretreatment size. The gonadal growth was due primarily to the stimulation of

spermatogenesis by androgen, but morphometric analysis of the seminiferous epithelium of the monkeys revealed that the smaller testicular size was accounted for by a deficit in the numbers of all type B spermatogonia. Replacement of FSH in testosterone-treated hypophysectomized adults resulted in a greater number of all four generations of type B spermatogonia. These results led to the conclusion that testosterone alone stimulates spermatogenesis, but FSH is necessary to restore spermatogenesis completely. This action of FSH is posited to be the rescue of type B spermatogonia from programmed cell death.

Unilateral orchidectomy in adult macaques results in a compensatory growth of the remaining testis. The number of Sertoli cells per testis was identical in the gonad removed at the time of unilateral orchidectomy

and the gonad that remained in the animal for 45 days. The number of all germ cells more mature than type Ap spermatogonia was greater in the remaining testis than in the removed testis. Moreover, the removal of one testis was occasioned by a transient decline in testosterone that in turn led to a transient increase in LH. By 4 days after surgery, the testosterone and LH concentrations were restored to those measured prior to surgery. The removal of one gonad in these primates was marked also by a decline in inhibin B, which is secreted by Sertoli cells into the circulatory system. The concentrations of FSH in the circulation increased, confirming the role of inhibin B in the negative feedback on FSH secretion by the pituitary gland of the primate (Fig. 3). The role of inhibin B is less clear in rodents and the steroid testosterone may play a greater role in the regulation of FSH secretion in those species (Fig. 4).

In contrast to the results reported above, other investigators have presented results indicating that FSH increases the number of germ cells in the primate testis indirectly, by acting on type Ap spermatogonia, the renewing stem cells. The administration of FSH to adult macaques resulted in an increase in the type Ap spermatogonia in the seminiferous epithelium, but an analysis using the kinetics of spermatogenesis does not

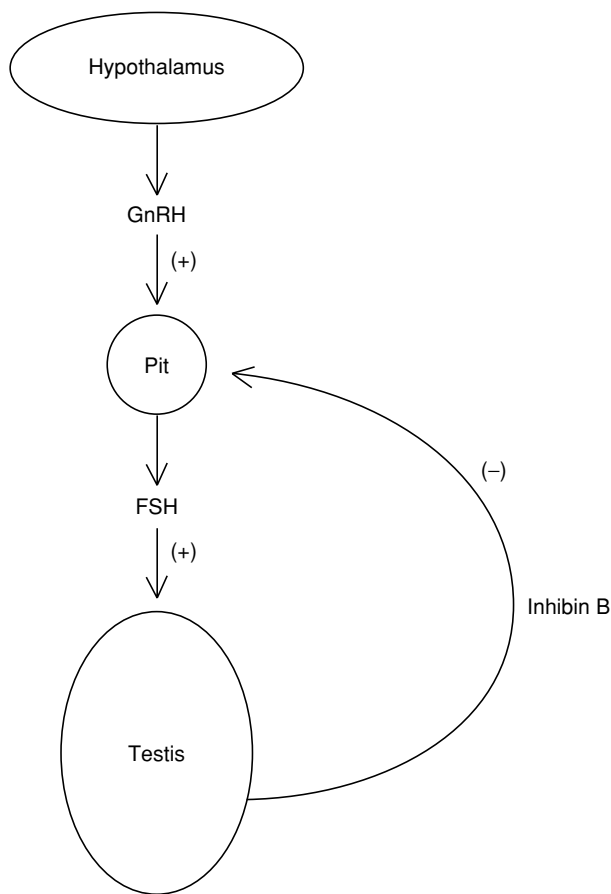

Figure 3 The regulation of FSH secretion in the male primate. GnRH, secreted by the hypothalamus, stimulates (+) the pituitary gland (Pit) to synthesize and release FSH. FSH is transported by the circulatory system to the testis, where the hormone binds to receptors on the Sertoli cells and stimulates the transcription and translation of several gene products, including the protein hormone, inhibin B. In male primates, inhibin B acts at the pituitary gland to inhibit (-) FSH secretion.

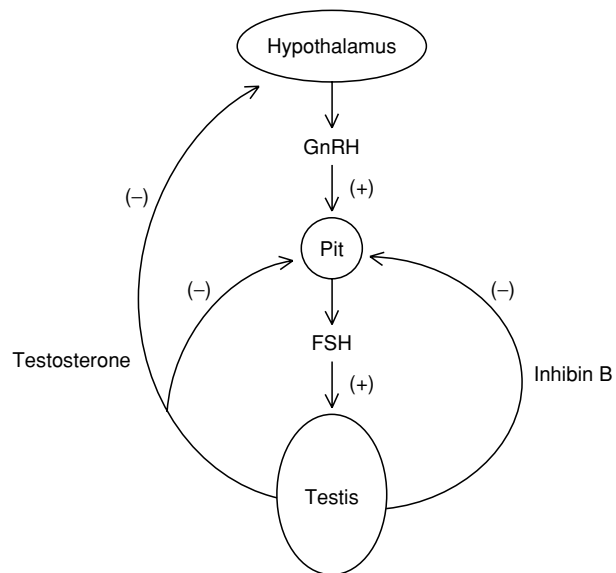

Figure 4 The negative feedback (-) of the androgen testosterone and the protein inhibin B on FSH secretion in male mammals. As explained in the legend to Fig. 3 and in the text, inhibin B from the Sertoli cells of the testis inhibits the secretion of FSH by the pituitary (Pit) in higher primates (right-hand side of figure). In other male mammals, this action of inhibin B may be less important and the steroid testosterone may play the major role in regulating FSH secretion (left-hand side of figure).

support the notion that the increase in germ cell production is due to an action of FSH to increase the number of Ap spermatogonia.

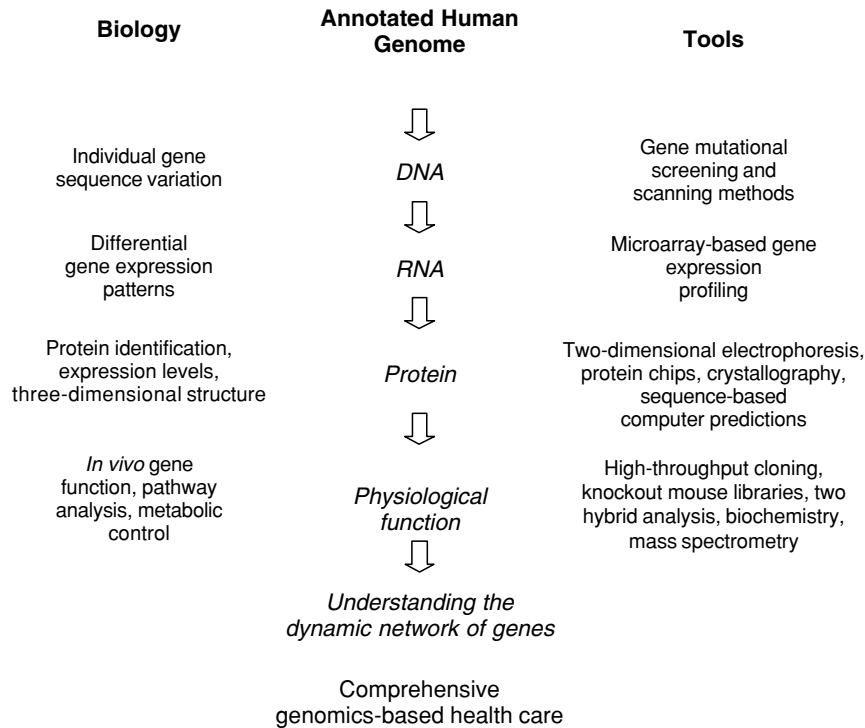

Figure 1 Schematic representation of the various levels of functional genomics as discussed in the text.

GENETIC VARIATION

First-level functional genomics activities on an annotated genome mainly involve individual genetic variation and its association with particular phenotypes. The most common type of such variation is called a single-nucleotide polymorphism (SNP) and accounts for heritable interindividual differences such as susceptibility to disease and response to medication. Because most of the common human diseases are now age related, the identification of SNPs in genes and their association with aging-related phenotypes is important. Assessing the genetic component of aging will contribute to our understanding of functional diversity in aging human populations. In addition to environmental factors, many distinct aging-related phenotypes involving functional decline or age-related disease risk are likely to have a genetic component. Similarly, healthy aging could also have a genetic component. Examples of the latter are unusual longevity, extended preservation of function such as cognitive or vascular function, and resistance to age-related disease. Genetic control of normal aging in humans is likely to be determined by SNPs in many genes involved in multiple functional pathways. The challenge is to identify these gene variants and to apply the tools of modern bioinformatics to associate combinations of

alleles with particular phenotypes. This is illustrated by some recent work in our laboratories.

SNP HAPLOTYPE ANALYSIS OF AN AGING-RELATED DISEASE

Methods that are capable of analyzing entire gene-coding regions for unknown mutations and polymorphisms are still rare. Indeed, semiautomated nucleotide sequencing, according to the principle originally described by Sanger and colleagues, is still the gold standard. Despite some obvious advantages of DNA sequencing, including its high level of automation and ability to provide complete information about the location and nature of sequence variants, its high cost makes it less suitable as a primary DNA variation detection method in large genetic epidemiological studies. Two-dimensional gene scanning (TDGS), developed in our laboratory, is a prescreening method based on denaturing gradient gel electrophoresis (DGGE), allowing for the separation of DNA fragments differing by as little as 1 bp on the basis of differences in their melting temperature in a two-dimensional format (Fig. 2). TDGS has been applied to detect mutational variants in a number of large human genes as well as the mitochondrial genome. With the recent introduction

Figure 2 Schematic representation of the various steps involved in two-dimensional gene scanning. The target regions, such as gene coding regions, are amplified by polymerase chain reaction (PCR) in two steps. First, a long-distance PCR generates overrepresentation of the target regions as part of large PCR amplicons (i.e., about 10 kb). Then, using the large amplicons as template, target regions of 250 bp on average are amplified in an extensive multiplex PCR, with the primers chosen in a way as to create optimal conditions for detecting all possible sequence variants using the denaturing gradient principle. For this purpose, it is also essential that all primers be attached to a GC-rich fragment approximately 40 bases long. At the end of the PCR process, all amplicons are heteroduplexed by a round of complete denaturation and renaturation and then are separated based on size and base pair sequence by a denaturing gradient gel electrophoresis (DGGE). The presence of sequence variation is revealed by four different double-stranded fragments: two homoduplex molecules and two heteroduplex molecules.

of high-speed, two-dimensional electrophoresis with multicolor fluorescent detection, TDGS has become at least an order of magnitude more cost-effective than nucleotide sequencing, at equal accuracy, for large-scale SNP discovery and genetic testing.

Using TDGS, we have compared SNP haplotypes of Korean diabetes patients with normal controls in a case-control study in collaboration with Kyong Soo Park of Seoul National University in Korea. Mitochondrial DNA (mtDNA) variation has emerged as a candidate susceptibility factor in aging-related degeneration and disease, including premature aging, cancer, diabetes mellitus, Parkinson's disease, Alzheimer's disease, epilepsy, sensory losses (hearing and vision), and a variety of syndromes involving the muscles and the central nervous system. MtDNA is a maternally inherited, 16,568-bp haploid genome that encodes 13 subunits of the respiratory chain complexes. Its mutation rate

is 10 times faster than that of the nuclear genome, and this high mutation rate is attributable partly to the lack of an effective DNA repair mechanism and partly to the constant exposure of mtDNA to oxygen-free radicals from oxidative phosphorylation (OXPHOS). Polymorphisms in mtDNA may cause subtle differences in the encoded proteins and, therefore, subtle changes in OXPHOS activity and free radical production. Therefore, variant mtDNA sequences may predispose to an earlier onset of degenerative cellular processes or could be beneficial. Such SNP variation may exert its effect, for example, by influencing the energy production or by interacting with the nuclear genome.

We used a TDGS test for mtDNA that covers all of the regions implicated in human diseases. The test involves a two-step multiplex polymerase chain reaction (PCR) amplification: a long-distance PCR to

amplify the entire mitochondrial genome, except for the D-loop region, from total genomic DNA, which then serves as a template for the amplification of 25 short PCR fragments in two multiplex groups. Because mtDNA is a maternally inherited haploid genome, TDGS cannot be used to detect heterozygotes (heteroduplexes) unless there is heteroplasmic variation. To detect all possible SNPs in mtDNA using TDGS, we chose to use a reference DNA to create heteroduplexes with the individual DNA samples to be screened to detect variants that are different from the reference DNA. Our reference DNA sample was chosen on the basis of its lack of heteroplasmy (Fig. 3) and was fully sequenced. After PCR, the amplicons of the reference DNA were combined with the amplicons of an individual DNA sample and then were heteroduplexed by a round of complete denaturation and reannealing. TDGS analysis identified heteroduplexed mtDNA fragments

(amplicons) resulting from sequence differences between the reference DNA and the individual DNA (ellipses in Figs. 3A–G).

After analyzing 195 Korean individuals (65 normal controls and 130 patients with type 2 diabetes), a total number of 215 unique variations were identified, approximately 50% of which were previously unknown novel variants, indicating the highly polymorphic nature of mtDNA. In addition, we found 10310A→G, a synonymous SNP in the ND3 gene-coding region, significantly less frequently in diabetes patients (44.6%) than in normal controls (96.9%, $P = 1.1 \times 10^{-14}$). Based on 9 common SNPs with a frequency of more than 10% in the two groups (Table I), mtDNA haplotypes were determined. A total of 15 common haplotypes were detected in the two groups, and a total of 18 rare haplotypes were group specific (“others” in Fig. 4) (data not shown). The frequencies of 3 haplotypes (haplotypes 6, 8, and 11) differed

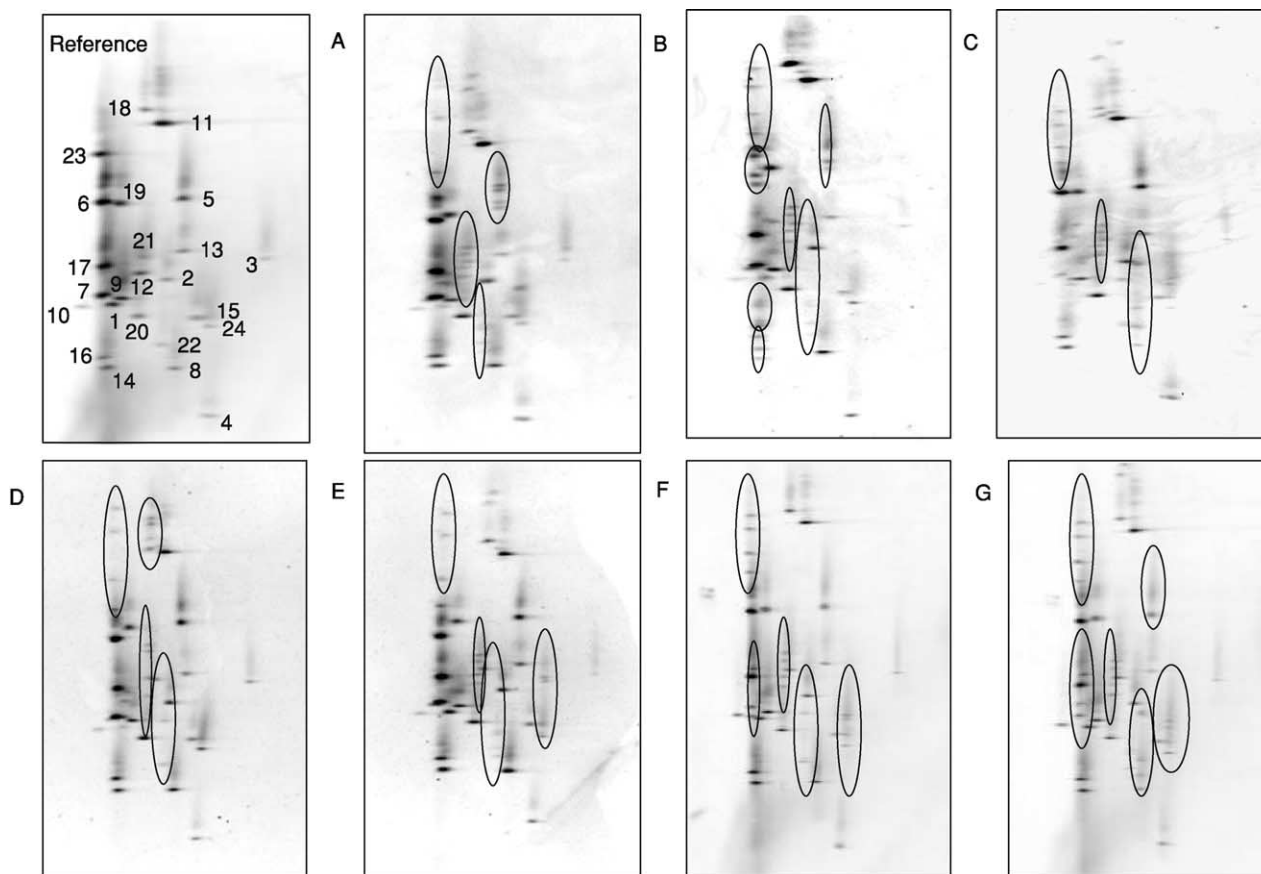

Figure 3 Detection of mitochondrial DNA variation by two-dimensional gene scanning (TDGS). To detect all possible SNPs in mtDNA by TDGS, a reference DNA, chosen on the basis of its lack of heteroplasmy and fully sequenced, was used to create heteroduplexes with the individual DNA samples to be screened to detect variants that are different from the reference DNA (A–G). The ellipses contain heteroduplexed mtDNA fragments (PCR amplicons) resulting from sequence differences between the reference DNA and individual DNAs.

Table I Haplotyping of Mitochondrial DNA Variation

The mtDNA haplotypes were determined based on nine common SNPs with more than 10% minor allele frequency in the two groups. The nine common SNPs used to generate the 15 haplotypes are indicated as coding region, amino acid change, and position and nature of the nucleotide change. Cyt b, cytochrome b; ND2, NADH dehydrogenase subunit 2; NC, noncoding intergenic region; ND3, NADH dehydrogenase subunit 3.

significantly between the two groups. Haplotype 8 ($P=0.0000025$) is significantly more frequent in normal controls than in diabetes patients, whereas haplotypes 6 ($P=0.0000042$) and 11 ($P=0.0172$) are significantly less frequent in normal controls than in diabetes patients (Fig. 4).

This example illustrates how a functional genomics approach can be built on the fruits of the human genome project by associating gene variants with medically relevant phenotypes of aging, in this case type 2 diabetes. A logical next step is to obtain information about the mechanistic basis of the functional

significance of such gene variants. When, as is the case in our example, the SNP variants occur in a gene-coding region and are nonsynonymous, it would be relevant to study the possible effect of the deduced protein alteration. This can be done by predictive modeling and biocomputational means as well as by using binding assays such as protein chips to study possible alterations in protein folding and protein-protein or protein-DNA interactions. Finally, SNP variants in gene regulatory regions such as promoter regions could affect the level of expression. Variation in gene expression levels involves the second and third

Figure 4 The frequency of common mitochondrial DNA haplotypes in normal controls and diabetes patients.

Table II Applications of Functional Genomics in Health Care

| Application | Purpose | Benefit |
|---|---------------------------------------|---|
| Gene-based diagnostics | Disease susceptibility/drug responses | Screening, specific preventive measures |
| Increase predictability of preclinical and clinical testing | Accelerate drug development | More and better drugs |
| Disease subtype-specific drugs | Refine therapy | High-quality personalized medicine |

levels of functional genomics analyses and has its own technological requirements.

GENE EXPRESSION

One level down from the DNA of the genome is the analysis of the entire message of each cell type. Whereas SNP maps can help to identify sequence variation in groups of genes, including their regulatory sequences, gene expression patterns are a quick way in which to bring the different gene functions together in patterns characteristic for a specific phenotype, including disease. The most popular vehicle for gene expression profiling is the microarray chip, in which hundreds to thousands of cDNAs or oligonucleotides specific for parts of individual mRNAs are attached to a glass slide. Hybridization of such slides with labeled RNA probes obtained from the tissues of interest permits the analysis of changes in expression of a large number of genes simultaneously.

As time goes on, it is recognized more and more frequently that analyzing genes and their mRNAs will not be sufficient to understand cell function and dysfunction. Many alterations in proteins are not reflected in corresponding changes in mRNAs, for example, due to posttranslational modifications. This has resulted in a return to protein analysis, most notably to the two-dimensional protein separation system first reported by Patrick O'Farrell in 1975. This method remains the only one suitable for protein discovery. Equipped with more powerful ancillary tools (e.g., mass spectrometry), it now forms the backbone of many proteomics platforms. However, a wealth of additional proteomics tools are currently under development. Ultimately, it will be necessary to recognize the need to link gene networks, as well as variations therein, to physiological end points. This brings us back to old-fashioned biochemistry but also to advanced gene knockout and knock-in techniques of mouse modeling.

Functional genomics approaches at the analysis levels described previously and applied in an integrated manner should greatly facilitate the unraveling of the intricate relationship between the degenerative processes of aging and the increased incidence of

disease among the elderly. This should ultimately lead to a comprehensive, genomics-based health care in which the complexity of the aging process and its many associated disease sequelae, as well as the bewildering individual variability of geriatric patients, is taken into account (Table II). Such personalized geriatric medicine can be successful only when integrated with new computational and informatics approaches. Indeed, the new discipline of "bioinformatics" will play a critical role in setting the pace for this endeavor. As indicated in Table III, bioinformatics is the true sine qua non for success in functional genomics. Bioinformatics uses information technology to organize, visualize, interpret, and distribute biological information to answer complex biological questions. It allows workers in functional genomics to cope with an enormous flood of data and to answer a variety of biological questions in a fraction of the time it would take using traditional analysis techniques. It is bioinformatics that enables functional genomics to bring order out of chaos.

CONCLUSION AND FUTURE PROSPECTS

In view of its extreme complexity and strong association with a variety of complex disease phenotypes, aging is the ideal target for the new discipline of functional genomics. Functional genomics can best be defined as a comprehensive approach to studying the dynamic network of genes that ultimately determines the physiology of an individual organism. As such, it is capable of overcoming the formidable barrier of the current lack of tools to define and understand complex functional organizations, consisting of multiple interacting subsystems, such as aging, the

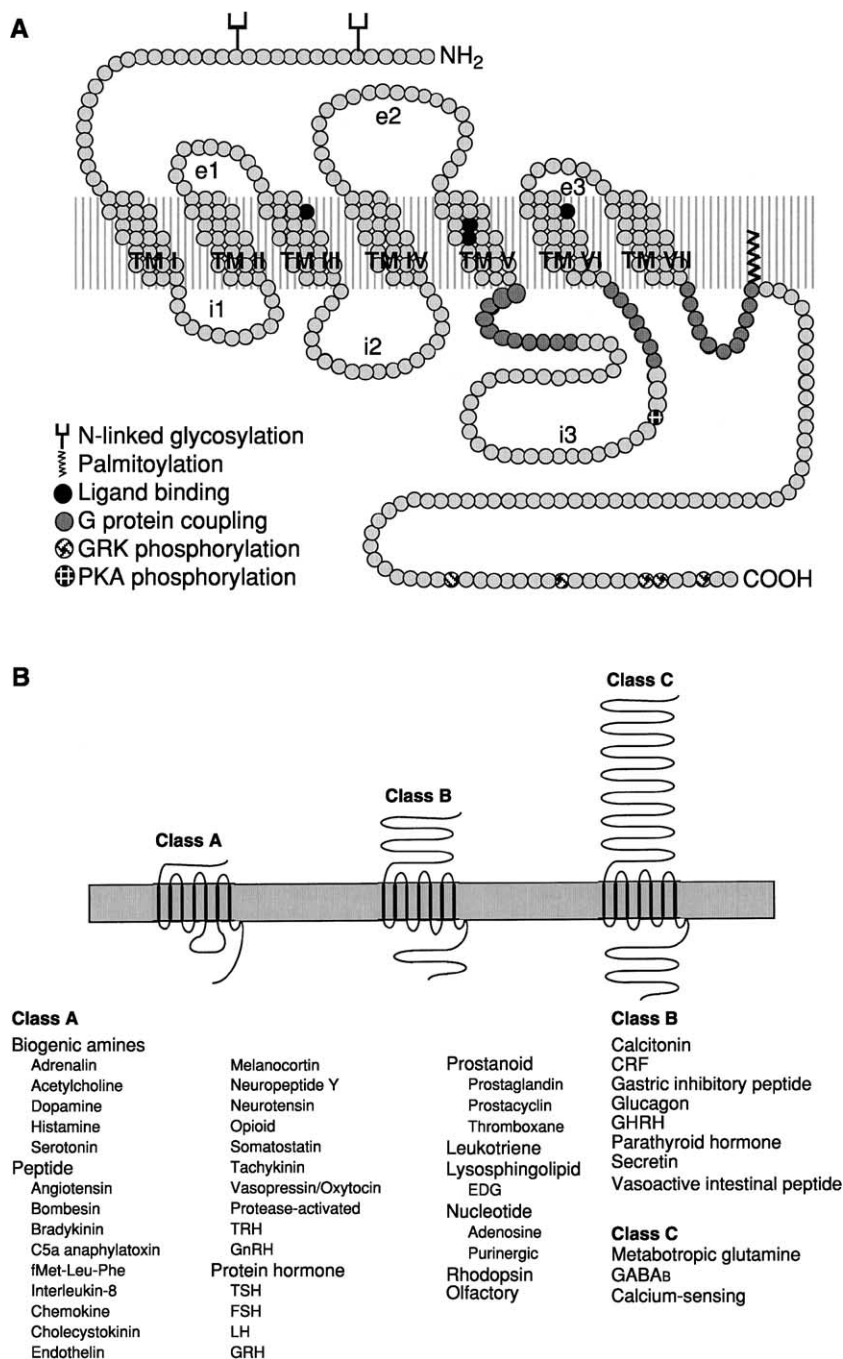

Figure 1 Architecture of G protein-coupled receptors. (A) Schematic diagram of the predicted heptahelical structure of the β_2 -adrenergic receptor, a Class A GPCR. Seven membrane-spanning domains (TMI–TMVII) are connected by three extracellular (e1–e3) and three intracellular (i1–i3) loops. The approximate positions of posttranslational modification, including N-glycosylation of the extracellular amino terminus and palmitoylation of the intracellular carboxy terminus, are indicated. Residues involved in epinephrine binding and predicted sites of PKA and GRK phosphorylation are shown. (B) Schematic comparison of the structure of the three classes of mammalian GPCR along with examples of the receptors belonging to each class.

transmembrane α helices (TMI–TMVII), linked by three alternating intracellular and extracellular loops (e1–3 and i1–3). The transmembrane domains share the highest degree of sequence conservation, whereas

the intracellular and extracellular domains exhibit great variability in size and complexity. The extracellular and transmembrane regions of the receptor are involved in ligand binding, whereas the intracellular

domains are important for signal transduction via heterotrimeric G proteins and for feedback modulation of receptor function.

The gene structure of GPCRs is highly variable. The genes encoding some GPCRs, such as the β 2-adrenergic receptor, are unusual among eukaryotic genes in that they are intronless. Others show typical intron–exon structure. Usually, the intron–exon borders correspond to functional domains, allowing for the insertion of large extracellular or intracellular domains into the basic heptahelical receptor architecture. Variation in the complexity of the extracellular and intracellular domains that connect to the more conserved transmembrane helices accounts for extensive variability in the size of GPCRs (Fig. 1B). The pattern of GPCR expression also varies widely, with some receptors (e.g., the β -adrenergic receptors) being nearly ubiquitous in distribution, whereas others (e.g., rhodopsin) are confined to a single cell type.

GPCRs undergo posttranslational modifications that can affect receptor function. One or more sites for N-glycosylation are present within the amino terminus or, less often, the extracellular loops. Most GPCRs have in common two Cys residues that form a disulfide bridge between e1 and e2 that is critical for normal protein folding and another Cys residue in the carboxy-terminal domain that serves as a site for palmitoylation. This lipid modification leads to the formation of a putative fourth intracellular loop.

Classification of Heptahelical Receptors

Structurally, GPCRs have been divided into three main classes (A, B, and C) that contain all of the known human receptors. Two additional classes (D and E) are made up of fungal pheromone and *Dictyostelium* GPCRs. Each class has been further divided into subclasses based on a combination of sequence homology, functional domains, and ligand-binding properties (Fig. 1B).

GPCRs of Class A, of which rhodopsin and the β 2-adrenergic receptor are members, make up the largest family. Class A GPCRs share approximately 20 conserved amino acid residues, including the three Cys residues in e1 and e2 and the carboxy terminus, an Asp–Arg–Tyr (DRY) motif in i2, and an Asn–Pro–x–x–Tyr (NPxxY) motif in TMVII. Within class A, the rhodopsin subclass contains a light reactive 11-*cis*-retinal moiety covalently linked to TMVII that serves as a detector for incoming photons of light. In a second subclass that contains receptors for biogenic

amines and other small nonpeptide ligands, the bound ligand resides within a ligand-binding “pocket” formed by the seven transmembrane helices. Another subclass includes receptors that respond to chemokines, opioids, and other small peptides. These ligands bind to the amino terminus, e1–3, and regions of the TMs that are close to e1–3. This group also contains protease-activated receptors such as the PAR1 thrombin receptor. The amino terminus of these receptors includes a peptide sequence that serves as a tethered ligand once it is exposed by regulated proteolysis. Class A receptors also include several GPCRs in which ligand binding occurs within a relatively large amino-terminal domain. This subclass includes receptors for glycoprotein hormones such as luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH).

Class B GPCRs, the second largest class, contain receptors that bind to hormones of higher molecular weight such as glucagon, calcitonin, and parathyroid hormone. Class B GPCRs are characterized by long amino-terminal domains involved in ligand binding, six well-conserved Cys residues in the amino terminus, two highly conserved Cys residues in e1 and e2, and approximately 15 other residues that are identical in all members of this class. Class C, the smallest class of mammalian GPCRs, contains the metabotropic glutamate receptors, the GABA_B receptor, and the calcium-sensing receptor. These receptors possess extremely long extracellular amino-terminal domains that are involved in ligand binding and contain several conserved Cys residues in the transmembrane and extracellular regions that are essential for receptor function.

G PROTEIN-COUPLED RECEPTOR SIGNALING VIA HETEROTRIMERIC G PROTEINS

The Receptor–G Protein–Effector Model of Signal Transduction

The binding of a “first messenger” hormone to the extracellular or transmembrane domains of a GPCR triggers conformational changes that are transmitted to the intracellular receptor domains and lead to coupling between the receptor and heterotrimeric G proteins. Ligand-bound GPCRs promote the activation of heterotrimeric G proteins by catalyzing the exchange of GTP for GDP on the G α -subunit and

Figure 2 The receptor–G protein–effector model of G protein-coupled receptor signaling. The three principal components of GPCR signaling are the heptahelical receptor, heterotrimeric G protein, and effector enzyme. The receptor detects the presence of a hormone (H) or “first messenger” in the extracellular milieu. The heterotrimeric G protein dissociates into a GTP-bound Gα subunit and Gβγ heterodimer on interaction with a ligand-bound receptor. The effector, which is typically an enzyme or ion channel, is activated by free Gα–GTP or Gβγ subunits and produces small molecule “second messengers” that transmit signals intracellularly.

dissociation of the GTP-bound Gα-subunit from the Gβγ-subunit heterodimer. Once dissociated, free Gα–GTP and Gβγ-subunits regulate the activity of enzymatic effectors, such as adenylate cyclases, phospholipase C isoforms, and ion channels, to generate small molecule “second messengers.” These second messengers, in turn, control the activity of protein kinases that regulate key enzymes involved in intermediary metabolism. Signaling continues until the intrinsic GTPase activity of the Gα-subunit returns the G protein to the inactive heterotrimeric state. This three-component system, originally discovered as the mechanism for hormonal control of adenylate cyclase, forms the basis of the classical GPCR signaling paradigm (Fig. 2).

Heterotrimeric G Proteins

The heterotrimeric G proteins are a group of GTPases that share a common multi-subunit structure. They function as intermediates in the transduction of external stimuli by linking GPCRs, which lack intrinsic enzymatic activity, to enzymatic effectors that convey information about the presence of an external stimulus to the cell interior. Heterotrimeric G proteins are composed of a 39- to 52-kD GTP-binding Gα-subunit that possesses intrinsic GTPase activity and a Gβ- and Gγ-subunit that form a tightly linked heterodimer that is noncovalently bound to the Gα-subunit in the inactive state.

In contrast to the immense diversity found in GPCRs, there are comparatively few genes encoding each of the heterotrimeric G protein subunits. The 16 known mammalian Gα-subunit genes are grouped by sequence homology into four families. With splice variants, approximately 20 distinct Gα-subunit proteins are expressed. The Gαs family contains the adenylate cyclase-stimulatory α-subunit, Gαs, and the olfactory α-subunit, Gαolf. The Gαi family includes the adenylate cyclase-inhibitory α-subunits, Gαi1, Gαi2, Gαi3, and Gαo; two isoforms of the retinal α-subunit, transducin or Gαt; the taste α-subunit, gustducin or Gαgust; and Gαz, an α-subunit whose function is not well understood. The Gαq family includes two α-subunits that regulate phospholipase C activity, Gαq and Gα11, as well as Gα14 and Gα15. Finally, the Gα12 family contains Gα12 and Gα13, two α-subunits whose function is poorly understood.

All Gα-subunits share considerable sequence homology (~40%) that corresponds to the regions of the protein that form the guanine nucleotide-binding pocket. More divergence is found in the amino terminus, which is required for Gβγ-subunit binding, and in the carboxy terminus, which is involved in the association with both receptors and effectors. Although none of the Gα-subunits possess membrane-spanning domains, all associate with the plasma membrane. Gαi and Gαo are posttranslationally modified by the addition of the fatty acid myristate to an amino-terminal glycine residue, and this

lipid modification is required for membrane association. All $G\alpha$ -subunits, with the exception of $G\alpha_t$, also undergo palmitoylation of one or more amino-terminal cysteine residues, and this is also important for membrane localization. Unlike myristoylation, however, this is a reversible modification. On binding of GTP and $G\beta\gamma$ -subunit dissociation, palmitate is cleaved. Reassociation of the $G\alpha$ - and $G\beta\gamma$ -subunits promotes repalmitoylation.

In addition to the $G\alpha$ -subunits, there are 5 known $G\beta$ -subunits and 12 $G\gamma$ -subunits. All $G\beta$ -subunits are approximately 36 kD in size and share a common three-dimensional structure with an amino-terminal, coiled-coil structure that associates tightly with the $G\gamma$ -subunit. The remainder of the protein resembles a seven-bladed propeller, with each blade composed of interlocking β -sheets. All $G\gamma$ -subunits are 7 to 8 kD and possess a carboxy-terminal Cys-Ala-Ala-x motif, which serves a site for prenylation, a lipid modification that is essential for membrane localization. Most, but not all, $G\beta$ - and $G\gamma$ -subunit pairs can form stable heterodimers *in vitro*, suggesting that they may combine *in vivo* to generate a diverse array of $G\beta\gamma$ -subunit heterodimers. Some combinations make up the predominant form of the heterodimer in specific tissues; for example, $G\beta_1\gamma_1$ is the predominant form associated with $G\alpha_t$ in the retina. Some evidence suggests that specific $G\beta\gamma$ -subunit heterodimers differentially regulate certain effectors; however, the overall contribution of $G\beta\gamma$ heterodimer diversity to GPCR signal transduction is poorly understood.

Although GPCRs generally exhibit preferential coupling to certain G proteins, the degree of coupling specificity varies widely. In some cases, such as the chemoattractant C5A receptor and the M4 muscarinic acetylcholine receptor, coupling is limited to specific members of a single G protein subfamily. In other cases, coupling is much more promiscuous, involving members of different G protein families. For example, the thyroid-stimulating hormone receptor couples to both G_s and $G_{q/11}$ family G proteins and stimulates both adenylyl cyclase and phospholipase activity, whereas the thrombin receptor couples to both $G_{q/11}$ and G_i family G proteins.

G Protein Effectors

The third component of the GPCR signaling system is the G protein-regulated effector, which is typically an enzyme or ion channel. Although it was once thought that only $G\alpha$ -subunits interacted with

effectors, it is now clear that both GTP-bound $G\alpha$ and $G\beta\gamma$ -subunits regulate effector activity.

The most widely studied G protein-regulated enzymes are the adenylyl cyclases, which catalyze the conversion of ATP to the intracellular second messenger cyclic-adenosine 3',5'-monophosphate or cyclic AMP (cAMP). cAMP regulates the activity of the cAMP-dependent protein kinase (PKA). The 10 cloned adenylyl cyclases all share a common 12-membrane-spanning domain architecture but vary significantly in tissue distribution and in regulation by G protein subunits. All of the adenylyl cyclases are stimulated by $G\alpha_s$. Some are also stimulated by $G\beta\gamma$ -subunits or by calcium-calmodulin, but only in the presence of active $G\alpha_s$, creating the prospect of "conditional stimulation" in which activation of more than one type of GPCR might be required for full activation of the cyclase. $G\alpha_i$ mediates inhibition of some, but not all, adenylyl cyclase isoforms, as does $G\alpha_o$ and intracellular calcium. The activity of some adenylyl cyclases is also modulated through phosphorylation by the second messenger-dependent protein kinases PKA and protein kinase C (PKC).

The four phospholipase C (PLC) β isoforms are also regulated by G proteins. Phospholipase C catalyzes the hydrolysis of membrane phosphatidylinositol to yield two intracellular second messengers: inositol 1,4,5-trisphosphate, which controls calcium efflux from the endoplasmic reticulum, and diacylglycerol, which along with calcium controls the activity of several isoforms of PKC. PLC β_1 –3 are independently activated by both $G\alpha$ -subunits of the G_q family and $G\beta\gamma$ -subunits. The PLC β_2 and PLC β_3 isoforms are more sensitive to $G\beta\gamma$ -subunit regulation than is PLC β_1 and usually account for the activation of PLC by GPCRs coupled to G_i family proteins. $G\beta\gamma$ -subunits may also directly regulate phospholipase A2 activity in some settings.

In the rod cells of the retina, activated transducin stimulates a cGMP phosphodiesterase, leading to closure of plasma membrane sodium channels, hyperpolarization of the plasma membrane, and signaling of second-order retinal neurons. Other ion channels may function as direct G protein-regulated effectors. Direct interaction between channel components and G protein subunits may account for the inhibition of high-voltage "N-type" calcium channels by GPCRs acting via subtypes of $G\alpha_o$ and the stimulation of "L-type" calcium channels by GPCRs acting via $G\alpha_s$. $G\beta\gamma$ -subunits appear to be the physiological activator of the inward-rectifying muscarinic-gated potassium channel IKACH, which mediates the cardiac response to vagal stimulation.

Finally, some kinases, notably the G protein-coupled receptor kinases (GRK)2 and GRK3, are directly regulated by G $\beta\gamma$ -subunits. These GRKs, which play a central role in receptor desensitization and may also phosphorylate nonreceptor substrates, possess carboxy-terminal regulatory domains that bind free G $\beta\gamma$ -subunits. Binding to the G $\beta\gamma$ -subunits of activated G proteins allows the kinase to translocate from the cytosol to the plasma membrane, where it gains access to substrate.

GPCRs are classically thought to act catalytically in that one GPCR may activate multiple G proteins. Free G protein subunits then act on enzymatic effectors or ion channels, producing a pool of second messengers that control protein kinase activity. The presence of multiple enzymatic steps in the GPCR signaling cascade creates the potential for tremendous signal amplification. As a result of this amplification process, a full biological response can often be obtained with as little as 5% receptor occupancy, a phenomenon that early pharmacologists referred to as “spare receptors.”

MODULATION OF G PROTEIN-COUPLED RECEPTOR SIGNALING

Positive Regulation of G Protein-Coupled Receptor Signaling

Over the past several years, it has become evident that the physical interaction of GPCRs with one another and with certain accessory proteins serves to expand the repertoire of GPCR signaling. Two examples of such phenomena are receptor dimerization and the interaction of GPCRs with receptor activity-modifying proteins (RAMPs).

GPCR Dimerization

A range of biochemical and biophysical data indicate that many, if not most, GPCRs can exist in the form of homo- or hetero-oligomers. In some cases, dimerization appears to be regulated by agonist binding. Limitations in currently available techniques have to this point precluded an accurate determination of the extent of GPCR oligomerization in intact cells. Nonetheless, some data support the concept that the formation of GPCR dimers or higher order oligomers may be required for receptor function or may contribute to diversity of ligand binding. The former concept is supported by the finding that the internal tethered ligand of one protease-activated receptor can

“transactivate” other family members, a signaling event that must occur over very short distances. The latter concept has been invoked to account for observed diversity in opioid receptor pharmacology that appears to extend beyond that attributable to any single receptor subtype.

The most compelling data for an obligatory functional role for receptor dimerization, however, comes from study of the class C GABA_B receptor. The GABA_BR1 receptor, which contains all of the structural determinants necessary for ligand binding and G protein activation, is retained in the endoplasmic reticulum as an immature glycoprotein unless it is coexpressed with a second GABA_B receptor transcript, the GABA_BR2. The GABA_BR2 receptor alone can reach the cell surface but cannot bind ligand. Dimerization of the two receptors, which is mediated by their carboxy-terminal tails, leads to occlusion of an endoplasmic reticulum retention sequence located in the tail of the GABA_BR1 and allows for correct processing and membrane transport of GABA_BR1. These data indicate that the GABA_BR2 functions as a chaperon for GABA_BR1 through the formation of an obligatory GPCR dimer. Similarly, expression of truncated class A D2 dopamine and V2 vasopressin receptors inhibits the trafficking and function of the intact receptor, suggesting that GPCR dimerization prior to membrane delivery may be a general process.

Receptor Activity-Modifying Proteins

The pharmacology of at least two class B GPCRs is determined not strictly by the intrinsic structure of receptor but also by their interaction with members of a family of novel transmembrane proteins, called receptor activity-modifying proteins (RAMPs). The three known RAMP proteins are 148- to 174-amino acid single transmembrane domain glycoproteins with large extracellular domains and short intracytoplasmic domains. RAMPs form complexes with the calcitonin receptor-like receptor (CRLR) and calcitonin receptor and control receptor trafficking and function. RAMP binding to the CRLR is required for transport of nascent CRLR to the plasma membrane. Furthermore, the specific CRLR–RAMP complex determines the ligand specificity of the receptor. The CRLR–RAMP1 complex acts as a receptor for the calcitonin gene-related peptides, a pleiotropic family of neuropeptides with homology to calcitonin, amylin, and adrenomedullin. When CRLR is complexed with RAMP2 or RAMP3 it functions as an adrenomedullin receptor. Similarly, complexes between a naturally occurring splice variant of the calcitonin receptor and RAMP1 or RAMP3 yield a functional amylin

receptor. RAMP expression is modified under various forms of physiological stress and in response to glucocorticoids, suggesting that cellular responsiveness to certain hormones may be regulated through control of accessory proteins.

Negative Regulation of G Protein-Coupled Receptor Signaling

A common principle of receptor biology is that of tachyphylaxis, the waning of signal intensity over time in the continued presence of agonist. Presumably, tachyphylaxis acts as a protective mechanism by allowing the cell to adjust its sensitivity to external stimuli and by preventing signal overload. Mechanisms to dampen GPCR signals exist at every level, from receptor to G protein to effector. Second messengers are enzymatically degraded, for example, by cAMP phosphodiesterases, phosphatidylinositol phosphatases, and diacylglycerol kinases. Effector activity is modulated both by the availability of free G protein subunits and by feedback inhibition, as in the regulation of certain isoforms of adenylate cyclase by PKA or PKC phosphorylation. $G\alpha$ -subunit activity is modulated by protein-protein interactions that accelerate the normally slow intrinsic GTPase activity of the protein. In some cases, this GTPase-activating protein (GAP) activity is an inherent property of the effector, such that interaction of the $G\alpha$ -GTP complex with the effector leads to an acceleration of GTP hydrolysis and a return to the inactive state. In other cases, GAP activity is conferred by members of a large family of proteins called regulators of G protein signaling (or RGS proteins) that interact with the $G\alpha$ -subunit and stabilize the transition state for GTP hydrolysis. Approximately 19 mammalian genes containing RGS core domains are known. Most act as GAPs toward G_i proteins, and some also act as GAPs for G_q proteins. $G\beta\gamma$ -subunit function is also under control. In the retina, the $G\beta\gamma$ -subunit-binding protein phosducin can sequester free $G\beta\gamma$ -subunits, thereby modulating the $G\beta\gamma$ -G α t interaction.

The GPCR itself is the target for extensive negative regulation. The processes that regulate GPCR responsiveness at the receptor level are typically divided, based on mechanism, into heterologous desensitization, homologous desensitization, receptor sequestration, and receptor down-regulation. Together, they lead sequentially to the uncoupling of receptor from G protein, removal of receptors from the plasma membrane, receptor degradation, and reduced synthesis of new receptors (Fig. 3).

Heterologous Desensitization

Desensitization begins within seconds of agonist exposure and is initiated by phosphorylation of the receptor. Second messenger-dependent protein kinases, including PKA and PKC, phosphorylate serine and threonine residues within the cytoplasmic loops and C-terminal tail domains of many GPCRs. Phosphorylation of these sites directly impairs receptor-G protein coupling. For example, PKA phosphorylation of purified β_2 -adrenergic receptors *in vitro* is sufficient to impair receptor-stimulated G_s activation in the absence of other proteins. Agonist occupancy of the target GPCR is not required for this process. Thus, receptors that have not bound agonist, including receptors for other ligands, can be desensitized by the activation of second messenger-dependent protein kinases. This lack of requirement for receptor occupancy has led to the use of the term "heterologous desensitization" to describe the process.

For some GPCRs, phosphorylation may also alter the specificity of G protein coupling, leading to feedback inhibition or activation of secondary G protein-mediated events. For example, phosphorylation of the β_2 -adrenergic receptor by PKA shifts receptor coupling from the adenylate cyclase-stimulatory G protein, G_s , to the adenylate cyclase-inhibitory G protein, G_i . This leads to reduced adenylate cyclase activation and couples the receptor to pathways leading to activation of mitogen-activated protein (MAP) kinases.

Homologous Desensitization and the Arrestins

Homologous desensitization is mediated by phosphorylation of the receptor by specialized kinases called G protein-coupled receptor kinases (or GRKs), followed by the binding of arrestins. There are seven known GRKs. GRK1 (rhodopsin kinase) and GRK7 are retinal kinases involved in the regulation of rhodopsin photoreceptors, whereas GRK2 to GRK6 are more widely expressed. Membrane targeting of all the GRKs apparently is critical to their function and is conferred by a carboxy-terminal tail domain. GRK1 and GRK7 each possesses a carboxy-terminal Cys-Ala-Ala-x motif. Light-induced translocation of GRK1 from the cytosol to the plasma membrane is facilitated by the posttranslational farnesylation of this site. The β -adrenergic receptor kinases (GRK2 and GRK3) have carboxy-terminal $G\beta\gamma$ -subunit-binding and pleckstrin-homology domains, and they translocate to the membrane as a result of interactions between these domains and free $G\beta\gamma$ -subunits and inositol phospholipids. Palmitoylation of GRK4 and GRK6 on carboxy-terminal cysteine

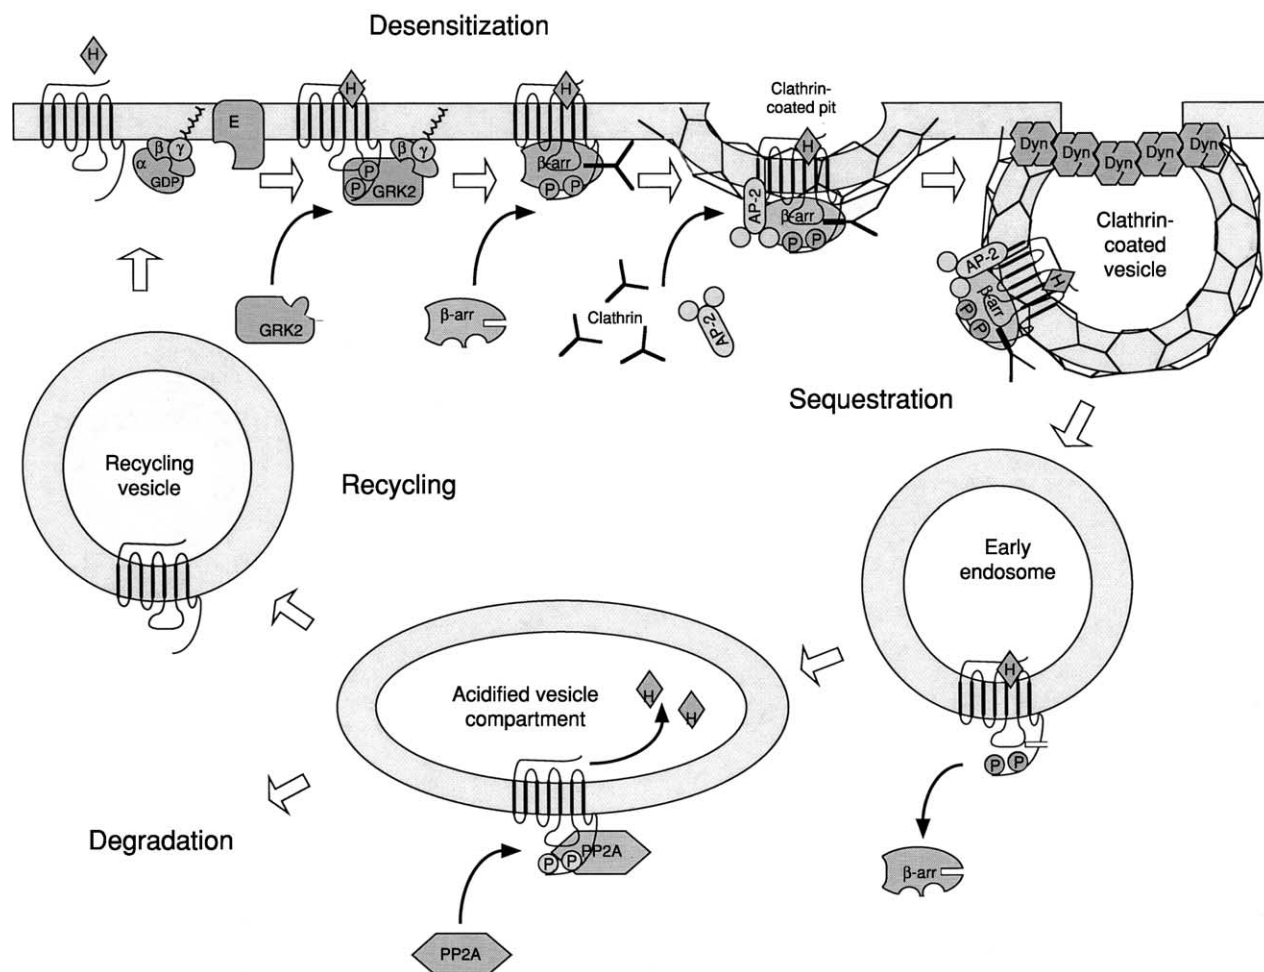

Figure 3 Desensitization, sequestration, and recycling of G protein-coupled receptors. Within seconds of hormone (H) binding, GPCRs are phosphorylated by both second messenger-dependent protein kinases and specialized G protein-coupled receptor kinases (GRKs). Heterologous desensitization is due to phosphorylation of the receptor by second messenger-dependent protein kinases that leads to impaired receptor–G protein coupling. Homologous desensitization of GPCRs results from the binding of β -arrestins (β -arr) to agonist-occupied receptors following phosphorylation of the receptor by GRKs. β -arrestin binding blocks coupling between the receptor and G protein, leading to termination of signaling by G protein effectors (E). Receptor-bound β -arrestins also bind to components of the clathrin endocytic machinery, including clathrin, β 2-adaptin (AP-2), and NSF. Receptor sequestration reflects the dynamin (Dyn)-dependent endocytosis of GPCRs via clathrin-coated pits. Once internalized, receptors may traffick to an acidified endosomal compartment, where the ligand is dissociated and the receptors are dephosphorylated by a GPCR-specific protein phosphatase PP2A isoform, after which they are recycled to the plasma membrane. Alternatively, receptors are targeted for degradation as part of the process of receptor down-regulation.

residues leads to constitutive membrane localization. Targeting of GRK5 to the membrane is thought to involve the electrostatic interaction of a highly basic 46-residue carboxy-terminal domain with membrane phospholipids.

Like PKA and PKC, GRKs phosphorylate GPCRs on serine and threonine residues in the i3 loop and carboxy-terminal tail. Unlike the second messenger-dependent kinases, GRKs preferentially phosphorylate receptors that are in the agonist-occupied conformation. Furthermore, GRK phosphorylation alone has little direct effect on receptor–G protein

coupling. Rather, the role of GRK phosphorylation is to increase the affinity of the receptor for arrestins. It is the binding of an arrestin to the receptor domains involved in G protein coupling, rather than GRK phosphorylation, that leads to uncoupling of receptor and G protein.

To this point, four functional members of the arrestin gene family have been cloned. Two arrestins, visual arrestin (arrestin 1) and cone arrestin, are expressed almost exclusively in the retina, where they regulate photoreceptor function. The β -arrestins, β -arrestin 1 and β -arrestin 2 (also called arrestin 2 and

arrestin 3) are ubiquitously expressed proteins whose highest levels of expression are in brain and spleen. All arrestins are 48- to 50-kD proteins that bind specifically to light-activated or agonist-occupied GPCRs that have been phosphorylated by GRKs. The crystal structure of visual arrestin indicates that the arrestins contain two major domains, an amino-terminal domain and a carboxy-terminal domain, each composed of a seven-stranded β sandwich and joined by a phosphate sensor region that maintains the protein in an inactive conformation until it interacts with a GRK-phosphorylated GPCR. Additional regulatory motifs reside at the amino- and carboxy-termini of the protein.

Receptor Sequestration, Resensitization, and Down-Regulation

Internalization of GPCRs, also termed receptor sequestration or endocytosis, occurs more slowly than does desensitization, occurring over a period of several minutes after agonist exposure. It is likely that several mechanisms exist for the removal of GPCRs from the membrane, but the most universal and best-understood mechanism involves β -arrestins acting as adapter proteins to target GPCRs to clathrin-coated pits for endocytosis.

The carboxy-terminal tail of the β -arrestins, but not the visual arrestins, contains structural motifs that allow them to link GPCRs to components of the clathrin-dependent endocytic machinery. β -arrestins bind with high affinity to both clathrin and the β 2-adaptin subunit of the heterotetrameric AP-2 adapter complex. In addition, β -arrestin 1 binds to the N-ethylmaleimide-sensitive fusion protein (NSF), an ATPase involved in intracellular transport. Through these interactions, agonist-occupied GPCRs are directed to clathrin-coated pits and subsequently removed from the cell surface. β -arrestin 1 function is also modulated by phosphorylation of a carboxy-terminal serine, whereas β -arrestin 2 has been shown to undergo rapid ubiquitination, catalyzed by an E3 ubiquitin ligase, Mdm2, which binds directly to the β -arrestin. Ubiquitination of β -arrestin 2 apparently is required for receptor internalization, although its exact role is not currently understood.

Once internalized, GPCRs either are degraded or are dissociated from ligand, dephosphorylated, and returned to the cell surface through a process termed "resensitization" or "recycling." For many GPCRs, most notably the β 2-adrenergic receptor, resensitization requires β -arrestin binding and internalization because receptor dephosphorylation must occur within acidified endosomal vesicles. The stability of the receptor- β -arrestin complex appears to play an

important role in determining rate of receptor recycling. Recent data suggest that GPCRs can be grouped based on their pattern of interaction with β -arrestins. One group of receptors, represented by the β 2- and α 1B-adrenergic, μ opioid, endothelin A, and dopamine D1A receptors, bind to β -arrestin 2 *in vitro* with higher affinity than to β -arrestin 1 and do not bind to visual arrestin. In addition, their interaction with β -arrestin is transient. β -arrestin is recruited to the receptor at the plasma membrane and translocates with it to clathrin-coated pits, but the receptor- β -arrestin complex dissociates on internalization of the receptor, such that the β -arrestin recycles to the plasma membrane as the receptor proceeds into an endosomal pool. A second group of receptors, which includes the angiotensin AT1a, neurotensin 1, vasopressin 2, thyrotropin-releasing hormone, and neurokinin NK-1 receptors, bind β -arrestin 1 and β -arrestin 2 with equal affinity *in vitro* and also interact with visual arrestin. These receptors form stable complexes with β -arrestin, such that the receptor- β -arrestin complex internalizes as a unit that is targeted to endosomes. The presence of specific clusters of serine and threonine residues in the carboxy-terminal tail of the receptor apparently dictates the stability of the receptor- β -arrestin complex. Data obtained using chimeric receptors, in which the carboxy-terminal tail of receptors of various groups have been exchanged, suggest that the formation of a transient receptor- β -arrestin complex favors rapid dephosphorylation and return to the plasma membrane, whereas formation of a stable receptor- β -arrestin complex retards resensitization and may favor targeting of the receptor for degradation.

Down-regulation of GPCRs, the persistent loss of cell surface receptors that occurs over a period of hours to days, is the least understood of the processes controlling GPCR responsiveness. Control of cell surface receptor density occurs at least partially at the transcriptional level, but the removal of agonist-occupied receptors from the cell surface and their sorting for either degradation or recycling to the membrane is also important, at least during the early stages of down-regulation. Consistent with this is the finding that down-regulation of β 2-adrenergic receptors does not occur in murine fibroblasts lacking both β -arrestin 1 and β -arrestin 2.

Other factors contribute in as yet poorly understood ways to regulate receptor recycling and down-regulation. Ubiquitination of the β 2-adrenergic receptor, which appears to be a β -arrestin-dependent event but is mediated by an as yet unidentified ubiquitin ligase, is not required for receptor internalization

but does appear to determine the rate of proteosomal degradation of receptors. In addition, an interaction between the distal carboxy-terminal tail of some GPCRs and the PDZ domain containing protein NHERF1/EBP-50 may regulate endosomal sorting. The NHERF1/EBP-50 protein links β 2-adrenergic receptors to the actin cytoskeleton, and disruption of this interaction leads to missorting of the endocytosed receptor and accelerated receptor degradation.

NOVEL MECHANISMS OF G PROTEIN-COUPLED RECEPTOR SIGNALING

Certain physiological responses to GPCR stimulation have been difficult to explain in the context of the classical receptor–G protein–effector paradigm of heptahelical receptor signaling. Notable among these is the ability of GPCRs to stimulate cell proliferation, which in many systems is demonstrably independent of the activation of second messenger-dependent protein kinases. Study of the mechanisms underlying these responses has led to the discovery that GPCRs can employ novel signal transduction mechanisms, some of which appear not to require G protein activation.

Heterologous Receptor Cross-Talk

In many cell types, GPCR-mediated activation of the extracellular signal-regulated kinase (ERK) MAP kinase cascade, a central pathway in the control of cell proliferation, shares many early steps with signals arising from classical receptor tyrosine kinase growth factor receptors. The basis for this convergence of signaling is that at least two receptor tyrosine kinases, those for platelet-derived growth factor and for epidermal growth factor (EGF), can be “transactivated” by GPCRs.

The best-understood mechanism of cross-talk between GPCRs and receptor tyrosine kinases is the transactivation of EGF receptors resulting from the autocrine/paracrine release of EGF receptor ligands from the cell surface via a process termed “ectodomain shedding.” Each of the known ligands for the EGF receptor—EGF, transforming growth factor α , heparin-binding (HB)–EGF, amphiregulin, betacellulin, and epiregulin—is synthesized as a transmembrane precursor that is proteolyzed to produce a soluble growth factor. In fibroblasts, both G_i/o - and $G_q/11$ -coupled receptors have been shown to stimulate HB–EGF release. For G_i/o -coupled GPCRs,

HB–EGF shedding and EGF receptor transactivation are mediated by $G\beta\gamma$ -subunits, whereas HB–EGF shedding in response to stimulation of $G_q/11$ -coupled receptors is mediated by $G_q/11\alpha$ -subunits. Proteolysis of the HB–EGF precursor is mediated by GPCR-regulated matrix metalloprotease activity, possibly by a member of the membrane-associated ADAM family of matrix metalloproteases. The immediate G protein effectors that regulate ectodomain shedding are incompletely defined, although phosphatidylinositol 3'-kinases and Src family nonreceptor tyrosine kinases have been implicated in the process.

GPCRs as Scaffolds

A recent development in the field of GPCR signal transduction has been the discovery that GPCRs can signal by interacting with proteins other than heterotrimeric G proteins. This model of signaling, in which the agonist-occupied receptor recruits proteins to form a signaling complex, is fundamentally different from the classical model G protein-mediated signaling, which is thought of as a catalytic event (Fig. 4).

In some cases, the GPCR itself has been proposed to act as a scaffold for the binding of signaling molecules. Assembly of these complexes involves noncovalent interaction between the intracellular domains of a GPCR and putative effector enzymes or adapters.

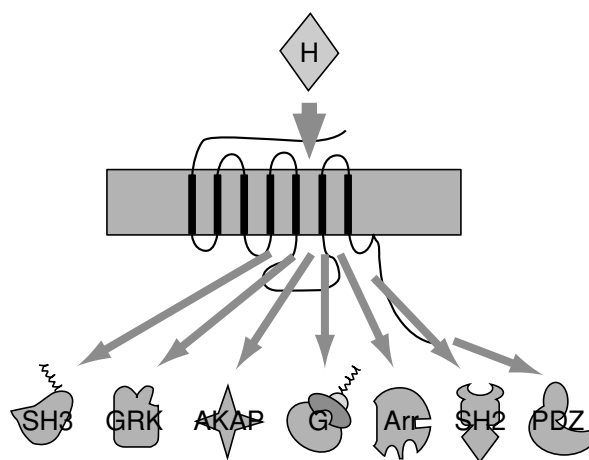

Figure 4 Alternative mechanisms of G protein-coupled receptor signaling. Recent research has indicated that GPCRs use many intermediates in addition to G proteins (G) to signal intracellularly. Potential novel mediators of GPCR signals include *src* homology 2 (SH2) and *src* homology 3 (SH3) domain-containing proteins, G protein-coupled receptor kinases (GRKs), protein kinase A anchoring proteins (AKAP), arrestins (Arr), and PDZ domain-containing proteins.

Some GPCRs are substrates for tyrosine phosphorylation, which can lead to their association with proteins containing *src* homology 2 (SH2) domains, motifs that confer specific recognition of phosphotyrosine residues. The β 2-adrenergic receptor can be phosphorylated on tyrosine residues by the insulin receptor tyrosine kinase. This has been reported to lead to direct association of the receptor with the adapter proteins Grb2 and Shc, central elements in the control of the low-molecular-weight G protein, Ras. Stimulation of the JAK-STAT pathway of transcriptional regulation by angiotensin AT1a receptors apparently involves angiotensin-dependent tyrosine phosphorylation of Tyr319 in the AT1a receptor tail by an Src family kinase, followed by association of JAK2 with the receptor. In this case, the binding of JAK2, which does not have an SH2 domain, appears to be indirect but may be mediated by members of the SHP family of SH2 domain-containing tyrosine phosphatases.

Some GPCRs contain relatively large proline-rich inserts in their intracellular loops that may mediate binding to proteins containing *src* homology 3 (SH3) domains. For example, the β 3-adrenergic receptor, which does not recruit β -arrestin, binds to the c-Src SH3 domain in an agonist-dependent manner via proline-containing motifs in its i3 loop and carboxy-terminus. This interaction may contribute to the ability of β 3-adrenergic receptors to activate the ERK pathway.

Direct GPCR-adapter protein interactions may also regulate the activity of serine/threonine kinases. The PKA anchoring protein, AKAP79/150, coprecipitates with the β 2-adrenergic receptor from brain lysates and interacts with peptides derived from the i3 and carboxy-terminal tail of the receptor *in vitro*. This interaction, which does not appear to be agonist regulated, promotes PKA-mediated phosphorylation of the receptor following G protein-dependent activation of adenylate cyclase and facilitates downstream activation of MAP kinases.

PDZ Domain Interactions

The intracellular tails of a small number of heptahelical receptors terminate in variations of the Thr/Ser-x-Val motif required for binding to PDZ domains. More than 50 PDZ domain-containing proteins have been cloned that selectively recognize variants of this motif, and a few GPCR-PDZ domain-binding interactions have been described. The β 2-adrenergic receptor has been shown to bind the Na^+/H^+ exchanger regulatory factor (NHERF/EBP-50) in an agonist-dependent manner. This association, which

is apparently G protein independent, accounts for β 2-adrenergic receptor-mediated stimulation of renal Na^+/H^+ exchange. Another PDZ domain-containing protein, PSD-95, binds to the carboxy-terminus of the β 1-adrenergic receptor. This interaction is regulated by receptor phosphorylation in that GRK5 phosphorylation of the receptor dramatically enhances binding. PSD-95 facilitates the physical association of β 1-adrenergic receptors with other synaptic proteins such as N-methyl-D-aspartate receptors and, thus, may provide the physical basis for another form of heterologous receptor cross-talk.

Rhodopsin is another GPCR that has been found to associate with a PDZ domain-containing protein in a functionally relevant manner. Rhodopsin binds to InaD, a multiple PDZ domain-containing scaffolding protein that associates with a number of signaling intermediates involved in rhodopsin-initiated pathways such as phospholipase C, protein kinase C, and the TRP ion channel. Analogous to the proposed function of PSD-95 in the synapse, the rhodopsin-InaD interaction may allow the formation of signaling complexes necessary for signal transduction in the visual system.

GRKs and β -Arrestins as Scaffolds

GRKs have been shown to phosphorylate protein substrates other than GPCRs. For example, GRK2, a $\text{G}\beta\gamma$ -subunit-regulated kinase, associates with and phosphorylates tubulin. In this respect, GRK2 functions as G protein-regulated kinase. In addition, GRKs may act as noncatalytic adapters that recruit signaling intermediates into complex with GPCRs. GRKs have been shown to associate with actin and with a novel ARF6 GTPase-activating protein called GIT1. ARFs are small GTPases involved in vesicle trafficking and sorting, and both GIT1 and ARF6 are involved in GPCR internalization.

As discussed previously, β -arrestins bind tightly to agonist-occupied, GRK-phosphorylated GPCRs and act as adapters between the receptor and components of the cellular endocytic machinery. β -arrestins also serve to recruit regulatory enzymes to the GPCR complex. Endogenous β -arrestin is found in complex with ARNO, an ARF nucleotide exchange factor that, along with GIT-1, regulates ARF function. However, the role of β -arrestins as adapter proteins appears to extend well beyond their role in the regulation of receptor trafficking. Data obtained by a variety of techniques indicate that β -arrestins are able to bind to a number of proteins involved in signal transduction. By simultaneously binding to Src family tyrosine

kinases and to agonist-occupied β 2-adrenergic, neurokinin NK-1, chemokine CXCR-1, or endothelin ET1a receptors, β -arrestins have been shown to confer tyrosine kinase activity on the GPCR- β -arrestin complex. The β -arrestin-Src interaction involves the SH3 domain and the amino-terminal portion of the catalytic domain of Src, which interact with epitopes in the amino-terminal half of β -arrestin molecule. The formation of β -arrestin-Src complexes has been implicated in several aspects of GPCR signaling, including β 2-adrenergic and NK-1 receptor-mediated activation of the ERK cascade; β 2-adrenergic receptor internalization, a process that is modulated by Src-dependent tyrosine phosphorylation of dynamin; CXCR-1 receptor-mediated neutrophil degranulation; and ET1a receptor-mediated translocation of the GLUT4 glucose transporter.

The MAP kinases are regulated via a series of parallel kinase cascades. Each MAP kinase pathway is composed of three kinases, each of which phosphorylates and activates the next kinase in succession. In many cases, MAP kinase activation is controlled by binding of the component kinases to a scaffolding protein. These scaffolds serve at least three functions in cells: to increase the efficiency of signaling between successive kinases in the phosphorylation cascade, to ensure signaling fidelity by dampening cross-talk between parallel MAP kinase cascades, and to target MAP kinases to specific subcellular locations. Recent data suggest that β -arrestins function as scaffolds for some MAP kinase modules. Overexpression of β -arrestin 1 or β -arrestin 2 increases the efficiency of angiotensin II AT1a receptor-mediated ERK activation by binding to each of the three kinases of the ERK cascade: Raf-1, MEK, and ERK. For both the AT1a receptor and the proteinase-activated PAR2 receptor, receptor activation triggers assembly of a multiprotein complex containing the internalized receptor, β -arrestin, Raf-1, and activated ERK1/2. Perhaps significantly, ERK activated in the context of a β -arrestin scaffold is targeted, along with the receptor, into endosomal vesicles rather than translocating to the nucleus, as is the case when it is activated via β -arrestin-independent mechanisms. Thus, β -arrestins may control both MAP kinase activity and MAP kinase function by targeting it to a specific subcellular location.

β -arrestins may also be involved in scaffolding other MAP kinase pathways. β -arrestin 2 forms complexes with the components of the neuronal c-Jun N-terminal kinase (JNK) cascade: Ask1, MKK4, and JNK3. As with the ERK cascade, Ask1-dependent

JNK3 activation is dramatically enhanced by β -arrestin 2 overexpression, and in the presence of β -arrestin 2, activated JNK3 is retained in the cytosol following stimulation of AT1a receptors. Because JNK pathways are involved in apoptotic signaling, these data suggest that β -arrestin scaffolds may provide a mechanism for the GPCR regulation of programmed cell death.

CONCLUSION

As the most diverse type of cell surface receptor, the importance of GPCR signaling to clinical medicine cannot be overestimated. Visual, olfactory, and gustatory sensation; intermediary metabolism; and cell growth and differentiation all are influenced by GPCR signals. The basic receptor-G protein-effector mechanism of GPCR signaling is tuned by a complex interplay of positive and negative modulatory events that amplify the effect of a hormone binding the receptor or that adjust the gain on cellular responsiveness. The association of heptahelical receptors with a variety of intracellular partners other than G proteins has led to the discovery of potential mechanisms of GPCR signaling that extend beyond the classical paradigms. Although the physiological relevance of many of these novel mechanisms of GPCR signaling remains to be established, their existence suggests that the mechanisms of GPCR signaling are even more diverse than was imagined previously.

it takes several minutes to be inactivated. The activation of the G_α subunit is, however, usually reversed more quickly under physiological conditions, because its GTPase activity is greatly enhanced by the binding of a second protein, which can be either its target protein (e.g., phospholipase $C\beta$) or a specific modulator known as a regulator of G protein signaling (RGS). RGS proteins act as α -subunit-specific GTPase-activating proteins (GAP) and they have been shown to play a crucial role in shutting off G protein-mediated cell responses in eukaryotes.

Heterotrimeric G proteins are usually grouped into four subfamilies, e.g., G_s , G_i , G_q , and G_{12} , on the basis of their amino acid sequences and functions (Table I). G_s (stimulatory G protein) was first defined functionally by its ability to activate adenylyl cyclases. GTP-bound $G_{s\alpha}$ dissociates from the $\beta\gamma$ -subunits and binds instead to adenylyl cyclase, which is then activated to produce cAMP. $G_{s\alpha}$ is sensitive to cholera toxin, an enzyme that catalyzes the transfer of ADP ribose from intracellular NAD^+ to α_s . The ADP ribosylation alters the α_s so that it can no longer hydrolyze its bound GTP, resulting in an indefinite activation. The prolonged elevation in cAMP levels within intestinal epithelial cells causes a large efflux of Na^+ and water into the gut, which leads to severe diarrhea.

Another G protein, called inhibitory G protein (G_i), is known to inhibit the adenylyl cyclases. G_i signaling not only decreases the enzyme activity of adenylyl cyclases, it also decreases the direct regulation of ion channels, such as cardiac K^+ and neuronal Ca^{2+} channels. Characteristically, $G_{\beta\gamma}$ subunits, not

$G_{i\alpha}$ subunits, play major roles in this regulation. Pertussis toxin, which is made by the bacterium that causes pertussis (whooping cough), catalyzes ADP ribosylation of the α -subunit of G_i , preventing the subunit from interacting with receptors, which results in the continuous inactivation of the $G_{i\alpha}$ subunit.

Some G protein-coupled receptors exert their effects through the G proteins, G_q , that activate the plasma membrane-bound enzyme, phospholipase $C\beta$. The phospholipase acts on a phosphoinositide, phosphatidylinositol 4,5-bisphosphate [PIP_2]. The activated phospholipase $C\beta$ cleaves PIP_2 to generate two products, inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol. IP_3 is a small, water-soluble molecule that diffuses rapidly in the cytosol. When IP_3 reaches the endoplasmic reticulum (ER), it binds to the IP_3 receptor on the ER membrane. The IP_3 receptor is a Ca^{2+} channel, through which the Ca^{2+} stored in the ER is rapidly released on the binding of IP_3 . On the other hand, diacylglycerol plays a role in the activation of a family of serine/threonine protein kinases, the protein kinase C (PKC) family.

The G_{12} subfamily has two members, α_{12} and α_{13} . These are thought to participate in cell transformation and embryonic development, but their signaling pathways have remained unknown for a long time. p115 RhoGEF, which is a GEF for the small GTPase Rho, has been shown to function as a RGS for G_{12} and G_{13} . It was also shown that the GEF activity of p115 is enhanced by G_{12} and G_{13} . These results may provide evidence for the novel concept that G_{12} and G_{13} signaling directly couples with

Table I The Family of G Protein α -Subunits and Their Effectors

| Subfamily | Toxin sensitivity | Tissue distribution | Target effectors | |
|------------|-------------------|---------------------------------|-------------------------------|--|
| G_s | α_s | Cholera toxin | Ubiquitous | Adenylyl cyclase \uparrow |
| | α_{olf} | Cholera toxin | Olfactory cell | Adenylyl cyclase \uparrow |
| G_i | α_{i-1} | Pertussis toxin | Ubiquitous | Adenylyl cyclase \downarrow |
| | α_{i-2} | Pertussis toxin | Ubiquitous | |
| | α_{i-3} | Pertussis toxin | Ubiquitous | |
| | α_o | Pertussis toxin | Neuron | K^+ channel \uparrow |
| | α_{gust} | Pertussis toxin | Taste cell | (N, P/Q type) Ca^{2+} channel \downarrow (via $\beta\gamma$ -subunits) |
| | α_{t-1} | Pertussis toxin/cholera toxin | Rod photoreceptor cell | cGMP phosphodiesterase \uparrow |
| | α_{t-2} | | cone photoreceptor cell | |
| α_z | None | Neuron, adrenal gland, platelet | Adenylyl cyclase \downarrow | |
| G_q | α_q | None | Ubiquitous | Phospholipase $C\beta$ \uparrow |
| | α_{11} | None | Ubiquitous | Phospholipase $C\beta$ \uparrow |
| | α_{14} | None | Lung, kidney, liver | Phospholipase $C\beta$ \uparrow |

| | α_{13} | None | Ubiquitous | p115 RhoGEF \uparrow |

small (monomeric) G protein signaling via p115 RhoGEF.

ADENYLYL CYCLASE

At least 10 isoforms of adenylyl cyclases, which are responsible for the synthesis of cAMP from ATP, have been identified in mammals. Each isoform consists of two hydrophobic domains, each of which comprises six transmembrane-spanning domains and two cytoplasmic catalytic domains, resulting in a pseudo-symmetrical structure. The regulatory properties and tissue distributions of the different adenylyl cyclases are shown in Table II. Almost all of the adenylyl cyclases can be activated directly by the $G_{s\alpha}$ subunit and by forskolin, which is a toxin isolated from the root of a herb, whereas they are differentially modulated by proteins such as $G_{i\alpha}$, $G_{\beta\gamma}$, protein kinases [cAMP-dependent protein kinase (PKA) or PKC], and Ca^{2+} /calmodulin (CaM). $G_{s\alpha}$ -, $G_{i\alpha}$ -, Ca^{2+} /CaM-, and forskolin-insensitive adenylyl cyclase (type X) is found only in testis.

Direct interaction of $G_{i\alpha}$ with adenylyl cyclase is the most obvious mechanism for inhibition of cAMP synthesis. $G_{s\alpha}$ - and forskolin-stimulated adenylyl cyclase activity of type V or VI is substantially (60–80%) inhibited by the $G_{i\alpha_1}$, $G_{i\alpha_2}$, $G_{i\alpha_3}$, and $G_{z\alpha}$ subunits.

A G protein $\beta\gamma$ -subunit complex is a very potent inhibitor of type I adenylyl cyclase. The $\beta\gamma$ -subunits appear to associate directly with this enzyme. On the other hand, the $\beta\gamma$ complex exhibits remarkable stimulatory effects on type II and IV adenylyl cyclases, although concurrent activation with $G_{s\alpha}$ is a prerequisite for these stimulatory effects.

Adenylyl cyclase activity of type V and VI is directly inhibited by low concentrations ($\sim 0.5 \mu M$) of calcium ions. According to these results, it has been proposed that the wave of intracellular calcium could lead to a rhythmic mobilization of the cAMP concentration. On the other hand, certain isoforms of adenylyl cyclase (types I, III, and VIII) are directly activated by Ca^{2+} /CaM. A 10 nM concentration of CaM is sufficient for activation of type I and type VIII adenylyl cyclase, whereas the effect of Ca^{2+} /CaM on type III is less obvious and micromolar concentrations of Ca^{2+} /CaM and concurrent stimulation of $G_{s\alpha}$ are required. Type IX adenylyl cyclase is inhibited by calcium-dependent protein phosphatase (calcineurin).

Type V and type VI adenylyl cyclases are phosphorylated by PKA, which results in the reduction of the enzyme activity. Thus, this modulation is thought to be a negative feedback mechanism of adenylyl cyclase signaling. Stimulation of G_{q-} and phospholipase

C-coupled receptor leads to the mobilization of intracellular Ca^{2+} , the synthesis of diacylglycerol, and the activation of PKC. PKC phosphorylates and activates some isoforms (types II, IV, V, and VI) of adenylyl cyclases. In particular, type V enzyme is shown to be a direct substrate for phosphorylation *in vitro* by PKC α and PKC ζ .

As shown above, the regulatory mechanisms of the adenylyl cyclases are diverse. In addition to their ability to respond to $G_{s\alpha}$, the different isoforms can receive signals from a variety of sources, such as $G_{i\alpha}$, $G_{\beta\gamma}$, protein kinases (PKA and PKC), protein phosphatase (calcineurin), and Ca^{2+} /CaM. Such diversity in the control of adenylyl cyclase activity may contribute to the significant variation in the production of cAMP in different cell types on stimulation of multiple receptor-mediated cell signal systems.

PHOSPHOLIPASE C

Eleven distinct isoforms of phospholipase C (PLC), which can be grouped into four subfamilies (PLC β , PLC γ , PLC δ , and PLC ϵ), have been identified in mammals. These enzymes catalyze the hydrolysis of PIP $_2$ to IP $_3$ and diacylglycerol in response to the stimulation of various kinds of membrane receptors. The α -subunits (α_q , α_{11} , α_{14} , and α_{16}) of all four members of the G_q subfamily activate PLC β isozymes but not PLC γ , PLC δ , or PLC ϵ . The four mammalian PLC β isozymes differ in their tissue distribution as well as in their sensitivity to G proteins. Expression of PLC β_2 is restricted to hematopoietic cells and that of PLC β_4 is limited to the retina and neuronal cells, whereas PLC β_1 and PLC β_3 are expressed ubiquitously. G protein-coupled receptors that activate the G_q -PLC β pathway include those for α_1 -adrenergic agonists, acetylcholine (muscarinic m_1 or m_3), endothelin-1, angiotensin II, histamine, and C-X-C chemokines.

With the exception of PLC β_4 , PLC β isozymes are also activated by the $G_{\beta\gamma}$ dimer. The relative sensitivity of PLC β isozymes to $G_{\beta\gamma}$ subunits differs from the sensitivity to the $G_{q\alpha}$ subunit. PLC β_2 is the most sensitive to $G_{\beta\gamma}$ and PLC β_1 is the least sensitive.

A characteristic feature of PLC β_1 is its GTPase-activating property for $G_{q\alpha}$. In the reconstituted system of m_1 muscarinic receptor, G protein, and PLC β_1 in lipid vesicles, PLC β_1 increases the rate of GTP hydrolysis by $G_{q\alpha}$ more than 10-fold. A fragment of the C-terminal region of PLC β_1 (amino acids 903–1042) has also been shown to exhibit GAP activity. In addition, the GTPase activity of $G_{q\alpha}$ has been shown to be facilitated by a family of RGS proteins.

Table II Regulatory Properties and Tissue Distribution of Mammalian Adenylyl Cyclases

| Isoforms | Modulators of enzyme activity | | | | Protein kinases | Tissue distribution | Specific function | Chromosomal location |
|-----------|-------------------------------|-----------------|---|----------------------------|--------------------|-------------------------------|---------------------------------------|----------------------|
| | G _{αs} | G _{αi} | G _{βγ} | Calcium | | | | |
| Type I | ↑ | ↓ | ↓ | ↑ (CaM) | | Brain (neuron), adrenal gland | Synaptic plasticity, learning, memory | 7p12–p13 |
| Type II | ↑ | → | ↑ (When stimulated with G _{αq}) | | ↑(PKC) | Brain, lung, skeletal muscle | Synaptic plasticity | 5q15.3 |
| Type III | ↑ | ↓ | | ↑ (CaM) | | Brain, olfactory cell | Odorant stimulation | 2q22–q24 |
| Type IV | ↑ | ↓ | ↑ | | ↑ (PKC) | Brain | | 14q11.2 |
| Type V | ↑ | ↓ | ↓ | ↓ (Free Ca ²⁺) | ↑ (PKC) ↓ (PKA) | Heart, brain | | 3q13.2–q21 |
| Type VI | ↑ | ↓ | ↓ | ↓ (Free Ca ²⁺) | ↓ (PKA, PKC) | Ubiquitous | Cell proliferation | 12q12–q13 |
| Type VII | ↑ | ↓ | ↑ | | ↑(PKC) | Brain, platelet | | 16q12–q13 |
| Type VIII | ↑ | ↓ | | ↑ (CaM) | | Brain, lung | Synaptic plasticity | 8q24.2 |
| Type IX | ↑ | ↓ | | ↓ (Calcineurin) | | Brain, skeletal muscle | | 16q13.3 |
| Type X | → | → | | | | Testis | | 1q24 |

CGMP PHOSPHODIESTERASE

Vision begins when the chromophore 11-*cis*-retinal, covalently attached to the visual pigment, is isomerized to its all-*trans* form by a captured photon. Within a millisecond, rhodopsin (R) undergoes a conformational change into metarhodopsin (R*), which is capable of activating the photoreceptor-specific G protein, transducin (G_t) (G_t belongs to the G_i subfamily). R* triggers the exchange of GDP to GTP on G_{tα}, which leads to the dissociation of active G_{tα}-GTP and G_{tβγ}. G_{tα}-GTP stimulates the activity of its effector enzyme, cGMP phosphodiesterase (PDE). PDE is a heterotetramer consisting of two catalytic subunits (αβ in rods and αα in cones) and two identical regulatory γ-subunits (γγ), which serve as inhibitors of PDE activity in the resting state. Activation of cGMP PDE causes a reduction of the intracellular cGMP concentration, which leads to the closure of cGMP-gated cation channels located in the plasma membranes of photoreceptor cells. These channels are nonselective cation channels, through which Na⁺ and Ca²⁺ flow into the cell in the resting (dark) state and thus the closure of these channels causes a membrane hyperpolarization and decreased release of the neurotransmitter (glutamate) at the synaptic termini.

GTP hydrolysis on the G_{tα} subunit is accelerated by a RGS protein, RGS9, which is predominantly expressed in photoreceptor cells. It has been shown that RGS9 constitutes a complex with the long splice variant G protein β-subunit type 5 via the G protein γ-subunit-like domain, located next to the RGS domain, of RGS9. RGS9 facilitates GTPase activity on the G_{tα} subunit and thus accelerates the time course of recovery from the flash response approximately 45-fold.

ION CHANNELS

Modulation of ion channels by G proteins can be direct (via physical coupling between G protein and channels) or indirect (via protein kinases). A direct regulation has been firmly established for the G protein-gated inwardly rectifying potassium channel and for the neuronal (N- and P/Q-type) voltage-dependent calcium channel. G_{tβγ} subunits, but not G_{tα} subunits, have been shown to play major roles in these examples of direct regulation.

G protein-gated inwardly rectifying K⁺ (K_G) channels are directly activated by the βγ-subunits released from pertussis toxin-sensitive G_i proteins, hyperpolarize the membrane potential, and contribute to neurotransmitter (acetylcholine)-induced deceleration of the heart beat, formation of slow inhibitory

postsynaptic potentials in neurons, and inhibition of hormone release in endocrine cells.

K_G channels are tetramers of inwardly rectifying K⁺ (Kir) channel subunits, Kir3.x. The combination of Kir3.x subunits constituting each K_G channel varies among tissues and cell types. The cardiac K_G channel is composed of Kir3.1 and Kir3.4, whereas neuronal K_G channels mainly exist as heterotetramers of Kir3.1 and Kir3.2. Each four-subunit channel possesses one G_{tβγ}-binding site within the N- and C-terminal regions. The binding of G_{tβγ} does not alter the fast open-close gating transition of the K_G channel, but increases the number of functional K_G channels via a mechanism that can be described by the Monod-Wyman and Monod-Changeux allosteric models.

Electrophysiological and pharmacological characterizations define multiple classes of voltage-dependent calcium channels, i.e., T, N, L, P/Q, and R types. Among these, the N and P/Q types, which are expressed predominantly in neurons, are inhibited by direct interaction with G_{tβγ} subunits under the effects of a variety of neurotransmitters, including opioids, γ-aminobutyric acid, and somatostatin. The N-type calcium channel is inhibited to a greater extent than the P/Q-type channel. Because both N- and P/Q-type calcium channels mediate neurotransmitter release from presynaptic membranes, their differential modulation by G proteins may suggest a unique contribution of these channels to neurotransmission. Voltage-dependent calcium channels, including N and P/Q types, consist of a pore-forming α₁-subunit, which has four domains, each containing six putative transmembrane segments, and accessory β, γ, and α₂-δ subunits. G_{tβγ} subunits have been shown to interact with cytoplasmic linker regions between domains I and II (I-II linker) of the α₁-subunit.

investigation strategies to understand disease states and to devise therapeutic interventions to enhance dysfunctional physiological inhibition.

PHYSIOLOGY OF THE GABA SYSTEM

The inhibitory neurotransmitter GABA affects neuronal activity mainly by gating selective Cl^- channels associated with GABA_A receptors. GABA function is also mediated by metabotropic receptors (GABA_B), which exert their action by indirectly activating K^+ efflux from neurons through specific channels. The most significant advances in GABA neurophysiology derived from the increased understanding of the role of GABA in the regulation of synaptic functions of various interneuron subtypes in many areas of the neo- and limbic cortices. Although principal inhibitory neurons such as Purkinje cells exist, advances in the understanding of neuronal networks have derived from the study of the properties of GABAergic interneurons.

GABAergic interneurons in the hippocampus and neocortex are typically nonpyramidal in shape and include a wide variety of cellular morphologies (basket, bitufted, horizontal, Martinotti and chandelier cells, etc.). They are distinguished by their voltage- and ligand-gated channels, afferent input, and a complement of neuropeptides colocalized in GABAergic interneurons such as parvalbumin and other calcium-binding proteins. Also, interneurons selectively innervate certain target cells at well-defined cellular regions. For instance, the axo-axonic connections of GABAergic chandelier cells of the neocortex and hippocampus innervate the initial axon segments of pyramidal neurons. In many cortical regions, GABAergic basket cells form dense networks of terminals on the somata of principal pyramidal neurons. The specificity of the chandelier and basket cell targets on principal neurons suggests that GABAergic inhibition in the first case controls somatic integration and in the second case regulates the initiation of action potentials; both actions reflect a major modulatory mechanism of the target cell function.

At the other extreme of the functional interactions between GABAergic interneurons and principal neurons (usually glutamatergic) are some interneurons that terminate on the distal dendrites of principal cells, often at a distance from the somata of principal neurons. Thus, in many cases, the synaptic activation of distal dendrites may not influence the action potential threshold. The main role of this distal inhibitory innervation by GABAergic neurons may be the

modification of local dendritic integration. In the neocortex and cerebellum, interneurons often establish synaptic contact with other interneurons. When the axons of interneurons have such a broad target, they may affect the functional integration among populations of principal cells.

Networks formed by interneurons play a major role in generating rhythmic activity in a neuronal circuit. However, sometimes the details of the functional role of interneurons in a circuit cannot be readily defined because it adapts to changing variables of the circuit afferent and/or efferent functions. The difficulties of developing criteria for classification of interneurons are demonstrated by a study in 1998 by Parra *et al.* on the functional variability of interneurons expressed in the hippocampal CA1 region. This variability is not unique to the hippocampus and supports the view that rigidly definable classes of interneurons subserving specific functions may not be expressed in cortex and hippocampus. However, the possibility must not be ignored that interneuron interactions may be flexible and may change and adapt to contribute to a physiologically important neuronal plasticity.

ELECTROPHYSIOLOGICAL PROPERTIES OF INTERNEURONS

The response properties that distinguish different interneuron subtypes are determined in large part by the expression of different ion channels in their membranes. A distinctive signature of many interneurons is a “fast spiking” firing pattern. The action potential duration of an interneuron often lasts one-half that of the target principal neuron timed at half-maximal amplitude. However, since this definition cannot be extended to every interneuron, a converse argument cannot be made. A burst firing pattern mode is frequent in interneurons and it may be indicative of the participation of a low-threshold Ca^{2+} spike in the initiation of the burst. Efforts to identify the ion channel complement operative in the initiation of burst firing of the interneurons include investigations using single cell reverse-transcriptase polymerase chain reaction techniques to link the structure of a specific ion channel to electrophysiological findings. Such studies have indicated that the fast spiking properties of basket cells in the dentate gyrus of the hippocampus may be due to the translation of mRNA encoding $\text{Kv}3,1/\text{Kv}3,2$ vs $\text{Kv}4,2/\text{Kv}4,3$ channel subunits.

The brevity of the interneuron excitatory postsynaptic potential (EPSP) duration often depends on the presence of AMPA receptors and the absence of

NMDA receptors in the synapses expressed on the interneuron membranes. When the interneuron postsynaptic densities express kainate receptors, the EPSP may last more than 100 ms. Temporal summation of long-lasting kainate-mediated EPSP may also be possible. Thus, an interneuron may act as a coincidence detector or as an integrator when glutamate secreted by the afferent terminals binds to AMPA kainate receptors.

In the early stages of CNS development, GABA often acts as a main excitatory transmitter. In adult neurons activation of GABA_A receptors can stimulate biphasic responses; that is, it can depolarize (stimulate) or hyperpolarize (inhibit) neuronal membranes excitability. During the first week of postnatal life, spontaneous bicuculline-inhibited giant depolarizing potentials trigger an action potential in the neurons of the hippocampal CA3 region. This excitatory effect of GABA in immature neurons is due to a typical outward Cl⁻ gradient; this action potential becomes inward after neuronal maturation. The switch from a depolarizing to a hyperpolarizing GABA_A response during neuronal maturation is correlated with a change in ion transport at postsynaptic membranes from K⁺ to Cl⁻ transport.

At many central synapses during development, only one active zone for transmitter release is expressed in each nerve terminal and only one quantum of neurotransmitter is released by each impulse. In this case, the inhibitory postsynaptic current (IPSC) is short lasting. Multiquantal release may be established with neuronal maturation, leading to an increase in the duration of IPSC. In some hippocampal CA1 neurons, spontaneous quantal releases occur at low rates (~1 Hz); in others, rates of transmitter releases may be higher. A steady-state "tonic" inhibition may be caused by a summation due to a temporal overlap between two spontaneous events. When the summated background conductance is blocked by GABA_A antagonists, increased cell excitability is usually observed. The effect of tonic inhibition may present as a subtle change in firing rates of the principal neuron. For instance, in the cerebellar Purkinje cell, tonic inhibition may elicit irregularities in Purkinje cell firing patterns.

MOLECULAR ARCHITECTURE OF GABA_A AND GABA_B RECEPTORS

It is accepted that GABA is the major inhibitory transmitter in mammalian CNS. There are two important families of GABA receptors: GABA_A and GABA_B. The GABA_A receptor (Fig. 1) is a ligand-gated Cl⁻ ion

Figure 1 A model of GABA_A receptors showing localization of binding sites for GABA and benzodiazepine allosteric modulators. From Costa *et al.*, *Neuropharmacology* **43**, 925–937 (2002).

channel that functions as a polymorphic structure throughout the brain. This polymorphism is due to the expression of specific subunit subtypes (α_6 , β_3 , and γ_3). These subunit subtypes have been cloned and form heteromeric (mainly pentameric) structures. Each GABA_A receptor subunit includes four presumptive transmembrane domains. The GABA_B metabotropic receptors consist of a single subunit with seven presumptive transmembrane domains (Fig. 1). The neurotransmitter binding pocket is buried within the bilayer. GABA_B receptors are coupled to a G protein that regulates an enzymatic effector system (adenylyl cyclase, phospholipase C, or a K⁺ channel).

MODULATION OF GABA RECEPTORS BY NEUROSTEROIDS

In 1984, Harrison and Simmonds demonstrated that the steroidal anesthetic alpraxalone potently and selectively enhances the action of GABA at GABA_A receptors. The rapidity of this modulatory action in single cell studies and the alpraxalone affinity in radioligand binding studies performed on membrane homogenates allow the exclusion of a traditional steroid action on genomic mechanisms. In fact, GABA_A receptors harbor multiple binding sites for steroids that modulate GABA_A receptor function nongenetically, very likely allosterically. An α -hydroxyl group at C3 and a ketone moiety at C20 of the steroid ring probably serve as points of attachment of neurosteroids within the primary binding pocket at the GABA_A receptors, which function by donating and accepting hydrogen bonds, respectively. Additional important stabilizing influences include hydrophobic interactions between the steroid ring system and the receptor protein. Substitutions in β -orientation at C2 and C21 are well tolerated, whereas the effects of chemical modifications at C11 are dependent on a precise substitution. Steroid metabolism can be retarded by

substitution at the 3 β position, which, in the case of phenyl ethylanyl derivatives, may also contribute to the potency of the steroidal modulation of GABA_A receptors by contacting an auxiliary binding pocket.

ANXIOLYTIC ACTION AND ALLOSTERIC MODULATION OF GABA_A RECEPTORS BY BENZODIAZEPINES

GABA_A receptors are molecular substrates for the regulation of vigilance, anxiety, muscle tension, epileptogenic activity, and the onset of anterograde amnesia, which is evident from the spectrum of actions elicited by clinically effective drugs acting at the benzodiazepine (BZ) binding sites expressed by GABA_A receptors. These sites are located at the interfaces of two subunits (α_1 , α_2 , α_3 , or α_5 and γ_2 , γ_3) (Fig. 1). The GABA_A receptor opening frequency is enhanced by BZ receptor agonists; this enhancement is the basis for the BZ efficacy in the treatment of anxiety disorders. Among the BZs, diazepam interacts indiscriminately with every BZ-sensitive GABA_A receptor subtype. Usually, the presence of α_6 or γ_1 subunits in the GABA_A receptors tends to obliterate the BZ-induced positive allosteric modulation of GABA at GABA_A receptors. A conserved histidine residue is critical for the function of ligand binding at BZ receptors expressed in GABA_A receptors. In fact, substitution of the histidine residue with arginine abates the BZ binding site function. Note that other compounds that do not have a BZ chemical structure can also act at BZ sites of GABA_A receptors (e.g., zolpidem and various β carbolines) modulating these receptor positively or negatively (Table I). No endogenous positive or negative modulators of GABA_A receptors have been identified. BZs are also prescribed for absence epilepsy (clonazepam) and status epilepticus (diazepam and lorazepam).

ANTICONVULSANTS ACTING ON GABA SYSTEM

GABA_A receptors are also an important target for anti-convulsants. There are a number of modulatory sites on GABA_A receptors through which various drugs can act to potentiate or inhibit allosterically the actions of GABA. A number of these sites are being exploited to generate useful drugs in the treatment of convulsions, anxiety, sleep disorders, and psychoses.

Barbiturates have been used as anticonvulsants since the early 20th century. Phenobarbital is prescribed for both generalized and partial motor seizures. The primary site of action of barbiturates, such as phenobarbital, is the GABA_A receptor. The barbiturates increase GABA_A receptor open time. At low concentrations, barbiturates positively modulate the GABA_A receptor response to GABA via an allosteric mechanism, increasing the hyperpolarization of the postsynaptic membranes. At higher concentrations, barbiturates are GABA-mimetic. In fact, they are able to activate GABA receptors in the absence of GABA. This ability reflects in part the poorer safety profile of these drugs compared with that of benzodiazepines, which are never agonists per se but allosterically modulate GABA_A receptor responsiveness to GABA at a wide range of doses.

GABAERGIC SYSTEM CHANGES IN DISEASE

It is widely accepted that pathological anxiety depends on a neurobiological and genetic underpinning. A crucial role has been delineated for the amygdala and its array of connections to higher cortical and subcortical areas, particularly the brainstem and hippocampus (both structures are operative in the acquisition and retention of conditioned fear in animals). These connections facilitate acquisition of sensory and interpretative information necessary to select fear responses according to context and allow the coordinated expression of the cognitive, affective, motor, and autonomic components of anxiety.

GABA_A receptor deficits have been identified in patients with anxiety disorders and panic attacks; these deficits were localized in the hippocampus, parahippocampus, and orbitofrontal area. A GABA_A receptor deficit has also been identified in generalized anxiety disorders. Whether GABA_A receptor dysfunction is sufficient to induce anxiety still is debated. Since γ_2 GABA_A receptor subunits are required for GABA_A receptor clustering in postsynaptic densities, mice heterozygous for this γ_2 subunit show decreased binding of benzodiazepines in the hippocampal and parahippocampal area. These heterozygous mice were shown to have decreased binding for BZs. However, there is insufficient evidence that anxiety depends on a GABA_A receptor abnormality.

Another disease in which the function of GABAergic neurons is related to GABA is schizophrenia. Documented in this disease is a GABAergic

neuron downregulation of GAD₆₇ and reelin mRNA expression. Reelin is an important protein that during embryonic corticogenesis guides the layering in the cortex of neurons migrating via radial glia toward the cortical marginal zone from a ventricular proliferative center. It was formerly believed that reelin disappeared from the brain when the embryonic corticogenesis was terminated (i.e., approximately the sixth month of gestation in humans). However, it has been established that reelin persists throughout the life span and may play a crucial role in activating the translation of extrasomatic mRNA in the dendritic spines. Thus, it has been suggested that reelin plays a fundamental role in activating event-related protein synthesis leading to spine morphological changes that establish memory traces related to these events. It has also been found that in schizophrenia, there is an increase in the mRNA encoding for a DNA methylating enzyme in cortical GABAergic neurons. From this seminal finding, it can be speculated that GABAergic neurons may become an important target for new treatments of psychosis.

Key hormonal regulators of these processes are cholecystokinin (CCK) and secretin, both representing gastrointestinal peptide hormones. Both are produced in endocrine cells scattered among the mucosal cells lining the upper intestine. They are secreted in response to various components of chyme in the lumen of the intestine and they go on to act on mucosal epithelial cells and smooth muscle within the gallbladder and bile duct.

REGULATION OF GALLBLADDER SECRETION AND CONTRACTILITY

The major physiologic stimulant of gallbladder emptying is CCK. This peptide hormone is secreted from I cells scattered throughout the duodenum and proximal two-thirds of the jejunum in response to the products of digestion of protein and fat components of a meal. The secreted hormone then binds to high-affinity type A CCK receptors present on gallbladder smooth muscle and neurons in the gallbladder and pancreas. These receptors are members of the Class I guanine nucleotide-binding protein (G protein)-coupled receptor family. Key physiologic actions of this hormone are the stimulation of gallbladder contraction and pancreatic exocrine secretion, both representing events critical to the intraluminal digestion of fats and protein. As such, this represents a logical and appropriate regulatory loop.

The gallbladder is predominantly an absorptive organ, in which water and electrolytes are absorbed in the process of concentrating the bile, considered to represent a constitutively active process. Little is known about the hormonal regulation of absorption and secretion at the level of the gallbladder mucosa.

REGULATION OF BILIARY SECRETION

Secretin is a key physiologic stimulant of the secretion of bicarbonate-rich fluid from biliary epithelial cells. This regulatory loop is also beautifully designed. Secretin is secreted from S cells scattered within the mucosal layer of the duodenum. This hormone is secreted in response to acid in the lumen. It binds to receptors that are prototypical of the Class II family of G protein-coupled receptors, all of which bind moderately large peptide hormones having diffuse and complex pharmacophoric domains. By stimulating alkaline secretion from the pancreaticobiliary ductular tree, the resulting exocrine secretion works to

neutralize the luminal contents. This is critically important to provide a nondamaging milieu for bile acids and for digestive enzymes.

IMPLICATIONS OF DYSFUNCTION OF THE GALLBLADDER AND BILIARY TREE

An intact excretory/secretory pathway that provides a conduit for bile and links the liver with the upper gastrointestinal tract is critical. Obstruction of this ductular structure leads to cholestasis, with damage to the liver and with retention of toxic compounds in the circulation. Even partial obstruction of the biliary tree has substantial clinical implications. Gallstones are the major clinical problem in these structures, often being formed in the gallbladder, where the bile is concentrated and where stasis can occur. Gallstones can be expelled from the gallbladder and can obstruct the bile or pancreatic duct, leading to a cholestatic pattern or pancreatitis or both. Tumors of the bile ducts and gallbladder can also occur.

Surgical removal of the gallbladder eliminates the reservoir and bile concentration function, but normally has relatively little clinical effect. Bile continues to enter the duodenum, without the advantage of titration and regulation provided by hormonal stimulation of gallbladder contraction. Although the bile acid concentration achieved in the intestinal lumen is lower than normal, it is adequate for most critical digestive functions.

There are no common recognized abnormalities of CCK or secretin secretion. Maldigestion leads to inadequate stimulation of CCK secretion that only exacerbates the digestive problem. In this setting, it is key to correct the underlying digestive problem.

Gastric Inhibitory Polypeptide

see GIP

Figure 1 Schematic representation of the biosynthesis of gastrin. Preprogastrin is translated in the endoplasmic reticulum (ER) and is converted there to progastrin, which translocates through the Golgi complex to secretory vesicles. In the trans-Golgi network (TGN), progastrin may be phosphorylated on Ser-96, sulfated on Tyr-86, or both. In secretory vesicles, it is cleaved to yield a COOH-terminal Gly peptide of 34 residues (G34-Gly), which may then be converted by COOH-terminal α -amidation to G34 or cleaved to G17-Gly. In pyloric antral G cells, G17 and (to a lesser extent) G34 are the main products of regulated secretion. In some tumor cells, progastrin may be secreted by the constitutive pathway direct from the TGN to the cell surface.

in secretory vesicles, where it may be cleaved by enzymes of the prohormone convertase family. Biosynthetic intermediates with a COOH-terminal glycine residue (Gly-gastrins) provide substrates for the enzyme peptidyl α -amino mono-oxygenase, which yields COOH-terminally amidated gastrins (Fig. 1). The amidated gastrins are typically peptides of 17 and 34 amino acid residues (G17 and G34), both of which occur as tyrosine-sulfated and unsulfated peptides. G34 corresponds to an NH₂-terminal extended form of G17. Human gastrin (G) cells normally secrete mainly amidated gastrins, but small amounts of both progastrin and Gly-gastrins may also be released. The COOH-terminal pentapeptide amide of G17 (-Gly-Trp-Met-Asp-Phe-NH₂) is identical to that in the related hormone cholecystokinin (CCK).

Circulating Forms and Metabolism

The concentrations of amidated gastrins in the plasma of normal fasting humans are generally less than 30 pM. A mixed meal increases gastrin concentrations up to about threefold. The major circulating form of gastrin in humans is G34; however, this form is typically less than 10% of gastrin stored in G cells. In humans, it is cleared with a half-life of approximately 35 min, compared with approximately 7 min for G17. The difference in clearance accounts in part for the tendency of G34 to accumulate in plasma.

Figure 2 Schematic representation of cellular relationships in the pyloric antral epithelium. The release of gastrin from G cells is stimulated by peptides and amino acids in the gastric lumen and by neurotransmitters (not shown). Acid releases somatostatin from D cells, and this inhibits gastrin release. In the presence of the gastric bacterium *Helicobacter pylori*, proinflammatory cytokines may inhibit D cells and stimulate G cells and so enhance gastrin release indirectly and directly.

THE G CELL AND ITS CONTROL

G cells are found in the pyloric antral mucosa of all mammalian species. In humans, there are also some G cells in the duodenum. After a meal, gastrin is released in response to gastric luminal stimuli (mainly protein, peptides, and amino acids) and in response to nervous stimuli (Fig. 2). One candidate neurotransmitter regulating the G cell is gastrin-releasing peptide (GRP), which is a mammalian relative of the amphibian skin peptide bombesin. Gastric acid inhibits gastrin release, producing a negative feedback loop. Therefore, decreases in gastric acid secretion, either through disease (e.g., gastritis) or by drug treatment (e.g., proton pump inhibitors), tend to increase gastrin release. The effects of acid are mediated by release of somatostatin from D cells in the antrum, which then suppresses the G cell by a paracrine mechanism (Fig. 2). In patients with *Helicobacter pylori*, there is a tendency for increased gastrin release. This is attributable to proinflammatory cytokines that are thought to act partly by inhibiting D-cell function and partly by directly stimulating G cells (Fig. 2).

GASTRIN RECEPTORS

The effects of gastrin are exerted at gastrin-CCK_B receptors (also known as CCK-2 receptors). These are found on gastric parietal and ECL cells, some smooth muscle cells, and some central nervous system (CNS) neurons. This receptor has high affinity for both gastrin and CCK; gastrin is the main ligand for receptors on parietal and ECL cells because its plasma concentrations are roughly 10 times higher than those of CCK. However, CCK is the main ligand for CNS

receptors because there is abundant CCK, but little or no gastrin, in the brain. The gastrin–CCK_B receptor belongs to the family of G protein-coupled receptors, characterized by seven transmembrane domains. It acts via the G $\alpha_{q/11}$ group of G proteins to increase intracellular calcium concentrations and protein kinase C activity. Several antagonists have been generated, including YF476 and L-740,093.

THE PHYSIOLOGY OF GASTRIN

Acid Secretion

The primary action of gastrin is the stimulation of acid secretion. The question of whether gastrin acts primarily on the acid-producing parietal cells or indirectly via histamine release from ECL cells has been the subject of intense debate. It is now generally thought that gastrin acts mainly via histamine release from ECL cells (Fig. 3). Immunoneutralization of circulating gastrin, or administration of gastrin–CCK_B receptor antagonists, inhibits gastric acid responses to food. In mice in which the gastrin or gastrin–CCK_B receptor genes have been deleted by homologous recombination, there is a loss of acid secretion that is refractory to acute stimulation by gastrin, histamine, or cholinergic agonists. However,

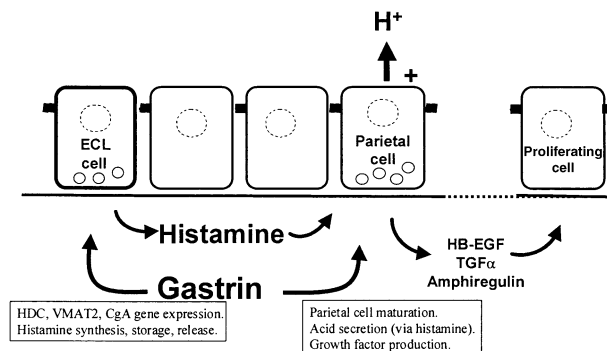

Figure 3 Schematic representation of some effects of gastrin in the gastric corpus. Gastrin stimulates histamine release from enterochromaffin-like (ECL) cells, and this in turn stimulates acid secretion from parietal cells. In ECL cells, gastrin also increases the production of histidine decarboxylase (HDC), which makes histamine from histidine; vesicular monoamine transporter type 2 (VMAT2), which sequesters histamine in secretory vesicles; and chromogranin A (CgA), which is co-stored with histamine. ECL cell numbers are regulated by gastrin. Parietal cells may also respond directly to gastrin. In addition to acute effects on acid secretion, gastrin controls the maturation of parietal cells and stimulates the production of growth factors, particularly members of the epidermal growth factor (EGF) family, including heparin-binding EGF, transforming growth factor (TGF)- α , and amphiregulin, which increase proliferation of other cells in the epithelium.

acid secretory capacity can be restored by infusion of gastrin, indicating a role for this hormone in maturation of the parietal cell as well as in acute secretory responses after a meal.

ECL Cells

Gastrin increases the expression of several genes in ECL cells that are important for histamine synthesis and storage; these include histidine decarboxylase (HDC), which makes histamine from histidine; vesicular monoamine transporter type (VMAT2), which transports histamine into secretory vesicles; and chromogranin A, which is co-stored with histamine in secretory vesicles (Fig. 3). In addition, gastrin increases ECL cell number, probably by a direct effect on proliferation. In patients with prolonged increases in plasma gastrin, there is a tendency for ECL cell hyperplasia; in extreme cases, these patients may exhibit ECL cell carcinoid tumors that may resolve after removal of gastrin by antrectomy.

Proliferation

Gastrin increases the proliferation of epithelial cells in the stomach. Apart from ECL cells, it is not clear whether proliferating cells express the gastrin–CCK_B receptor. Therefore, proliferative responses are thought to be due to release of growth factors, including those of the epidermal growth factor (EGF) family (Fig. 3).

Motility

Gastrin contracts smooth muscle and may regulate gastrointestinal motility, but the physiological significance of these effects is still uncertain.

Central Nervous System

There are abundant gastrin–CCK_B receptors on CNS neurons, but it is thought that the related peptide CCK is the main ligand for these receptors. There is little evidence to suggest that circulating gastrin released from antral G cells in mammals influences CNS function.

GASTRIN IN GASTROINTESTINAL DISEASE

Elevated plasma gastrin concentrations occur in patients with gastrin-secreting tumors of the pancreas (Zollinger–Ellison syndrome, gastrinoma) and are

associated with increased acid secretion and intractable peptic ulcer. There are also high plasma gastrin concentrations in patients with pernicious anemia, which is attributable to autoimmune destruction of parietal cells and loss of acid inhibition of the G cell. In both groups of patients, there is a tendency for ECL cell carcinoid tumors. Moderately elevated plasma gastrin concentrations also occur in some patients infected with *H. pylori* (Fig. 2). When the infection is limited to the antrum, increased gastrin release may lead to increased acid secretion and duodenal ulcer.

Recent work suggests that the gastrin gene is expressed in colorectal carcinoma, but the main products of expression are progastrin and Gly-gastrin (Fig. 1). These are thought to be growth factors for colon tumor cells. They do not act at gastrin-CCK_B receptors, and the relevant receptor is still uncertain.

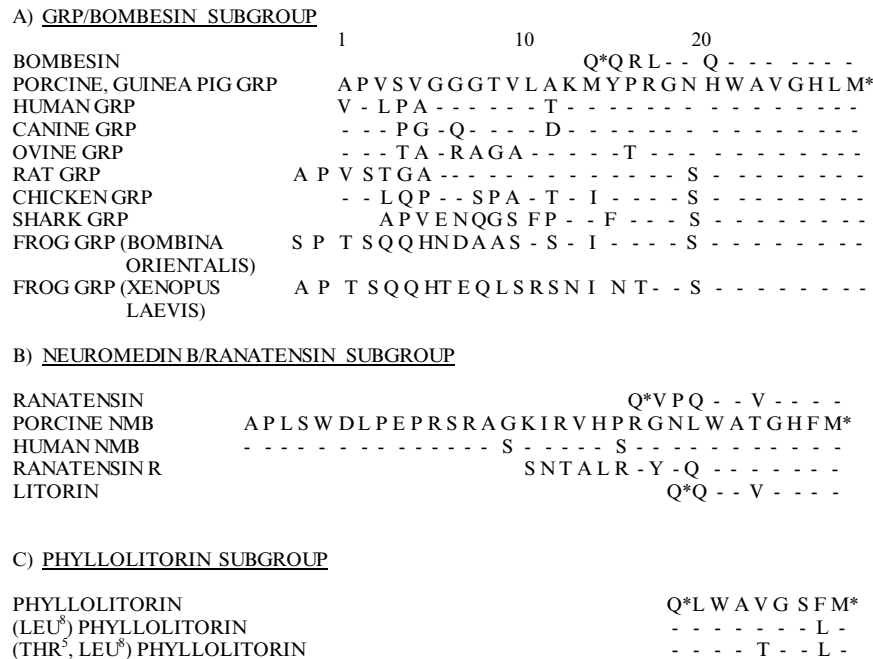

Figure 1 Bombesin-related peptide families. The amino acid sequences of the bombesin-related peptide family members are portrayed using the one-letter identification nomenclature (*Eur. J. Biochem.* 5, 151 [1968]). All members are aligned at their C-terminal residues. Amino acid residues identical to those in the sequence of porcine and guinea pig GRP are identified by a space (-). M*, methionyl amide; Q*, pyroglutamyl; NMB, neuromedin B.

multiple forms occur both in normal neural and endocrine tissue and in neoplastic cells, but the physiological significance of their presence is not fully understood.

GRP/BOMBESIN FAMILY RECEPTOR SUBTYPES

Four distinct receptor subtypes interacting with members of the GRP/bombesin peptide family have been characterized. All are members of the seven-transmembrane G protein-linked receptor family, and each has approximately 50% structural homology with the others, acts through second messenger pathways and promotion of cellular calcium fluxes to produce the recognized bioactivities, and has distinct ligand-binding affinities and tissue distributions. The first subtype characterized was the GRP-preferring receptor (designated BB-2), which has a higher affinity for GRP than for bombesin. The second subtype (designated BB-1) has a greater affinity for neuromedin B than for GRP. The third receptor subtype (designated BB-3) was identified in the pregnant (but not the nonpregnant) guinea pig uterus and subsequently in the human pregnant uterus and other mammalian

tissues. The BB-3 receptor subtype is GRP rather than neuromedin B preferring but has a lower binding affinity for GRP than would be expected, suggesting that a natural ligand for this receptor has not yet been identified. Interestingly, synthetic peptide analogues of members of this family have been shown to have high affinity for BB-3. The fourth receptor subtype (designated BB-4), recently identified in frog brain, is a Phe-13 bombesin-recognizing receptor.

LOCATIONS AND ACTIONS

The anatomical locations and recognized biological actions of GRP have been reviewed. In the mammal, GRP is principally confined to neural elements of the central, peripheral, and enteric nervous systems but is also found in neuroendocrine cells of peribronchial epithelial tissue, in certain neuroendocrine neoplastic cells (e.g., small cell lung cancer, medullary carcinoma of the thyroid, carcinoid tumors), and in certain epithelial-derived cancers.

Intracerebral administration of GRP to mammals results in potent and diverse biological effects, including the production of hypothermia and hypoglycemia, alteration of the sensation of satiety, and increased sympathetic tract outflow. Peripheral intravenous

administration of GRP results in a multitude of activities; it potently affects the release of a number of biologically active peptides (hormones and neuropeptides) and alters gastrointestinal smooth muscle activity and exocrine secretions of the pancreas and stomach. However, there is no single activity that has been demonstrated to be unequivocally physiological. There is evidence for a role for GRP in vagal mechanisms resulting in the stimulation of gastric acid secretion and gastrin release, although a physiological role for the latter activity has been questioned.

OTHER DIRECTIONS OF STUDY

Having been first identified in neural tissues of the CNS and gastrointestinal tracts, most early studies were directed toward target tissues in these areas. A new direction of studies occurred with the finding that GRP was present in small cell carcinoma of the lung and that it might act as a trophic agent in these cells. These findings provided the impetus for other studies that demonstrated the presence of GRP and/or its receptor in a number of epithelial cell-derived and neural tissue-derived cancers and that GRP might act as a trophic agent in a number of these tissues. One study demonstrated the presence of GRP and its receptor in colon cancers. Both GRP and its receptor were often present in adenomas and well-differentiated colon cancers but not in normal colon epithelial cells or in poorly differentiated cancer cells, findings that are consistent with earlier observations made in small cell carcinoma of the lung. Of interest, although a number of studies have shown inhibition of tumor growth by blocking GRP's interaction with its receptor, certain studies have provided evidence that the presence of GRP and its receptors is associated with a survival advantage.

In a very different line of studies, GRP and GRP-like peptides have been demonstrated to be present and produced in the ovine pregnant uterus and ovine pregnancy fluids as well as in human maternal and fetal placental membranes, with rapid disappearance of the peptide postpartum. Given that a number of studies have demonstrated GRP's trophic effects on fetal tissues, GRP may have important but as yet unelucidated roles in developmental biology. Further clues to its potential importance in this regard are the early observations of GRP's presence in human fetal and pathological neonatal lung together with studies that demonstrate its trophic effects on lung. Early (and little noted) studies demonstrated that GRP is present not only in neoplastic adult lung tissues

but also in nonneoplastic pathological lung lesions, suggesting that a pathological process, but not necessarily a neoplastic process, will result in the reappearance of GRP. The findings that GRP has been seen in well differentiated but not in poorly differentiated neoplastic lesions, and that it has been seen in certain nonneoplastic but pathological tissues, lead to the suggestion that GRP has an undefined role during pathological processes that may be related to its roles in ontogeny. GRP may play an important role not solely as a mitogen but also as a differentiation agent in normal development, and such a regulatory role may be replayed in pathology. Hence, it has been suggested that GRP may play a role as a "morphogen" as well as a mitogen.

Because GRP appears to be present in certain neoplasms, a few studies have suggested that the presence of GRP in body fluids may act as an aid to the diagnosis of disease. In addition, given the presence of receptors for GRP on a number of neoplastic cells, it has been suggested that radiolabeled GRP and GRP analogues may be useful in the imaging of neoplasms.

Further studies into GRP's role as a developmental agent and its potential use as a diagnostic tool may prove to be fruitful.

Table I Clinical Features of Patients with ZES

| Feature | NIH data (n = 261) | Literature data (range) |
|--|-----------------------|----------------------------|
| Gender (percentage male) | 56 | 44–70 |
| Mean age onset (years) | 41 | 41–53 |
| Initial symptom (percentage) | | |
| Abdominal pain | 75 | 26–98 |
| Diarrhea | 73 | 17–73 |
| Heartburn | 44 | 0–56 |
| Nausea | 30 | 8–37 |
| Vomiting | 25 | 26–51 |
| Bleeding | 24 | 8–75 |
| Pain and bleeding | 19 | 19–44 |
| Pain and diarrhea | 55 | 28–56 |
| Mean duration of symptoms (years) | 5.2 | 3.2–8.7 |
| MEN1 present (percentage) | 22 | 10–48 |
| History-confirmed peptic ulcer (percentage) | 71 | 71–93 |
| Esophageal stricture (percentage) | 4 | 4–6 |
| Abdominal perforation (percentage) | 5 | 5–18 |

Note. NIH data are from 261 patients with ZES. Literature data are from 10 series with 12 to 369 patients.

Gastrinomas were originally reported to be non-beta cell tumors of the pancreas, but currently approximately one-half are found in the duodenum, one-fourth in the pancreas, and the remainder in other sites (Table II). One controversial area is whether primary gastrinomas occur in abdominal lymph nodes. A long-term National Institutes of Health (NIH) study suggests that 10 to 11% of all primary gastrinomas may occur in lymph nodes. Other unusual intra-abdominal sites include the gastric antrum, biliary tract or liver, mesentery, ovary, and spleen. Extra-abdominal gastrinomas also occur rarely (<0.5%) in the cardiac intraventricular septum and due to a small cell lung cancer secreting gastrin. In the duodenum, 57% of the gastrinomas occur in the first portion and 31% occur in the second portion. Most patients have localized disease at presentation (83%) with no liver metastases, although 17% have or develop liver metastases. Approximately one-third of patients have a primary tumor only found at surgery, one-third have a primary tumor with lymph node metastases, one-fourth have a primary tumor with liver metastases, and one-fifth have either only liver metastases (3%) or only lymph node metastases (19%) (Table II).

Table II Characteristics of Gastrinomas (percentages)

| Feature | NIH data | Literature data (range) |
|------------------------------|----------|----------------------------|
| Location | | |
| Pancreas | 24 | 21–70 |
| Duodenum | 49 | 6–32 |
| Lymph node | 11 | <1 |
| Other | 9 | 0–18 |
| Unknown | 16 | 7–48 |
| Duodenal location | | |
| D-1 | 57 | ND |
| D-2 | 31 | ND |
| D-3 | 6 | ND |
| D-4 | 3 | ND |
| Extent of disease | | |
| No tumor found | 13 | 7–48 |
| Localized disease | 70 | 23–51 |
| Metastatic disease to liver | 17 | 13–53 |
| Extent metastases | | |
| Primary only | 36 | 23–51 |
| Primary and lymph nodes | 29 | 8–61 |
| Primary and liver metastases | 23 | 15–38 |
| Liver metastases only | 3 | 4–14 |
| Lymph node metastases only | 16 | 4–23 |

MOLECULAR PATHOGENESIS OF GASTRINOMAS

Similar to other gastrointestinal neuroendocrine tumors (NETs) (e.g., carcinoids, pancreatic endocrine tumors [PETS]), abnormalities in common oncogenes (e.g., ras, c-Jun, 1-fos) are uncommon in gastrinomas, as are alterations in common tumor suppressor genes (e.g., retinoblastoma, p53). In contrast, studies suggest that alterations in the HER2/neu gene (a member of the Erb β -like oncogene family), the MEN1 gene on 11q13, and the p16^{INK4a} gene on chromosome 9p21, as well as overexpression of epidermal growth factor and hepatocyte growth factor receptors (EGFRs and HGFRs, respectively), may be important in the molecular pathogenesis of gastrinomas and other PETS. Of these alterations, only overexpression of EGFRs has been shown to correlate with invasiveness.

DIAGNOSIS/DIFFERENTIAL DIAGNOSIS

The diagnosis remains elusive, with a 4- to 7-year delay in diagnosis from onset of symptoms (Table I). This delay occurs because ZES is uncommon (1–3

new cases/1 million population/year) and its presentation closely mimics common disorders: idiopathic PUD (2300 cases/1 million population/year) and idiopathic gastroesophageal reflux disease (GERD), which occurs in 3 to 4% of the population. A recent study provides evidence that the widespread use of proton pump inhibitors (PPIs) is complicating and delaying the diagnosis of ZES further. This is occurring because PPIs are powerful acid suppressants that can control symptoms in patients with ZES, thereby masking the diagnosis. Furthermore, PPIs can cause hypergastrinemia in patients without ZES, and this can complicate the diagnosis of ZES in these patients. The diagnosis of ZES should be particularly suspected in patients with PUD with diarrhea, endocrinopathies, family history of PUD or endocrinopathies, and/or recalcitrant PUD disease as well as in patients with PUD without *Helicobacter pylori* or with PUD complications. Diagnosis is made by measuring fasting gastrin levels after stopping all antisecretory drugs (e.g., PPIs \times 1 week, histamine H₂ antagonists \times 1 day), which are elevated in 90 to 98% of patients. If the fasting gastrin level is elevated, gastric fluid pH should be assessed and the fasting gastrin should be repeated. If the gastric pH is more than 2.0 and the fasting serum gastrin is elevated, it is unlikely that ZES is present. If the fasting gastrin is elevated more than 10-fold with a gastric pH of less than 2.1, ZES is confirmed when there is no previous history of gastric resection. Unfortunately, two-thirds of patients have fasting gastrin levels increased less than 10-fold (101–999 pg/ml), and a number of other conditions can mimic ZES in this range (e.g., *H. pylori* infection, gastric outlet obstruction, antral G-cell hyperplasia/hyperfunction, chronic renal failure, short bowel syndrome). These can be excluded by both measuring a basal gastric secretory rate for 1 h and performing a secretin test. The secretin test yields no false positives except in patients with achlorhydria, and it is positive in 87% of patients with ZES in this fasting gastrin range.

TUMOR LOCALIZATION

Localizing the primary tumor, as well as determining the extent of the tumor, is essential for all management steps. It is necessary to determine whether surgical exploration should be undertaken, the extent of possible resection, and the location of the primary tumor (to enhance the possibility of cure), as well as to assess changes in tumor size with patients with advanced metastatic disease, either in response to antitumor treatment or in determining the need

for it. Somatostatin receptor scintigraphy (SRS) with [¹¹¹In-DTPA-DPhe¹]octreotide (Figs. 1 and 2) and single photon emission computed tomography (SPECT) is now the initial imaging study of choice due to its greater sensitivity and ability to image all body areas at one time. SRS is more sensitive than all conventional imaging modalities combined (e.g., computed tomography [CT], magnetic resonance imaging

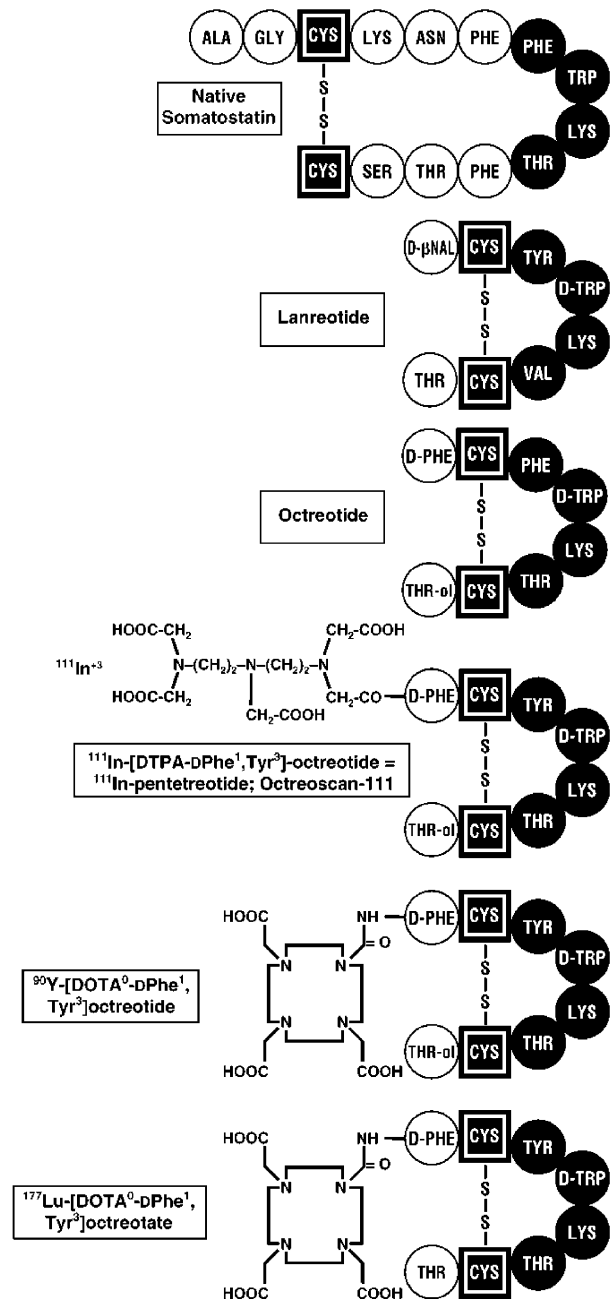

Figure 1 Structure of somatostatin and synthetic analogues used for tumor localization or radiotherapy.

Figure 2 Comparison of the ability of CT scan and SRS to localize a primary gastrinoma in a patient with ZES. Only the SRS is positive, showing its greater sensitivity.

[MRI], ultrasound), but it does not give reliable information on tumor size (Figs. 2 and 3). Therefore, a CT scan with contrast is also recommended. Endoscopic ultrasound is recommended by some but rarely localizes duodenal tumors; therefore, it is helpful in a minority of the patients. For patients with negative SRS, functional/localization studies measuring gastrin gradients with angiography are recommended.

MANAGEMENT

General

Treatment needs to be directed at controlling the gastric acid hypersecretion initially and long term as well as directed at the gastrinoma per se. It is also

Figure 3 Comparison of the ability of CT scan and SRS to localize metastatic disease in the liver in a patient with ZES. Only the SRS localizes a metastasis in the left lobe, showing its greater sensitivity.

important to determine whether the patient has ZES due to the presence of MEN1 because this requires additional treatment strategies. MEN1 is generally recognized by a careful family and personal history for endocrinopathies (especially hyperparathyroidism, pituitary disease, and other PETs) and assessment for these endocrinopathies by appropriate hormonal assays. The hyperparathyroidism is usually present prior to ZES onset and is best diagnosed by measuring serum ionized calcium levels and plasma-intact PTH (Table III).

Control of Acid Hypersecretion

Many patients with ZES have basal acid secretory rates elevated more than fivefold and can rapidly develop complications due to the gastric acid hypersecretion if

Table III Management of ZES

| |
|---|
| Treatment of gastric acid hypersecretion |
| Drugs of choice: PPIs (e.g., omeprazole, lansoprazole, pantoprazole, rebepirazole, esomeprazole) |
| PPIs control acid secretion >99% |
| Histamine H ₂ receptor antagonist less effective (frequent high doses needed) |
| Total gastrectomy (needed only in rare patient who cannot take oral drugs) |
| Treatment of gastrinoma |
| In patients without MEN1 (75%) (sporadic ZES) |
| Surgery cures 60% in short term (<1 year); 30–35% at 5 years postresection |
| At surgery, routine duodenotomy and intraoperative ultrasound needed, with tumor enucleation used most frequently |
| Aggressive resection (Whipple procedure) rarely needed |
| In patients with MEN1/ZES (25%) |
| Tumor enucleation rarely (<1%) curative given that 60–80% of gastrinomas are duodenal in location, multiple, and/or with lymph node metastases (50–70%) |
| Surgery generally recommended if tumor is imaged ≥ 2 –3 cm |

Note. PPIs, proton pump inhibitors.

it is not controlled both acutely and for the long term. PPIs (e.g., omeprazole, lansoprazole, pantoprazole, rabeprazole, esomeprazole) are now the mainstay of treatment, starting at a dose equivalent to 60 mg per day of omeprazole. Patients with MEN1, severe GERD, or previous gastric acid-reducing surgery should be started on this dose given twice a day. With time, the dose can be decreased in most patients. During periods when parenteral antisecretory drugs are needed, intravenous PPIs (intravenous pantoprazole in the United States) are now the drugs of choice. Oral or intravenous histamine H₂ receptors can be used, but high frequent oral dosing is needed and continuous intravenous infusions are recommended. Total gastrectomy is rarely used today and is reserved for the rare patient who cannot take oral medication (Table III).

Treatment of the Gastrinoma

Surgical

In all patients with sporadic ZES (without MEN1), without liver or distant metastatic disease, and without concomitant illnesses that shorten life expectancy or increase the risk of surgery, exploratory laparotomy by a surgeon experienced in the treatment of this disease should be performed. Enucleation of pancreatic head/

body tumors should be performed. If needed, distal pancreatectomy for pancreatic tail lesions should be performed. Whipple resection is generally not recommended. In 5 to 15% of patients with advanced disease with liver metastases, cytoreductive surgery should be considered if more than 90% of the visible tumor can be removed.

In patients with MEN1/ZES, the type of surgery and when it should be performed are controversial because these patients cannot be cured generally but still have an excellent long-term prognosis. We recommend exploration when any lesion more than 2 cm in diameter is imaged because numerous studies demonstrate that tumor size is a strong prognostic factor for metastatic spread to the liver, which is associated with decreased survival. Lymph node metastases are frequent, even with small duodenal gastrinomas, but have not been shown to be associated with decreased survival.

Medical

Patients with metastatic gastrinoma in the liver have a decreased survival rate. Studies show that survival is especially decreased in the 40% of patients with a rapidly growing metastatic tumor. In this subset of patients, antitumor treatment is indicated. Long-acting somatostatin analogues, such as octreotide-LAR (Fig. 1) (given once monthly) alone or in combination with α -interferon (given three times/week), are now the recommended initial treatments. These agents cause a decrease in tumor size in only 15 to 20% of patients; however, they cause a cessation of growth in 50 to 70% of patients and continue to remain effective for years in many patients. Chemotherapy (e.g., streptozotocin, doxorubicin \pm 5-fluorouracil) causes a decrease in tumor size in 5 to 50% of patients but has significant toxicity and has not been shown to extend life in patients with gastrinomas.

CONCLUSION

Gastrinomas are an uncommon cause of PUD, but if diagnosed, the gastric acid hypersecretion can be controlled in every patient. The natural history of the gastrinoma is becoming an increasingly important determinant of long-term survival, so the typical 5-year delay in diagnosis remains a major challenge to instituting treatment early in the disease course in many patients. Furthermore, studies suggest that the widespread use of PPIs may further delay the diagnosis of ZES.

Table I General Characteristics of Gastrointestinal Neuroendocrine Tumors (NETs) (Pancreatic Endocrine Tumors and Carcinoids)

| |
|---|
| Share general neuroendocrine cell markers |
| Chromogranins (Cgs) (A, B, C) are acidic monomeric-soluble proteins found in the large secretory granules. CgA is most widely used. |
| Neuron-specific enolase is the γ - γ dimer of the enzyme enolase and is a cytosolic marker of neuroendocrine differentiation. |
| Synaptophysin is an integral membrane glycoprotein (38 kDa) found in small vesicles of neurons and neuroendocrine tumors. |
| Pathologic similarities |
| All NETs show amine precursor uptake and decarboxylation (APUDomas). |
| Ultrastructurally, they have dense-core secretory granules (> 80 nm). |
| Histologically, they appear similar with few mitoses and uniform nuclei. |
| Frequently, they synthesize multiple peptides/amines, which can be detected immunocytochemically but may not be secreted. |
| The presence or absence of clinical syndrome or type cannot be predicted by immunocytochemical studies. |
| Histological classifications do not predict biologic behavior. Only invasion or metastases establish malignancy. |
| Similarities of biologic behavior |
| They are generally slow growing, but a proportion are aggressive. |
| They secrete biologically active peptides/amines, which can cause clinical symptoms. |
| They generally have high densities of somatostatin receptors, which are used for both localization and treatment. |

distinguish between benign and malignant NETs unless metastases or invasion are present.

PETs are classified according to the specific clinical syndrome they cause or, if no clinical syndrome occurs, as nonfunctional (Table II). Nonfunctional PET in the strict sense is a misnomer because these tumors frequently secrete multiple peptides (pancreatic polypeptide, CgA, and neurotensin); however, they do not cause a specific clinical syndrome. The symptoms caused by nonfunctional PETs are due to the tumor per se.

Carcinoid tumors are frequently classified by location of origin (foregut, midgut, or hindgut) because they share histochemical, functional, and biologic characteristics within these areas (Table III). Foregut carcinoids generally have low serotonin (5-HT) content, are argentaffin negative on silver staining, synthesize several hormones, and occasionally secrete ACTH or 5-hydroxytryptophane (5-HTP) causing an atypical carcinoid syndrome. Midgut carcinoids are generally argentaffin positive, have high serotonin content, frequently multihormonal, rarely secrete 5-HTP or ACTH, and most frequently cause carcinoid syndrome when they metastasize (Table III). Hindgut carcinoids (transverse colon to rectum) are argentaffin negative; rarely contain serotonin, 5-HTP, and ACTH or cause carcinoid syndrome; contain numerous peptides; and frequently metastasize to bone. Most carcinoids (70%) occur in one of four sites—bronchus, jejunum/ileum, rectum, or appendix—although they can occur in any tissue (Table III). Overall, the GI tract is the most common site for carcinoids (74% of

cases), and the respiratory tract the second most common site (25% of cases).

The frequency of NETs varies according to whether they are symptomatic. The incidence of clinically significant PETs is 10 cases/1 million population/year. Their relative incidence is insulinoma, gastrinoma, and nonfunctional (0.5–2.5 cases/1 million/year) > VIPomas (2–8 times less common) > glucagonomas (17–30 times less common) > somatostatinomas. In autopsy studies, 0.5–1.5% of all cases have PETs, with less than 1 in 1000 symptomatic. Clinically significant carcinoids occur in 7–13 cases/1 million/year and malignant cases at autopsy in 21–84 cases/1 million/year.

Both PETs and carcinoids can show malignant behavior. With PETs, 50–100% are malignant, except for insulinomas, in which < 10% are malignant (Table II). With carcinoid tumors the percentage that are malignant varies with different locations (Table III). A number of factors are predictive of tumor aggressiveness and/or survival for NETs (Table IV). The presence of liver metastases is the most important prognostic factor. Primary tumor size is also an important predictor. The factors in Table IV need to be considered when determining the aggressiveness of treatment of NETs.

Until recently, the molecular pathogenesis of NETs was largely unknown because common oncogenes (*ras*, *fos*, etc.) and common tumor suppressor genes (retinoblastoma gene, *p53*) were usually not altered. Recent studies provide evidence that alteration in the *HER2/neu* oncogene, *MEN-1* gene, and *p16INK4a*

Table II Gastrointestinal Neuroendocrine Tumor Syndromes

| Syndrome | Biologically active peptide(s) secreted | Incidence (new cases/10 ⁶ population/year) | Tumor location | Malignant (%) | Main symptoms/signs |
|---|--|---|---|---------------|---|
| Established specific functional syndrome | | | | | |
| Pancreatic endocrine tumor | | | | | |
| Zollinger–Ellison syndrome (gastrinoma) | Gastrin | 0.5–1.5 | Duodenum (70%) Pancreas (25%) Other sites (5%) | 60–90 | Pain (79–100%) Diarrhea (30–75%) Esophageal symptoms (31–56%) |
| Insulinoma | Insulin | 1–2 | Pancreas (> 99%) | < 10 | Hypoglycemic symptoms (100%) |
| VIPoma (Verner–Morrison syndrome, pancreatic cholera, WDHA) | Vasoactive intestinal peptide | 0.05–0.2 | Pancreas (90%; adult) Other (10%; neural, adrenal, periganglionic) | 40–70 | Diarrhea (90–100%) Hypokalemic (80–100%) Dehydration (83%) |
| Glucagonoma | Glucagon | 0.01–0.1 | Pancreas (100%) | 50–80 | Rash (67–90%) Glucose intolerance (38–87%) Weight loss (66–96%) |
| Somatostatinoma | Somatostatin | Rare | Pancreas (55%) Duodenum/jejunum (44%) | > 70 | Diabetes mellitus (63–90%) Cholelithiasis (65–90%) Diarrhea (35–90%) |
| GRFoma | Growth hormone-releasing hormone | Unknown | Pancreas (30%) Lung (54%) Jejunum (7%) Other (13%) | > 60 | Acromegaly (100%) |
| ACTHoma | ACTH | Rare | Pancreas (4–16% all ectopic Cushing's) | > 95 | Cushing's syndrome (100%) |
| PET ^a causing carcinoid syndrome | Serotonin ? Tachykinins | Rare (43 cases) | Pancreas (< 1% all carcinoids) | 60–80 | Same as carcinoid syndrome above |
| PET causing hypercalcemia | PTHrP Others unknown | Rare | Pancreas (rare cause of hypercalcemia) | 84 | Abdominal pain due to hepatic metastases |
| Carcinoid tumor | | | | | |
| Carcinoid syndrome | Serotonin, possibly tachykinins, motilin, prostaglandins | 0.5–2 | Midgut (75–87%) Foregut (2–33%) Hindgut (1–8%) Unknown (2–15%) | 95–100 | Diarrhea (32–84%) Flushing (63–75%) Pain (10–34%) Asthma (4–18%) Heart disease (11–41%) |
| Possible specific functional PET syndrome | | | | | |
| PET secreting calcitonin | Calcitonin | Rare | Pancreas (rare cause of hypercalcitonemia) | > 80% | Diarrhea (50%) |
| PET secreting renin | Renin | Rare | Pancreas | Unknown | Hypertension |
| No functional syndrome | | | | | |
| PPoma/nonfunctional | None | 1–2 | Pancreas (100%) | > 60 | Weight loss (30–90%) Abdominal mass (10–30%) Pain (30–95%) |

and overexpression of growth factors (epidermal growth factor, vascular endothelial growth factor, insulin-like growth factor-1, and transforming growth factor-2) and their receptors may be important in the pathogenesis (Table IV). An increased understanding of their molecular pathogenesis may lead to newer treatments as well as have prognostic significance.

SPECIFIC PANCREATIC ENDOCRINE TUMOR SYNDROMES

Functional PETs almost always present with symptoms due to the specific hormone ectopically secreted. Non-functional PETs present with symptoms due to the tumor per se and usually present late in the disease course with advanced metastatic disease. Treatment of functional PETs requires strategies directed at controlling the hormone-excess state as well as at the PETs per se because they are frequently malignant. Unfortunately, these tumors are not curable by surgery due to the extent of the disease; therefore, both treatment aspects cannot adequately be dealt with by curative resection.

Table IV Molecular Abnormalities and Prognostic Factors in NETs^a

| Molecular abnormalities | |
|--|--|
| PETs | |
| <i>HER2/neu (erbB-2)</i> expressed in 100% GAS | |
| <i>MEN1</i> gene LOH, 46%; mutation, 42% GAS/10% INS | |
| p16 ^{INK4a} , 30% gene abnormality | |

| Alterations in common oncogenes (<i>ras</i> , <i>fos</i> , etc.) or common tumor suppressor (p53, Rb) uncommon | |
| Prognostic factors | |
| PETs | |
| <i>Ha-Ras</i> oncogene or p53 overexpression | |
| Female gender | |
| MEN-1 syndrome absent | |
| Laboratory findings (increased chromogranin A in some studies; gastrinomas, increased gastrin level) | |
| Carcinoid tumors | |
| The presence of carcinoid syndrome | |
| Laboratory results: urinary 5-HIAA level ($p < 0.01$), plasma neuropeptide K ($p < 0.05$), serum chromogranin A ($p < 0.01$) | |
| The presence of a second malignancy | |
| Male gender ($p < 0.001$) | |
| Older age ($p < 0.01$) | |
| Mode of discovery (incidental > symptomatic) | |
| Both carcinoid tumors and PETs | |
| The presence of liver metastases ($p < 0.001$) | |
| Extent of liver metastases ($p < 0.001$) | |
| The presence of lymph node metastases ($p < 0.001$) | |
| Depth of invasion ($p < 0.001$) | |
| Primary tumor site ($p < 0.001$) | |
| Primary tumor size ($p < 0.005$) | |
| Various histologic features | |
| Tumor differentiation ($p < 0.001$) | |
| High growth indices (high Ki-67 index, PCNA expression) | |
| High mitotic counts ($p < 0.001$) | |
| Vascular or perineural invasion | |
| Flow cytometric features (i.e., aneuploidy) | |

^aAbbreviations used: TGF- α , transforming growth factor- α ; EGFR, receptor for epidermal growth factor; IGF/IGFR, insulin-like growth factor and its receptor; IHC, immunohistochemistry; MEN-1, multiple endocrine neoplasia type 1; PCR, polymerase chain reaction; PET, pancreatic endocrine tumor; VEGF, vascular endothelial growth factor; MEN, multiple endocrine neoplasia; NET, neuroendocrine tumor; PCNA, proliferating cell nuclear antigen; Ki-67, proliferation-associated nuclear antigen recognized by Ki-67 monoclonal antibody.

Zollinger–Ellison Syndrome

Zollinger–Ellison syndrome (ZES) is only briefly discussed here because it is included in a separate article in this encyclopedia.

Clinical Features

ZES is a clinical syndrome caused by ectopic secretion of gastrin by a PET (gastrinoma) that results in gastric hypersecretion. The acid hypersecretion characteristically causes peptic ulcer disease (often severe and refractory), diarrhea, or esophageal reflux disease (Table II).

Pathology/Pathogenesis

Almost all the presenting symptoms are due to the effects of gastric hypersecretion because they disappear when the acid secretion is treated. Sixty to 90% of gastrinomas are malignant. Most gastrinomas (50–70%) are found in the duodenum, followed by the pancreas (20–40%). Other intraabdominal sites include mesentery, lymph nodes, and ovary. Approximately 20–25% of ZES patients have multiple endocrine neoplasia type 1 (MEN-1).

Treatment

Acid hypersecretion can be controlled medically in almost every patient. Proton pump inhibitors (PPIs) are the drugs of choice because of their long duration of action. Histamine H₂ receptor antagonists are also effective but frequent (every 4–6 h) high doses are usually needed. Long-term surgical cure is possible in 30% of patients with ZES without MEN-1 but is rare (< 1%) in patients with ZES with MEN-1.

Insulinomas

Insulinomas are neuroendocrine tumors of the pancreas thought to be derived from the β cells of the islets that ectopically secrete insulin, which results in hypoglycemia.

Clinical Features

The most common symptoms are due to the effects of hypoglycemia on the central nervous system (neuroglycemic symptoms), including confusion, headache, altered consciousness, and even seizure (Table V). Many patients also have symptoms due to excess catecholamine release, including sweating or tremulousness. Attacks characteristically occur during fasting.

Pathology/Pathophysiology

Almost all insulinomas (> 98%) occur in the pancreas. Insulinomas are usually small (40% < 1 cm), solitary,

Table V Frequency of Clinical Symptoms, Signs, and Laboratory Findings in Patients with Insulinoma

| Clinical symptoms signs | Frequency (%) |
|--|---------------|
| Occurrence anytime during clinical course | |
| Neuropsychiatric (loss of consciousness, confusion, dizziness, diplopia) | 92 |
| Confusion or abnormal behavior | 80 |
| Obesity | 52 |
| Amnesia or coma | 47 |
| Convulsions (grand mal) | 12 |
| Cardiovascular symptoms, palpitations, tachycardia | 17 |
| Occurrence during first attack | |
| Neuroglycopenic | |
| Visual disturbances (diplopia, blurred vision) | 59 |
| Confusion | 51 |
| Altered consciousness | 38 |
| Weakness | 32 |
| Transient motor defects, hemiplegia | 29 |
| Dizziness | 28 |
| Fatigue | 27 |
| Inappropriate behavior | 27 |
| Speech difficulty | 24 |
| Headache | 23 |
| Seizure | 23 |
| Syncope | 21 |
| Adrenergic | |
| Sweating | 43 |
| Tremulousness | 23 |
| Hunger, nausea | 12 |
| Palpitations | 10 |

and distributed evenly throughout the pancreas. In adults with hyperinsulinism with islet disease, 86% have an insulinoma, 5–15% have adenomatosis, nesio-blastosis occurs in 4%, and hyperplasia occurs in 1%. Insulin is normally synthesized and stored in islet β cells. It is derived from proinsulin, which consists of a 21-amino acid α chain and a 30-amino acid β chain connected by a 33-amino acid connecting peptide (C-peptide). In normal subjects, < 25% of serum insulin is proinsulin, whereas > 90% of patients with an insulinoma have an elevated serum proinsulin.

Diagnosis/Differential Diagnosis

Whipple's triad, published in 1933, was long used as the diagnostic criteria for insulinoma and consists of the occurrence of hypoglycemic symptoms, hypoglycemia (blood glucose < 50 mg/dl), and relief of symptoms following glucose injection. Unfortunately, this

Table VI Causes of Spontaneous Hypoglycemia

| Postprandial (reactive) hypoglycemia | |
|---|--|
| Functional: recognizable anatomic lesion | |
| Alimentary hyperinsulinoma, usually secondary to previous gastric surgery such as Billroth gastrectomy | |
| Secondary to mild diabetes | |
| Idiopathic | |
| Due to specific hepatic enzyme deficiencies | |
| Hereditary fructose intolerance (infants, children) | |
| Galactosemia (infants, children) | |
| Familial fructose and galactose intolerance (rare) | |
| Fasting hypoglycemia | |
| Organic hyperinsulinism: specific anatomic lesion present | |
| Pancreatic islet disease | |
| Insulinoma, single or multiple | |
| Microadenomatosis with or without macroscopic adenomas | |
| Carcinoma | |
| Hyperplasia | |
| Nesidioblastosis | |
| Nonpancreatic tumors | |
| Severe congestive heart failure | |
| Severe renal insufficiency in non-insulin-dependent diabetes | |
| Due to hepatic enzyme deficiencies or decreased hepatic glucose output (primarily in infants, children) | |
| Glucogen storage diseases | |
| Glucogen synthetase deficiencies | |
| Other enzyme deficiencies (fructose-1,6-diphosphate deficiencies) | |
| Endocrine hypofunction | |
| Anterior pituitary (usually in infants, children) | |
| Adrenocortical (Addison's disease) | |
| Diffuse acquired liver disease | |
| Ethanol | |
| Severe malnutrition, sepsis | |
| Due to exogenous agents (factitious) | |
| Sulfonylureas, biguanides | |
| Insulin administration | |
| Ingestion of ackee fruits (hypoglycine) | |
| Other drugs (aspirin, pentamidine) | |
| Functional hypoglycemia with no persistent anatomical defect | |
| Autoantibodies to insulin receptor | |
| Spontaneous autoimmune anti-insulin antibody syndrome | |
| Transient hypoglycemia on infancy | |

triad is not specific for insulinoma (Table VI). The diagnosis requires the establishment of hypoglycemia (< 40 mg/dl) at the time of an elevated fasting plasma insulin level. The usual method of diagnosing insulinoma is to perform a fast of up to 72 h, with assessment of serum glucose, insulin, and C-peptide every 4–8 h. If at any time the patient becomes symptomatic, the test should be terminated by giving

glucose after obtaining the previously mentioned serum measurements. During the first 24 h, 70–80% of patients with insulinomas develop symptoms, and 98% of patients develop symptoms by 48 h. In non-obese normal subjects, blood insulin values should decrease to < 6 μ M/ml if blood glucose decreases to \leq 40 mg/dl and the ratio of insulin to glucose (mg/dl) is < 0.3. Some investigators also require elevated serum C-peptide and proinsulin levels and/or insulin:glucose ratio > 0.3 for an insulinoma diagnosis. There are numerous causes of hypoglycemia besides insulinoma, including pancreatic islet disease and factitious use of insulin or hypoglycemic agents (Table VI). Combinations of proinsulin levels, C-peptide levels, assessment of antibodies to insulin, and sulfonylurea levels may be required to make the correct diagnosis.

Treatment

Only 5–15% of insulinomas are malignant; therefore, after tumor localization studies, surgery should be performed. Between 75 and 95% of patients are cured by surgery. Prior to surgery, hypoglycemia is usually controlled by frequent, small meals and the use of diazoxide (150–800 mg/day). Diazoxide controls symptoms in 50–60% of patients. Other drugs used to control the hypoglycemia include verapamil and diphenylhydantoin. Long-acting somatostatin analogues such as octreotide are effective in 40–50% of patients. However, in some patients octreotide may worsen the hypoglycemia. The preferred tumor localization studies include computed tomography (CT) scan to exclude liver metastases and endoscopic ultrasound. Somatostatin receptor scintigraphy (SRS), which is the preferred imaging modality in all other NETs, is frequently negative (40–70%) in patients

Table VII Clinical Characteristics of Patients with VIPoma Syndrome

| | Frequency (%) |
|----------------------------|---------------|
| Symptoms/signs | |
| Secretory diarrhea | 89–100 |
| Dehydration | 44–100 |
| Weight loss | 36–100 |
| Abdominal cramps, colic | 10–63 |
| Flushing | 14–28 |
| Laboratory findings | |
| Hypokalemia | 67–100 |
| Hypochlorhydria | 34–72 |
| Hypercalcemia | 41–50 |
| Hyperglycemia | 18–50 |

with insulinomas due to low numbers of somatostatin receptors.

VIPomas

VIPomas are neuroendocrine tumors that occur primarily in the pancreas, secrete excessive amounts of vasoactive intestinal peptide (VIP), and cause a distinct syndrome characterized by large-volume diarrhea, hypokalemia, and dehydration (Tables II and VII). This syndrome is also called the Verner–Morrison syndrome, pancreatic cholera, or WDHA syndrome (watery diarrhea, hypokalemia, achlorhydria; Table II).

Clinical Features

The mean age of occurrence is 49 years; however, the syndrome can occur in children. The principal symptoms are large-volume diarrhea leading to dehydration, acidosis, and hypokalemia. Other symptoms/signs due to the actions of VIP include flushing, hypochlorhydria, hyperglycemia, and hypercalcemia. Steatorrhea is uncommon (16%). The diarrhea is characteristically secretory in nature (persists during fasting).

Pathology/Pathophysiology

VIP is a 28-amino acid neuropeptide normally present in the GI tract and central nervous system. It causes stimulation of small intestinal chloride secretion, has effects on smooth muscle contractility, inhibits acid secretion, and has vasodilatory effects, which explain many of the symptoms of the VIPoma syndrome. In adults, 80–90% of VIPomas are pancreatic, whereas in children the syndrome is usually caused by gangliogliomas/ganglioblastomas. VIPomas are usually solitary, with 50–75% in the pancreatic tail, and 40–70% of patients have liver metastases at diagnosis.

Diagnosis/Differential Diagnosis

The diagnosis requires the demonstration of an elevated plasma VIP level and the presence of large-volume diarrhea. Almost all patients have a stool volume > 1 liter/day (most have a volume > 3 liters/day), and it is proposed that the diagnosis be excluded if the volume is not > 700 ml/day. A number of other causes of large-volume diarrhea can be excluded by fasting the patient. Other diseases that can cause fasting large volume diarrhea include Zollinger–Ellison syndrome, chronic laxative abuse, systemic mastocytosis, diabetic diarrhea, AIDS, carcinoid syndrome, and, rarely, medullary thyroid cancer.

Treatment

The most important first step in treatment is to control the diarrhea and correct the dehydration, hypokalemia, and acidosis. Patients may require > 5 liters/day of fluid and > 350 mm/day of potassium when the diarrhea is not controlled. Octreotide will control the diarrhea in 85–90% of VIPoma patients. In non-responders or patients who have become refractory, combinations of octreotide and glucocorticoids may be helpful. Other drugs that may help in individual patients include clonidine, indomethacin, prednisone, lithium, phenothiazine, loperamide, lidamide, propranolol, and metoclopramide.

In 40–70% of adult patients with VIPoma, diffuse metastatic disease in the liver is present initially; therefore, surgical cure is not possible. For these patients, long-acting somatostatin analogues such as octreotide or lanreotide (Fig. 1) are the drugs of choice for treatment. If these fail or tumor growth continues, treatment with chemoembolization, hepatic embolization, or chemotherapy or radiolabeled somatostatin analogues (Fig. 1) may be helpful. If the majority of the metastatic disease in the liver can be safely resected, cytoreductive surgery may be of value in helping to control the symptoms of the hormone-excess state.

Glucagonomas

Glucagonomas are neuroendocrine tumors of the pancreas that ectopically secrete excessive amounts of glucagon and cause a syndrome characterized by a dermatitis (migratory necrolytic erythema), glucose intolerance or diabetes, and weight loss (Table VIII).

Clinical Features

Glucagonomas usually occur in middle-aged and elderly populations. Migratory necrolytic erythema usually starts as an erythematous area typically at perifacial or intertriginous areas, such as the groin, buttocks, or thighs. It subsequently becomes raised and bullae form and break, resulting in eroded areas. The skin lesions may wax and wane and frequently precede the diagnosis of glucagonoma (mean, 6–8 years). Hypoaminoacemia is a characteristic feature of glucagonomas, with plasma amino acid levels decreasing to < 25% of normal, especially glycogenic amino acids such as alanine and glycine. Weight loss is another prominent feature of this syndrome and is not seen early in other PETs unless malabsorption is present, suggesting that it is an intrinsic feature of this syndrome. Experimental studies support

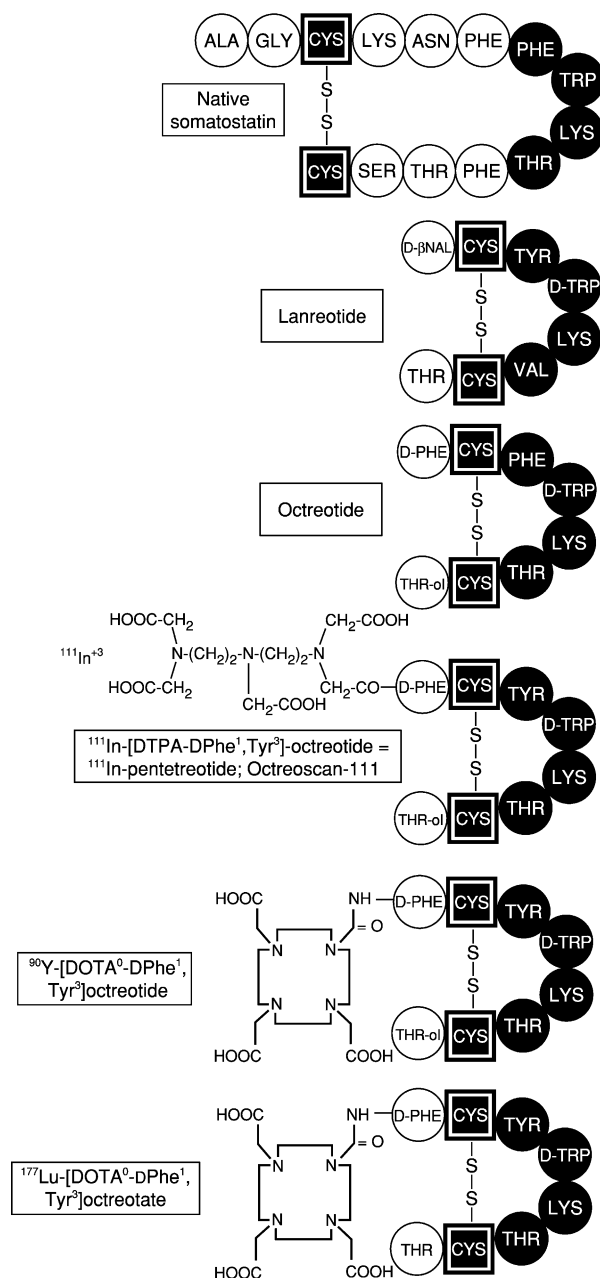

Figure 1 Structure of somatostatin and synthetic analogues used for diagnostic (tumor localization) or therapeutic indications in patients with neuroendocrine tumors. The indium (^{111}In), yttrium (^{90}Y), or lutetium (^{177}Lu) compounds are used for therapeutic purposes. DOTA-1,4,7,10-tetra-azacyclododecane- N,N',N'',N''' -tetra-acetic acid.

the conclusion that a novel anorectic substance, independent of glucagon, is released by these tumors and is responsible for the weight loss. Other prominent symptoms/clinical findings include glossitis

Table VIII Frequency of Clinical Symptoms and Laboratory Findings in Patients with Glucagonoma

| | Frequency (%) |
|--------------------------------|---------------|
| Clinical symptoms | |
| Dermatitis | 64–90 |
| Diabetes/glucose intolerance | 38–96 |
| Weight loss | 56–96 |

| Pulmonary emboli | 11 |
| Psychiatric disturbance | 0–17 |
| Laboratory abnormality | |
| Anemia | 33–90 |
| Hypoaminoacidemia | 26–100 |
| Hypocholesterolemia | 80 |

or stomatitis, glucose intolerance or diabetes that may precede the diagnosis by years, and anemia (Table VIII).

Pathology/Pathophysiology

Glucagonomas are characteristically diagnosed late in their course and are usually large (average, 5–10 cm), and 50–80% have evidence of metastatic spread at diagnosis, usually to the liver (43–80%). Glucagonomas are usually single tumors and 50–80% occur in the pancreatic tail.

Glucagon is a naturally occurring, 29-amino acid peptide characteristically released by the pancreatic A cells. Most of the findings of the syndrome are compatible with the known actions of glucagon stimulating glycogenolysis and gluconeogenesis and affecting gut secretion and motility. The exact pathogenesis of the migratory necrolytic erythema remains unclear and has been attributed by some to hypoaminoacidemia or to nutritional deficiencies such as zinc.

Diagnosis/Differential Diagnosis

The diagnosis is established by demonstrating an elevated plasma glucagon level (normal level is usually < 150 ng/liter). Plasma glucagon levels usually exceed 1000 ng/liter in glucagonoma patients (90%), and in patients with symptoms/laboratory findings of glucagonoma (Table VIII), a level > 1000 ng/liter is diagnostic. Other conditions can also cause elevated plasma glucagon levels, including pancreatitis, hepatic failure disease, renal failure, Cushing's syndrome, prolonged fast, or familial hyperglucagonemia. Except

for cirrhosis, these disorders usually do not cause increases in plasma glucagon levels > 500 ng/liter.

Treatment

Diffuse hepatic metastases are usually present at diagnosis (in up to 80% of patients), so curative surgical resection is usually not possible. Surgical debulking or other antitumor treatments may be of palliative benefit. The drugs of choice are the long-acting somatostatin analogues (octreotide and lanreotide) (Fig. 1), which improve the rash in 75–80% of patients and may improve the weight loss, pain, and diarrhea but usually do not improve the diabetes/glucose intolerance.

Somatostatinoma Syndrome

The somatostatinoma syndrome is caused by a neuroendocrine tumor of the GI tract that ectopically secretes excess amounts of somatostatin (Fig. 1), which frequently causes diabetes mellitus, gallbladder disease, diarrhea, and steatorrhea (Table IX). There is no general agreement on what constitutes a somatostatinoma, and there is no distinction in the literature regarding the presence of a somatostatinoma and/or the somatostatinoma syndrome. In the literature, the term somatostatinoma is generally used to mean a GI neuroendocrine tumor possessing somatostatin-like immunoreactivity, and it may (11–45%) or may not (55–89%) be associated with clinical symptoms due to ectopic release of somatostatin (Table IX). Because of this confusion, the term somatostatinoma syndrome is used here to indicate a PET-releasing

somatostatinoma, which causes clinical symptoms, and the term somatostatinoma is used to indicate a PET containing somatostatin immunoreactivity.

Clinical Features

The mean age of onset is 51–53 years. In one large review ($N = 173$), only 11% of all somatostatinomas in the literature were associated with the somatostatinoma syndrome. The principal clinical features of the somatostatinoma syndrome are gallbladder disease, diabetes mellitus, diarrhea, weight loss, and steatorrhea. The frequency of these symptoms depends on the location of the somatostatinoma (Table IX). Each symptom characteristic of the syndrome is reported more frequently with pancreatic than intestinal somatostatinomas.

Pathology/Pathophysiology

Somatostatin is a naturally occurring tetradecapeptide (Fig. 1) found widely in the central nervous system and GI tract, where it functions as a neurotransmitter or has paracrine or autocrine actions. In general, it is a potent inhibitor of processes, including the release of numerous hormones, gastric and intestinal pancreatic secretion, and absorption. The hypochlorhydria, diabetes, steatorrhea, and gallbladder diseases that occur in somatostatinoma syndrome are caused by the known inhibitor effects of somatostatin.

Somatostatinomas occur in the pancreas in 56–74% of cases and are mainly found in the pancreatic head. In most of the remaining cases, they are found in the intestine, with 90% in the duodenum, particularly in the periampullary area. They are usually solitary, large tumors (mean, 3.6–4.9 cm), and 53–84% have metastatic spread at diagnosis (usually to the liver).

Diagnosis/Differential Diagnosis

In most cases in the literature, somatostatinomas have been found incidentally either at the time of cholecystectomy or during endoscopy. The presence of psammoma bodies in a duodenal neuroendocrine tumor should raise this possibility. Duodenal somatostatinomas are associated with von Recklinghausen's disease. Most of these patients do not develop the somatostatinoma syndrome and have normal plasma somatostatin levels. The diagnosis of the somatostatinoma syndrome requires the demonstration of an elevated plasma somatostatin level.

Table IX Clinical and Laboratory Findings in Patients with Somatostatinomas with or without Somatostatinoma Syndrome

| Clinical finding | Somatostatinoma ^a | | Overall frequency in somatostatinoma syndrome (%) ^a |
|---------------------|------------------------------|----------------|--|
| | Pancreatic (%) | Intestinal (%) | |
| Diabetes mellitus | 95 | 21 | 95 |
| Gallbladder disease | 94 | 43 | 68 |
| Diarrhea | 66–97 | 11–36 | 37 |
| Weight loss | 32–90 | 20–44 | 68 |
| Laboratory finding | | | |
| Steatorrhea | 83 | 12 | 47 |
| Hypochlorhydria | 86 | 17 | 26 |

^aSomatostatinoma is the occurrence of a pancreatic endocrine tumor containing somatostatin by immunocytochemistry that can occur with (11%) or without (89%) the somatostatinoma syndrome, which is due to ectopically released somatostatin.

Treatment

Symptoms of the somatostatinoma syndrome are improved by administration of long-acting synthetic somatostatin analogues such as octreotide (Fig. 1). Pancreatic tumors (70–92%) and intestinal tumors (30–69%) are associated with liver metastases at presentation and antitumor treatment is frequently needed.

GRFomas AND OTHER RARER FUNCTIONAL PET SYNDROMES

GRFomas are neuroendocrine tumors that ectopically secrete growth hormone-releasing factor (GRF). GRF is a 44-amino acid peptide that stimulates growth hormone release. GRFomas occur in lung (47–54%), PETs (29–30%), small intestinal carcinoids (8–10%), and other sites (12%). The symptoms are those of acromegaly and the mean age of patients is 38 years. The acromegaly is indistinguishable from classical acromegaly due to a pituitary adenoma. Pancreatic GRFomas are usually large (mean, > 6 cm) and liver metastases are present in 39% of cases. They should be suspected in a patient with acromegaly with an abdominal tumor, MEN-1, or hyperprolactinemia, which occurs in 70% of GRFomas. The diagnosis is established by performing plasma assays for GRF and growth hormone. Surgery is the treatment of choice if possible. Symptoms can be controlled in > 75% of patients by long-acting somatostatin analogues, such as octreotide or lanreotide (Fig. 1).

Cushing's syndrome due to a PET occurs in 4–16% of all patients with ectopic Cushing's syndrome. It occurs in 5% of patients with sporadic gastrinomas and is associated with hepatic metastases and a poor prognosis. Paraneoplastic hypercalcemia due to a PET releasing PTH-related peptide is rare. These tumors are usually large and malignant. PETs secreting calcitonin may cause a specific syndrome associated with diarrhea (Table II). PETs also cause the carcinoid syndrome (Table II). These are characteristically large and malignant (68–88%) and may cause an atypical carcinoid syndrome because they lack DOPA decarboxylase. A renin-producing PET was described in a patient presenting with hypertension (Table II). Ghrelin is a 28-amino acid peptide with a number of metabolic functions. Although expression has been demonstrated in most PETs, in a one study only 1 of 24 patients (4%) with a PET had an elevated plasma ghrelin level. This patient was asymptomatic, suggesting that no specific syndrome is associated with ectopic release of ghrelin by a PET.

NONFUNCTIONAL PETs

Nonfunctional PETs are neuroendocrine tumors of the pancreas that secrete no products or the secreted products do not cause a distinct functional syndrome. The symptoms from these tumors are therefore due entirely to the tumor per se (i.e., pain, jaundice, weight loss, etc.). Nonfunctional PETs frequently secrete chromogranin A (CgA) (80–100%), CgB (90–100%), pancreatic polypeptide (PP) (58%), and the α -subunit of hCG (40%), and many secrete other hormones such as neurotensin. These tumors characteristically present late in the disease course. They are generally large (72% > 5 cm) and invasive, and hepatic metastases are usually present (64–92%). The most common symptoms are abdominal pain (30–50%), jaundice (20–35%), weight loss, fatigue, and bleeding. In 10–15% of cases, they are found incidentally. The diagnosis is established by histology with appropriate neuroendocrine tumor immunohistochemistry and by assessing plasma hormone levels/clinical symptoms. Plasma PP is increased in 22–71% of patients, CgA levels are increased in 80–100%, and in patients with a pancreatic mass without a functional syndrome, this finding suggests that a nonfunctional PET is present. Curative surgical resection is rarely possible, and treatment needs to be directed against the malignant PET.

FUNCTIONAL SYNDROMES DUE TO CARCINOID TUMORS

Carcinoid tumors can cause a specific functional syndrome, the carcinoid syndrome, or occasionally can release biologically active peptides that cause the specific PET syndromes discussed previously. Because carcinoids are also malignant (Table III), specific treatments need to be directed at both the carcinoid tumor and the functional syndrome it produces.

Carcinoid Syndrome

The carcinoid syndrome is caused by a neuroendocrine tumor, usually present in the gastrointestinal tract, ectopically secreting bioactive amines/peptides, which results in a clinical syndrome characterized by diarrhea, flushing, asthma/wheezing, and, occasionally, heart disease (Table X).

Clinical Features

The mean age at presentation is 57 years, but it occurs over a wide age range (9–91 years) (Table X). The principal symptoms are diarrhea and flushing, which occur in up to 73% of cases initially and 84% during

Table X Clinical Features in Patients with Carcinoid Syndrome

| | At presentation | During course of disease |
|-----------------------------|-----------------|--------------------------|
| Symptoms/signs | | |
| Diarrhea (%) | 32–73 | 68–84 |
| Flushing (%) | 23–65 | 63–74 |
| Pain (%) | 10 | 34 |
| Asthma/wheezing (%) | 4–8 | 3–18 |
| Pellagra (%) | 2 | 5 |
| None (%) | 12 | 22 |
| Carcinoid heart disease (%) | 11 | 14–41 |
| Demographics | | |
| Male (%) | 46–59 | 46–61 |
| Mean age, years (range) | 57 (25–79) | 53 (9–91) |
| Tumor location | | |
| Foregut (%) | 5–9 | 2–33 |
| Midgut (%) | 78–87 | 60–87 |
| Hindgut (%) | 1–5 | 1–8 |
| Unknown (%) | 2–11 | 2–15 |

the course of the disease. The flush is usually of sudden onset, associated with a deep red to violaceous erythema of the upper body, and often associated with a feeling of warmth and occasionally with lacrimation, pruritis, or diarrhea. It may be precipitated by food, exercise, alcohol, or drugs, particularly serotonin reuptake inhibitors. Flushing is usually caused by metastatic midgut tumors. Flushing with midgut tumors and bronchial or gastric carcinoids may differ in duration, associated symptoms (salivation and lacrimation), and skin color. Diarrhea usually occurs with flushing (85% of cases) and is usually watery and of small volume (60% < 1 liter/day). Steatorrhea is present in 67%, and in 50% of patients it is > 15 g/day of fecal fat. Cardiac manifestations occur in 11% initially and 14–41% during the disease course (Table X), and they are due to endocardial fibrosis, primarily on the right side (tricuspid > pulmonary), but they can also occur on the left side. Fibrosis results in valve constriction and up to 80% of patients develop heart failure. Pellagra-like symptoms (2–25%) and symptoms due to increased fibrotic tissue (i.e., retroperitoneal fibrosis, Peyronie's disease, and intraabdominal fibrosis) are unusual features of this disease.

A life-threatening complication of the carcinoid syndrome is the development of a carcinoid crisis. This is most frequently seen in patients with high 5-hydroxyindoleacetic acid (5-HIAA) levels and may be provoked by anesthesia, endoscopy, stress, surgery, a

radiological procedure, or a biopsy. Patients develop intense flushing, diarrhea, abdominal pain, hypotension, and cardiac abnormalities. If not adequately treated, it can be fatal.

Pathology/Pathobiology

Carcinoid symptoms occurred in 8% of 8876 patients with carcinoid tumors. Carcinoid syndrome occurs only when tumor-secreted products reach the systemic circulation in sufficient concentrations. In 91% of cases, this occurs due to liver metastases, and in the remainder it occurs due to retroperitoneal invasion by gut or pancreatic tumors or due to lung or ovary carcinoids with direct access to the systemic circulation. Midgut carcinoids account for 60–67% of cases of the carcinoid syndrome, foregut tumors account for 2–33%, hindgut accounts for 1–8%, and an unknown primary accounts for 2–15%.

One of the main secretory products of carcinoid tumors is serotonin (5-HT), and overproduction occurs in 90–100% of patients with carcinoid syndrome. Serotonin is thought to primarily mediate diarrhea by its effects on gut motility and intestinal secretion. However, prostaglandins and tachykinins (substance P, K; neuropeptide K) may also be important in causing diarrhea in some patients. Flushing is not relieved by serotonin antagonists, and in patients with gastric carcinoids it can be due to histamine secretion. Tachykinins are released during flushing and may be important in its mediation. Both histamine and serotonin may be responsible for the wheezing/asthma as well as the fibrotic reactions characteristic of this disease. The heart disease is likely due to the actions of serotonin because it is similar to that seen with appetite-suppressant drugs (e.g., fenfluramine) that have high affinity for serotonin receptors.

Patients may develop a typical or atypical carcinoid syndrome. The typical syndrome is due to a midgut tumor oversynthesizing serotonin from tryptophan. The atypical syndrome occurs when there is a deficiency in the enzyme required to convert 5-HTP to 5-HT and there is overproduction of 5-HTP. The atypical syndrome is more likely to occur with foregut carcinoids.

Diagnosis/Differential Diagnosis

The diagnosis of carcinoid syndrome requires measurement of urinary or plasma serotonin or its metabolites. The measurement of urinary 5-HIAA is most frequently performed. False positives may occur if a patient eats serotonin-rich foods (bananas, walnuts, pecans, and pineapple) or takes certain medications (L-Dopa, cough syrups with guaniforesin, and

salicylates). If an atypical carcinoid syndrome is suspected, urinary 5-HIAA may be only slightly elevated, and other metabolites of tryptophan such as 5-HTP should be considered. Serum cgA levels are elevated in 50–100% of patients with carcinoid tumors, and the level correlates with tumor bulk. However, serum CgA levels are not specific for carcinoids because they can occur with other NETs, including PETs.

Flushing can be caused by other conditions, including systemic mastocytosis, reactions to alcohol or glutamate, effects of drugs, and menopause. These need to be excluded.

Treatment

Treatment consists of avoiding conditions that precipitate attacks and treatment of wheezing with bronchodilators, treatment of heart failure with diuretics, and treatment of diarrhea with antidiarrheal agents, such as loperamide or diphenoxylate. If symptoms present, somatostatin analogues (octreotide and lanreotide) (Fig. 1) or serotonin receptor antagonists are the drugs of choice. Somatostatin analogues control symptoms in 80% of patients with flushing or diarrhea, and 70% show a >50% decrease in urinary 5-HIAA. Approximately 40% of patients show some resistance after 4–6 months and doses may have to be increased. Sustained-release preparations, such as octreotide-LAR (long-acting release) and lanreotide-PR (prolonged release), are widely used because they can be given less frequently. Octreotide-LAR is usually given monthly and lanreotide-PR every 10–14 days as opposed to the usual preparation of octreotide/lanreotide that is given subcutaneously every 6–12 h. Somatostatin analogues can be given to both treat and prevent carcinoid crises. Prior to a possible precipitating event, such as surgery, anesthesia, or stress, it is recommended that octreotide be administered.

Side effects from the somatostatin analogues occur in 40–60% of patients with subcutaneous analogues. Pain at the injection site and GI side effects (discomfort, nausea, diarrhea, and cramping) are the most common. They are usually short-lived and do not interrupt treatment. Long-term complications include an increased incidence of gallstones/biliary sludge (52%), steatorrhea, and worsening glucose tolerance. Interferon- α may also control symptoms in some patients.

Surgery should be performed if possible; however, almost all patients with carcinoid syndrome have metastatic disease in the liver and curative resection is not possible. Treatment directed against the tumor may be needed.

NET TUMOR LOCALIZATION

Tumor localization is needed for all management phases of both PETs and carcinoid tumors. Both the localization of the primary tumor and the determination of the location and extent of metastatic disease are required to appropriately manage these patients. Conventional imaging studies [CT, magnetic resonance imaging (MRI), ultrasound, and angiography] and SRS are widely used. For PETs, endoscopic ultrasound is also widely used. Bronchial carcinoids are usually detected by chest X-ray and assessed by CT. Rectal, duodenal, colonic, and gastric carcinoids are usually detected by GI endoscopy.

Both PETs and carcinoids frequently (90–100%) overexpress somatostatin receptors, which have a high affinity for radiolabeled somatostatin analogues (Figs. 1–3) that can be used to localize them. Because of its greater sensitivity compared to that of conventional imaging studies and its ability to localize a number of tumors throughout the body simultaneously, SRS is the imaging modality of choice for localizing all primary and metastatic NET tumors except insulinomas. Insulinomas are usually small and have a low density of somatostatin receptors, with the result that SRS is positive in only 12–50% of patients with insulinomas. In contrast, SRS is positive in 73–89% of patients with carcinoids and 60–100% of patients with PETs other than insulinomas. Figures 2 and 3 show two examples of the ability of SRS to image a primary PET and metastatic disease in the liver when conventional imaging studies were negative. For PETs localized in the pancreas, endoscopic ultrasound is highly sensitive, localizing 73–100% of insulinomas, which occur almost exclusively within the pancreas. SRS occasionally gives false positives (12% in one study) because normal and abnormal cells can have increased somatostatin receptors such as granulomas, thyroid disease, and activated lymphocytes (abscess and infection). Furthermore, SRS does not provide information on tumor size or the exact location of metastases, and a CT scan or MRI are frequently used to provide this information.

TREATMENT OF ADVANCED DIFFUSE METASTATIC DISEASE IN PATIENTS WITH MALIGNANT NETs

Of the numerous prognostic factors identified for NETs (Table IV), the presence and the extent of the hepatic metastases are the most important in almost every study. For patients with gastrinomas, 5-year

Figure 2 Computed tomography (CT) scan (top) and somatostatin receptor scintigraphy (SRS) (bottom) of a patient with a pancreatic endocrine tumor (gastrinoma). This patient previously had a duodenal tumor removed. The CT scan was negative, whereas the SRS showed a tumor medial and anterior to the right kidney. At surgery, a PET was found in a metastatic lymph node in the peri-duodenal area. This case illustrates the greater sensitivity of SRS compared to conventional imaging studies.

survival is 98–100% without liver metastases, 78% with limited metastases in one lobe, and 16% with diffuse metastases. For carcinoid tumors without liver metastases, 5-year survival is 80–90%, and with diffuse metastases it is 50%. A number of treatments are reported to be effective, including embolization, chemoembolization, chemotherapy, cytoreductive surgery (removal of all visible tumor), somatostatin analogues, α -interferon, radiotherapy using radiolabeled somatostatin analogues to target the tumor (Fig. 1), and liver transplantation.

Specific Antitumor Treatments

Unfortunately, cytoreductive surgery is only possible in 10–20% of patients who have limited hepatic metastases, allowing surgical removal of at least 90% of visible tumor. Although it is reported to provide palliative treatment, there are no control studies to

Figure 3 Computed tomography (CT) scan and somatostatin receptor scintigraphy (SRS) of a patient with a metastatic PET to the liver. The CT scan showed no liver lesions, whereas the SRS showed two hepatic metastases (one in the right lobe and one in the left lobe). This case illustrates the increased sensitivity of SRS compared to conventional imaging studies for localizing hepatic metastases.

support this conclusion. However, studies suggest that it may increase survival; therefore, cytoreductive surgery is recommended, if possible.

Chemotherapy for metastatic carcinoids is generally disappointing, with response rates of 0–40% with various two–three drug combinations. With PETs, chemotherapy has been more successful, with response rates of 30–70%. The regimen of choice is streptozotocin and doxorubicin. Unfortunately, chemotherapy is almost never curative and has substantial toxicity. Therefore, it is generally reserved for patients with rapidly growing PETs who fail other treatments.

Long-acting somatostatin analogues (Fig. 1) and α -interferon rarely decrease tumor size (i.e., 0–15%); however, these drugs have prominent tumoristatic effects, stopping growth in 50–90% of patients with NETs. Studies suggest that they are particularly effective in slower growing tumors. It has not been proven that these agents extend survival; however, because of

the availability of long-acting formulations (e.g., one injection of somatostatin/month), their low toxicity, and their long-term effectiveness in some patients, they are the antitumor agents of choice.

Hepatic embolization or chemoembolization (i.e., chemotherapy with embolization) can decrease tumor bulk and help control the symptoms of the hormone-excess state. This approach is usually reserved for patients who have disease largely confined to the liver, who have a patent portal vein, and who fail treatment with other modalities.

Somatostatin receptor-directed cytotoxicity using radiolabeled somatostatin analogues that are internalized by somatostatin receptors (Fig. 1) overexpressed on the NET are being widely investigated. The following are being evaluated for treatment: ^{111}In (^{111}In)-labeled compounds, which emit gamma rays, internal conversion, and Auger electrons; ^{90}Y yttrium-coupled analogues, which emit high-energy β particles; and ^{177}Lu lutetium (^{177}Lu)-coupled analogues, which emit both. The ^{177}Lu and ^{111}In compounds have respectively been shown to stabilize disease in 41 and 40% and decrease tumor size in 38 and 30% of patients with advanced metastatic NETs.

Liver transplantation, although largely abandoned for most metastatic tumors, is still a consideration for patients with metastatic NETs because of their slower growth. In 103 cases of malignant NETs (43 carcinoid, 48 PETs), liver transplantation achieved 2- and 5-year survival rates of 60 and 47%, respectively. Liver transplantation has been suggested for younger patients with metastatic NETs limited to the liver.

Gastrointestinal Hormone

see GI Hormone entries

of the twentieth century. It was generally assumed that, if gender assignment had been carried out correctly, that is, in agreement with the true sex, the final outcome would be a heterosexual man or a heterosexual woman, in agreement with the assigned gender. There were problems with the true-sex policy, however. The presumed definitive criterion of the true sex did not always agree with a person's somatic physical appearance as a man or woman, and also did not always agree with the person's gender identity, and could therefore lead to dramatically adverse social and legal consequences for the intersexed individual.

The Optimal-Gender Policy

On the basis of a critical examination of the true-sex policy and studies of the overall psychosocial outcome and quality of life of intersex patients, John Money and the Hampsons at Johns Hopkins Hospital in Baltimore, Maryland, formulated an optimal-gender policy during the 1950s. This policy had a number of underlying assumptions. (1) There is no single biological criterion that determines the development of psychological gender; rather, there is a cascade of biological processes that culminate in the development of gender identity. (2) Socialization factors have the decisive role in psychological gender development. (3) If one minimizes the barriers to socialization in the assigned gender, the outcome will be a heterosexual man or a heterosexual woman, in agreement with the assigned gender. (4) The condition of the body and particularly the genitalia limits the psychosocial and especially psychosexual functioning of the intersexed person in later years. Therefore, the newborn with intersexuality should be assigned to that gender that permits the optimal psychosexual and psychosocial functioning when all available medical treatment options are taken into account. So, in contrast to the question of the true-sex policy—"Is this a boy or a girl?"—the optimal-gender policy asked "Will this newborn have a better function later in life as a male or a female?"

From the central role of socialization followed the concept of the birth of an intersex newborn as a psychosocial emergency, with the implication that the decision time for gender assignment should be kept as short as possible. Another consequence was the recommendation of early feminizing or masculinizing surgery of the external genitalia so that their appearance would be as similar to the gender norm as possible and would therefore not interfere with gender-typical rearing conditions and body-image

development. A third consequence was the instruction to keep the intersex status of the child secret from all people who do not belong to the core family and to educate the child gradually, in line with his or her cognitive development. These guidelines were intended to prevent the parents from developing chronic doubts about the sex of their child and to protect the child from stigmatization by other people, but have frequently led to parental attempts of preventing the disclosure of details of the medical history to the intersex children themselves, sometimes even after they attained adulthood.

The True-Brain-Sex Policy

Increasingly over the past decade, the optimal-gender policy has come under criticism. One reason is that also under this policy some individuals will turn out dissatisfied with their assigned gender and may seek gender reassignment, which is made more difficult if the external genitalia have been operated on to be more compatible with the originally assigned gender. A second argument is that, even without later gender change, genital surgery carries a risk of damage to sexual functioning in adolescence and adulthood. Intersex activists, therefore, demand that psychosocially indicated genital surgery be performed only with the informed consent of the mature individual. Some critics advocate a moratorium on genital surgery, unless necessary for strictly medical indications, and claim—without data—that psychological counseling can take care of all attending psychosocial problems that children with marked genital ambiguity and their families may face. Third, the optimal-gender policy is blamed (although unjustly; see above) for keeping the medical facts secret, especially from the patient him- or herself, which contributes to the maintenance of the social stigma of intersexuality and thereby to the negative self-image (especially shame) of the intersexed individual. Many intersex activists, therefore, argue for early comprehensive disclosure of their medical history to intersex patients. A fourth criticism of the optimal-gender policy derives from the extensive data, especially data generated by animal research, regarding the influence of sex hormones on the developing brain and long-term sex-dimorphic behavior. Because of these data, some biological determinists suggest that the decisive factor for gender identity formation is the prenatal androgenization of the brain and that psychosocial factors have only a secondary role. If such a "true-brain-sex policy" is valid, gender assignment decisions should be based on the

degree of androgenization/masculinization of the brain and minimization of barriers to socialization is unimportant. However, because brain imaging techniques are not yet capable of rendering such assessments, these theorists must fall back on the status of the genitalia as a—rather uncertain—indicator of brain androgenization/masculinization.

Policy Effects on Gender Assignment

The three major policies outlined above may lead to quite varied decisions on gender assignment. Two cases will illustrate this: (1) a chromosomally female newborn with extreme genital masculinization (Prader stage V) due to prenatal androgen excess associated with classical congenital adrenal hyperplasia (CAH) and (2) a chromosomally male newborn with penile agenesis. According to the true-sex policy, case (1) should be raised female because of the clearly female histology of the gonads (ovaries) and female chromosomes (see Table I). By contrast, a 46,XY newborn with penile agenesis would be assigned to the male gender, because of the normal-male histology of the testicular gonads and the clearly male karyotype. Under the optimal-gender policy, case (1) would be assigned to the female gender, because the external genitalia can be feminized so as to permit coitus and to thereby retain the option of conception and pregnancy, because the internal female reproductive organs are intact. The 46,XY infant with penile agenesis would also be assigned to the female gender, because the surgical *de novo* construction of a functioning penis is not yet possible and therefore sexual functioning as a male would be compromised. Advocates of the true-brain-sex policy would recommend assigning the CAH case to the male gender because of the putative effects of prenatal androgens on the brain and recommend the same for the case of penile agenesis. Some activists recommend assigning the intersex child to the gender that seems to offer the more promising outcome, but to do so provisionally and to consider from the outset the possibility of later gender change and therefore not to operate on the genitals before the age of consent, unless medically necessary.

Table I Gender Assignment as a Function of Policy

| Disorder | True-sex policy | Optimal-gender policy | True-brain-sex policy |
|--------------------|-----------------|-----------------------|-----------------------|
| Penile agenesis | Male | Female | Male |
| CAH/Prader stage V | Female | Female | Male |

The Status of the Evidence

The major objections to the optimal-gender policy are important to consider, but a consensus about a new management policy has yet to emerge, especially for 46,XY individuals with intermediate degrees of genital ambiguity. The major problem is insufficient data concerning the long-term psychological outcome. Patient-initiated later gender change, for instance, can be observed in intersex individuals in both directions, from male to female and from female to male (and, in some cases, from the assigned gender to “intersex”). This is not surprising, because such gender change is also well known—as transsexualism—in non-intersex individuals, but the relative frequency of later gender change is increased in intersex patients. Given the psychological, social, and medical problems that are associated with later gender change, clinicians usually favor a policy that minimizes its occurrence. Thus, long-term follow-up data are needed that will allow clinicians to state the relative frequency of gender change of patients with a given syndrome who were managed under a defined policy and in a particular cultural context. Because gender change can take place as late as in midlife, follow-up studies need to reach at least into that age range. Given the relative rarity of intersex patients, it is not surprising, therefore, that the data thus far available are clearly insufficient.

As an extreme example, consider the question of gender reassignment in chromosomal males with traumatic loss of the penis in infancy. One such case, in which reassignment to female at 17–21 months of age was followed by patient-initiated re-reassignment to male in adolescence, has drawn enormous attention among care providers as well as in the media, once his unfortunate story was investigated and published, when he was in his mid-thirties. However, only one other case with a history of traumatic loss of the penis in infancy and reassignment to female has been followed into adulthood and published and this person continues to live as a woman without gender dysphoria. Two cases with strikingly different outcomes are not sufficient for evidence-based policy decisions. Even for intersex syndromes that are more prevalent and less shrouded in secrecy than the cases of traumatic loss of the penis, long-term outcome data are hard to come by and those that have become available all suffer from problems that limit their validity: loss to follow-up of patients who have moved and cannot be found, who have died (especially if for other than medical reasons), or who have refused to participate in research (especially if for reasons of disappointment with their medical treatment).

Outcome data are also insufficient with regard to the question of impairment of sexual functioning after gender-confirming genital surgery. From a neuroanatomic standpoint, it is plausible that excision of the clitorophallus—widely practiced as a feminizing technique in the 1950s and 1960s—would lead to a diminution of erotic sensitivity and orgasmic capacity, although the limited outcome data available show considerable variability. But surgical techniques have undergone many changes since then and reduction of the clitoropenis rather than excision has become the norm. To evaluate sexual functioning in patients who were operated on with these newer surgical techniques, researchers need to wait at least until the patients are sexually active, sufficiently sexually experienced, and able to talk about these intimate details of their lives, and this in a population that is known to be relatively delayed in attaining psychosexual milestones. The same applies to patients with a similarly ambiguous genital status at birth who for one reason or another have not undergone genital surgery and could therefore serve as comparisons. Most surgical outcome reports are limited to anatomical data and the few that include data on sexual functioning leave much to be desired in terms of sample representativeness, assessment methods, and study details provided, quite apart from the fact that patients who have undergone surgeries with the newer techniques are not yet old enough for sexual functioning studies.

The true-brain-sex policy appears very plausible at first glance, but becomes more problematic on closer scrutiny. The assumption that the effects of prenatal hormones on the brain are the decisive biological factor in the development of gender and therefore the best criterion for the assignment of gender is primarily derived from research on the sexual differentiation of brain and behavior in nonhuman mammals, especially rodents, which has yielded several neuroendocrine models of the sexual differentiation of brain and behavior. In humans, most pertinent studies have been limited to androgens. In general, the resulting data allow the preliminary conclusion that effective prenatal androgens are indeed associated with the masculinization of gender-role behavior. However, the core gender identity, for instance, as a girl or as a woman, is compatible with large variability in gender-role behavior, as is vividly demonstrated in girls and women with CAH, thus making a close linkage to prenatal hormones less likely. It also must be kept in mind that in the limited literature available, the association between prenatal androgens and later gender change takes place predominantly in the context of further postnatal and pubertal cross-gender

hormonalization and the associated increased somatic sexual ambiguity. Therefore, in all likelihood, it is not the prenatal hormonal milieu by itself that determines such later gender change.

Inferring Brain Masculinization from Genital Masculinization

Adherents of the true-brain-sex policy recommend a male assignment for a newborn with intersexuality if the child's brain was prenatally strongly masculinized, independent of the status of the genitalia. However, how can one determine in a newborn whether and to what extent the brain was prenatally masculinized and/or defeminized? Appropriate brain imaging techniques are not yet available, and even if they were available, it is rather uncertain that the brain is, at the time of birth, already sufficiently sexually dimorphic to show such clear-cut gender dimorphic structures. Some advocates of the true-brain-sex policy therefore suggest using the genital status at birth (staged according to Prader for excess masculinization in chromosomal females and according to Quigley for undermasculinization in chromosomal males) as an indicator of brain androgenization/masculinization. There are several problems with this approach. (1) Genital staging at birth is not suitable for all syndromes of interest. For instance, Prader staging is problematic for many prenatally dexamethasone-treated cases of 46,XX CAH and Quigley staging is problematic for 46,XY newborns with 5 α -reductase deficiency, and Quigley staging is not at all suitable for other conditions of interest, such as 46,XY penile agenesis and 46,XY cloacal exstrophy of the bladder. (2) The growth of the penis does not depend exclusively on sex hormones. (3) The hormone model of genital differentiation is not identical with the hormone models of brain differentiation. As far as is known, the prenatal development of the genitalia is determined by testosterone, dihydrotestosterone, and anti-Müllerian hormone, whereas the development of the brain depends on androgens and, possibly, estradiol. (4) Attempts to correlate in the 46,XX CAH syndrome the Prader stage with gender-role behavior have had only very limited success. (5) Available (scanty) data on patient-initiated gender change in adults with a given intersex syndrome show little relationship to genital status at birth. (6) It also must be kept in mind that gender identity incongruence occurs in non-intersexed persons as well, although prior to surgery the genitals of transsexuals are compatible with their original gender assignment. (7) Research has made it

likely that contributions to the sexual differentiation of brain and behavior by hormone-independent genetic factors and brain-tissue-specific hormonal factors need to be taken into account. (8) There may be early effects of the social environment on central nervous system structures, as is already known from animal research. If any of these mechanisms participate in the development of persons with gender identity incongruence without somatic intersexuality, they are likely to also contribute to the variability and development of intersex patients. It can be concluded from all of these considerations that the genital status at the time of birth cannot be interpreted as a clear-cut indicator of brain masculinization.

Gender Assignment by Diagnostic Category

Intersex children and their families cannot be left in gender limbo. Despite controversies and uncertainties, clinicians must continue making decisions in this area. The degree of uncertainty varies with the syndrome. The situation is relatively clear-cut for the most frequent syndrome, CAH in 46,XX newborns, for which there is a general consensus that the assignment should be to the female gender, because the internal reproductive structures (ovaries, fallopian tubes, distal vagina) permit reproduction, provided that external genitalia and vaginal introitus are surgically corrected where necessary. Although many girls with CAH show variable degrees of behavioral masculinization, gender identity typically is female. Some genitally highly masculinized 46,XX children with CAH have been inadvertently raised as males and maintain a male gender identity when correctly diagnosed in adolescence, and a few CAH females change to male in adolescence or adulthood, apparently mostly in cases of protracted marked genital ambiguity and inconsistent hormonal control. However, the evidence is not sufficient to support the routine assignment of the most masculinized (Prader stage V) newborns to the male gender (as has been recommended).

Also, among 46,XY intersex syndromes not all gender assignment decisions are problematic. There is a consensus that 46,XY newborns with complete androgen insensitivity should be raised as female, because they will never respond to male sex hormones, neither somatically nor psychologically, and, given that it is (mostly) prenatal rather than postnatal androgens that affect gender-related behavior, the argument can be extended to the rare syndrome of complete gonadal dysgenesis. Even in the syndromes of partial androgen

insensitivity and/or testosterone biosynthesis defect, there is a consensus that the least undermasculinized cases should be raised male and the most undermasculinized cases should be raised female. However, given the scarcity of long-term follow-up reports on such syndromes, the best cutoff point on the Quigley scale for assignment to the male or female gender cannot be arrived at on an empirical basis and what is known about the variability of gender outcome in individuals with a given molecular genotype and endocrine or genital phenotype lets one expect that any cutoff point on the Quigley scale will be associated with occasional later patient-initiated gender reassignment, however rare. Similar uncertainties also affect the decision-making in cases of micropenis [i.e., a fully differentiated penis with the urethral meatus at the tip, but a (stretched) length $2\frac{1}{2}$ standard deviations or more below the norm]. Individual cases of satisfactory long-term outcome have been shown among female-assigned as well as male-assigned individuals, but unsatisfactory outcomes have also been documented in both types of assignments, and evidence-based decision-making requires substantially larger samples and more comprehensive assessments to weigh the advantages and disadvantages of either assignment. Also problematic are the relatively rare pubertal change syndromes such as 5α -reductase deficiency and 17β -hydroxysteroid-dehydrogenase deficiency in 46,XY. At birth, such children appear more female than male and they are typically assigned to the female gender, unless diagnosed correctly. There are a number of clinical-medical reports from resource-poor countries showing that, in the absence of medical intervention, the majority of such individuals start virilizing dramatically during spontaneous puberty and later change to the male gender, but very few data are available on the long-term outcome of such cases when medical intervention is introduced at newborn age or at the beginning of puberty. Similarly, the long-term outcome of those few cases who reportedly have had early hormone replacement therapy to masculinize the genitalia is not yet known.

Most controversial is the gender assignment of 46,XY infants who presumably had a normal-male sex-hormonal environment *in utero* so that the brain was normally masculinized, but who, for nonhormonal reasons, had genital abnormalities, for instance, in cases of penile agenesis, cloacal exstrophy of the bladder, or traumatic loss of the penis due to a circumcision accident. Although there are some well-known individual cases of later patient-initiated gender reassignment to male, there are other cases where this has not occurred, and in general, the

long-term outcome data are much too limited for an evidence-based decision.

In the syndrome of true hermaphroditism, the gender assignment decision is based on considerations of the preponderance of masculine or feminine structures in both the external and internal genitalia and the level of anti-Müllerian hormone, but again there is uncertainty regarding the best cutoff point for male versus female assignment, and more long-term follow-up data are needed for the formulation of a consensus policy. In the case of “XX males” secondary to a translocation of the SRY locus onto an X chromosome and consequent differentiation of a male gonad, there is no doubt that such infants should be raised as boys. Although the rapidly expanding knowledge on multiple genes participating in the sexual differentiation of the gonads and the brain complicates the picture and leads to the discovery of additional genotypes associated with intersex syndromes, it can be expected that over the next decade these discoveries will help refine both the diagnostic picture and the prognostic picture, especially when complemented by data about sexual brain dimorphism from brain imaging.

Conclusion

Overall, the available data from both earlier and newer studies can be tentatively summarized in the statement that, with the exception of the pubertal gender-change syndromes, the majority of intersex patients develop a gender identity commensurate with the assigned gender. Later initiation of gender change by an intersex person appears to be the more likely the more the prenatal and postnatal biological factors and the postnatal psychosocial factors push in the same cross-gender direction. It follows that the gender assignment of the newborn should be based on the best prognosis for the future psychosocial and psychosexual functioning of the patient in the given cultural context, taking into account everything that is known about the likely steroid effects on the brain in the syndrome in question and what is known from follow-up investigations.

PSYCHOSOCIAL MANAGEMENT

Introduction

The issues of gender assignment and genital surgery and the potential implications for the development of gender, sexuality, and parenthood—three highly salient, emotional, moral, and frequently controversial social issues—make intersex conditions a challenge not only for patients and their families, but also for

physicians and other professionals involved in their clinical care and psychosocial management. Moreover, the psychosocial management itself is in a period of flux, since the optimal-gender policy of the second half of the twentieth century has come under severe criticism, whereas the evidence on which to base systematic improvements where warranted leaves much to be desired and no systematic randomized trials of psychosocial management procedures for intersex patients have been conducted. In these circumstances, recommendations for specific treatment options need to be more tentative, and not only the providers, but also the parents and, when old enough, the patients themselves will be burdened by more uncertainties in their decision-making than desirable.

The professionals involved in the medical and psychosocial management of intersex patients, especially when gender assignment is problematic, may involve multiple disciplines and subspecialties, e.g., specialists in neonatology, pediatric endocrinology, pediatric urology, gynecology, genetics, genetic counseling, and mental health. To minimize the burden on intersex patients and their families, these professionals should form a smoothly operating team and follow a common policy, also with regard to criteria for decisions on gender. Parents of intersex newborns are typically in a state of high stress while the gender of their child remains uncertain, and most are not in a position to decide between conflicting professional opinions. Those team members—both medical and mental health staff—who have the most influence on decisions regarding gender assignment and genital surgery and those who most likely will be involved with the parents and patients over the coming years must keep up with medical advances, emerging new treatment options, the growing research on psychosocial outcomes, and the prognostic alternatives for both health and psychological development in the intersex field. To be fully effective, they need to acquire up-to-date information on all psychosocially relevant aspects of the patient’s syndrome and specific symptoms. For instance, some intersex syndromes may be associated with short stature or neuropsychological impairments, both of which have psychosocial consequences of their own.

Gender Assignment and Reassignment

Gender Assignment at Birth

The identification of ambiguous genitalia in a newborn only occasionally constitutes a medical emergency. Yet, having a newborn of undetermined

gender is highly stressful for most parents and thus presents a psychosocial emergency and speedy processing of necessary medical tests and rapid decision-making with regard to gender assignment are important. Prolonged periods of nondecision are thought to run the risk of chronically ambiguous or inconsistent sex typing by the family, or of rejection of the child altogether.

Given the diverse factors that influence gender identity development in intersex patients, the decision on gender assignment required in a patient with highly ambiguous genitalia is not only based on medical criteria, but also needs to take into account the differential prognosis for psychological (including psychosexual and reproductive) functioning in either gender role as well as the prognosis for how well the family will be able to cope with either decision. The prognostic considerations take into account the various options of genital surgery and sex-hormone treatment and their respective implications for future functioning, especially in terms of gender-role fit, sexuality, reproduction, and overall quality of life. As gender-related values differ in various societies, cultural factors have significant impact on gender assignment decisions. In many Asian countries, for example, gender assignment to male is more strongly favored, and infertility in the female more stigmatized, than in the West.

Intersex counseling at this stage should involve both parents and the inclusion of other family members should be considered. Legally, gender assignment is the parents' decision, but they are likely to rely on expert medical advice. Along with medical education about the nature and origin of the problem and the medical tests involved, the parents must be adequately informed by their clinicians about the diversity of long-range outcomes and not given overly optimistic assurances. Commensurate with their cognitive capacity, the parents need to be made aware of significant gaps in scientists' knowledge about intersex disorders or major controversies about management decisions. Such parent counseling requires a careful balance between providing gross oversimplification on the one hand and too much detail on the other, with a resulting paralysis of decision-making. If either parent is not convinced that the gender decision was correct, appropriate child rearing may be in jeopardy.

Monitoring Behavioral Development

The psychosocial management needs of intersex patients vary with developmental stage. Once the diagnosis is established and the decision on gender assignment made, an approximate timetable for future

medical procedures and preventive psychosocial measures can be projected and visits planned accordingly. Again, a team approach in which medical procedures and psychosocial management are closely integrated is highly recommended. Active outreach by the mental health professional may facilitate prevention of psychosocial problems and adherence to medical treatment.

As for other congenital disorders, regular monitoring of behavioral development is also recommended for intersex children. This includes monitoring for medical problems and treatment compliance, as needed, and monitoring for cognitive and behavioral problems, with a special emphasis on atypical gender-role behavior. Some parents (and even some children) need help with handling atypical gender-role behavior. If symptoms of gender dysphoria emerge, parents and the child may need some help in dealing with gender issues and in persistent extreme cases the option of gender reassignment needs to be considered.

Gender Reassignment

Sometimes, intersex children are initially misdiagnosed, especially when born outside of intersex-experienced medical settings, and receive their correct diagnosis later from medical specialists. The definitive diagnosis may alter the prognostic considerations and make a gender reassignment desirable. Such reassignment, if well justified, is usually not a problem during infancy, provided the parents are adequately counseled.

After infancy, during the toddler and preschool years, many intersex children develop some degree of gender-atypical behavior, but these rarely indicate a problem of gender dysphoria. Parents who are anxious about their child's gender atypicality may need reassurance and counseling. Gender reassignment decisions after infancy, which are quite uncommon, should never be based on purely medical considerations, but require careful psychological evaluation (over a prolonged period of time) of the child's overall behavioral development, with particular attention to the child's gender-role behavior and to any symptoms of gender dysphoria, as well as to the behavioral niche the child has occupied in the family system.

Gender dysphoria and wishes to change one's gender may also emerge later in adolescence or adult life, usually as the result of a long and gradual process. Even if the problem is of long standing, through counseling the patient can consider various options, and gender change and the attendant hormone treatment and surgical procedures are not the invariable outcome.

Genital Surgery

Some children with intersexuality require genital surgery for medical reasons. In the majority of cases, however, genital surgery has been performed for psychosocial reasons in order to confirm the assigned gender by genital appearance and to thereby facilitate gender-appropriate rearing, help develop a gender-typical body image, and avoid social stigmatization and also to facilitate later peno-vaginal intercourse. Because genital surgery is associated with some risk to sexual tissues and erotic innervation and thereby sexual functioning, a vigorous debate has ensued as to whether such nonmedically necessitated surgery should be delayed until the intersex child is old enough to give informed consent. Surgeons argue that modern surgical techniques are much improved, but it may still require years until the patients so treated are old enough to provide data on sexual functioning. Experienced clinicians are concerned that obviously ambiguous genitalia put an unoperated intersex child at risk of undue attention and stigmatization. Moreover, in the absence of sufficient sexual experience, even an older adolescent or young adult may not be capable of giving appropriately informed consent, and the very fact of genital ambiguity may contribute to the delay of sexual initiation and some patients may never reach that developmental stage. Thus, there is as yet no consensus regarding the issue of early genital surgery, except to say that milder cases of genital ambiguity are less likely to be operated on than they would have been one or two decades ago and that there is a growing consensus that genital surgery should be confined to intersex-experienced centers of excellence.

If the decision for genital surgery has been made, both medical and psychological considerations determine the choice of time. From a psychological perspective, genital surgery is performed more easily in infancy, when counseling for the child is not an issue, and in adolescence, when cognitive maturation facilitates counseling and the patient has achieved a degree of autonomy, than in early and middle childhood. The older the child, the more he or she should be empowered to have the decisive vote in the decision for or against genital surgery and in choosing the time when it should take place.

Before and after genital surgery, genital examinations of intersex children and adolescents are frequent. Given the low prevalence rates of the various syndromes of intersexuality, it has been common medical practice to have many different physicians, especially medical students and residents, perform genital examinations on the same patient. However,

considerable evidence has accumulated showing that this practice has negative and often severe psychological aftereffects. In medical training, this practice should be replaced by the use of photographs, videotapes, and physical models. Also, older children and teenagers should have a say in whether someone, and, if yes, who, should accompany them during the examination.

In adolescence and adulthood, psychosocial monitoring needs to include concerns about romantic relationships and sexual functioning, because of the increased problems associated with genital ambiguity and related surgery.

Sex-Hormone Treatment

During infancy, androgen treatment is sometimes used for chromosomally male children with underdeveloped male genitals to test for an androgen-receptor defect or, if the assignment decision was for male, to enhance penile size. Occasionally, such children show behavioral change that normalizes with the end of the treatment and the parents may need reassurance.

Intersex children who have no gonads or underfunctioning gonads will need sex-hormone replacement therapy to initiate or support pubertal maturation. This is best done at the age when their classmates experience endogenous puberty. Undue delay of pubertal development may add to difficulties in the later development of romantic and sexual relationships.

Information Management

The medical and sexual education of intersex children and their parents and related counseling (including information about how to deal with relatives and friends) is a crucially important part of psychosocial management. The most difficult issue is the disclosure of their medical status and history to the intersex patients themselves, especially to those assigned to a gender discrepant with sex chromosomes and/or gonadal structure. Professionals generally support the right of patients to have access to their medical information and many experienced professionals agree that by the time of graduation from high school the patient should be fully informed, commensurate with the level of cognitive capacity. However, many parents are anxious and would like to postpone full disclosure, sometimes permanently. Appropriate timing of disclosure is important. Early disclosure runs into the problem of cognitive limitations. Late disclosure implies cover-up and deception and may lead to the

patient's long-term distrust of and anger at medical professionals and even endanger appropriate future utilization of medical services. Disclosure is best conceptualized as a long-term process starting in late preschool age, with many installments, preferably in conjunction with meaningful events. Substantively, there are the issues of past genital surgery and their tell-tale signs, namely, scars on the abdomen, possibly persisting abnormalities in genital appearance, and plans for future surgery; the need for the induction of puberty by sex-hormone treatment and the maintenance of secondary sex characteristics by its lifelong continuation; the issue of infertility or, better, the potential realization of parenthood by means other than pregnancy or insemination; the question of variability in gender-role behavior among individuals of the same core gender identity; and the potential for romance, sexuality, and sexual pair-bonding—regardless of sexual orientation. All of these issues of functional potential are more important to the average developing intersex person than the details of the molecular structure of genes, the variants of hormone synthesis, receptor defects, enzyme abnormalities, and the organization and activation of neural networks—although the occasional adolescent or adult patient may have specialized interests or even choose a career path in the respective biological sciences and may seek as complete an understanding of his or her biological condition as is possible.

For the developing child and adolescent, the medical information must be carefully tailored to the cognitive maturity level. The fact that the meaning and connotations of terms differ vastly between medical personnel and lay persons makes a deliberate and cautious choice of terminology necessary. The intended medical “truth” may be dramatically at variance with what the patient or parents perceive. Visual aids are often very helpful.

For both the patients and the parents, discussing the medical aspects of intersexuality tends to be highly emotional, so adequate retention is problematic. In the author's unit, the ideal procedure for the medical education of a newly referred family is that the physician in charge of the overall coordination of care, usually a pediatric endocrinologist or urologist, gives a carefully worded summary of the medical information to the parents, in the presence of the mental health professional, who then takes over. Typically, the parents are asked to recount in detail how they understand the medical condition, its origin, and its prognosis. Then, the instruction is repeated, the

parents' misunderstandings are corrected, and their particular concerns are addressed. At subsequent visits, the procedure is repeated as necessary, keeping in mind that new misunderstandings and different concerns develop over time. Similar procedures are used with intersex children, once they are old enough, except that, in addition, the clinician lets them explain to their parents (in the clinician's presence) what they have learned from the instruction, to open the channels of communication.

Support Groups

One of the recurrent problems of persons suffering from rare disorders and their families is the feeling of isolation and having no one to talk to who really understands what they must cope with. Many support groups have sprung up, including groups specific for intersex persons and/or their parents, and the internet has greatly aided in this development. Generally, such groups have been a great help to many patients and their families. However, the quality of the groups is highly variable and the medical and other information that comes from them is sometimes quite misleading. Thus, frequent exchanges between support groups and professionals are recommended and group participants should be strongly encouraged to seek second opinions from their physicians and other care providers regarding the information they receive.

GENES INVOLVED IN EARLY GONADAL DEVELOPMENT

A number of genes have been shown to be crucial for the earliest steps of gonadal morphogenesis. These include *WT1*, *SF1*, *LIM1/LHX1*, *LHX9*, and *EMX2*. Since these genes act prior to sex determination, they are required for early gonadal development in both sexes. Mice deficient in these genes either fail to develop genital ridges or have an early block in genital ridge development. Human mutations involving the *LIM1*, *LHX9*, and *EMX2* genes have not yet been linked to cases of human gonadal agenesis or dysgenesis. The *WT1* and *SF1* genes merit further discussion since these genes are known to be required for both early gonadal development and sex differentiation.

WT1

The *WT1* gene, encoding a DNA-binding protein containing four zinc-fingers, was first identified as a tumor suppressor gene via genetic studies of Wilms' tumor patients in humans. Mutations in the *WT1* gene in humans were shown to be responsible for both Denys-Drash syndrome and Frasier syndrome, characterized by anomalies in kidney development and gonad formation including sex reversal. Mice homozygous for a null mutation in the *Wt1* gene show a phenotype of renal and gonadal agenesis and adrenal dysgenesis, demonstrating that *Wt1* is required for genital ridge formation prior to the events of sex determination. It is evident that the *WT1* gene can result in multiple protein isoforms via posttranscriptional processes including alternative splicing; these isoforms can function not only as transcription factors but also as RNA-processing factors. Important among these isoforms is the presence of a 3-amino-acid insertion (+KTS) between the third and fourth zinc-fingers or the absence of the insertion (-KTS). The *WT1* (-KTS) isoform functions as a transcription factor that can activate the *AMH* and *DAX1* promoters as well as the *SRY* promoter *in vitro*. The *WT1* (+KTS) isoform shows little transactivation activity but has been implicated in RNA-processing events. Isoform-specific null allele mouse studies have been reported and they show that the *Wt1* (+KTS) null allele results in a phenotype of XY sex reversal. This indicates that *WT1* (+KTS) isoforms as well as RNA processing are important contributors to the molecular mechanisms leading to sex determination.

SF1

Steroidogenic factor 1 (SF1; also known as Ad4BP and NR5A1) is a transcription factor belonging to the nuclear receptor superfamily. SF1 was first identified as an essential regulator of the P450 hydroxylases in the adrenals and gonads. Later studies showed that SF1 is also present in the pituitary and ventromedial nucleus of the hypothalamus (VMH). In agreement with its expression pattern, *Sf1* knockout mice lack adrenal glands and gonads, exhibit VMH and pituitary gonadotrope abnormalities, and display female internal genitalia. At the transcriptional level, SF1 regulates the expression of many genes involved in reproduction, steroidogenesis, and sexual differentiation. An important SF1 target for sexual differentiation is the anti-Müllerian hormone gene (*AMH/MIS*) involved in Müllerian duct regression in the developing male embryo. In humans, the role of SF1 in male sex differentiation is supported by the identification of *SF1* gene mutations in a subpopulation of 46,XY sex-reversed patients: a dominant *de novo* heterozygous G35E mutation, a recessive homozygous R92Q mutation, and a heterozygous deletion of eight nucleotides causing a frameshift mutation and C-terminal truncation of the SF1 protein. For two of these *SF1* mutations (G35E and R92Q), the presence of normal Müllerian structures and the retention of a uterus in the affected individuals is indicative of insufficient AMH production. This suggests that the mutated SF1 proteins might interfere with the expression of a *Sf1* target gene(s) involved in the male sexual differentiation pathway, including *AMH*.

GENES INVOLVED IN SEX DETERMINATION AND DIFFERENTIATION

The era of molecular genetics of mammalian sex determination was launched more than a decade ago with the identification and cloning of the elusive Y chromosome-linked testis determining gene, termed *SRY*. Since then, a multitude of additional genes have been described as being involved in testis differentiation; these include *SOX9*, *DMRT1*, *GATA4*, *FOG2*, *DAX1*, and *FGF9*.

SRY

The first major advance in the molecular characterization of mammalian sex determination was reported

in 1990 with the positional cloning of the *SRY* gene, a candidate for the testis-determining factor (TDF) located on the Y chromosome. The equivalence of *SRY* and TDF was subsequently demonstrated via gain-of-function studies in the transgenic mouse, whereby a transgene coding for Sry caused an XX animal to develop with a male phenotype. Biochemical studies showed that *SRY* can bind to DNA via a structural motif termed an HMG-box and mutations in the HMG-box were shown to be of clinical relevance in cases of XY females in the human population. Structural comparisons of the *SRY* gene between mammalian species revealed a notable lack of sequence conservation. Although this is unremarkable for a gene located on the Y chromosome, it was not anticipated for such a key player in the mammalian sex determination process. Also surprising is the fact that after 13 years of study, no direct target genes of *SRY* have yet been identified, and the mechanisms by which *SRY* causes the activation of male-specific gene expression, cell proliferation, and cell migration within the male genital ridge remain obscure. However, some progress has been made in deciphering *SRY* promoter function, with *in vitro* evidence that WT1, SF1, SOX9, and GATA4 can activate *SRY* gene transcription. Genetic evidence suggests that DAX1 competes with *SRY* activity and additional *in vitro* evidence suggests that DAX1 inhibits the function of proteins that activate *SRY* activity.

SOX9

The description of the HMG-box of *SRY* allowed the cloning of a family of related HMG-box-containing genes, termed SOX (SRY-related HMG-box) genes. One of these new SOX family members, *SOX9*, was associated via positional cloning with the musculo-skeletal disease campomelic dysplasia and also with autosomal sex reversal in humans. Demonstration of *SOX9* gene expression within the male genital ridge at approximately the time of sex determination in mammals as well as in birds suggested a conserved role for *SOX9* in sex determination and/or sex differentiation. Transgenic expression of *SOX9* within the genital ridge in the absence of *SRY* resulted in a male phenotype within XX animals, suggesting that *SOX9* expression is sufficient for sex determination and can account for downstream functions of *SRY* expression. Like *SRY*, *SOX9* contains a DNA-binding HMG-box domain, but unlike *SRY*, it also contains a recognizable transactivation domain. A key event in sex differentiation is the activation of the *AMH* gene, which codes for a secreted protein of the TGF- β family.

Sox9 has been shown by both *in vitro* and *in vivo* studies to transactivate the *Amb* promoter. *In vitro* evidence suggests that at least in some species, *SOX9* can also transactivate the *SRY* promoter, placing it both upstream and downstream of sex determination. Whether *SOX9* is necessary for sex determination per se, or can be compensated for by other SOX genes known to be expressed within the genital ridge, awaits further experimentation.

DMRT1

DMRT1 was initially identified and cloned via a conserved DNA-binding domain sequence (DM domain) identified within the *Drosophila melanogaster* Doublesex gene, the *Caenorhabditis elegans* Mab-3 sex regulator gene, and human expressed sequences derived from a testis cDNA library. The chromosomal location of human *DMRT1* (9p) makes it a candidate gene responsible for XY gonadal dysgenesis seen with 9p deletions in humans. This region is syntenic with the chicken Z chromosome, making chicken *DMRT1* a candidate for a dosage-sensitive sex determination system in birds. Unlike most other genes involved in sex determination and differentiation that show fairly wide tissue expression patterns, *DMRT1* expression is restricted to the gonads. Furthermore, *DMRT1* expression is up-regulated concurrently with testis development, not just in humans and mice but also in other vertebrates. Male mice that are deficient for the *Dmrt1* gene display problems with cell differentiation and cell survival in the postnatal testis, but these animals undergo normal sex determination. These results could indicate that DMRT1 is simply not involved in sex determination or that functional redundancy can compensate for the absence of DMRT1; there are seven *DMRT* genes in mouse and humans. A DMRT family member (*Dmrt1bY*) was proposed as the sex-determining factor in the Medaka fish; however, this gene was found to be absent in closely related fish species. Thus, although DMRT1 sequences are widely distributed within the animal kingdom and are unquestionably implicated in gonadal development, a universal involvement of DMRT1 sequences in sex determination does not appear likely. Where mammalian *DMRT1* integrates with other genes known to be involved in mammalian sex determination and differentiation pathway also remains to be determined.

GATA4

GATA4 is one of six proteins belonging to the GATA family of transcription factors. GATA factors are

named for the nucleotide sequence (WGATAR) that they bind to in the promoter regions of target genes. They were originally identified as crucial regulators of cardiac development and hematopoietic cell differentiation. *GATA* expression, however, is not limited to these two systems. In the mouse, the *Gata4* gene is abundantly expressed in the somatic cell population of the developing genital ridge prior to and during the time of *Sry* expression. Thus, based on its expression pattern, GATA4 was proposed to play a central role in early gonadal development and sex determination. This hypothesis has been confirmed in the mouse, where *in vivo* disruption of GATA4 function via a mutation of the *Gata4* gene leads to a block in testis development and a marked down-regulation of *Sry* expression. Thus, GATA4 appears to function as a direct upstream regulator of *SRY* expression in the developing testis. Although the latter has yet to be conclusively demonstrated, the presence of multiple GATA regulatory motifs in the mouse, human, and pig *SRY* promoters strongly supports this notion. After gonadal differentiation, GATA4 has been shown to be recruited as an important regulator of the *AMH* gene involved in Müllerian duct regression and, consequently, male sexual differentiation. GATA4 has been shown to regulate both the mouse and human *AMH* promoters through direct transcriptional cooperation with SF1. Although no human *GATA4* gene mutations have yet been linked to gonadal defects, evidence suggests that disruption of GATA4/SF1 synergism may account for some cases of human male-to-female sex reversal involving insufficient *AMH* expression.

FOG2

GATA factors regulate the expression of target genes through cooperative interactions with other transcription factors. These include the Friend of GATA proteins (FOG1 and FOG2), which were cloned as GATA-specific cofactors. Although the FOG proteins do not directly bind to DNA, they have been shown to act as either enhancers or repressors of GATA transcriptional activity depending on the cell and promoter context being studied. In this regard, it has been suggested that the FOG proteins act as bridging molecules that link GATA proteins with other factors involved in either activation or repression. In the mouse, *Fog2* is coexpressed with *Gata4* in the developing genital ridge. Like *Gata4*, *Fog2* is likely expressed upstream of *Sry* in the sex determination pathway since *Fog2* knockout mice have markedly diminished *Sry* expression and do not develop a normal testis.

DAX1

The X chromosome-linked *DAX1* [dosage-sensitive sex reversal-adrenal hypoplasia congenital (AHC) critical region on the X chromosome, gene 1; NR0B1] gene encodes an atypical member of the nuclear receptor superfamily. *DAX1* is expressed in several endocrine tissues, including the gonads, where it is present in the Sertoli and Leydig cells of the testis and the granulosa and theca cells of the ovary. *DAX1* plays a critical role in adrenal development and gonadal function; it was originally identified as the causative gene for AHC associated with hypogonadotropic hypogonadism (HHG), a recessive disorder affecting males. Indeed, several different groups have characterized numerous *DAX1* mutations (nucleotide substitutions, insertions, and deletions) in individuals affected with AHC and HHG. Females carrying heterozygous mutations in the *DAX1* gene are normal and there has been no report of homozygous females since males needed to transmit the nonfunctional allele are infertile. Since *Dax1* expression is down-regulated in the developing male gonad after overt testis differentiation in the mouse, the *Dax1* gene was initially believed to be an important ovarian determinant. However, female *Dax1* knockout mice are phenotypically normal. In contrast, male *Dax1* knockout mice are infertile due to a loss of germ cells. Thus, *Dax1* is apparently not required for ovarian differentiation but rather is essential for the maintenance of the integrity of the seminiferous epithelium of the testis. Closer examination of *Dax1*-deficient mice has revealed that *Dax1* is also essential for testis cord formation and, consequently, testis determination. In addition to *DAX1* mutations, another human disorder has been associated with the *DAX1* gene. In this case, duplication of a small region on the X chromosome that encompasses the *DAX1* gene leads to dosage-sensitive sex reversal in XY males. Overexpression of *Dax1* in transgenic mice has also been shown to induce sex reversal in males carrying a weakened *Sry* allele. Thus, adequate *Dax1* levels are required for normal testis development and function, but too much *Dax1* appears to have an “anti-testis” effect. In the female developing gonad, *Dax1* transcription appears to be up-regulated by *Wnt4*, a member of the *Wnt* family of signaling molecules. *Wnt4* signaling has been shown to function via activation of β -catenin and its subsequent interaction with SF1 on the *Dax1* promoter. In the developing male gonad, the action of *Wnt4* has been suggested to be inhibited by *Sry*.

AMH

In mammals, male sexual differentiation is regulated by two hormones produced by the fetal testis: testosterone, secreted by Leydig cells, and AMH, produced by Sertoli cells. In the male embryo, AMH induces regression of the Müllerian ducts (the anlagen of the internal female reproductive tract). AMH is the earliest marker of testis formation; it is found in Sertoli cells of the developing human testis starting at approximately 8 weeks of gestation. In the mouse, Amh is first detected in Sertoli cells on embryonic day 12.5; its expression remains high throughout fetal life before declining markedly after birth. Consistent with its role in male sexual differentiation, the absence of *AMH* expression in humans causes persistent Müllerian duct syndrome, a form of pseudo-hermaphroditism characterized by the retention of Müllerian duct structures. The transcriptional regulation of the *AMH* gene has been intensely studied. Interestingly, several transcription factors involved in primary sex determination (SF1, WT1, SOX9, and GATA4) are later recruited as important regulators of *AMH* expression. Although many of these factors have been shown to activate *AMH* transcription on their own by directly binding to the *AMH* promoter, functional cooperation between these factors appears to be of paramount importance in directing the proper spatiotemporal expression of the *AMH* gene.

OTHER GENES INVOLVED IN GONADAL DEVELOPMENT AND SEX DETERMINATION

Ever since the discovery of *SRY*, the majority of newly identified genes involved in gonadal development and sex determination have been transcription factors. Signaling molecules such as FGF9 and WNT4 have also been implicated in these processes. In the mouse, Fgf9 was shown to be involved in the induction of mesonephric cell migration into the XY gonad, an essential step required for seminiferous cord formation and, hence, proper testis organization. *Wnt4* expression is detected in the genital ridge of both sexes but its expression becomes largely restricted to the ovary after overt gonadal differentiation. *Wnt4*-deficient female mice are masculinized due to the expression of genes involved in testosterone biosynthesis that are normally not expressed in the fetal ovary. Much like *DAX1*, overexpression of WNT4 in humans has been reported to cause male-to-female sex reversal; this

anti-testis effect of too much WNT4 is thought to occur via up-regulation of *DAX1*.

PERSPECTIVES

Although significant progress has been made in elucidating how the different genes in the gonadal development and sex determination pathway come together to form a complex regulatory network, it remains evident that many pieces of the genetic puzzle are still missing. Indeed, the majority of the cases of human XY sex reversal and approximately one-quarter of the cases of XX maleness have not yet been defined at the genetic level. Technologies for large-scale gene identification based on differential expression have the potential for making important inroads into finding new genes in this fundamental developmental process. For example, expression-based strategies such as gene microarray technology have begun to be successfully applied to the discovery of genes involved in testis and ovary development. The *vanin 1* gene, which encodes a glycosylphosphatidylinositol-anchored cell surface protein, is an example of a gene identified through the sex-specific screening process. Clearly, other genes are likely to be identified in coming years. This is especially true for genes that might control ovarian development, an area that has been long overlooked by the drive to study testis differentiation.

unclear because autosomal dominant disorders usually occur as a result of either haploinsufficiency or secondary to dominant negative activity. IGHD-3 may be associated with hypogammaglobulinemia and is inherited as an X-linked disorder. No mutations in *GHI* or other candidate genes have been identified for this type.

Mutations causing MPHD have been identified in the genes encoding pituitary transcription factors that direct the embryonic development of the anterior pituitary gland, including *POU1F1* (formerly referred to as *Pit-1*), *PROPI*, *HESX1*, and *LHX3* and *LHX4*. Autosomal recessive and dominant mutations of *POU1F1* (POU domain, class 1, transcription factor 1), which is located on chromosome 3p11, result in deficiency of GH, prolactin, and thyroid-stimulating hormone (TSH); adrenocorticotropin hormone (ACTH) and the gonadotropins are spared. Autosomal recessive mutations of *PROPI* (*Prophet of Pit-1*), located on chromosome 5, cause deficiency of GH, prolactin, and TSH, as well as the gonadotropins. ACTH is spared initially, but there is a tendency toward the development of deficiency with increasing age. Mutations of *HESX1* (also referred to as *RPX*), a pituitary transcription factor that also plays a role in the development of the optic nerves, have been implicated in septo-optic dysplasia. This is a heterogeneous disorder characterized by midline neurological abnormalities associated with pituitary hypoplasia and optic nerve hypoplasia. Mutations of *LHX3* have been identified in humans with abnormal neck and cervical spine development in whom there is a deficiency of all anterior pituitary hormones except ACTH. Mutations have been identified in *LHX4* in a family with GH, TSH, and ACTH deficiency in combination with cerebellar and skull-base malformations.

Potentially, inactivating mutations of SST, or one of the five specific G protein-coupled receptor subtypes (SSTR1–5) to which somatostatin binds, could lead to loss of inhibition and subsequent excess GH production. Although a mutation of the *sst5* gene has been demonstrated in a patient with a GH-secreting pituitary adenoma, the simultaneous presence of a *gsp* mutation makes the role of the *SSTR5* mutation unclear.

Activating Mutations

GHRHR signals through a $G_{s\alpha}$ -containing G protein. Activating somatic mutations of the gene encoding the $G_{s\alpha}$ subunit give rise to the *gsp* oncogene. These *gsp* mutations have been identified as the molecular cause of 30–40% of GH-producing pituitary tumors. They have also been found in GH-producing tumors, which occur in patients with McCune–Albright

syndrome. The mutations result in continuous and markedly elevated levels of intracellular cAMP, with subsequent increases in the secretion of GH and the proliferation of somatotrophs.

Thyroid-Stimulating Hormone

TSH is a glycoprotein hormone that consists of α and β subunits. The α subunit is common to TSH, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and human chorionic gonadotropin, whereas the β subunit in each of these hormones is unique and confers specificity of action. Production of TSH is stimulated by thyrotropin-releasing hormone (TRH) and inhibited by triiodothyronine.

Inactivating Mutations

Central hypothyroidism, which is a rare disorder characterized by insufficient production of TSH by the anterior pituitary, occurs most commonly as part of MPHD. Rare cases of isolated TSH deficiency have been described, typically resulting from missense, nonsense, or frameshift mutations of the TSH- β gene on chromosome 1; a nonsense mutation of the *TRHR* gene has also been identified in a patient with isolated central hypothyroidism. Central hypothyroidism secondary to the production of a mutant TSH molecule has been demonstrated in two families in which the affected members demonstrated thyroid hormone levels consistent with hypothyroidism but TSH levels that were inappropriately in the normal range.

Activating Mutations

TSH-secreting pituitary adenomas are a rare cause of central hyperthyroidism. Potential molecular causes that have been investigated, such as activating mutations of the $G_{s\alpha}$ subunit, *TRHR* and *POU1F1*, have not been identified.

Adrenocorticotropin Hormone

ACTH is a peptide hormone derived from a precursor polypeptide, pro-opiomelanocortin (POMC). The POMC gene encodes several peptides, including an N-terminal peptide, β -lipotropin, and ACTH. Synthesis of ACTH is primarily stimulated by hypothalamic corticotropin-releasing factor (CRF) through its interaction with the CRF receptor, another G protein-coupled receptor.

Inactivating Mutations

Although rare cases of isolated ACTH deficiency have been described, deficiency of this hormone usually

occurs as part of MPHD. ACTH deficiency can be simulated by isolated glucocorticoid deficiency because there is resistance to the action of ACTH at the level of the adrenal cortex. In approximately half of cases identified with this disorder, there is a demonstrable mutation in the ACTH receptor (also known as the melanocortin-2 receptor). This condition, referred to as GCCD1, is inherited in an autosomal recessive manner. Subjects are biochemically characterized by low serum cortisol and high ACTH levels, with normal mineralocorticoid activity.

Activating Mutations

The prevalence of *gsp* mutations in ACTH-secreting pituitary adenomas has been demonstrated to be less than 10%.

Luteinizing Hormone and Follicle-Stimulating Hormone

The pituitary gonadotropins LH and FSH, which belong to the family of glycoprotein hormones, are produced by the anterior pituitary in response to stimulation by the hypothalamic peptide gonadotropin-releasing hormone (GnRH). The α subunit, common to both LH and FSH, is encoded by a gene on chromosome 6q12.21. The hormone-specific LH β subunit is encoded by the *LH β* gene on chromosome 19q13.32, whereas the FSH β subunit is encoded by the *FSH β* gene on chromosome 11p13.

Inactivating Mutations

Five subjects with isolated FSH deficiency have been reported with inactivating mutations of *FSH β* . Two different mutations (a 2-base pair deletion and a missense mutation) were described in three women who presented with primary amenorrhea, poorly developed secondary sexual characteristics, and infertility. Mutations of *FSH β* have also been reported in two men, one of whom presented with azoospermia but normal puberty, and the other with azoospermia and delayed puberty. These mutations consisted of the same 2-base pair deletion detected in the females plus a new missense mutation. Only one homozygous missense mutation causing inactivation of *LH β* has been reported in a male, who presented with delayed puberty. No mutations of the human α subunit gene have been described in the literature.

Hypogonadotropic hypogonadism (HH), which results from deficiency of both gonadotropins, can occur in isolation, in association with anosmia such

as in Kallmann's syndrome (KS), or with adrenal insufficiency such as in adrenal hypoplasia congenita. Inactivating mutations of the gene encoding the GnRH receptor (*GnRHR*), a member of the G protein-coupled receptor family located on chromosome 4q21.2, have been reported in isolated HH.

The defects in KS and adrenal hypoplasia congenita both occur at the hypothalamic rather than pituitary level. Briefly, KS is a form of HH that is associated with anosmia/hyposmia. X-linked recessive KS results from mutations of the *KAL1* gene that is located in the pseudo-autosomal region of Xp. This gene encodes the KAL protein (also known as anosmin), which plays a central role in the migration of both GnRH and olfactory neurons during embryonic development. However, the majority of KS is not X-linked and has been shown to have either autosomal recessive or dominant patterns of inheritance in familial cases. Adrenal hypoplasia congenita (AHC) is a rare X-linked disorder characterized by primary adrenal insufficiency and HH. It is caused by missense, nonsense, and frameshift mutations of the *DAX-1* gene (dosage-sensitive sex reversal, AHC-critical region of the X chromosome, gene 1), located on the short arm of the X chromosome Xp21. More than 60 different mutations of *DAX-1*, which is expressed in the hypothalamus, pituitary, adrenals, and gonads, have been reported in X-linked AHC.

Activating Mutations

These mutations have not been identified in the *LH β* , *FSH β* , or *GnRHR* genes.

Prolactin

Prolactin (PRL) is a polypeptide hormone encoded by the *PRL* gene on chromosome 6. Its release is stimulated by a number of prolactin-releasing factors, including vasoactive intestinal peptide, TRH, and PRL-releasing peptide. It is inhibited by prolactin-inhibiting factors, predominantly dopamine but possibly also by the 56-amino acid portion of the precursor to GnRH, known as GnRH associated peptide.

Inactivating Mutations

Isolated PRL deficiency is extremely rare, usually occurring as a component of MPHD.

Activating Mutations

No such mutations of genes encoding receptors for the hypothalamic factors or of *PRL* have been identified.

Pituitary Disease Associated with Other Disorders

Multiple Endocrine Neoplasia

This disorder is characterized by the presence of tumors involving two or more endocrine glands in a single patient. The two major forms, multiple endocrine neoplasia 1 (MEN1) and 2 (MEN2, which comprises 2A and 2B), are inherited as autosomal dominant conditions, with penetrance that increases with age.

MEN1 is characterized by tumor development in the parathyroid glands, pancreatic islet cells, and the anterior pituitary. Biochemically, approximately 60% of MEN1-associated pituitary tumors secrete prolactin, less than 25% secrete GH, and 5% secrete ACTH. The remainder appear to be nonfunctioning tumors.

There is variability in the phenotype, although some manifestations tend to be more common. This variability also occurs within family members of an affected kindred. Since penetrance is incomplete (especially early in life), MEN should always be considered in the diagnosis of “isolated” endocrine tumors, especially when familial.

MEN1 tumors are caused by inactivation of a tumor suppressor gene, *MEN1*. This gene is located on chromosome 11q13 and consists of 10 exons that encode a 610-amino acid protein, referred to as menin. Approximately 140 germ-line mutations of *MEN1* have been identified: approximately 25% are nonsense mutations, 45% deletions, 15% small insertions, 10% missense mutations, and less than 5% donor splice mutations.

Carney Complex

Carney complex is an autosomal dominant condition that may be considered a multiple endocrine neoplasia syndrome. Endocrine tumors in Carney complex may involve the adrenal gland, the thyroid, the gonads, and the anterior pituitary gland. The majority of the pituitary tumors secrete GH and prolactin. The disorder is caused by mutations in one of two genes—the tumor suppressor gene *PRKAR1* (the type 1 α regulatory subunit of cAMP-dependent protein kinase A), located on chromosome 17q, or an unknown gene on chromosome 2p16.

POSTERIOR PITUITARY

Arginine Vasopressin

Arginine vasopressin (AVP) is synthesized in the supraoptic nuclei of the hypothalamus and transported within axons to the posterior lobe of the

pituitary for storage. The gene encoding AVP is arginine vasopressin–neurophysin II (*AVP–NP2*), located on chromosome 20p13. It encodes the precursor protein of AVP, consisting of AVP (i.e., antidiuretic hormone) and neurophysin II, the carrier protein for AVP. Diabetes insipidus may result from a mutation of the AVP portion of the neurophysin portion of the gene. Deficiency of AVP results in central or neurogenic diabetes insipidus. There are a number of genetic forms, such as familial neurohypophysial diabetes insipidus (FNDI) and Wolfram’s syndrome.

FNDI is a rare autosomal dominant syndrome in which more than 35 different germ-line mutations of *AVP–NP2* have been reported. Wolfram’s syndrome, also known as DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness), is an autosomal disorder that is caused by inactivating mutations of the gene encoding wolframin (*WFS1*) on chromosome 4p16.1.

CELL SIGNALING DURING SPERMATOGENESIS

Differentiation of male germ cells within the seminiferous epithelium proceeds in a complex series of stages, including the multiplication of spermatogonia, the successive phases of meiosis, the extensive remodeling of the nucleus and cellular structures during the haploid phase, and the final release of sperm cells. The whole process depends on a coordinated network of endocrine, paracrine, and cell-to-cell communication involving a variety of somatic partners. The kinds of extracellular molecules that are involved in signaling to the diverse types of spermatogenic cells are thought to be numerous, and not all have been identified. The most common are the gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which have their target cells in the testicular somatic Leydig cells and Sertoli cells, respectively. Under hormonal signaling, Leydig cells secrete the male hormone testosterone, whereas Sertoli cells, under stimulation by FSH and testosterone, produce factors that induce germ cell proliferation, meiosis, and spermiogenesis.

Among the well-established Sertoli factors are inhibins, activins, and follistatin. In addition to the endocrine action of these peptides, which are generally considered endocrine regulators of FSH secretion, experimental evidence shows that activins, inhibins, and follistatin act locally within the testis as paracrine and autocrine factors involved in the regulation of spermatogenesis. Some studies suggest that inhibin can inhibit spermatogonial proliferation, whereas activin A seems to stimulate spermatogonial proliferation and follistatin may neutralize the action of activin. Other Sertoli factors reported to have a possible role in male germ cell differentiation are specific neurotrophins and cytokines and also putative “contacting” molecules—that is, the membrane components with selective expression and exposure on the Sertoli cell’s surface that exert a specific stage- or age-related action on spermatogenesis.

How is the message carried by so many different types of signaling molecules transduced in male germ cells? The answer is not known because of the inability to culture male germ cells for long periods of time. In fact, in contrast to cultured cells, no male germ cell lines are available for transfection experiments or to assay the signaling pathway evoked by a growth factor, an activator or inhibitor, a mutagen, and so on. Only recently have successful conditions for culturing primary spermatocytes and spermatogonia been reported; these may provide the groundwork

for future physiological or transfection studies. However, no cell lines are able to differentiate—that is, to undergo the spermiogenetic process to yield spermatozoa. Therefore, the only way to study spermatogenesis physiologically is to test *in vivo*-specific constructs by creating individual transgenic mice or mutant mice. The question is, what kind of mutant animal? To find an answer to this question, one has to ask the following: What are the major mechanisms regulating cell signaling?

PROTEIN PHOSPHORYLATION

Protein phosphorylation is generally accepted as the universal tool that cells have developed to switch on or off dynamic processes. Phosphorylation can regulate the activity of transcription factors at multiple levels, including nuclear transport, dimerization, DNA binding and transcriptional activation, as well as a series of enzyme-catalyzed reactions, including enzyme-linked membrane receptor signaling, G protein-linked receptor signaling, and nutritional functions such as glycogen breakdown. It can also regulate complex phenomena, such as learning and memory. Consequently, protein phosphorylation may play a key role in spermatogenesis; this has been recognized for at least 40 years. How can the hierarchy of phosphorylation events that constitute a signaling pathway be identified?

c-kit/SCF Signaling

Under cAMP and FSH stimulation, Sertoli cells express a growth factor that exists in both a soluble form and a transmembrane form and that is known as steel factor or stem cell factor (SCF). The SCF receptor is the c-kit transmembrane tyrosine kinase that is expressed by spermatogonia in the testis. In the whole organism, the c-kit/SCF system is required for normal hematopoiesis, melanogenesis, and gametogenesis; regarding spermatogenesis, c-kit/SCF signaling has been shown to be essential for proliferation and survival of the only proliferating germ cells, the spermatogonia. Which transduction pathway elicited by c-kit/SCF is able to support these effects? Among the c-kit/SCF-mediated pathways, there is direct activation of phosphatidylinositol (PI) 3'-kinase, which in turn leads to activation of Akt, a serine–treonin kinase with a key role in the growth factor-dependent proliferative and survival responses. Since PI 3'-kinase is active when it binds to a specific tyrosine phosphorylated residue of c-kit (Tyr⁷¹⁹ in the mouse),

Blume-Jensen and coworkers generated homozygous mutant mice carrying a Phe⁷¹⁹ instead of Tyr⁷¹⁹ in c-kit (Y719F/Y719F mutant mice) to search for c-kit/SCF signaling via PI 3'-kinase. No hematopoietic or pigmentation defects were found in homozygous mutant mice, but males were sterile due to a block in spermatogenesis, with a decrease in proliferation and then extensive apoptosis of spermatogonia. In contrast, female homozygotes were fully fertile. With such an approach, the researchers demonstrated the role of an individual signaling pathway downstream of c-kit/SCF in intact animals. Also, they demonstrated the cell line specificity of cell signaling because melanogenesis and hematopoiesis were not impaired by the inhibition of the transduction pathway acting through PI 3'-kinase.

UBIQUITIN SYSTEM

The importance of post-translational protein modification for cell signaling within the cell is well recognized. In addition to protein phosphorylation, post-translational glycosylation also plays an essential role in the control of biological activities as the ligand receptor recognizing crosstalk; however, its dynamism and reversibility of action are not comparable to those of protein phosphorylation/dephosphorylation. Less canonical in comparison to protein phosphorylation and glycosylation is another highly dynamic mechanism, protein ubiquitination, involved in regulation of cell signaling. The ubiquitin system determines the half-life, stabilization, refolding, and translocation of proteins crucial for cell physiology. Ubiquitination is crucial for the downregulation of plasma membrane receptors, steroid hormone receptors, plasma membrane transporters, and ion channels. The ubiquitin machinery is complex; in fact, although the signaling is in the ubiquitin moiety covalently ligated to a well specified protein, other indispensable components are the ubiquitin-activating enzymes, the ubiquitin-conjugating enzymes, and the ubiquitin protein ligases that, through the cooperation of members of molecular chaperones, deliver the ubiquitinated protein to the proteasome or endocytotic vacuolar compartment. In addition to the enzymes involved in linking ubiquitin to proteins, there are a large number of deubiquitinating enzymes, which remove ubiquitin from the ubiquitinated proteins, allowing the ubiquitin moiety to recycle. Therefore, as phosphatases switch out the signal elicited by protein kinases, deubiquitinases counterbalance the signaling by ubiquitin ligases. The ubiquitin pathway is undoubtedly important for spermatogenesis. Using mouse transgene and knockout

models, it has been shown that certain components of the ubiquitin system are required for successful spermatogenesis. Different phases of mammalian spermatogenesis require different specialized activities of the ubiquitin machinery.

HR23B Knockout

The *HR23B* gene encodes a mammalian homolog of *Saccharomyces cerevisiae* RAD23, an ubiquitin-like fusion protein involved in nucleotide excision repair (NER). To study its biological relevance, Ng and coworkers generated *HR23B*^{-/-} mice. Unexpectedly, *HR23B* deficiency does not result in a NER defect, but *HR23B*^{-/-} mice show impaired embryonic development and a high rate of intrauterine or neonatal death. When they survive, animals display abnormalities such as retarded growth and male sterility. Considering that *HR23B* is expressed in all mouse tissues and organs, why does male sterility occur? Because disruption of *HR23B* causes a failure of spermatogenesis, yielding a phenotype like that of the Sertoli cell-only syndrome. This finding indicates that *HR23B*, and consequently the protein stability via the ubiquitin/proteasome pathway, may be required for the postnatal initiation phase of spermatogenesis.

Siah1a Knockout

Experimental evidence indicates a strict link among DNA repair, the ubiquitin system, the heat shock proteins/chaperones machinery, and the control of the meiotic cycle in spermatocytes. Dickins and coworkers used gene targeting to analyze the function of *Siah1a*, a component of E3 ubiquitin ligase complexes, during mammalian development. Mutant mice have normal weights at term but are postnatally growth retarded, despite normal levels of pituitary growth hormone. Also, serum gonadotropin levels are normal in mutant animals; however, females are subfertile, whereas males are sterile. Male sterility is due to a block in spermatogenesis. Although spermatocytes display normal meiosis I spindle formation, they accumulate at metaphase and then undergo apoptosis. Consequently, *Siah1a*, as a component of a male germ cell-specific ubiquitin ligase complex, is necessary for normal progression of meiosis.

HR6B Knockout

It is during the postmeiotic phase, spermiogenesis, that ubiquitin signaling plays more roles. This cyto-differentiative process implies a massive remodeling

of cell structure and loss of most of the cytoplasm and a large fraction of cellular proteins. Some of this reorganization occurs due to condensation of cytoplasm into the residual body, phagocytosed by Sertoli cells while the residue is eliminated as cytoplasmic droplets by epididymal spermatozoa. However, this is not sufficient. In 1996, the first mammalian model of a defect in an enzyme involved in the ubiquitin pathway indicated the essential role of protein ubiquitination during spermatogenesis. To acquire its stream-like structure and simultaneously protect the genetic material during the long trip to the egg, the spermatozoon has evolved a very peculiar chromatin organization. Nucleosomes are disassembled, somatic and testis-specific histones are replaced by transition proteins, which in turn are replaced by protamines, and a highly condensed and inaccessible organization of chromatin is obtained. Roest and co-workers developed *HR6B*-deficient mice by gene targeting. The mouse *HR6B* gene is an autosomal homolog of the *S. cerevisiae Rad6* gene that codifies an ubiquitin-conjugating enzyme. This gene is highly conserved from yeast to mammals. The phenotype of *HR6B* knockout mice is remarkable and, at first glance, surprising: Although the *HR6B* gene is expressed throughout the body, the only pronounced defect of *HR6B*^{-/-} mice is male infertility. This defect is due to impairment of the process of postmeiotic chromatin remodeling, indicating the involvement of the ubiquitin pathway in chromatin dynamism. The mouse *HR6B* knockout does not cause a complete and uniform block of spermatogenesis at a given point, but spermatozoa of knockout mice are morphologically abnormal and not able to complete fertilization. This finding advanced the study of the ubiquitin system and spermatogenesis, and since 1996 numerous laboratories have been investigating the signaling supported by the ubiquitin system during male germ cell differentiation. Not surprisingly, it has been found that the ubiquitin machinery during spermiogenesis is involved not only in chromatin remodeling but also in the targeted destruction of certain proteins. It appears that whereas the removal of residual cytoplasm as residual body displays the features of a rough phenomenon, the signal-mediated degradation/elimination or rescue of specific proteins by the ubiquitin/proteasome system plays a key role in yielding a fully fertile spermatozoon.

CONCLUSION

Cell signaling is a complex network of various interacting objects. Paradoxically, in some cases, data

obtained in the past two decades have complicated our understanding because it has been found that most molecular signal transducers operate in the context of networks in which there is a considerable overlap of functions, some with a synergizing and some with an antagonizing effect. On the other hand, male germ cell signaling is the Cinderella of cell signaling. Historically, these cells have been the model for morphological, caryological, and comparative studies, but because of the lack of a cell culture technology they have attracted the interest of very few researchers engaged in signal transduction.

In this article, I have tried to provide a glimpse of the underexplored and fascinating isle of male germ cell signaling. Of course, due to space limitations and my intention to focus onto two fundamental mechanisms of control of cell signaling (i.e., the traditional protein phosphorylation and the emerging protein ubiquitination), I have not provided a comprehensive review of the topic. However, I hope to communicate to the scientific community that male germ cell signaling is a matter worthy of attention and study. A better understanding of the mechanisms governing spermatogenesis is highly desirable.

extent, thereby depriving it of its ability to bind and activate the ghrelin receptor, GHS-R1a. It is curious, however, that a peptide encoded obviously without a fatty acid side chain, in which form it also circulates in large quantities, would have no biological activity, and some findings suggest a possible biological role for unacylated ghrelin, i.e., in cell proliferation processes. Future research will shed light on this apparent paradox.

DETERMINANTS OF GHRELIN ACTION

Whereas an enormous amount of data on ghrelin biology and physiology is emerging, the possibility that additional ghrelin receptors (in addition to GHS-R1a/b), as well as other endogenous ligands, might exist and could play a relevant role should not be overlooked. The vast majority of data either focus on GHS-R1a or extrapolate from changes in the overall concentration of circulating (bioactive and biologically inactive) ghrelin peptide. Whereas the detection of relative differences in total circulating ghrelin levels (predominantly representing bio-inactive peptide) between disease states or in response to physiological challenges can be regarded as useful, it is important that these data not be overinterpreted. When more sophisticated methods become available for monitoring the plasma concentrations of active ghrelin and the expression and activation levels of specific ghrelin receptor subtypes, substantial parts of the view on ghrelin physiology might have to be readjusted. The extent and magnitude of ghrelin action most likely involve multiple regulatory levels that may sometimes be independent of one another. Relevant mechanisms include the following: the regulation of transcription and translation of the ghrelin gene, the level of enzymatic activity of the putative acyltransferase that is responsible for the posttranslational octanoylation of the ghrelin molecule, secretion rates of the bioactive ghrelin molecule, putative enzymatic processes that deactivate circulating ghrelin, the possible influence of ghrelin-binding proteins on the hormone's bioactivity (e.g., binding of HDL), the variable accessibility of target tissue (i.e., blood-brain barrier transport), the clearance or degradation of ghrelin by passage through the kidney or liver, the circulating concentration of additional endogenous ligands or other possibly cross-reacting hormones, the level of expression of the ghrelin receptor(s) in target tissues, and the sensitivity of the target tissues at the level of intracellular signaling mechanisms.

GASTRIC AND HYPOTHALAMIC GHRELIN

Ghrelin is primarily expressed in the stomach and upper intestinal tract. However, studies using polymerase chain reaction (PCR) amplification techniques have revealed the potential localization of ghrelin mRNA in several other tissues, such as the kidneys, immunocompetent blood cells, placenta, testes, ovaries, pancreas, pituitary, and hypothalamus. With respect to the putative role of ghrelin in the regulation of energy homeostasis, as well as other homeostatic mechanisms, localization in the hypothalamus seems to be particularly interesting (Fig. 1). In a study using antibodies as well as reverse transcription-PCR (RT-PCR), a uniquely distributed hypothalamic group of mostly bipolar neurons has been shown to produce small amounts of ghrelin. These neurons are not

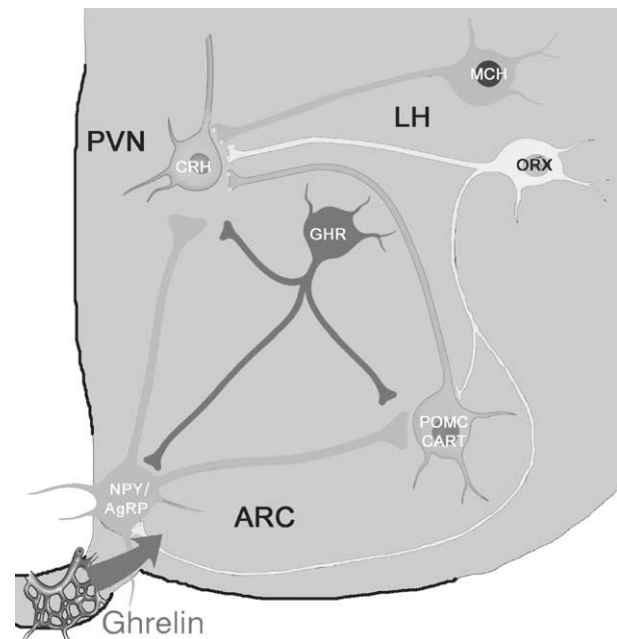

Figure 1 Schematic illustration of the relationship between ghrelin and hypothalamic peptidergic circuits. Ghrelin may reach the hypothalamus via the circulation and affect neuronal activity within the arcuate nucleus (ARC), where the NPY/AgRP- and POMC-producing neurons are located. Ghrelin is also produced in a subset of hypothalamic neurons located in the periventricular area. Ghrelin axon terminals innervate arcuate and paraventricular neurons (PVN), including those producing CRH. It is also likely that the central ghrelin system affects the lateral hypothalamic orexin (ORX) and MCH neuronal systems. Note that the hypothalamus operates with many more peptidergic and classical neuromodulators, such as γ -aminobutyric acid and glutamate, and this part of the brain is only one component in the central regulation of homeostasis. Therefore, it is reasonable to suggest that ghrelin's effect in the central nervous system will involve a variety of neurotransmitters and regions not depicted in this figure.

colocalized with any known centrally expressed hormone or neuropeptide, but, intriguingly, they do project directly to several previously identified hypothalamic appetite control centers. Ghrelin receptor expression and binding can furthermore be localized in multiple hypothalamic areas that directly neighbor cells containing neuropeptide Y (NPY), agouti-related protein (AgRP), proopiomelanocortin (POMC), orexin, and other neuropeptides and neurotransmitters that are substantially involved in appetite control. These neuroanatomical findings, complemented by electrophysiological studies, provide evidence for the existence of a central circuit that involves ghrelin as a key modulator. The full understanding of the role of hypothalamic ghrelin in endocrine and autonomic regulation remains elusive.

The main source of circulating endogenous ghrelin is the stomach. Circulating ghrelin derived from the gastrointestinal tract could be comodulating central networks regulating energy balance together with ghrelin derived from the hypothalamus after crossing the blood–brain barrier or by neural projection from areas that are not protected by the blood–brain barrier (circumventricular organs, e.g., the median eminence). Gastrointestinally derived circulating ghrelin could be responsible for the peripheral effects of ghrelin, including direct effects on the endocrine axes at the pituitary level and cardiovascular, anti-proliferative, or adipocyte-specific effects, whereas centrally derived ghrelin modulates mainly energy balance control circuits. Gastrointestinally derived ghrelin comodulates the central regulation of energy balance at the gastric level via the vagal nervous system and the brainstem. There is no reason that ghrelin could not act concurrently via paracrine mechanisms in the brain, via endocrine mechanisms by way of the circumventricular organs or after crossing the blood–brain barrier, and via the parasympathetic nervous system at the gastrointestinal level to regulate energy balance.

Ghrelin administration induces adiposity, raises the respiratory quotient (reflecting reduced fat utilization), and suppresses spontaneous locomotor activity in rodents. Neutralization studies with polyclonal ghrelin antibodies yielded encouraging results, showing decreased food intake in rodents after intracerebroventricular injection. These data were confirmed by a transgenic rat model that overexpresses antisense oligonucleotides against the ghrelin receptor, GHS-R1a, and decreased food intake and lower body fat were observed as a consequence. There is clear evidence that, despite its relatively short half-life, administration of ghrelin in physiologically relevant doses

induces a positive energy balance. Ghrelin affects body weight and food intake more than 1000-fold more potently following central administration, strongly supporting the hypothesis that ghrelin influences energy homeostasis predominantly by the modulation of central mechanisms. Therefore, whatever the derivation of the decisive endogenous amount of ghrelin that regulates energy balance, neutralizing or blocking its endogenous actions acutely as well as chronically will, at the very least, provide a valuable physiology lesson, yet has the potential to pave the way for the development of a new drug.

REGULATION OF GASTRIC GHRELIN EXPRESSION AND SECRETION

Ghrelin is secreted mainly by gastric A/X-like cells within the oxyntic glands; the half life of ghrelin is relatively short (5–15 min) and less than 20% of the circulating immunoreactive ghrelin appears to be octanoylated and therefore bioactive. Gastrointestinal X/A-like cells represent approximately one-quarter of all endocrine cells in the oxyntic mucosa, and other cells within these glands, such as histamine-rich enterochromaffin-like cells (ca. 70%) and D-(somatostatin) cells (10%), are ghrelin-negative. From the stomach to the colon, ghrelin is found with caudally decreasing expression. Most ghrelin-containing enteroendocrine cells have no continuity with the lumen, probably respond to physical and/or chemical stimuli from the basolateral side, and are closely associated with the capillary network running through the lamina propria. Ghrelin-secreting cells occur as open- and closed-type cells (open or closed toward the stomach lumen), with the number of open-type cells gradually increasing in the direction from the stomach to the lower gastrointestinal tract. A closer look at the structural and functional relationship between ghrelin and its receptor, as well as the structure of motilin and its receptor, suggests that a larger family of peptide hormones is comodulating gastrointestinal motility, appetite, secretion of pituitary hormones, and other physiological processes. This peripheral endocrine network most likely also includes gastrointestinal hormones such as cholecystikinin, peptide YY (PYY1-36, PYY3-36), glucagon-like peptide 1, and gastric inhibitory peptide. Both ghrelin peptide secretion and ghrelin mRNA expression are regulated according to metabolic challenges. Acute and chronic periods of food deprivation increasing from mild to severe (e.g., fasting) raise ghrelin peptide levels and ghrelin mRNA concentrations, whereas refeeding reduces both.

OTHER SOURCES OF GHRELIN

It is evident that ghrelin plays a classical endocrine role as a peptide hormone that is secreted into a capillary network, but local, paracrine activities of ghrelin might play an additional role. Removal of the stomach or of the acid-producing part of the stomach in rodents reduces serum ghrelin concentration by approximately 80%, further supporting the notion that the stomach is the main source of this endogenous GHS receptor ligand. However, in another study, plasma levels of ghrelin after total gastrectomy gradually increased again, suggesting that other tissues can compensate for the loss of ghrelin production after gastrectomy. The fact that total plasma ghrelin is barely detectable following gastric bypass surgery was interpreted by Cummings and co-workers as a “shutdown” of gastric ghrelin secretion due to a complete lack of contact with ingested nutrients.

Ghrelin mRNA and ghrelin peptide have also been detected in rat and human placenta. Here, ghrelin is expressed predominantly in cytotrophoblast cells and very sporadically in syncytiotrophoblast cells. A pregnancy related time-course, represented by an early increase in ghrelin expression in the third week, decreasing levels in the latest stages of gestation, and still detectable amounts of ghrelin at term, was found in rats. In human placenta, ghrelin is expressed mainly in the first half of pregnancy and is not detectable at term, whereas a putative involvement of ghrelin in fetal-maternal interactions via autocrine, paracrine, or endocrine mechanisms still remains to be shown.

Small concentrations of ghrelin are found in the pancreas, where ghrelin immunoreactivity has been localized in a subgroup of endocrine cells that are also immunopositive for pancreostatin. Ongoing, partially contradictory studies suggest that ghrelin-positive cells must be either the pancreatic alpha or beta cells.

In normal pituitary cells as well as in pituitary tumors, ghrelin mRNA expression and ghrelin-immunopositive cells were detected. This is in addition to the known presence of GHS receptors in pituitary cells. This suggests a possible autocrine or paracrine role for hypophyseal ghrelin, although only approximately 5% of the detected ghrelin peptide derived from the pituitary has been found to be octanoylated.

Using real-time PCR methodology, small amounts of ghrelin were detected in the adrenal glands, esophagus, adipocytes, gallbladder, muscle, myocardium, ovary, prostate, skin, spleen, thyroid, blood vessels, and liver. Preproghrelin production was shown in rat mesangial cells and mouse podocytes,

indicating the production of ghrelin in kidney, glomerulus, and renal cells and suggesting possible paracrine roles for ghrelin in the kidney. Human ghrelin expression and GHS receptor mRNA expression were shown by real-time PCR and confirmed by DNA sequencing in human T lymphocytes, B lymphocytes, and neutrophils from venous blood of healthy volunteers. Cell type and the maturity of the cells did not seem to have an influence on ghrelin production in immune cells. Interestingly, it has been shown that the small molecule GHS has a considerable immune-enhancing effect. In summary, ghrelin is predominantly expressed by the stomach and is expressed at decreasing levels as one moves caudally through the gastrointestinal tract. Although its physiological significance as a paracrine factor in extra-gastrointestinal tissue is the subject of ongoing studies, a classical endocrine role for extra-gastrointestinal ghrelin appears to be unlikely since ghrelin expression levels in other organs are relatively low in comparison. Thus, published studies on the regulation of ghrelin expression primarily focused on gastric ghrelin. However, studies on ghrelin expression or secretion in rodents are not necessarily relevant to the physiological regulation of ghrelin in humans.

REGULATION OF CIRCULATING GHRELIN LEVELS

A very intriguing series of clinical studies by Cummings *et al.* indicates that each daily meal is followed by decreases in circulating ghrelin levels, most likely reflecting acutely reduced ghrelin secretion from the gastrointestinal tract. The authors speculate further that an observed premeal rise in circulating human ghrelin levels might reveal a role for ghrelin in meal initiation, which fits well with the observation that ghrelin administration in healthy volunteers causes hunger sensations. Ghrelin levels might also reflect the acute state of energy balance, signaling to the central nervous system in times of food deprivation that increased energy intake and an energy-preserving metabolic state are desirable.

Only a few determinants of circulating ghrelin concentration have been identified; these include insulin, glucose, somatostatin, and possibly growth hormone, leptin, melatonin, and the parasympathetic nervous system tone. In several species (e.g., mice, rats, cows, and humans), ghrelin mRNA expression levels or circulating ghrelin levels have been shown to be increased by food deprivation and to be decreased postprandially. This phenomenon further supports

the concept of ghrelin as an endogenous regulator of energy homeostasis that has apparently been preserved throughout evolution in all species. Rat ghrelin expression can also be stimulated by insulin-induced hypoglycemia, leptin administration, and central leptin gene therapy. Ingestion of sugar suppresses ghrelin secretion in rats *in vivo*, indicating a direct inhibitory effect of glucose/caloric intake on ghrelin-containing X/A-like cells in the oxyntic mucosa of the rat stomach rather than an exclusively insulin-mediated effect. The fact that insulin is an independent determinant of the circulating ghrelin concentration has been shown by several research groups using hyperinsulinemic–euglycemic clamp studies in humans. These findings add further evidence that ghrelin provides the link between mechanisms governing energy balance and the regulation of glucose homeostasis. However, it remains to be shown whether postprandially occurring insulin peaks are sufficient to decrease circulating ghrelin levels, since hyperinsulinemic–euglycemic clamp studies causing decreased ghrelin secretion involve either supraphysiological or markedly prolonged (e.g., > 120 min) periods of hyperinsulinemia. Further insight into the complex mechanisms regulating ghrelin secretion is based on studies showing an increase in circulating ghrelin levels in rats following surgical interventions such as vagotomy and hypophysectomy. Human growth hormone (GH) deficiency, however, does not seem to lead to increased plasma ghrelin levels. On the other hand, administration of synthetic GH in rats decreases circulating ghrelin levels and therapeutic intervention causing normalization of GH levels in patients with acromegaly increases endogenous ghrelin levels. Somewhat contradictory observations could be caused by species-specific differences between rodents and humans or could indicate that an acute, but not a chronic, change in GH levels modulates ghrelin concentrations. A previously neglected pathophysiological factor that might increase circulating ghrelin levels is the production of ghrelin by tumors of the stomach and the intestine, such as carcinoids.

In summary, ghrelin expression and ghrelin secretion are predominantly influenced by changes in energy balance and glucose homeostasis and influenced to a somewhat lesser degree by alterations in the endocrine axes (e.g., increasing GH concentrations). Based on the available data, ghrelin seems to represent a molecular regulatory interface between energy homeostasis, glucose metabolism, and physiological processes regulated by the classical endocrine axes, such as growth and reproduction. One particular biological purpose of these multiple roles of ghrelin

might be to ensure the provision of calories that GH requires for growth and repair.

GHRELIN AND OBESITY

In contrast to earlier models that expected the endogenous ligand of the growth hormone secretagogue receptor to exclusively govern growth hormone secretion, ghrelin is believed to play its main physiological role in the regulation of energy balance. As the only peripherally circulating orexigenic agent known, ghrelin triggers appetite and nutrient intake. Ghrelin might even represent the first known “meal initiation factor.” However, conclusive evidence that meal-related circadian changes in plasma ghrelin concentrations are responsible for the initiation of nutrient intake rather than representing an epiphenomenon of trained meal patterns is still missing. Based on clinical investigations of meal-related changes in plasma ghrelin levels and data generated by insulin- and glucose-clamp studies, plasma insulin and blood glucose levels are very likely to be involved in the general regulation of ghrelin secretion. Although hyperinsulinemic–euglycemic clamps have been repeatedly shown to decrease circulating ghrelin levels, it remains unclear whether experimental conditions during clamp studies are comparable with the lower maximum peaks and the shorter duration of postprandial insulin levels. The possibility cannot be excluded that additional blood-derived factors may be responsible for meal-related changes in ghrelin concentrations or that gastrointestinal nutrient sensors may modulate ghrelin expression and secretion rates.

Although counterintuitive, the finding that circulating ghrelin concentrations are low in obesity not only mirrors earlier observations of hyperleptinemia in obesity, but may be explained by compensatory mechanisms aiming to communicate to the central regulatory centers that energy stores are full. Though it is unclear which signal communicates increased adipocyte size to ghrelin-secreting cells (leptin, interleukin-6, and adiponectin would be candidates), other phenomena and symptoms that commonly occur during obesity (such as a frequently filled stomach or insulin resistance) should be carefully investigated to determine their contribution to hypoghrelinemia. Ghrelin gene polymorphisms have been described by several groups; linkage analysis studies, however, failed to prove a solid association between ghrelin and obesity. Although diet-induced human obesity and polygenic (e.g., Pima Indians) or monogenic (e.g., MC4-R defect) causes of human obesity all present with low plasma ghrelin levels, there is one group

of severely obese patients in whom markedly increased plasma ghrelin concentrations have been observed. Prader-Willi syndrome, an impressive hunger syndrome in which patients exhibit morbid obesity and numerous other symptoms, is caused by a defect in the short arm of chromosome 15 and is accompanied by circulating ghrelin levels that are three- to fivefold higher than in healthy controls. Although the overlap between symptoms of Prader-Willi syndrome and the effects of ghrelin administration is impressive, only treatment with a potent, but safe ghrelin antagonist compound will reveal whether ghrelin is part of the pathogenesis in Prader-Willi syndrome. Discussion is ongoing as to whether increased plasma ghrelin is only a consequence of the severe caloric restrictions that are a central part of the treatment strategies for patients with Prader-Willi syndrome in an attempt to control their energy balance. The only other population in which comparably high ghrelin levels have been reported are patients with cachexia or anorexia nervosa, in whom high ghrelin levels are believed to reflect a physiological compensation effort in response to either a chronically empty stomach or a markedly decreased fat mass. Though circulating ghrelin levels are significantly lower in obese individuals, these levels are still very substantial when compared to nearly undetectable ghrelin concentrations in patients after gastric bypass surgery. The superior effectiveness of this bariatric procedure is considered to be partially due to a “knock-down” of endogenous ghrelin secretion caused by the lack of stimulation of gastric cells by incoming nutrients. On the other hand, an increase in endogenous ghrelin in response to diet-induced weight loss could contribute to the very high likelihood of recurrence of obesity. Carefully conducted clinical studies are imperative to discover the answer to this important question.

SUMMARY

In summary, ghrelin represents a gastric hormone that induces hunger and increases fat deposition via central and possibly peripheral mechanisms in response to a negative energy balance. Ghrelin is one of the most potent orexigenic agents and the only known peripherally circulating orexigenic agent; it may also represent the first meal initiation factor. Although, normally, plasma ghrelin concentrations are negatively correlated with fat mass, substantial levels are still secreted in the vast majority of obese individuals, whereas weight loss occurs along with the loss of circulating ghrelin in patients with a gastric bypass.

Apart from the possible effectiveness of a ghrelin antagonist for the general prophylaxis and treatment of adiposity, the blockade of ghrelin could be the first specific pharmacotherapeutic approach to successfully treat patients with Prader-Willi syndrome. However, although the various additional effects of ghrelin on physiological processes and organ systems suggest other possible therapeutic uses, they also make unwanted cardiovascular, gastrointestinal, or proliferative effects caused by the blockade of ghrelin action a likely occurrence.

Figure 1 Evolutionary relationship of the chordate classes. Apart from the tunicates (or urochordates), the remaining classes are vertebrate animals. The lengths of the horizontal lines indicate the period when the respective classes are assumed to have segregated.

Thus, observations in one species based on antibodies raised against peptides from another species must be evaluated with caution, since both false-positive and false-negative results can occur.

During evolution, duplication of genes and exons followed by substitutions, insertions, and deletions has been an important mechanism for the creation of new peptides with new functions. Two major rounds of duplications occurred during the evolution of vertebrates, one at the beginning of the “Cambrian explosion” (approximately 500 million years ago) and one in the early Devonian (approximately 400 million years ago), to produce up to four copies of the original genome. In fish, a third duplication appears to have occurred in the late Devonian. Many of the duplicated gene products developed into new proteins with new functions, thus giving rise to distinct families of proteins (e.g., regulatory peptides), with family members having related or even very distant functions.

Many of the gastrointestinal hormones can clearly be classified as belonging to families originating from a common ancestor. Others appear as singular peptides although they can be traced to most vertebrate classes. The following discussion of the relationships between specific peptides and peptide families considers mainly solid structural information and to some extent function and anatomical origin. Also, only hormones from the Chordata (including tunicates) are considered.

HORMONE FAMILIES

The PACAP/Glucagon Superfamily

The PACAP/glucagon superfamily includes nine structurally related hormones in human, namely, PACAP, GHRH (also known as growth hormone-releasing factor), glucose-dependent insulinotropic polypeptide (GIP), peptide histidine–methionine (PHM) or peptide histidine–isoleucine (PHI), secretin, vasoactive intestinal peptide (VIP), glucagon, and glucagon-like peptide-1 and-2 (GLP-1 and-2). In mammals, these peptides are encoded by six genes: VIP and PHM are encoded by the same gene, glucagon, GLP-1, and GLP-2 are encoded by a single gene, and the remaining peptides come from separate genes.

PACAP/GHRH

The PACAP/GHRH superfamily can be traced back to tunicates, in which PACAP and GHRH have been identified; actually, there are two different precursors in tunicates, each coding for both peptides. Throughout evolution, PACAP and GHRH have remained together on the same precursor until the emergence of mammals, in which they appear on separate genes. This could be due to a late gene duplication in a common ancestor of mammals. Alternatively, it has been suggested that a second

gene remains undetected in nonmammalian vertebrates and that one has evolved into the mammalian PACAP preceded by a related flanking peptide and the other has evolved into the mammalian GHRH followed by another related flanking peptide. Interestingly, PACAP has been extremely well conserved from tunicate to human, whereas the structure of GHRH is highly variable and even between different mammals there is a low degree of similarity.

The Glucagon Family

Glucagon, GLP-1, and GLP-2 have been detected in all vertebrate classes, but not (yet) in tunicates. The three peptides are derived from a common precursor and this organization has been conserved from jawless fish to mammals. Glucagon is highly conserved in all vertebrates but both GLP-1 and GLP-2 appear to be considerably more variable.

GIP, PHM/PHI, Secretin, and VIP

GIP has been identified only in mammals and secretin and PHM/PHI have been identified only in mammals and birds. Whether they are represented in the other vertebrate classes remains an open question. In contrast, VIP has been detected in all vertebrates except jawless fish. Furthermore, the structure of VIP is highly conserved with only minor variations allowed at nine positions of the 28-residue peptide.

The PP-fold Family

The PP-fold family of peptides derives its name from a structural characteristic of all the members: a hairpin-like fold with an extended proline helix containing three proline residues, a turn, and an α -helix with two tyrosine residues that fit in between the three proline residues. The family consists of neuropeptide Y (NPY) and peptide YY (PYY), present in all vertebrate classes, pancreatic polypeptide (PP), found only in tetrapods, and a pancreatic peptide Y (PY), found in some fish. NPY and PYY most likely originate from duplication of a common ancestor before the development of the jawless fish. NPY displays a high degree of sequence conservation, whereas PYY is more varied. The occurrence of PP only in tetrapods suggests that it is the result of yet another gene duplication that occurred before the emergence of the amphibians. The sequence variability of PP is quite high, with only 50% identity between mammals, birds, and amphibians. PY constitutes a special case and probably arose from a duplication of the PYY gene unrelated to the duplication event that generated PP.

The Cholecystokinin/Gastrin Family

Cholecystokinin (CCK) and gastrin constitute a small family comprising only these two members. They are characterized by a common amidated C-terminal tetrapeptide sequence, which also constitutes the minimal structure necessary for biological activity of both peptides. Hence, it appears most likely that CCK and gastrin have evolved from a common ancestor. Cionin, isolated from *Ciona intestinalis*, a representative of the tunicates, which occupy a key position at the transition to vertebrates, also contains the characteristic tetrapeptide sequence and thus represents the oldest genuine member of the CCK/gastrin family thus far known, dating the emergence of these peptides back to at least 500 million years ago. The CCK/gastrin family is represented throughout the entire chordate phylum, including cartilaginous and bony fish, amphibians, reptiles, birds, and mammals. A duplication of the ancestral gene appears to have occurred at the level of cartilaginous fish, giving rise to two peptides most likely homologous to CCK and gastrin. At the amphibian level, the two separate peptide systems have been shown to exert distinct physiological gastrin and CCK actions. Interestingly, though CCK is well conserved in all vertebrate species, the gastrins vary more and the mammalian gastrins at first sight appear as a distinct group with little similarity to the nonmammalian gastrins outside the invariant C-terminal tetrapeptide. However, closer examination reveals that even if a major structural change was introduced at the transition to mammals, there exists a clear evolutionary relationship between mammalian and nonmammalian gastrins.

The Tachykinin Family

The tachykinins share a C-terminally amidated pentapeptide, -Phe-Xaa-Gly-Leu-Met-amide, where Xaa can vary among a few possible amino acids. In mammals, the family comprises four peptides encoded by two genes: preprotachykinin A, encoding substance P (SP), neurokinin A (NKA), and neuropeptide γ (NP γ , which is an N-terminally extended form of neurokinin A); and preprotachykinin B, encoding neurokinin B. SP, NKA, and NP γ have been identified in most vertebrate classes, whereas NKB has been identified only in mammals and a frog (Amphibia). NKA (a decapeptide) has been highly conserved and SP (an undecapeptide) somewhat less so. Interestingly, SP from amphibians shows less identity to the mammalian form than SP from the phylogenetically more distant fish. However, the peptides are rather short

and even if many tachykinins from nonmammalian vertebrates have been identified, almost no genes for these tachykinins have been discovered. Thus, solid conclusions regarding the evolution of the tachykinins are difficult to make, but there is no doubt that the tachykinins constitute a family, that they must have arisen from a common ancestor, and that their diversity must have been brought about by exon duplication, gene duplication, and point mutations.

The Somatostatin Family

In mammals, the somatostatin family contains two members, somatostatin (known since 1973) and cortistatin, which shows a high degree of similarity to somatostatin. The bioactive forms of somatostatin are somatostatin-14 and the N-terminally extended somatostatin-28. Somatostatin-14 is highly conserved, being identical in all vertebrates from jawless fish to mammals. In addition to genuine somatostatin, many fish and amphibian species express a second gene very similar to preprosomatostatin-I. It has been suggested that the duplication of the original somatostatin gene occurred early in evolution, predating or concomitant with the development of the chordates. Then, a second duplication may have occurred in the bony fish after divergence from the line leading to tetrapods.

The Gastrin-Releasing-Peptide/Bombesin/Neuromedin B Family

Gastrin-releasing peptide (GRP) has been identified in all major vertebrate classes except jawless fish. It consists of 22 (goldfish) to 29 (rat) amino acid residues and has an invariant C-terminal octapeptide sequence in all species. Neuromedin B, which shows similarity to GRP, has been identified only in mammals and a toad (Amphibia) and is encoded by a separate gene. The bombesins constitute an interesting subgroup, all being isolated from the skin of amphibians, where they may serve protective purposes, and also arising from independent genes. Since only GRP is known to exist in many vertebrate classes, it is not possible to further elaborate on the phylogeny of these peptides.

HORMONES WITH NO OBVIOUS FAMILY RELATIONSHIPS

Galanin

Galanin is a widespread neuropeptide and is also common in the gut. Since its discovery in 1983,

galanin has been identified in a number of species representing all major vertebrate classes. It comprises 29 (or 30, in human) amino acid residues, of which the 14 N-terminal residues are identical in all species investigated. Despite repeated efforts to discover related peptides, none were found until 1999, when a new peptide, galanin-like peptide (GALP), was isolated from hypothalamus based on its stimulation of galanin type 2 receptors. Thirteen residues (positions 9–21) of GALP are identical to the N terminus of galanin. GALP has been identified only in mammals (human, pig, and rat). Thus, it still remains to be seen whether a galanin family can be identified.

Motilin and Ghrelin

Motilin is produced in endocrine cells of the upper intestine. Since the identification of porcine motilin in 1972, motilin has been identified in a number of mammals but in only one nonmammalian species, the chicken. The mature form of motilin consists of 22 amino acid residues and between human and chicken there are seven substitutions, although most are conservative. Thus, little can be said about the evolution of motilin. In 1999–2000, a new GHRH was identified independently by two groups and was designated ghrelin and prepromotilin-related peptide, respectively. The latter name refers to a limited structural similarity with motilin. Identification of the two hormones from more vertebrate classes will be needed before possible relationships can be evaluated.

GI hormone cholecystokinin (CCK) is expressed in the postnatal rat pancreas. Transgenic overexpression of gastrin and transforming growth factor- α has been found to result in islet hyperplasia, perhaps reflecting a trophic role of gastrin during early islet development.

Secretin

Secretin is the main product of endocrine S cells of the duodenum and jejunum. S cells occur on villi, but never in crypts, documenting their identity with postmitotic cells. Secretin is transiently expressed in insulin cells of the developing pancreatic islets.

Preprotachykinin A

Expression of substance P was first noted in endocrine, enterochromaffin (EC) cells of the intestinal mucosa. Subsequently, preprotachykinin A (PPTA) was found to be transiently expressed in both insulin- and non-insulin-producing endocrine cells of the fetal and neonatal pancreas. Postnatally, the number of PPTA-positive cells declines and no such cells can be detected in adults. It has been suggested that substance P and neurokinin A, which both are encoded by the PPTA gene, could serve as growth factors during islet development.

Vasoactive Intestinal Polypeptide

VIP is normally expressed by nerve cells of the GI tract and pancreas but is also expressed by pancreatic tumors causing the WDHA (watery diarrhea, hypokalemia, achlorhydria) syndrome, showing that neoplastic pancreatic endocrine cells have the capacity for VIP production.

Serotonin

Serotonin (5-hydroxytryptamine) is produced by endocrine EC cells of the GI tract and pancreas and is also detected in pancreatic insulin cells of certain species, such as the guinea pig. Early maturing GI endocrine cells coexpress serotonin with other hormones.

Insulin

Transient insulin expression occurs in a few neuron-like cells present at the juxtaduodenal myenteric plexus at embryonic days 18–19 in the rat.

Glucagon

The glucagon gene is expressed by both pancreatic A cells and intestinal L cells. Differences in proteolytic processing account for the production of classical glucagon in A cells and of glucagon-like peptide-1 and -2 and other fragments in L cells.

Somatostatin

Somatostatin is produced by D cells present in the GI tract and pancreas and is expressed by both the adult and the developing gut and pancreas. It is believed to act primarily as a local paracrine regulator of hormone release. In some species, both pancreatic and GI somatostatin cells emit long neuron-like processes with which they contact their target cells.

PP Family

The PP family includes three structurally related peptides: pancreatic polypeptide (PP), neuropeptide Y (NPY), and peptide tyrosine tyrosine (PYY). PP was originally localized to the fourth (PP) cell type of the pancreas. Cat and dog PP (F) cells are characterized by large granules. In other species, such as human and rat, PP cells are small granulated cells, distinct from the fifth (D_1) islet cell type, believed to produce an as yet unidentified hormone. Reverse transcription-polymerase chain reaction data show that pancreatic PP expression occurs before PP cells can be immunocytochemically identified and transgenic data indicate that insulin cell progenitors express PP. Only limited GI expression of PP occurs. PYY is expressed by both gut and pancreatic endocrine cells (including antropyloric gastrin cells) and may be a marker for the earliest appearing endocrine pancreatic cells. NPY is expressed in a subpopulation of insulin cells in rat pancreas and by nerves in the GI tract.

Islet Amyloid Polypeptide (Amylin)

Amylin was originally discovered as the chief constituent of amyloid present in insulinoma tissue and in islets of patients with non-insulin-dependent diabetes. Amylin occurs in islet insulin and somatostatin cells as well as in a majority population of somatostatin cells and a minority population of gastrin cells of the antropyloric mucosa of the stomach.

HORMONE COEXPRESSION IN THE GASTRODUODENOPANCREATIC REGION

Many studies have shown that mature endocrine cell types frequently coexpress multiple hormones. Although these observations challenged well-guarded concepts, such as “the one cell–one hormone principle,” they have stood the test of time better than the original concepts. It is widely accepted that many endocrine cells secrete a host of molecules that act in concert to elicit coordinated biological responses.

Also, developing or maturing endocrine cells frequently express multiple hormones. Observations of such coexpression led to the finding that the three main antropyloric endocrine cell types (gastrin, serotonin, and somatostatin cells) develop from common multihormone-expressing precursors in the isthmus of gastric glands. In addition, duodenal endocrine cells develop from multihormonal precursors present in the crypts of Lieberkühns. Cells coexpressing insulin and glucagon have been detected in the developing pancreas and it has been suggested that they represent islet cell precursors. However, transgenic studies have documented that insulin and glucagon cells are derived from cell lineages that do not coexpress these two hormones. Instead, mature insulin cells may develop from cells transiently expressing PP. Moreover, the large increases in insulin cell numbers that occur during rat pancreatic development suggest that most of these cells are derived from insulin-negative precursors.

TRANSCRIPTION FACTORS AND ENDOCRINE DIFFERENTIATION

Gene knockout studies have demonstrated that a number of transactivating factors are important for the differentiation of both pancreatic and gastroduodenal endocrine cells. This is not surprising since the distal stomach, duodenum, and pancreas develop from closely adjacent parts of the primitive foregut. Furthermore, overlaps in the distribution of these factors may explain the transient and permanent overlaps in the expression of gut hormones in the pancreas and of pancreatic hormones in the gut.

Such factors include pancreatic(-antropyloric)-duodenal homeobox-1 (Pdx-1), β 2/NeuroD, Pax4, and Pax6. Additionally, indirect data suggest that factors such as islet-1 (Isl-1) and Nkx6.1 may share this dual importance.

Table I Effects of Gene Knockouts of Pdx-1, Pax4, Pax6, and β 2/NeuroD on Hormone Expression in the Gastroduodenopancreatic Region

| Deficiency | Pancreas | Duodenum | Stomach |
|-----------------------------------|---|--|-------------------------------|
| Pdx-1 | No pancreas | Neurotensin ↓ GIP ↓ Secretin ↓ | Gastrin ↓ Serotonin ↑ |
| Pax4 | Insulin ↓ Somatostatin ↓ Glucagon ↑ | Serotonin ↓ CCK ↓ GIP ↓ PYY ↓ Secretin ↓ | Serotonin ↓ Somatostatin ↓ |
| Pax6 | Glucagon ↓ | GIP ↓ | Gastrin ↓ Somatostatin ↓ |
| β2/NeuroD | Insulin ↓ Glucagon ↓ Somatostatin ↓ | CCK ↓ Secretin ↓ | |

Pdx-1 was identified as a factor that interacts with the insulin and somatostatin promoters. In Pdx-1-deficient mice, the pancreas fails to develop, the rostral duodenum shows anomalies, and in the antropyloric mucosa, gastrin cells fail to develop, whereas somatostatin cells occur in normal numbers and serotonin cells occur in increased numbers (Table I). These data show that Pdx-1 is not required for gastric somatostatin expression, but is needed for the differentiation of gastrin cells, probably from a common gastrin–somatostatin precursor cell. Additionally, Pdx-1^{−/−} mice show normal gastric expression of amylin, probably reflecting normal expression in somatostatin cells and reduced expression of PYY, reflecting the decrease in gastrin cells. The pancreas of Pax4^{−/−} mice is deficient in insulin and somatostatin cells, but contains increased numbers of glucagon cells. In the antropyloric mucosa, Pax4 deficiency eliminates somatostatin cells and severely reduces the number of serotonin cells, while leaving gastrin cells unaffected (Table I). The duodenum of Pax4^{−/−} mice shows near total elimination of serotonin, secretin, CCK, GIP (gastric inhibitory polypeptide), and PYY cells. Mice deficient in Pax6 show abnormal pancreatic development with no glucagon cells. In the antropyloric mucosa, Pax6^{−/−} mice are deficient in gastrin and somatostatin cells, but show normal numbers of serotonin cells, whereas in the duodenum severe reductions in CCK and GIP, but not in serotonin, secretin, or PYY cells, are observed. These data show that the two Pax genes are needed for the differentiation of virtually all endocrine cells of the gastroduodenopancreatic region. Pax4 is transiently

expressed during pancreatic development and may constitute a transcriptional repressor. A fourth factor of proven importance is $\beta 2$ /NeuroD. Mice deficient in this factor show reductions in the number of secretin and CCK cells, while expressing apparently normal numbers of PYY, GIP, and somatostatin cells. In the pancreas, $\beta 2$ /NeuroD $^{-/-}$ mice show a 75% reduction in insulin cells, a 40% reduction in glucagon cells, and a 20% reduction in somatostatin cells. A number of additional signaling or transactivating factors have been shown to be important for cell-specific hormone expression in the pancreas but have not yet been tested for their effects on gut endocrine development. Primary candidates include transforming growth factor- β family cytokines, sonic hedgehog, neurogenin-3, Nkx6.1, and Isl-1.

CONCLUSIONS

The distal stomach, duodenum, and pancreas develop from closely adjoining areas of the primitive foregut that show very similar hormone and transcription factor expression profiles. Targeted deletion of genes shows that several factors, such as Pdx-1, Pax4, Pax6, and $\beta 2$ /NeuroD, are important in the development of both pancreatic and gastroduodenal endocrine cell types. As documented by gene knockout experiments, these factors are required for the expression of multiple hormones (Table I). Thus, they probably act together in different combinations to direct the cell-specific expression of different hormones. This helps to explain why certain gut hormones are transiently expressed in the pancreas and vice versa. Moreover, these observations may help to explain why certain hormones, such as gastrin, are expressed in pancreatic endocrine tumors. Interestingly, many of the factors identified are also important in the development of specific subsets of neurons. This adds to the long list of factors that are shared by endocrine cells and neurons, but does not indicate a common embryological origin. Thus, many observations solidly

document that GI and pancreatic endocrine cells are of endodermal origin. It appears that different combinations of factors, acting in a strict spatial and temporal hierarchy as permanent or transient transcriptional activators and repressors, drive cell-specific hormone gene expression in the gastroduodenopancreatic region. The quest for new factors and/or combinations that may be important for directing insulin expression and tumor-specific hormone expression is ongoing.

demonstrated the expression of heparin-binding epidermal growth factor-like growth factor (HB-EGF) during pancreas development. This factor, expressed abundantly in ductal cells and immature endocrine cells, can be potentially regulated by PDX-1 as both molecules colocalize during development. It is tempting to suggest that HB-EGF could mediate the effects of PDX-1 along with betacellulin and TGF- β 2 via the EGF receptor expressed in the endocrine and exocrine cells of the fetal pancreas. It would seem that EGF itself is not involved since it is not expressed in these cells during development. Furthermore, Sarvetnick clearly demonstrated significant immunoreactivity of heregulin isoforms in fetal pancreatic ducts; these factors bind to the Erb β receptors, of which Erb β 1 is the EGF receptor. It is strongly suggested that this receptor family operates through receptor heterodimerization between family members, with Erb β 2 being the preferred partner. The association of these receptor-ligands with endocrine cells and islet formation strongly supports their involvement in mediating islet growth during pancreatic development.

Hayek's group established that hepatocyte growth factor (HGF), an expressed fetal mesenchyme-derived factor, can regulate beta cell growth and differentiation as the HGF receptor is preferentially expressed in developing beta cells. When used alone in monolayer culture, this factor was associated with a tremendous increase in the number of fetal pancreatic epithelial cells and marked down-regulation of insulin and glucagon gene expression. However, when cells were combined into three-dimensional aggregates, hormone gene expression increased, suggesting the importance of cell-cell contact for the complete biological effect of HGF. The implication of vascular endothelial growth factor (VEGF) in endocrine pancreas development was suggested when coculture of isolated endoderm with tissue fragments containing vascular endothelium induced the expression of both PDX-1 and insulin in the endodermal cells; however, tissues without vascular endothelium did not support pancreatic differentiation. Furthermore, mice expressing VEGF under the control of the PDX-1 promoter to target the factor to the developing pancreas exhibited hypervascular islets with islet hyperplasia. Although VEGF increased mitogenesis, insulin content, and insulin release in response to glucose from fetal islets, it did not stimulate direct differentiation of ductal epithelial cells into endocrine islet cells. Instead, VEGF increased the number of blood vessels or the production of an unknown factor from the vascular endothelial cells. These few examples

clearly indicate the importance of specific growth factors in the physiological processes leading to the development and differentiation of the fetal pancreatic islets.

Hormones

Experimental data that clearly show the involvement of hormones and more specifically GI hormones during fetal pancreas development are rather scattered. Studies by Swenne indicate that growth hormone (GH) can stimulate the *in vitro* replication of fetal rat beta cells, an effect mimicked by prolactin and placental lactogen. However, because of the doses used, the physiological significance of the observed effects was called into question. Later, Swenne proposed that part of GH's mitogenicity in beta cells could be attributed to insulin-like growth factor-I (IGF-I). Rhodes described IGF-I and GH signal transduction pathways and suggested that each molecule operates via its own specific route to activate different mitogenic signals.

Although cholecystokinin (CCK), a gastrointestinal peptide hormone, can stimulate proliferation of the exocrine pancreas after birth, it remains unlikely that it would be involved during fetal development since its expression in fetal life is negligible. However, by immunochemistry and immunofluorescence methods, Sarvetnick detected CCK in pancreatic cells located in the acinar region of the pancreas on embryonic day 16. These data suggest that CCK signaling could be established early in development but its exact function remains unknown. However, treatments throughout pregnancy with caerulein, a CCK analogue, led Morisset to show that it induced pancreas aplasia in the mature fetus; unfortunately, the endocrine pancreas was not examined in this study. Another GI hormone that could influence the growth of the endocrine pancreas is gastrin, as it is transiently expressed in the islets, its major source in the fetus. Although the role of pancreatic gastrin in islet development remains undefined, it may influence islet growth since fetal pancreas has high levels of CCK_B/gastrin receptor mRNA transcripts and high concentrations of gastrin. Although once again endocrine pancreas was not investigated, Morisset clearly demonstrated that pentagastrin treatment throughout pregnancy resulted in fetal pancreas hypertrophy, whereas treatment with L365,260, a specific CCK_B receptor antagonist, caused pancreas atrophy. It may be hypothesized that the endocrine pancreas could also have been affected.

POSTNATAL ENDOCRINE PANCREAS GROWTH

Normal Growth

Discovery of the mechanisms of islet cell development and regeneration remains an important medical issue because of the steady increase in the incidence of diabetes among populations. For this reason, research has mostly focused on beta cell proliferation. As indicated by Bonner-Weir, an increase in islet mass in the adult can occur by neogenesis (islet formation from ductal precursor cells), replication of existing islet cells, or beta cell hypertrophy. Although the adult beta cell population has a limited proliferative potential, a considerable number of endocrine cells can regenerate. Such a process involves an orchestration of hormones and growth factor stimuli.

Response to Growth Factors

Kim showed that a mutation in the activin receptors led to hypoplastic pancreatic islets with a normal exocrine pancreas. Along this line, Korc established the presence of TGF- β isoforms in the adult human pancreas. TGF- β 2 and TGF- β 3 in particular are present and coexpressed with insulin. These observations led Korc to suggest that these factors may participate in the regulation of the biological functions of the endocrine pancreas. In perinatal rats fed a low-protein diet, reduced expression of IGF-I led to hypoplastic islets. With the HGF receptor preferentially expressed in beta cells, adult beta cells proliferate in response to HGF stimulation. These few experimental data indicate the importance of certain growth factors in controlling the normal functions of the endocrine pancreas, including turnover of their representative cell components.

Response to Hormones and GI Hormones

GH, prolactin, and placental lactogen are implicated in regulating marked beta cell hyperplasia and increased islet proliferation during gestation in mice and humans. From studies performed on the pancreatic beta cell line INS-1, it seems that the effect of GH on DNA synthesis would be direct and dependent on glucose concentration. Among the gastrointestinal hormones, pituitary adenylate cyclase-activating protein (PACAP), a member of the secretin/glucagon/VIP family, was first shown to be a potent insulin secretagogue and its distribution in pancreatic nervous fibers surrounding the islets suggests a paracrine effect. However, studies by Petruzzo raised the possibility of PACAP being a growth factor. Indeed,

incubation of the peptide with purified islets resulted in the appearance of PACAP in nuclei of 80% of the islet cells; such an observation may suggest a genomic action of the internalized PACAP. Intestinal glucagon-like peptide-1, known to modulate insulin, glucagon, and somatostatin release, has been shown to stimulate PDX-1 expression and to increase islet size in mouse pancreas. Even though it has been reported that in the rat pancreas, free CCK_A receptors lost their ability to secrete insulin and glucagon, the fact remains that chronic CCK treatment alone or with secretin in normal rats did not affect total insulin content while inducing exocrine pancreas growth. Similarly, as shown by Morisset, caerulein, a CCK analogue, did not modify the labeling index of the endocrine cells after 4 days of treatment, whereas all the other cell populations had their labeling index significantly increased, by even as much as 26% in acinar cells. Finally, data presented by Brand convincingly indicated that gastrin does not stimulate islet cell growth. Indeed, the pancreas of transgenic mice overexpressing gastrin had normal histology with an islet mass comparable to that of the controls.

Endocrine Pancreas Regeneration

The aims of most studies related to endocrine pancreas regeneration have been to restore the beta cell mass to maintain euglycemia. After the neonatal period, the replication rate of the beta cells is low although it is known that its mass continues to grow well into adulthood. In order to study islet regeneration, different experimental animal models were used, including partial pancreatectomy, duct ligation, cellophane wrapping, and overexpression of specific genes.

Pancreatectomy

In 40% pancreatectomized rats, Leahy observed regrowth of much of the excised islet mass after 3 weeks. Similarly, in 60% pancreatectomized rats, beta cell regeneration was still observed but remained incomplete, with the islet non-beta-cell mass remaining unchanged. In large animals, such as the dog, there is a critical threshold of resection at approximately 88 to 92% that causes the immediate onset of diabetes. Development of diabetes is also a major setback for regeneration; indeed, after 74–92% pancreatectomy, the regeneration rate, evaluated as changes in pancreas size, was more than 40% in the nondiabetic dogs but only 15 to 23% in the diabetic animals. Treatment with insulin enhanced DNA synthesis in the remnant

pancreas, thus promoting regeneration. Unfortunately, the factors other than insulin that are involved in islet regeneration are still unknown.

Pancreatic Duct Ligation

Previous studies indicated that pancreatic duct ligation induced islet cell neogenesis from duct cells in the adult rat pancreas. Klöppel found that, in response to this procedure, gastrin mRNA was strongly expressed in the newly developed duct-like cell structures along with gastrin. Expression of three isoforms of the transforming growth factor- α (TGF- α) protein was also observed. The appearance of these two growth factors preceded the peak of DNA synthesis in beta cells. These data strongly suggest that gastrin and TGF- α act as growth factors during islet neogenesis. Using a similar duct ligation model in rats, Bouwens found that infusion of gastrin for 3 days increased the beta cell mass. However, there was no mitogenic effect of gastrin on the beta cells, which is not surprising since they do not express CCK_B receptors. It was then suggested that gastrin extends the process of neogenesis already under way by the duct ligation procedure with an up-regulation of gastrin and the CCK_B receptors in the ductal complexes of the ligated part of the pancreas. Under these conditions, gastrin would have a paracrine effect on the responsive ductal cells through its newly expressed CCK_B receptor.

Cellophane Wrapping

A new factor was discovered in response to cellophane wrapping of the head of the pancreas in Syrian golden hamsters. This surgical procedure led to the induction of new islet formation from ductal cells within 2 weeks through a paracrine or autocrine mechanism responsible for islet neogenesis. The responsible factor was cloned and designated INGAP (islet neogenesis-associated protein) and is a member of the Reg family. Its administration resulted in a two- to threefold increase in DNA synthesis in ductal epithelial cells, the potential precursor cells; the peptide had no effect on existing beta cells. The INGAP site of origin would be the acinar cells and its action on ductal cells would likely be paracrine, leading to islet neogenesis, as proposed by Vinik. The phenomenon was also observed in monkeys, with the same wrapping procedure being used.

Overexpression of Growth Factors

From studies by Brand, it was shown that pancreatic coexpression of gastrin and TGF- α resulted in significant increases in islet mass in mice with both

transgenes. These studies indicate that both factors can act in synergy to stimulate islet growth, whereas each peptide alone failed to do so. In transgenic mice expressing interferon- γ in their islets, pancreatic duct cell proliferation and new islet formation were observed. These specific modifications were associated with the expression in the islets of the Erb- β receptors and their specific agonists, the heregulin isoforms, suggesting their involvement in islet neogenesis. Finally, the overexpression of insulin-like growth factor-II in mouse pancreas led to oversized islets with no change in the number of islets per area. In pancreas, the area occupied by insulin cells was decreased, the area occupied by glucagon cells was increased, and the area occupied by somatostatin cells was unchanged. However, given the islet cell hyperplasia, the total number of beta cells per islet was increased in these transgenic animals. Overexpression of this growth factor also resulted in increased cell replication and reduced apoptosis.

AN APPROACH TO ENDOCRINE PANCREAS GROWTH CONTROL BY GI HORMONES

From data presented in this article, it is clear that the role played by the GI hormones in the development and regeneration of the pancreatic islets has remained underinvestigated over the years. Although the involvement of the various GI hormones in secretion of the different islets' hormones has been well investigated, results on this specific subject remain controversial. As an example, ambiguity can come from the location of CCK in the pancreas. Indeed, the hormone colocalized either with insulin in rat or with glucagon in mice. Similar divergent data regarding the location of the CCK_A and CCK_B receptor subtypes exist. The research groups of Fourmy and Bouwens established the presence of the CCK_B receptor on glucagon cells in human and rat pancreas, respectively, and Amselgruber identified the CCK_A receptor on glucagon cells in the pig pancreas. Neither Fourmy nor Bouwens was able to localize the CCK_B receptor on pancreatic somatostatin cells; however, Morisset and co-workers clearly showed their colocalization in human, rat, mouse, pig, dog, and calf pancreas.

The authors' approach to evaluating the growth potential of the GI hormones on pancreatic endocrine cells is systematic. Indeed, before any experimental assays on islet cell proliferation are performed, the rat purified islets were adopted as a model and the GI

Figure 1 CCK_A and CCK_B receptor mRNA (A) and protein expression (B) in total rat pancreas and purified islet. (A) RT-PCR was performed using the TITANIUM One-Step RT-PCR Kit (Clontech Laboratories, Palo Alto, CA) and 1 μ g of total RNA from purified islets. Amplification of CCK_AR, CCK_BR, and somatostatin (SS) mRNA is observed. The amplified product sizes are 812, 669, and 231 bp for CCK_AR, CCK_BR, and SS, respectively. (B) Western blots of total pancreas homogenate (H), purified membranes (M), purified islets (I), and acini (A) represent 25 μ g protein fractionated on a 12% sodium dodecyl sulfate-acrylamide gel transferred to a polyvinylidene difluoride membrane and probed with the polyclonal rabbit anti-CCK_AR and anti-CCK_BR described in Table I. Specificity was established by preincubation of each antibody with its specific peptide. Bands were visualized by enhanced chemiluminescence. Localization of CCK_AR, CCK_BR, insulin (INS), glucagon (GLUC), and somatostatin by confocal microscopy of purified rat islets (C) and specificity of the reactions (D). The primary and secondary antibodies were incubated in 1 \times phosphate-buffered saline, 0.2% Triton X-100, and 1.4% normal donkey serum overnight at 4 $^{\circ}$ C and 1 h at room temperature. For specificity (D), the peptide antigens and hormones were preincubated at 40 μ g/ml with their respective antibodies.

Table I Origin and Characteristics of the Antibodies

| Primary antibody | Dilution and source | Secondary antibody |
|-------------------------------------|---|---|
| Mouse anti-insulin | 1:50 (Santa Cruz Biotechnologies) | Rhodamine-conjugated donkey anti-mouse IgG (Santa Cruz Biotechnologies) |
| Mouse anti-glucagon | 1:200 (Sigma Chemical Co.) | Rhodamine-conjugated donkey anti-mouse IgG (Santa Cruz Biotechnologies) |
| Goat anti-somatostatin | 1:50 (generous gift from P. Brazeau) | Alexa Fluor 546 donkey anti-goat (Molecular Probes) |
| Rabbit anti-CCK _A R 1122 | 1:1500 (generous gift from M. L. Kruze) | Alexa Fluor 488 donkey anti-rabbit (Molecular Probes) |
| Rabbit anti-CCK _B R 9262 | 1:200 (generous gift from J. Walsh) | Alexa Fluor 488 donkey anti-rabbit (Molecular Probes) |

hormones CCK and gastrin were chosen because their receptors are well characterized and because specific antibodies, raised against parts of these molecules, are also readily available. On these islets, the authors have thus far evaluated (1) the expression of the CCK_A and CCK_B receptor mRNA, (2) the presence of these two receptor proteins by Western blot, and (3) the specific localization of each receptor protein subtype among the islet cells by confocal microscopy.

As shown in Fig. 1, the data clearly show that rat purified islets express both CCK_A and CCK_B receptor subtypes as indicated by the presence of their respective mRNA (Fig. 1A) and protein (Fig. 1B). Note that the specificity of the two CCK receptor antibodies used was established by preincubation with their specific antigens (Fig. 1B, Peptide; see also Table I). Furthermore, by confocal microscopy, the CCK_A receptors were specifically localized on insulin and glucagon cells, whereas the CCK_B receptors appeared exclusively on the somatostatin cells (Fig. 1C). As shown in Fig. 1D, preabsorption of each antibody with its corresponding peptide or hormone confirms the specificity of the data. With this CCK receptor distribution in mind, it becomes possible to design more accurate protocols (1) to study the anti-diabetogenic action of CCK₈ in type 2 diabetics as shown by Ahren, (2) to explain the increased pancreatic contents of somatostatin in diabetic animals and its potential role in the development of type 2 diabetes, and (3) to determine the growth potential of CCK and gastrin on specific islet cells using hormone concentrations corresponding to the affinity of each CCK receptor subtype. It will also become easier to test and eventually use specific CCK receptor antagonists to target and treat pathologies of

the endocrine pancreas. It is sincerely believed that characterization of the receptors and determination of their specific cellular location are critical data needed to study the role of GI hormones in any physiological response attributed to these hormones.

number of gastric inhibitory peptide-, substance P-, somatostatin-, and serotonin-producing enteroendocrine cells was also observed in these mice, suggesting that several small intestinal endocrine cell lineages are developmentally related. Finally, expression of a dominant negative Pax6 allele in SEY^{Neu} mice results in reduced levels of proglucagon mRNA transcripts in the small and large intestine and an almost complete absence of enteroendocrine cells containing glucagon-like peptide-1 (GLP-1) or glucagon-like peptide-2 (GLP-2) immunoreactivity.

Enteric Nervous System

The ENS consists of autonomic ganglia located in the submucosal and myenteric plexus and associated connecting neural structures in the bowel wall. Afferent sensory neurons detect both chemical and mechanical stimuli arising from the intestinal wall and lumen and efferent motor neurons interact with effector cells including smooth muscle cells, pacemaker cells, mucosal glands, blood vessels, epithelia, and cells that regulate both immune response and intestinal endocrine function.

The neurons and glial cells of the ENS are derived from the neural crest. During early fetal development, a wave of migrating neural crest (NC) cells (somites 1–5 in the mouse) enters the foregut mesenchyme and colonizes the entire length of the gastrointestinal tract in a rostral-to-caudal manner. Truncal-derived NC cells (somites 6 and 7 in the mouse) also contribute to the development of the ENS in the foregut (esophagus and stomach) and sacral-derived NC cells contribute to the development of the hindgut. As NC cells colonize the gut, these precursor cells undergo cellular proliferation and differentiation into glial cells and other cell types that constitute the ENS. Little is known about the various factors that regulate cellular differentiation; however, genetic loss-of-function experiments in rodents have identified several genes that are essential for regulating the spatial development of the ENS. For example, the transcription factor MASH1 is required for the development of the ENS in the esophagus; glial-derived neurotrophic factor and its receptors RET and GDNF family receptor α -1 as well as the transcription factor Phox2b are essential for the development of the ENS distal to the stomach; whereas endothelin 3 and its receptor Ednrb/edn3/ece1 as well as the transcription factors sox10 and Hoxa-4 are essential for the development of the ENS in the hindgut. Several members of the *hedgehog* gene family are also important for developmental formation of the ENS.

ENTEROENDOCRINE CELL-DERIVED PEPTIDES

Gastrin

In the gastrointestinal tract, gastrin is produced predominantly in G cells located in the gastric antrum and duodenal bulb. The 101-amino-acid progastrin precursor polypeptide is posttranslationally processed into several biologically active molecular forms, including G-34, G-17, and G-14, which can be either amidated or glycine-extended. The amidated forms of gastrin are essential for regulating gastric acid secretion and the progastrin-derived peptides exhibit multiple trophic effects on the stomach, pancreas, and colon.

Oncofetal Relationships

Stomach

Gastrin content increases gradually from birth and reaches a peak at 5 weeks of age, after which levels decrease in adult rats. Although glycine-extended gastrin (G-Gly) precursors increase in the first day of life, the process of weaning results in a further increase in gastric gastrin content and enhanced gastrin amidation. The amidated forms of gastrin (gastrin-17 and -34) stimulate proliferation of gastric stem cells and enterochromaffin-like (ECL) cells in the oxyntic mucosa, resulting in an increased parietal and ECL mass and ensuring adequate gastric acid production in the rodent stomach during the weaning process.

Mice with a null mutation in the gastrin gene exhibit decreased numbers of parietal and ECL cells and reduced gastric acid production. Gastric carcinoid tumors occur in approximately 30% of patients with hypergastrinemia due to gastrin-producing tumors as part of the multiple endocrine neoplasia type 1 syndrome, whereas approximately 5% of patients with pernicious anemia and hypergastrinemia secondary to reduced parietal cell mass will develop ECL cell carcinoid tumors, which may resolve following surgical resection of the antrum. Long-term treatment of animals with proton pump inhibitors is also associated with hypergastrinemia, ECL hyperplasia, and the development of carcinoid tumors.

Pancreas

The biological effects of the progastrin-derived peptides on the endocrine pancreas have yet to be clearly defined. The fetal pancreas of rodents contains a large amount of amidated gastrin that is first detected by E15 and persists until just after weaning. This time period is associated with considerable fetal islet

growth and differentiation and suggests a possible role for gastrin in pancreatic endocrine cell development. Transgenic mice expressing amidated gastrin in the islet adult beta cell exhibit a minimal phenotype; however, a doubling of islet cell mass is detected when these mice are crossed with transgenic mice expressing transforming growth factor- α (TGF- α). Gastrin is not essential for islet development, as gastrin-deficient mice do not demonstrate abnormalities in pancreatic islet morphology.

Colon

Progastrin and the progastrin-derived peptides can be detected in the rat colon during fetal development. Following birth, amidated gastrins are no longer detected in the colon and the levels of glycine-extended gastrins gradually decrease such that only progastrin can be detected in the adult rat colon. The mechanisms underlying the trophic effects of progastrin and G-Gly on the colonic epithelium remain incompletely defined. Transgenic mice expressing progastrin or G-Gly exhibit increased colono-cyte proliferation and mucosal thickness and are more prone to form aberrant crypt foci following the administration of azoxymethane. Consistent with these observations, targeted inactivation of the gastrin gene results in reduced rates of colonic epithelial proliferation. Gastrin stimulates the proliferation of several colon cancer cell lines expressing the gastrin receptor (CCK₂); however, the majority of colon cancer cell lines and normal colonic epithelium do not normally express CCK₂. A truncated gastrin-binding receptor and a constitutively active CCK₂ receptor mutant have been identified in some human colorectal cancers. These findings form the basis for the potential use of gastrin-neutralizing antisera for the treatment of subsets of patients with colon cancer.

Cholecystokinin

CCK was initially described as a factor that stimulates gallbladder contraction. In the gastrointestinal tract, CCK is expressed in "open-type" enteroendocrine I cells located in the proximal small intestine and in nerve fibers branching to the gastric and colonic myenteric plexus and submucosal plexus, where it acts as a neurotransmitter. The CCK gene encodes a 94-amino-acid prohormone that is posttranslationally processed in a tissue-specific fashion into CCK₈₃, CCK₅₈, CCK₃₉, CCK₃₃, CCK₂₂, CCK₈, and CCK₅, all sharing a common C terminus. The major active form of CCK is an octapeptide containing a sulfated

tyrosine residue and an amidated C-terminal phenylalanine residue.

Oncofetal Relationships

CCK cannot be detected in fetal and neonatal pancreatic islet cells but is expressed in islets during and after weaning, suggesting that CCK is probably not important for development of the endocrine pancreas. CCK stimulates pancreatic enzyme secretion and exhibits trophic effects on pancreatic acini. Chronically elevated levels of CCK are associated with pancreatic hyperplasia and enhanced tumor formation. Rats fed a soybean trypsin inhibitor that enhances the release of CCK develop preneoplastic pancreatic lesions that eventually progress to carcinoma (Table I). Similarly, long-term pancreatobiliary diversion in the rat causes elevated levels of plasma CCK, pancreatic growth, and premalignant changes. Elevated circulating levels of CCK also enhance the development of preneoplastic acinar lesions induced by azaserine, a potent pancreatic carcinogen in rats. In contrast, loss of CCK signaling produces variable effects on the pancreas. The Otsuka Long-Evans Tokushima Fatty rat fails to express the CCK-A receptor and exhibits reduced pancreatic size, whereas the CCK-A receptor knockout mouse exhibits normal pancreatic morphology. CCK may also play a role in stimulating the growth and invasiveness of human pancreatic cancer cell lines.

GLP-1 and GLP-2

The proglucagon gene is expressed in pancreatic A cells, in enteroendocrine L cells, and in the brainstem and hypothalamus. In mammals, both glucagon and the glucagon-like peptides are encoded within a single proglucagon precursor prohormone. Post-translational processing of proglucagon occurs in a tissue-specific manner, resulting in the liberation of the proglucagon-derived peptides, which possess remarkably diverse biological actions. In the pancreatic A cell, posttranslational processing liberates glucagon and the major proglucagon fragment, whereas in enteroendocrine L cells and brain, posttranslational processing liberates glicentin, oxyntomodulin, GLP-1, GLP-2, and several spacer or intervening peptides.

Oncofetal Relationships

Proglucagon-immunoreactive cells and proglucagon mRNA transcripts are first detected in the rat intestine by E14; however, an intestinal profile of

Table 1 Intestinal-Derived Factors and Their Growth-Promoting Effects

| Growth factor | Site of intestinal expression | Trophic effects | Oncogenic effects |
|-------------------------------|-------------------------------|--|---|
| Gastrin | G cells | Stomach oxyntic mucosa, colonic epithelium, pancreas (?) | ECL cellular hyperplasia, carcinoid tumors, colonic adenocarcinoma |
| CCK | I cells and ENS | Pancreatic acini | Pancreatic hyperplasia/carcinoma, tumor invasion (?) |
| GLP-1 | L cells | Pancreatic beta cell differentiation and neogenesis | ? |
| GLP-2 | L cells | Stomach, small intestine, colonic epithelium | ? |

Note. ECL, enterochromaffin-like; ENS, enteric nervous system; CCK, cholecystokinin; GLP-1, glucagon-like peptide-1; GLP-2, glucagon-like peptide-2; NT, neurotensin; PYY, peptide YY; TRH, thyrotropin-releasing hormone; VIP, vasoactive intestinal peptide.

glucagon-like immunoreactive peptides cannot be detected until E17–19 when the molecular machinery associated with posttranslational processing of proglucagon has developed.

GLP-1

GLP-1 inhibits food intake, gastric emptying, and glucagon secretion and stimulates insulin secretion. Although the GLP-1 receptor is expressed in multiple tissues during murine development, a role for GLP-1 during embryonic development has not been established. GLP-1 stimulates beta cell proliferation, beta cell differentiation, and beta cell neogenesis; however, GLP-1 receptor^{-/-} mice develop normally and GLP-1R^{-/-} islets exhibit only minor abnormalities in islet cell formation, precluding a major role for GLP-1 in islet cell development. Administration of GLP-1 to aging rats leads to an increase in beta cell mass, whereas activation of GLP-1R signaling enhances islet proliferation in rats and mice with experimental diabetes.

GLP-2

GLP-2 is produced in the gut during late gestation, following which levels increase progressively in neonatal rats and then subsequently decrease to adult levels. Similarly, GLP-2 receptor expression can be detected along the entire length of the gastrointestinal

tract during late fetal development and during the neonatal period. Exogenously administered GLP-2 induces growth of the stomach, small intestine, and colon of neonatal rats. In contrast, administration of GLP-2 to fetal pigs does not produce an intestinotrophic response. Furthermore, although Pax6 mutant SEY^{Neu} mice exhibit a marked reduction in the number of GLP-2-producing L cells, intestinal development appears relatively normal in these mice, strongly suggesting that GLP-2 is not essential for the development of the fetal murine intestine.

GLP-2 exerts trophic effects on the small intestine and colonic mucosa by stimulating crypt cell proliferation and inhibiting apoptosis within the crypt and villus compartments. GLP-2 also exerts multiple actions independent of intestinal growth including enhancement of intestinal epithelial barrier function and stimulation of intestinal hexose transport. The therapeutic utility of GLP-2 has been demonstrated in pilot studies of human subjects with short bowel syndrome and in rodent models of intestinal disease including major small bowel resection, total parenteral nutrition (TPN)-induced intestinal hypoplasia, small and large intestinal inflammation, chemotherapy-induced mucositis, and intestinal ischemia-reperfusion injury. Intriguingly, the GLP-2 receptor has been localized to human endocrine cells and to murine submucosal and myenteric neurons, highlighting the

interaction between the enteric endocrine and nervous systems in controlling intestinal epithelial growth.

Neurotensin

Neurotensin (NT) is a 13-amino-acid peptide originally discovered in bovine hypothalamus. Peptides that share structural homology with NT include neuromedin N, xenin, and xenopsin. In the gastrointestinal tract, NT is synthesized by N cells located within the small intestinal mucosa, predominantly the ileum, and can also be detected within enteric neurons.

Oncofetal Relationships

In the human fetal colon, NT is transiently expressed at midgestation between 16 and 18 weeks and the extent of NT expression in the adult human colon is unclear. In the adult rat, NT administration augments the adaptive response to small bowel resection in the intestinal remnant and stimulates growth of the colonic epithelium *in vivo*. NT receptor expression has been detected in human colonic adenocarcinomas and pancreatic cancer cell lines. The importance of NT for pancreatic growth remains unclear as NT binding is detectable by autoradiography in pancreatic cancer cells but not in normal human pancreas.

Peptide YY

PYY, neuropeptide Y, and pancreatic polypeptide are members of the pancreatic polypeptide superfamily. All three peptides contain 36 amino acids, share considerable amino acid homology, demonstrate amidated C-terminal ends, and possess several tyrosine residues (single-letter abbreviation Y) including tyrosines at both the amino and carboxy termini. Only PYY has been implicated as a putative intestinal epithelial growth factor.

Oncofetal Relationships

PYY is one of the first hormones to be expressed in the developing fetal gastrointestinal tract and colocalizes with GLP-1 in a subset of enteroendocrine L cells present in the ileum, colon, and rectum. PYY coexpression is detected in the majority of colonic enteroendocrine cells throughout fetal and postnatal development, with the exception of serotonin-producing cells, suggesting a possible common PYY⁺ progenitor cell for enteroendocrine cells in the intestine. Immunoreactive PYY has also been detected

in the developing endocrine pancreas and in a subpopulation of glucagon-producing A cells in mature islets, although a role for PYY in the endocrine pancreas has yet to be elucidated.

In the intestine, PYY regulates small and large bowel motility and inhibits both water and chloride secretion. PYY expression is first detected in the rat colon at E17 and levels remain relatively elevated until after weaning (postnatal day 21) when PYY mRNA transcripts decline to adult levels. Administration of PYY to nursing rats increased the weight and DNA content of the duodenum, suggesting a potential trophic role for PYY during intestinal development and dietary adaptation.

In the adult mouse, administration of PYY increased the weight and DNA content of the duodenum, ileum, and colon, whereas co-infusion of PYY in TPN-fed rats increased jejunal mass and protein content. In the pancreas, PYY inhibits pancreatic exocrine secretion but does not exhibit direct trophic effects on either the exocrine or the endocrine pancreas.

Thyrotropin-Releasing Hormone

Thyrotropin-releasing hormone (TRH) is expressed throughout the gastrointestinal tract in gastric G cells, in pancreatic islet beta cells, and in neurons constituting the myenteric plexus of the esophagus, stomach, and intestine. In the stomach, TRH modulates pentagastrin-stimulated gastric acid secretion and may attenuate acid secretion in subjects with acid secretory disorders.

In the pancreas, TRH is expressed during perinatal development and TRH administration in the adult rodent induces pancreatic hyperplasia and inhibits amylase release. TRH also reduces CCK-induced gallbladder smooth muscle contraction and inhibits cholesterol synthesis within the intestinal mucosa but is not trophic to the intestinal mucosa.

ENS-DERIVED PEPTIDES

Vasoactive Intestinal Peptide

Vasoactive intestinal peptide (VIP) is a 28-amino-acid neuropeptide originally isolated from porcine small intestine. VIP belongs to a family of neuropeptides that includes pituitary adenylate cyclase-activating peptide, peptide histidine isoleucine, and peptide histidine methionine, which function as neurotransmitters and neuromodulators of the enteric nervous system.

Oncofetal Relationships

In the human digestive tract, immunoreactive VIP can be detected as early as 10 weeks gestation and in the pancreas as early as 9 weeks gestation. VIP stimulates the release of neurotrophic factors from glial cells, promotes the growth of astrocytes and several non-small-cell lung cancers, stimulates the growth of VIP-1 receptor-bearing pancreatic adenocarcinoma-derived cells *in vitro*, and inhibits the growth of colon adenocarcinoma cells *in vitro*.

Bombesin and Related Peptides

The bombesin family of peptides was originally isolated from frog skin extracts and includes bombesin, gastrin-releasing peptide (GRP; the mammalian homologue of bombesin), neuromedin B, and neuromedin C. Bombesin is a tetradecapeptide, both neuromedin B and neuromedin C are decapeptides, and GRP is a 27-amino-acid peptide.

Oncofetal Relationships

Administration of bombesin to 7-day-old rats resulted in increased stomach, intestinal, and pancreatic weights. GRP is also expressed in human cancer cells, including neuroendocrine tumors of the lung (carcinoids and small-cell lung cancer), breast cancer, neoplastic human thyroid C cells, pancreatic cancer, stomach cancer, and colon cancer. Bombesin stimulates the growth of several human small-cell lung cancers and pancreatic cancer cell lines and the detection of GRP and GRP RNA in neoplastic cells suggests that GRP may potentially function as an autocrine growth factor. Bombesin stimulates enhanced growth of xenografted tumors *in vivo* and GRP receptor mRNA has been detected in colonic tumors but not in normal colonic epithelium.

SUMMARY

Trophic peptides exert effects on the intestinal epithelium via stimulation of crypt cell proliferation and/or inhibition of apoptosis in the crypt and villus compartments. These biological actions may be important for intestinal development and for ensuring adequate epithelial regeneration following intestinal injury. Although the enteric endocrine and nervous systems secrete peptides important for gut growth, intestine-derived growth factors, such as epidermal growth factor, TGF- α , hepatocyte growth factor,

and keratinocyte growth factor, along with growth hormone, insulin-like growth factor-I, interleukin-11, and interleukin-15, also exhibit trophic effects on the gastrointestinal epithelium. These factors function in a coordinated interdependent manner to regulate fetal organ maturation and mucosal healing and repair following epithelial injury. Understanding how these peptides interact to exert their cytoprotective and regenerative effects may be important for realizing the clinical potential of one or more gut peptides and growth factors for the treatment of human intestinal injury.

Elevation of serum gastrin levels is a common occurrence via a number of pathological, physiological, and pharmaceutical mechanisms. First, it occurs as a result of pernicious anemia, in which autoimmune antibodies directed against parietal cells result in reduced acid secretion. Second, it can occur in patients with Zollinger-Ellison syndrome, caused by islet cell tumors secreting gastrin. Finally, *Helicobacter pylori* infection and administration of proton pump inhibitors lead to an increase in mainly amidated, mature forms of gastrin. Colonic proliferation has been shown to be altered in these conditions of hypergastrinemia, with an increase in normal crypt cell proliferation. Preclinical models evaluating the effect of hypergastrinemia, induced by proton pump inhibitors (PPIs), on the development of carcinogen-induced colon cancer, show no deleterious effect of the hormone. However, in the APC^{Min} mouse model of familial adenomatous polyposis and in a human colonic adenoma xenograft grown in nude mice, PPI-induced hypergastrinemia resulted in increased adenoma proliferation and reduced survival. A carefully controlled clinical study has consolidated these preclinical findings by showing that elevated gastrin levels (>90 pg/ml) were associated with a three- to fourfold increased risk of colorectal cancer development.

A number of studies have demonstrated cholecystokinin-2 (CCK₂)/gastrin receptors on GI tumor cells and exogenously administered gastrin peptides were found to have proliferative effects both *in vitro* and *in vivo*. In addition to the endocrine mechanism of gastrin's action, activation of the gastrin gene within GI adenocarcinoma cells results in the production of immature gastrin peptides, mediating proliferation in an autocrine/paracrine manner. Specific gastrin peptides implicated in the promotion of GI tumor growth include amidated G17, GlyG17, glycine-extended G34, and progastrin.

Gastrin mediates its physiological effects through the G protein-coupled seven-transmembrane domain CCK₂ receptor. The receptors mediating the effects of trophic precursor forms of gastrin still require clarification and universal agreement. However, a number of CCK₂ receptor isoforms that result from alternative splicing have been described, including an amino-terminal truncation and retention of introns 2 and 4. Certain members, in particular those with retained introns, may be tumor-specific and have been implicated in binding precursor gastrin species.

The gastrin gene is a downstream target of β -catenin-mediated transcription, suggesting that

the gastrin autocrine pathway is operational early in the adenoma-carcinoma sequence and may play a role in CCK₂ receptor up-regulation and tumor progression.

Gastrin circumvents apoptosis in a number of experimental systems. Gastrin stimulated the phosphorylation and subsequent activation of the survival-inducing protein kinase B/Akt, activated in many cancers, promoting proliferation and resistance to chemotherapy and radiation. Furthermore, autocrine gastrin produced by the colorectal cancer cell line HCT116 reduced the activation of caspase-3 and up-regulated cytochrome c oxidase Vb. This resulted in a decreased sensitivity of the cells to pro-apoptotic stimuli by retaining cytochrome c within the mitochondria. Camptothecin activation of caspases 3 and 9 was also reduced by progastrin in the intestinal cell lines IEC18 and IEC6.

The incidence of mutated p53 was elevated in *Mastomys natalensis* carcinoid model mice with serum hypergastrinemia. *In vitro* gastrin stimulation of the AGS gastric cancer cell line increased the expression of p53. Such an effect on mutant p53 may also increase resistance to apoptotic stimuli.

The role of gastrin as a transcriptional activator has expanded to include many key targets involved in the establishment and maintenance of malignancy. Gastrin activates the transcription of heparin-binding epidermal growth factor, a potent angiogenic factor, and amphiregulin. This leads to a concomitant up-regulation of the EGF receptor. Gastrin peptides increase activated matrix metalloproteinase 2 secretion in the human colon cancer cell line LoVo, resulting in enhanced invasion, as well as up-regulated cyclooxygenase 2 (COX-2) gene and protein expression. The *Reg* family of genes, which are activated during regeneration of intestinal mucosa and which are positively correlated with colorectal cancer recurrence, have been shown to be up-regulated by gastrin. Long-term administration of the PPI lansoprazole strongly increased the expression of the *Reg* gene, which was reversed by inclusion of a CCK₂ receptor antagonist.

OPTIONS FOR BLOCKADE OF GASTRIN-MEDIATED GROWTH PATHWAYS

Gastrin Receptor Blockade

Higher affinity CCK₂ receptor antagonists have been developed, including the benzodiazepam derivative L-365,260, which, in preclinical studies, reverses gastrin-stimulated GI tumor growth. Another CCK₂

receptor antagonist, Gastrazole (JB5008), has been shown to be highly potent in preclinical studies and has been used in an open-labeled pilot clinical trial in patients with pancreatic cancer. When compared to historical controls, a significant survival advantage was suggested.

A number of CCK₂ receptor antagonists block the effect of Gly-gastrin peptides, thus circumventing potential autocrine gastrin pathways. YM022 was shown to reverse both G17- and GlyG17-stimulated proliferation of the human colon cancer cell line LoVo, in addition to inhibiting basal growth. JMV1155 reduced the GlyG17-stimulated *in vivo* growth of the human colon tumor DLD1.

CCK₂ receptor antagonists that block endocrine and potential autocrine pathways exist. Studies delineating the importance of splice variants in terms of tumor expression and ligand specificity will direct development of the next generation of CCK₂ receptor antagonists.

Gastrin Immunoneutralization

Anti-gastrin antibodies have been shown to be effective at reducing the basal growth of a gastrin-secreting colon cancer cell line *in vivo* and *in vitro*. A continuous infusion of anti-gastrin antibodies is difficult to administer, may be unstable, may cause anaphylaxis, and may fail to achieve consistent therapeutic serum levels sufficient to neutralize postprandial gastrin surges. Such limitations can be overcome by the use of active immunization against gastrin species. G17DT is a gastrin immunogen, composed of a nonapeptide derived from the amino-terminal of human gastrin-17 linked to diphtheria toxoid which acts as an immunogenic carrier. The G17 epitope is monovalent, thereby preventing complement fixation. Antibodies raised do not cross-react with other hormones, such as G34, smaller C-terminal fragments, or CCK. G17DT antibodies raised in rabbits have a high affinity for G17 and GlyG17 and functionality was confirmed by their ability to competitively displace gastrin ligands (¹²⁵I-G17) from the CCK₂ receptor expressed by a tumor cell line even at dilutions of 1:100 of the original serum titer.

Preclinical Efficacy of G17DT Antibodies

G17DT has been shown to exert therapeutic effects following passive immunization in nude mouse models of gastric, pancreatic, and colorectal cancer.

Clinical Studies of G17DT

G17DT has been assessed in phase I/II trials in advanced colorectal cancer patients; increased survival of G17DT patients compared to a well-matched placebo group was observed.

A dose-finding phase II study of G17DT in 22 patients with pancreatic carcinoma demonstrated greater survival in patients who mounted an adequate antibody response than in nonresponders. G17DT is being assessed in phase III trials for gastric, pancreatic, and colorectal cancer.

SOMATOSTATIN

Somatostatin exerts its actions through interaction with specific heptahelical G protein-coupled plasma membrane receptors. Five different somatostatin receptor subtypes have been cloned in humans. Different receptor subtypes are coupled to different intracellular transmission cascades in a cell type-dependent manner. Somatostatin can also exert cytostatic (G₁-phase cell arrest) or cytotoxic (apoptosis induction) effects, depending on the receptor subtype expressed on the target cell. In gastroenteropancreatic neuroendocrine tumors, a predominance of sst1 and sst2 with a lesser extent of sst3 and sst5 subtype receptors has been demonstrated.

Since the short half-life of somatostatin makes continuous intravenous infusion mandatory, several long-acting analogues have been synthesized. Of these, octreotide (which binds mainly to somatostatin receptor subtypes sst2 and sst5) has been the most extensively investigated. These synthetic analogues have specific decreasing affinity for sst2 > sst5 > sst3 receptor subtypes and have been used as antiproliferative drugs in the treatment of gastroenteropancreatic tumors. Octreotide and lanreotide treatment resulted in a modest growth-inhibition activity, in functioning or nonfunctioning tumors. Longer-lasting formulations of somatostatin analogues have been developed to provide patients with the convenience of monthly administration and to ensure stable drug serum concentrations between injections. Side effects of these agents consist mainly of gastrointestinal complaints, cholelithiasis, and effects on glucose metabolism.

Inoperable liver tumors have an unfavorable natural course despite various therapeutic modalities. Octreotide, a somatostatin analogue, has shown considerable antitumoral activity in animal models of various hepatic tumors and in isolated cell culture lines. A randomized controlled trial of octreotide in the treatment of advanced hepatocellular carcinoma

has shown a significant survival benefit in the treated patients. Literature reports indicate a stimulatory effect of octreotide on Kupffer cells as a possible antitumor mechanism. Octreotide administration is the best available treatment for advanced inoperable hepatocellular carcinoma and better patient selection, based on receptor subtypes, might further improve the results in the future.

Somatostatin analogues have been used in numerous preclinical studies providing contradictory evidence on the growth inhibition of ductal pancreatic adenocarcinoma. Monotherapy did not result in a prolongation of survival; however, in 15–20% of patients, the progression of the process was halted for several months accompanied by a significant improvement of the clinical condition without notable side effects. Somatostatin analogues have also been used in combination with tamoxifen in which patients with unresectable and resected ductal adenocarcinoma of the pancreas had an apparently increased survival when compared to historical controls.

Octreotide has been used to treat hypersecretion in Zollinger-Ellison syndrome in a small study. It had an antitrophic effect on parietal cell mass.

Octreotide is extremely useful for palliative care. It has analgesic properties when administered by the spinal and intraventricular routes. Its actions in reducing gut motility and secretions make it a valuable adjunct in the management of inoperable bowel obstruction, fistulae, and intractable diarrhea. Octreotide, for example, has been extensively used to ameliorate the gut motor dysfunction that characterizes carcinoid diarrhea.

SOMATOSTATIN AS A DIAGNOSTIC TOOL

Radiolabeled somatostatin analogues have been employed for the localization of primary and metastatic tumors expressing somatostatin receptors. The so-called “somatostatin receptor scintigraphy” is an important clinical diagnostic investigation for patients with suspected neuroendocrine tumors.

SOMATOSTATIN TARGETED THERAPY

An extension of somatostatin scintigraphy is somatostatin receptor-targeted chemotherapy and radiotherapy (with conjugates of somatostatin peptides and cytotoxic drugs) and gene therapy (e.g., transferring the *ss2* gene into neoplastic cells). Having been successfully tested in experimental studies, these therapies are being evaluated in clinical trials.

GASTRIN-RELEASING PEPTIDE

Gastrin-releasing peptide (GRP) and its seven-transmembrane-domain G protein-coupled receptor (GRPR) are frequently expressed by cancers of the gastrointestinal tract, breast, lung, and prostate. Most studies have found that GRP acts to increase tumor cell proliferation, leading to the hypothesis that it is an important mitogen for the growth of these cancers.

Gastrin-releasing peptide receptors are normally expressed on intestinal smooth muscle cells rather than epithelial cells of the GI tract. However, aberrant receptor expression has been shown on GI adenocarcinomas. Early studies revealed that 24–40% of human colon cancers overexpressed GRP receptors. However, a later study showed that 62% of the 50 colonic cancers examined aberrantly overexpressed both GRPR and the GRP hormone, unlike the normal adjuvant epithelium. The receptors were expressed equally across the different grades of tumor and appeared to be down-regulated in metastases, being expressed in only 1 of 37 metastases.

Poorly differentiated tumors were less likely to coexpress GRP and GRPR than well-differentiated tumors and it was concluded that the proteins act as morphogens rather than as mitogens.

GRPR mutations have also been described and result in the lack of production of functional receptor protein, indicating that studies exclusively examining gene expression of the GRPR may not reflect their biological significance in malignant progression. Such mutated GRPRs have also been shown in nonantral gastric adenocarcinomas.

Further evidence for the role of GRPR as a morphogen was provided in both wild-type and GRPR-deficient C57BL/J6 mice treated with the carcinogen, aoxymethane. Tumors that were induced in wild-type mice expressed GRPR and were well differentiated, whereas tumors in GRPR-deficient mice were poorly differentiated mucinous adenocarcinomas.

It was concluded that aberrant expression of GRPR and GRP did not result in larger tumors but due to GRP increasing focal adhesion kinase, the receptors promoted a well-differentiated phenotype.

The lack of a proliferative effect of GRP via GRPR was reinforced in a study of colorectal tumor specimens, where it was shown that 93% of tumor specimens expressed GRPR mRNA, which was expressed at higher levels in tumors with lymphatic vessel invasion but there was no relationship with p53 expression or proliferation index. Activation of GRPR results in stimulation of activation protein 1 expression, which has been shown to impact on

COX-2 expression. In a rat intestinal cell line over-expressing GRPR, bombesin was shown to stimulate COX-2 mRNA and protein expression in addition to prostaglandin E₂ production.

These data suggested that a COX-2-dependent pathway may be responsible for the effect of GRP on GRPR expressed by colon cancer cells.

A number of bombesin receptor antagonists have been described by Schally's group. The bombesin/GRP antagonist RC-3095 inhibited the growth of the human gastric MKN45 xenograft model and the HT29 human colon xenograft model in nude mice.

FUTURE THERAPEUTIC APPLICATIONS

Radiolabeled agonists may be used for imaging and therapy, as they appear to be internalized, yielding a higher target:background ratio.

(and tumors). The gene encoding a specific regulatory peptide may also be expressed by multiple cell types. These patterns may themselves change during evolution, giving rise to species differences in cellular expression.

Receptors

Hormonal and neurotransmitter peptides typically act at G protein-coupled receptors (GPCRs). GPCRs constitute a large family of structurally related proteins that are thought to have evolved by the duplication and divergence of ancestral genes. Multiple GPCRs may exhibit differential affinity for the various members of regulatory peptide families. The receptors may themselves be expressed by multiple cell types including CNS or PNS neurons and nonneuronal cells, e.g., secretory cells or smooth muscle cells.

CRITERIA FOR THE IDENTIFICATION OF GUT HORMONES IN PNS OR CNS NEURONS

Evidence for the presence of gut hormones in PNS and CNS neurons should be based on the following lines of evidence: (1) expression of the gene identified by techniques such as reverse transcription-polymerase chain reaction, Northern blot analysis, and *in situ* hybridization and confirmation by cloning and sequencing of the relevant cDNA; (2) the presence of the relevant peptide determined by radioimmunoassay, preferably using antibodies to several epitopes, coupled with high-performance liquid chromatography and confirmation by bioassay, chemical isolation, and amino acid sequencing; and (3) demonstration of cellular origins by immunocytochemistry, preferably using multiple antibodies to several epitopes. Localization of neuropeptides may be a useful way of distinguishing subsets of neurons already identified by the presence of classical transmitters and for this purpose double-labeling immunocytochemistry is useful. There may be problems with the specificity of particular antibodies. For these reasons, the interpretation of studies based on the use of a single experimental method, e.g., immunohistochemistry, using a single antibody should be approached with caution.

CELLULAR ASPECTS

Regulatory peptides produced in gut endocrine cells, CNS neurons, or PNS neurons are, in each case, generated by mRNA translation at the rough

endoplasmic reticulum (Fig. 1). The product (prepro-peptide) is usually biologically inactive and is rapidly converted to a precursor peptide (propeptide) that progresses through the Golgi complex and is sequestered in secretory vesicles that bud from the *trans*-Golgi network. During transit through the Golgi complex, or in secretory vesicles, the propeptide is subject to any of a variety of different posttranslational modifications. These may include glycosylation, Tyr sulfation, and Ser phosphorylation (all of which occur in the Golgi complex), cleavage of the peptide chain, or COOH-terminal α -amino amidation (which occurs in secretory vesicles). The patterns of posttranslational modification for a specific peptide may differ in neurons and endocrine cells. The Golgi-derived secretory vesicles often possess electron-dense cores and their morphology is characteristic of particular cell types. These vesicles are distinct from the small, clear, synaptic vesicles that recycle at nerve terminals and contain classical transmitters such as acetylcholine, monoamines, γ -aminobutyric acid (GABA), and glutamate. Expression of the genes encoding gut hormones is physiologically regulated, but different mechanisms may regulate the expression of these genes in PNS or CNS neurons.

COTRANSMISSION

Increased intracellular Ca^{2+} leads to exocytosis of both Golgi-derived (neuropeptide-containing) and synaptic vesicle populations (Fig. 2). The actions of neuropeptides are exerted at GPCRs, which are not exclusively localized to postsynaptic membranes or even to neurons. As a consequence, peptides may act over longer distances and for longer times than classical neurotransmitters. Where both neuropeptide and classical transmitters act on the same postsynaptic cell, there may be interactions between them. For example, increased or decreased sensitivity to the classical transmitter may be mediated by neuropeptides.

OVERVIEW OF GUT HORMONES EXPRESSED BY PNS NEURONS

Representatives of the gut hormone families are commonly expressed in the major divisions of the autonomic nervous system. In postganglionic parasympathetic neurons, the secretin-like peptides VIP, peptide histidine isoleucine amide (PHI), and pituitary adenylate cyclase-activating peptide (PACAP) are

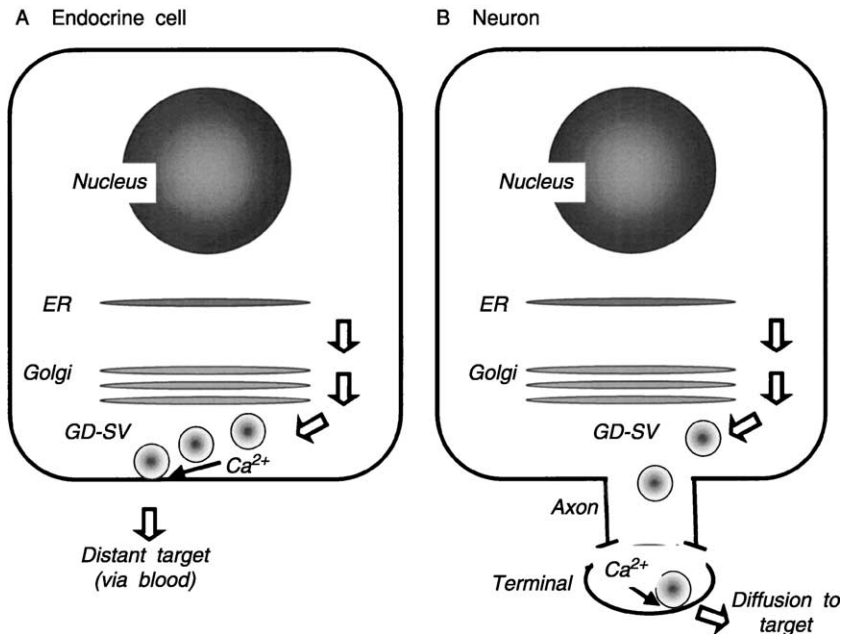

Figure 1 Schematic representation of the intracellular progression of hormonal peptides produced by gut endocrine cells (A) and by central or peripheral neurons (B). In both cases, mRNA is translated at the endoplasmic reticulum (ER) and precursor peptides progress through the Golgi complex; mature peptides are stored in Golgi-derived secretory vesicles (GD-SV) and released by calcium-dependent exocytosis. Peptide released at the basolateral membrane of endocrine cells is conveyed to target cells via the circulation. In neurons, secretory vesicles progress along the axon to nerve terminals for release; in this case, the secreted peptide typically diffuses to its target cells, although peptides released into the hypothalamo-hypophyseal portal vessels are an exception.

commonly expressed, whereas in postganglionic sympathetic neurons, neuropeptide tyrosine (NPY) is commonly expressed. The enteric nervous system, which is sometimes considered to be a third division of the autonomic nervous system, is an abundant source of neuropeptides, including VIP, CCK, and NPY. Many primary afferent neurons express neuropeptides; some of those belonging to the main families of gut hormones (VIP, NPY) are up-regulated after nerve damage. Gut hormonal peptides are not generally found in somatic efferent neurons.

OVERVIEW OF GUT HORMONES EXPRESSED BY CNS NEURONS

The expression of neuropeptides is a property of very many CNS neurons. Gut hormones or related peptides, e.g., somatostatin, CCK, and NPY, are expressed in hypothalamic neurons, where they may act in local circuits or in the control of pituitary hormone release after secretion into hypothalamo-hypophyseal portal vessels. In addition, these and other gut hormones are found in many other CNS

regions, including cerebral cortex, hippocampus, brainstem, and striatum.

MAJOR GUT HORMONE FAMILIES AND THEIR EXPRESSION IN CNS AND PNS NEURONS

The following brief sketches are grouped on the basis of peptide families that include at least one member that is produced and released by gut endocrine cells and at least one that is produced and released by CNS or PNS neurons.

The Cholecystokinin/Gastrin Family

The *CCK* gene is expressed in intestinal I-type endocrine cells and in many CNS neurons and some PNS neurons. There are differences in posttranslational processing that account for the reported variation between neurons and endocrine cells in the major form of CCK present. In cerebral cortical neurons, CCK may occur together with GABA and in some nigrostriatal neurons it occurs with dopamine.

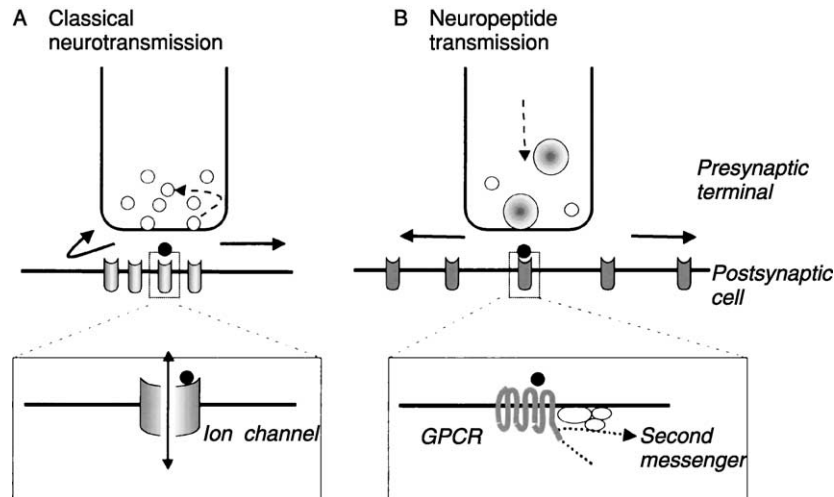

Figure 2 Schematic representation of some events involving neurotransmission by classical (A) and neuropeptide (B) transmitters. Classical transmitters are stored in small, clear synaptic vesicles that are recycled at the nerve terminal. There are reuptake mechanisms for the neurotransmitter, which is resequenced in these vesicles. Receptors for classical transmitters are concentrated in the postsynaptic membrane and are often ion channels. In contrast, neuropeptides are located in Golgi-derived dense-cored vesicles and after secretion they diffuse away from the release site. Neuropeptides typically act at G protein-coupled receptors (GPCR) to trigger second-messenger responses; the receptors may be diffusely distributed on postsynaptic cells and may be some distance from the release site. (●) Putative transmitter.

Gastrin originates from pyloric antral G cells and may be found in small amounts in hypothalamus. The CCK_A (also called CCK_1) receptor has high affinity for CCK and low affinity for gastrin; it is expressed in pancreas, gallbladder, and some CNS and PNS neurons. The gastrin- CCK_B (also called CCK_2) receptor has high affinity for both gastrin and CCK and is found on parietal and enterochromaffin-like cells and many CNS neurons. The main function that has been ascribed to CCK in the brain is inhibition of food intake. In addition, CCK is thought by some to be associated with anxiety or panic attacks and it may modulate noxious sensations.

The Secretin/Glucagon/VIP/PHI/PACAP/GIP Superfamily

The superfamily of structurally related peptides that includes the classical gut hormones secretin and glucose-dependent insulinotropic peptide (GIP) and the pancreatic hormone glucagon also includes major neuropeptide transmitters such as VIP, PHI, and PACAP. In the case of glucagon, there is good evidence that a single precursor molecule may yield several different products through alternative post-translational processing. In the pancreatic islet alpha cells, glucagon itself is a primary product; in intestinal L cells, glucagon-like peptide-1 (GLP-1) and GLP-2

are primary products (but not glucagon). CNS neurons resemble intestine more closely than pancreas in the processing of the glucagon precursor; one possible role for the CNS GLPs is in the control of food intake. Two members of the family that seem to be predominantly expressed in neurons, and not endocrine cells, are VIP (the precursor of which also gives rise to the related peptide PHI) and the closely related peptide PACAP.

Somatostatin

Somatostatin-producing endocrine (D) cells are found throughout the gastrointestinal tract and in the islets of Langerhans. In these systems, somatostatin acts locally as a paracrine inhibitor of secretion from nearby cells, e.g., G cells in the pyloric antrum and beta cells in the pancreas. In addition, somatostatin is produced in hypothalamic neurons and functions as an inhibitor of growth hormone secretion from the anterior pituitary. It is also found in enteric neurons, sympathetic neurons, and some somatic afferent neurons.

Neurotensin

Neurotensin was first isolated from the hypothalamus and then discovered to be produced in N-type

endocrine cells of the ileum and colon, where it is a putative mediator of the ileal brake in the gut. Neurotensin has been identified in multiple CNS neurons; interactions with dopamine have been identified and possible actions as an anti-psychotic agent reported.

The Peptide YY/NPY/Pancreatic Polypeptide Family

Peptide YY is named for the presence of tyrosine residues (Y in the single-letter notation) at both the COOH- and NH₂-terminal positions. It is normally produced in endocrine cells of the ileum and colon. Putative hormonal actions include the inhibition of pancreatic secretion, intestinal transit, and food intake. There is little evidence for neurotransmitter functions. But the closely related NPY is widely expressed in CNS and peripheral neurons. One of its most striking actions is the stimulation of food intake on injection into the hypothalamus. In addition, it is present in sympathetic postganglionic neurons and may modulate responses to noradrenaline. Another member of the family is pancreatic polypeptide, produced in the islets of Langerhans; its functions as either a hormone or a neurotransmitter remain uncertain.

Ghrelin and Motilin

The related peptides ghrelin and motilin are produced in gastric and small intestinal endocrine cells,

respectively. They are distinct from other gut hormones in that they are released from these cells during fasting. Ghrelin is a naturally occurring ligand for an orphan receptor originally identified as a putative mediator of growth hormone secretion. Small amounts are thought to be produced in the hypothalamus. It is a powerful stimulant of food intake and it is thought that the peptide released from the stomach may stimulate food intake by delivery to the hypothalamus through the circulation.

Secretin Family

Several members of the secretin family [secretin, glucagon, vasoactive intestinal polypeptide (VIP), pituitary adenylate cyclase-activating peptide (PACAP), and growth hormone-releasing factor (GRF)] have been localized to Leydig cells, germ cells, or both. Additionally, PACAP, VIP, and GRF have been localized to the ovaries and GRF has also been localized to the placenta. Secretin expression has been detected in the pituitary and VIP expression has been noted in adrenal chromaffin cells, in mast cells, and in leukocytes. VIP suppresses T cell proliferation and production of interleukin-2 (IL-2), IL-4, and IL-10 and acts as an anti-inflammatory mediator. However, VIP may also enhance certain aspects of lymphocyte function and these opposing actions may be mediated by different subtypes of VIP receptors. The effects of VIP on lymphocytes also reflect the rather abundant innervation of lymphoid tissues by VIP nerves.

Neurotensin

Neurotensin has been detected in adrenal chromaffin cells and in leukocytes. In addition, neurotensin is produced by SCLC cells.

Somatostatin

Somatostatin shows a widespread distribution and has been localized to neuroendocrine neurons ending on hypophyseal portal blood vessels in the median eminence, thyroid parafollicular C cells, parathyroid cells of some species, adrenal chromaffin cells, Langhans cells of the epidermis, endocrine-like cells of the prostate and toad urinary tract, and leukocytes. In all of these locations, it seems certain that somatostatin acts as a local paracrine mediator or as a short-range (portal system-delivered) hormone. In general, somatostatin acts as an inhibitor of secretory activities and also reduces cell proliferation, possibly through actions on specific phosphatases. Somatostatin has also been localized to several types of tumors, including breast cancers. It inhibits the proliferation of several normal and neoplastic cell types. Interestingly, antisense oligonucleotides blocking somatostatin expression stimulate the proliferation of rat splenocytes. This effect could be inhibited by the addition of exogenous somatostatin. Additionally, somatostatin inhibits the release of mediators (histamine, leukotriene D₄) from human and leukemic basophils.

Gastrin-Releasing Peptide/Bombesin

Gastrin-releasing peptide (GRP) has been localized to somatotrophs in the anterior lobe and to melanotrophs of the intermediate lobe of the pituitary and it exerts growth hormone-stimulating activity. GRP also occurs in NEBs of the bronchopulmonary tree, particularly during fetal and neonatal life, and has been localized to endocrine-like cells of the prostate. It is produced by a wide selection of human cancer cells of lung (SCLC), mammary, and prostate origin in which it may act as an autocrine growth factor.

CONCLUSIONS

The above data clearly demonstrate that many regulatory peptides simultaneously are produced by cells derived from all three germ layers and that their designation as either gastrointestinal or hormonal is contextual rather than absolute. Many of the peptides may play roles in normal organs, in reproductive functions, and in the immune and cellular defense system of the body (Fig. 1). Additionally, some factors are transiently expressed during development and may serve as tumor growth factors. Indeed, an impressive array of peptides are expressed by lung, gastrointestinal, pancreatic, breast, and prostate cancers and pre-clinical data suggest that they are potential targets for therapy.

formaldehyde vapors under certain conditions (the Falck-Hillarp technique). Using this technique, it was found that the endocrine cells in the GI tract had the capacity to form fluorogenic monoamines, such as dopamine and 5-HT, on administration of the corresponding amine precursor (L-DOPA and 5-hydroxytryptophan, respectively) and to store them in large amounts in their secretory granules. These properties of the cells have sometimes been referred to as APUD (amine precursor uptake and decarboxylation) and became an important means of collectively demonstrating gut endocrine cells, at the same time providing the possibility of discriminating the

EC cells (displaying a yellow fluorescence due to their high endogenous content of 5-HT) from other endocrine cells (displaying green fluorescence due to the newly formed dopamine after L-DOPA administration). These amine-handling properties of gut endocrine cells, as well as some other histochemical features, resemble those of neurons and it was long thought that the embryonic origin of the gut endocrine cells was neuroectodermal. However, it is generally agreed that the endocrine cells, like other epithelial cells lining the GI tract, are of endodermal origin.

During the past few decades, immunocytochemistry, with the use of antibodies against individual hormones or other specific cell markers, has become the most important technique for distinguishing the individual endocrine cell populations with respect to their cellular morphology, their regional and topographic distribution, and—when hormone antibodies are used—their function. However, there are still histochemically or ultrastructurally defined cell populations to which a hormone has not yet been linked. Conversely, there are cell populations that differ in their hormone content, but nevertheless share both light microscopic features and secretory granule appearance.

REGIONAL DISTRIBUTION

The endocrine cells have as a rule a regional distribution along the GI tract that is characteristic for each

Figure 1 Schematic diagram illustrating the distribution and relative frequency (number of cells/unit length of mucosa) of several different populations of endocrine/paracrine cells in the human intestine. Data are based on immunocytochemical observations using hormone antibodies. (Left) Black dots on the outline of the intestine indicate tissue sampling sites. (Right) A compilation of the data. Note that some cell types are distributed throughout the intestine, whereas other cell types have a more restricted distribution. Note also that the rectum is almost as rich in endocrine/paracrine cells as the duodenum.

cell type (Table II, Fig. 1). Thus, certain cell types are restricted to, or greatly predominate, in the stomach. Others are restricted to the upper small intestine and still others predominate in the distal small intestine and/or the large intestine. A few cell types are distributed all along the GI tract. Interestingly, there are several indications that such widely distributed cells may serve to influence cells in their vicinity rather than to deliver their product(s) to the circulation. Such widely distributed cells are therefore often described as paracrine cells. However, since the possibility cannot be excluded that they may, in fact, have dual paracrine and endocrine functions, and since they may share several major morphological features with cells known to be genuinely endocrine, they are sometimes referred to as endocrine/paracrine. With respect to genuinely endocrine cells, it has been argued that each such population should have a restricted distribution along the GI tract in order for the target cells to be able to respond to a circulating messenger in a meaningful way. Nevertheless, an established endocrine function of a cell does not preclude an additional paracrine function.

Stomach

Based on various histochemical techniques, including silver stains, the APUD properties, and immunohistochemistry, and, in particular electron microscopy, with special emphasis on the morphological features of the secretory granules (exemplified in Fig. 2), at least seven endocrine cell types have been described in the stomach. They comprise G cells, D cells, EC cells, enterochromaffin-like (ECL) cells, A-like cells (also referred to as X cells), and two types of cells with small

granules and designated P cells and D₁ cells (Table II). Additionally, in certain species, notably carnivores such as dogs and cats, “true” glucagon-producing A cells, being well-known constituents of the pancreatic islets, are also present in substantial numbers in the stomach. The ECL cells constitute one—and possibly the only—gastric endocrine cell type that is confined to the acid-producing, upper part (corpus fundus or body) of the stomach (Table III). This seems to be the case in all vertebrate species examined, from fish to human. Moreover, the ECL cells are the largest endocrine cell population in this area of the stomach. The ECL cells have a very characteristic secretory granule ultrastructure, which at least in part seems to be linked to the histamine production of these cells. Also, the A-like cells, and, when present, the A cells, are primarily found in this part of the stomach, but they may also occur in smaller numbers in the distal non-acid-producing part (antrum, pylorus) of the stomach.

The G cells are exclusively found in the antrum, where they are located within a zone at the upper part of the glands in most species. However, in rodents they predominate at the basal portion of the glands. The EC cells greatly predominate in the antrum in certain mammals, such as rodents, whereas in the stomach of human and many larger mammals they also occur in the acid-producing part of the stomach in quite high numbers. The D cells are diffusely distributed all over the stomach in all species. These cells very often have narrow cytoplasmic processes that can have a beaded, nerve fiber-like appearance, ending with a knob-like swelling filled with granules (Fig. 3). The small granule cells (P and D₁ cells), like the D cells, seem to occur all over the stomach. The

Figure 2 Electron micrographs of secretory granules of endocrine/paracrine cells in the rat stomach. (A) A-like cell. The granules are round and highly electron-dense. (B) ECL cell. The granules are of the vesicular type with a flocculent electron-dense core surrounded by a wide electron-lucent halo. (C) G cell. Note the varying electron density of the granules. (D) EC cell. Note granule pleomorphism.

Table III Relative Frequency of Different Endocrine Cells in Gastric Oxyntic Mucosa of Rat and Human

| Cell type | Rat (%) | Human (%) |
|---------------------------------------|---------|-----------|
| ECL cells | 65 | 35 |
| A-like (X) + P + D ₁ cells | 24 | 14 |
| Somatostatin cells | 10 | 26 |
| EC cells | 0 | 25 |

D cells have been found to often make direct contact with G cells in the antrum and with parietal cells in the acid-producing part of the stomach. This contact is usually established via the cytoplasmic processes of the D cells. These features, together with the wide distribution of the cells both within the GI tract and outside of it (the pancreatic islets in particular), have contributed to the designation of the D cells as paracrine cells.

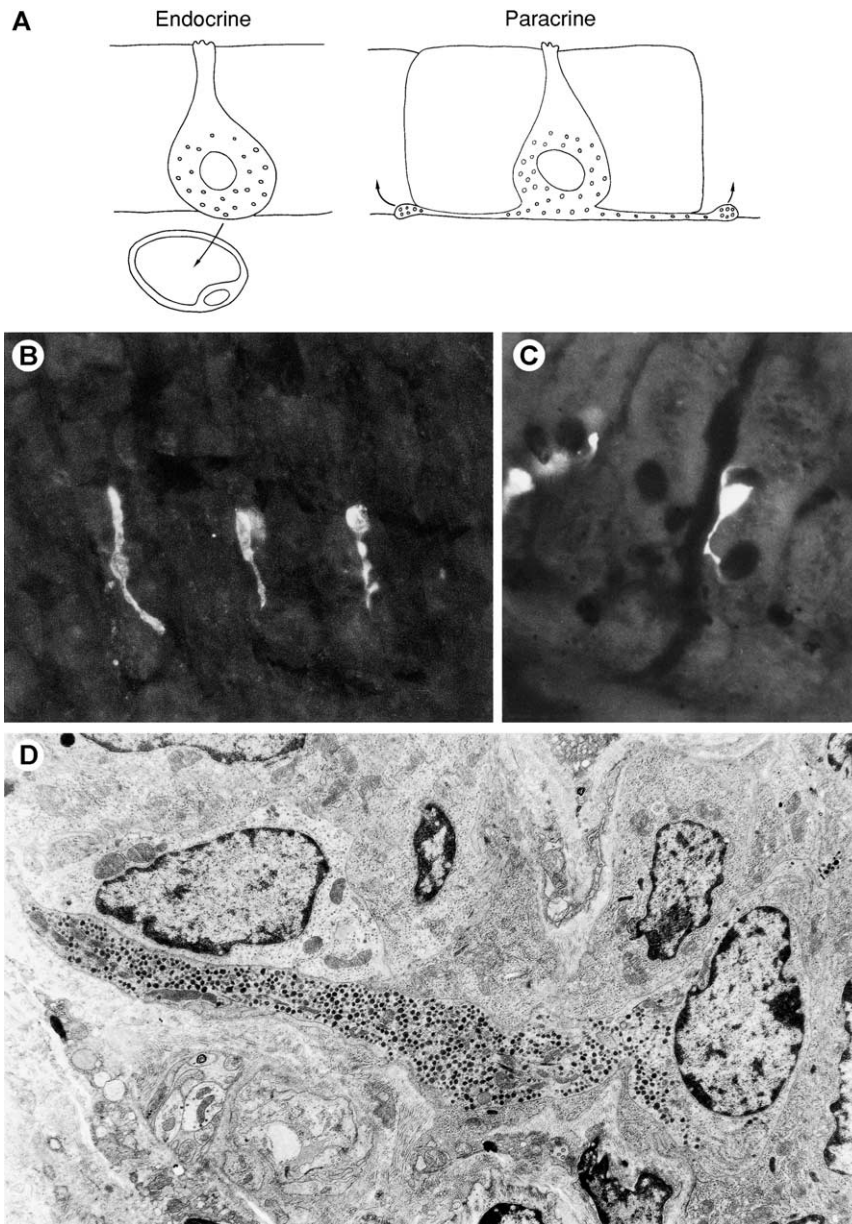

Figure 3 (A) Schematic morphological distinction between endocrine and paracrine cells. (B and C) D cells of rat gastric mucosa (somatostatin immunofluorescence). (B) The cells issue long, slender cytoplasmic processes, sometimes ending in a knob-like swelling. (C) D cell process ending on a G cell (stained black by gastrin immunoperoxidase). (D) Electron micrograph showing a D cell process filled with secretory granules. The process runs along the base of the gland epithelium near the top of the figure.

A general morphological characteristic of the endocrine cells in the upper, acid-producing part of the stomach (i.e., the corpus or fundus) is that they are “closed” in that the apical end of the cell does not reach the gland lumen. In the antrum, on the other hand, the vast majority of cells do reach the lumen via a narrow neck (Fig. 4). One possible explanation for this morphological difference is that open cells respond to luminal stimuli (e.g., nutrients, pH

changes), whereas closed cells are sensitive to other types of stimuli (e.g., distension, temperature changes, neuronal and hormonal messengers).

Small Intestine

Endocrine cells are distributed as single cells within the epithelium of both crypts and villi, but collectively they predominate in the crypts. They are

Figure 4 Electron micrographs illustrating (A) an endocrine cell of closed type (A-like cell) in the acid-producing mucosa and (B) an open endocrine cell in the antral mucosa (G cell) of the rat stomach. Note numerous microvilli at the luminal surface.

characteristically flask-shaped with a narrow, often quite elongated neck reaching the lumen and thus of open type. The secretory granules accumulate at the base of the cell, but may sometimes be more diffusely distributed, although they are always confined to the cytoplasm and are never found in the nucleus. The classification and naming of the intestinal endocrine cells were for a long time based primarily on the size and morphology of the secretory granules. Accordingly, the cells were categorized as, e.g., S (small granules), I (intermediate-size granules), and L (large granules) cells ([Table II](#), [Fig. 1](#)). Subsequent immunohistochemical observations about the cellular localization of various hormones complicated matters and resulted in attempts to retain the letter classification, the inevitable renaming of some cells, and the addition of hormonally classified cells that did not fit into previous classifications. Thus, the classification of endocrine cells in the small intestine is often a mixture of letter naming and naming based on the hormone content of the cells. At least 11 different cell types have been identified ([Table I](#)). The EC cells are distributed throughout the small intestine. The D cells also occur throughout the small intestine, although in gradually smaller numbers distally. Some cell types are more restricted in their regional distribution. Thus, S cells, I [cholecystokinin (CCK)] cells, K cells, and MO (motilin) cells predominate in the duodenum and upper jejunum and are only rarely found in the ileum. The opposite is true for L cells and N cells, which predominate in the ileum, but are scarce in the duodenum. According to ultrastructural criteria, P cells are also present in the small intestine, with a distribution mainly in the upper part. One cell type with very large granules (VL cells) has been reported to occur throughout the human small intestine.

Large Intestine

The large intestine also harbors endocrine cells of several different kinds, although it seems that the number of different populations is somewhat smaller than in the small intestine. Interestingly, the endocrine cells are collectively more numerous in the rectum than in the colon, as calculated in the human gut ([Fig. 1](#)). At least five different endocrine cell populations can be distinguished in the large intestine. It is notable that there is a marked overlap in the distribution of certain cell populations between the distal small intestine and the large intestine ([Table II](#)). Thus, EC cells and L cells are quite numerous also in the large intestine. N cells, on the

other hand, are only rarely found in the large intestine and D cells are also clearly fewer in number here than in the small intestine. As to morphology, many of the endocrine cells have a very characteristic appearance in that each cell at its base issues a long, tapering, sometimes beaded process running along the base of the epithelium. Furthermore, the process often seems to be directed toward the base of the crypt. This gives the cells a paracrine-like appearance. However, since cells thought to play a role as hormone producers, such as the L cells, also have this morphology, it is still open to speculation why the cells are equipped with such long processes. It is not inconceivable that the cells serve both endocrine and paracrine functions.

CONCLUDING REMARKS

As is obvious from the data presented here, there is some confusion and remaining uncertainties as to the classification and naming of endocrine cells in the GI tract. This is due to the fact that endocrine cells sharing staining characteristics with cells occurring outside the GI tract, notably, the pancreatic islets, which are known by the “islet” name. This applies to islet A cells and D cells. Another problem arose when an ultrastructurally defined cell type, e.g., the L cell, was later found to comprise at least two functionally distinct cell populations, one producing proglucagon-derived peptides (retaining the L cell designation) and another producing neurotensin (renamed N cells).

Figure 5 Endocrine cell plasticity illustrated by the marked hyperplasia of rat ECL cells (B) and G cells (D) on pharmacological blockade of acid secretion for 8 weeks. Acid blockade causes G cell activation and hyperplasia with hypergastrinemia, which in turn brings about activation of the ECL cells with increased histamine secretion and, with time, proliferation. ECL cells are visualized with histidine decarboxylase immunofluorescence and G cells are visualized with gastrin immunofluorescence.

Another problem is related to the I cell. Obviously, several functionally distinct endocrine cell populations fall into this somewhat vague category. Thus, CCK cells, K cells, and MO cells are all “I” cells, but with the current possibilities of a more detailed functional classification, the hormone name, or its short name, is gradually replacing the original letter name.

Furthermore, the largest population of endocrine cells, the EC cells, are probably not one single cell type, but rather several functionally distinct populations, unified merely because they produce large amounts of serotonin. This view is favored by available ultrastructural data showing different types of granules in EC cells in different regions of the gut, and sometimes even in different EC cells within the same region, together with the fact that certain regulatory peptides are restricted to subpopulations of EC cells only.

Finally, it ought to be mentioned that there is a remarkable potential for plasticity in gut endocrine cell systems. This is perhaps most readily observed in the stomach, where each of the endocrine cell populations has a restricted regional distribution and the cells are more frequent per unit area. Thus, marked hyperplasia of G cells and ECL cells (within their normal regional boundaries) evolves within some time (days to a few weeks) after, e.g., profound pharmacological blockade of acid secretion (Fig. 5) and ECL cell hypoplasia after, e.g., removal of the G cells (antrectomy).

manipulation in mice. Proliferating or transformed gut endocrine cells may variably express the same antigens as their normal counterpart depending on their differentiation status. Expression of the SSR2 in endocrine tumor cells is important for both diagnostic and therapeutic applications.

NONNEOPLASTIC GROWTHS OF GUT ENDOCRINE CELLS

Nonneoplastic growths of gut endocrine cells have been reported only in the stomach and occasionally in the small intestine.

Stomach

Nonneoplastic growths are restricted to proliferation of histamine-producing enterochromaffin-like (ECL) cells in the corpus/fundus and of gastrin-producing (G) and somatostatin-producing (D) cells in the antrum/pylorus. Hypergastrinemia-promoted ECL cell hyperplasia is categorized as diffuse (an increase in endocrine cells of more than twice the standard deviation compared to age- and sex-matched controls), linear (sequences of five or more cells inside the basement membrane of the gastric gland), micronodular (clusters of five or more endocrine cells up to 150 μm in diameter), and adenomatoid (collection of five or more micronodules adherent to one another but with interposition of basement membranes and thin strands of lamina propria). Dysplasia is characterized by 150 to 500 μm lesions formed by moderately atypical endocrine cells and defined as

enlarged micronodules (nodules of $\geq 150 \mu\text{m}$), adenomatous micronodules (collections of at least five micronodules), fused micronodules (disappearance of the intervening basal membrane between adjacent micronodules), and microinfiltrative lesions (microinfiltration of the lamina propria by endocrine cells filling the space in between glands).

G cell hyperplasia is defined as an increase in gastrin cell number (above 140) when counted per linear millimeter of mucosa in 5 μm thick histological sections. It may be associated with reduced somatostatin (D) cell count, resulting in an elevated G/D cell ratio.

Long-standing hyperchlorhydria associated with duodenal G cell tumor may result in increased D cells of the antrum and a reduced G/D cell ratio.

Intestine

Increased numbers of somatostatin D cells are observed in the small intestine of patients with celiac disease. Hyperplasia of unspecified argyrophil endocrine cells was reported in chronic inflammatory bowel disease.

TUMORS

General

Endocrine tumors of the gut are found at any level of the gastrointestinal tract (Table II). According to epidemiological data, in Western countries endocrine tumors more commonly display an age-standardized rate of approximately 1/100,000 and more frequently

Table II Tumor Type, Distribution, and Cell Features of the Endocrine Tumors of the Gastrointestinal Tract

| Tumor type | Preferred site | Main cell type | Hormonal products |
|---|---------------------------------|-----------------|------------------------|
| Well-differentiated endocrine/tumor/carcinoma | Stomach, body/fundus | ECL | Histamine 5-HT/5-HTP |
| | Duodenum, antrum, jejunum | G | Gastrin |
| | Duodenum | D | Somatostatin |
| | Appendix, ileum, jejunum, cecum | EC | Serotonin ^d |
| | Rectum, colon | L | Glicentin, PP, PYY |
| Gangliocytic paraganglioma | Duodenum | PP, D | PP, somatostatin |
| Poorly differentiated endocrine carcinoma | Stomach intestine | Proto-endocrine | None |

Note. ECL, enterochromaffin-like cell; EC, enterochromaffin; 5-HT, 5-hydroxytryptamine (serotonin); 5-HTP, 5-hydroxytryptophan; PP, pancreatic polypeptide; PYY, peptide tyrosine tyrosine.

^dSubstance P, tachykinins, and other peptides.

occur in the colorectum, followed by the small intestine and stomach, occur more frequently in females, and increase in incidence with age.

The diagnosis of endocrine tumors is based on the identification of their characteristic morphology and of their antigenic asset, as defined by the expression of markers of endocrine differentiation (as described above) and hormones. According to the new World Health Organization classification, gut endocrine tumors are classified as follows: (1) well-differentiated endocrine tumors, including tumors with benign behavior and tumors with indefinite behavior at diagnosis; (2) well-differentiated endocrine carcinomas, low grade; and (3) poorly differentiated endocrine carcinomas, high grade.

Well-Differentiated Neoplasms

Well-differentiated tumors are characterized by bland histological and cytological features, low cytological atypia, low mitotic index, and diffuse expression of general markers of endocrine differentiation. Cell-specific markers are in general observed in tumor cell subpopulations.

The definition of carcinoma is restricted to well-differentiated endocrine neoplasms with overt malignancy at diagnosis, i.e., synchronous metastasis, and/or deep wall invasion. In the absence of the above features, the behavior of well-differentiated tumors may be unpredictable, though independent of tumor cell typing and related to various clinicopathological variables. Predictors of poor outcome are as follows: tumor size (larger tumors usually are more aggressive); invasion of nearby tissue (appendix) or wall invasion beyond the submucosa; angioinvasion and invasion of perineural spaces; solid, nonorganoid structure; necrosis; overt cell atypia; more than two mitoses in 10 microscopic high-power fields (HPF); Ki67 proliferation index higher than 2% or of >100 in 10 HPF; reduction in or loss of chromogranin A immunoreactivity, argyrophilia, and/or nuclear p53 protein accumulation. The predictive value of most of these variables still needs confirmation from investigations on large series of endocrine tumors of the small and large intestine.

Stomach

ECL Cell Tumors

By far the most frequent endocrine tumor of the stomach, ECL cell tumors display strong argyrophilia by silver impregnation techniques, immunoreactivity for chromogranin A and vesicular monoamine

transporter 2, and no or focal immunoreactivity for ghrelin, serotonin, gastrin, and somatostatin.

Three clinicopathologic subtypes are defined as follows: type I, associated with diffuse chronic atrophic gastritis of autoimmune or A type; type II, associated with hypertrophic gastropathy, usually in conjunction with MEN1 and Zollinger-Ellison syndrome (ZES); and type III or sporadic, not associated with a specific gastric pathology. Of the three subtypes, type I tumors are the most frequent (70–80% of published series), occur in elderly female patients, and, though multiple and multicentric, are small, limited to the mucosa and submucosa and demonstrate an excellent prognosis for survival. Type II tumors are rare (~6% of published series), multiple, and multicentric; they usually display a good prognosis, though metastases may be present and rare cases with an aggressive course have been described. In contrast, the solitary type III tumors are less frequent (~15% of published series), occur more frequently in male patients, are larger, and, in general, display a more aggressive behavior with frequent metastases and malignant course. Of note, type III tumors may associate with the so-called “atypical carcinoid syndrome” due to histamine and/or 5-hydroxytryptophan hypersecretion.

Other Tumor Types

Exceedingly rare gastrin G cell tumors have been reported in the antrum, similar to rare D cell tumors of both the oxyntic and antral mucosa. Such tumors usually are not associated with any hyperfunctional syndrome.

Intestine

Gastrin G Cell Tumors

Gastrin G cell tumors occur in the duodenum or upper jejunum of male patients. When “functioning,” they can be defined as gastrinomas, are the cause of the ulcerogenic ZES, and frequently are associated with MEN1. Though small in size, G cell tumors, especially when functioning, frequently metastasize, especially to local lymph nodes.

D Cell Tumors

Somatostatin D cell tumors are rare tumors of the duodenum (preferentially at the ampulla of Vater) and upper jejunum in patients in the fifth decade of life. Often associating with type 1 neurofibromatosis and only rarely with diabetes and/or gallstones, they may be defined as functioning, though the complete somatostatinoma syndrome (diabetes mellitus, diarrhea, steatorrhea, hypo- or achlorhydria, anemia, and

gallstones) has been described for pancreatic D cell tumors only. Intestinal D cell tumors are often malignant and may metastasize to both local lymph nodes and the liver.

Ganglioneuromatous Paraganglioma

Rare tumors composed of endocrine cells, mature ganglion cells, and Schwann-like spindle cells develop in the submucosa of the periampullary duodenal region in middle-aged patients. In general, ganglioneuromatous paragangliomas display benign behavior, though local lymph node metastases of the endocrine component have been reported in occasional cases.

Serotonin EC Cell Tumors

Most serotonin-producing enterochromaffin (EC) cell tumors develop in the intestine, with decreasing frequency in the ileum, cecum, appendix, jejunum, duodenum, distal colon, and rectum. Intestinal EC cell tumors may display relatively aggressive behavior since often they are multiple (small intestine), are of large size (colon), and deeply infiltrate the intestinal wall, with frequent lymph node metastases. A typical carcinoid syndrome due to the unregulated release of serotonin and other active substances by tumor EC cells may occur in association with such tumors, depending on the establishment of liver metastases. In contrast, appendiceal EC cell tumors, despite the deep wall invasion often observed, in general run a benign course.

Glicentin/PYY L Cell Tumors

L cell tumors most frequently develop in the colon and rectum and rarely at other sites of the intestine and appendix. The majority of L cell tumors are small, do not associate with any hyperfunctional syndrome, and run a benign course.

Poorly Differentiated Endocrine Carcinomas

Poorly differentiated endocrine carcinomas are aggressive carcinomas reported to occur at any site

in the gut, except the appendix, of patients in the seventh decade of life. Poorly differentiated endocrine carcinomas display a solid structure, abundant necrosis, small cell cytology, severe cellular atypia, a high mitotic index, no or faint chromogranin A expression, and diffuse expression of NSE and synaptophysin. Additional features include a high Ki67 index and p53 accumulation as observed with immunohistochemistry, whereas cell-specific endocrine markers are absent. Similar to undifferentiated carcinomas, poorly differentiated endocrine carcinomas run a very aggressive course.

Figure 1 Comparison of the amino acid sequences of human and rat CGRP- α and CGRP- β , human amylin, and human adrenomedullin.

CGRP RECEPTORS

The biological effects of CGRP are brought about by interaction with specific membrane receptors, two subtypes of which, the CGRP₁ and CGRP₂ receptors, have been proposed to exist on the basis of bioassay observations. Characteristic of the CGRP₁ receptors is their sensitivity to the antagonistic effect of the human CGRP₈₋₃₇ fragment. The molecular identification of functional CGRP receptors turned out to be very difficult because they are assembled from three different proteins (Fig. 2): the calcitonin receptor-like receptor (CRLR), the receptor-associated membrane protein 1 (RAMP-1), and the receptor component protein (RCP). Although CRLR is the CGRP-recognizing protein, the CGRP receptor becomes functional only if CRLR is associated with RAMP-1. This chaperone protein is important for the intracellular translocation of CRLR and its insertion into the plasma membrane and for conferring a CGRP₁ receptor-like binding profile on CRLR. RCP seems to be required for efficient coupling of the receptor to the G protein-adenylate cyclase signaling machinery (Fig. 2).

CRLR can associate not only with RAMP-1 and RCP to produce a CGRP₁ receptor, but also with RAMP-2 or RAMP-3, two other chaperone proteins sharing approximately 30% sequence homology with RAMP-1. These RAMPs dictate the pharmacological profile of the receptor complex inasmuch as CRLR associated with RAMP-2 behaves as an adrenomedullin receptor and human calcitonin receptor isotype 2 associated with RAMP-1 or RAMP-3 behaves as an amylin receptor.

EXPRESSION AND RELEASE OF CGRP IN THE GI TRACT

The principal sources of CGRP in the digestive system are extrinsic primary afferent nerve fibers and

intrinsic enteric neurons. Although the CGRP that is expressed in primary afferents of the rat is CGRP- α , the only form of CGRP in enteric neurons is CGRP- β . The relative contribution of extrinsic afferent and intrinsic neurons to the overall CGRP content of the GI tract varies among different gut regions and different mammalian species. Most of the CGRP found in the esophagus and stomach of small rodents is derived from primary afferents, whereas the small intestine and large intestine contain a sizable number of CGRP-positive enteric neurons that issue specific projections to other enteric ganglia, muscle, and mucosa.

The majority of the CGRP-expressing extrinsic afferent neurons in the rodent gut originate from cell bodies in the dorsal root ganglia and reach the gut via sympathetic and sacral parasympathetic nerves. Within the wall of the GI tract, they innervate primarily arteries and arterioles but also project to the mucosa, enteric nerve plexuses, and muscle layers. CGRP-positive vagal afferents originating from the nodose ganglion supply the esophagus and proximal part of the stomach but make a relatively small contribution to the content of CGRP in the gastric corpus, antrum, and intestine.

As is expected for substances with a vesicular localization, CGRP is released from GI neurons in a calcium-dependent manner when these cells are stimulated. This is, for instance, the case when the mucosa of the stomach and duodenum is exposed to excess acid, which releases CGRP from primary afferent nerve fibers. Peptide release from spinal afferents in the gut can also be elicited by the vanilloid capsaicin because these nerve cells, but not enteric neurons, express vanilloid receptors of type 1. With the use of capsaicin, it has furthermore been found that CGRP in the general circulation represents primarily an overspill of peptide released from peri- and paravascular afferent nerve fibers.

Figure 2 Diagram of the CGRP receptor complex consisting of the calcitonin receptor-like receptor (CRLR), the receptor-associated membrane protein 1 (RAMP-1), and the receptor component protein (RCP). Association of CRLR with RAMP-1 forms a high-affinity CGRP₁ receptor, which, through RCP, is coupled to the G protein G_s and thereby can activate adenylylate cyclase (AC) to produce cAMP.

Apart from neurons, CGRP is also found in endocrine cells of the human GI mucosa and rat pancreas and in blood-derived or resident immune cells within the lamina propria of the rat gastric mucosa. However, the quantitative and functional significance of these sources is still not very well understood.

EFFECTS, PHYSIOLOGICAL ROLES, AND PATHOLOGICAL IMPLICATIONS OF CGRP IN THE GI TRACT

Motor Activity

The most prominent motor action of CGRP in the active gut is muscle relaxation via CGRP₁ receptors, which leads to retardation of gastric emptying and attenuation of motor activity throughout the digestive tract. However, CGRP is also able to excite cholinergic motor pathways, which is in keeping with the peptide's ability to depolarize intrinsic sensory neurons of the myenteric plexus, to enhance the release of acetylcholine from enteric neurons, and to cause contraction of the resting muscle.

There is still scarce information as to whether CGRP released from intrinsic or extrinsic neurons of the gut plays a physiological role in the neural control of GI motility. The claim that CGRP released from sensory neurons contributes to distension-induced peristalsis is not universally accepted. There is, however, evidence that CGRP released from extrinsic afferent nerve fibers contributes to the pathological shutdown of GI motility in postoperative and peritonitis-induced ileus. This is consistent with the

observation that CGRP acting via CGRP₁ receptors contributes to the inhibition of intestinal peristalsis that ensues after sensory neuron stimulation.

Secretory Processes

Electrolyte and fluid secretion in the small intestine of the dog and in the colon of the guinea pig and rat is stimulated by CGRP. Whereas the secretory effect of CGRP in the rat colon arises from a direct action on enterocytes, as is the case with human epithelial cell lines, CGRP's secretory action in the guinea pig colon is mediated by enteric neurons. Although a physiological role for CGRP in the control of intestinal secretory activity has not yet been determined, it seems as if the peptide contributes to the pathological fluid secretion that in the rat ileum is evoked by *Clostridium difficile* toxin A. The secretagogue-evoked secretion of enzyme, bicarbonate, and fluid from the pancreas of the dog and rat *in vivo* is blunted by CGRP through an action involving somatostatin, whereas amylase secretion from isolated acini of the rat and guinea pig pancreas is enhanced by the peptide.

There is good evidence that, in the stomach, CGRP contributes to the homeostatic regulation of endocrine and exocrine secretory processes. Thus, CGRP potently depresses basal and secretagogue-evoked output of acid and pepsin in the stomach of human, dog, rabbit, and rat, an action that is brought about by CGRP₁ receptors, depends on somatostatin as an essential mediator, and goes along with attenuation of the release of acetylcholine, gastrin, and

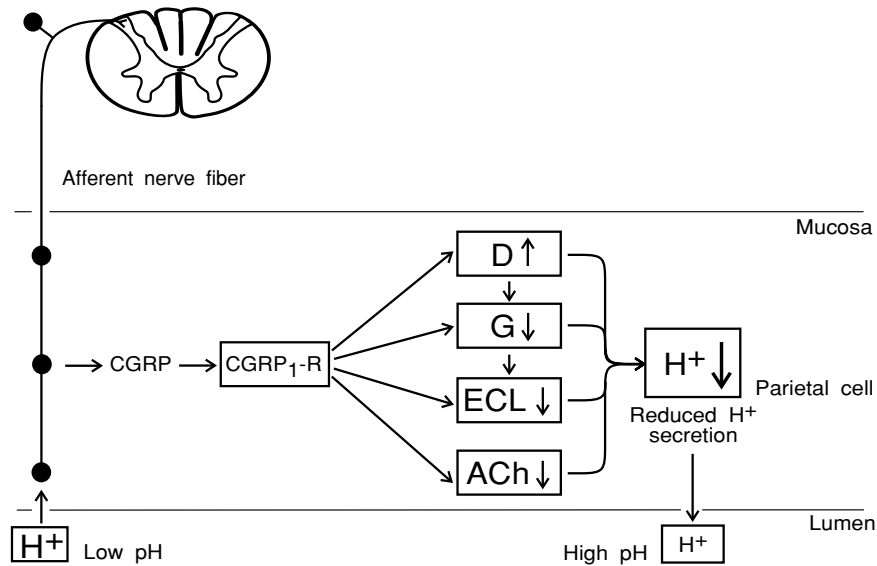

Figure 3 Diagram illustrating the role of CGRP-releasing afferent nerve fibers in the feedback control of gastric acid secretion in the rat stomach. When the acidity in the lumen rises, afferent nerve fibers release CGRP, which, via activation of CGRP₁ receptors (CGRP₁-R), stimulates the release of somatostatin and inhibits the release of gastrin, histamine, and acetylcholine. D, endocrine D cells releasing somatostatin; G, endocrine G cells releasing gastrin; ECL, enterochromaffin-like cells releasing histamine; ACh, neurons releasing acetylcholine.

histamine (Fig. 3). These effects are physiologically relevant, given that the CGRP₁ receptor antagonist CGRP₈₋₃₇ augments basal and stimulated acid secretion and acid accumulation in the gastric lumen releases CGRP from sensory nerve fibers. Through its effects on the release of somatostatin, gastrin, histamine, and acetylcholine, CGRP halts further secretion of acid and thus mediates feedback inhibition of gastric acid output (Fig. 3).

Vascular Functions

The arteries and submucosal arterioles of the GI tract receive the densest innervation by extrinsic afferents containing CGRP. This finding, the expression of CGRP₁ receptors on the endothelium and smooth muscle of arteries and arterioles, and the peptide's vasodilator activity point to a vasoregulatory function of CGRP. Indeed, nonadrenergic noncholinergic dilation of the rat superior mesenteric artery is mediated by capsaicin-sensitive afferent nerve fibers releasing CGRP. In contrast, the physiological significance of CGRP in the microcirculation of the small and large intestine is little known. Although CGRP dilates submucosal arterioles in the guinea pig ileum, it fails to alter mucosal blood flow in the rat small and large intestine.

The situation is different in the rat stomach, where CGRP is highly potent in causing a CGRP₁

receptor-mediated dilation of submucosal arterioles, but not venules. Vasodilation induced by low doses of CGRP is mediated through a mechanism that involves nitric oxide, whereas high doses of the peptide increase blood flow independent of nitric oxide. Although CGRP does not seem to regulate gastric blood flow in physiological circumstances, there is evidence that CGRP comes into play under pathological conditions. This role is best exemplified by the hyperemic response that ensues when the gastric mucosal barrier is disrupted by ethanol or bile salts so that acid can enter the tissue and damage the gastric mucosa. The CGRP-mediated rise in blood flow in response to acid influx serves a protective role in the gastric mucosa as it helps to neutralize and wash away intruding acid and delivers bicarbonate and other factors to defend and repair the mucosa. Another example relates to the *C. difficile* toxin A-evoked inflammation in the rat ileum, which involves CGRP as a pro-inflammatory mediator.

Mucosal Homeostasis

There are several lines of evidence to indicate that GI mucosal integrity and repair are under the control of extrinsic afferent neurons releasing CGRP. First, CGRP protects the mucosa in a number of experimental models of gastric injury and colonic inflammation. The action of CGRP to reduce

ethanol-induced damage in the gastric mucosa is mediated by CGRP₁ receptors and involves nitric oxide. Second, CGRP mediates the gastroprotective effect of a number of factors and drugs that stimulate capsaicin-sensitive afferent nerve fibers. Thus, blockade of CGRP₁ receptors with CGRP₈₋₃₇ prevents the ability of intragastric capsaicin to attenuate experimentally imposed injury as does immunoneutralization of CGRP with polyclonal and monoclonal antibodies to the peptide. Third, CGRP₈₋₃₇ and active immunization of rats against CGRP exacerbate experimental injury in the stomach.

In summary, CGRP released from sensory nerve fibers strengthens gastric mucosal defense and facilitates repair of the wounded mucosa via vasodilation, hyperemia-dependent processes, such as appropriate delivery of bicarbonate, and hyperemia-independent mechanisms, such as secretion of mucus. Complementary evidence for such a homeostatic role for CGRP-releasing nerve fibers in the GI mucosa comes from the observation that sensory neuropathies weaken the resistance of the tissue to injury. This applies not only to the stomach, but also to the esophagus, small intestine, and colon, where experimentally induced inflammation and damage are aggravated.

Gastrointestinal Sensitivity and Nociception

Since CGRP is a transmitter of nociceptive afferent neurons innervating the gut, it does not come as a surprise that CGRP can mediate GI pain and inflammatory hyperalgesia. Intraperitoneal administration of exogenous CGRP or acetic acid-induced release of endogenous CGRP in the rat peritoneum triggers abdominal muscle contractions, a reaction that is indicative of pain. Of particular importance is the finding that CGRP₈₋₃₇ prevents inflammation-induced hypersensitivity to colonic distension. Since, in this respect, intrathecal CGRP₈₋₃₇ is more potent than intravenous CGRP₈₋₃₇, the site of CGRP-mediated hyperalgesia is primarily in the spinal cord.

SUMMARY

CGRP is a transmitter candidate of intrinsic enteric neurons and extrinsic afferent nerve fibers in the GI tract. As such, this neuropeptide seems to be involved in the neural regulation of GI functions. Its major

actions include depression of GI motility, rise of gastric blood flow, inhibition of gastric acid secretion, enforcement of GI mucosal resistance, and mediation of inflammatory hyperalgesia. Furthermore, there is evidence that a disturbance of the GI CGRP system may contribute to a number of GI disorders and that a correction of these perturbations may be of therapeutic potential.

| Ectopic |
| Somatostatin deficiency |

Pituitary GH Excess Caused by Activation of the $G_{s\alpha}$ Subunit of the G Protein Receptor with or without McCune-Albright Syndrome

The G protein-coupled receptors are the largest family of membrane receptors. Peptides (vasopressin, glycoproteins, adrenocorticotrophic hormone [ACTH], GHRH, melanocyte-stimulating hormone [MSH]), neurotransmitters, and prostaglandins can bind to this receptor family. When a stimulatory ligand binds to the receptor, the α subunit of the G protein ($G_{s\alpha}$) is activated by replacement of GDP by GTP. This subsequently leads to activation of adenylate cyclase and cyclic AMP formation. It finally results in phosphorylation of substrates that control metabolism, gene transcription, secretion, and cell proliferation. Normally, intrinsic GTPase stops activation of $G_{s\alpha}$. A mutation in the gene encoding the α subunit of the stimulatory G protein receptor results in constitutive activation of the protein, by inhibiting the intrinsic GTPase activity. This has a tumorigenic effect. Thirty to 50% of pituitary adenomas in gigantism are caused by this mechanism.

McCune-Albright syndrome is a rare disorder, classically defined by fibrous dysplasia, café au lait spots, precocious puberty, and other hyperfunctional endocrinopathies. In all patients with the McCune-Albright syndrome, a mutation in the gene for the α subunit is found. It is assumed that the timing of the mutation in development determines which tissues are affected and in this way contributes to the heterogeneity of the clinical presentation. Approximately 20% of the cases of gigantism are associated with McCune-Albright syndrome. GH-producing tumors in these patients are the result of a mutation in the gene encoding the α subunit of the G protein receptor of somatotroph cells, leading to constitutive activation of the $G_{s\alpha}$ protein, resulting in hyperplasia and adenoma with GH overproduction.

| Miscellaneous tumors |
| Plurihormonal adenomas |

Pituitary GH Excess Caused by an Adenoma by Other Molecular Causes

Pituitary adenomas are benign tumors consisting of adeno-hypophysial cells. They are often slowly growing, expansive tumors confined to the sella turcica, which are usually detected because of the clinical effects of the oversecreted hormones. Adenomas can be classified according to their size, microadenomas (<10 mm) and macroadenomas (>10 mm), but a morphological classification (Table II) is more useful.

In gigantism, mammomatotroph adenomas are the most frequent histological type. The mammomatotroph cells, producing prolactin and GH, observed in these adenomas resemble the mammomatotrophs identified in the fetal pituitary at 9.5 weeks gestation. It is thought that pituitary adenomas are derived from an intrinsic pituitary cell defect, leading to clonal expansion of a single transformed cell. The exact mechanisms by which these cells transform into tumorous cells is unknown. Inactivating mutations of tumor suppressor genes are associated with pituitary tumorigenesis, as shown in multiple endocrine neoplasia (MEN-I) syndrome, which is characterized by hyperfunction or tumor formation in the parathyroids, anterior pituitary, and pancreatic cells and rarely in the thyroid and adrenal cells. Pei and Melmed cloned a novel pituitary tumor-transforming gene. High-level expression of this gene in GH-secreting adenomas suggests that it plays a role in pituitary tumorigenesis.

Excess of GHRH

Eutopic GHRH Excess

Secondary GH overproduction due to hypothalamic GHRH excess is an important cause of gigantism. GHRH excess usually results in mammomatotroph hyperplasia and rarely in adenoma formation.

In a case report of congenital gigantism due to GH and prolactin-producing cell hyperplasia, high serum levels of GHRH were found. There was no evidence of a hypothalamic GHRH-producing tumor, suggesting that a congenital hypothalamic regulatory defect resulting in early GHRH exposure leads to mammosomatotroph hyperplasia.

Ectopic GHRH Excess

Ectopic GHRH-producing tumors are a well-known cause of acromegaly, but very rarely cause gigantism. Thus far, only two cases have been described. In one patient, a 15-year-old girl, the GHRH-producing primary tumor was located in the jejunum and resulted, together with GHRH-producing liver metastases, in severe GH hypersecretion causing gigantism. The other case is an 18-year-old boy with GHRH-like activity in a metastatic carcinoid tumor in the foregut.

Another cause of intracranial GHRH excess occurs in the setting of neural tumors, such as gangliocytoma or neurocytoma, within or in close proximity to the sella.

GH Excess by Somatostatin Deficiency

A few cases have been documented in which GH excess is found in children with neurofibromatosis and optic gliomas or astrocytomas. It has been suggested that infiltration of the glioma in the medial temporal lobe causes a reduction in somatostatin, leading to increased GH levels and interference with the normal pulsatility of GH release.

DIAGNOSIS

In all patients with an increased growth velocity and progressive upward deviation from the population reference curves, GH excess should be considered. In young children, body proportions are normal and usually the increased growth is the only sign of gigantism. In adolescents, the typical features of acromegaly, such as thickening of the skin, enlargement of the lower jaw, hands, and feet, coarsening of facial features, and excessive body sweating, may be present. Later, a eunuchoid habitus can develop because of incomplete or absent puberty. Depending on the type and expansion of the adenoma, secretion of other pituitary hormones can be affected. As adenomas often secrete GH as well as prolactin, hyperprolactinemia may occur, manifesting as galactorrhea. Gonadotropin deficiency leads to hypogonadotropic hypogonadism and incomplete or absent puberty.

Less often, ACTH or TSH deficiency occurs. Because of compression of the optic chiasm, impaired vision and visual field abnormalities can be presenting symptoms.

Serum GH levels are elevated in gigantism. Whereas in overnight GH profiles of healthy individuals, baseline levels do not exceed 0.5 ng/ml, in giants these levels are seldom less than 5 ng/ml. Serum levels of IGF-I and IGF-binding protein 3 (BP3) are elevated compared with age and gender references. However, interpretation of IGF-I levels is difficult during puberty because of the physiological IGF-I increase at that time.

Normally, oral glucose ingestion (1.75 g per kilogram of body weight) suppresses GH levels to less than 1 ng/ml, whereas in patients with GH excess, GH levels are not suppressed and may even show a paradoxical increase. However, in children and adolescents, the oral glucose tolerance test is less useful for diagnosing GH excess, as absent suppression is also common in healthy tall children and adolescents. Similarly, the presence of paradoxical GH response to thyrotropin-releasing hormone and luteinizing hormone-releasing hormone is of little use in this age group.

In the diagnostic workup, the other pituitary hormones should obviously also be assessed. Prolactin is elevated in approximately half the cases and may be associated with galactorrhea and contribute to hypogonadism. Gonadotropin secretion is often decreased because of compression of gonadotropin-secreting cells by the hyperplastic or adenomatous somatotroph cells. The thyroid-stimulating hormone and ACTH axes should be investigated, although these are mostly not affected. GHRH measurement can be helpful in differentiating GHRH excess from primary GH hypersecretion.

As insulin resistance can occur, the insulin response to glucose must be measured. Bone age should be assessed, but is usually not advanced, or only little advanced, during childhood. A skull X ray may reveal enlargement of the sella turcica. When GH excess is confirmed, neuroradiological studies including magnetic resonance imaging for tumor localization and extension are essential.

For illustrative purposes, two cases with gigantism are shown in [Figs. 1 and 2](#). Case 1 presented with tall stature at 8.5 years of age. He had serum GH levels fluctuating between 100 and 150 ng/ml, very elevated serum IGF-I levels, and a GH-producing adenoma with suprasellar extension. After transsphenoidal resection of the adenoma, a small tumor remnant remained. Bromocriptine treatment was sufficient for

Figure 1 Growth curve of a patient with a growth hormone-producing adenoma.

a normalization of plasma GH levels and final height was limited by supraphysiologic testosterone treatment. His growth pattern is shown in Fig 1. Case 2 presented with pseudo-precocious puberty, a pigmented macula with irregular margins, resembling the coast of Maine, typical for McCune-Albright syndrome, and polyostotic fibrous dysplasia. Initially, he was treated with cyproterone acetate and ketoconazole for his pseudo-precocious puberty, but soon it became clear that he also had GH excess, with mean GH levels between 10 and 15 ng/ml. From 12.4 years of age, he was subsequently treated with bromocriptine, octreotide, and cabergoline. Bisphosphonates were prescribed to restrict the damage of the fibrodysplastic lesions. His growth curve is shown in Fig 2.

Figure 2 Growth curve of a patient with McCune-Albright syndrome.

DIFFERENTIAL DIAGNOSIS

Tall stature in childhood and adolescence can be classified in various ways. The authors prefer the classification summarized in Table III, in which three main groups are distinguished: constitutional tall stature, primary growth disorders (with a defect presumably in the growth plate), and secondary growth disorders (abnormalities in the milieu interieur).

By far the most frequent cause of tall stature is constitutional (familial) tall stature, which is a reflection of the fact that 50–90% of height variation is accounted for by genetic factors. In most cases, height standard deviation scores (SDS) lie within a range of 1.3 SDS above or below the target height SDS (the sex- and secular trend-corrected midparent height). Measurements of parental height and calculating target height are therefore of critical importance. Birth length is usually more than +0.7 SDS (75th percentile). In the first 3–4 years, height velocity is accelerated, followed by a growth pattern parallel to, but above, the +1.9 SDS (97th percentile). No abnormalities are present on physical examination.

Primary growth disorders include a number of genetic syndromes. There are a number of sex chromosome-related disorders, of which Klinefelter syndrome (47, XXY) is most frequent. Usually, boys with this syndrome are not exceptionally tall in childhood, but adolescents and adults can be tall and often have eunuchoid body proportions. It is assumed that the additional chromosomal material and inadequate pubertal development account for the tall stature in this syndrome.

Sotos syndrome, Weaver syndrome, and Marshall-Smith syndrome are characterized by increased birth length and head circumference, increased growth velocity during the first year of life, tall stature during childhood and adolescence, advanced bone age, and moderately increased final height. All these syndromes have psychomotor retardation and their own set of typical craniofacial features. The phenotype of fragile X syndrome is very similar to that of Sotos syndrome. In Beckwith-Wiedemann syndrome, birth weight and length are increased and infants have a large protruding tongue. Final height is often within the normal range due to advanced bone maturation.

Marfan syndrome is an autosomal dominant inherited disorder, in which tall stature is the most prominent feature. Associated symptoms are arachnodactyly, joint hyperlaxity, cardiovascular anomalies, and lens subluxation. Homocystinuria is an autosomal recessive disorder caused by an enzyme deficiency. Its

Table III Causes of Tall Stature

| |
|---|
| Constitutional (familial) |
| Primary growth disorders |
| Sex chromosome-related disorders: Klinefelter syndrome (XXY), XXX syndrome, XYY syndrome |
| Fragile X syndrome |
| Syndromes characterized by advanced growth and maturation: Sotos syndrome, Weaver Syndrome, Marshall-Smith syndrome |
| Marfan syndrome |
| Marfan-like phenotype: MEN type IIB, homocystinuria |
| Secondary growth disorders |
| GH excess |
| Hyperthyroidism |
| Precocious puberty |
| True (central) precocious puberty |
| Pseudo-precocious puberty: Leydig cell hyperplasia (testotoxicosis), McCune-Albright syndrome, congenital adrenal hyperplasia, gonadal tumors |
| Impaired estrogen effect (estrogen receptor defect or aromatase deficiency) |

clinical features are similar to those of Marfan syndrome, with the exception of mental retardation, which is always present in homocystinuria. MEN-IIB syndrome mimics the signs of Marfan syndrome, but has additional signs, such as nodules at the tongue and lips.

Of the secondary growth disorders, GH excess is most important. Hyperthyroidism can cause an increased growth velocity and bone maturation, but in childhood tall stature is rare and final height is normal. In infants, hyperinsulinism, due to nesidioblastosis or as a result of diabetes mellitus of the mother, can result in overgrowth in terms of weight and length, but this usually normalizes shortly afterward. Pseudo-precocious puberty temporarily leads to increased growth and thus tall stature in childhood, but due to premature closure of the epiphyses final height is usually in the lower normal range. It has been observed that an absence of estrogen effect (in one case occurring due to a mutation in the estrogen receptor and in two cases occurring due to aromatase deficiency) results in normal growth in childhood, but brings about an absence of epiphyseal closure and thus failure to stop growing, leading to very tall stature in adulthood.

COMPLICATIONS

In addition to the psychological and social problems that patients with extremely tall stature encounter, complications of gigantism include increased risk of

cardiovascular, neuromuscular, and pulmonary problems as in acromegaly. The risk of colorectal tumors and other malignancies seems to be correlated with the degree of GH control. The diabetogenic effects of GH cause insulin resistance in acromegaly. In young children with GH excess, diabetes is rare because of their increased islet reserve. Periods of stress, however, can exhaust these reserves and result in temporary diabetes and even diabetic ketoacidosis.

TREATMENT

If an adenoma is present, transsphenoidal surgery is the treatment of choice. Irradiation can cause permanent damage to the pituitary and the central nervous system and is therefore not desirable in children. Primary or adjuvant pharmacotherapy is used pre- and postoperatively and in cases of pituitary hyperplasia.

Dopamine agonists (bromocriptine and cabergoline) release GH in normal individuals but paradoxically suppress GH hypersecretion in some patients with gigantism. The reaction to this therapy depends on the expression of dopamine receptor type D2 on the tumor cells. Often dopamine agonists alone fail to achieve complete biochemical control. In cases with pituitary hyperplasia or in cases with an insufficient response to transsphenoidal surgery, somatostatin analogues (octreotide) are often used. Somatostatin receptor subtypes 2 and 5 mediate the inhibitory effect of somatostatin. Complete biochemical control was reported in a case with an acidophilic stem cell adenoma using a combination of a long-acting dopamine agonist and a long-acting somatostatin analogue.

A GH receptor antagonist has shown to be effective in acromegaly. It is a mutated human GH molecule that binds to the GH receptor, but does not lead to signal transduction. Thus far, it has not been used in gigantism, but theoretically it should be as effective as in acromegaly. A competitive GHRH antagonist, blocking the GHRH receptor, has proven to be effective in the ectopic GHRH syndrome.

Acknowledgments

The authors are grateful to Dr. M. Jansen and Dr. A. M. Pereira Arias for providing information on both patients.

Glucose stimulation of GIP release appears to be direct as it occurs *in vitro* from a GIP-secreting cell line. The GIP response to fat is slower to develop, greater in magnitude, and more prolonged. The delayed GIP response to fat may be in part due to delayed gastric emptying caused by fat. It should be noted that GIP released by fat would not be insulinotropic unless circulating glucose values were also elevated. In addition to carbohydrates and fat, there are reports of GIP release by ingested amino acids as well as peptone and protein hydrolysate.

GIP GENE STRUCTURE AND STRUCTURE–ACTIVITY RELATIONSHIPS

The secreted form of GIP is a 42-amino-acid peptide derived by proteolytic processing of precursors that are 144 and 153 amino acids in length in rat and human, respectively. The gene coding for the human GIP precursor spans approximately 10 kb, whereas that for the rat spans only 8.2 kb. Both consist of six exons, with exons 3 and 4 coding for GIP_{1–42} (Fig. 1A). The promoter region of the human GIP gene contains potential binding sites for a number of transcription factors including Sp1, activator protein-1 (AP-1), and AP-2. The human GIP gene has been assigned to chromosome 17q21.3–q22.

A number of studies have been directed at determining the regions of the GIP molecule that are important for biological activity. Experimental evidence indicates that there are four dissociable domains in GIP_{1–42}. Residues 6–30 in the GIP molecule constitutes a high-affinity binding domain. Truncation of 12 amino acids from the carboxyl terminus of GIP_{1–42} was shown to result in a peptide with intact insulinotropic activity, but without the ability to stimulate gastric somatostatin secretion, indicating the existence of two bioactive domains in the native molecule. The insulinotropic domain of GIP has been further localized to residues 19–30 and Hinke and co-workers presented evidence suggesting that a third bioactive domain of GIP resides in residues 1–14.

THE GIP RECEPTOR

The pancreatic islet GIP receptor is a glycoprotein with an estimated molecular weight of 59 kDa that belongs to the class B family of heptahelical G protein-coupled receptors. GIP receptor cDNAs have been

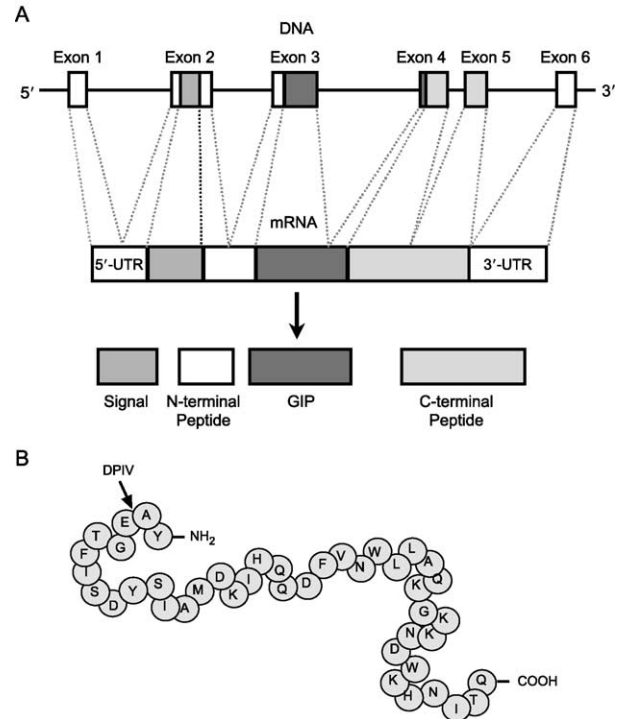

Figure 1 (A) Diagrammatic representation of the GIP gene, propeptide, and the peptides produced by processing. (B) Primary structure of human GIP showing the cleavage site for dipeptidyl peptidase IV.

cloned and it has been shown that the amino acid sequences of the rat, human, and hamster receptors share 40–47% identity with the glucagon-like peptide-1 (GLP-1) and glucagon receptors. Splice variants of the GIP receptor exist in some tissues and it is possible that there is variability in hormone–receptor interaction.

Through the study of mutant and chimeric receptors expressed in different cell lines, it has been shown that the N-terminal domain and first extracellular loop are important for GIP binding and that intracellular (IC) loops are involved in G protein coupling, whereas threonine and serine residues in IC3 and the C-terminal tail are important for receptor internalization. Localization studies have confirmed the broad distribution of the GIP receptor in pancreatic islets, fat, stomach, brain, heart, lung, endothelium, adrenal cortex, and bone, in agreement with GIP's broad pleiotropic actions.

The GIP Receptor Gene

The human receptor gene contains 14 exons and 12 introns, with a protein coding region of 12.5 kb, whereas that of the rat receptor gene spans ~10.2 kb

and contains 13 exons. The promoter region of the human gene has not yet been characterized, but 5'-flanking sequences of the rat gene contain several transcription factor-binding motifs, including a cyclic AMP (cAMP)-response element, an octamer-binding site, three Sp1 sites, and an initiator element. One potential Sp1-binding site has been shown to be important for transcriptional activity and distal negative regulatory sequences have been suggested to control cell-specific expression. Missense mutations in the receptor gene have been identified in Japanese and Danish populations. Cells expressing one of the mutated receptors (Gly¹⁹⁸/Cys) exhibited elevated EC₅₀ values for cAMP production. However, allelic frequency studies have shown no association of the mutations with type 2 diabetes, although in the Danish group those homozygous for a Glu³⁵⁴/Gln variant had decreased fasting serum C-peptide levels, suggesting that GIP normally regulates beta cell secretion even in the fasting state. Lynn and co-workers showed that GIP receptor mRNA and protein levels are dramatically reduced in the Vancouver Diabetic Zucker fatty rat, thus partially explaining the resistance to GIP found in these animals.

GIP-Activated Signal Transduction Pathways

The endocrine pancreas is the only target organ for which there is information on the mode of action of GIP. Glucose is the main nutrient stimulator of insulin secretion (Fig. 2). Glucose enters the pancreatic beta cell and its metabolism results in an increase in the ratio of cytosolic ATP:ADP. The resulting closure of ATP-dependent K⁺ channels leads to membrane depolarization and opening of voltage-dependent Ca²⁺ channels. The increase in cytosolic Ca²⁺ is the major stimulus for insulin secretion. Agents such as GIP, GLP-1, and PACAP (pituitary adenylate cyclase-activating polypeptide) act as both competence factors for glucose-induced secretion and potentiators of the glucose-induced responses. GIP has been shown to stimulate adenylyl cyclase (AC) in pancreatic beta cells and the major pathway by which GIP potentiates insulin secretion is thought to be at the level of Ca²⁺-induced exocytosis via activation of protein kinase A (PKA). Although the pathways involved have not been completely identified, GIP is capable of increasing Ca²⁺ influx through both L-type Ca²⁺ channels and nonselective ion channels and releasing

Figure 2 Diagram of a pancreatic islet beta cell showing K⁺-dependent ATP channel-associated glucose stimulation of insulin secretion and proposed mechanisms by which GIP activation of adenylyl cyclase and phospholipase A₂ can potentiate glucose-mediated responses.

Ca²⁺ from intracellular stores. Ehses and co-workers have demonstrated that GIP can also activate a Ca²⁺-independent phospholipase A₂ (PLA₂) in beta cells, resulting in the generation of arachidonic acid. Interestingly, in different cell types, GIP may stimulate PLA₂ via receptor coupling to G_{βγ} dimers or via coupling of G_α and adenylyl cyclase.

GIP, Insulin Gene Transcription, and Beta Cell Proliferation

In addition to its effect on insulin secretion, glucose is the most important stimulator of proinsulin gene transcription. Its action involves stimulation of cytosolic/nuclear transport of the transcription factor PDX-1 and increased PDX-1 gene transcription. However, both GIP and GLP-1 stimulate the expression of several genes in the beta cell, including those of proinsulin, glucose transporters, and hexokinases. Additionally, these peptides appear to be involved in regulating the differentiation of beta cells from ductal progenitor cells and stimulating beta cell proliferation. Incretins are therefore important regulators of beta cell replication. Although it is not known exactly how GIP and GLP-1 exert their mitogenic actions, it is known that they can induce *c-fos* activity and activate mitogen-activated protein kinase pathways.

METABOLISM

Through the use of assays of immunoreactive GIP levels, it was determined that the kidney is the major site of GIP clearance. By measuring the rate of disappearance of infused peptide, the circulating half-life in humans was calculated to be 20 min. These measurements can be called into question as it is known that postsecretory degradation of incretins results in products that may be immunoreactive but biologically inactive. Thus, RIAs may overestimate their biological half-lives. Dipeptidyl peptidase IV (DP IV) is a ubiquitously distributed enzyme with substrate specificity for small peptides with proline or alanine residues in the penultimate position from the N terminus. Both GIP and GLP-1 serve as substrates for this enzyme (penultimate alanine residues), yielding N-terminally truncated, biologically inactive products (GIP₃₋₄₂, GLP-1₉₋₃₆). It has been determined that DP IV degradation is the major route of GIP inactivation in the circulation and that the biological half-life of the hormone is approximately 2 min. The fact that most RIAs employ antibodies

directed against the C-terminal region of GIP calls much of the previously published data on circulating GIP levels into question since biologically inactive GIP contributes to immunoreactive GIP levels measured with these RIAs. The physiological role played by DP IV in the regulation of incretin activity, and thus the regulation of blood glucose, has been exploited by Pederson and co-workers in strategies used to enhance insulin secretion and improve glucose tolerance in type 2 diabetes. These strategies have taken the form of administration of DP IV inhibitors that increase the circulating half-life of incretins and the design and synthesis of DP IV-resistant GIP and GLP-1 analogues. An extensive body of evidence indicates that altering plasma incretin concentrations by inhibition of DP IV is a valid therapeutic approach to type 2 diabetes.

BIOLOGICAL ACTIONS

Acid Secretion—The Enterogastrone Concept

As discussed earlier, GIP was isolated on the basis of its acid inhibitory properties. GIP was pursued as a candidate for the inhibitor of gastric acid secretion: enterogastrone. This proposal gained considerable support when, in addition to its inhibitory actions on the stomach, it was determined that ingestion of fat was the most potent stimulus for the release of GIP into the circulation. Initial studies were carried out in the denervated canine stomach and subsequent studies in the intact innervated stomach of humans and rats demonstrated weaker inhibitory effects. In later studies, GIP was shown to be a potent stimulus for somatostatin release from the stomach and this release could be inhibited by the vagus or cholinomimetic agents. These studies suggested an indirect pathway for the action of GIP on the parietal cell, i.e., by GIP-induced somatostatin release with neuronal modulation by the parasympathetic nervous system. GIP is undoubtedly not the only enterogastrone and it is likely that it acts in concert with other peptides and/or nervous inhibitory mechanisms that would be initiated during the digestive and absorptive process in the upper small bowel.

GIP Stimulation of Islet Hormones—The Incretin Concept

As outlined earlier, both enterogastrone and incretin actions of GIP were hypothesized as a result of studies

on impure (GIP-containing) preparations of CCK that demonstrated their ability to inhibit acid secretion and stimulate insulin release. Dupre and co-workers showed that concomitant infusion of porcine GIP and glucose in humans produced a pronounced increase in circulating insulin levels and improved glucose tolerance compared to glucose infusion alone. The insulin response was sustained for the duration of the GIP infusion and was not observed in fasted (euglycemic) individuals. This glucose dependency was subsequently verified in the isolated perfused rat pancreas and a threshold of 5.5 mM glucose for the insulinotropic action of GIP was established. Elegant studies by Anderson *et al.* established conclusively that endogenous GIP released by oral glucose could account for a major part of the enteric contribution to the insulin response to oral glucose in human. The glucose-dependent insulinotropic action of GIP has been demonstrated in many mammalian species as well as a variety of tumor-derived insulin secreting beta cell lines. The action of other insulin secretagogues, such as CCK, acetylcholine, GLP-1, and arginine, have also been demonstrated to be glucose-dependent. A common mechanism whereby glucose metabolism in the beta cell permits stimulation by nonglucose secretagogues has been proposed. GIP has been shown to be glucagonotropic in both the isolated rat pancreas and pancreatic islets. Several studies support a direct effect of GIP on glucagon release. Receptors for GIP are found on rat A cells and GIP increased whole-cell Ca^{2+} currents and potentiated exocytosis in purified rat pancreatic A cells.

GIP and Fat Metabolism

In addition to its effect on insulin secretion, GIP has been implicated in the regulation of fat metabolism, an action that could also be of paramount importance in the normal regulation of insulin secretion. Ingestion of triglycerides increases circulating GIP by a pathway that involves both metabolism and absorption of fatty acids. Several lines of evidence support a role for GIP in the subsequent disposal of circulating triglycerides. Administration of GIP promotes chylomicron-associated triglyceride clearance from blood in dogs and reduces plasma triglyceride levels during intraduodenal fat infusion in rats. GIP has also been shown to stimulate lipoprotein lipase activity in cultured preadipocytes. Regarding the effects of GIP on adipocyte metabolism, it has been reported that GIP enhances the incorporation of

both fatty acids and glucose into lipids and inhibits glucagon-stimulated lipolysis and cAMP production. This seemed paradoxical, however, in that GIP signals via cAMP, which is known to stimulate hormone-sensitive lipase and thus would be expected to exert a lipolytic effect. It was hypothesized by McIntosh and co-workers that the response of the adipocyte to GIP may depend on the prevailing circulating insulin concentration and evidence that GIP exerts a lipolytic effect on adipocytes that is inhibited by insulin was provided. One can postulate a physiological role for GIP in fat metabolism in light of the demonstration that critical levels of circulating free fatty acids (FFAs) are required for optimal glucose stimulation of insulin secretion during fasting. GIP could be capable of stimulating lipolysis under conditions in which insulin levels are of insufficient magnitude to inhibit its action and this may ensure that levels of circulating FFAs are optimal for glucose- and GIP-stimulated insulin secretion.

Gitelman's Syndrome

see Bartter's Syndrome

Figure 1 Homology of amino acid sequences of glucagon and the glucagon-like peptides.

of the gut GLP-1 and GLP-2 are the main gene products. The steps in the expression of the preproglucagon gene are outlined in Fig. 2. Several other potentially bioactive peptides are generated from proglucagon such as IP2 (intervening peptide 2) (as shown in Fig. 2) but this article focuses on glucagon and the glucagon-like peptides.

HORMONE RECEPTORS AND CELL SIGNALING

The functional effects of glucagon and the GLPs are mediated by specific receptors located within the plasma membrane of target cells. Like the peptide hormones, the hormone-specific receptors share extensive amino acid sequence homology and form part of a closely related subfamily of receptors as part of the larger superfamily of G protein-coupled receptors. This superfamily is distinguished by the tertiary structure of its members, comprising seven transmembrane domains, and the coupling to trimeric G proteins. The coupling to the stimulatory G protein G_s, the activation of adenylyl cyclase, and the subsequent increase in the intracellular production of cyclic AMP (cAMP) constitute the most established functional responses elicited by all the members of the

glucagon receptor subfamily. This uniform response in intracellular function suggests that the divergent physiological effects of glucagon, GLP-1, and GLP-2 are due primarily to tissue-specific expression of the receptors, whereby cAMP imparts distinct cellular functions due to the equally diverse array of gene expression patterns in different cell types. Furthermore, temporal and tissue-specific patterns of secretion of the hormones themselves play a critical role in initiating the appropriate functional response. Notably, in the pancreatic beta cell, in which GLP-1 and glucagon receptors are expressed, both glucagon and GLP-1 stimulate insulin secretion, mediated at least in part by cAMP. Paradoxically, however, insulin gene expression is inhibited by glucagon and stimulated by GLP-1. This contradiction suggests that more subtle distinctions in receptor signaling exist, leading to differential intracellular responses to the two hormones, glucagon and GLP-1.

PHYSIOLOGY

Glucagon

The glucagon receptor is widely expressed and can be found in the liver, adipose tissue, heart, kidney,

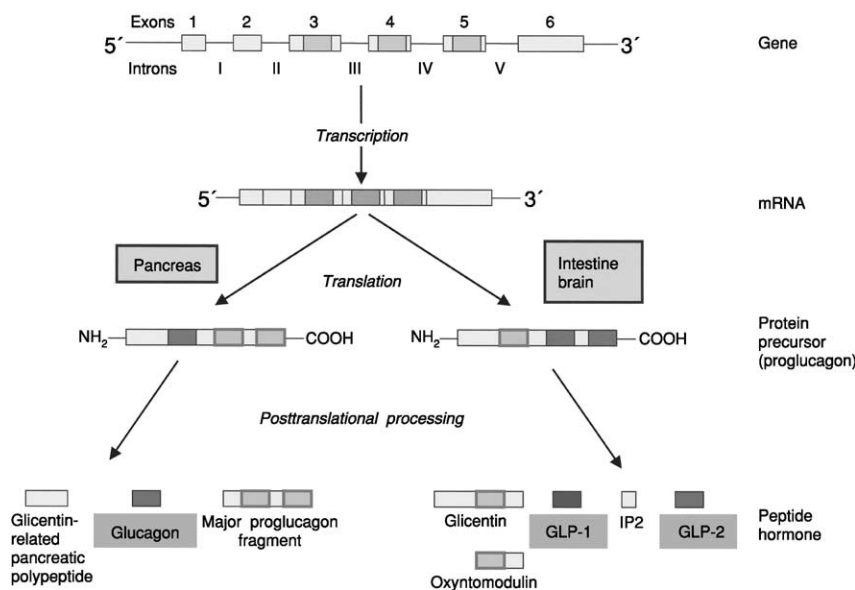

Figure 2 Tissue-specific processing of the preproglucagon gene.

pancreatic islets, stomach, small intestine, thyroid, and skeletal muscle. Although contradictions in the specific expression pattern exist, likely due to the sensitivity of detection techniques between laboratories, the less ambiguous targets with high receptor levels correspond to the most well-established physiological actions of glucagon. The hepatocyte is a primary target cell of glucagon to which it is exposed when the hormone is released in the portal vein following secretion from the pancreatic alpha cells. Glucagon increases glucose output from the liver, an effect that results from inhibition of glycogen synthesis and stimulation of both glycogenolysis and gluconeogenesis (Table I). Evidence suggests that these effects of glucagon are mediated by cAMP, although the glycogenolytic effect of glucagon may occur via a cAMP-independent mechanism. It is not surprising, therefore, that glucagon helps to maintain hepatic glucose output and thereby to sustain blood glucose levels. There exists a general consensus that the hyperglycemic activity of glucagon represents the first line of defense against hypoglycemia. Accordingly, stimulants of glucagon secretion from alpha cells include the presence and actions of factors at times when the body requires glucose for sustenance (during fasting) or fuel (during exercise).

The interplay between insulin and glucagon provides a tightly controlled equilibrium in blood glucose concentration. Insulin stimulates glucose uptake into fat and muscle cells and also inhibits glucagon expression and secretion from alpha cells. Thus, during periods when plasma insulin levels are low, such as during periods of fasting and exercising, plasma glucagon levels are elevated. The anatomical structure of the pancreatic islets of Langerhans further reflects this mechanistic action of insulin on glucagon secretion. Morphological studies have shown that in a given islet, the microcirculation goes from the core to the mantle. This circumstance suggests that *in vivo*, peripheral alpha cells are exposed to high concentrations of insulin released from the more centrally located beta cells in the islets. Thus, insulin and glucagon function inversely to regulate blood glucose levels.

Table I Actions of Glucagon

| | |
|---|--------------------------------------|
| ↑ | Hyperglycemia |
| ↑ | Glycogenolysis |
| ↑ | Gluconeogenesis |
| ↑ | Glycerol and free fatty acid release |
| ↑ | Lypolysis |
| ↓ | Glycogen synthesis |

Dysregulation of glucagon by a breakdown in the intra-islet insulin–glucagon relationship appears to be a substantial component in the pathogenesis of diabetes. As a result of insufficient insulin secretion, plasma glucagon levels are elevated in type 1 (insulin-dependent) diabetes and also to a lesser extent in type 2 (non-insulin-dependent) diabetes, thereby exacerbating the hyperglycemic state. This effect is further heightened when plasma glucagon levels fail to be suppressed following a meal and postprandial hyperglycemia ensues. It is compelling to speculate, therefore, that agents that are able to antagonize glucagon action or secretion may be of value in the treatment of patients with diabetes.

Paradoxically, a major feature of long-term diabetes is the impaired response to insulin-induced hypoglycemia, a condition of impairment that is almost universally present after 5 years of duration of type 2 diabetes. Studies have shown that hyperinsulinemia, which may be caused by insulin therapy, and insulin resistance can induce defective counterregulation in the manifestation of hypoglycemia, via defective glucagon release. These examples serve to emphasize the finely balanced hormonal equilibrium that characterizes the normal physiological state of glucose homeostasis.

Consistent with the role of glucagon in providing the body with usable energy, additional established targets of glucagon action are the adipocyte and skeletal myocytes (Table I). Although studies of the effects of glucagon on adipose tissue and other tissues are difficult to evaluate owing to the rapid breakdown of the peptide by proteolytic activity associated with these cells, substantial evidence demonstrates that glucagon induces lipolysis, stimulates the release of glycerol and free fatty acids in adipocytes, and stimulates glycogenolysis in myocytes. Therefore, glucagon could qualify as the “hormone of fuel need” rather than just a “hormone of glucose need.”

GLP-1

The major secreted and bioactive form of GLP-1 from enteroendocrine L cells is a truncated isopeptide cleaved from the full 37-amino-acid peptide. Cleavage of the six N-terminal amino acids of GLP-1(1–37) to form GLP-1 (7–37) and removal of the glycine residue at position 37 followed by amidation of the exposed arginine at position 36 generate GLP-1(7–36)amide. The most significant physiological function of GLP-1 is the stimulation of the synthesis and secretion of insulin from pancreatic islet beta cells

Table II Actions of GLP-1

| | |
|---|------------------------------------|
| ↑ | Insulin biosynthesis and secretion |
| ↑ | Islet proliferation and neogenesis |
| ↑ | Islet cell differentiation |
| ↑ | Glucose uptake |
| ↓ | Gastric emptying |
| ↓ | Acid secretion |
| ↓ | Food intake (appetite) |
| ↓ | Glucagon secretion |

(Table II). The mechanism of action of GLP-1 is a potentiation of glucose-induced insulin secretion. In the absence of glucose, GLP-1 fails to stimulate insulin secretion, whereas at elevated glucose concentrations, GLP-1 stimulates secretion at a rate that exceeds that induced by glucose alone and thus potentiates secretion in a glucose-dependent manner. Notably, the secretion of GLP-1 from L cells is stimulated by glucose (and other nutrients) following oral ingestion. Thus, the temporal release of GLP-1, coincident with enhanced blood glucose levels, cooperates synergistically to provide a highly sensitive insulin-releasing mechanism. GLP-1 is thus regarded as a “glucose competence factor.” As described above, insulin suppresses plasma glucagon levels and activates glucose uptake and metabolism, thus returning blood glucose levels to normal following a meal and maintaining glucose homeostasis in general. In this regard, insulin and GLP-1 play an important role in preventing hyperglycemia.

Evidence for additional mechanisms of action of GLP-1 in lowering blood glucose levels have emerged; GLP-1 has been shown to augment insulin-mediated glucose uptake in patients with diabetes. Extrapancreatic targets of GLP-1 actions, particularly those of adipose and skeletal muscle tissues, are under investigation. It seems possible that a novel GLP-1 receptor mediates these effects of GLP-1 on adipose tissue and skeletal muscle, as well as liver.

Additional functions of GLP-1 include the inhibition of gastric emptying (by inhibiting intestinal motor activity in response to nutrients in the distal gut) and of meal-stimulated gastric acid secretion. A role for GLP-1 in feeding behavior has also been identified. Centrally administered GLP-1 inhibited both feeding and drinking activity in rats, suggesting that GLP-1 may be a central neurotransmitter that modulates visceral functions. Finally, in addition to the detection of pluripotential stem cells within the pancreas, some evidence suggests that GLP-1 stimulates the proliferation and differentiation of these

stem/progenitor cells into beta cells and thus GLP-1 may play a developmental role in the endocrine pancreas.

As the characterization of GLP-1 action continues and a clearer picture of its multifunctional profile appears, it is evident that GLP-1 offers considerable potential as a therapeutic treatment for diabetes mellitus. By enhancing both the means to secrete insulin (by incretin action and differentiation of new beta cells) and the functional ability of insulin to induce glucose disposal, it may be possible to better control circulating blood sugar levels in diabetic patients.

GLP-2

GLP-2 is synthesized in the enteroendocrine L cells (along with GLP-1) and in the brainstem and hypothalamus of the central nervous system. GLP-2 may act on the hypothalamus to curtail appetite and food intake. However, the regulation and function of GLP-2 in the intestinal system are better understood than those of GLP-2 in the central nervous system.

Initially, several lines of evidence suggested the importance of GLP-2 in maintaining the functional integrity of the gastrointestinal epithelium. Examples included the coincidence of intestinal injury and inflammatory bowel disease with elevated levels of circulating GLP-2 and patients with glucagon-secreting tumors who presented with small bowel villus hyperplasia (Table III). It was subsequently shown that administration of GLP-2 to mice leads to induction of intestinal epithelial proliferation. Furthermore, following treatment of mice and rats with exogenous GLP-2 for 7–10 days, a marked increase in villus height and small bowel mass and a smaller increment in small bowel length are observed. GLP-2 also appears to slow the ingestion and transit of food through the gastrointestinal tract, while increasing the absorption of nutrients from the small intestine.

As with glucagon and GLP-1, the tissue-specific effects of GLP-2 action are closely reflected by the expression profile of the GLP-2 receptor, which is predominantly found in the stomach, jejunum, ileum, and colon. Although GLP-2 presumably exerts direct effects on cells expressing its putative receptor, some physiological effects of GLP-2 in the intestine are thought to be exerted indirectly in an autocrine, paracrine, or endocrine manner by stimulating the release of as yet unknown factors from GLP-2 receptor-positive cells. This hypothesis arose due to conflicting data regarding the exact tissue distribution of the GLP-2 receptor. Whereas one group observed

Table III Actions of GLP-2

| | |
|---|--------------------------------|
| ↑ | Nutrient absorption |
| ↑ | Crypt cell proliferation |
| ↑ | Small and large bowel growth |
| ↑ | Villus height |
| ↓ | Food intake (appetite) |
| ↓ | Gastric motility |
| ↓ | Enterocyte and crypt apoptosis |

that binding of labeled GLP-2 localized diffusely along the villous epithelium, others have reported the absence of the receptor among several intestinal epithelial cell lines. Thus, because the localization profile of the GLP-2 receptor is not known with certainty, the mechanism of the pleiotropic biological actions of GLP-2 in the gut, such as modulation of gastric motility, small bowel permeability, and both crypt cell proliferation and apoptosis, is confined to speculation. However, some evidence suggests that GLP-2 can directly mediate proliferative and anti-apoptotic effects through its receptor in cultured cells.

Apart from its intestinal functions, GLP-2 is also expressed and received in the brain. Receptors were located in the hypothalamus and in certain cell groups in the cerebellum, medulla, amygdala, and hippocampus. Although studies of GLP-2 action in the brain are just beginning, a functional role of GLP-2 appears to be in the regulation of food intake. Pharmacological and behavioral studies indicate that GLP-2 acts as a specific transmitter that may inhibit feeding behavior and has potential long-term effects on body weight homeostasis.

INACTIVATION OF GLPs

The active half-life of both GLP-1 and GLP-2 is regulated by dipeptidyl peptidase IV (DPP IV/CD26), an extracellular soluble or membrane-anchored protease, which cleaves the two N-terminal amino acids and subsequently inactivates the hormones, with respect to their known functions. This potent inactivation restricts the circulating bioactive

half-lives to 2–3 min *in vivo*. Particularly high levels of expression of DPP IV are found in the kidney, lung, liver, and jejunum. Expression in endothelial cells of the blood vessels and the presence of small amounts of DPP IV as a soluble enzyme in the blood result in close contact with circulating substrate and added rapidity of peptide inactivation. Consequently, specific DPP IV inhibitors are of special interest for physiological investigations and for potential clinical applications, such as treatment of type 2 diabetes and improvement of mucosal regeneration. Studies have shown that prolonged activation of GLP-1 by DPP IV inhibitors results in a potentiation of the insulinotropic effect of GLP-1 *in vivo* and administration of GLP-2 to DPP IV-deficient rats markedly increased the bioactivity of GLP-2, resulting in a significant increase in small bowel weight. A second approach to enhance the bioactive half-life of the GLPs is the synthesis of DPP IV-resistant analogues of the GLPs for pharmacological administration. These approaches are in development.

Figure 1 Structure of proglucagon and biological actions of GLP-2.

GLP-2 administration reduces epithelial permeability in the small intestine, effects noted within hours of peptide administration. The capacity of the GLP-2-treated bowel for nutrient absorption appears to be normal to enhanced, as assessed by nutrient challenge studies in normal mice following chronic GLP-2 administration.

GLP-2 ACTIONS IN THE BRAIN

GLP-2 is synthesized in the brain, predominantly in the nucleus of the solitary tract in the brainstem and to a lesser extent in the hypothalamus. GLP-1 and GLP-2 are transported from the brainstem to distant central nervous system (CNS) nuclei via axonal transport. Within the hypothalamus, GLP-2 is distributed in a pattern similar to that of GLP-1; however, GLP-2 administration specifically activates neurons in the dorsomedial nucleus of the hypothalamus, where GLP-2 receptors have been localized by *in situ* hybridization. The GLP-2 receptor is also expressed in thalamic, cortical, cerebellar, hippocampal, and amygdaloid nuclei. Although the physiological role of GLP-2 in the CNS remains unclear, intracerebroventricular administration of pharmacological amounts of GLP-2 transiently inhibits food intake in mice and rats.

GLP-2 AND GUT DEVELOPMENT

GLP-2 and GLP-2 receptors are expressed in the fetal and neonatal gut and GLP-2 stimulates intestinal epithelial proliferation in neonatal pigs and rats. The trophic effects of GLP-2 in the gastrointestinal tract may be restricted to postnatal life, as exogenous GLP-2 does not stimulate gut growth in late-gestational fetal pigs despite the presence of immunoreactive circulating GLP-2 in the fetal pig.

THE GLP-2 RECEPTOR

GLP-2 exerts its actions through a distinct 550-amino-acid G protein-coupled GLP-2R (GLP-2 receptor). The cDNA encoding the GLP-2R was initially cloned from human and rat hypothalamic and intestinal cDNA libraries. Consistent with the known actions of GLP-2, GLP-2R expression is predominantly confined to the stomach, duodenum, jejunum, ileum, and colon. GLP-2R transcripts have also been detected in the brain and lung, although the biological significance of GLP-2R expression in lung remains unclear. Within the gastrointestinal tract, GLP-2 receptor-like immunopositivity has been localized to a subset of human endocrine cells using GLP-2R-specific antisera and GLP-2R expression was demonstrated in the murine enteric nervous system by *in situ* hybridization.

Although cell lines expressing an endogenous GLP-2 receptor have not yet been identified, GLP-2 increases intracellular cyclic AMP (cAMP) and activates protein kinase A but does not increase intracellular Ca^{2+} release in cells expressing a transfected human or rat GLP-2 receptor. GLP-2 directly activates immediate-early gene expression and cellular growth in serum-starved fibroblasts *in vitro*; however, the growth-promoting effects of GLP-2 in the gut are largely indirect *in vivo*. GLP-2 also prevents apoptosis following administration of cycloheximide (an inhibitor of protein synthesis) or chemotherapeutic agents to cells expressing a GLP-2R through cAMP-dependent mechanisms; hence, GLP-2R activation directly and indirectly signals intracellular pathways regulating both mitogenic and anti-apoptotic actions.

THERAPEUTIC POTENTIAL OF GLP-2

GLP-2 infusion completely prevented the mucosal atrophy associated with withdrawal of enteral

nutrients in the small intestine but not the large intestine of the rat. Similarly, GLP-2 administration following small bowel resection in rats increased intestinal remnant adaptation and improved absorptive function. Reparative and protective effects of GLP-2 have also been observed in mice following ischemic injury induced by occlusion of the superior mesenteric artery.

GLP-2 exerts reparative and cytoprotective effects in rodents in the setting of intestinal inflammation. The protease-resistant GLP-2 analogue h[Gly2]-GLP-2 significantly reduced the severity of enteritis, bacterial sepsis, and mortality in mice following administration of the nonsteroidal anti-inflammatory agent indomethacin. Similarly, mice treated with h[Gly2]-GLP-2 exhibit reduced large bowel injury and significantly less weight loss in the setting of dextran sulfate colitis. The anti-apoptotic actions of GLP-2 are also detectable *in vivo* following chemotherapy administration. Administration of h[Gly2]-GLP-2 prior to irinotecan or 5-fluorouracil attenuated epithelial injury in the gut, decreased intestinal epithelial apoptosis, and reduced mortality in mice. Although GLP-2 promotes intestinal epithelial proliferation in the gastrointestinal tract, co-infusion of GLP-2 and parenteral nutrition does not affect tumor progression or tumor growth in tumor-bearing rats.

The reparative and proabsorptive effects of GLP-2 have been examined in a pilot trial in human subjects with short bowel syndrome. Eight patients with stable chronic intestinal insufficiency without a colon in continuity were treated with human GLP-2, 400 μ g twice daily by subcutaneous injection for 35 days. GLP-2-treated subjects exhibited significantly increased energy, wet weight, and nitrogen absorption, as measured in metabolic balance studies. Body weight and lean body mass increased, whereas fat mass decreased and the time to 50% gastric emptying was increased in GLP-2-treated subjects. Analysis of intestinal histology revealed increases in crypt depth and villus height following GLP-2 administration.

SUMMARY

GLP-2 has been established as the elusive proglucagon-derived peptide with potent effects on gut growth and nutrient absorption. The essential physiological role(s) of GLP-2 has not yet been elucidated due to the lack of effective specific antagonists or immunoneutralizing antisera. The cytoprotective, proabsorptive, and regenerative properties of GLP-2 *in vivo*

appear to be indirect, mediated by a GLP-2 receptor expressed on endocrine cells and enteric neurons. The downstream effectors released following GLP-2R activation are unknown. Although intracerebroventricular administration of GLP-2 inhibits food intake in rodents, it seems likely that GLP-2 exerts additional as yet unknown actions in the central nervous system. The rapid degradation and clearance of GLP-2 suggest that protease-resistant analogues may exhibit advantages for long-term therapeutic administration *in vivo*. The diverse actions of GLP-2 in the gut are focused on maintaining the integrity of the epithelial mucosa and optimizing nutrient absorption, consistent with the physiological importance of proglucagon-derived peptides in the integrated control of energy homeostasis.

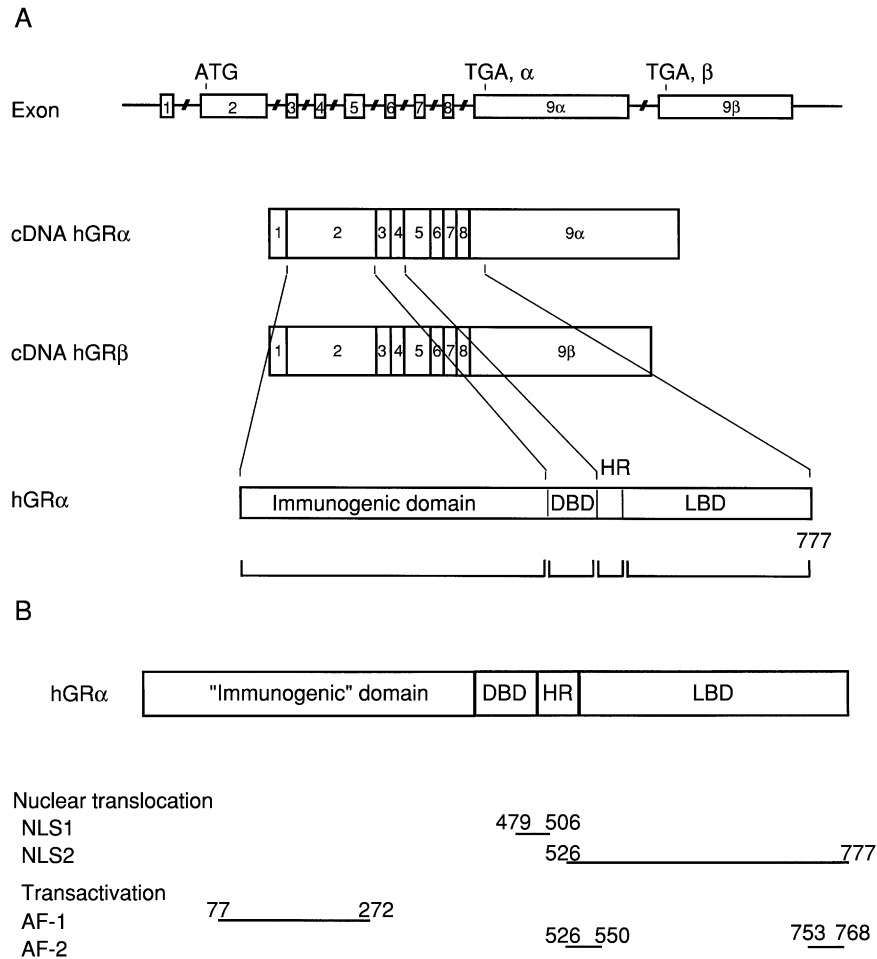

Figure 1 (A) Genomic, complementary DNA, and protein structures of the human glucocorticoid receptor (hGR). The hGR gene consists of 10 exons. Exon 1 is an untranslated region, exon 2 codes for the amino-terminal domain, exons 3 and 4 code for the DNA-binding domain, and exons 5–9 code for the hinge region and the ligand-binding domain. The glucocorticoid receptor gene contains two terminal exons 9 (exon 9 α and 9 β), alternatively spliced to produce the hGR α and hGR β isoforms. (B) Functional domains of the glucocorticoid receptor. The functional domains and subdomains are indicated beneath the linearized protein structures. AF, activation function; DBD, DNA-binding domain; LBD, ligand-binding domain; NLS, nuclear localization signal.

MOLECULAR MECHANISMS OF GR ACTION

Nucleocytoplasmic Shuttling of GR

In the absence of ligand, hGR α resides primarily in the cytoplasm of cells as part of a large multiprotein complex, which consists of the receptor polypeptide, two molecules of hsp90, and several other proteins. The hsp90 molecules are thought to sequester hGR α in the cytoplasm of cells by maintaining the receptor in a conformation that masks or inactivates its nuclear localization signals (NLSs). Upon hormone binding, the receptor undergoes an allosteric change, which results in dissociation from hsp90 and other proteins,

unmasking of the NLSs, and exposure of the ligand-binding pocket. In its new conformation, the activated, ligand-bound hGR α translocates into the nucleus, where it binds as homodimer to glucocorticoid-response elements (GREs) located in the promoter region of target genes. hGR α then communicates with the basal transcription machinery and regulates the expression of glucocorticoid-responsive genes positively or negatively, depending on the GRE sequence and promoter context (Fig. 2). The receptor can also modulate gene expression, as a monomer, independently of GRE binding, by physically interacting with other transcription factors, such as activating protein-1 (AP-1) and nuclear factor κ B (NF- κ B).

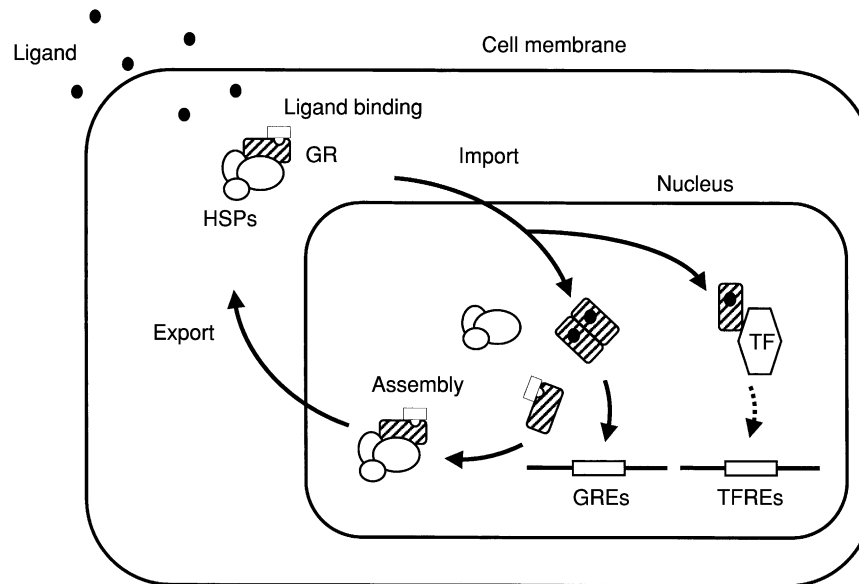

Figure 2 Nucleocytoplasmic shuttling of the glucocorticoid receptor. GR, glucocorticoid receptor; GREs, glucocorticoid-response elements; HSPs, heat shock proteins; TF, transcription factor; TFREs, transcription factor-responsive elements.

Mechanisms of Transcriptional Activation by GR

Following binding to GREs, the liganded, activated hGR α enhances the expression of glucocorticoid-responsive genes by regulating the assembly of a transcriptional preinitiation complex at the promoter region of target genes. This is achieved by interaction of the liganded receptor with the basal transcription factors, a group of proteins composed of RNA polymerase II, TATA-binding protein (TBP), and a host of TBP-associated proteins (TAFIIs). The interaction between the activated receptor and the basal transcription factors is mediated by the coactivators, which are nucleoproteins with chromatin-remodeling activity and other enzymatic activities (Fig. 3).

Like other transcriptional activators, hGR α uses its transcriptional activation domains AF-1 and AF-2 as surfaces to recruit chromatin remodeling factors and to interact with the coactivators that link enhancer-bound transcription factors to general transcription factors, thereby initiating transcription. At least two regions of hGR α possess intrinsic transcriptional activation functions: AF-2, which maps to the carboxyl terminus, is glucocorticoid-dependent, with ligand binding promoting the formation of a surface that permits protein-protein contacts between AF-2 and additional regulatory factors. In contrast, AF-1 is located at the amino terminus of the receptor, is glucocorticoid-independent, and can recruit both positive and negative regulatory factors that differentially regulate hGR α transcriptional enhancement.

Several families of nuclear hormone receptor coactivators have been described, including the p160 coactivators, such as the steroid receptor coactivator 1 and the glucocorticoid receptor-interacting protein 1, the p300 and cyclic AMP-responsive element-binding protein (CBP) cointegrators, and the p300/CBP-associated protein (p/CAF). The p160 coactivators are the first to be tethered to the promoter region of steroid target genes, thus playing a pivotal role in hGR α -mediated transactivation. These coactivators interact directly with both the AF-1 of hGR α through their carboxyl-terminal domain and the AF-2 of hGR α through multiple amphipathic LXXLL signature motifs, which are located in their nuclear receptor-binding domain (NRB). They also contain an additional binding site for hGR α , called auxiliary nuclear receptor-interacting domain, which is located between the NRB and the carboxyl-terminal AF-1-binding site. The p160 proteins have intrinsic histone acetyl-transferase activity, which disrupts the DNA nucleosomal interactions at these promoters, allowing the initiation of transcription. Other coactivators that interact with hGR α include the switching/sucrose nonfermenting complex and the newly described chromatin remodeling complex, vitamin D receptor-interacting protein (DRIP)/thyroid hormone-associated protein (TRAP) complex. The DRIP/TRAP complex interacts with both the AF-2 and AF-1 domains of hGR α via its components DRIP205 and DRIP150, respectively. Through coordinated interactions with AF-1 and AF-2, the

coactivators enhance the transmission of signals from the DNA-bound hGR α to the transcriptional initiation machinery, loosen chromatin structure, and facilitate access and/or binding of other transcription factors and transcription initiation components to DNA, leading to full transcriptional activity of ligand-bound hGR α .

Interaction of GR with Other Transcription Factors

In addition to binding to GREs, glucocorticoids may regulate transcription by physically interacting with other transcription factors. Protein-protein interactions between hGR and NF- κ B and between AP-1 and signal transducers and activators of transcription result in negative or positive regulation of their responsive genes, mediating many of the anti-inflammatory and immunosuppressive effects of glucocorticoids. hGR may also interact with transcription factor Nur77 to regulate the expression of the proopiomelanocortin gene, p53, which functions as a tumor suppressor gene, as well as others, such as HNF6, Oct-1 and-2, and GATA-1.

FACTORS THAT MODULATE GR ACTIVITY

Phosphorylation of GR

Following ligand binding, hGR is phosphorylated at several sites. The mitogen-activated protein kinase

(MAPK) and the cyclin-dependent kinases (CDKs) phosphorylate hGR and modulate its transcriptional activity. MAPK suppresses the activity of hGR in yeast, whereas CDKs stimulate it. JNK, another mitogen-activated kinase, also phosphorylates hGR and suppresses its transcriptional activity. All these kinases phosphorylate hGR at different sites, indicating that the function of hGR may be also regulated by other signal transduction pathways through phosphorylation.

Chaperones and Cochaperones

hGR forms heterocomplexes with several heat shock proteins, including hsp90, hsp70, hsp56, and possibly hsp23, which may affect its transcriptional activity. hsp90 and receptor-associating protein 46 regulate the transcriptional activity of hGR negatively.

Chemicals and Compounds

Several chemical compounds may modulate the transcriptional activity of hGR. 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin, a widespread environmental contaminant that produces adverse biological effects such as carcinogenesis, reproductive toxicity, immune dysfunction, hepatotoxicity, and teratogenesis, suppresses the activity of hGR by decreasing binding to glucocorticoids. Geldanamycin, a benzoquinone ansamycin, suppresses hGR function by inhibiting its translocation into the nucleus. On the other hand, thioredoxin, a compound that is accumulated during

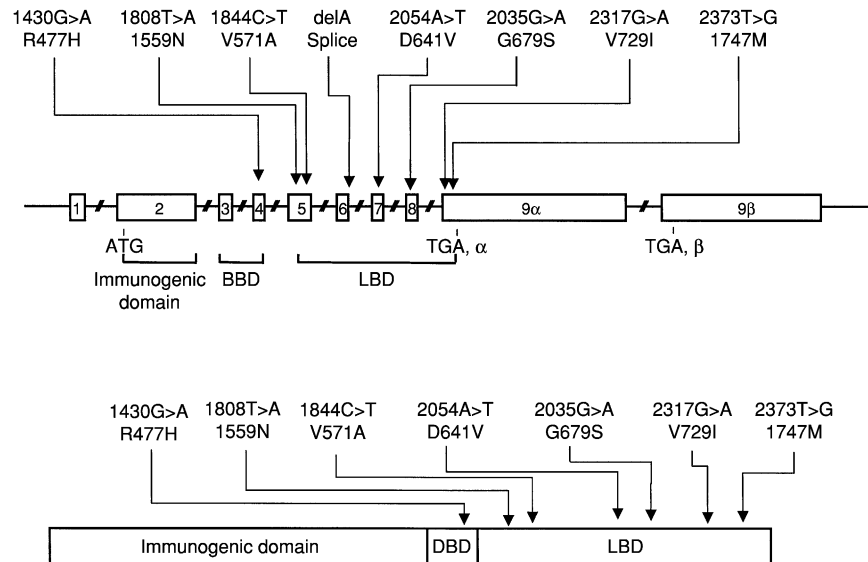

Figure 4 Location of the known mutations of the human glucocorticoid receptor in the genomic structure and its linearized molecule.

oxidative stress, and ursodeoxycholic acid, one of the hydrophilic bile acids, enhance hGR transactivation.

Natural GR Mutations

Mutations in the hGR α gene may impair one or more of the molecular mechanisms of hGR function, resulting in alterations in tissue sensitivity to glucocorticoids and the clinical phenotype of glucocorticoid resistance. Glucocorticoid resistance is a rare, familial or sporadic condition characterized by generalized, partial end-organ insensitivity to physiologic glucocorticoid concentrations. Patients have compensatory elevations in circulating cortisol and adrenocorticotropic hormone concentrations and resistance of the hypothalamic–pituitary–adrenal axis to dexamethasone suppression, but no clinical evidence of hypo- or hypercortisolism. More than 10 kindreds and sporadic cases with the condition have been reported. Abnormalities of several hGR α characteristics, including cell concentrations, affinity for glucocorticoids, stability, and translocation into the nucleus, have been associated with this condition (Fig. 4).

Glucocorticoid Receptor- β Isoform

hGR β functions as a dominant-negative inhibitor of hGR α activity and inhibits hGR α -mediated transactivation of many target genes in a dose-dependent manner. The mechanism(s) underlying this inhibition

has not been fully elucidated, but may involve competition between hGR α and hGR β for binding to GREs, formation of hGR α –hGR β heterodimers that are transcriptionally inactive, and/or titration or sequestration of coactivators needed by hGR α for full transcriptional activity. The ability of hGR β to antagonize the function of hGR α suggests that hGR β may play a critical role in regulating target tissue sensitivity to glucocorticoids. Increased expression of hGR β has been documented in generalized and tissue-specific glucocorticoid resistance and leads to a reduction in the ability of hGR α to bind to GREs. Therefore, an imbalance in hGR α and hGR β expression may underlie the pathogenesis of several clinical conditions associated with glucocorticoid resistance, such as rheumatoid arthritis, systemic lupus erythematosus, and ulcerative colitis.

Glossary

glucocorticoids Any of several hormones, including cortisol, corticosterone, and cortisone, released by the cortex of the adrenal gland.

receptor Molecule on the cell surface or inside the cell that recognizes a specific antigen or hormone.

resistance Degree of nonresponsiveness to a particular hormone or disease in the body. Also called insensitivity.

Glucocorticoids (GCs) are major effectors of basal and stress-related homeostasis, influencing cardiovascular function, regulating carbohydrate, protein, and fat metabolism, and modifying the immune/inflammatory response.

INTRODUCTION

GCs activate the central nervous system and participate in the development and basal functions of several organs and systems. Glucocorticoids bring about these effects by binding to specific intracellular receptor proteins, called glucocorticoid receptors (GRs).

Abnormalities of steroid sensitivity can be divided into two major groups: resistance and hypersensitivity. Resistance syndromes have been described for all steroids; they can be transient or permanent, partial or complete, and compensated or noncompensated. Complete glucocorticoid resistance is incompatible with life because of severe neonatal respiratory distress syndrome, as demonstrated in an *in vivo* study in which GR^{-/-} knockout mice died within a few hours after birth. On the other hand, when partial steroid resistance occurs, the hypothalamic–pituitary–adrenal (HPA) axis is reset at higher circulating levels of adrenocorticotrophic hormone (ACTH) and cortisol.

The increased ACTH levels compensate for the insensitivity of tissues to glucocorticoids, but also result in increased secretion of glucocorticoid precursors with mineralocorticoid activity [deoxycorticosterone (DOC) and corticosterone] and adrenal androgens.

Congenital glucocorticoid resistance has been described in over 10 kindreds and in a few sporadic cases and the molecular mechanisms of resistance in some of these patients have been analyzed.

MOLECULAR ACTIONS OF GLUCOCORTICOIDS

At the cellular level, GCs carry out their actions through an ~94 kDa intracellular receptor protein, the GR. This receptor belongs to the nuclear receptor superfamily (Fig. 1) of steroid/thyroid/retinoic acid receptor proteins, which function as ligand-dependent transcription factors. Since 1985, when the sequence of GR cDNA was first published, two alternative splicing products of the same gene located on chromosome 5 have been described (Fig. 2): the classic, active receptor, GR- α , and the dominant-negative isoform, GR- β . The two receptors are highly homologous, differing in just the last 50 and 15 amino acids, respectively. Therefore, the first eight exons of the GR gene containing the 5' noncoding and coding sequences are common to both receptor isoform cDNAs, whereas exons 9 α and 9 β containing the coding and 3' noncoding sequences are specific for GR- α and GR- β , respectively.

In the absence of the ligand, GR- α resides mostly in the cytoplasm of cells in a multiprotein complex consisting of the receptor polypeptide, two molecules of heat shock protein 90 (Hsp90), and several other proteins. The Hsp90s are thought to allow proper folding and stabilization of the receptor, maintaining the latter in a high-affinity, hormone-binding friendly

Figure 1 Members of the nuclear receptor superfamily and their major homologies.

state and preventing its interaction with proteins of the importin system, which are involved in the cytoplasm-to-nucleus translocation of many proteins. Experimental evidence supports a model of constant bidirectional shuttling of the complex in the unliganded state between the cytosol and the nucleus. Once the hormone binds, the receptor–ligand complex releases the Hsps and homodimerizes with another activated GR- α . This complex interacts with the importin system and translocates via the nuclear pore into the nucleus, where it positively or negatively regulates gene expression by binding as a homodimer with GC-response elements (GREs) in the presence of coregulators [CBP/p300 and SRC-1 (p160) families of “coactivators”; NcoR/RIP13 and SMRT/TRAC families of “corepressors”] or as a monomer via protein–protein interactions with other transcription factors (Fig. 3A). Through those transcription factors, including activator protein-1 (AP-1), nuclear factor κ B (NF- κ B), and Stat-5, the GR modulates the transcription rates of non-GRE-containing genes regulated by these factors (Fig. 3B).

In contrast to GR- α , GR- β does not bind to glucocorticoids and functions as weak dominant inhibitor of GR- α . This action is mediated by GRE binding, since no major protein–protein interaction with other transcription factors has been described. The intracellular localization of GR- β is uncertain; green fluorescent protein–GR- β fusion hybrids have been found in the nucleus of transfected cells, confirming the potential presence of GR- β in the nucleus, at a site other than the cytoplasm, under certain conditions even in the absence of ligand. The export of GR- β from the nucleus is much slower than that of GR- α , which could explain its accumulation in the nucleus.

MOLECULAR MECHANISMS OF GLUCOCORTICOID RESISTANCE

The molecular basis of glucocorticoid resistance has been ascribed to mutations in the GR- α gene that impair one or more of the molecular mechanisms of GR function, thus altering tissue sensitivity to GCs. Inactivating mutations within the DNA- and ligand-binding domains, as well as a 4 bp mutation at the 3' boundary of the GR- α gene, have been described in five kindreds and three sporadic cases (Table I).

In 1976, Vingerhoeds *et al.* described the first two patients, a father and a son, with long-term “hypercortisolism” not associated with clinical manifestations of Cushing’s syndrome. In 1982, Chrousos *et al.* demonstrated that these patients had abnormal glucocorticoid receptor properties and suggested that they suffered from glucocorticoid resistance. In 1991, this group described the molecular mechanism underlying the disease in this family: the proband was a homozygote for a single nonconservative point mutation, replacing aspartate at amino acid position 641 with valine, in the hormone-binding domain of the GR. This mutation reduced glucocorticoid receptor-binding affinity for dexamethasone by threefold and caused loss of transactivation activity on the mouse mammary tumor virus (MMTV) promoter.

The second family was described in 1993 by the Chrousos group as well; the proband of this family was a young woman with manifestations of hyperandrogenism. Molecular analysis showed a 4 bp deletion at the 3' boundary of exon 6, removing a donor splice site. This resulted in complete ablation of expression of one of the GR alleles associated with a 50% decrease in GR protein in the affected members of the family.

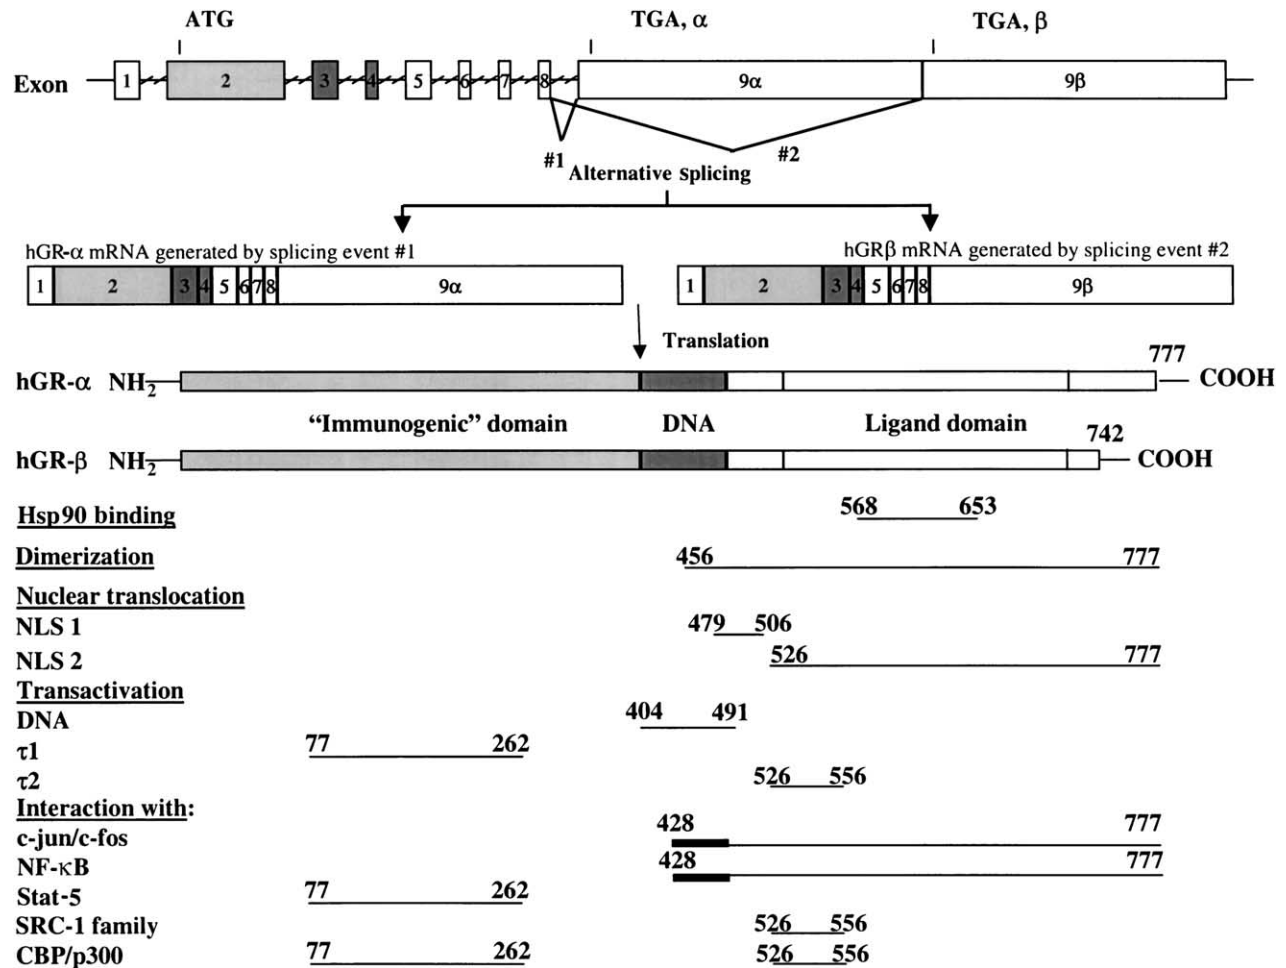

Figure 2 Structure of the hGR gene and gene products. Alternative splicing events, No. 1 (default splicing pathway) and No. 2 (alternative splicing pathway), generate two different hGR messages, which differ in size due to the use of alternative polyadenylation signals. Translation of the messages produces two isoforms of the glucocorticoid receptor, hGR-α and hGR-β, the structures of which are identical through amino acid 727 but then diverge. hGR-α, 777 amino acids long, has a molecular weight of approximately 98 kDa, whereas hGR-β, 742 amino acids long, has a molecular weight of approximately 94 kDa. Functional domains and their putative sites for these functions are indicated below the linearized GR protein. Boxes and lines represent exons and introns, respectively.

The propositus of the third kindred, a boy with precocious puberty, had a single homozygotic point mutation at amino acid 729 (valine to isoleucine) in the hormone-binding domain, which reduced both the affinity and the transactivation activity of the GR.

In 1996, another interesting, sporadic case of a man with a history of infertility, hypertension, and 5- to 10-fold elevation of urinary free-cortisol levels was described by the Chrousos group. This patient had a *de novo*, germ-line heterozygotic mutation at amino acid 559 (isoleucine to asparagine) in the hormone-binding domain, at the hinge region of the GR. This receptor had a 2- to 3-fold more potent dominant-negative activity than GR-β on the wild-type receptor

and was expressed at a 1:1 ratio with the normal GR-α in the patient’s cells. Interestingly, this mutant receptor prevented translocation of the normal receptor into the nucleus, an effect that would be overcome at very high dexamethasone concentrations. Later this patient developed severe Cushing’s disease due to an ACTH-secreting pituitary adenoma.

A fifth case/kindred with glucocorticoid resistance was studied; the proband was a young woman with signs of hyperandrogenism but no other complaint. Molecular analysis detected a heterozygotic T-to-G substitution at nucleotide 2373 of exon 9α of the GR, in the ligand-binding domain at amino acid position 747, replacing isoleucine with methionine. This

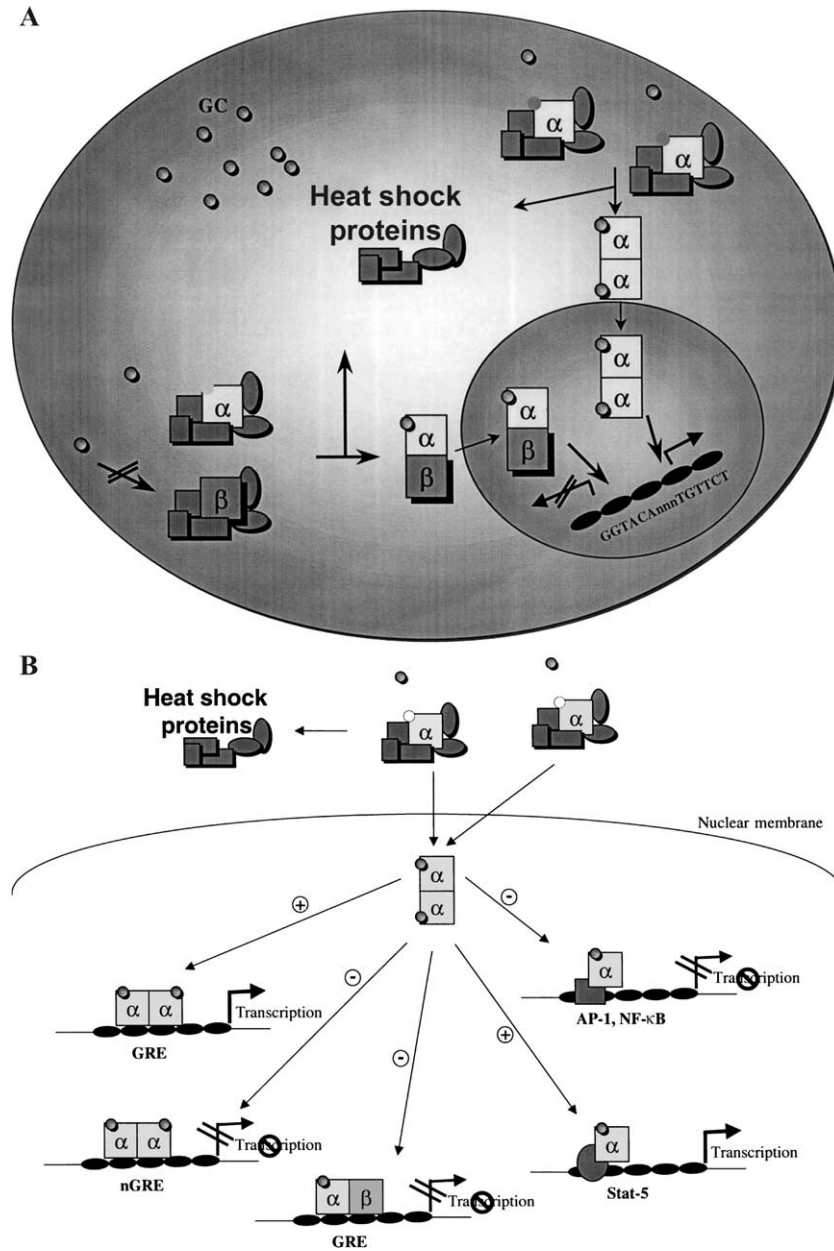

Figure 3 (A) Putative mechanisms of action of hGR- α and hGR- β . In the unliganded state, the classic glucocorticoid receptor- α resides predominantly in the cytoplasm as part of a heteromeric complex including at least five molecules of heat shock proteins. After binding to the hormone, the GR- α molecule changes its conformation and is released by the heat shock proteins. It thus homodimerizes with another hormone-activated receptor molecule and translocates to the cell nucleus, where it can regulate the transcriptional activity of target genes. hGR- β is unable to bind glucocorticoids and is transcriptionally inactive, but may have a cell-specific dominant-negative effect on GR- α , primarily on GRE-mediated actions. The GRE consensus sequence (15 bp) is shown. (B) Nuclear actions of GR- α and GR- β . After entering the nucleus, ligand-bound GR- α influences the transcription of target genes by different mechanisms: as a homodimer, it may activate transcription by binding to GRE; as a heterodimer with GR- β , it may have a diminished ability to transactivate a GRE-containing gene and, hence, may act as a dominant-negative inhibitor. Binding of a GR- α homodimer to a negative GRE (nGRE) may also lead to repression; a GR- α -GR- β heterodimer may lose the ability to repress a nGRE. Monomeric GR- α interacts with other transcription factors, such as AP-1 and NF- κ B, and prevents them from carrying out their activities, as their target genes contain AP-1 and NF- κ B sites, respectively. In a protein-protein interaction similar to that occurring between GR- α and Stat-5, GR- β acts synergistically with Stat-5 in the activation of Stat5-responsive genes. There is no evidence that GR- β interacts with or influences the activity of AP-1 or NF- κ B.

Table I Glucocorticoid Resistance: Molecular Findings

| cDNA position | Amino acid position | Mutation | Domain | Reference |
|---------------|---|---|-----------------|-------------------------------|
| 2054 (exon 7) | 641 D → V | A-to-T mutation (nonconservative) (new site for <i>Hae</i> II) | Hormone binding | Hurley <i>et al.</i> (1991) |
| 2317 (exon 9) | 729 V → I | G-to-A mutation | Hormone binding | Malchoff <i>et al.</i> (1993) |
| 1220 (exon 2) | 363 A → S (conservative change) | A-to-G mutation (conservative) | Amino-terminal | Karl <i>et al.</i> (1993) |
| | 4 bp deletion (exon 6–intron 6) | Deletion = no splice in 1 allele (segregating) | Hormone binding | Karl <i>et al.</i> (1993) |
| 1808 (exon 5) | 559 I → N | T-to-A mutation | Hormone binding | Karl <i>et al.</i> (1996) |
| 1430 (exon 4) | 477 R → H | G-to-A mutation | DNA binding | Ruiz <i>et al.</i> (2001) |
| 2035 (exon 8) | 679 G → S | G-to-A mutation | Hormone binding | Ruiz <i>et al.</i> (2001) |
| 1844 (exon 5) | 571 V → A | C-to-T mutation | Hormone binding | Mendonca <i>et al.</i> (2002) |
| 2373 (exon 9) | 747 I → M | T-to-G mutation | Hormone binding | Vottero <i>et al.</i> (2002) |

mutation was located close to helix 12 at the C-terminus of the ligand-binding domain, which plays a pivotal role in the formation of activation function-2, a subdomain that interacts with p160 coactivators. The mutant receptor had an approximately 2-fold reduced affinity for dexamethasone and its transcriptional activity on the glucocorticoid-responsive MMTV promoter was compromised by 20- to 30-fold; interestingly, it also had dominant-negative activity on the wild-type receptor, probably secondary to the defective interaction of the mutant receptor with p160 coactivators.

Two novel mutations in the GR gene were found in two unrelated patients with primary cortisol resistance as defined by a pathologic dexamethasone suppression test: R477H in the DNA-binding domain, which is the first reported mutation in that region of the human GR gene, and G679S in the ligand-binding domain. The R477H mutation showed no transactivating capacity, whereas the G679S mutation had reduced transactivation capacity and 50% binding affinity compared to the wild-type GR.

A new phenotype, female pseudo-hermaphroditism and severe hypokalemia, caused by a novel inactivating mutation of the GR gene has been described. A homozygous T-to-C substitution at nucleotide 1844 in exon 5 of the GR gene, which caused a valine to alanine substitution at amino acid 571 in the ligand-binding domain of the receptor, was identified

in the patient. This phenotype indicated that both pre- and postnatal virilization can occur in females with the glucocorticoid resistance syndrome.

The molecular mechanisms of action of some of the natural glucocorticoid receptor mutants causing familial glucocorticoid resistance have been studied. In particular, each of the mutations analyzed imparted different functional defects on the GR signal transduction pathway, which might partly explain the variable clinical phenotype of generalized glucocorticoid resistance. This variability includes patients with no abnormalities in the coding sequences and intron–exon boundaries of their GR genes.

The importance of GR- β under physiologic conditions is controversial, but it has been proposed that in pathologic situations, such as glucocorticoid resistance, it might play a pathophysiologic role. Taking into consideration the finding that increasing amounts of GR- β produce a dose-dependent decrease in wild-type GR- α transcriptional activity, an imbalance in the expression of these two isoforms might determine an altered sensitivity to glucocorticoids. Supporting a possible role of GR- β in glucocorticoid sensitivity, a genetically determined imbalance in the expression of the glucocorticoid receptor isoforms was observed in cultured lymphocytes from a patient with congenital generalized glucocorticoid resistance and chronic leukemia; in this patient, a low GR- α to GR- β ratio was found compared to a group of normal controls,

possibly explaining the glucocorticoid resistance since no abnormalities in the sequence of the entire cDNA or in individual exons of this patient's gene were found. In keeping with these findings, a significantly higher number of GR- β immunoreactive cells were found in peripheral blood and bronchial lavage cells from glucocorticoid-resistant asthma type 1 patients than from glucocorticoid-sensitive asthmatic patients and normal controls.

Animal models of systemic glucocorticoid resistance, such as New World primates, including squirrel monkeys, marmosets, and owl monkeys, have been described. These animals have total plasma cortisol levels that are 7–20 times higher than in humans or other Old World primates, whereas the concentration, affinity, and predicted amino acid sequence of their GRs are similar to those of the human receptor. Interestingly, these animals exhibit resistance to a variety of other steroid/sterol hormones, including estrogens, progesterone, androgens, aldosterone, and vitamin D. Immunoreactivity of both isoforms of the GR has been found in Epstein-Barr virus-transformed B lymphocytes from marmosets, with the β -isoform being \sim 10 times overexpressed compared to the corresponding human cells. An altered splicing pattern of the GR pre-mRNA or differential rates of mRNA translation, mRNA degradation, and/or GR protein degradation might contribute to the steroid resistance of these animals. Alternatively, these animals may have decreased coactivator activity and/or increased corepressor activity, leading to their "pansteroid" resistance.

Two sisters with manifestations of glucocorticoid resistance were described by New *et al.* Their evaluation revealed resistance not only to glucocorticoids, but also to mineralocorticoids and androgens; however, they displayed no resistance to vitamin D or thyroid hormones. The diagnosis of these patients was multiple, partial steroid resistance. The New World primate physiologic and biochemical syndrome and the two pathologic human multiple steroid resistance syndrome cases are the first conditions in which a defective steroid receptor coregulator has been suggested to be responsible for an altered clinical and/or biochemical picture.

CLINICAL CHARACTERISTICS OF GLUCOCORTICOID RESISTANCE

Patients with glucocorticoid resistance syndrome have compensatory elevations in circulating cortisol and ACTH concentrations, which maintain circadian

rhythmicity and appropriate responsiveness to stressors, albeit at higher hormone concentrations, and resistance of the HPA axis to dexamethasone suppression, but no clinical evidence of hypo- or hypercortisolism. The excess of ACTH results in increased production of adrenal steroids with mineralocorticoid and/or androgenic activity.

The clinical spectrum of this disease is quite broad, ranging from completely asymptomatic to mild to severe symptomatic conditions. A large number of subjects may be asymptomatic or display biochemical alterations only. Clinical manifestations due to the excess of mineralocorticoids (including cortisol itself), acting on the intact mineralocorticoid receptor of the patients, are hypertension with or without hypokalemic alkalosis. The increased amounts of androgens, on the other hand, lead to acne, hirsutism, male pattern baldness, menstrual irregularities (oligo-amenorrhea), oligo-anovulation, and infertility in women. In children, early and excessive prepubertal adrenal androgen secretion has been associated with ambiguous genitalia and precocious puberty. In adult men, oligospermia and infertility have been observed, possibly as the result of interference with follicle-stimulating hormone feedback regulation by the excessive adrenal androgens or by the ACTH-induced intratesticular growth of adrenal rests, which may occur as they do in classic and "late-onset" congenital adrenal hyperplasia. Because of the excessive secretion of adrenal androgens, bone mass density is usually high-normal to elevated in patients with glucocorticoid resistance, in contrast to patients with Cushing's syndrome, in whom osteoporosis is observed.

DIAGNOSIS

The hallmark of the diagnostic evaluation of glucocorticoid resistance is increased serum cortisol and urinary free-cortisol levels without Cushing's syndrome clinical stigmata. Despite cortisol excess, plasma ACTH concentration is normal or high. The circadian rhythm of cortisol and its responsiveness to stress are intact in patients with glucocorticoid resistance who are also resistant to single or multiple doses of dexamethasone. Differential diagnosis includes (1) early or mild forms of Cushing's syndrome; (2) pseudo-Cushing states, such as generalized anxiety disorder, melancholic depression, and/or chronic active alcoholism, conditions associated with obesity and increased cortisol secretion; (3) other causes of mineralocorticoid-induced hypertension; and (4) hirsutism (including idiopathic hirsutism), polycystic

ovary syndrome, and late-onset congenital adrenal hyperplasia.

THERAPY OF GLUCOCORTICOID RESISTANCE SYNDROME

Asymptomatic, normotensive subjects with primary glucocorticoid resistance do not require any treatment. In contrast, patients with symptomatic generalized glucocorticoid resistance are treated with high, individualized doses of oral dexamethasone (0.5–1.0 mg two or three times daily), a synthetic, potent glucocorticoid with minimal intrinsic mineralocorticoid activity. The goal is to suppress ACTH and, therefore, endogenous cortisol, DOC, corticosterone, and adrenal androgen secretion, correcting the states of mineralocorticoid and androgen excess in these patients.

Hypertensive patients should receive the smallest dose that lowers the serum concentration of cortisol and other mineralocorticoids and corrects electrolyte abnormalities. Hirsute patients should be treated with doses able to reduce the androgen excess.

Untreated patients have no risk of adrenal insufficiency and do not need extra doses of dexamethasone in particularly stressful situations, such as surgery and illness. In contrast, patients undergoing chronic treatment should receive the appropriate glucocorticoid coverage.

administration. Also, glucocorticoids decrease in a timely manner the expression of L-selectin on bone marrow progenitors and on differentiating neutrophils that, then, reach the bloodstream with low L-selectin levels. Chemokines released from the inflamed tissue are important for activating neutrophils and initiating the program of cell transmigration. The inhibition of the release of chemokines, such as interleukin-8 (IL-8) and other cysteine-X-cysteine (CXC) chemokines, also participates in the inhibition of neutrophil transmigration by glucocorticoids.

Eosinophils, basophils, and T helper 2 (Th2) cells are recruited by chemokines, which are released by immune and nonimmune cells, such as epithelial cells or airway smooth muscle cells. These β -chemokines, or cysteine-cysteine (CC) chemokines, enhance adhesion molecule expression on endothelial cells to allow eosinophils and basophils to roll through the vessel wall. In fact, glucocorticoids prevent tissue invasion of eosinophils by inhibiting the release of CC chemokines, such as eotaxin, eotaxin 2, MCP4 (macrophage inflammatory protein 4), and RANTES (regulated on activated normal T-cell expressed and secreted), released by bronchial epithelial cells. Simultaneously, whereas glucocorticoids decrease the expression of some chemokine receptors, they enhance the expression of others on eosinophils, further complicating the overall picture of eosinophil trafficking.

The flow and movement of monocytes seem tightly regulated by glucocorticoids via similar mechanisms, namely, through the repression of monocytes and endothelial adhesion molecules and the regulation of chemokines and their receptors.

Innate Immune Response

Glucocorticoids act on the immune system by both suppressing and stimulating a large number of pro-inflammatory or anti-inflammatory mediators. In many ways, glucocorticoids lead to the termination of inflammation by enhancing opsonization and the activity of scavenger systems and by stimulating macrophage phagocytotic ability and antigen uptake. Glucocorticoids stimulate the expression of the mannose receptor or the scavenger receptor CD163, promoting the clearance of microorganisms, dead cell bodies, and antigens. Moreover, they potentiate interferon- γ (IFN- γ)-induced Fc γ RI. At the same time, they prevent inflammation from overshooting, by suppressing the synthesis of many inflammatory mediators, such as several cytokines and chemokines, prostaglandins, leukotrienes, proteolytic enzymes, free oxygen radicals, and nitric oxide.

A large number of cytokines [including IL-1 β , tumor necrosis factor α (TNF α), IL-6, IL-8, IL-12, and IL-18] are broadly down-regulated by glucocorticoids. Similarly, the secretion of many CC and CXC chemokines is strongly suppressed. Interestingly, anti-inflammatory cytokines such as IL-10 and transforming growth factor- β (and to some extent, although it is a matter of some debate, IL-1RA, the IL1 receptor antagonist) are up-regulated by glucocorticoids. Although the negative regulation of pro-inflammatory cytokines by glucocorticoids has been clearly demonstrated both *in vitro* and *in vivo*, glucocorticoids enhance the receptor of some of these pro-inflammatory cytokines and chemokines. It is tempting to speculate that they increase receptor expression to improve the sensitivity of target immune cells to these mediators and help these cells to resolve inflammation. Soluble or decoy receptors inhibiting or further enhancing the inflammatory process are also regulated by glucocorticoids. For example, the decoy receptor IL-1RII, which binds IL-1 without driving its signaling, is enhanced by glucocorticoids. This represents an anti-inflammatory mechanism of action of glucocorticoids. Inversely, the soluble IL-6R is increased by glucocorticoids and further amplifies the pro- or anti-inflammatory response to interleukin-6.

An intriguing inflammatory mediator is the macrophage inhibitory factor (MIF), whose secretion is triggered by glucocorticoids. Synthesized by anterior pituitary cells and macrophages in response to endotoxin challenge and pro-inflammatory cytokines such as TNF α , MIF exerts a major pro-inflammatory effect on macrophages and T cells and overrides the anti-inflammatory and immunosuppressive actions of glucocorticoids. In fact, MIF increases lethality, whereas genetic deletion or therapeutic neutralization confers protection against endotoxemia, acute distress respiratory syndrome, and septic shock. The finding that Toll-like receptor (TLR) 4 expression is increased by MIF underscores the essential role of MIF in the macrophage response to endotoxins and gram-negative bacteria. This indeed may explain why MIF-deficient mice were hyporesponsive to lipopolysaccharide (LPS). Thus, the notion that glucocorticoids enhance the secretion of a major pro-inflammatory cytokine that counteracts their effects represents a yin/yang mechanism of control of the acute-phase response or septic shock.

By inhibiting phospholipase A2, inducible cyclooxygenase 2 (COX2), and inducible prostaglandin (PG) synthase 2 (PGS2), glucocorticoids block the release of arachidonic acid and the synthesis of prostaglandins (PGE2, PGH2, and PGD2) and platelet-activating factor; both constitutive COX1 and PGS1 remain

unaffected by glucocorticoids. Several lines of evidence suggest that glucocorticoids prevent COX2 expression through both posttranscriptional and post-translational mechanisms. Strikingly, glucocorticoids could enhance 5-lipoxygenase and 5-lipoxygenase-activating protein expression in monocytes and eosinophils. This is rather surprising given the overall reduced secretion of leukotrienes after glucocorticoid exposure. It seems that the decreased production of leukotrienes is related to the inhibition of phospholipase A2 expression and activity by glucocorticoids. Glucocorticoids may also suppress the reduced form of nicotinamide adenine dinucleotide phosphate oxidase and superoxide dismutase expression and, hence, the production of free oxygen radicals. Nitric oxide appears to be an important intra- and intercellular signaling molecule in shaping the innate and adaptive immune response with both detrimental and protective effects. Glucocorticoids suppress inducible nitric oxide synthetase expression, which results in a decrease in nitric oxide release by endothelial cells. This inhibition also seems to be mediated by the glucocorticoid second-messenger lipocortin 1 and would prevent early endothelial cell-mediated inflammatory reaction.

ADAPTIVE IMMUNITY

Antigen Presentation and Adaptive Immune Response

Dendritic cells (DCs) represent the crucial interplay between innate and adaptive immunity. On encountering microorganisms or antigens, tissue-resident DCs rapidly differentiate and migrate to secondary lymphoid organs. These immature DCs demonstrate increased antigen uptake ability and specialized antigen-processing machinery. Glucocorticoids potentiate this "immature" phenotype. They improve opsonization and the activity of scavenger systems and stimulate macrophage phagocytosis, pinocytotic ability, and antigen uptake. TLRs mediate patterns of microorganism antigen recognition in macrophages, immature DCs, and mature DCs. Interestingly, glucocorticoids modulate the expression of TLR4, the LPS receptor, emphasizing the crucial role of glucocorticoids early in the innate immune response.

During their migration, DCs mature and express major histocompatibility complex (MHC) class II and costimulatory molecules to efficiently present the antigen, as professional APCs (antigen-presenting cells), to naive or memory T cells. Crosstalk between

T cells and dendritic cells through TCR (T-cell receptor)/MHC II-bound antigen, costimulatory molecules, and cytokines allows the development of a T cell immune response and T cell expansion or deletion. When exposed to glucocorticoids during maturation, these DCs have a decreased ability to present antigens and elicit a T cell response, primarily because glucocorticoids prevent MHC class II up-regulation and the expression of the costimulatory molecules, such as B7.2 (CD86) and to some extent B7.1 (CD80), CD40, and the ICAM-1/LFA-1 (intercellular adhesion molecule-1/lymphocyte function associated antigen-1) complex. It is noteworthy that terminally differentiated DCs continue to express these molecules due to their relative resistance to glucocorticoids. The timing of exposure to glucocorticoids thus appears to be essential during dendritic cell maturation.

Once a T cell immune response has flared up, glucocorticoids may modulate and interfere with the type of T cells involved. The differentiation of CD4⁺ T cells into T helper 1 (Th1) lymphocytes, which drive cellular immunity, or into Th2 lymphocytes, which drive humoral immunity, depends on the type of antigen encountered and the type of cytokines produced during antigen presentation. Indeed, glucocorticoids block IL-12 secretion by monocytes and DCs. Interleukin-12 is the link between innate and cellular immunity and is crucial for the development of the Th1-directed cellular immune response. On the other hand, glucocorticoids promote Th2 development by enhancing IL-10 secretion by macrophages and immature DCs. In fact, several studies clearly showed, in both mice and humans, that the presence of glucocorticoids during the primary immune response, associated with defective IL-12 production by macrophages or DCs, enhanced Th2 cytokine secretion and decreased Th1 cytokine secretion by CD4⁺ lymphocytes on secondary stimulation. This effect seemed IL-12-dependent since it was reversed by the addition of exogenous IL-12 to glucocorticoid-treated APCs during the primary stimulation. Moreover, the poor glucocorticoid regulation of costimulatory molecules in mature DCs ruled out any role for costimulation in this process. Terminally differentiated DCs have been classified into DC1 and DC2, depending on their cytokine secretion profile and their aptitude to force the differentiation of naive T cells into Th1 and Th2 mature lymphocytes. Thus, DC phenotypes seem to be twisted by glucocorticoids into a DC2 program that will ultimately generate a Th2 immune response and the secretion of Th2 cytokines.

Cellular Immune Response

Interleukin-12 is required for Th1 lymphocyte differentiation and secretion of Th1 cytokines, such as IFN- γ and TNF α . Alterations in IL-12 signaling, such as those observed in IL-12^{-/-} and IL-12R-deficient mice, are associated with a defective Th1 immune response. In fact, glucocorticoids not only block IL-12 secretion by monocytes/macrophages and DCs, they also suppress IL-12R β 1 and IL-12R β 2 expression on T cells. They also interfere with IL-12 signaling and prevent IL-12-induced signal transducer and activator of transcription 4 (Stat4) phosphorylation and Stat4-dependent gene expression such as that for interferon regulatory factor-1. Blocking Stat4 activation mimics the situation in Stat4-deficient mice, which are unable to elicit a Th1 immune response. Glucocorticoids also profoundly suppress secretion of the Th1 cytokines IFN- γ and TNF α , lessening NK and T cytotoxic effector functions. Such massive inhibition of the Th1 immune response by glucocorticoids led to severe cellular immunodeficiency and impaired defense against intracellular and opportunistic infections.

Humoral Immune Response

Whereas glucocorticoids profoundly decrease the secretion of Th2 cytokines during primary stimulation, they promote Th2 differentiation during secondary stimulation. Independent of monocytes/macrophages and DCs, glucocorticoids prime naive T cells to Th2 commitment during secondary immune response. Glucocorticoids that are present during primary stimulation promote IL-10 secretion during secondary stimulation in both naive and memory T cells. Sequential contact with glucocorticoids during the primary and/or secondary immune response may thus influence the pattern of Th2 cytokines. This context-dependent action of glucocorticoids may explain some discrepancies reported in the literature on the regulation of Th2 cytokines by glucocorticoids. Very interestingly, by up-regulating IL-10 secretion by macrophage/DCs and Th2 cells, glucocorticoids may participate in the emergence of regulatory T cells, high-IL-10-producing T cells with major *in vivo* immunoregulatory properties as shown in experimental allergic encephalomyelitis.

Following exposure to endogenous or exogenous glucocorticoids, a progressive shift takes place from a cellular Th1 immune response to a humoral Th2 immune response. A major question remains regarding

how glucocorticoids induce Th2 lymphocyte differentiation and the humoral immune response. First, it is well recognized that the lack of commitment in developing a Th1 immune response, namely, the absence of IL-12, is associated with Th2 development. Therefore, the profound suppression of Th1 differentiation by glucocorticoids may undoubtedly participate in Th2 immune response development. Second, glucocorticoids also have differential action on IL-12 and IL-4 signaling. Interleukin-12 and IL-4 activate Stat4 and Stat 6, respectively. Deletion of Stat4 or Stat6 in mice is associated with poor Th1 and Th2 immune responses, respectively. In fact, glucocorticoids block IL-12-mediated Stat4 activation without altering IL-4-induced Stat6 phosphorylation and, hence, help a Th2 immune response to develop. Finally, a growing number of transcription factors have been shown to play a critical role in the hierarchical control of Th1 and Th2 lymphocyte differentiation. Thus, by acting directly on either lymphocytes or DCs, endogenous glucocorticoid hypersecretion or administration of excessive amounts causes a progressive shift from a Th1-directed cellular immune response to a Th2-driven humoral immune response.

It is undeniable that glucocorticoids favor a humoral immune response and antibody production. *In vivo* administration of glucocorticoids raises immunoglobulin E (IgE) serum levels in asthma or atopic patients. Despite the paucity of information, glucocorticoids modulate B cell development. They restrain B cell proliferation and early steps in B cell development but promote the generation of antibody-secreting plasma cells and the secretion of IgE and IgG4. Like DCs and effector T cells, B cells become resistant to the inhibitory actions of glucocorticoids as they proceed through the different stages of differentiation and maturation. Surprisingly, the question of how these hormones influence B cell receptor signaling compared to TCR signaling has never been explored, underscoring the lack of interest in glucocorticoid-mediated actions on B cells. Interleukin-4 is the critical cytokine that induces Th2 differentiation and promotes B cell differentiation and IgE isotype switching. Interestingly, glucocorticoids act in synergy with IL-4 in B cell differentiation and isotype switching, leading to IgE-secreting B cells. Such IgE isotype switching is dependent on the CD40/CD40L complex since it is not observed in X-linked hyper-IgM (CD40L-deficient) patients. In fact, glucocorticoids up-regulate CD40L expression on B cells and this finding may explain their synergistic actions on IgE isotype switching.

Allergy-Mediated Immune Response and Inflammation

The fact that glucocorticoids are used in the treatment of atopy and asthma and promote humoral Th2 immune response and IgE secretion represents a disturbing and challenging paradox. In truth, glucocorticoids may enhance IgE secretion but they strongly suppress allergic inflammation and chemokine-driven tissue infiltration of eosinophils. Furthermore, it has been suggested that glucocorticoids would inhibit antigen-specific IgE production while raising total IgE levels. This may elucidate why IgE serum levels remained high in asthma patients in clinical remission during steroid treatment. Although they prime DCs and T cells for Th2 development on secondary stimulation, glucocorticoids inhibit Th2 cytokine secretion during primary antigen exposure. Despite an ongoing Th2 immune response, glucocorticoids can still prevent the potentially deleterious IgE-induced allergic immune response by mast cells. Indeed, they interfere with IgE receptor-mediated release of inflammatory mediators and deplete bronchial mucosa from resident mast cells. Suffice it to say, mucosal mast cells are the predominant effector cells orchestrating allergic inflammation. *In vivo* studies suggest that glucocorticoids deplete tissue mast cells by inhibiting essential survival factors such as IL-4 and fibroblast-derived stem cell factor. Cross-linking of their FcεRI with specific IgE results in the degranulation of preformed inflammatory mediators such as histamine, proteases, cytokines, and lipid mediators responsible for the early phase of type I hypersensitivity manifestations. Interestingly, glucocorticoids block IgE-triggered degranulation of human mast cells. They also prevent the late phase of type I hypersensitivity characterized by mast cell activation with *de novo* synthesis of inflammatory mediators and secondary infiltration of Th2 cells, basophils, and eosinophils. Glucocorticoid-induced down-regulation of high-affinity FcεRI and low-affinity FcεRI (CD23) expression may account for the poor response of IgE-triggered mast cell activation only in the late phase. Glucocorticoids also interfere with FcεRI signaling through the disruption of raf-1/heat shock protein 90 and the subsequent mitogen-activated phosphokinase activation and phospholipase A2 responsible for the *de novo* synthesis of arachidonic acid-derived metabolites. Finally, glucocorticoids inhibit cytokine synthesis of pro-inflammatory cytokines and chemokines by mast cells necessary for their own survival and the chemotaxis and expansion of eosinophils and basophils.

T CELL DEVELOPMENT AND HOMEOSTASIS

Though supra-pharmacologic doses of glucocorticoids induce T cell apoptosis, adrenal- or thymus-derived glucocorticoids or physiologic doses of glucocorticoids can induce T cell survival or apoptosis, depending on the cell type and differentiation stage. Moreover, both the degree of T cell activation and the timing of glucocorticoid exposure (before, during, or after activation) render T cells sensitive or resistant to glucocorticoid-induced apoptosis. Several studies have shown that concomitant TCR signaling and glucocorticoid receptor (GR) signaling promote T cell survival, whereas either TCR signaling alone or GR signaling alone induces T cell apoptosis. Indeed, thymus-derived glucocorticoids appear to play a role in early thymocyte expansion and in central positive selection. Yet, GR^{-/-} knockout mice demonstrate a normal thymus, suggesting that glucocorticoid actions on TCR signaling could occur through nongenomic actions that are independent of GR transcriptional activity. Similarly, there is some evidence suggesting that glucocorticoids could influence peripheral T cell development and selection by simultaneously preventing TCR-induced T cell deletion and enhancing T cell survival. Interestingly, glucocorticoids enhance a key cytokine receptor for T cell development, IL-7Rα, whose deletion in mice and humans is associated with a lack of T cells. Moreover, IL-7 potently enhances thymic-independent peripheral expansion and restores immunity in athymic T cell-depleted hosts in mice. The positive regulation of IL-7Rα expression by glucocorticoids suggests their strong influence in the maintenance of peripheral T cell pool homeostasis.

CONCLUDING REMARKS

The description of the actions of glucocorticoids on the immune response elucidates their positive and negative effects on several components of the innate and adaptive immune responses. Glucocorticoid-induced immunomodulation requires both immunoenhancing and immunosuppressive actions at the same time and these should be integrated in a dynamic, ongoing process. Indeed, pro-inflammatory mediators participate, to the same extent, with anti-inflammatory mediators in the so-called immunosuppressive actions of glucocorticoids. The great advantage of their clinical use in Th1-inflammatory and Th1-autoimmune diseases is obvious because they restrain the inflammatory reaction, prevent tissue

destruction, and block Th1-driven immune responses. Also, the fact that there are glucocorticoids that favor innate immunity and antibody responses may explain why they exhibit clinical benefit in bacterial infections such as in bacterial meningitis. Similarly, the fact that glucocorticoids enhance the phagocytotic ability of neutrophils and macrophages, boosting scavenging and opsonization systems, underscores the clinical benefit and importance of early and continuous administration of glucocorticoids in patients in septic shock. However, these beneficial effects coexist with deleterious adverse effects. Because of their suppressive actions on Th1 immunity, they increase susceptibility to intracellular and opportunistic infections such as tuberculosis or viral infections. Finally, glucocorticoids may worsen disease activity due to their selective immunoenhancing actions. This was hieratically reported in steroid-resistant asthma and ulcerative colitis.

The overall knowledge of the actions of glucocorticoids on adaptive immunity clearly revealed that by decreasing the ability of DCs to elicit a T cell immune response, by promoting Th2 differentiation and helping the development of regulatory T cells, glucocorticoids may induce tolerance. Therefore, glucocorticoids could be extremely helpful in cell therapy through their *ex vivo* action not only on DCs but also potentially on regulatory T cells. This *ex vivo* therapeutic use of glucocorticoids would be very beneficial, thanks to their immune modifier effect, and avoid their long-term deleterious adverse effects. Glucocorticoids could thus represent an adjuvant treatment for cell therapies in autoimmune diseases and organ transplantations.

REGULATION OF THE HYPOTHALAMIC–PITUITARY–ADRENAL CORTEX AXIS

Glucocorticoids serve a critical role in adaptation to the changing environment. Their levels are invariably increased by subconscious alterations in homeostasis as well as by what we personally define as “stressful,” be it an external stimulus or an internal perception. On realization of the stressor, higher order neural circuits lift the inhibition imposed by the hippocampus on the hypothalamic–pituitary–adrenal cortex (HPA) axis. As a result, corticotropin-releasing hormone (CRH) is secreted from the paraventricular nucleus of the hypothalamus, which in turn stimulates release of adrenocorticotropin (ACTH) from the anterior pituitary and subsequently secretion of glucocorticoids (CORT: cortisol in humans; corticosterone in rodents) from the adrenal cortex. During its initial phase, this elevation of CORT helps to address the challenge by improving cognition through mineralocorticoid receptors (MRs) in the hippocampus and increasing the energy availability to the brain and skeletal muscles. Once the stressor has been properly addressed, the HPA axis is inhibited by negative feedback mainly through the glucocorticoid receptors (GRs) in the hippocampus, hypothalamus, and pituitary. After the CORT levels return to baseline, MRs in the hippocampus take over the control of regulating basal CORT levels.

AGE-RELATED ALTERATION IN CORTICOSTERONE PROFILE IN RODENTS

Age-related changes in the human HPA axis are susceptible to a myriad of factors that can be generally divided into genetic differences, nonpsychological environmental factors, complex daily personal interactions, various life histories, and interactions among these factors that define our attitude toward life experiences. In contrast, most of these factors are well controlled in experiments examining aging in laboratory rodents. However, even here, the data have been highly variable. After analyzing the available data on age-related alterations in plasma CORT in several different rat strains, Sapolsky concluded that there was more than a twofold increase in CORT with age. This has been corroborated by other more recent studies. A more descriptive picture of the age-related plasma CORT levels was gained from a longitudinal study in Fischer 344 rats by Sabatino and colleagues. They

found that the free CORT levels increased twofold between middle age and old age. Furthermore, the diurnal pattern showed an expansion of the circadian peak into the trough. This suggests that with progressing age, there is more activation of GRs and for a longer period. Another important result from this study was that when the rats were young, restraint stress-induced CORT levels started to decline soon after termination of the stressor, whereas in old age the stress-induced CORT levels stayed elevated for an additional 30 min prior to the decline. Because these animals were not chronically stressed, these age-related differences arise due to mechanisms that are not well appreciated.

Age also seems to affect the expression levels of the MR and GR. The most consistent observation is the age-related decline in MR mRNA and protein levels within the hippocampus. On the other hand, changes in hippocampal GR levels appear to be strain dependent, with age-related decreases in both mRNA and protein levels in some rat strains but not in others. Interestingly, decreases in hippocampal MRs and GRs are also observed in chronically stressed animals, and the extent of reduction in these receptors may be associated with the severity of stress. Thus, the age- and stress-related modulation of MR and GR expression has a serious impact on regulation of the HPA axis.

In light of the importance of these receptors in the regulation of the HPA axis, it should be mentioned that life histories play an important role in expression of these receptors in the hippocampus. Meaney and colleagues reported that maternal affection (licking) during postnatal development in rodents increases GR expression and that these pups, during their adulthood, show an attenuated CORT response to stress, have a lower age-related increase in CORT, and are less cognitively impaired than their counterparts. In contrast, pups that were deprived of maternal care or infected with endotoxins show a decrease in their hippocampal receptor levels and show an accentuated CORT response to stressors during adulthood. Furthermore, elevated CORT levels during fetal development decrease the expression of these receptors and possibly predispose these animals to age-related increases in CORT. Thus, experiences over a lifetime should be considered as an important variable in age-related CORT elevations.

CORTICOSTERONE LEVELS, AGE, AND COGNITIVE IMPAIRMENT IN RATS

As with age-related increases in plasma CORT levels, the within-group variability in cognitive performance

among the aged animals is large. In one study by Meaney and colleagues, 20% of the aged rats were cognitively unimpaired (AU) and performed as well as young controls, whereas 28% of the aged rats showed dramatic cognitive impairment (AI). Furthermore, these two aged groups differed significantly for several hippocampus-HPA parameters. The plasma CORT levels across the diurnal cycle in the AU rats were similar to those in the young rats with a single peak of elevated CORT levels at the beginning of the dark cycle, whereas the AI rats showed an expansion of the diurnal peak such that the body was exposed to elevated CORT levels for an extended period of time (12 h); this diurnal pattern is similar to that observed by Sabatino and colleagues mentioned previously. The AI rats also had elevated plasma ACTH levels at the beginning of the acrophase, and this was probably responsible for the extended period of elevated CORT in this group. The termination of stress-induced CORT response was also different in these two aged groups, such that the total CORT exposure (area under the curve) in the AI rats was much greater. Consistent with this profile, the hippocampal MR and GR levels in the AI animals were lower than those in the AU rats.

The data from McEwen's laboratory has clearly established that stress-related increases in CORT are associated with atrophy of the dendritic tree, such that the number of branching points is decreased. This is likely to yield a dramatic reduction in the number of synapses. This is supported by Jucker and colleagues' observation that the number of synaptic boutons in the dentate gyrus region of the hippocampus is associated with performance in the Morris water maze.

An added cellular complexity should also be mentioned. Plasma CORT levels are not necessarily the "true" indication of total cellular CORT exposure. Intracellular CORT levels are regulated by 11β -hydroxysteroid dehydrogenase (11β -HSD). The type 1 isoform, 11β -HSD1, can convert inactive CORT metabolites (11-dehydrocorticosterone, cortisone) back to active CORT. Seckl's group has shown that old mice lacking 11β -HSD1 perform as well as young controls in the Morris water maze, whereas old control mice take twice as long to find the hidden stage. Because the levels of the CORT metabolites are in excess of the free CORT levels, regulation of this activity can prove to be extremely beneficial in decreasing CORT-related cognitive impairment.

AGE-RELATED ALTERATION IN THE CORTISOL PROFILE IN HUMANS

Despite all of the previously mentioned concerns regarding examination of age-related changes in CORT in humans, it is important to assess whether the human HPA axis is susceptible to dysregulation with age. However, these concerns cannot be undermined and should be evaluated further because doing so may set forth hypotheses that are directly relevant to successful aging as well as to age-related disorders in which etiology remains unclear. For example, it is possible to subdivide healthy volunteers based on their anticipatory stress responses, dexamethasone suppression of CORT levels, and ACTH responsiveness. All of these parameters are quantitative, and if they are to be followed longitudinally, they might allow identification of progressive steps that increase susceptibility to age-related disorders.

The data regarding age-related alteration in basal plasma CORT levels in humans are inconsistent. Because most of these studies have also evaluated cognitive functions, the data are discussed in more detail in the next section. However, an important difference in the experimental design between the rodent studies and the human studies should be emphasized here: in the human studies, unhealthy individuals are either excluded or considered as an independent variable, whereas the same level of discretion is hard to attain, and is often ignored, in rodent studies. Proinflammatory cytokines can activate the HPA axis and may contribute to the age-related cognitive impairment observed in rodents. This may explain some of the inconsistencies observed between the human data and the rodent data.

The HPA axis in humans is not spared by aging. It is now widely accepted that elderly humans also show a delayed termination of the CORT response after a stressful situation. One possible explanation for this increase in latency is the "accumulative effect of stress" over the life span. Allostasis refers to constant alterations in the HPA axis that are necessary to maintain homeostasis in the new environment/situation. As the frequency of HPA activation and/or total exposure to CORT increases, so do the side effects of hypercortisolemia. The HPA axis is designed to minimize this consequence by a negative feedback mechanism, but as the "allostatic load" on the hippocampus increases, the regulation of HPA deteriorates and CORT levels stay elevated for longer than necessary. A subgroup of elderly persons also show elevated

nighttime CORT levels, leading to the suggestion that pharmacological intervention to reduce nighttime CORT may have therapeutic value in these individuals.

COGNITIVE IMPAIRMENTS AND PLASMA CORTISOL LEVELS IN HUMANS

The human data do not show a direct relationship between age and cognition or between age and cortisol levels. However, elderly persons tend to have a greater risk of both cognitive impairment and elevated cortisol levels. In the MacArthur Foundation Study on Successful Aging, healthy elderly individuals residing in three different communities were followed for $2\frac{1}{2}$ years. During this period, 20% of the women showed a progressive increase in CORT, whereas 15% showed a decline in urinary CORT levels. In the subgroup with increasing CORT, 75% of the women showed poor performance on the delayed recall of a story task as compared with their performance at the start of the study. In contrast, in the subgroup with decreasing CORT, 70% of the women showed an improvement in their performance on this task. Similarly, Lupien and colleagues found that individuals with increasing CORT over a 5-year period performed poorly on the delayed memory and spatial memory tests as compared with individuals with stable/decreasing CORT levels. Furthermore, those with increasing CORT had a mean 15% decrease in the hippocampal volume. Hippocampal atrophy of a similar extent ($>10\%$) is also seen in AD. More than half of the studies that have examined basal cortisol levels in AD reported an association between AD and increased plasma cortisol. Furthermore, the few studies that have examined the HPA axis overactivity by the dexamethasone suppression test found that a greater number of individuals with AD failed the test as compared with controls. Thus, the age-related risk of elevated CORT levels may also increase the risk of AD.

A decrease in hippocampal volume is also observed in other disorders with hypercortisolemia: depression, posttraumatic stress disorder (PTSD), and Cushing's syndrome. In the cases of PTSD and depression, it is possible that altered brain physiology could have confounding effects on this measure. However, in Cushing's syndrome, hypercortisolemia occurs as a consequence of peripheral tumors that secrete excessive amounts of ACTH or CRH. Moreover, on surgical correction of hypercortisolemia in Cushing's

syndrome, the hippocampal volume increases. These observations support the notion that cortisol leads to cognitive decline by damaging the hippocampus.

GLUCOCORTICOID'S EFFECTS ON LONG-TERM POTENTIATION

The associative, specific, and relatively long-lasting characteristics of long-term potentiation (LTP) have led to its acceptance as an excellent model of the molecular mechanism underlying learning and memory. Similar synaptic efficacy can also be elicited by a physiologically patterned, lower threshold primed-burst stimulation. In contrast, low-frequency stimulation of the synapse yields long-term depression (LTD) of the synapse. Both of these mechanisms rely on Ca^{2+} influx and the N-methyl-D-aspartate (NMDA glutamate analogue) receptor. A well-known target of NMDA-mediated Ca^{2+} influx is the calcium-calmodulin-dependent kinase II (CaMKII), which on activation auto-phosphorylates and becomes autonomously active to maintain the sensitivity of the synapse to future stimulation. Similar mechanisms are also employed during a low-frequency stimulation, but because the Ca^{2+} influx is gradual and of low intensity, it fails to induce the Ca^{2+} -mediated pathways that are activated during high-frequency stimulation.

CORT shifts the balance between LTP and LTD by differential activation of the MR and GR. For example, treatment of adrenalectomized rats with an MR-specific agonist, aldosterone, enhanced LTP, whereas treatment with a GR-specific agonist, RU-28362, suppressed synaptic efficacy. Under basal conditions, preferential activation of MR in the hippocampus is associated with short-lived Ca^{2+} currents that promote LTP. On the other hand, activation of GR increases expression of the NMDA receptor subunit NR2B. This substitution in the NMDA receptor leads to enhanced Ca^{2+} influx. Because this alteration is at the receptor level, the effects are observed for a longer time and lead to increased Ca^{2+} influx even during low-frequency stimulation. Kim and Yoon proposed that the intracellular Ca^{2+} ($[\text{Ca}^{2+}]_i$) has a metaplastic effect on synaptic efficacy. They suggested that if the $[\text{Ca}^{2+}]_i$ is high, the subsequent stimulus would have to be of much greater intensity to favor synaptic efficacy. If the stimulus is smaller than the previous stimulus, it will fail to induce Ca^{2+} -calmodulin pathways but will still elicit other effects of Ca^{2+} such as activation of phosphatases and Ca^{2+} -dependent K^+ channels. Activation of K^+ channels increases the afterhyperpolarization

current (refractory period) of the hippocampal neurons. This would block the cells' ability to respond to high-frequency stimuli, further decreasing the cells' ability to shift back in favor of synaptic efficacy. Consistently, the aged rats have a propensity for LTD and are susceptible to reversal of LTP. In one study, the number of potentiations observed after a primed-burst stimulation in 24-month-old Fischer 344 rats was only 40% that in 6-month-old controls.

EFFECTS OF CHRONIC DISEASES ON GLUCOCORTICOIDS

One of the earliest systemic responses to immune system activation is the release of interleukin-1 (IL-1), IL-6, and tumor necrosis factor- α (TNF- α). These cytokines trigger an acute phase response in other organs to alter their function during an infection. These cytokines also activate the HPA axis at several levels; all of these cytokines can also stimulate the HPA axis through the brain; IL-1 and TNF- α can increase CRH, all three increase secretion of ACTH, and IL-6 can also activate the adrenocortical cells directly to secrete CORT. A classic function attributed to CORT is as an anti-inflammatory agent, presumably to reduce "nonspecific" inflammation elsewhere in the body. CORT also increases expression of macrophage migration inhibitory factor (MIF) in various organs in a tissue- and time-dependent manner. MIF exhibits an anti-CORT effect by reversing CORT's effects on both apoptosis and cytokine expression in T lymphocytes and macrophages. This action may serve to overcome the anti-inflammatory effects of CORT within the local area of inflammation. However, in chronic illness, elevated levels of both MIF and CORT may lead to dysregulation by decreasing CORT's effectiveness.

IL-1, IL-6, and TNF- α have been associated with aging and/or age-related disorders and may also be responsible for the observed age-related elevation of CORT in a subgroup of elderly persons. Thus, individuals in preclinical stages of a disease could

have elevated cytokines, elevated CORT, and (as a consequence) cognitive impairment. This is supported by the observation that cognitive impairment is associated with mortality. Furthermore, most of the commonly used rat strains develop multiple lesions with age. Thus, the age-related increase in CORT levels in rodents may be indicative of disease pathology.

In conclusion, age-related increases in CORT might not be a consequence of the aging process but rather might be a consequence of disease, and this elevation of CORT leads to cognitive impairment by damaging the hippocampus.

REGULATION OF CORTISOL SECRETION

Plasma glucocorticoid concentrations are regulated in ways that reflect the varying physiologic needs for the hormones under basal conditions and in response to stress. Cortisol secretion is primarily regulated by ACTH, a 39-amino-acid peptide released by the anterior pituitary. ACTH is synthesized as part of a higher molecular weight precursor peptide, proopiomelanocortin. ACTH is secreted in regular pulses of variable amplitude over 24 h, with peak concentrations attained in the early morning hours (4:00–8:00 AM), thus forming the basis of the circadian pattern of cortisol secretion.

The acute action of ACTH is to increase the flux of cholesterol through the steroidogenic pathway, resulting in the rapid production of steroids. ACTH also influences the remaining steps of steroidogenesis as well as the uptake of cholesterol from plasma lipoproteins, thus ensuring a continuous supply of cholesterol to the mitochondria to meet the demands of activated pregnenolone biosynthesis. It also maintains the size of the adrenal glands, stimulates melanocytes, and results in hyperpigmentation when secreted in excess.

Corticotropin-releasing hormone (CRH) is the principal hypothalamic factor that stimulates the pituitary production of ACTH. It is produced in the paraventricular nuclei of the hypothalamus, but is also found in other parts of the central nervous system as well as in noncentral locations. CRH is secreted in a pulsatile fashion that results in the episodic secretion of ACTH and the circadian variation of cortisol secretion. The magnitude of cortisol response to each ACTH burst remains relatively constant; it is therefore the number of secretory periods, rather than the magnitude of each pulse of CRH or ACTH, that determines the total daily cortisol secretion. In addition to CRH, vasopressin, a peptide product of the posterior pituitary gland, stimulates ACTH release by acting synergistically with CRH. Although CRH increases the amount of ACTH secreted from each responsive corticotroph, vasopressin appears to increase the number of CRH-responsive corticotrophs. In addition to ACTH, other factors may play an important role in the regulation of the adrenal cortex.

Cortisol is the primary negative regulator of basal hypothalamic–pituitary–adrenal (HPA) axis activity through negative feedback on ACTH and CRH secretion. The negative feedback effects of cortisol are exerted at the level of both the hypothalamus and the pituitary and are mediated by type II corticosteroid

receptors. Whether and to what extent direct glucocorticoid feedback on the adrenal cortex itself regulates cortisol synthesis is not clear.

SECRETION AND METABOLISM

In normal subjects, the secretion of glucocorticoids follows a diurnal pattern, with peak concentrations observed between 6:00 and 8:00 AM and the lowest concentrations observed at approximately 12:00 AM. The cortisol production rate is approximately 12 mg/m²/day. More than 90% of circulating cortisol, and to a lesser extent aldosterone, is bound tightly to corticosteroid-binding globulin (CBG) or transcortin. The remaining (10%) of the circulating cortisol is free or loosely bound to albumin. The free and albumin-bound fractions of cortisol represent the biologically active form of the hormone. When plasma cortisol concentrations exceed 20 µg/dl, CBG becomes fully saturated and most of the excess cortisol is biologically active. CBG is synthesized in the liver. Estrogens, thyroid hormones, pregnancy, and oral contraceptives are associated with increased CBG concentrations, whereas hypercortisolism, hepatic disease, or renal disease results in decreased CBG concentrations. In the presence of an intact HPA axis, alterations in CBG concentrations are likely not to affect circulating free cortisol concentrations.

The primary site of cortisol metabolism in humans is the liver, and a number of cytosolic and microsomal enzymes, including cytochrome P450, 5 α /5 β -reductase, 3 α /3 β -oxidoreductase, and 11 β -hydroxysteroid dehydrogenase, play an important role in the hepatic metabolism of cortisol. The major routes of hepatic metabolism involve A-ring and side-chain reduction followed by conjugation with glucuronic acid and sulfate. The inactive glucuronide and sulfate metabolites are excreted by the kidneys, whereas less than 1% of cortisol is excreted unchanged in the urine. The metabolic clearance of cortisol, therefore, is influenced primarily by factors altering hepatic clearance and to a much lesser degree by factors affecting renal excretion.

MECHANISMS OF GLUCOCORTICOID ACTION

At the cellular level, the actions of glucocorticoids are mediated by an intracellular receptor protein, the glucocorticoid receptor, which functions as a hormone-activated transcription factor that regulates the expression of glucocorticoid target genes.

TREATMENT WITH GLUCOCORTICOIDS

Natural and synthetic glucocorticoids can be used for both endocrine and nonendocrine disorders. In clinical practice, glucocorticoids are used to establish the diagnosis and cause of Cushing's syndrome and in the treatment of adrenal insufficiency and congenital adrenal hyperplasia. Glucocorticoids are also given in pharmacologic doses to treat patients with inflammatory, allergic, or immunologic disorders. Chronic therapy has many side effects, ranging from suppression of the HPA axis and Cushing's syndrome to infections and changes in mental status. Factors that influence both the therapeutic and adverse effects of glucocorticoids include the pharmacokinetic properties of the glucocorticoid, daily dosage, timing of doses during the day, individual differences in steroid metabolism, and the duration of treatment.

Glucocorticoid Replacement Therapy

In deficiency states, physiologic replacement is best achieved with a combination of hydrocortisone and the mineralocorticoid fludrocortisone; hydrocortisone alone does not usually provide sufficient mineralocorticoid activity for complete replacement. In Addison's disease or following adrenalectomy, hydrocortisone at 10–15 mg/m² daily by mouth is usually required. This is given in two doses, the larger in the morning and the smaller in the evening, mimicking the normal diurnal rhythm of cortisol secretion. The optimum daily dose is determined on the basis of clinical response. Glucocorticoid therapy is supplemented by fludrocortisone 50 to 300 µg daily. In acute adrenocortical insufficiency, hydrocortisone is given intravenously (preferably as sodium succinate) at doses of 100 mg every 6 to 8 h in 0.9% sodium chloride intravenous infusion. In hypopituitarism, glucocorticoids should be given as in adrenocortical insufficiency, but since the production of aldosterone is regulated by the renin–angiotensin system, a mineralocorticoid is not usually required. Additional replacement therapy with levothyroxine and sex hormones should be given as indicated by the pattern of hormone deficiency.

Glucocorticoid Therapy

In comparing the relative potencies of corticosteroids in terms of their anti-inflammatory (glucocorticoid) effects, it should be borne in mind that high

glucocorticoid activity in itself is of no advantage unless it is accompanied by relatively low mineralocorticoid activity. The mineralocorticoid activity of fludrocortisone is so high that its anti-inflammatory activity is of no clinical relevance. The equivalent anti-inflammatory doses of corticosteroids are shown in Table I.

The relatively high mineralocorticoid activity of cortisone and hydrocortisone and the resulting fluid retention make them unsuitable for disease suppression on a long-term basis. However, they can be used for adrenal replacement therapy; hydrocortisone is preferred because cortisone requires conversion to hydrocortisone in the liver. Hydrocortisone is used on a short-term basis by intravenous injection for the emergency management of some conditions. The relatively moderate anti-inflammatory potency of hydrocortisone also makes it a useful topical corticosteroid for the management of inflammatory skin conditions because side effects (both topical and systemic) are less marked; cortisone is not active topically.

Prednisolone has predominantly glucocorticoid activity and is the corticosteroid most commonly used by mouth for long-term disease suppression. Betamethasone and dexamethasone have very high glucocorticoid activity but insignificant mineralocorticoid activity. This makes them particularly suitable for high-dose therapy in conditions where fluid retention would be a disadvantage. Betamethasone and dexamethasone also have a long duration of action and this, coupled with their lack of mineralocorticoid action, makes them particularly suitable for conditions that require suppression of ACTH secretion (e.g., congenital adrenal hyperplasia). Some esters of betamethasone and beclomethasone (beclomethasone)

Table I Equivalent Anti-inflammatory Doses of Corticosteroids

| | |
|----------------------|--------|
| Prednisolone | 5 mg |
| ≡ Betamethasone | 750 µg |
| ≡ Cortisone acetate | 25 mg |
| ≡ Deflazacort | 6 mg |
| ≡ Dexamethasone | 750 µg |
| ≡ Hydrocortisone | 20 mg |
| ≡ Methylprednisolone | 4 mg |
| ≡ Triamcinolone | 4 mg |

Note. This table takes no account of mineralocorticoid effects, nor does it take account of variations in duration of action.

exert a considerably more marked topical effect (e.g., on the skin or the lungs) than when given by mouth; use is made of this to obtain topical effects while minimizing systemic side effects (e.g. for skin applications and asthma inhalations). Deflazacort is derived from prednisolone and has high glucocorticoid activity.

SIDE EFFECTS OF CORTICOSTEROIDS

Overdosage or prolonged use may exaggerate some of the normal physiologic actions of corticosteroids, leading to mineralocorticoid and glucocorticoid side effects. Mineralocorticoid side effects include hypertension, sodium and water retention, and potassium loss. They are most marked with fludrocortisone, but are significant with cortisone, hydrocortisone, corticotropin, and tetracosactide (tetracosactrin). Mineralocorticoid actions are negligible with the high-potency glucocorticoids betamethasone and dexamethasone and occur only slightly with methylprednisolone, prednisolone, and triamcinolone. Glucocorticoid side effects include diabetes and osteoporosis, avascular necrosis of the femoral head, mental disturbances (a serious paranoid state or depression with risk of suicide may be induced, particularly in patients with a history of mental disorder), euphoria, and muscle wasting (proximal myopathy) (Table II). Corticosteroid therapy is also weakly linked with peptic ulceration. High doses of corticosteroids may cause Cushing's syndrome, which is usually reversible on withdrawal of treatment, but this must always be gradually tapered to avoid symptoms of acute adrenal insufficiency. In children, administration of corticosteroids may result in suppression of growth. Other complications include increased susceptibility to infection, poor wound healing, and activation of latent granulomatous infections.

Adrenal Suppression

During prolonged therapy with corticosteroids, adrenal atrophy develops and may persist for years after stopping. Abrupt withdrawal after a prolonged period may lead to acute adrenal insufficiency, hypotension, or death. Withdrawal may also be associated with fever, myalgia, arthralgia, rhinitis, conjunctivitis, painful itchy skin nodules, and weight loss.

To compensate for a diminished adrenocortical response caused by prolonged corticosteroid treatment, any significant intercurrent illness, trauma, or surgical procedure requires a temporary increase in

Table II Effects of Chronic Pharmacologic Use of Glucocorticoids

Endocrine and metabolic

- Suppression of HPA axis (adrenal suppression)
- Growth failure in children
- Carbohydrate intolerance
 - Hyperinsulinism
 - Insulin resistance
 - Abnormal glucose tolerance test
 - Diabetes mellitus
- Cushingoid features
 - Moon facies, facial plethora
 - Generalized and truncal obesity
 - Supraclavicular fat collection
 - Posterior cervical fat deposition (buffalo hump)
 - Glucocorticoid-induced acne
 - Thin and fragile skin, violaceous striae
- Impotence, menstrual disorders
- Decreased thyroid-stimulating hormone and triiodothyronine
- Hypokalemia, metabolic alkalosis

Gastrointestinal

- Gastric irritation, peptic ulcer
- Acute pancreatitis (rare)
- Fatty infiltration of liver (hepatomegaly) (rare)

Hematopoietic

- Leukocytosis
- Neutrophilia
 - Increased influx from bone marrow and decreased migration from blood vessels
- Monocytopenia
- Lymphopenia
 - Migration from blood vessels to lymphoid tissue
- Eosinopenia

Immunologic

- Suppression of delayed hypersensitivity
 - Inhibition of leukocyte and tissue macrophage migration
 - Inhibition of cytokine secretion/action
- Suppression of the primary antigen response

Musculoskeletal

- Osteoporosis, spontaneous fractures
- Aseptic necrosis of femoral and humeral heads and other bones
- Myopathy

Ophthalmologic

- Posterior subcapsular cataracts (more common in children)
- Elevated intraocular pressure/glaucoma

Neuropsychiatric

- Sleep disturbances, insomnia
- Euphoria, depression, mania, psychosis
- Pseudo-tumor cerebri (benign increase of intracranial pressure)

Cardiovascular

- Hypertension
 - Congestive heart failure in predisposed patients
-

corticosteroid dose or, if already stopped, a temporary reintroduction of corticosteroid treatment. Anesthetists must therefore know whether a patient is taking or has been taking a corticosteroid, to avoid a precipitous fall in blood pressure during anesthesia or in the immediate postoperative period. A suitable regimen for corticosteroid replacement, in patients who have taken more than 10 mg prednisolone daily (or equivalent) within 3 months of surgery, is as follows:

- Minor surgery under general anesthesia—usual oral corticosteroid dose on the morning of surgery or hydrocortisone 25–50 mg (usually sodium succinate) intravenously at induction; the usual oral corticosteroid dose is recommenced after surgery.
- Moderate or major surgery—usual oral corticosteroid dose on the morning of surgery and hydrocortisone 25–50 mg intravenously at induction, followed by hydrocortisone 25–50 mg three times a day by intravenous injection for 24 h after moderate surgery or for 48–72 h after major surgery; the usual preoperative oral corticosteroid dose is recommenced on stopping hydrocortisone injections.

Patients on long-term corticosteroid treatment should carry a Steroid Treatment Card, which gives guidance on minimizing risk and provides details of prescriber, drug, dosage and duration of treatment.

Infections

Prolonged courses of corticosteroids increase susceptibility to infections and severity of infections; clinical presentation of infections may also be atypical. Serious infections, e.g., septicemia and tuberculosis, may reach an advanced stage before being recognized and amebiasis or strongyloidiasis may be activated or exacerbated (they should be excluded before corticosteroid treatment is initiated in those at risk or with suggestive symptoms). Fungal or viral ocular infections may also be exacerbated.

Chickenpox

Unless they have had chickenpox, patients receiving oral or parenteral corticosteroids for purposes other than replacement should be regarded as being at risk of severe chickenpox. Passive immunization with varicella-zoster immunoglobulin is needed for exposed nonimmune patients receiving systemic corticosteroids or for those who have used them within the previous 3 months; varicella-zoster immunoglobulin

should preferably be given within 3 days of exposure and no later than 10 days. Confirmed chickenpox warrants specialist care and urgent treatment. Corticosteroids should not be stopped and dosage may need to be increased. Topical, inhaled, or rectal corticosteroids are less likely to be associated with an increased risk of severe chickenpox.

Measles

Patients taking corticosteroids should be advised to take particular care to avoid exposure to measles and to seek immediate medical advice if exposure occurs. Prophylaxis with intramuscular normal immunoglobulin may be needed.

ADMINISTRATION OF CORTICOSTEROIDS

Whenever possible, local treatment with creams, intra-articular injections, inhalations, eye drops, or enemas should be used in preference to systemic treatment. The suppressive action of a corticosteroid on cortisol secretion is lowest when it is given as a single dose in the morning. In an attempt to reduce pituitary–adrenal suppression further, the total dose for 2 days can sometimes be taken as a single dose on alternate days; alternate-day administration has not been very successful in the management of asthma. Pituitary–adrenal suppression can also be reduced by means of intermittent therapy with short courses. In some conditions, it may be possible to reduce the dose of corticosteroid by adding a small dose of an immunosuppressive drug.

Dosage of corticosteroids varies widely in different diseases and in different patients. If the use of a corticosteroid can save or prolong life, high doses may need to be given, because the complications of therapy are likely to be less serious than the effects of the disease itself. When long-term corticosteroid therapy is used in some chronic diseases, the adverse effects of treatment may become greater than the disabilities caused by the disease. To minimize side effects, the maintenance dose should be kept as low as possible.

WITHDRAWAL OF CORTICOSTEROIDS

A gradual withdrawal of systemic corticosteroids should be considered in those subjects whose disease is unlikely to relapse and who have: (1) recently received repeated courses (particularly if taken for

longer than 3 weeks); (2) taken a short course within 1 year of stopping long-term therapy; (3) other possible causes of adrenal suppression; (4) received more than 40 mg daily prednisolone (or equivalent); (5) been given repeat doses in the evening; or (6) received treatment for more than 3 weeks.

Systemic corticosteroids may be stopped abruptly in those whose disease is unlikely to relapse and who have received treatment for 3 weeks or less and who are not included in the patient groups described above. During corticosteroid withdrawal, the dose may be reduced rapidly to physiological doses (equivalent to prednisolone at 7.5 mg daily) and then reduced more slowly. Assessment of the disease may be needed during withdrawal to ensure that relapse does not occur.

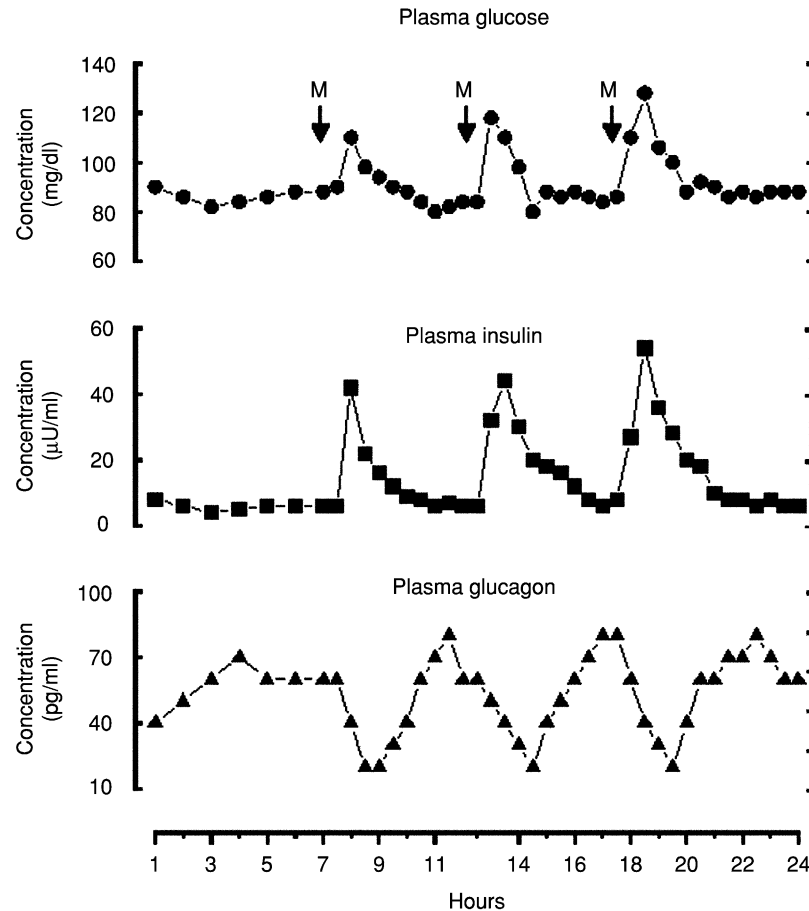

Figure 1 Diurnal changes in plasma glucose, insulin, and glucagon concentrations.

FACTORS THAT REGULATE GLUCOSE FLUXES

Insulin

Insulin plays a central role in glucose homeostasis mainly by its action on liver, kidney, adipose tissue, and skeletal muscle. In liver and kidney, it suppresses glucose production by regulating the rate-limiting key enzymes of gluconeogenesis (glucose-6-phosphatase and fructose-1,6-bisphosphatase) and glycogenolysis (glycogensynthase and phosphorylase). In skeletal muscle, its main action is to promote glucose uptake by causing the translocation of Glut-4 transporters to the cell membrane from an intracellular pool. In adipose tissue, insulin will also increase glucose transport and the resultant increase in glycolysis provides α -glycerophosphate to promote triglyceride formation but its main effect is to inhibit hormone-sensitive lipase. This will lead to a decrease in circulating FFA levels, which will affect glucose production in liver and kidney and glucose uptake in various tissues (Fig. 2).

Binding of insulin to its receptor activates a complex intracellular cascade of autophosphorylation by protein kinases. Intracellular receptor substrates and members of the phosphatidylinositol 3-kinase family seem to be the most important participants. The latter triggers the migration of glucose transporters from an intracellular pool toward the plasma membrane, thereby increasing the number of transporters located on the cellular surface and thus promoting the efficiency of glucose uptake (Fig. 3). This will also result in decreases in intracellular cyclic AMP (cAMP) levels, which mediate the effects of insulin on glucose production and lipolysis. Insulin will also alter the activity of various genes that will affect the amount of certain enzymes. Finally, via its action on amino acid transport, insulin suppresses protein degradation and lipolysis, which will diminish the availability of gluconeogenic precursors and thereby reduce glucose production indirectly.

The main regulator of insulin release is the prevailing plasma glucose concentration. An increase in the

Figure 2 Postprandial insulin secretion; regulation of glucose production and disposal.

plasma glucose concentration stimulates insulin secretion, whereas a decrease in plasma glucose inhibits insulin secretion so that throughout the day, plasma glucose and insulin levels change in parallel (Fig. 1). Amino acids, e.g., arginine, and to a lesser extent FFA can also stimulate insulin secretion. The small intestine produces factors called incretins (e.g., gastrointestinal peptide, glucagon-like peptide-2), which are secreted after meal ingestion and augment postprandial insulin secretion. This explains

why insulin concentrations increase to a greater extent when glucose is given orally than intravenously.

Glucagon

Glucagon acts solely on the liver, having effects mediated by changes in intracellular cAMP levels that are opposite of those of insulin. Its secretion is also regulated in a reciprocal manner to that of insulin. An increase in plasma glucagon will increase hepatic glucose release within minutes via an increase in glycogen breakdown. Binding of glucagon to its receptor immediately increases intracellular cAMP levels, which increases glycogenolysis and inhibits glycogen synthase by stimulation of phosphorylase and inactivation of glycogen synthase. Prolonged elevation of plasma glucagon can increase gluconeogenesis in the liver, whereas it has no effect on renal gluconeogenesis.

Glucagon secretion is suppressed by increases in plasma glucose and insulin and is increased by hypoglycemia and catecholamines. Amino acids are a potent stimulator of glucagon release. Thus, after protein-rich meals, glucagon release might not be suppressed despite increases in plasma insulin and glucose concentrations.

Catecholamines

Epinephrine and norepinephrine are released by the adrenal glands and norepinephrine is released from sympathetic nerves during exercise, various stresses (e.g., trauma, infection), and hypoglycemia. They

Figure 3 Insulin binding and intracellular cascade. Glut, glucose transporter; IRS, intracellular receptor substrates; PI3-Kinase, phosphatidylinositol 3-kinase.

have complex effects on glucose mediated by both direct and indirect mechanisms. Such actions include stimulation of renal gluconeogenesis, hepatic and muscle glycogenolysis, adipose tissue lipolysis, and glucagon release, which are mediated by β -adrenergic receptors. Catecholamines also inhibit insulin release directly via α -adrenergic receptors. Indirect effects include suppression of glucose uptake in skeletal muscle due to the elevation of plasma FFA and stimulation of gluconeogenesis in liver and kidney via increases in plasma FFA and gluconeogenic precursors (mainly glycerol from lipolysis and lactate from skeletal muscle glycogenolysis). Along with glucagon, catecholamines are the most important counterregulatory factors protecting against hypoglycemia.

Growth Hormone, Cortisol, and Thyroid Hormone

Growth hormone, cortisol, and thyroid hormone largely act to regulate the response of target tissues to insulin, glucagon, and catecholamines on a long-term basis, e.g., reducing responses to insulin and increasing responses to glucagon and catecholamines. Under conditions similar to those during which catecholamines are released, growth hormone and cortisol are released and within an hour or two reduce the effectiveness of insulin and enhance the action of glucagon and catecholamines. Prolonged elevation of these hormones, such as is seen in acromegaly and Cushing's syndrome, can cause severe insulin resistance and diabetes mellitus.

FFA

FFA are a major fuel used by most tissues of the body except the brain, renal medulla, and erythrocytes. Increases in plasma FFA and consequently their uptake into cells have numerous direct and indirect effects that influence glucose homeostasis. These include direct effects on hormone secretion (a moderate stimulating action on insulin secretion and a potent inhibitory action on glucagon and growth hormone) as well as stimulating effects on hepatic and renal gluconeogenesis and an inhibitory effect on muscle glucose uptake. The effects on liver, kidney, and muscle are mediated in part by changes in hormonal environment and competition with glucose as an oxidative fuel (mediated primarily by changes in pyruvate dehydrogenase and interference with insulin signaling pathways, both of these being mediated by coenzyme

A metabolites of FFA). In general, opposite effects are observed when plasma FFA are low.

Circulating FFA levels, like those of glucose, are the net result of changes in FFA entry and exit from plasma. FFA entry into plasma largely depends on the balance between the activation of hormone-sensitive lipase by catecholamines, growth hormone, and cortisol and the inhibition of lipase by insulin. The exit of FFA from plasma is stimulated by insulin.

THE POSTABSORPTIVE STATE

General Considerations

In the period after an overnight fast, referred to as the postabsorptive state, plasma glucose ranges between 70 and 110 mg/dl (average 90 mg/dl). This state is considered to represent a steady-state condition since the rate of appearance of glucose approximates its rate of disappearance ($\sim 10 \mu\text{mol kg}^{-1} \text{min}^{-1}$). However, even though removal is often undetectable, the rate of removal is slightly greater than the rate of appearance so that with more prolonged fasting, plasma glucose concentrations decrease. However, even after 72 h of fasting, plasma glucose does normally not decrease below 50 mg/dl (2.9 mM).

Glucose Utilization

In the postabsorptive state, plasma insulin levels are low and therefore glucose uptake in tissues is largely dependent on tissue needs. The majority of glucose is taken up by the brain ($\sim 50\%$) and is completely oxidized; glucose taken up by muscle ($\sim 20\%$), adipocytes ($\sim 5\%$), erythrocytes ($\sim 5\%$), splanchnic organs ($\sim 10\%$), and kidney ($\sim 5\%$) (Fig. 4) undergoes mostly nonoxidative glycolysis, resulting in the release of 3-carbon precursors (lactate, pyruvate, and alanine), which are used for gluconeogenesis, into the circulation.

Glucose Production

Glucose production in the postabsorptive state is regulated to match tissue demand, which may increase during exercise or stresses such as infection and trauma. Normally, approximately 50% of the glucose released into the circulation is the result of hepatic glycogenolysis; the remaining 50% is due to gluconeogenesis (30% liver; 20% kidney).

The proportion of glucose produced due to gluconeogenesis increases with the duration of the fast since glycogen stores are rapidly depleted. The liver

Figure 4 Glucose production and utilization after an overnight fast.

contains a total of 75 g glucose. Assuming that the liver releases glucose from glycogen at a rate of $5 \mu\text{mol kg}^{-1} \text{min}^{-1}$, glycogen stores would be depleted within 20 h. Thus, the proportion due to gluconeogenesis must increase so that after 72 h, glucose production by the liver is almost exclusively due to gluconeogenesis. The kidney, in contrast, contains little glycogen stores and the cells that could make glycogen lack glucose-6-phosphatase; consequently, all the glucose released by the kidney is due to gluconeogenesis. (Renal gluconeogenesis increases with fasting to a greater extent than hepatic gluconeogenesis.) Insulin suppresses both hepatic and renal glucose release; however, glucagon promptly increases hepatic glucose release, whereas catecholamines stimulate more renal glucose release.

Prolonged Fasting

With the duration of fasting, plasma insulin levels decrease, whereas those of glucagon, catecholamines, growth hormone, and cortisol increase. Therefore, the oxidation of glycerol, plasma FFA and FFA products, and the ketone bodies β -hydroxybutyrate and acetoacetate increases. Hepatic glycogen stores become depleted and after 60 h virtually all of glucose released is due to gluconeogenesis. During the first 60–72 h of fasting, the decrease in glucose release is greater than the decrease in glucose uptake, so that plasma glucose levels decrease. At approximately 60 h, with plasma glucose averaging 60 mg/dl, a new pseudo-steady state is achieved (Table I). This stabilization is the basis for the 72 h fast for the diagnosis of patients with hypoglycemia due to insulin-producing tumors of the pancreas (insulinoma). In such patients, insulin

secretion is not appropriately reduced and leads to a further reduction of endogenous glucose production together with increased glucose uptake and consequently to the development of hypoglycemia with plasma glucose levels below 50 mg/dl.

THE POSTPRANDIAL STATE

General Considerations

The major function of meal ingestion is to replenish tissue glucose (glycogen) and lipid (triglyceride) stores that have been depleted due to fasting and physical activity. Thus, after meal ingestion, endogenous glucose and FFA release is suppressed, favoring glycogen accumulation. Glucose replaces FFA as the predominant energy fuel as plasma FFA decrease,

Table I Glucose Release and Disposal after Prolonged Fasting (~60 h)

| | Glucose release ($\mu\text{mol kg}^{-1} \text{min}^{-1}$) | | Glucose disposal ($\mu\text{mol kg}^{-1} \text{min}^{-1}$) |
|-----------------|--|-------------------|---|
| Overall | 6.0 | Overall | 6.0 |
| Gluconeogenesis | 5.5 | Oxidation | 4.8 |
| Glycogenolysis | 0.5 | Glycolysis | 1.2 |
| Tissues | | Tissues | |
| Liver | 2.7 | Brain | 3.5 |
| Kidney | 2.8 | Skeletal muscle | 1.0 |
| | | Splanchnic organs | 0.5 |
| | | Kidney | 0.4 |
| | | Adipose tissue | 0.2 |
| | | Blood cells | 0.4 |

favoring FFA incorporation into triglyceride stores, so that ingested carbohydrate becomes the major fuel used by the body. Various factors, such as the size of the meal, prior physical exercise and duration since the last meal, and composition of the meal, can affect postprandial glucose homeostasis. However, from a practical point of view, the most important factors are changes in insulin and glucagon secretion and their effects on hepatic sequestration of meal carbohydrates, suppression of endogenous glucose production, and finally stimulation of the uptake, storage, glycolysis, and oxidation of glucose in hepatic and posthepatic tissues.

Postprandial Glucose Concentrations and Fluxes

After a meal, plasma glucose concentrations increase since the rate of appearance of glucose in plasma exceeds the rate of disappearance. Subsequently, plasma glucose decreases when the rate of disappearance exceeds the rate of appearance. The appearance of glucose in plasma represents the sum of glucose from the meal reaching the circulation and the remaining

endogenous glucose production. The time courses of these changes are shown in Fig. 5. Endogenous glucose release is suppressed $\sim 60\%$ after a meal. The appearance of ingested glucose is detected within 15 min after a meal, reaches a maximum at ~ 60 min, and decreases gradually thereafter. Only 75% of the glucose in a meal reaches the systemic circulation; the remaining 25% is sequestered by the splanchnic bed.

Of a theoretical meal containing 100 g of glucose, 20–30% is initially extracted in the splanchnic bed. At least half of this is taken up by the liver and incorporated into hepatic glycogen; the remainder is probably released as lactate due to hepatic glycolysis. Of the glucose in the meal that reaches the systemic circulation, approximately 30–40% is taken up by skeletal muscle to be initially oxidized in favor of FFA and later to be stored as glycogen. Little of the glucose taken up by muscle is released as lactate or other gluconeogenic substrates into the circulation. Of the remaining glucose released into the systemic circulation, 20% is taken up by the brain, 10% by the kidney, and 5% by adipose tissue.

Approximately 40% of the glucose disposed of after a meal is stored predominantly as glycogen in

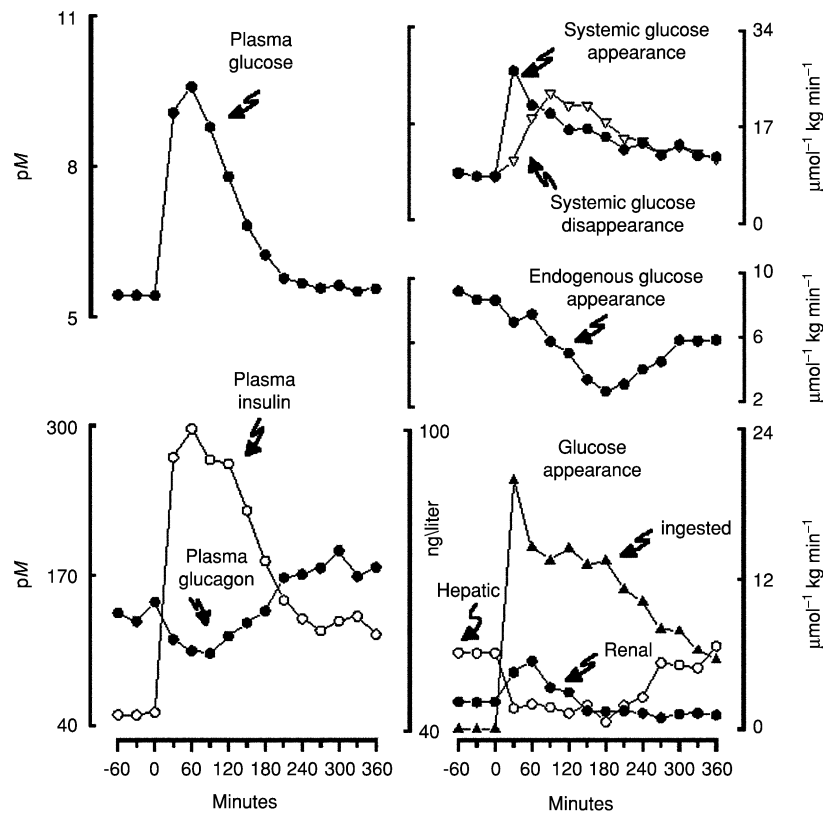

Figure 5 Postprandial changes in plasma glucose, insulin, glucagon concentrations, rates of plasma glucose appearance/disappearance, and hepatic and renal glucose production.

Figure 6 Contribution of storage and glycolysis to the disposal of glucose after a meal.

liver and muscle and, to a lesser extent, as triglycerides in adipose tissue. The remaining 60% is undergoes glycolysis either oxidatively to CO_2 and H_2O (~40%) or nonoxidatively to lactate (~20%) (Fig. 6). That a substantial amount of glucose undergoes nonoxidative glycolysis is not surprising if one considers that glycolysis is needed to provide 3-carbon fragments for gluconeogenesis and precursors for the indirect pathway of hepatic glycogen formation.

Renal glucose production initially increases after a meal (Fig. 5). The physiological role of this increase still needs to be elucidated. Teleologically, postprandial renal glucose release may facilitate efficient liver glycogen repletion by permitting substantial suppression of hepatic glucose release.

It can be readily appreciated that three main factors regulate postprandial glucose levels: suppression of hepatic glucose release, hepatic sequestration of the ingested glucose, and uptake of glucose from the systemic circulation. Initial suppression of endogenous glucose release and hepatic sequestration depend largely on the reciprocal secretion of glucagon and insulin. Insulin increases the number of glucose transporters in muscle and thereby increases glucose fractional extraction, an index of the efficiency of glucose uptake; glucose fractional extraction by brain and other insulin independent tissues actually decreases.

SUMMARY

In most circumstances, regulation of glucose production is more important than regulation of glucose utilization in determining plasma glucose

concentrations. Recall that in the fasting state, 80% of glucose utilization is insulin independent. Insulin levels are low and are needed only to suppress excessive endogenous glucose production and lipolysis. Another example of the importance of glucose production is fasting hyperglycemia in type 2 diabetes. Rates of glucose utilization are generally normal, whereas rates of glucose production are increased. Of interest is the finding that renal glucose release initially increases after a meal, whereas hepatic glucose release decreases; these reciprocal changes permit efficient repletion of glycogen stores. This finding and other observations have provided convincing evidence for the concept of hepatorenal reciprocity. According to this concept, when the release of glucose by either liver or kidney is reduced, the other organ will increase its glucose release to maintain euglycemia. Similar reciprocal changes are found during recovery from insulin-induced hypoglycemia in patients with type 2 diabetes. The strongest support for the concept of hepatorenal reciprocity has been provided by the observation that during the anhepatic stage of liver transplantation (when liver glucose release is absent), the kidney increases its release of glucose threefold so that hypoglycemia does not occur.

after as little as a few hours of exposure to high levels of glucose and, in these earlier stages, the damage is reversible. Thus, the impaired insulin secretion observed in early human type 2 diabetes can improve significantly with control of hyperglycemia. Ultimately, however, the damage to the beta cells becomes irreversible (“beta cell failure”).

It is likely that different mechanisms come into play as these processes evolve. The initial events, such as desensitization to glucose, may be related to changes in the levels and/or activities of transcription factors and other key regulatory molecules involved in glucose sensing, whereas the subsequent loss of beta cell function involves down-regulation of insulin mRNA and may proceed to apoptotic cell loss. It is possible, however, that these events represent a continuum that shares a common signaling mechanism. Other workers, for example, Unger, have noted that other nutrients that are found in excess in type 2 diabetes, such as free fatty acids, can also impair beta cell function. These hypotheses—glucose toxicity and “lipotoxicity”—are not mutually exclusive. For example, both free fatty acids and glucose can lead to chronic oxidative stress and both can activate the hexosamine signaling pathway, both being potential mechanisms underlying beta cell failure.

GLUCOSE-INDUCED INSULIN RESISTANCE IN TYPE 1 AND TYPE 2 DIABETES

Another of the pathophysiologic hallmarks of type 2 diabetes is insulin resistance. Although it is considered by many to be involved in the initial pathogenesis of the disease, there are also numerous studies that illustrate that insulin resistance can be an acquired defect, the result of excess nutrient delivery to tissues. The laboratories of Rossetti, Yki-Jarvinen, and DeFronzo have pioneered work in this area and have also reviewed the topic extensively. As was the case for decreased insulin secretion, the glucose-induced insulin resistance has been convincingly demonstrated in a variety of experimental systems and in humans, nondiabetic as well as those with type 1 or type 2 diabetes. Most often, the experimental paradigm involves decreased insulin-mediated glucose disposal after a period of hyperglycemia, but the definition has been broadened to include any defect in insulin signaling or responsiveness observed after treatment with high concentrations of glucose.

The ultimate mediators of glucose-induced insulin resistance are not known, although much work has

illuminated some of the mechanisms involved. In skeletal muscle, the effect of hyperglycemia is decreased insulin-stimulated glucose uptake caused by a failure of translocation of the specific glucose transporter GLUT4 to the plasma membrane. Why this occurs is less clear. Interest has focused on the early steps in insulin signal transduction, specifically the insulin receptor substrate/phosphatidylinositol 3-kinase/Akt (PKB) pathways, and several defects have been described in these pathways in glucose-induced insulin resistance. However, there is no consistent or universally accepted mechanism that can completely explain the phenomenon.

Glucose-induced insulin resistance shares many features with that induced by excess levels of free fatty acids. This has given rise to the hypothesis that glucose-induced insulin resistance might be more appropriately termed nutrient-induced insulin resistance. A possible common denominator that could explain both glucose- and fatty acid-induced insulin resistance is hexosamine signaling, because high levels of both glucose and fatty acids result in increased hexosamine pathway products. This hypothesis is also attractive in that it would predict that insulin resistance would occur in the presence of excess nutrient *flux* even before nutrient *levels* were significantly increased in plasma. Thus, insulin resistance by this mechanism would be expected to occur before overt hyperglycemia and there could be a unifying mechanism to explain insulin resistance in obesity as well as in clinical diabetes.

Glucose toxicity for insulin action is manifest in the clinical setting in two major ways that deserve mention. First, the typical patient presenting with a prolonged history of weight loss, polyuria, and severe hyperglycemia is likely to improve his or her glucose disposal rate once the hyperglycemia is brought under control; that is, the glucose toxicity will reverse. Thus, it will be harder to achieve glycemic control than to maintain glycemic control. This means that the therapy needed to attain normoglycemia may cause hypoglycemia a few days later as the glucose toxicity component resolves. Conversely, it has also been shown that an initial period of normoglycemia produced by intense insulin therapy will, by breaking the vicious cycle of glucose toxicity, allow better responsiveness to oral agents. Thus, there will be fewer oral agent “failures” after such a period of normoglycemia.

A second major clinical consequence of glucose-induced insulin resistance is that huge doses of insulin may be required to lead to disposal of the nutrient load from a meal and in some cases even the maximal

glucose disposal rate of the individual can be exceeded, meaning that no amount of insulin will lead to normoglycemia. Interestingly, Yki-Jarvinen and others have noted that in such situations, muscle glycogen content and net glucose flux into muscle are essentially normal. Furthermore, there are few if any ill effects of diabetes on skeletal muscle function. This has led to the proposal that nutrient-induced insulin resistance may be an adaptation to excess nutrient flux. That is, skeletal muscle is able to autoregulate glucose uptake by down-regulating glucose transporters in the face of hyperglycemia. If this is the case, it may be more appropriate to view glucose-induced insulin resistance in terms of normal physiology rather than as toxicity.

MEDIATION OF DIABETIC COMPLICATIONS BY GLUCOSE

There is substantial evidence that most if not all of the classic complications of diabetes are mediated by hyperglycemia and/or excessive nutrient flux. This was most clearly demonstrated in the Diabetes Control and Complications Trial for type 1 diabetes and by the “Kumamoto Study” and the United Kingdom Prospective Diabetes Study for type 2 diabetes. Although not usually referred to as glucose toxicity, some of the pathways leading to these complications—nephropathy, neuropathy, and retinopathy—may be shared and it may be informative to group them together with beta cell failure and insulin resistance as “adverse consequences of excess nutrient flux.”

PROPOSED MECHANISMS FOR GLUCOSE TOXICITY

The precise mechanisms and mediators of glucose toxicity are not known. Given the complex regulation of glucose metabolism, the many pathways of known regulation by glucose, and the many fates of intra- and extracellular glucose, it is likely that there will be multiple pathways through which glucose exerts its adverse effects. Some of the leading proposals can be very briefly summarized as follows:

- Nonenzymatic glycation of proteins. Covalent attachment of free glucose to amino groups in proteins or other macromolecules can occur via formation of a Schiff's base. These can subsequently rearrange, leading to the elaboration of advanced glycation end-products that can have toxic effects on

cells. Nonenzymatic glycation is contrasted to the enzymatic linkage of carbohydrates (usually uridine diphosphate amino sugars) to specific residues of proteins. Given that the effects of high levels of glucose on insulin secretion and insulin action can be seen in hours to a few days and that these effects are likely to be mediated intracellularly, it is unlikely that this process plays a large role in beta cell failure or insulin resistance.

- Aldose reductase pathway. Sorbitol, generated by the enzyme aldose reductase, has been postulated to act normally as an intracellular osmolyte to buffer changes in extracellular osmolality. In the presence of chronic hyperglycemia, however, untoward effects of sorbitol accumulation, such as depletion of myoinositol or increased oxidative stress, may occur. This pathway has not been specifically linked to insulin resistance or beta cell failure.

- Protein kinase C. Hyperglycemia-induced activation of diacylglycerol/protein kinase C-dependent pathways has been postulated to lead to changes in gene regulation that could play a role in diabetic complications, although no studies provide a specific link to the classic glucose toxicity effects.

- Hexosamines. Since the demonstration by Marshall that glucosamine can induce insulin resistance in adipocytes, and his discovery of the hexosamine signaling pathway, much evidence that this pathway plays an important role in nutrient sensing and adaptation to excess nutrient flux has accumulated. In particular, it has been shown in several animal and cell culture models that high concentrations of glucose lead to high levels of products of the hexosamine biosynthesis pathway that in turn can mimic very well the diabetic phenotypes of beta cell failure and glucose-induced insulin resistance. The hypothesis is further attractive in that the pathway may provide a common mechanism for the similar effects of free fatty acids, which also result in increased hexosamine flux. The signaling function of the pathway is thought to occur by the enzymatic O-linked glycosylation of cytosolic signaling proteins. This dynamic process occurs on residues otherwise used for regulatory phosphorylation, so that high levels of hexosamine flux can generate a dominant signal downstream to abrogate hormone signaling in situations of excess nutrients. Thus, insulin would no longer be able to stimulate glucose uptake or glycogen synthesis if intracellular fuel stores were already replete, protecting the cell from excess nutrient accumulation and allowing the excess calories to be shunted to adipocytes.

- Oxidative stress. This has been shown to be a factor in a large variety of tissues that are harmed by the diabetic milieu. Brownlee has proposed that many features of glucose toxicity and diabetic complications may be functionally linked to this mechanism, including activation of the hexosamine signaling pathway.

Prospective studies in people with IGT have revealed rates of progression to diabetes (usually type 2) in the range of 5–10% per year. The rates translate to a three- to sevenfold increase in the risk of diabetes relative to people with normal glucose levels. Factors that may alter the risk of diabetes among people with IGT vary from study to study, but include glucose levels, insulin resistance, B cell defect, obesity, lipid levels, and blood pressure (greater values for each factor indicate increased risk). Clinical cardiovascular events have been reported to be more frequent in people with IGT than in people with normal glucose tolerance in some, but not all studies. In general, the excess risks were accounted for by the presence of cardiovascular risk factors other than mild hyperglycemia.

PATHOPHYSIOLOGY

In general, glucose levels rise above normal when insulin secretion from the pancreas is insufficient to meet the insulin needs of tissues that make glucose (the liver) or take it up in response to insulin (skeletal muscle and adipose tissue). Diabetes reflects a large imbalance between these two factors. IGT represents a relatively milder imbalance, albeit not a trivial one. Cross-sectional data from the Insulin Resistance and Atherosclerosis Study indicate that people with IGT have ~60% less insulin secretion for their degree of insulin resistance than people with normal glucose tolerance. Similar findings have been reported for women with gestational diabetes, a separate form of impaired glucose tolerance. Causes of insufficient insulin secretion vary among people with IGT. Some people have circulating autoimmune markers directed at the pancreatic islets or insulin-secreting B cells. Those individuals appear to have IGT as part of evolving type 1 diabetes. Other individuals with IGT (the majority) are obese or have other reasons to have increased insulin requirements of their tissues (“insulin resistance”). They may make considerable insulin, but less than equally insulin-resistant people

with normal glucose tolerance. Evidence from the Troglitazone in Prevention of Diabetes (TRIPOD) study indicates that, at least in Hispanic Americans, the increased insulin secretory demands that are imposed on pancreatic B cells by chronic insulin resistance cause loss of B cell function. Treatment of insulin resistance can delay or prevent progressive B cell failure and diabetes.

The insulin resistance from which IGT frequently evolves is at the center of a cluster of clinical conditions that are collectively known as the insulin resistance syndrome. Like IGT, atherosclerosis is a component of this syndrome. Many mechanisms have been proposed as links between insulin resistance and atherosclerosis, including hyperinsulinemia, dyslipidemia (especially elevated triglycerides and low levels of high-density lipoprotein cholesterol), hypertension, impaired fibrinolysis, and chronic inflammation. In people with IGT, mild hyperglycemia could promote atherosclerosis as well, although solid evidence for this in humans (i.e., lowering of mild hyperglycemia to mitigate atherosclerosis) is lacking.

TREATMENT

There is no standard treatment for IGT. Four different randomized trials to evaluate the effects of different interventions on the risk of diabetes in people with IGT have been completed. In two of them [the Finnish Diabetes Prevention Study (DPS) and U.S. Diabetes Prevention Program (DPP)], intensive lifestyle interventions were designed to achieve modest weight reduction (e.g., 7% of body weight in the DPP) and a modest increase in physical activity (e.g., brisk walking or the equivalent for 150 min per week in the DPP) in adult men and women with IGT. The risk of diabetes was reduced 58% compared to the control group in each study. The U.S. DPP also included an arm in which subjects were randomized to metformin 1500 mg/day instead of intensive lifestyle intervention. The risk of diabetes in the metformin arm was reduced by 31% compared to the control group. In the STOP-NIDDM trial, acarbose (100 mg three times daily) was given to adult men and women with IGT. The incidence of diabetes was reduced by 25% compared to placebo-treated subjects. Survival curves in the Finnish DPS, U.S. DPP, and STOP-NIDDM trials revealed a slowing of the onset of diabetes in treated arms rather than true diabetes prevention. In the TRIPOD study cited above, a medium dose of an insulin-sensitizing thiazolidinedione drug (troglitazone, which is no longer available for clinical use) reduced the incidence of diabetes by

55% in Hispanic American women with prior gestational diabetes. Women who responded to the drug with reduced endogenous insulin requirements had complete stabilization of pancreatic B cell function and glucose levels for 4.5 years, indicating true diabetes prevention during that period of time. These four studies reveal that it is possible to delay or prevent the onset of diabetes in people with IGT using behavioral and/or pharmacological interventions. Efficient strategies for screening to find people with IGT and optimal approaches to clinical management remain to be defined. Likewise, whether treatment of mild hyperglycemia per se in IGT can reduce cardiovascular events independent of changes in other cardiovascular risk factors remains to be determined. People with IGT should be evaluated and treated for standard cardiovascular risk factors.

efficient enzymatic detoxification of these α -oxoaldehydes. Glyoxal and methylglyoxal are detoxified to glycolate and D-lactate, respectively, by the glutathione-dependent glyoxalase system. 3-Deoxyglucosone is detoxified by NADPH-dependent 3-deoxyglucosone reductase to 3-deoxyfructose. In addition, there is a high cysteinyl thiol pool that binds α -oxoaldehydes reversibly and thereby suppresses their irreversible reactions to form AGEs. Fructosamine residues are removed from proteins by phosphorylation to fructosamine-3-phosphate, catalyzed by fructosamine 3-phosphokinase, and degraded to 3-deoxyglucosone. Once formed *in vivo*, AGEs must be repaired or replaced and degraded. The reactions of saccharide derivatives with proteins, nucleotides, and phospholipids to form AGEs occurs intra- and extracellularly. Inside cells, the impact of glycation is countered by high turnover (short half-life) of many cellular proteins, phospholipids, and RNA as well as by mechanisms of DNA repair. Degradation of extracellular glycation occurs by specific recognition by receptors, internalization, and proteolytic processing of the glycation protein ligand.

PROTEIN GLYCATION IN MONITORING GLYCEMIC CONTROL

Fructosamine concentrations change in response to persistent hyperglycemia but are unresponsive to short postprandial hyperglycemia. The assay of fructosamine residues is a diagnostic marker of medium-term glycemic control in diabetes mellitus. Approximately 6 to 15% of the human serum albumin (HSA) is glycation with a fructosamine *in vivo*, primarily at Lys-525. Glycation HSA reflects glycemic control during the 2 to 3 weeks preceding analysis. Glycation hemoglobin HbA_{1c} accounts for approximately 7.5% of total hemoglobin in normal human individuals. The various forms are designated HbA_{1a1}, HbA_{1a2}, HbA_{1b}, and HbA_{1c}. HbA_{1c} is the most abundant of the minor components in normal human red blood cells *in vivo*, accounting for approximately 5% of total hemoglobin. It too is a mixture of mostly the fructosamine adducts of the β -val-1 (60%) and α -Lys-61 (40%). HbA_{1a1} and HbA_{1a2} are the β -chain N-terminal adducts of

fructose-1,6-bisphosphate and glucose-6-phosphate, respectively. HbA_{1b} is thought to result from a deamidation in the β -chain of HbA_{1c}. The measurement of HbA_{1c} reflects glycemic control over the 6 to 8 weeks preceding analysis. In diabetes mellitus, the concentration of fructosamine of serum proteins is typically increased twofold relative to that of normal human individuals (approximately 5 vs 2 nmol/mg protein). Glycation hemoglobin HbA_{1c} is typically increased from 5% of total hemoglobin in normal controls to $\leq 7\%$ (good glycemic control), 7 to 10% (moderate control), and $> 10\%$ (poor control). There is no significant increase of fructosamine and glycation hemoglobin in prediabetic impaired glucose tolerance.

PROTEIN GLYCATION A RISK MARKER OF DIABETIC COMPLICATIONS

Glycation hemoglobin is a risk factor for the development of chronic clinical complications, probably as a surrogate indicator of hyperglycemia. Increased concentrations of AGE have been associated with diabetic complications in cross-sectional studies. AGE content of skin collagen (CML, pentosidine, and others) was shown to be a risk marker for microvascular complications of diabetes. Serum protein AGE content at baseline was shown to be a risk predictor for development of early morphological kidney damage leading to diabetic nephropathy.

FUNCTIONAL CONSEQUENCES OF PROTEIN GLYCATION

Glycation occurs inside and outside of cells. Glycation of nucleotides in DNA normally induces DNA repair but may induce apoptosis if glycation is excessive. Glycation of basic phospholipids may induce changes in membrane structure and lipid peroxidation. Glycation of cellular proteins produces changes in structure and loss of enzymatic activity. These effects are countered by protein degradation and renewal. Glycation of the extracellular matrix produces changes in macromolecular structure affecting matrix-matrix and matrix cell interactions associated with decreased

Figure 1 Formation of early glycation adducts and advanced glycation end products: (A) glycation adducts, (B) early glycation adducts (fructosamines), (C) reactive α -oxoaldehydes in physiological glycation process, and (D) molecular structures of AGEs. 3DG-H, N₈-[5-(2,3,4-trihydroxybutyl)-5-hydro-4-imidazolone-2-yl]ornithine; DOLD, 3-deoxyglucosone-derived lysine dimer, 1,3-di(N^ε-lysino)-4-(2,3,4-trihydroxybutyl)-imidazolium salt; G-H, N₈-(5-hydro-4-imidazolone-2-yl)ornithine; GOLD, glyoxal-derived lysine dimer, 1,3-di(N^ε-lysino)imidazolium salt; MG-H, N₈-(5-hydro-5-methyl-4-imidazolone-2-yl)-ornithine; MOLD, methylglyoxal-derived lysine dimer, 1,3-di(N^ε-lysino)-4-methyl-imidazolium salt.

elasticity and increased fluid filtration across arterial walls and endothelial cell adhesion. When the concentration of AGEs increases above a critical level, cell surface AGE receptors become activated. This is associated with increased expression of extracellular matrix proteins, vascular adhesion molecules, cytokines, and growth factors. Depending on the cell type and concurrent signaling, this is associated with chemotaxis, angiogenesis, oxidative stress, and cell proliferation or apoptosis. These processes are thought to contribute to disease mechanisms associated with the development of diabetic complications. Strategies for therapeutic interventions to counter the effects of glycation by preventing increased α -oxoaldehyde formation in hyperglycemia, scavenging of α -oxoaldehydes, and blocking of AGE receptor activation are in experimental development, and all hold promise for the eventual prevention of diabetic complications clinically.

POLYOL PATHWAY AND DIABETIC COMPLICATIONS

Aldose reductase (ALR2) is the first enzyme in the polyol pathway (Fig. 2). It catalyzes the NADPH-dependent reduction of glucose and many other carbonyl compounds to sorbitol and the corresponding alcohol derivatives. ALR2 has a low affinity (high K_M) for glucose. Hence, there is an increased flux of glucose metabolism via the polyol pathway in hyperglycemia; in human red blood cells, glucose metabolism increases from 3% of total glucose metabolism in normoglycemia to 11% in hyperglycemia. Sorbitol produced in the first step of the polyol pathway is oxidized by NAD^+ -dependent sorbitol dehydrogenase (SDH) to fructose in the second step. The complete traverse of the polyol pathway involves oxidation of NADPH to $NADP^+$ and reduction of NAD^+ to NADH, that is, a net hydride transfer from NADPH in the pentosephosphate pathway to NAD^+ in the Embden–Meyerhof pathway. Therefore, there is a net reduction of NAD^+ to NADH in the Embden–Meyerhof pathway and an increase in the cytosolic NADH/ NAD^+ ratio (Fig. 2). The effects of activation of the polyol pathway in diabetes have been attributed to osmotic stress arising from intracellular accumulation of sorbitol, decreased Na^+K^+ ATPase activity, *in situ* inhibition of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) by change in the NADH/ NAD^+ ratio, and *in situ* inhibition of glutathione reductase by depletion of NADPH-exacerbating intracellular oxidative stress. Diabetes induced in homozygous knock-out mice deficient in ALR2 neither decreased the

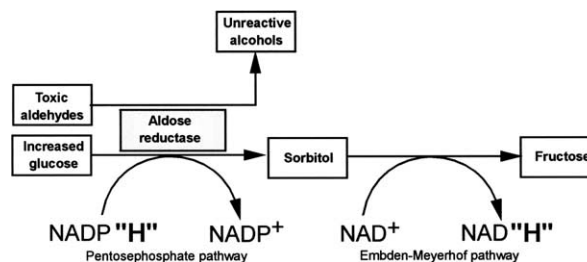

Figure 2 The polyol pathway.

glutathione content of sciatic nerve nor had decreased motor nerve conduction velocity—in contrast to wild-type mice. Studies of the inhibition of the polyol pathway *in vivo* with specific inhibitors have given inconsistent results. An ALR2 inhibitor prevented the development of diabetic neuropathy in dogs but failed to prevent retinopathy or thickening of the capillary basement membrane in the retina, kidney, and muscle. Several clinical trials have been performed with negative outcomes. The prevention of clinical diabetic neuropathy with a potent aldose reductase inhibitor was found in a multiple-dose, placebo-controlled trial. Effect on the redox balance is the most likely mechanism by which increased flux through the polyol pathway has deleterious consequences.

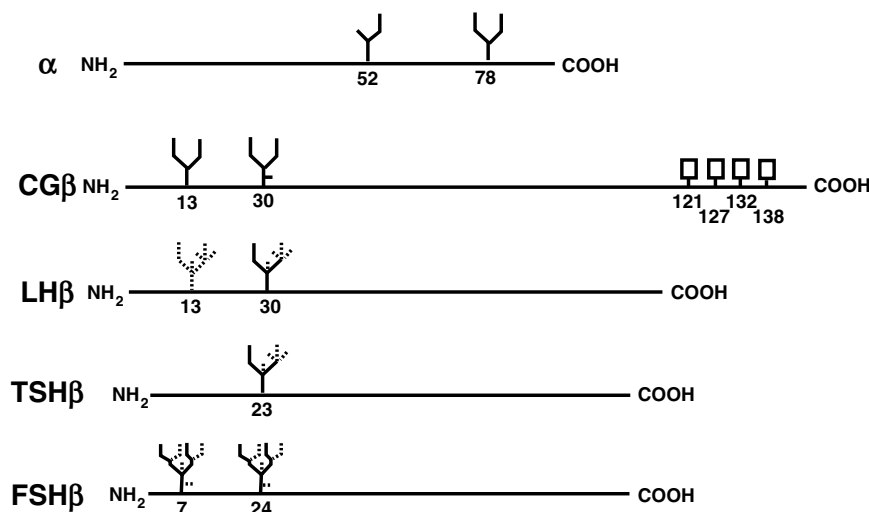

Figure 1 Structures of the subunits of human glycoprotein hormones. N-linked sugar chains and O-linked sugar chains are shown by “trees” and “boxes,” respectively, together with their positions. The N-linked sugar chains of α -subunit are those of hCG, and the α -subunit of other glycohormones have different sugar chains. Dotted portions of the trees in the β -subunits of LH, TSH, and FSH indicate heterogeneity in branching structures. LH β in the case of human hormone is glycosylated at the Asn 30. In contrast, a sugar chain is linked only at the Asn 13 of LH β of most other animal species. Reproduced, with slight modifications, from Bielinska and Boime (1995).

sugar chains of glycoproteins. However, comparative study of the N-linked sugar chains of hCG α and hCG β revealed that sialylated N5 is distributed mainly in hCG β and that sialylated N8 is distributed mainly in hCG α , whereas sialylated N6 is detected as a major sugar chain of both subunits. The specific distribution of different N-linked sugar chains at the four N-glycosylation sites of hCG molecule cannot be explained by our current knowledge of the biosynthetic mechanism of the N-linked sugar chains. An unknown control mechanism involving the steric effects of the polypeptide moiety may play a role in the formation of N-linked sugar chains of hCG. This assumption was supported by the study of the N-linked sugar chains of the free α -subunit.

A small amount of α -subunit occurs in free form in the urine of pregnant women. Interestingly, this free α -subunit cannot bind to hCG β , in contrast to hCG α dissociated from hCG heterodimer. Because the free α -subunit has the same amino acid sequence as does hCG α , it was assumed that the free α -subunit contains different sugar chains from hCG α . Structural studies of the sugar chains of the free α -subunit revealed that it contains sialylated N5 as its major sugar chains. This evidence indicated that bulky sialylated N5 on the free α -subunit may sterically inhibit its association with hCG β . Maturation of the N-linked sugar chains of the free α -subunit to larger complex-type sugar chains might be induced because

the subunit did not bind to β -subunit. Therefore, uneven distribution of the N-linked sugar chains at the four N-glycosylation sites of hCG may be produced only when the two subunits are associated before the N-linked sugar chains start maturation at the Golgi apparatus.

Later on, the structures of the N-linked sugar chains of LH and TSH of various mammals, including human (hLH and hTSH), were elucidated (as shown in Fig. 4), as were those of human FSH (hFSH) (as shown in Fig. 5). In contrast to hCG, the three pituitary glycoprotein hormones contain triantennary and tetraantennary complex-type sugar chains, and their sialic acids are linked at the C-3 and C-6 positions of galactose residues. Occurrence of bisected sugar chains was also found. The most interesting evidence is that a part of the N-linked sugar chains of hLH and hTSH contain the SO₄-4GalNAc β 1-4GlcNAc group as their outer chains.

An *N*-acetylgalactosaminyltransferase, which forms the GalNAc β 1-4GlcNAc group, was found to occur in the pituitary but not in the placenta. This enzyme requires presence of the -Pro-X-Arg- motif in the polypeptide portion of the substrate glycoprotein. Such sequence is present in hLH and hTSH but not in hFSH, explaining the absence of *N*-acetylgalactosamine residue in hFSH. The enzyme responsible for sulfation of the sugar chains of pituitary

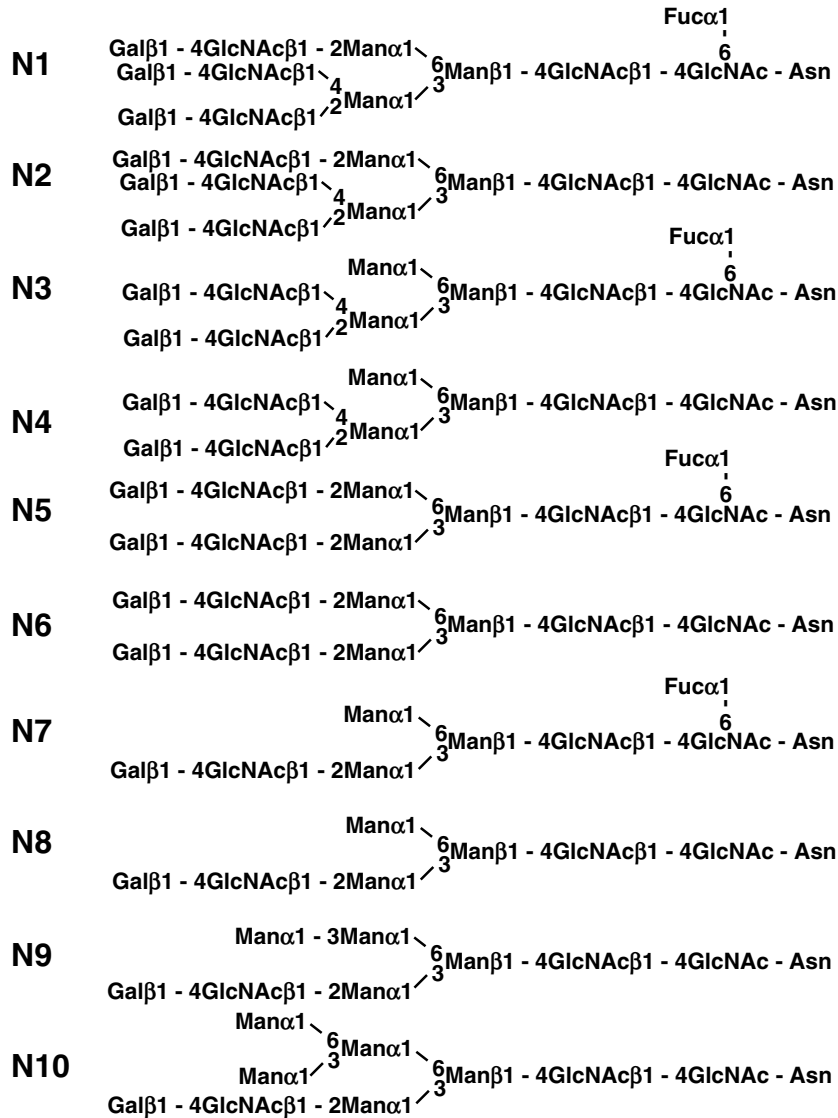

Figure 2 Structures of desialylated N-linked sugar chains isolated from various hCG preparations. All sialic acid residues are exclusively linked at the C-3 position of the galactose residues. Gal, galactose; GlcNAc, *N*-acetylglucosamine; Man, mannose; Fuc, L-fucose.

glycoprotein hormones was detected in the Golgi membrane preparation of pituitary gland by the transfer of sulfate residues from 3'-phosphoadenosine 5'-phosphosulfate. This 4-*O*-*N*-acetylgalactosamine sulfotransferase does not require any specific peptide motif and can transfer sulfate even to the trisaccharide: GalNAcβ1-4GlcNAcβ1-2Man. Therefore, addition of a β-*N*-acetylgalactosamine residue to the sugar chains is a prerequisite for the sulfation of the sugar chains.

Both FSH and LH are synthesized by gonadotrophs in the anterior pituitary. Although they share the same α-subunit polypeptide, their sugar chains

differ in branching and terminal modification. Therefore, assembly of the two subunits should control the maturation of the sugar chains, as discussed previously for the site-directed maturation of the sugar chains of hCG. Actually, assembly of the two subunits of glycoprotein hormones was found to occur when the N-linked sugar chains are still in the state of high mannose types, which are sensitive to endo-β-*N*-acetylglucosaminidase H digestion. In further processing and maturation steps to lead to complex-type sugar chains, association to different β-subunits will result in different sugar chain formation.

hCGs OF TROPHOBLASTIC DISEASES

A large amount of hCG is detected in the sera and urine of patients with various trophoblastic diseases such as hydatidiform mole and choriocarcinoma. Some of the hydatidiform moles show malignant characteristics, such as invasion into the surrounding tissues and metastasis, and are discriminated by the term “invasive mole.” Structural studies of the sugar chains of hCG samples purified from the urine of these patients revealed many interesting structural alterations that can be used for the diagnostic purposes. The N-linked sugar chain patterns of the urinary hCG samples, obtained from patients with hydatidiform mole, were identical to those of the samples from healthy pregnant women. In contrast, quite different patterns were obtained from the hCG samples, purified from the urine of patients with choriocarcinoma. In all choriocarcinoma hCGs, eight

Figure 4 Structures of N-linked sugar chains found in LH and TSH. R represents the Neu5Ac α 2–3 or 6Gal β 1– group, and R' represents the SO₄–4GalNAc β 1– group. Abbreviations of the sugar units are the same as in Figs. 2 and 3.

oligosaccharides, N1 to N8 as shown in Fig. 2, were detected in either their sialylated or nonsialylated forms. Interestingly, the hCG samples purified from the urine of patients with invasive mole gave another alteration in their glycosylation pattern. These samples contained sialylated N1, N2, N5, N6, N7, and N8 but not sialylated N3 and N4.

Although the structural alteration found in the sugar chains of choriocarcinoma hCGs is quite complicated, it can be explained by the changes induced in the two glycosyltransferases. An increase in the molar ratio of total fucosylated oligosaccharides (N1, N3, N5, and N7 in Fig. 2) indicated that expression of the fucosyltransferase responsible for formation of the Fuca1–6GlcNAc group is enhanced in choriocarcinoma cells. Appearance of oligosaccharide N7 may indicate that the enhanced fucosyltransferase has wider specificity than that in normal syncytiotrophoblasts. Structurally, oligosaccharides N1, N2, N3, and N4 can be formed by addition of the Gal β 1–4GlcNAc β 1–4 outer chain to N5, N6, N7, and N8, respectively. Therefore, *N*-acetylglucosaminyltransferase IV (GnT-IV), which forms the GlcNAc β 1–4Man group and is suppressed in syncytiotrophoblasts, must be strongly expressed in choriocarcinoma. Detection of N1 and N2 in invasive mole indicated that GnT-IV is expressed in these cells as well. However, absence of N3 and N4 indicates that the newly expressed GnT-IV can transfer an *N*-acetylglucosamine residue to biantennary sugar chains but not to monoantennary sugar chains.

Cloning of the structural gene of GnT-IV from a human liver cDNA library revealed that two active GnT-IV genes are present. The translation products of these two genes were named GnT-IVa and GnT-IVb. When activities of the five glycosyltransferases (GnT-I to GnT-V), which are related to the formation of the antennary portion of the complex-type sugar chains, were studied comparatively in normal placenta and several choriocarcinoma cell lines, only GnT-IV activity was strikingly increased in the cancer cells. Northern blot analysis revealed that the GnT-IVa gene was strongly overexpressed in the cancer cells, whereas the GnT-IVb gene was expressed at the same level as in the normal placenta. So far, no difference in the substrate specificities of GnT-IVa and GnT-IVb has been found. The data have indicated that overexpression of the GnT-IVa gene and the resulting increase in GnT-IV activity are the enzymatic basis of formation of the abnormal sugar chains in choriocarcinoma cells. An enzymatic basis to form the different sugar patterns of choriocarcinoma and invasive mole hCGs remains to be elucidated.

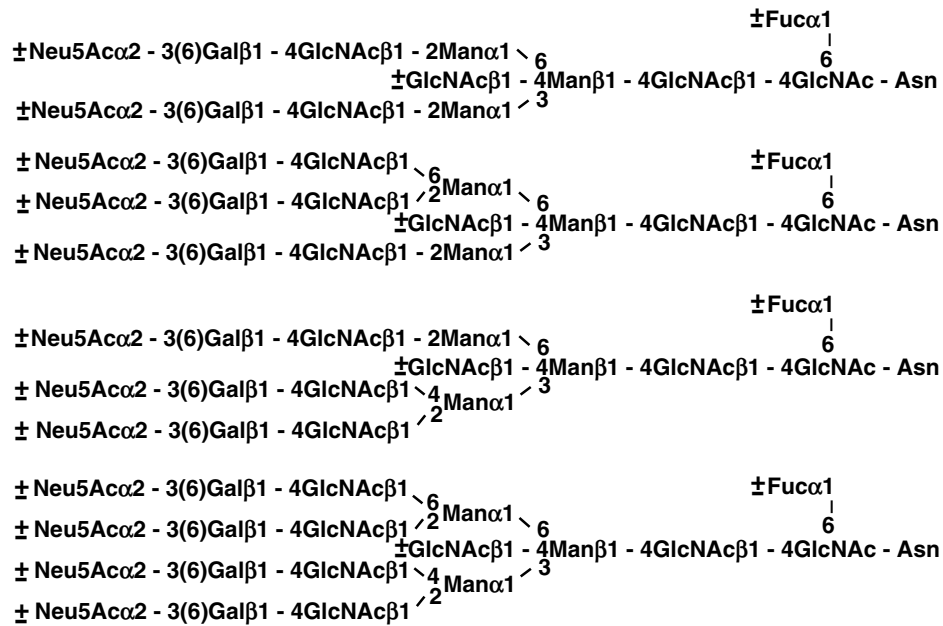

Figure 5 Structures of the N-linked sugar chains found in hFSH. Abbreviations of the sugar units are the same as in Figs. 2 and 3.

Because oligosaccharides N1 and N2 were detected in invasive mole and choriocarcinoma hCGs but not in normal pregnant hCGs and hydatidiform mole hCGs, this difference can be used for the diagnosis of malignant trophoblastic diseases. Actually, a *Datura stramonium* agglutinin-Sepharose column, which has an affinity to the Gal β 1-4GlcNAc β 1-4(Gal β 1-4GlcNAc β 1-2)Man group, can discriminate hCGs in the urine of patients with malignant diseases from those in the urine of pregnant women and patients with hydatidiform mole.

Alteration of the O-linked sugar chains of hCG by malignant transformation was also found. hCG samples obtained from patients with hydatidiform mole, invasive mole, and choriocarcinoma all contain both O-a and O-b in Fig. 3. However, the proportion of O-b increased prominently in choriocarcinoma. Although hydatidiform mole hCGs contain a similar proportion of the sialylated tetrasaccharide to normal hCG, the proportion increased moderately but significantly in invasive mole hCGs.

FUNCTIONAL ROLE OF THE SUGAR CHAINS OF GLYCOPROTEIN HORMONES

The specific distribution of different sugar chains in the two subunits of hCG indicated that even the

smallest N-linked sugar chain, such as sialylated N8, may work as an important signal in expression of the hormonal action of hCG. That modification of the N-linked sugar chains of hCG alters its hormonal activity was proposed by many studies. Complete removal of sialic acid residues from hCG reduces its hormonal activity (as measured by cyclic AMP (cAMP) production and steroidogenesis in the target cells) to 50%, although its binding to target cells is enhanced. Removal of the whole N-linked sugar chains from hCG further increases the binding of hCG to its target cells but completely eliminates its hormonal activity. These results indicate that absence of the sugar chains dissociates receptor binding of hCG from its signal transduction. The deglycosylated hCG behaves as an antagonist to native hCG. It was also reported that the glycopeptides mixture, obtained from hCG by exhaustive pronase digestion, blocked hCG signal transduction. These results suggest that binding of hCG to a lectin-like membrane component in addition to an hCG receptor is necessary to induce the signal transduction.

Comparative study of the biological activities of hCGs, in which only one of the N-glycosylation sites was eliminated by recombinant DNA technology, revealed that N-glycosylation at the Asn-52 of hCG α is essential for the expression of hormonal activity, whereas removal of the N-linked sugar chains at either Asn-13 or Asn-30 of hCG β or Asn-78 of hCG α had no effect. Other important evidence

shown by this line of study is that removal of Asn-78 glycosylation of hCG α markedly reduces its assembly with hCG β . Glycosylation of the two N-glycosylation sites of hCG β is not essential for its assembly with hCG α , but elimination of Asn-30 glycosylation inhibits the secretion of uncombined hCG β . These results indicated that the N-linked sugar chains of hCG are important for constructing the correct conformation of each subunit. That the presence of at least one N-acetylglucosamine residue at each of the four N-glycosylation sites of hCG is enough to keep the correct folding of the two subunits was shown two decades ago by investigating the effects of digestion with exo- and endoglycosidases on the folding and assembly of the two subunits.

Although exact structures of the sugar chains essential for proper expression of the functional role of hCG were not presented, the role of sialic acid residues was further investigated. As described previously, removal of all sialic residues of the N-linked sugar chains of hCG, which exclusively occur as the Neu5Ac α 2-3Gal group, reduces the hormonal activity of hCG to 50%. When the desialylated hCG was resialylated by incubation with CMP-Neu5Ac and Gal β 1-4GlcNAc: α 2-6 sialyltransferase, the isomeric hCG containing only the Neu5Ac α 2-6Gal group gave almost the same dose-response curve as did the natural hCG. This recovery of hormonal activity is not obtained by the addition of the Gal α 1-3 residue to the nonreducing terminal galactose residues. Interestingly, extensive sialylation of desialylated hCG reduced the hormonal activity of the isomeric hCG. Further investigation revealed that sialylation of the outer chain on the Man α 1-3 arm, rather than the Man α 1-6 arm, of the N-linked sugar chains of hCG is favorable for the signal transduction.

Addition of 2 mM N-acetylneuraminic acid hexamer, obtained by incomplete sialidase digestion of colominic acid, to the mixture of hCG and MA-10 cells, a mouse Leydig tumor cell line established by Ascoli, revealed that the oligosaccharide did not inhibit the binding of hCG to the surface of the target cells but that cAMP production was reduced to 50%. This result indicated that the hexasaccharide can inhibit the interaction of the sialic acid residues of hCG with the specific binding site on the cell surface but does not influence the binding of the peptide portion of hCG to the hCG receptor. The possibility that the action of the sialic acid hexamer may be due to a nonspecific anionic polymer effect was defuted because the addition of fucoidin did not show any inhibition of the [3 H]hCG binding to the cell surface receptor or cAMP production by hCG.

Presence of the sialic acid binding site on the surface of MA-10 cells was confirmed by using 3'-sialyllactose-conjugated bovine serum albumin as a probe. Based on the data indicating that sialic acid residues bind directly to the cell surface, a model of the hCG-receptor complex was proposed. A dual interaction of the peptide portion and the sialylated sugar chain of hCG with respective binding sites is essential for the signal transduction. Interestingly, a region homologous to the soybean lectin was found in the hCG receptor.

Compared to hCG, the functional roles of the sugar chains of pituitary hormones were not investigated aggressively. Like other serum glycoproteins, sialylation of the N-linked sugar chains of glycoprotein hormones will protect them from clearance by hepatic galactose-binding receptor. In contrast, sulfation of the N-linked sugar chains of hLH and hTSH leads to more rapid clearance of them. It was reported that sulfated LH is cleared from circulation by binding to a receptor, which specifically recognizes the SO $_4$ -4GalNAc β 1-4GlcNAc group, on the surface of hepatic endothelial cells. Fully sialylated hTSH, made by recombinant technique, showed a longer half-life in circulation than did natural TSH. Because the sulfation versus sialylation pattern of TSH is regulated by thyrotropin-releasing hormone, the rapid clearance may be important in controlling the serum level of this glyco-hormone.

affected by goiter. Cassava, a staple food in these areas, has antithyroid effects in humans and experimental animals. Thus, daily consumption of cassava, in the presence of severe iodine deficiency, is thought to be the cause of endemic goiter and cretinism in these areas of Zaire. The goitrogenic action of cassava is due to endogenous release of thiocyanate from linamarin, a cyanogenic glucoside present in cassava, particularly in the tuberous roots. Thiocyanate is also present in Pearl millet, the staple food of people living in iodine-deficient endemic goiter areas of western Sudan. Pearl millet is rich in C-glycosylflavones, which in combination with thiocyanate exert additive and complementary antithyroid and goitrogenic effects. Thiocyanate is also found in high concentrations (1 g/L) in wastewater effluents of coal conversion processes and in body fluids as a metabolite of hydrogen cyanide gas consumed while smoking. Studies in Sweden indicate that cigarette smoking may produce goiter. Similarly, goiter and hypothyroidism were documented in patients receiving long-term thiocyanate treatment for hypertension. This goitrogenic effect of thiocyanate is more evident in the presence of iodine deficiency. Several observations suggest that thiocyanate crosses the human placenta and may cause both goiter and neonatal hypothyroidism.

Thiocyanate

Thiocyanate and thiocyanate-like compounds primarily inhibit the iodine-concentrating mechanism of the thyroid, and their goitrogenic activity can be overcome by iodine administration (Fig. 1). Thiocyanate at low concentrations inhibits iodide transport by increasing the velocity constant of iodide efflux from the thyroid gland. At high concentrations, the iodide efflux is greatly accelerated, whereas the unidirectional iodide clearance into the gland is inhibited. Thiocyanate at these high concentrations also inhibits the incorporation of iodide into thyroglobulin by competing with iodide at the thyroid peroxidase (TPO) level. Thiocyanate is rapidly converted to sulfate in the thyroid gland. Administration of thyroid-stimulating hormone (TSH) increases the intrathyroidal catabolism of thiocyanate and is capable of reversing the block of iodide uptake produced by this ion.

Isothiocyanates

The isothiocyanates and cyanogenic glycosides act on the thyroid mainly by their rapid conversion to thiocyanate. However, isothiocyanates also react spontaneously with amino groups to form thiourea derivatives, which produce a thiourea-like antithyroid effect. Isothiocyanates also possess intrinsic antithyroid activity, as demonstrated by *in vitro* inhibition of iodide uptake in the case of methyl- and allyl-isothiocyanates and of both iodide uptake and organification in the case of butyl-isothiocyanate.

Thio-Oxazolidone (Goitrin)

The thionamide or thiourea-like goitrogens interfere in the thyroid gland with the organification of iodide and formation of the active thyroid hormones, and their action usually cannot be antagonized by iodine. Naturally occurring goitrin is representative of this category (Fig. 1). Long-term administration of goitrin to rats results in increased thyroid weight and decreased radioactive iodide uptake and hormone synthesis by the thyroid gland. Actually, goitrin possesses 133% of the potency of propylthiouracil in humans. Goitrin is unique in that it is not degraded like thioglycosides. Additive antithyroidal effects of thiocyanate, isothiocyanate, and goitrin also occur with combinations of these naturally occurring goitrogens.

Disulfides

The small aliphatic disulfides ($R-S-S-R$; R = methyl-, ethyl-, *n*-propyl, phenyl-), the major components of

onion and garlic, exert marked thiourea-like antithyroid activity. None of these disulfides inhibits *in vitro* the TPO enzyme, but fractions with sulfur-bearing organic compounds, possibly aliphatic disulfides from the goitrogenic well supplying a Colombian district with endemic goiter, inhibited *in vitro* ^{125}I -organification. Disulfides are also present in high concentrations (0.3–0.5 g/L) in aqueous effluents from coal conversion processes, and they have also been identified as water contaminants in the United States, where the most frequently isolated compounds are dimethyl, diethyl, and diphenyl disulfides.

FLAVONOIDS

Flavonoids are important stable organic constituents of a wide variety of plants. Flavonoids are universally present in vascular plants and in a large number of food plants. Because of their widespread occurrence in edible plants such as fruits, vegetables, and grains, flavonoids are an integral part of the human diet. They are present in high concentrations in polymeric (tannins) and oligomeric (pigments) forms in various staple foods in the Third World such as millet, sorghum, beans, and ground nuts.

Flavonoids are polyhydroxyphenolic compounds with a $\text{C}_6\text{--C}_3\text{--C}_6$ structure. Mammalian organisms are unable to synthesize the flavone nucleus. Flavonoids are strictly exogenous food components of exclusively vegetable origin. They have high chemical reactivity with multiple important biological implications. Flavonoids are quickly metabolized in higher organisms, and that is the reason why they are not found in normal tissue constituents. Most flavonoids are present as β -glucosides that cannot be absorbed in tissues. No mammalian enzymes have been found that deglycosylate these compounds to their bioactive aglycone species. Following ingestion by mammals, flavonoid glycosides are hydrolyzed by intestinal microbial glycosidases to flavonoid aglycones. These may be absorbed and undergo metabolism by mammalian tissues, or they may be further metabolized by intestinal micro-organisms to undergo B-ring hydroxylation and middle-ring fission, with production of various metabolic monomeric compounds, including phenolic acids, phloroglucinol, resorcinol, and gallic acid. Each metabolic step is characterized by a marked increase in antithyroid effects. Flavonoid aglycones, such as apigenin and luteolin present in Fonio millet (*Digitaria*

exilis), and a variety of flavonoid metabolites (e.g., phloroglucinol, resorcinol, phenolic acids) are several times more potent than the parent glycosides glucosylvitexin, glucosylorientin, and vitexin present in Pearl millet (*Pennisetum* [L.] *leek*, also known as typhoides or americanum), as inhibitors of TPO, the enzyme-catalyzing iodide oxidation and hormone synthesis in the thyroid gland. This greater inhibitory effect is further enhanced by the additive effects exerted by mixtures of flavonoid aglycones and flavonoid metabolites that are formed after ingestion of mixtures of flavonoid glycosides present in many plant foodstuffs. In addition, these metabolic products may produce adverse effects on other parameters of thyroid function not observed with the glycosides. As a result, the antithyroid effects of flavonoid glycosides in foodstuffs may be greatly enhanced by metabolic alterations after ingestion by mammals, as in the case of the flavonoids present in the Pearl millet grain, the staple food of people living in iodine-deficient endemic goiter areas of western Sudan, which make a major contribution to and are primarily responsible for its antithyroid and goitrogenic effects. Furthermore, antithyroid effects *in vivo* of vitexin, one of the three major flavonoids in Pearl millet, has been demonstrated to provide evidence that C-glycosylflavones are the goitrogens in this cereal grain. It is of interest that a significant portion of the flavonoids isolated from Fonio millet, the staple food of people living in the severely affected endemic goiter area of Guinea in Western Africa, are already present as the aglycones apigenin and luteolin, with more potent antithyroid activity than their parent glycosides. Flavonoids not only inhibit TPO but, acting on iodothyronine deiodinase enzymes, also inhibit the peripheral metabolism of thyroid hormones. Flavonoids also affect serum thyroid hormone binding and thyrotropin (TSH) regulation. Thus, this class of compounds alters thyroid hormone economy in a complex manner.

At this point, there is substantial evidence indicating, first, that various millet species used as staple food by the populations in the semi-arid tropics are rich in flavonoids; second, that flavonoids have potent and diverse antithyroid properties; and third, that under the appropriate environmental dietary conditions of low iodine and protein-calorie intakes, which are prevalent in most countries of the Third World, flavonoids become an important etiological determinant of endemic goiter and hypothyroidism.

POLYHYDROXYPHENOLS AND PHENOL DERIVATIVES

Coal is a source of a large variety of antithyroid and goitrogenic compounds such as, phenol, dihydroxyphenols (resorcinol), substituted dihydroxybenzenes, thiocyanate, disulfides, phthalic acids, pyridines, and halogenated and polycyclic aromatic hydrocarbons (PAH) (Table I). Most of these compounds have been identified in drinking water from the iodine-sufficient goitrous areas of Kentucky (United States) and Colombia (South America). Phenolics are the major organic pollutants in wastewater effluents from various types of coal treatment processes. Resorcinol, substituted resorcinols, and other antithyroid phenolic pollutants are present at levels of as high as 5 g/L in coal-derived effluents. Up to 8% of shale bitumen is also composed of phenols. Phenol, dihydroxyphenols, trihydroxyphenols, and halogenated phenols are readily absorbed from the gastrointestinal tract. Phenol, resorcinol, and catechol, in suitable preparations, are readily absorbed through human skin. Essentially all phenols, polyhydroxyphenols, and halogenated phenols are readily absorbed after injection. A major route of metabolism of polyhydroxyphenols, polyhydroxyphenolic acids, and halogenated phenols is by conjugation to glucuronic or sulfuric acids. The major route of excretion of these compounds is the urinary tract, and various amounts of the free parent compound and its monoglucuronide and monosulfate conjugates are excreted in the urine.

Resorcinol, the prototype of this group of compounds, is antithyroid and goitrogenic both in man and in experimental animals. During the early 1950s, the goitrogenic effect of resorcinol was demonstrated when patients applying resorcinol ointments for the treatment of varicose ulcers developed goiter and hypothyroidism. Several observations also suggest that resorcinol crosses the human placenta and may cause both goiter and neonatal hypothyroidism. Resorcinol has been shown both *in vivo* and *in vitro* to inhibit thyroidal organification of iodide. A comparison of the antiperoxidase activity of resorcinol (1,3-dihydroxybenzene), catechol (1,2-dihydroxybenzene), and hydroquinone (1,4-dihydroxybenzene) (Table I) indicates the importance of hydroxyl groups in the meta position for maximal activity. Furthermore, the net antiperoxidase effects of mixtures of dihydroxyphenols, as well as dihydroxyphenols and thiocyanate (also a coal-derived pollutant), are equivalent to or greater than the sum of the effects produced by individual compounds, indicating that the true goitrogenic potential of the major water-soluble compounds present

in coal and shales are due to the combined effects of the individual constituents rather than to any single compound. Demonstration *in vivo* and *in vitro* of antithyroid and goitrogenic activities of coal-water extracts from iodine-sufficient goiter areas indicate that shale- and coal-derived organic pollutants appear to be a major factor contributing to the high goiter prevalence and associated disorders observed in certain areas with aquifers and watersheds rich in these organic rocks. Studies of the physical state of organic goitrogens in water indicate that the active compounds form dissociable complexes and that they are part of larger organic molecules, possible humic substances (HS). Furthermore, resorcinol and other parent antithyroid phenolic and phenolic-carboxylic compounds are degradation monomeric by-products of reduction, oxidation, and microbial degradation of HSs. HSs, high-molecular-weight complex polymeric compounds, are the principal organic compounds of soils and waters. More than 90% of total organic matter in water consists of HSs, which are also present in coals and shales. Decaying organic matter becomes the substrate of lignin and flavonoid types of HS during the process of fossilization (or coalification). Actually, cyanidin, a naturally occurring flavonol used as a model subunit of flavonoid-type HS, yields the following antithyroid compounds by reductive degradation: resorcinol, phloroglucinol, orcinol, and 3,4-dihydroxybenzoic acid (Table I). Demonstration *in vivo* and *in vitro* of antithyroid effects of vitexin, a major C-glucosylflavone in Pearl millet, provides evidence that flavonoid structures are the link for phenolic goitrogens in foodstuffs (e.g., millet) and those present in coals, shales, soils, and water, all of which are an obligatory step and integral part of the biogeochemical cycle of organic-phenolic goitrogens in nature (Fig. 2).

In addition to thiocyanate, cigarette smoke contains various goitrogenic resorcinol derivatives, flavonoids, and hydroxypyridines. As mentioned previously, cigarette smoking may produce goiter, and smoking increases the severity and metabolic effects of hypothyroidism, probably by alteration of both thyroid function and hormone action.

The presence of halogenated organic compounds with known or potential harmful effects has prompted public health and environmental concerns. These compounds are produced by the chlorination of water supplies, sewage, and power plant cooling waters. Present at micrograms-per-liter concentrations (parts per billion) in treated domestic sewage and cooling waters, 4-chlororesorcinol and 3-chloro-4-hydroxybenzoic acid possess antithyroid activities as inhibitors of TPO and thyroidal iodide organification.

Table I Environmental Agents Producing Goitrogenic and/or Antithyroid Effects

| Compound | Goitrogenic/Antithyroid effects | | |
|---|---------------------------------|---------|----------------------|
| | <i>In vivo</i> | | <i>In vitro</i> |
| | Humans | Animals | |
| Sulfurated organics | | | |
| Thiocyanate (SCN) ^a | + | + | + |
| Isothiocyanates | NT | + | + |

Figure 2 Simplified scheme of the biogeochemical cycle of phenolic goitrogens and interrelationships among plant flavonoids (e.g., millet), polyhydroxyphenols, humic substances (HS), coals, and shales. Reproduced with permission from the *Annual Review of Nutrition*, volume 10, (©)1990 by Annual Reviews.

Whether these pollutants exert additive or synergistic antithyroid effects or act as “triggers” of autoimmune thyroiditis, or both, requires investigation, particularly because more than 60 soluble chloro-organics have been identified in the primary and secondary effluents of typical domestic sewage treatment plants.

Derivatives of 2,4-dinitrophenol (DNP) are widely used in agriculture and industry. An insecticide, a herbicide, and a fungicide, DNP is also used in the manufacture of dyes, to preserve timber, and as an indicator as well as being a by-product of ozonization of parathion. DNP is readily absorbed through intact skin and respiratory tract. DNP causes toxicity by the uncoupling of oxidative phosphorylation in the mitochondria of cells throughout the body. Administration of 2,4-DNP to human volunteers resulted in rapid and pronounced decline of circulating thyroid hormones. A decrease in TSH secretion results in decreased synthesis and release of thyroxine (T_4) and triiodothyronine (T_3) and possibly involution of the thyroid gland. The antithyroid effect of 2,4-DNP is due in part to an inhibition of the pituitary TSH mechanism. Once T_4 and T_3 are released into the circulation, they are instantaneously bound to serum carrier proteins. DNP also interferes with T_4 binding, further decreasing serum T_4 concentration. In addition to inhibiting the TSH mechanism and interfering with T_4 binding, DNP accelerates the disappearance of T_4 from the circulation; thus, the serum concentration is lowered even more. The public health impact of this pollutant on the thyroid is still unknown.

PYRIDINES

Hydroxypyridines also occur in aqueous effluents from coal conversion processes as well as in cigarette smoke. Dihydroxypyridines and 3-hydroxypyridine are potent inhibitors of TPO, producing effects comparable to or greater than those of propylthiouracil. After ingestion, mimosine, a naturally occurring amino acid in the seeds and foliage of the tropical

legume *Leucaena leucocephala*, is metabolized to 3,4-dihydroxypyridine (3,4-DHP), a potent antithyroid agent that produces goiter in mammals. 3,4-DHP crosses the placenta barrier, producing goitrous offspring. The phenolic properties of the 3-hydroxy group in various hydroxypyridines are reflected in the metabolism of these compounds *in vivo*. 3-hydroxypyridine fed to rabbits is converted to ethereal glucuronide and sulfate conjugates. 3,4-DHP glucuronide and sulfate conjugates account for the majority of 3,4-DHP in the blood of cattle grazing on leucaena. The ring structure of dihydroxypyridines does not appear to be broken down in the body and also appears to be relatively stable to bacterial degradation.

PHTHALATE ESTERS AND METABOLITES

Phthalic acid esters, or phthalates, are ubiquitous in their distribution and have been frequently identified as water pollutants. Dibutyl phthalates (DBPs) and dioctyl phthalates (DOPs) have been isolated from water-supplying areas of endemic goiter in western Colombia and eastern Kentucky. Although phthalate esters are most commonly the result of industrial pollution, they also appear naturally in shale, crude oil, petroleum, plants, and fungal metabolites and as emission pollutants from coal liquefaction plants.

Phthalate esters are well absorbed from the gastrointestinal tract. Prior to intestinal absorption, there is hydrolysis to the corresponding monoester metabolite. This is particularly true of the longer chain derivatives such as DOPs. Phthalates are widely distributed in the body, with the liver being the major initial repository organ. Clearance from the body is rapid. Short-chain phthalates can be excreted unchanged or following complete hydrolysis to phthalic acid. Prior to excretion, most longer chain compounds are converted, by oxidative metabolism, to polar derivatives of the monoesters. The major route of phthalate esters elimination from the body is urinary excretion.

Phthalate esters are commonly used as plasticizers to impart flexibility to plastics, particularly polyvinylchloride polymers (PVCs), which have a wide variety of biomedical and other uses such as building and construction, home furnishings, cars, clothing, and food wrappings. A small fraction of phthalate esters are used as nonplasticizers for pesticide carriers, oils, and insect repellents. Phthalates may be present in concentrations of up to 40% of the weight of the plastic.

Phthalate esters are known to leach out from finished PVC products into blood and physiological solutions. The entry of these plasticizers into a patient's bloodstream during blood transfusion, intravenous fluid administration, or hemodialysis has become a matter of concern among public health officials and the medical community. A high incidence of goiter in patients receiving maintenance hemodialysis has been reported. It remains to be determined whether phthalate ester metabolites, contaminants in the water entering the patient's bloodstream, or middle molecules (e.g., hydroxybenzoic and vanillic acids) that accumulate in uremic serum and are poorly removed by hemodialysis are responsible for this condition.

Although phthalate esters and phthalic acids do not possess intrinsic antithyroid activity (Table I), they undergo degradation by gram-negative bacteria to form dihydroxybenzoic acid (DHBA). DHBAs are known to possess antithyroid properties (Table I). The 3,4- and 3,5-DHBAs also inhibit *in vitro* TPO and the incorporation of iodide into thyroid hormones. The proven effective role of gram-negative bacteria in phthalate biodegradation may explain, in part, the relationship established between frequency of goiter and bacterial contamination of water supplies. Furthermore, marked ultrastructural changes of the thyroid gland, similar to those seen after administration of TSH, and decreased serum T₄ concentration have been observed in rats treated with phthalic acid esters. Thus, phthalates may become goitrogenic under appropriate conditions and are also actively concentrated and metabolized by several species of fish. Whether these widely distributed pollutants exert deleterious effects on the thyroids of humans has not been investigated.

POLYCHLORINATED AND POLYBROMINATED BIPHENYLS

These are aromatic compounds containing two benzene nuclei with two or more substituent chlorine or bromine atoms. They have a wide variety of industrial applications, including electric transformers, capacitors, and heat transformers. There is growing evidence that atmospheric transport is the primary mode of global distribution of polychlorinated biphenyls (PCBs) from sites of use and disposal. Plant foliage accumulates the vapor of PCBs from the atmosphere. In addition to their occurrence in surface water (e.g., rivers, lakes), PCBs have been detected in drinking water. Perhaps the most significant human exposures are limited to individuals consuming freshwater fish

from contaminated streams and lakes and to occupational exposure of industrial workers. PCBs can also be found in the milk of nursing mothers who have eaten large amounts of sport fish or who have been occupationally exposed. Currently, PCBs are targeted by bioremediation strategies, and some strains of *Pseudomonas* spp. (*Pseudomonas cepacia*) can degrade these stable aromatic pollutants. PCBs and polybrominated biphenyls (PBBs) have high-lipid solubility and resistance to physical degradation. They are slowly metabolized, and their excretion is limited. Long-term low-level exposure to the organohalides results in their gradual accumulation in fat, including the fat of breast milk. PCBs have been found in the adipose tissue of 30 to 45% of the general population. The biological and toxicological properties of PCB mixtures may vary depending on their isomeric composition. Oral administration of PCBs to various mammals results in rapid and nearly complete (90%) intestinal absorption. The degradation and elimination of PCBs depend on the hepatic microsomal enzyme system. The excretion of PCBs is related to the extent of their metabolism. Those with greater chlorine content have a correspondingly longer biological half-life in mammals. This resistance to metabolism is reflected in their deposition in adipose tissue. The PCBs, however, have very low acute toxicity in all animal species tested, and PBBs have biological properties similar to PCBs.

Despite the lack of evidence that dietary PCBs and PBBs have any deleterious effects on health, there is a growing concern and uncertainty about the long-range effects of bioaccumulation and contamination of our ecosystem with these chemicals. The uncertainty extends to the potential harmful effects of these pollutants on the thyroid. For instance, an increased prevalence of primary hypothyroidism (11%) was documented among workers from a plant that manufactured PBBs and PBB oxidases. These individuals had elevated titers of TPO-microsomal antibodies, indicating that hypothyroidism was probably a manifestation of lymphocytic autoimmune thyroiditis, perhaps a PBB-induced pathogenic autoimmune response or exacerbation of underlying subclinical disease.

PCBs are potent hepatic microsomal enzyme inducers. Rats exposed to PCBs exhibit a greatly enhanced biliary excretion of circulating T₄. The T₄ is excreted as a glucuronide that is then lost in the feces. This response is probably secondary to induction of hepatic microsomal T₄-uridine diphosphate-glucuronyl transferase. The enhanced peripheral metabolism and reduced binding of T₄ to serum proteins

in PCB-treated animals result in markedly decreased serum T_4 concentrations. These low levels stimulate the pituitary–thyrotropin–thyroid axis, and this eventually results in goiter formation. Although PCB-treated animals exhibit decreased serum T_4 , their T_3 levels are unchanged. The relative iodine deficiency brought about by the accelerated metabolism of T_4 may induce increased thyroidal T_3 secretion as well as increased peripheral deiodination of T_4 to T_3 . PBBs appear to act similarly to PCBs. There is, however, some indication that they may also interfere directly with the process of hormonal synthesis in the thyroid gland.

OTHER ORGANOCHLORINES

DDT (2,2-bis(p-chlorophenyl)-1,1,1-trichloroethane) is polychlorinated and nondegradable. The substance is practically insoluble in water and is resistant to destruction by light and oxidation. Its stability has created difficulties in residue removal from water, soil, and foodstuffs. The dominant degradative reaction of DDT is dehydrochlorination to form DDE (2,2-bis(p-chlorophenyl)-1,1-dichloroethylene), which has the same low solubility in water and high lipid–water partitioning as did its precursor. This substance is almost undegradable, both biologically and environmentally. Dieldrin is one of the cyclodiene insecticides. It is almost insoluble in water and, like DDT and DDE, is very stable, both environmentally and biologically. DDT has been used extensively, both in malaria control and in agriculture, all over the world. Because of biomagnification and persistence, DDT and its breakdown products, DDE and DDD (dichlorodiphenyldichloroethane), are ubiquitous contaminants of water and of virtually every food product. Most of the fish from Lake Michigan in North America contain DDT residues. The substance is also present in milk; humans are at the top of the food pyramid, so human milk is especially contaminated. The situation is basically similar for dieldrin, which is found in surface waters virtually everywhere. Dieldrin is heavily bioconcentrated in the lipids of terrestrial and aquatic wildlife, humans, and foods, especially animal fats and milk. Global distribution of high concentrations of organochlorines, including DDT, DDE, DDD, and dieldrin, were recently found not only in developing countries but also in industrialized countries, which continue to be highly contaminated even though the use of many of these compounds is restricted.

DDT is reductively dechlorinated in biological systems to form DDE and DDD. DDE, the predominant

residue stored in tissues (reaching about 70% in humans), is much less toxic than DDT. DDE is eliminated from the body slowly, and little is known about its degradation pathway. DDT is also eliminated from the human body slowly through reduction to DDD and other more water-soluble derivatives.

DDT is known to cause marked alterations in thyroid gland structure such as thyroid enlargement, follicular epithelial cell hyperplasia, and progressive loss of colloid in birds, and DDD is known to cause goiter and increased hepatobiliary excretion of thyroid hormones in rats. All of these compounds (DDT, DDE, DDD, and dieldrin) induce microsomal enzyme activity that may affect thyroid hormone metabolism in a similar way to that of the polyhalogenated biphenyls and PAH. The impact of these pollutants on the human thyroid is unknown.

Dioxin (or tetrachlorodibenzodioxin, TCDD), one of the most toxic small organic molecules, is a contaminant in the manufacturing process of several pesticides and herbicides, including Agent Orange. Also a potent inducer of hepatic microsomal enzymes, TCDD markedly enhances the metabolism and biliary excretion of T_4 -glucuronide. Rats treated with TCDD concomitantly develop hypothyroxinemia, increased serum TSH concentrations, and goiter, probably as a result of T_4 loss in the bile. The impact on the thyroid of humans exposed to this agent is unknown, and studies of thyroid gland function and thyroid hormone metabolism in those affected are needed.

POLYCYCLIC AROMATIC HYDROCARBONS

PAHs have been found repeatedly in food and domestic water supplies as well as in industrial and municipal waste effluents. They also occur naturally in coal, soils, ground water, and surface water as well as in their sediments and biota. One of the most potent of the carcinogenic PAH compounds, 3,4-benzopyrene (BaP), is widely distributed and, as in the case of other PAHs, is not efficiently removed by conventional water treatment processes.

The PAH carcinogens, BaP and 3-methylcholanthrene (MCA) by enhancement of hepatic UDP-glucuronyltransferase and glucuronidation, accelerate T_4 metabolism and excretion of T_4 -glucuronide, resulting in decreased serum T_4 concentrations, activation of the pituitary–thyrotropin–thyroid axis, and (eventually) goiter formation. There is also indication that MCA interferes directly with the process of hormonal synthesis in the thyroid gland. Furthermore, MCA, as well as 7,12-dimethylbenzanthracene,

induces goitrous thyroiditis in the BUF rat. Thus, MCA exerts its deleterious effects on the thyroid gland by at least three different mechanisms. Finally, the coal-derived PAH methylanthracene (MA), which has been identified in drinking water from the goitrous coal-rich district of eastern Kentucky, was found to produce goiter in the BUF rat without alteration of hormone synthesis or lymphocytic infiltration of the thyroid gland.

Table I Comparison of Various Ovulation Induction Agents

| Agent | How given | Mechanism of action | Indications | Multiple pregnancy rate (percentage) |
|--|--|---|---|--------------------------------------|
| Clomiphene citrate | Oral | Blockade of estrogen receptors | Ovulatory dysfunction Superovulation | 8 |
| Dopamine agonists Bromocriptine Cabergoline Pergolide | Oral | Dopamine antagonist | Hyperprolactinemia | 1 |
| GnRH | Subcutaneous or intramuscular pump | Restoration of GnRH pulses | Hypothalamic amenorrhea | 1 |
| Gonadotropins Human menopausal gonadotropins Follitropin | Subcutaneous or intramuscular injections | Direct stimulation of ovarian follicle growth | Ovulatory dysfunction Superovulation | 20–25 |

Note. GnRH, gonadotropin-releasing hormone.

is not discussed here because it is not used in humans. The categories of gonadotropins in clinical use and their trade names are summarized in Table II.

hMG products were the first, and for many years the only, gonadotropins available for human use.

Table II Gonadotropin Preparations

| Drug | Trade names | |
|--|-------------|----------|
| Human menopausal gonadotropins (hMG) | Humegon | Merional |
| | Lepori | Pergonal |
| | Menogon | Pertisol |
| | Menopur | Repronex |
| Urofollitropin (urinary derived) | Bravelle | |
| | Fertinex | |
| | Fertinorm | |
| | Fostimon | |
| Follitropin (recombinant) | Metrodin | |
| | Follistim | |
| | Gonal-F | |
| Lutropin (LH) [not available–United States] | Puregon | |
| | Luveris | |
| Human chorionic gonadotropin (hCG) (urinary derived) | A.P.L. | |
| | Choragon | |
| | Novarel | |
| | Pregnyl | |
| Human chorionic gonadotropin (hCG) (recombinant) | Profasi | |
| | Ovidrel | |
| | Ovitrelle | |

They contain an equal mixture of FSH and LH and are extracted from the urine of postmenopausal donors. The medications must be reconstituted before each use and are given intramuscularly or subcutaneously. In the United States, they are sold under the trade names Pergonal and Repronex.

The earliest preparations of purified FSH were extracted from urinary sources much like hMG (e.g., urofollitropin, Metrodin) and were indicated for intramuscular use only. Techniques were then developed for purification of urinary products to enable subcutaneous administration (e.g., Fertinex, Bravelle). Today, most FSH used comes from recombinant DNA technology and mammalian cell culture. Recombinant products provide a much higher degree of purity and batch-to-batch consistency and include follitropin- α (Gonal-F) and follitropin- β (Follistim). They are designed for subcutaneous use but may be injected intramuscularly as well. Until recently, all preparations required fresh daily reconstitution from powder, although one multidose formulation is currently available in the United States.

The final stages of ovulation induction require a surge in circulating luteinizing hormone (LH) levels. In gonadotropin cycles, LH is substituted with human chorionic gonadotropin (hCG). Because LH and hCG work via the same receptor and hCG has a far longer circulating half-life, hCG is a logical agent to induce ovulation. hCG has been available for many years as a urinary-derived product for intramuscular injection. More recently, these older products, as well as newer recombinant products, have been given by subcutaneous injection.

INDICATIONS FOR THERAPY

There are essentially two categories of indications for treatment with gonadotropins. The first subset is the use of these medications in anovulatory women. This group may be further broken down into two groups. The first group consists of women with hypogonadotropic hypogonadism, also known as hypothalamic amenorrhea, or WHO class I. These women do not have regular menstrual cycles due to very low levels of endogenous gonadotropins, are hypoestrogenic, and do not respond to clomiphene. They are prime candidates for hMG injections and have excellent pregnancy rates. The other subgroup consists of anovulatory women with normal estrogen levels and includes women with polycystic ovarian syndrome and luteal phase defects. Often, these patients have failed clomiphene- and/or insulin-sensitizing agents. The goal in all anovulatory women on gonadotropins is the production and release of one or two mature oocytes.

The second category for gonadotropin use is for controlled ovarian hyperstimulation (COH), also known as superovulation. With this technique, higher doses of gonadotropins are used to recruit multiple follicles, usually as an adjunct to intrauterine insemination (IUI) or *in vitro* fertilization (IVF). Indications for COH with IUI or IVF include unexplained, tubal, cervical, male, and endometriosis-related infertility. The objective in non-IVF gonadotropin cycles is to recruit no more than three or four mature eggs, but with IVF even more oocytes may be desirable.

THE TREATMENT CYCLE

The gonadotropin treatment cycle begins on the third day of the menstrual cycle, commonly referred to as "day 3." At this time, a transvaginal ultrasound is performed, and blood is obtained for estradiol and FSH levels. On that day, gonadotropin injections are begun. Doses range from 75 to 600 IU of FSH or hMG daily or some combination thereof. They may be daily or twice a day and may be intramuscular or subcutaneous.

Patients then return to the clinic on a frequent basis over the next 7 to 10 days for serial ultrasounds to monitor follicular growth. At the same visits, serum estradiol levels are obtained as an adjunct in follicular monitoring, and serum LH levels are checked to ensure that premature luteinization does not occur. One should note that this monitoring protocol may differ significantly from clinic to clinic.

When the dominant follicle(s) reaches a mature size as seen on ultrasound, usually somewhere between 16 and 20 weeks, the decision is made to trigger ovulation. Human chorionic gonadotropin at 5,000 to 10,000 IU or 250 μ g is given by intramuscular or subcutaneous injection. Approximately 36 h later, ovulation will occur, and at this time IUI is performed or timed intercourse is encouraged. If an IVF procedure is planned, oocyte retrieval will be performed at this time.

During the subsequent week, many clinicians will choose to provide support of the luteal phase. This may be accomplished by supplemental lower dose hCG injections or progesterone by various routes. Ovulation may be confirmed by a mid-luteal serum progesterone level.

Gonadotropin cycles may be performed back to back without skipping a month in between provided that no large cysts are noted on the interval baseline ultrasound. Doses of gonadotropins may be adjusted in between or during cycles. The course of therapy is continued for three or four cycles. If it is unsuccessful, IVF or other treatments may be contemplated.

SIDE EFFECTS

Gonadotropins are potent medications, and although they are generally safe in experienced hands, they clearly have the potential to cause serious problems when not used with caution. Common side effects include headache, abdominal discomfort, pain at the injection site, and mood swings. One may also see skin reactions when hMG is used subcutaneously. More troublesome is the potential for multiple gestation and ovarian hyperstimulation.

The chance for multiple pregnancy among women who achieve pregnancy on gonadotropins is 20 to 25%. Although twins and triplets predominate, quadruplets and other higher order multiple gestations have become more commonplace. This phenomenon is due almost exclusively to gonadotropin use. The risks for many complications of pregnancy, including preterm delivery, diabetes, and preeclampsia, increase exponentially with increasing numbers of feti. Therefore, it behooves the clinician to limit the number of mature follicles permitted and, if necessary, to recommend cycle cancellation to the patient. Multifetal reduction may be used to reduce triplet or higher gestations down to twins. Although fraught with ethical and emotional concerns, this procedure can significantly reduce maternal and fetal morbidity

in such cases. However, as stated earlier, the best treatment is prevention.

The other serious concern is the development of the ovarian hyperstimulation syndrome (OHSS). This disorder, which occurs only with ovulation induction, may in some cases involve massive ovarian enlargement, ascites, abdominal discomfort, hydrothorax, and/or a hypercoagulable state. The syndrome has been classified into mild, moderate, and severe, based on symptomatology, ovarian size, and the degree of hemoconcentration. Treatment is generally supportive, with maintenance of urine output, bed rest, and monitoring for increase of severity. The use of albumin infusions for prophylaxis remains controversial. More severe cases may require hospitalization, paracentesis, and/or (occasionally) prophylaxis for deep venous thrombosis, intensive care unit (ICU) admission, and dopamine drips. More extensive reviews can be found elsewhere. As with multiple gestation, the best treatment is prevention.

The long-term concern with gonadotropin therapy revolves around the issue as to whether these medications increase the risk for ovarian cancer. Whittemore and colleagues demonstrated an elevated risk for ovarian tumors (malignant and low-malignant potential) in patients on various ovulation-inducing drugs, a risk that disappeared when treatment was successful. Rossing and colleagues showed an increased risk of ovarian cancer in women on long-term clomiphene but not short-term clomiphene or gonadotropins. Several studies from large IVF programs that use gonadotropins suggested no change in the risk of ovarian carcinoma. In contrast, Shushan and colleagues found a threefold increase in ovarian cancer in women on gonadotropin preparations. In summary, one can conclude that the bulk of the literature suggests no effect of these drugs on cancer risk, but the question is far from answered.

FUTURE DIRECTIONS

The future of ovulation induction likely will involve a refinement in the agents available to the clinician as well as the development of protocols for optimal stimulation. Recombinant DNA technology has enabled pharmaceutical companies to develop recombinant FSH products during recent years. These new products have enabled easier delivery of the drug via the subcutaneous route and have been a great leap forward in quality control. In the future, it might even be possible to develop an orally active

gonadotropin via emerging technologies, further enhancing ease of use.

Extension of molecular engineering techniques may also enable the development of “designer gonadotropins” in which the potency and half-life may be altered. One might even envision a time where very specific molecules might be engineered to meet the needs of individual patients. By optimizing the stimulation of each patient, we may better succeed in the concurrent goals of improving pregnancy rates while minimizing multiple gestation and ovarian hyperstimulation.

CONCLUSION

Gonadotropin-induced ovulation involves the use of FSH with or without LH to stimulate the growth of ovarian follicles, followed by injection of hCG to induce release of the oocytes. This treatment may be used for women who are anovulatory but refractory to clomiphene or for controlled ovarian hyperstimulation in preparation for insemination or IVF. These drugs are potentially dangerous and require monitoring with serial ultrasounds and estradiol levels. Women on injectable gonadotropins are at risk for multiple gestation and the ovarian hyperstimulation syndrome. For these reasons, gonadotropin therapy is best prescribed by clinicians familiar with the use of the drugs and with the management of the associated complications.

Table I Summary of Gene Mutations Known to Cause Hypogonadotropic Hypogonadism in Humans

| Gene | Principle effects | Inheritance |
|-------------|--|---------------------|
| KAL1 | Hypothalamic (disrupts neuronal migration) | X-linked recessive |
| AHC | Hypothalamus, pituitary, adrenal | X-linked recessive |
| LEP | Hypothalamus—leptin deficiency | Autosomal recessive |
| LEPR | Hypothalamus—leptin resistance | Autosomal recessive |
| GNRHR | Pituitary—GnRH resistance | Autosomal recessive |
| PROP1 | Pituitary—combined pituitary deficiency | Autosomal recessive |
| HESX1 | Pituitary—septo-optic dysplasia | Autosomal recessive |
| FSH β | Pituitary—isolated FSH deficiency | Autosomal recessive |
| LH β | Pituitary—isolated LH deficiency | Autosomal recessive |

neurons fail to synapse normally and Kallmann syndrome ensues.

Up to about half of obvious X-linked Kallmann syndrome families possess KAL1 mutations, and of these, half also have unilateral renal agenesis. The frequency of KAL1 mutations in unselected IHH males is considerably less (5–10%), indicating that this X-linked gene is not the most common cause of human IHH, as was originally proposed. Although the sample size is small, males with KAL1 mutations uniformly tend to demonstrate the most severe gonadotropin defect—an apulsatile pattern of LH secretion. No KAL1 gene mutations have been identified in females with IHH and anosmia, suggesting that other autosomal genes may be involved.

AHC Gene

Males with adrenal hypoplasia congenita (AHC) display adrenal failure during infancy or childhood because of a failure to form the permanent zone of the adrenal gland. They are deficient in both glucocorticoid and mineralocorticoid hormones. If they are properly treated, they fail to undergo puberty due to IHH. Mutations in the AHC gene have been

demonstrated to cause both adrenal failure (AHC) and IHH. The AHC gene encodes a protein termed DAX1. DAX1 is an orphan receptor (with no known ligand) that belongs to the steroid hormone superfamily. DAX1 is a transcription factor that is important in the development of the adrenal cortex and pituitary gonadotropes and that appears to regulate gonadotropin secretion at both the hypothalamus and the pituitary.

A large number of AHC gene mutations have been described in patients with AHC/IHH, most of which are nonsense and frameshift inactivating mutations throughout the gene. Missense mutations occur almost exclusively in the C terminus. Although AHC is an X-linked recessive disease affecting males, one mutation was identified in a female with normal adrenal function and IHH only. Mutations in the AHC gene probably do not cause IHH without adrenal disease given that no mutations were detected by DNA sequencing of DNAs from 100 IHH males. Although the gene was originally hypothesized to be an ovarian determinant gene because of its localization within the DSS region of the X chromosome, a region of Xp that, when duplicated, is associated with sex reversal (feminization) of 46,XY males, conditional knockout studies do not support its role in ovarian determination but do indicate a role in spermatogenesis.

Table II KAL1 Expression in Chick and Human Correlates with Phenotypic Findings of KAL1 Mutations (1–10)

| Olfactory epithelium | Anosmia |
|-----------------------------|-------------------------------|
| Cerebellum | Nystagmus, abnormal balance |
| Corticospinal tracts | Synkinesia (mirror movements) |
| Oculomotor nucleus | Visual abnormalities |
| Retina | Visual defects |
| Facial mesenchyme | Midline facial clefting |
| Mesonephros and metanephros | Unilateral renal agenesis |
| Limb buds | Pes cavus |

GNRHR Gene

The GnRH receptor (GNRHR), a G protein-coupled receptor, constituted the first autosomal-recessive gene identified to possess mutations in human IHH. Although the hypogonadal mouse had a naturally occurring GnRH gene deletion, no GnRH gene mutations had been identified in humans. Several investigators characterized mutations in the larger receptor for GnRH—the GNRHR gene. One group

hypothesized that partial loss-of-function GNRHR mutations could occur in patients with incomplete IHH, that is, IHH patients with evidence of puberty. Others suggested that the GNRHR gene was a likely candidate gene for mutation in IHH patients because of the absence of mutations in the ligand and the variability in response to exogenous GnRH that some IHH patients have.

More than a dozen GNRHR mutations have been identified to date, but they are almost exclusively compound heterozygous missense mutations affecting binding and/or signal transduction. The phenotypic spectrum of GNRHR mutations producing GnRH resistance ranges from complete IHH (no evidence of puberty or fertility) to incomplete IHH (partial pubertal defects). Even in patients who have no evidence of puberty, GnRH administration may improve pituitary gonadotropin responses, suggesting marginal GNRHR function. The true prevalence of GNRHR mutations among all IHH patients is difficult to assess but in one study was 2.2% (1 of 46) of total IHH patients and 7.1% (1 of 14) of patients where an affected female was present. A more recent study corroborated these findings.

LEP and LEPR Genes

Leptin (LEP) possesses important roles in metabolism and puberty. LEP-deficient (*ob/ob*) and LEP-resistant (*db/db*) mice manifest obesity and hypogonadotropic hypogonadism. LEP mutations have been described in only a few families with obesity, low serum LEP concentrations, and absent pubertal development. Similar to LEP-deficient *ob/ob* mice, patients with LEP mutations had extreme obesity, hyperinsulinemia, and hypogonadism, but unlike the mice, they did not have stunted height, hyperglycemia, or hypercortisolemia. An LEP receptor (LEPR) mutation resulted in a similar phenotype of obesity and hypogonadotropic hypogonadism except that serum LEP levels were elevated, indicating LEP resistance. These rare human autosomal-recessive diseases involving LEP and its receptor strongly implicate a role for LEP action in normal pubertal development.

PROPI Gene

Mutations in *Prop1*, the mouse orthologue of human *PROPI*, produce the Ames dwarf mouse. Human *PROPI* mutations cause combined pituitary hormone deficiency (CPHD), with varying deficiencies of growth hormone, thyroid-stimulating hormone

(TSH), prolactin, FSH, LH, and (occasionally) adrenocorticotrophic hormone (ACTH). Affected individuals display short stature, absent puberty, and hypothyroidism. A variety of *PROPI* mutations have been identified, including missense mutations and deletions, but a particular two-base pair deletion is common, being a hot spot in the *PROPI* gene for mutations. In a large cohort of patients with IHH only, no *PROPI* mutations were identified, indicating that *PROPI* mutations generally cause a more universal pituitary failure.

HESX1 Gene

Mutations in the *HESX1* gene have been identified in some families with septo-optic dysplasia, a disorder characterized by panhypopituitarism, optic nerve atrophy, and other midline central nervous system (CNS) abnormalities such as agenesis of the septum pellucidum and corpus callosum. Both autosomal-recessive and autosomal-dominant *HESX1* mutations have been described in this disorder. *Hesx1*, the mouse orthologue of *HESX1*, is expressed in the early forebrain and later becomes restricted to Rathke's pouch, which ultimately becomes the anterior pituitary gland. Hypogonadotropic hypogonadism, due to pituitary gonadotropin deficiency, is a common component of the phenotype in patients with septo-optic dysplasia.

FSH β Gene

FSH, LH, TSH, and human choriogonadotropin (hCG) comprise the pituitary glycoprotein hormones. Each dimeric protein consists of a common α -subunit encoded by a single gene and a specific β -subunit. No human α -subunit mutations have been described, but similar to the α -subunit knockout mouse, the phenotype would be expected to include hypogonadotropic hypogonadism and hypothyroidism. It is possible that α -subunit gene mutations could be lethal in humans given that hCG would be predicted to be deficient (mice do not have hCG).

Female homozygous *FSH β* knockout mice had low serum FSH levels and were sterile because of arrested ovarian follicular development. Surprisingly, serum estradiol was normal in these mice despite unmeasurable serum FSH levels. Male homozygous *FSH β* knockout mice had normal levels of serum testosterone, small testes, and oligospermia but were fertile. The phenotype of humans with *FSH β* mutations is similar except that estradiol levels are low. Affected

females presented with absent or incomplete breast development, low FSH and estradiol, high LH, and sterility. Despite the elevated LH level similar to that of women with polycystic ovary syndrome (PCOS), hirsutism is not present, suggesting that FSH might be necessary for normal LH-induced androgen production by the theca cells.

Males with FSH β mutations present with azoospermia, but puberty may be normal or absent. Contrary to the FSH β knockout mice, humans with mutations suggested that FSH was essential for spermatogenesis in human males. In addition, more severe mutations affect androgen production, manifested clinically by delayed puberty and low testosterone.

LH β -hCG β Genes

The LH β -hCG β gene complex, consisting of a single LH β gene and six hCG β genes, is polymorphic, but there is only one known human mutation in the LH β gene. The proband presented with pubertal delay, bilaterally small descended testes, low testosterone, and elevated gonadotropins. He responded to hCG administration, suggesting that the LH ligand might be defective. He was homozygous for a missense mutation of the LH β gene, which was detectable by immunoassay but undetectable by radioreceptor assay.

Although LH β polymorphisms have been identified, it is more problematic that they are definitive causes of LH dysfunction; however, they may modify LH effects. No LH β mutations have been identified in females, but the phenotype would be expected to be normal pubertal development and anovulation without hirsutism.

CONCLUSION

The genetic basis of IHH remains unknown for most patients; however, mutations in X-linked and autosomal genes may account for approximately 20% of cases. It is highly likely that additional autosomal genes that cause IHH will be identified. However, it is also possible that a large percentage of patients will have complex disease caused by a large number of modifying gene mutations and environmental factors.

receptors demonstrated a 421-fold preference for GnRH-II versus GnRH-I. Unlike the GnRH-II receptor and most other GPCRs, the GnRH-I receptor contains no large cytoplasmic C-terminal tail. The C termini of both types of receptors are phosphorylated in response to GnRH, leading to receptor desensitization.

GnRH activation of its receptor results in stimulation of several signaling pathways. Phospholipase C transmits its signal to diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP₃). DAG activates the intracellular protein kinase C pathway, and IP₃ stimulates release of intracellular calcium. Protein kinase C activation in response to GnRH also leads to increases in the mitogen-activated protein kinase (MAPK) pathway in pituitary cells. These pathways modulate gonadotropin synthesis and release from pituitary cells.

DEVELOPMENTAL REGULATION OF GnRH

In contrast to most cells of the CNS and all other hypothalamic-releasing factor neurons, GnRH neurons do not initially develop within the brain. GnRH neurons originate in the olfactory placode, migrate across the cribriform plate, and ultimately reside in the diencephalic region of the basal hypothalamus in a dispersed neuronal network. Although born in the olfactory placode, GnRH neurons are not derived from olfactory neurons. In rodents, GnRH neuronal migration begins on embryonic day 10.5 to 11 and final migration occurs by day 15 or 16. During this migratory phase, GnRH neurons express low levels of GnRH mRNA and protein. Identification of the factors that modulate both migration and expression of GnRH in migratory neurons is currently an area of active research. Cell adhesion molecules, including neural cell adhesion molecule (NCAM), are thought to be important. In addition, an adhesion related kinase (Ark) has been shown, in cell culture models, to modulate both neuronal migration and expression of GnRH. Soluble factors such as γ -amino butyric acid (GABA) and netrins have also been implicated in GnRH neuronal migration.

The human hypothalamus only contains a few thousand GnRH neurons (in contrast to approximately 800 neurons in the rodent) that are also arranged in a neuronal network in the basal hypothalamus after migration. Release of GnRH from these neurons occurs in a pulsatile fashion. Immortalized GnRH neuronal cell culture models, as well as isolated

GnRH neurons, demonstrate that the GnRH “pulse generator” is intrinsic to the neuronal cells. During human development, the GnRH pulse generator and subsequent gonadotropin release is active in the early neonate but decreases by 6 months of age. Until puberty, the GnRH pulse generator is repressed. The exact mechanisms of repression are not known and may involve central GABAergic neuronal activity. Similarly, the factors that reactivate the GnRH pulse generator at puberty are not completely understood. Neuronal decreases in GABAergic activity and increased glutaminergic, norepinephrine, and neuropeptide Y activities have been implicated in reactivation of the GnRH pulse generator at the time of sexual maturation. Studies have also suggested a role for transforming growth factor- α /erbB-1 and neuregulin/erbB-4 secreted from glial cells, and nitric oxide from central endothelial cells, as factors that may influence the reactivation of GnRH pulsatile release at the time of puberty.

DISEASE STATES ASSOCIATED WITH GnRH

Precocious puberty is defined as puberty that occurs prior to 8 years of age in girls and prior to 9 years of age in boys. Central precocious puberty, which is more frequent in girls, is caused by premature reactivation of the GnRH pulse generator and is usually idiopathic. Hypothalamic lesions or tumors, which are more common in boys, have been shown to induce central precocious puberty. The exact mechanism is unknown but may involve premature activation of the glial production of transforming growth factor- α to cross-talk with GnRH neurons.

In contrast to precocious puberty, patients with hypogonadotropic hypogonadism (HH) display delayed or absent puberty, hypogonadism, and infertility. HH arises due to deficiency in either GnRH production or GnRH signaling to the pituitary. In Kallmann's syndrome, GnRH neurons fail to migrate to the hypothalamus from the olfactory placode; therefore, GnRH production is compromised. Anosmia, or lack of smell, is also associated with Kallmann's syndrome. This finding suggests that a common mechanism between GnRH neuronal migration and olfactory neuronal maturation is defective. A genetic defect in the KAL gene, whose product is anosmin, leads to incomplete migration of GnRH and olfactory neurons in an X-linked inheritance. The molecular bases of other forms of GnRH deficiency are unknown. GnRH deficiency affects 1

in 7500 males and 1 in 70,000 females. Other causes of HH involve defective signaling pathways downstream of GnRH. Mutations in pituitary GnRH receptors affect the ability of GnRH to activate gonadotropin synthesis and secretion. In addition, patients have been reported with mutations of the LH β or FSH β genes resulting in defective sexual maturation.

Clinically, GnRH is used in a pump delivery system to result in an episodic delivery to restore defects in patients with HH. Paradoxically, GnRH agonists such as nafarelin, leuprolide, histrelin, and goserelin block GnRH action. The pituitary is sensitive to pulsatile stimulation by GnRH to synthesize and release the gonadotropins. Continuous stimulation of pituitary GnRH receptors by exogenously administered GnRH agonists, rather than by pulsatile stimulation, down-regulates and desensitizes GnRH receptors. The ultimate effect of chronic stimulation of the pituitary GnRH receptors is to decrease LH and FSH production, with subsequent decreases in circulating estrogen or testosterone. Nafarelin, leuprolide, and histrelin are indicated for central precocious puberty. Nafarelin, leuprolide, and goserelin are indicated for treatment of endometriosis. Leuprolide and goserelin are also indicated for palliative treatment of advanced breast and prostate tumors due to the ability of GnRH agonists to decrease sex steroid hormone levels. More recently, GnRH antagonists have been used to directly block GnRH receptors on the pituitary and to inhibit LH and FSH production. They are indicated for the treatment of female infertility as adjunct therapy during ovarian hyperstimulation for *in vitro* fertilization.

CONCLUSION

GnRH is the hypothalamic hormone that stimulates the pituitary gland to produce FSH and LH. The reactivation of GnRH expression in the hypothalamus is responsible for the initiation of the onset of puberty

and sexual maturation. Aberrant reactivation of GnRH expression is associated with either premature, delayed, or absent puberty. Therefore, the GnRH pathway is a target for several drug therapies that target either inappropriately early or delayed puberty. In addition to their role in normal reproductive development, the sex steroids may have a pathological role in hormone-dependent tumors such as breast and prostate. As the first step in the hypothalamic-pituitary-gonadal axis, the GnRH pathway is also a therapeutic target to inhibit the production of sex steroids from the gonads in the treatment of hormone-dependent malignancies.

detected to date and briefly discusses their impact on the phenotypic expression of HH in individuals bearing such receptor defects.

THE GnRH RECEPTOR

The GnRHR belongs to the superfamily of G protein-coupled receptors (GPCRs), specifically the family related to the rhodopsin/ β -adrenergic receptors, which is the best-known member in terms of its structural and functional characteristics. Seven transmembrane hydrophobic domains (TMDs) oriented roughly perpendicular to the plasma membrane plane, with an extracellular NH_2 terminal, an intracellular COOH terminal, and three alternating

intra- and extracellular hydrophilic loops connecting the TMDs, characterize the structure of these receptors (Figs. 1A and 1C). The mammalian GnRHR exhibits more than 85% amino acid identity among the several species that have been cloned. Unlike other members of the rhodopsin/ β -adrenergic subfamily of GPCRs, the GnRHR exhibits several unique features, including the reciprocal exchange of the conserved Asp and Asn residues in TMDs 2 and 7, the replacement of Tyr with Ser in the Asp-Arg-Tyr motif located in the junction of the TMD 3 and the intercellular loop (IL) 2, and the lack of the COOH terminal domain. This latter feature, which is not exhibited by GnRH receptors from nonmammalian vertebrate species such as fish and avian GnRH

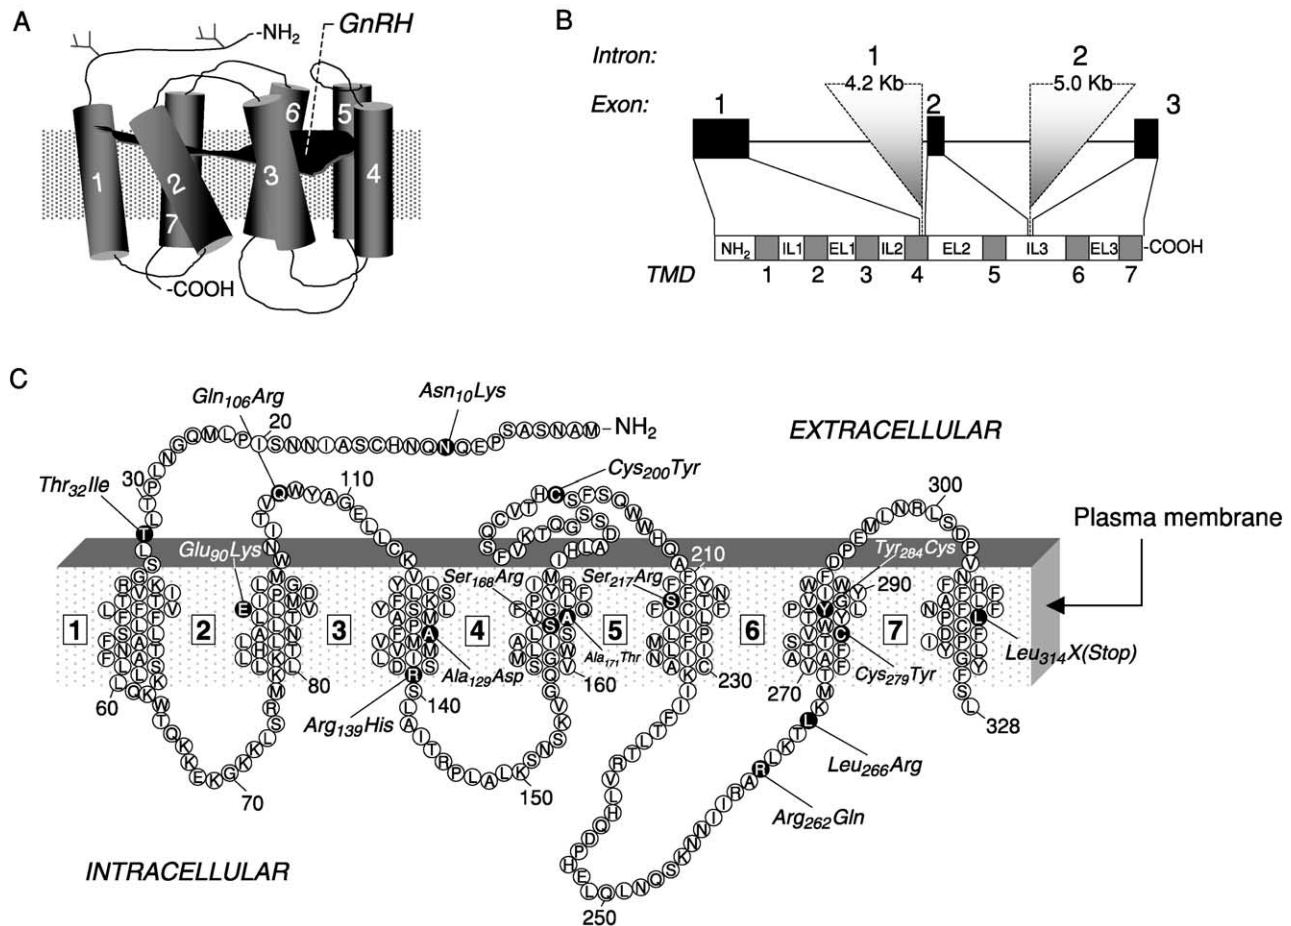

Figure 1 The human GnRH receptor. (A) Counterclockwise orientation of a prototypical G protein-coupled receptor from TMDs 1 to 7. The closed-loop structure is representative of receptors for peptide ligands such as GnRH. In this arrangement, the core consists mainly of TMDs 2, 3, 5, and 6, whereas domains 1 and 7 are peripherally sequestered. (B) Schematic of the human GnRHR gene. The open reading frame is distributed among three exons (black rectangles), spanning 18.9 Kb, that encode amino acids 1 to 174, 175 to 248, and 249 to 328, respectively. Intron 1 is located between amino acids 174 and 175 in the putative transmembrane domain (TMD) 4, and intron 2 is located between amino acids 248 and 249 in the intracellular loop (IL) 3 (shaded inverse triangles). (C) Sequence of the human GnRHR and location of the inactivating mutations identified to date (black circles).

receptors, is unique among the thousands of members of mammalian GPCRs and is apparently associated with differential physiological regulation (internalization, desensitization, and cell surface expression) of the receptor in mammals and nonmammals. In humans, the GnRHR is located in 4q13.2-3 and consists of three exons and two introns that encode for a 328-amino acid protein (Fig. 1B).

The GnRHR is preferentially coupled to the trimeric $G_{q/11}$ protein, localized in the cytoplasm, and associated with the intracellular domains of the receptor. Activation of the GnRHR by its ligand is associated with conformational changes in the receptor molecule that lead to activation of the $G_{\alpha_{q/11}}$ subunit followed by its dissociation from the $G\beta\gamma$ complex. The activation of the GnRHR- $G_{\alpha_{q/11}}$ protein complex stimulates the effector enzyme phospholipase- $C\beta$, which in turn induces phosphatidylinositol 4,5-bisphosphate hydrolysis, leading to formation of the second messengers inositol 1,4,5-triphosphate (IP3) and diacylglycerol. The former diffuses through the cytoplasm, promoting the release of intracellular calcium and the secretion of gonadotropins, whereas the latter activates the enzyme protein kinase C, triggering a cascade of protein-protein phosphorylation and interactions that eventually lead to the expression of biological effects.

MUTATIONS IN THE HUMAN GnRHR GENE

Structural alterations in key residues of the receptor molecule or the G proteins may potentially lead to altered function of the receptor-G protein system. Mutations in sites involved in ligand binding usually result in altered receptors unable to recognize the ligand and to become activated (loss-of-function mutations), whereas mutations in sites involved in receptor activation or G protein coupling may lead either to loss of function or to constitutive activation (activation in the absence of ligand or gain-of-function mutations) of the receptor molecule. Spontaneous mutations of this latter type have not yet been detected in the GnRHR.

Resistance to GnRH by inactivating (loss-of-function) mutations in the human GnRHR gene leads to distinct forms of autosomal-recessive HH (Table I). GnRHR mutations may also occur in individuals with sporadic HH, but with a lower frequency. The detected mutations in the human GnRHR gene are distributed along the entire coding sequence of the

receptor, including the NH_2 terminus, TMDs 2 to 7, extracellular loops 1 and 2, and the IL3 (Fig. 1C). However, two "hot spots" have been identified: the $Gln_{106}Arg$ and the $Arg_{262}Gln$ mutations. Expression of 15 mutated GnRH receptors in heterologous cell systems has shown that these mutations may influence ligand binding, receptor expression at the cell surface, and/or intracellular signal transduction. Although the expression of a given functional defect is apparently related to the structural modification introduced on specific microdomains involved in particular receptor functions, further studies are still necessary for this viewpoint to be accepted with certainty. In fact, in a number of these mutant receptors the function may be partially or completely rescuable *in vitro* by genetic or pharmacologic means, which indicates that the structural alteration may additionally lead to altered intracellular trafficking and reduced cell surface expression. Studies employing these GnRHR mutants have found that the $Arg_{262}Gln$, $Thr_{32}Ile$, $Cys_{200}Tyr$, $Leu_{266}Arg$, and $Cys_{279}Tyr$ mutations predominantly affect IP3 production, whereas in the $Gln_{106}Arg$, $Ala_{129}Asp$, $Ser_{168}Arg$, $Asn_{10}Lys$, and $Arg_{139}His$ mutations, agonist binding at the cell surface is decreased or severely impaired; all of these mutations apparently do not affect the membrane expression of the altered GnRHR in a significant manner. On the other hand, the $Tyr_{284}Cys$ and $Glu_{90}Lys$ mutations profoundly affect membrane receptor density as a consequence of either disruption of trafficking to the membrane or instability and subsequent degradation of the mutant receptor. Interestingly, deletion of K_{191} (which results in increased membrane expression and reduced rate of internalization of the wild-type human GnRHR) in the latter GnRHR mutant efficiently restores membrane expression and agonist-induced, receptor-mediated intracellular signaling. In the $Ser_{217}Arg$ mutation as well as in the $Leu_{314}X(Stop)$ mutation, GnRH binding is practically abolished. In this latter mutation, which leads to partial deletion of the TMD 7, the mRNA levels of the receptor were reduced considerably, suggesting that the truncated protein might not be adequately translated and expressed *in vivo*. A truncated nonfunctional GnRHR has also been reported for the homozygous splice junction mutation (G to A replacement) at the intron 1-exon 2 boundary, which results in a transcript showing splicing of exon 1 to exon 3 (i.e., complete deletion exon 2). Finally, the $Ala_{171}Thr$ mutation in the TMD 4 of the GnRHR presumably disrupts receptor function by impeding conformational mobility of the TMD 3 and 4,

Table 1 Mutations in the Human GnRH Receptor Gene, Genotypes, and Impact on Receptor Function

| Mutation | Genotype | Impact on GnRHR function |
|--|-----------------------|---|
| Gln ₁₀₆ Arg Arg ₂₆₂ Gln | Compound heterozygous | Decreased ligand binding—NME? Decreased IP3 production |

^aMutations in the same allele.

resulting in stabilization of the receptor in its inactive conformation.

Individuals with HH due to GnRHR mutations exhibit a strikingly wide spectrum of clinical and biochemical phenotypes, including variable alterations in pubertal development, plasma gonadotropin and sex steroid levels, response to exogenous GnRH administration, and pulsatile pattern of gonadotropin release. These alterations usually occur in the absence of anatomical or functional abnormalities of the hypothalamic–gonadotrope axis. Thus, the hypogonadism due to GnRHR mutations can be complete or partial. The differences between phenotypes in HH due to inactivating GnRHR mutations could be related to the particular allelic combination of the coexisting mutations, with the functional activity of a given mutant being more or less severely affected than that exhibited by the other. Nevertheless, the fact that different phenotypes may be present within affected kindred bearing the same molecular alteration suggests that other factors or mechanisms may be implicated in the phenotypic expression of the GnRH-resistant HH.

CONCLUSION

GnRH resistance due to inactivating mutations in the GnRHR gene leads to impaired synthesis and secretion of the pituitary gonadotropins and to a distinct form of hypogonadotropic hypogonadism. Several naturally occurring mutations in the GnRHR have been described. These mutations may occur along the entire coding sequence of the receptor and usually result in distinct alterations in receptor function. Naturally occurring mutations in the GnRHR represent unique models for the analysis of the structure–activity relationships of this particular receptor.

Figure 1 Hypothalamo-Hypophyseal (pituitary)-Gonadal axis. Through its control of the hypothalamo-pituitary-gonadal axis, GnRH regulates reproductive development.

GnRH-II (chicken GnRH-II) is the most ubiquitous form, present in the brain in all vertebrate classes except Agnathans. The ratfish and dogfish, both fish species of ancient origin in the class Chondrichthyes, possess a GnRH-II- and GnRH-I-type isoform, respectively. The ancestral GnRH molecule likely arose prior to the protochordates. In all GnRH peptides in vertebrates and protochordates, certain regions of the molecule have been highly conserved, including the NH_2 terminus (pGlu¹) and Ser⁴, and the COOH terminus. These regions and the length of the molecule have remained unchanged during the 500 million years of evolution of the chordates. The conservation of the NH_2 terminus (pGlu¹) and Ser⁴, and the COOH terminus suggests that these regions are significant for active conformation of the peptide, effective receptor binding, resistance to enzymatic

degradation, and receptor-mediated events required for gonadotropin release. This significance has been supported by numerous activity studies of GnRH analogues in mammalian and other vertebrate systems.

Further comparative studies on the GnRH family will help to provide clues on the evolution of reproductive mechanisms and insights into our understanding of gene duplication during the early development of vertebrates, structure-activity relations, and the molecular evolution and functional diversity of GnRH.

GnRH PRECURSOR

The prepro-GnRH molecule is tripartite, encoding a signal peptide that is followed directly by the GnRH

Table I GnRH Family of Peptides

| GnRH | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | Percentage identity to mGnRH |
|---------------|------|------------|------------|-----|------------|------------|------------|------------|-----|--------------------|------------------------------|
| Vertebrates | | | | | | | | | | | |
| Mammal | pGlu | His | Trp | Ser | Tyr | Gly | Leu | Arg | Pro | GlyNH ₂ | X |
| Guinea pig | pGlu | <u>Tyr</u> | Trp | Ser | Tyr | Gly | Val | Arg | Pro | GlyNH ₂ | 80 |
| Chicken-I | pGlu | His | Trp | Ser | Tyr | Gly | Leu | <u>Gln</u> | Pro | GlyNH ₂ | 90 |
| Rana | pGlu | His | Trp | Ser | Tyr | Gly | Leu | <u>Trp</u> | Pro | GlyNH ₂ | 90 |
| Seabream | pGlu | His | Trp | Ser | Tyr | Gly | Leu | <u>Ser</u> | Pro | GlyNH ₂ | 90 |
| Salmon | pGlu | His | Trp | Ser | Tyr | Gly | <u>Trp</u> | <u>Leu</u> | Pro | GlyNH ₂ | 80 |
| White fish | pGlu | His | Trp | Ser | Tyr | Gly | <u>Met</u> | <u>Asn</u> | Pro | GlyNH ₃ | 80 |

| Tunicate-II | pGlu | His | Trp | Ser | <u>Leu</u> | <u>Cys</u> | <u>His</u> | <u>Ala</u> | Pro | GlyNH ₂ | 60 |

Note. There are currently 16 known forms of GnRH: 14 in vertebrates and 2 in invertebrates.

decapeptide, a dibasic cleavage site, and the GnRH-associated peptide (GAP), as diagrammed in Fig. 2.

Similar to other neuropeptides, GnRH is first synthesized as a larger precursor protein, called prepro GnRH, which is then processed to its final decapeptide form. Neuropeptide precursors consist of at least 60 amino acids and include a signal sequence at the amino terminus and a spacer region at the carboxy terminus. The spacer region is separated from the neuropeptide by a dibasic amino acid cleavage site and may or may not have a biological function. The amino acid sequence of prepro GnRH has been indirectly identified by the isolation of its cDNA sequence.

Table III shows a complete list of the GnRH cDNAs/genes identified to date.

Of the 16 forms of GnRH identified, the cDNA or gene sequences of 11 forms have been determined. Due to the low identity of the prepro-GnRH cDNA sequence among forms, investigators are restricted to the use of degenerate oligonucleotide primers or probes based on the amino acid sequence of the specific GnRH for identification of GnRH. Classical molecular biological techniques were used for isolating the first GnRH cDNA. This entailed screening a genomic library with degenerate oligonucleotide probes. The full cDNA sequence was then cloned

Table II The Lineages of GnRH

| Type GnRH | Brain distribution/origin | Primary GnRH structures identified in vertebrates |
|-----------|---|---|
| GnRH-I | Hypothalamus, diencephalon/ Olfactory origin | Mammal GnRH in mouse, primate, human, sheep, pig, eel, newt, frog; chicken GnRH-I in chicken, lizard; salmon GnRH in goldfish, salmon; catfish GnRH in catfish; dogfish GnRH in dogfish |
| GnRH-II | Midbrain/Ventricular ependyma origin | Chicken GnRH-II in mouse, primate, human, chicken, lizard, frog, newt, eel, goldfish, catfish, salmon, medaka, red seabream, tilapia, ratfish |
| GnRH-III | Telencephalon/Olfactory origin | Salmon GnRH in medaka, red seabream, tilapia |
| GnRH-IV | Hypothalamus, diencephalon/ ventricular origin | Lamprey GnRH-I and lamprey GnRH-III in lamprey |

Note. GnRH is divided into four types based on a combination of function, location of expression, and molecular phylogenetic analysis.

Figure 2 Prepro-GnRH tripartite structure. The GnRH precursor is made up of three regions encoding the signal peptide, the GnRH decapeptide, and the GnRH-associated peptide.

from a brain cDNA library. Salmon GnRH (type GnRH-III) was also isolated by screening a brain cDNA library with degenerate oligonucleotides. Later in the 1990s, the polymerase chain reaction (PCR) was used to amplify specific gene sequences from a messenger ribonucleic acid (mRNA) population or from cDNA or genomic libraries. This method has now been used to isolate the nine additional GnRH cDNA sequences. The first cDNA sequences for chicken GnRH-I, chicken GnRH-II, catfish GnRH, and seabream GnRH all were determined using reverse transcription-PCR (RT-PCR) and/or rapid amplification of cDNA ends (RACE). Both of these methods are based on amplification via PCR.

In the African cichlid, the salmon GnRH gene was first isolated in 1991 by Bond and colleagues, and later the prepro-chicken GnRH-II gene was isolated from the same species. The presence of two cDNA sequences confirmed that multiple GnRH forms present in an organism were not produced from differential processing of one GnRH gene but rather were, in fact, transcribed from separate genes. Since that time, multiple GnRH genes have been isolated from many species.

The signal peptide contains a core of hydrophobic amino acids that is followed by alternating polar and nonpolar amino acids, except in the case of seabream GnRH, which contains only polar residues at the carboxy terminus of the signal peptide. The signal peptide is considered to aid in the prohormone's transport across the endoplasmic reticulum membrane for posttranslational processing.

The characteristic hydrophobic signal peptide targets the prohormone to the proper cellular organelle. The mechanism for this is currently being elucidated. It is thought that the hydrophobic residues may be interacting with the signal recognition particle

(SRP), which targets proteins to the rough endoplasmic reticulum (RER). The SRP is a ribonucleoprotein complex containing a 7S RNA molecule and six polypeptides. One of the associated polypeptides, SRP54, is a 54-kDa protein that binds to the signal portion of a prepro peptide as it is translated at the ribosome. SRP54 contains a putative guanosine 5'-triphosphate (GTP)-binding domain as well as a methionine-rich region. GTP is required for releasing SRP from the signal peptide and ribosome. The region that is rich in methionine residues is proposed to be the region that binds to the signal peptide. The methionine-rich region is predicted to form four amphipathic helices that position the hydrophobic residues entirely on one face, with polar residues exclusively on the opposite face. This secondary structure would suggest that the hydrophobic signal peptide could bind in the hydrophobic pocket lined by amphipathic helices. The methionine residues of SRP54 are proposed to form methionine bristles to accommodate a wide variety of hydrophobic signal sequences, and this could explain the lack of apparent consensus sequence of signal peptides apart from their generally high hydrophobicity.

After the signal peptide is cleaved from the prohormone, the glutamine residue at GnRH position 1 is cyclized to pyro-glutamate. Although the mechanism of this cyclization is unknown, the physiological spontaneous rate of formation occurs very slowly, and enzymatic activity catalyzing this formation has been described in brain, pituitary, and lymphocytes.

Following the GnRH decapeptide in the precursor hormone structure is a glycine residue that donates its amide group to the terminal glycine residue of GnRH. This amidation is catalyzed by peptidyl glycine α -amidating mono-oxygenase only after GAP is removed. This enzyme requires that the amide donor

Note. There are currently 57 GnRH precursor cDNAs and 17 genes (in boldface) identified and sequenced.

be at the C terminus of the peptide. It has been proposed that GAP-releasing enzyme initiates this posttranslational modification by an endoproteolytic event. The enzyme is a serine protease that recognizes the lysine¹²-arginine¹³ dibasic cleavage site sequence that typically acts in brain prohormones for proteolytic cleavage of the active peptide from the precursor molecule and cleaves the amide bond directly following the residues. The next enzyme proposed to be involved is hypothalamic carboxypeptidase E, which sequentially removes the arginine¹³ and the lysine¹² residues. This leaves the glycine¹¹ at the C terminus of the peptide as a substrate for peptidyl glycine α -amidating mono-oxygenase.

The initial cleaving event between residues 13 and 14 is thought to occur during vesicle formation at the Golgi apparatus, whereas further processing occurs within the secretory granules where GAP and bioactive GnRH are stored until needed for release. The function of GAP remains undetermined. GAP, in conjunction with the signal peptide, most likely functions to ensure that the hormone is long enough for

insertion into the endoplasmic reticulum for proper processing to occur. Researchers have questioned a possible biological role for GAP because there is *in vitro* evidence that human GAP is responsible for both inhibiting prolactin release and stimulating gonadotropin hormone (GTH) release in rat pituitary as well as inhibiting prolactin release in the teleost fish tilapia. A bioactive role for GAP is also supported by rat *in vivo* studies, in which the first 13 residues of the GAP molecule were shown to stimulate the release of GTH.

Although the molecular organization of GnRH precursors appears to be similar throughout various species, the amino acid composition is highly divergent. The sequence encoding the GnRH peptide and the following cleavage sites are highly conserved among all of the vertebrates, whereas the signal peptide and GAP remain quite divergent (Fig. 3).

In contrast to other known vertebrate GnRH precursors, which typically have one transcript (and in two cases have two transcripts), three distinct transcripts have been isolated and sequenced in lampreys.

Mammalian GnRH precursor identities

Figure 3 Prepro-GnRH sequence comparison. The GnRH precursor is highly conserved in structure and in the GnRH decapeptide sequence.

The lamprey GnRH-I (type GnRH-IV) transcripts, termed GAP49, GAP50, and GAP58, differed in the length of the GAP coding sequence and were demonstrated to be the products of a single gene. Analysis of the lamprey GnRH-I gene intron-2 splice junction demonstrated that alternate splicing produces the different lamprey GnRH-I transcripts. Lamprey GnRH-I is the first GnRH gene demonstrated to use splice sequence variants to produce multiple transcripts that may reflect an ancestral gene regulatory mechanism.

The GnRH genes that have been identified have maintained a highly conserved pattern of introns and exons (Fig. 2). The coding region is dispersed over four exons, where the first exon is untranslated; the second encodes the signal peptide, the GnRH decapeptide, the cleavage site, and the N-terminal portion of GAP; the third consists entirely of the middle portion of the GAP molecule; and the fourth contains the C-terminal of GAP as well as the 3' untranslated region. The only noticeable difference between the salmon and mammalian GnRH gene structures is their relative intron sizes. Because of the similar architecture, the emergence of multiple forms of GnRH has been attributed to nucleotide base changes and not to differential splicing of message or variable processing of the precursor protein.

GNRH RECEPTOR

In light of the crucial role GnRH plays in human physiology and disease, its receptor has been a subject of intense research for many years. Numerous studies

on the binding characteristics of the GnRH receptor were performed throughout the 1970s and 1980s. In 1992, the first successful cloning of a GnRH receptor from the mouse using a homology-based PCR amplification scheme was reported. Later that year, the human GnRH receptor cDNA was reported as well. Since these landmark studies, the GnRH receptor primary structure has been reported in several other organisms (Table IV). Multiple receptor forms have been reported in brains and pituitaries of primates, teleost fish (e.g., goldfish, medaka), and amphibians (e.g., bullfrog, Korean frog [*Rana dybowskii*]). The GnRH receptors have been classified into two major groupings, type I and type II, based primarily on sequence identity and major structural characteristics. Further subdivisions of these two groups have been proposed, but more studies on expression, activity, and pharmacological characteristics are required to establish a solid subdivision of these two major groups.

Analysis of the sequences of the first identified GnRH receptors defined them as belonging to the G protein-coupled receptor (GPCR) superfamily of receptors. The members of this superfamily share a common general structure composed of seven hydrophobic α -helical transmembrane domains connected by hydrophilic intracellular and extracellular loops, an extracellular N-terminal tail, and an intracellular C-terminal tail. The GnRH receptor belongs to the class A rhodopsin-like GPCR subfamily. This subfamily is characterized by conserved amino acids, or motifs, in certain positions of the receptor. The GnRH receptors exhibit an interesting pattern of evolutionary change from the otherwise highly conserved motifs of the class A GPCRs (Fig. 4). Of the structural variations seen in the GnRH receptors, most notable is the absence of any C-terminal tail in the type I mammalian GnRH receptors. These receptors are the only GPCRs without a C-terminal intracellular tail. The implications of this drastic modification of structure are still not well understood.

The identification of the GnRH receptors in the goldfish and the bullfrog marked the first time that multiple receptors had been cloned from one species. Recently, several studies have been published reporting the identification of multiple GnRH receptors in brains and pituitaries of other organisms. Two distinct receptors have been cloned in another teleost fish, the medaka, and the three receptor types identified in the bullfrog have been supported by isolation of three very similar receptors in another frog, the Korean frog *R. dybowskii*. A second GnRH receptor has been identified in the marmoset, and similar novel

Note. The amino acid sequences of 33 GnRH receptors have been deduced. Receptors that lack the evolutionarily conserved C-terminal tail are in boldface, whereas receptors that retain this domain are in regular type.

receptors have been described from the African green monkey and the rhesus monkey *Macaca mulatta*. These receptors have been shown to contain intracellular C-terminal tails, unlike all previously identified mammalian GnRH receptors. The discovery and description of these receptors opens up exciting new possibilities in the study of the importance of the C-terminal tail in receptor signaling, cycling, expression, and desensitization.

The gene structure of the GnRH receptor has also been described in multiple species: human, sheep,

mouse, rat, dog, Japanese eel, African clawed frog, and medaka. With the exception of the medaka receptor 2 and the clawed frog receptor, all of these genes have shown a conserved pattern of introns and exons. This pattern is composed of three exons and two introns. Exon 1 extends from the 5' end of the transcript through the middle of the region encoding transmembrane helix 4, exon 2 encodes from the middle of transmembrane helix 4 to the middle of intracellular loop 3, and exon 3 includes the rest of the coding sequence and the 3' untranslated region.

Class A GPCRs

Figure 4 Class A GPCR and GnRH-R motifs. The GnRH receptors exhibit an intriguing pattern of motif change over the course of vertebrate evolution. Most notably, mammalian type I GnRH receptors are the only GPCRs that lack an intracellular tail.

Investigations into the expression level and localization of the GnRH receptor have also indicated the presence of great complexity in the function and regulation of GnRH at the level of the receptor. These studies have shown wide distribution of the GnRH receptor in the brain, particularly in the hypothalamus and midbrain, and also in the pituitary (as expected). In addition, GnRH receptors have been found in detectable levels in other organs. In humans, GnRH receptor mRNA was shown to be present in the pituitary, ovary, testis, breast, and prostate. In fish and amphibians, GnRH receptor mRNAs have been found in the brain, pituitary, ovary, testis, and retina.

Interestingly, in the studies that have characterized multiple GnRH receptors in the same species, differential tissue distribution of receptor isoforms has been demonstrated. In the goldfish, differential tissue-specific expression was reported, whereas in the bullfrog, differential expression was also shown but only

within regions of the brain and pituitary rather than among many tissues. The variability of expression among the three bullfrog GnRH receptors was also shown to correspond with stages of the reproductive cycle. This is the first solid evidence of regulation of reproduction by expression variance of multiple GnRH receptors.

The extensive cloning of GnRH receptors from various species and the characterization and conservation of gene structure have enabled researchers to explore the structure–function aspects of the receptors and how their differences and similarities give insight into the complex integration and function of the GnRH system. Many studies have investigated the importance of the C-terminal tail in receptor signaling, internalization, desensitization, and expression. The unusual GnRH receptor variations in the conserved motifs typically found in the class A GPCRs have been investigated as well, as have specific

structural components of the GnRH receptor. This body of data, combined with modeling studies of the GnRH peptide and the hundreds of activity studies on GnRH analogues, has produced a putative picture of how GnRH binds to its receptor. In the absence of a crystallographic structure of the GnRH-bound receptor, these studies provide the best information on the mechanics of GnRH binding.

GnRH IN MAMMALS

GnRH was first isolated from porcine and ovine hypothalamic extracts, giving rise to the popularly held view that a single form of GnRH (mammalian GnRH) regulates the hypothalamo-pituitary-gonadal axis in all mammals. The question that has arisen over the years is how one GnRH differentially regulates the release of two gonadotropins: LH and FSH. Although there have been a number of different models proposed, questions remain and have fueled the quest for a separate FSH-releasing factor or novel GnRH isoform.

Recent studies have demonstrated that at least two different GnRH isoforms are expressed within the brain of a single vertebrate species. Current thought suggests that one GnRH (type GnRH-I) functions as a neurohormone regulating the pituitary in mediating the release of gonadotropin. The other form (type GnRH-II) may have a neurotransmitter or neuromodulatory function and is generally localized in areas outside the hypothalamus, particularly in midbrain regions. In mammals, the second GnRH isoform that has been identified to date is chicken GnRH-II. The only direct evidence of the existence of GnRH forms other than mammalian GnRH in mammals has come from the identification of GnRH complementary DNAs in three species: the tree shrew, the guinea pig, and the human. Two prepro-GnRH mRNAs identified in the tree shrew encoded mammalian and chicken GnRH-II. In the guinea pig, a prepro GnRH encodes for a unique form of GnRH, guinea pig GnRH. Most recently in the human, two genes for mammal GnRH and chicken GnRH-II were demonstrated.

Using indirect methods in mammals, a limited number of species, monotremes, marsupials, rats, and primitive eutherians have been examined for variant forms of GnRH through immunocytochemistry (ICC), high-performance liquid chromatography (HPLC), and radioimmunoassay (RIA) using specific antibodies to various GnRH forms. In most of the species examined, immunoreactive chicken GnRH-II

was shown to be present generally in the midbrain. In recent studies in rats using a double-labeled immunocytochemical technique, lamprey GnRH-III neurons not only were observed in regions that control FSH release but also were colocalized with mammalian GnRH neurons in areas primarily controlling LH release. These studies used indirect techniques with various heterologous antibodies. Immunoreactive (ir) GnRH will need confirmation by identification of these ir-variant GnRH forms through determination of the primary structure by protein purification or molecular cloning followed by extensive biological activity studies.

The first study to demonstrate that a lamprey-like GnRH was present in the human hypothalamus and median eminence used a combination of ICC, HPLC, and RIA. In these same studies, the hypothalamic distribution of immunopositive lamprey-like GnRH neurons was similar to that observed for those containing the mammalian GnRH. More recently, also using similar indirect methods, it was demonstrated that a chicken GnRH-II-like form was found in stump-tail and rhesus monkeys but that only a few of the ir-chicken GnRH-II cells were in the posterior basal hypothalamus; most of the immunopositive neurons to chicken GnRH-II antiserum were shown to be in the midbrain. These studies did not screen for other forms of GnRH such as the lamprey GnRH forms, nor did their data suggest that chicken GnRH-II is a neurohormone. Thus, there is incomplete and contrasting data on the nature of GnRHs in primates. Confirmation of the exact nature of a second or possibly third form of GnRH in primates and other mammals will require isolation, sequence analysis, determination of localization, and biological function studies.

STATUS OF AN FSH-RELEASING FACTOR

Although research has shown convincingly that GnRH regulates LH release, there are not any definitive data supporting GnRH control of FSH release. However, it has been suggested that regulation of FSH secretion involves a complex balance among stimulation by GnRH from the hypothalamus, inhibitory feedback by sex steroids (testosterone and estradiol) and inhibin B from the gonads, and autocrine/paracrine modulation by activin and follistatin within the pituitary. As a result, for many years there has been a quest for the identification of a separate FSH-releasing factor in mammals. It has been shown

that lamprey GnRH-III (type GnRH-IV) is highly selective in stimulating FSH release in rats and cows. Combined with the earlier immunocytochemical data of a lamprey GnRH-like form in various species of mammals, this provides convincing evidence for a lamprey GnRH-like molecule in the mammalian hypothalamus. In light of this more recent evidence that there might be a novel GnRH in mammals and other vertebrates, the possibility exists that a lamprey-like peptide might be an FSH-releasing factor. Thus, the possibility exists that there is a second GnRH-like molecule that is also a hypothalamic factor.

GNRH ANALOGUES

Since 1971, when the primary structure of mammalian GnRH was determined, more than 10,000 analogues have been made to GnRH and been tested in hundreds of studies in mammals. As a result of these studies, several mammalian GnRH analogues have been shown to be highly successful and are currently being used for sterilization, conception, and other therapeutic and clinical applications. For example, Lupron Depot, a GnRH analogue, is now one of the leading chemical treatments for advanced prostate cancer and endometriosis in humans. Continuous treatment with Lupron Depot results in decreased levels of LH and FSH. In males, testosterone is reduced to castrate levels; in premenopausal females, estrogens are reduced to postmenopausal levels. GnRH antagonists are also used clinically, and the most effective GnRH antagonists have substitutions of one amino acid in position 6 as well as substitutions in positions 1, 2, and 3. However, because of the lack of systematic examination in the characterization of these various analogues, there is still critical information that is needed in our understanding of their biological activity. Information on the comparative activities of the GnRH family in vertebrates may provide important hypotheses about the role of specific amino acids in GnRH binding and receptor activation and may lead to the development of more potent GnRH analogues.

CONCLUSION

Since the discovery of GnRH in 1971, research has exploded relating to the structure and function

of GnRH and its receptor. Our understanding of GnRH, as the central figure in the control of reproduction, is critical at the molecular, biochemical, and physiological levels. We have come to realize that the GnRH system has proven to be extremely complex and that there is still much to be learned. Importantly, GnRH has become an important subject of not only physiological research but also medical treatments.

are possible (inhibin $A_{\alpha\beta A}$ and inhibin $B_{\alpha\beta B}$). Activin, a member of transforming growth factor- β growth hormone superfamily, is a homodimer of two disulfide-linked β -subunits of inhibin. Thus, three possible forms of activin exist: $A_{\beta A\beta A}$, $B_{\beta B\beta B}$, and $AB_{\beta A\beta B}$. Activin is produced in many tissues, including the gonads and pituitary, where it has autocrine and paracrine effects. It stimulates FSH secretion from normal rat gonadotroph cells and human gonadotropinoma cells. Follistatin is produced in the pituitary by folliculostellate and gonadotroph cells and is a negative modulator of the effects of activin. It is believed that a decrease in follistatin could be responsible for enhanced activin activity, which could account for the increased cell division and FSH secretion characteristic of gonadotroph adenomas. Other studies found a positive correlation between the concentrations of activin, follistatin, and FSH secreted by gonadotroph adenomas *in vitro* and concluded that the production of activin A might explain the relatively high levels of FSH and follistatin, but the amount of follistatin was apparently insufficient to antagonize the stimulatory effects of activin A. Finally, an inhibitory effect of activin on DNA synthesis has been reported in a

subgroup of clinically nonfunctioning pituitary adenomas (NFPA) *in vitro*, suggesting an antiproliferative effect of this locally secreted peptide. This antiproliferative effect involves an up-regulation of p21, a cyclin-dependent kinase inhibitor. It is concluded that defects in activin-mediated signal transduction pathways and dysregulation of modulating peptides may be involved in abnormal activin-mediated growth control in pituitary tumors. It is likely that an alteration in these control mechanisms may play a role in the tumorigenesis of gonadotropinomas but further studies are required.

PATHOLOGY

As is the case with other pituitary adenomas, gonadotroph adenoma cells are usually arranged in cords and may vary in size from one adenoma to another. Before the advent of immunohistochemical techniques, NFPA were recognized by their chromophobe, agranulocytic appearance after Herlant tetrachromic staining. Electronic microscopy first revealed that these supposedly nonsecretory tumors contained cytoplasmic secretory granules. Later, immunohistochemical studies using monoclonal antibodies directed against the α -subunit or against the intact LH, FSH, hCG, and their respective β -subunits clearly identified the secretory nature of gonadotropinomas (Fig. 2). Prognostic proliferation markers, such as proliferating cell nuclear antigen (PCNA), p53, and Ki67, have been investigated in gonadotroph adenomas but with inconclusive results. The expression of the polysialylated neural cell adhesion

Figure 2 Gonadotropinoma immunohistochemistry. Staining was performed using anti-FSH antibodies. Positivity is observed at the periphery of the cell (vascular pole). Reprinted from Beckers (2003), with permission; also reprinted with kind permission from Dr. J. Trouillas, Lyon, France.

molecule, however, seems to be strongly associated with tumor invasion and an aggressive profile.

CLINICAL ASPECTS

The clinical recognition of gonadotroph adenoma is relatively difficult, as these tumors do not secrete efficiently and their secretory products, intact gonadotropins and/or their subunits, generally do not cause a recognizable clinical syndrome. Consequently, gonadotropinomas can grow undetected until they become sufficiently large to cause symptoms due to tumor expansion, such as visual impairment, headaches, pituitary insufficiency, and, more rarely, seizures, meningitis, and cerebrospinal fluid rhinorrhea.

Oligomenorrhea or amenorrhea can present in premenopausal female patients and is correlated with increased secretion of intact FSH, hyperprolactinemia caused by pituitary stalk compression, and/or secondary hypogonadism attributable to the destruction of normal residual pituitary gland. However, FSH secretion can also cause in premenopausal women a sustained ovarian stimulation, inducing multiple large ovarian cysts, elevated serum estradiol, and infertility.

There have been few reported cases of males with gonadotroph adenomas associated with a characteristic clinical syndrome due to hypersecretion of LH causing testis hyperstimulation (testicular enlargement, elevated serum testosterone). Most gonadotropinomas in men, however, cause secondary hypogonadism with decreased libido, normal to low serum testosterone levels, and normal testicular volume.

DIAGNOSIS

The overwhelming majority of NFPA are gonadotropinomas but, as noted above, they seldom cause a clinical hormonal hypersecretory syndrome.

Gonadotroph adenomas can be recognized by a supranormal basal serum concentration of intact gonadotropins, often FSH but less commonly intact LH and/or their subunits (α -and/or β -subunits). In relatively few cases, high levels of hCG have been found. When intact LH is elevated, male patients may also have supranormal serum testosterone concentrations.

When a supranormal serum α -subunit level exists as the sole abnormality in the presence of a pituitary mass, the diagnosis may be either a thyroid-stimulating hormone-secreting adenoma or a gonadotropinoma. In these cases, thyrotropin-releasing hormone (TRH)-induced stimulation of intact FSH and/or LH or their subunits would confirm a gonadotroph origin.

Basal concentrations of gonadotropins are not helpful in postmenopausal women because it is not possible to differentiate a sellar mass from normal postmenopausal gonadotroph cells as the source of gonadotropins. Only a marked discrepancy among FSH, LH, and/or their subunits would make such measurements useful in the diagnosis of a gonadotropinoma in a postmenopausal female patient.

Administration of TRH typically produces an increase in the secretion of FSH, LH, and especially the LH β -subunit and this finding could be of assistance in making a diagnosis in cases where gonadotroph adenomas are associated with basal levels of gonadotropins and/or their subunits in the normal range. However, other studies have suggested that the TRH test is unable to detect silent gonadotropinomas, but is useful in postmenopausal women and also in the confirmation of a diagnosis in patients with secreting gonadotroph adenomas. Usually, gonadotropinomas also remain sensitive to GnRH stimulation. It is difficult to interpret the response to the GnRH in NFPA, as the hormonal response may originate from the gonadotropinoma or from the remaining normal gonadotroph cells of the pituitary.

Pituitary magnetic resonance imaging is by far the best radiological tool to assess the dimensions and the invasiveness of gonadotropinomas (Fig. 3). Almost all reported gonadotropinomas are macroadenomas and nearly one-third of them are considered to be invasive. The incidence of microadenoma is largely unknown but should be suspected when a pituitary microincidentaloma is found.

TREATMENT

The initial treatment of gonadotroph adenoma is by transsphenoidal surgery, especially if visual disturbances or hemorrhage is present. However, tumor excision is usually incomplete in large macroadenomas and recurrence rates average approximately 30% in NFPA after a mean follow-up of 6 years. Incomplete tumor removal determines a low cure rate and additional treatment may be required. Some centers advocate routine radiotherapy after surgery to reduce the risk of tumor regrowth. When conventional irradiation is administered following surgery, it is usually effective in preventing regrowth of the adenoma. The efficacy of stereotactic radiation remains to be determined.

When the surgery is not curative, several drugs have been utilized in the treatment of gonadotroph adenoma, but thus far none have been found to reduce tumor size consistently and substantially.

Figure 3 Gonadotroph macroadenoma extending far above the sella, elevating the optic chiasm, and invading the cavernous sinus as observed with magnetic resonance imaging in coronal (A) and sagittal (B) views. Reprinted from Beckers (2003), with permission.

Dopamine receptors have been identified on gonadotroph adenomas and dopamine agonists decrease the levels of the gonadotropins and the α -subunit *in vitro* and *in vivo*. However, the use of dopamine agonists (e.g., bromocriptine, cabergoline, and quina-golide) has not been found to be useful in the majority of gonadotroph adenomas, although 20% of treated patients did experience a response. In any case, a significant positive correlation has been reported between the uptake score measured using pituitary scintigraphy with ^{123}I -labeled methoxybenzamide and the percentage inhibition of α -subunit levels and tumor shrinkage during dopamine agonist treatment.

Somatostatin analogues have been used to treat gonadotroph adenomas, as somatostatin receptors have been identified on gonadotropinomas and somatostatin can decrease the secretion of gonadotropins and/or their subunits by gonadotropinoma cells *in vitro*. Several clinical trials have studied the use of somatostatin analogues in patients with gonadotroph adenomas. Although dramatic decreases in the size of gonadotroph adenomas and some associated improvements in visual field defects have been occasionally reported following somatostatin analogue treatment, the majority of patients experience little if any improvement in adenoma size or visual fields.

GnRH agonists and antagonists have been considered as potential therapeutic agents for gonadotroph adenomas. However, their administration generally does not produce an effect on adenoma size.

Troglitazone, a PPAR (peroxisome proliferator activated receptor)- γ ligand, has been studied in mice as a novel medical therapy for NFPA with encouraging results.

CONCLUSION

In conclusion, the approach to gonadotroph adenomas is guided by the tumor size, the presence of effects of the tumor mass, and hypopituitarism. Surgery remains the first curative choice for gonadotroph macroadenoma. The gonadotroph microadenoma may be observed and treated only if significant growth is documented over the course of a year or more.

Radiotherapy may be useful in patients who are poor surgical candidates, in patients whose tumors are surgically inaccessible, or after surgery to reduce the risk of tumor regrowth.

Several pharmacologic treatments have been tried but only a minority of patients experience significant benefits. Further studies are necessary and novel drugs that can reduce the size of the tumor and/or prevent its regrowth are greatly needed.

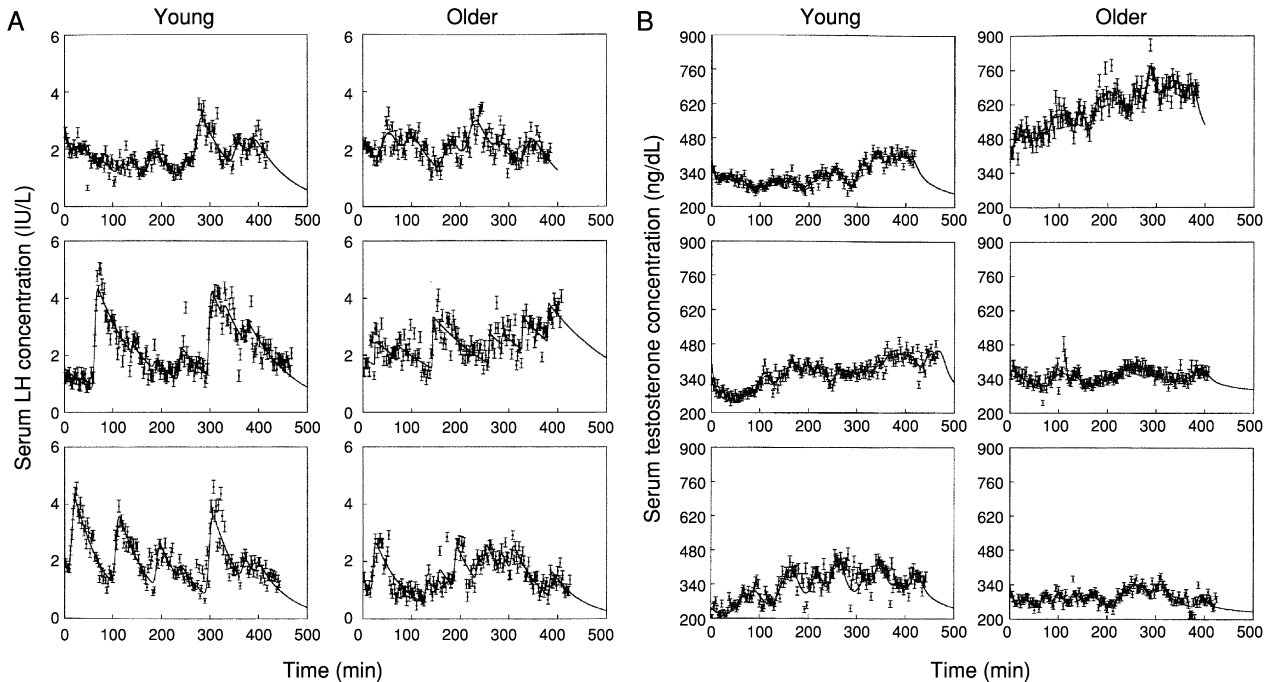

Figure 1 Serum LH (A) and testosterone (B) concentration profiles in three young and three older men sampled at 2.5-min intervals during sleeping hours. The continuous lines are predicted by deconvolution analysis. Deconvolution revealed loss of high-amplitude LH and testosterone secretory pulses in older individuals with preserved basal secretion rates. Entropy analyses disclosed more disorderly (less regular) release of LH and testosterone in older men. Reproduced with permission from the American Society of Andrology. Veldhuis, J. D. (1999). Recent insights into neuroendocrine mechanisms of aging of the human male hypothalamic-pituitary-gonadal axis. *J. Androl.* **20**, 1–17.

frequency with loss of high-amplitude LH secretory pulses, even though basal secretions are preserved. The dysfunctional GnRH-LH pulsing mechanism results in decreased LH mass per pulse values (Fig. 1). The release of LH showed more disorderliness in older men than in younger men. Moreover, sophisticated mathematical modeling techniques show that there is more disruption of synchrony between LH and FSH, as well as between LH and testosterone secretion, in older men than in their younger counterparts. This multifold synchrony disruption of neuroendocrine control of LH and subsequent testosterone secretion results in uncoupling of testosterone-related nocturnal penile tumescence activity that may be of physiological importance.

The abnormal neuroendocrine regulation of LH pulse secretion is also evident in the aging rat model, where decreased LH pulse amplitude is observed. Hypothalamic GnRH pulse generator dysfunction is suggested by the decreased GnRH response to excitatory amino acid stimulation.

There is evidence to show that inducible nitric oxide synthase (NOS) activity is increased in the aging GnRH secretory neurons in the hypothalamus.

The increase in inducible NOS activity might be a result of increased release of reactive oxygen species, cytokines, or other substances associated with aging. Increased NOS activity results in nitrosylation of cells and increased apoptosis of GnRH-secreting cells in the hypothalamus of aging rats.

From population-based studies, cross-sectional analyses fail to show significant trends of serum prolactin with aging, but the longitudinal data show a sharp increase in morning serum prolactin levels at 5.3% per year. In detailed studies of nocturnal prolactin secretory patterns in elderly men, serum basal concentration and secretory mass per burst of prolactin are decreased at night and serum prolactin is correlated with serum testosterone concentrations. The significance of the changes in prolactin with aging is not known but has been postulated to be reflective of neuroendocrine effects of aging.

TESTICULAR FUNCTION IN AGING

There is now ample evidence not only from cross-sectional studies but also from longitudinal

Figure 2 Longitudinal effects of aging on date-adjusted testosterone and free testosterone index. Linear segment plots for total testosterone and free testosterone index versus age are shown for men with testosterone and sex hormone-binding globulin values on at least two visits. Each linear segment has a slope equal to the mean of the individual longitudinal slopes during each decade and is centered on the median age for each cohort of men from the second to the ninth decades. Numbers in parentheses represent the numbers of men in the various cohorts. With the exception of free testosterone index during the ninth decade, segments show significant downward progression at every age, with no significant change in slopes for testosterone or free testosterone index over the entire age range. Reproduced with permission from The Endocrine Society. Harman, S. M., Melter, E. J., Tobin, J. D., Pearson, J., and Blackman, M. R. (2001). *J. Clin. Endocrinol. Metab.* **86**, 724–731.

epidemiological studies to show that aging in men is associated with a slow but progressive decline in serum total testosterone and bioavailable or free testosterone levels (Fig. 2). Serum total testosterone concentrations decline by 1.6% and bioavailable testosterone declines by 2.3% per year, and these decreases are accompanied by significant increases (1.3% per year) in serum sex hormone-binding globulin concentrations. There is also a concomitant decline in serum estrogens and adrenal androgens, androstenedione and dehydroepiandrosterone (DHEA) and DHEA sulfate. In contrast, serum 5 α dihydrotestosterone (DHT) concentrations tend to increase in older men (3.4% per year). Such increases in serum DHT are associated with stable intraprostatic DHT levels. The rise in DHT in the presence of declining testosterone may be due to increased 5 α reductase activity in the liver, skin, or prostate. The decline in serum testosterone is

associated with ill-defined symptoms of andropause, including asthenia, loss of motivation, failure of concentration, decreased libido and sexual activity, loss of muscle and bone mass, loss of strength, increased body fat, depressed mood, and decreased quality-of-life measures. The decrease in serum testosterone concentration is the result of defective Leydig cell steroidogenic capacity coupled with decreased responsiveness of the Leydig cells to endogenous LH. Studies in rodent models of the aging confirmed the decreased steroidogenic capacity of Leydig cells both *in vitro* and *in vivo*. Our laboratory has shown that although Leydig cell numbers are not reduced in aged animals, the Leydig cell volume is decreased. There is also evidence showing that some Leydig cells undergo apoptosis without evidence of renewal.

Despite the decline in steroidogenic capacity, the ability of the seminiferous tubules to produce normal spermatozoa appears to persist in elderly healthy men. There is some evidence that older men might have slightly lower sperm concentration and motility, with little impact on their fertility. Studies in aging men showed that circulating inhibin B (a marker of Sertoli cell function) is maintained. Serum inhibin B is related to serum FSH but not to age or serum testosterone levels in older men. The maintenance of normal serum inhibin B concentrations in older men indicates normal Sertoli cell function and spermatogenic activity.

Our laboratory and others have shown in the brown Norway rat model that aging is associated with decreased testis volume due to decreased seminiferous tubule volume and sperm concentration. The decrease in germ cells is nonuniform and affects some but not all tubules. We have also showed that this decline in germ cells is related to accelerated apoptosis affecting germ cells. Because the loss of germ cells appears to be patchy, it is likely that, in addition to decreased testosterone secretory capacity of Leydig cells, other factors such as increased cytokines, reactive oxygen species, and other paracrine factors induced by decreased blood flow or neuronal input may play important roles.

IMPLICATIONS IN MANAGEMENT OF AGING MEN

There is general agreement that aging in men is associated with declining serum testosterone and bioavailable/free testosterone concentrations. Although serum testosterone may be decreased, seminiferous tubule

function appears to remain relatively normal, with normal sperm output and reproductive capability even to the seventh decade. Low serum testosterone levels are implicated as a possible cause of the clinical features associated with andropause. Lack of energy, frailty, decreased general well-being, sexual dysfunction, loss of muscle, and loss of bone mass may be ameliorated by testosterone supplementation. Because of the probable abnormal functioning GnRH pulse generator in aging men, stimulation of the axis by clomiphene citrate might not result in favorable increases in LH pulse amplitude and testosterone secretion. Furthermore, because Leydig cell dysfunction appears to be the predominant cause of androgen deficiency in aging males, treatment with recombinant LH or human chorionic gonadotropin might not elicit a satisfactory response, although gonadotropin administration has not been tested in a large number of individuals. Based on our understanding of the gonadotropins and testicular dysfunction in aging men, replacement with androgens at the current time and replacement with selective androgen receptor modulators in the future appear to be the best choices for treatment of symptoms or signs of andropause. Studies are ongoing to determine the benefit versus risk ratios of androgen replacement therapy in aging men.

deposited in the dermal tissues. These deposits lead to disruption of the collagen bundles and marked edema. Lymphocytic infiltration is not always apparent.

ETIOLOGY

The reason why localized myxedema occurs in Graves' disease is unknown. The strong association with Graves' hyperthyroidism, and especially ophthalmopathy, suggests that it should have an autoimmune pathogenesis. Although nearly all patients afflicted with myxedema have high titers of thyroid-stimulating hormone (TSH) receptor autoantibodies, there is no clear relation between these titers and the severity of the skin lesions. Nevertheless, these antibodies may very well play a role given that skin fibroblasts express the TSH receptor. However, studies in which serum immunoglobulins (IgGs) from patients with dermopathy were added to cultured skin fibroblasts did not show any effect of the immunoglobulins on the production of glycosaminoglycans by the fibroblasts. Other studies showed that serum from patients with Graves' disease contains a factor—other than IgG—that is able to stimulate cultured skin fibroblasts to produce glycosaminoglycans. This factor may be a cytokine produced by lymphocytes.

The preponderance for the lower legs in Graves' dermopathy is unclear. One reason may be the influence of gravity and stasis, but there is also evidence that fibroblasts from different sites have a different regulation of glycosaminoglycan synthesis.

TREATMENT

Treatment is often not indicated because the lesions are usually asymptomatic. Only when there is local discomfort or the lesions become unsightly should

treatment be considered. There are no controlled studies on any treatment for Graves' dermopathy, but uncontrolled studies suggest that topical application of corticosteroids is beneficial. The corticosteroids containing cream should be applied directly to the lesions and then covered with a plastic occlusive dressing. After 3 to 10 weeks, the dose and frequency of the application may be gradually tapered. Compressive stockings during the daytime will diminish the fluid accumulation.

trigger in developing Graves' thyroid disease. Various infectious diseases have been considered risk factors. Infections with *Yersinia enterocolitica* have been implicated because this pathogen has thyroid-stimulating hormone (TSH) binding sites that presumably are homologous to the TSH receptor, the prime autoantigen in Graves' hyperthyroidism. The association between the occurrence of Graves' disease and the therapeutic use of interferon- α (IFN- α) in patients infected with the hepatitis C virus suggests that other conditions resulting in high Interferon alpha levels, such as certain viral infections, may also increase the risk of Graves' disease. Finally, the clear female preponderance suggests that estrogen levels may play an important role. Graves' disease often occurs during the postpartum period.

PATHOGENESIS

Although the cause of Graves' disease is unknown, autoimmunity directed against the TSH receptor is the hallmark of Graves' thyroid disease. Autoantibodies against this receptor mimic the action of its natural ligand, TSH, inducing hyperthyroidism and goiter. Whether these antibodies also are responsible for the other, extra-thyroidal manifestations of Graves' disease is uncertain, although the TSH receptor has been found in fibroblasts residing in the retrobulbar tissues and in the pretibial skin. The pathogenetic importance of TSH receptor autoantibodies as the cause of Graves' hyperthyroidism is, however, without doubt. Transfer of human immunoglobulin (IgG) samples containing these antibodies to rodents causes a prolonged release of previously radiolabeled thyroid hormone from mouse or guinea pig thyroids. This bioassay was used to make the diagnosis of Graves' disease in the past, and the transferred antibodies were named "long-acting thyroid stimulator" (LATS). Nowadays, different tests are applied. Patient IgGs can be incubated with cells transfected with the human TSH receptor, and the response of these cells in terms of the release of cyclic AMP (cAMP) can be measured in a TSH receptor-stimulating immunoglobulin (TSI) bioassay. Another widely used and less cumbersome assay measures the inhibition of binding of ^{125}I -labeled TSH to TSH receptor containing preparations by patient IgGs in the so-called TSH-binding inhibitory immunoglobulins (TBII) assay.

In the majority of patients, other antithyroidal autoantibodies are also present. In approximately 70% of patients, antibodies against thyroid peroxidase (TPO) can be detected. TPO antibodies are the

hallmark of Hashimoto's hypothyroidism, and their titers are related to the degree of lymphocytic infiltration of the thyroid gland. The importance of these antibodies in Graves' hyperthyroidism is unclear, but they might be related to the fact that some patients with Graves' hyperthyroidism become hypothyroid in the long run.

VARIOUS MANIFESTATIONS OF GRAVES' DISEASE

There are three manifestations that may occur in patients with Graves' disease: hyperthyroidism, ophthalmopathy, and pretibial myxedema. Hyperthyroidism is the most common manifestation, and some ophthalmopathy occurs in 25 to 50% of these patients, although severe eye disease is rather rare and develops in only approximately 5% of patients. Pretibial myxedema is even less common and is seen in fewer than 1% of patients. The reason why such diverse organs—thyroid, orbit, skin—can become affected in one patient is unclear, and it has even been reasoned that these three manifestations are, in fact, the expression of distinct disorders frequently occurring more or less simultaneously. This assumption cannot be disproved entirely, but it seems unlikely for a number of reasons.

First, there is a close temporal relationship between the onset of Graves' thyroid disease and the onset of Graves' ophthalmopathy; 80% of patients develop one manifestation within 18 months of the onset of the other. Second, when sensitive methods are used to assess eye involvement in patients with Graves' hyperthyroidism without clinically apparent ophthalmopathy, evidence for orbital tissue swelling is found in virtually all of them. Third, it has been observed that some patients with multinodular goiter develop Graves' hyperthyroidism and ophthalmopathy several months after treatment with radioactive iodine. Multinodular goiter is not an autoimmune thyroid disease and, as such, is not associated with ophthalmopathy. Radioactive iodine leads to a slow destruction of the thyroid, and thyroidal proteins (including the TSH receptor) will leak into the circulation and be presented to the immune system. A minority of patients subsequently mount an autoimmune response to the TSH receptor, leading to hyperthyroidism, and a small number also develop ophthalmopathy. This chain of events suggests that the two disorders are linked to each other. In fact, it supports another theory explaining the multiple-organ character of Graves' disease: autoantibodies against a thyroidal

antigen cross-react with a similar antigen in the skin and the retrobulbar tissues. The nature of this antigen is unknown, but the TSH receptor is a good candidate because TSH receptor autoantibodies are the cause of the hyperthyroidism and the TSH receptor is expressed on retrobulbar fibroblasts and possibly also on fibroblasts derived from skin affected by pretibial myxedema.

concentrations remain unaffected. Hypercalcemia and hypercalciuria are common but usually only moderate, serum magnesium levels tend to be decreased, and phosphate levels tend to be higher. There is no clear evidence for direct toxic effects of elevated thyroid hormones on the liver, although mild elevations of alkaline phosphatase and bilirubin are sometimes seen. An increased frequency of bowel movements is not uncommon and is associated with an increased motility of the intestines. Peristalsis of the esophagus is also increased, and patients occasionally may complain of swallowing difficulties. The red blood cells may be microcytic, but anemia is usually not seen. Mild thrombocytopenia due to shortened platelet survival may occur. Some muscular weakness and wasting occurs in nearly all patients, and this may lead to fatigue and weakness of the larger proximal limb muscles. Nervousness, anxiety, irritability, attention deficits, and some memory loss are common manifestations, but true psychiatric syndromes occur in only a minority of patients. In women, oligomenorrhea is common, but fertility is not severely impaired. In men, there is no evidence for an effect on spermatogenesis, but the biological activity of estrogens is increased and mild gynecomastia can often be found. Hyperthyroidism is a known risk factor for osteoporosis, and the bone mass is frequently decreased in hyperthyroidism. Most of these systemic effects of hyperthyroidism are restored to normal on successful reversal to the euthyroid state.

DIAGNOSIS

The biochemical diagnosis of thyrotoxicosis is usually straightforward. Laboratory tests will show elevated levels of T_4 and T_3 in the presence of low or undetectable TSH values. In Graves' disease, T_3 levels are relatively higher than T_4 levels, and in some patients only T_3 levels may be increased (T_3 toxicosis). To discriminate Graves' disease from other forms of hyperthyroidism (e.g., toxic multinodular goiter, toxic adenoma) or thyrotoxicosis (e.g., silent or subacute thyroiditis, exogenous thyroid hormone use), additional diagnostic procedures may be useful. A thyroid scintigram will show homogenous and often increased uptake. Determination of TSH receptor autoantibodies may sometimes be useful. An assay measuring the capability of patient immunoglobulins (IgGs) to displace binding of labeled TSH to TSH receptors (TSH binding inhibitory immunoglobulin assay, TBII) has a sensitivity of 96% for the diagnosis of Graves' hyperthyroidism. TBII is sometimes present in patients with multinodular goiter and destructive thyroiditis; hence, the specificity is only 84%.

MANAGEMENT

Initial treatment with a beta blocking agent will alleviate most of the signs and symptoms of hyperthyroidism because many are mediated through the sympathetic nerve system. This symptomatic treatment is usually followed by a therapy aimed at diminishing the synthesis and secretion of thyroid hormones. This can be achieved effectively by anti-thyroid drugs such as methimazole, carbimazole, and propylthiouracil (PTU); by ablating large parts of the thyroid gland with radioactive iodine; or by partly removing the gland surgically. Each of these options has its advantages and disadvantages.

Therapy with 30 mg of methimazole taken once daily, or with 300 to 400 mg of propylthiouracil in three or four divided doses, will render most patients euthyroid in 4 to 6 weeks. When euthyroidism has been achieved, one can choose between diminishing the dose ("titration method") or maintaining the same dose and adding L-thyroxine ("block and replace-ment"). This antithyroid treatment is then continued for 12 to 24 months, after which time approximately 50% of patients will enter into a complete remission. In general, chances to enter into a remission increase if there is a decrease in goiter size, TSH levels become normal during treatment, TSH receptor antibodies disappear, and the patient is a nonsmoker.

Disadvantages of antithyroid drugs include allergic reactions consisting of an often transient pruritic rash, and agranulocytosis, a very rare but life-threatening event. Prompt discontinuation of the antithyroid drugs will restore the leukocyte count to normal within a week. Other rare side effects include arthralgias, hepatitis, and drug fever.

The advantage of subtotal thyroidectomy is the rapid and instantaneous reversal of the thyrotoxic state. It is preferably performed in patients who have been rendered euthyroid by antithyroid drugs, but in emergency situations this can also be achieved by the administration of large doses of iodine (five drops of Lugol's solution daily for a maximum of 10 days) or by treatment with lithium carbonate or amiodarone. Although mortality rates are negligible, a subtotal thyroidectomy carries a small but unavoidable risk for damage to the recurrent laryngeal nerve leading to vocal cord paralysis and for hypoparathyroidism. Postoperative hypothyroidism occurs in a substantial minority of patients.

Radioactive iodine is a simple and economical way in which to control hyperthyroidism. It can be given to patients who have been rendered euthyroid by antithyroid drugs or can be used as a first line of therapy. Its main disadvantage is the induction of hypothyroidism, which occurs in 40 to 70% of patients within 10 years after treatment. Although hypothyroidism is easily treated with L-thyroxine substitution, not all patients like the idea of lifelong substitution treatment. Radioactive iodine may aggravate concomitant ophthalmopathy, especially in smokers, in patients with high pretreatment T₃ levels, and in patients whose eye disease is active. This can be prevented by concomitant administration of corticosteroids. Radiation thyroiditis occurs in a minority of patients during the first weeks after treatment and very rarely may result in a thyrotoxic storm. This is seen mainly in elderly patients with severe

hyperthyroidism; hence, the common practice is to treat these patients with antithyroid drugs first. There is no evidence of a carcinogenic or leukemogenic effect of radioactive iodine; in fact, a recent large follow-up study actually found a 10% decrease in risk for cancer mortality. Radioactive iodine and a 1-year course of antithyroid drugs are the most commonly used therapies in patients with newly diagnosed Graves' hyperthyroidism. Subtotal thyroidectomy is reserved for young patients, especially when a course of antithyroid drugs has failed. In the United States, a preference is seen for the use of high doses of radioactive iodine aimed at induction of hypothyroidism. In Europe, patients are more often treated with a course of antithyroid drugs in light of the 50% remission rate.

Figure 1 CT scanning of the orbits of a patient with unilateral Graves' ophthalmopathy. The eye muscles in the right orbit are small and ribbon-like, whereas one eye muscle (the medial rectus) on the left is obviously swollen.

ETIOLOGY

Like Graves' hyperthyroidism, Graves' ophthalmopathy is an autoimmune disorder with a multifactorial background. The majority of patients with Graves' ophthalmopathy have family members afflicted by Graves' hyperthyroidism, but a family history of ophthalmopathy itself is uncommon. This may be partly due to the relative rareness of this complication. Another plausible explanation is that certain environmental factors are necessary to bring about the eye disease in patients with (a genetic predisposition for) Graves' hyperthyroidism. No genetic loci have been found to be associated with an increased risk for ophthalmopathy, with the possible exception of a CTLA-4 polymorphism. Interestingly, one protective locus has been identified (HLA-DPB1*201).

On the other hand, an environmental factor, smoking, has been identified beyond any doubt as a strong risk factor for the development of this eye disease. Smoking increases the risk of ophthalmopathy 7.7-fold and is especially associated with more severe eye disease. The pathogenetic importance of smoking is further underscored by the fact that the results of various therapeutic interventions are not as good in smokers as in nonsmokers. The reason behind the influence of smoking on the eye disease is unknown. Another environmental risk factor for ophthalmopathy is the treatment of the underlying hyperthyroidism with radioactive iodine. This treatment carries a small but unequivocally higher risk than does antithyroid drug treatment for the development of (usually mild and transient) ophthalmopathy.

PATHOGENESIS

On histology, the enlarged retrobulbar tissues show a marked lymphocytic infiltration consisting mainly of T lymphocytes and only a small number of B cells. The autoantigen responsible for attracting these immunocompetent cells is unknown, unlike the situation in Graves' hyperthyroidism where the thyroid-stimulating hormone (TSH) receptor is the autoantigen. The current hypothesis suggests that autoreactive T lymphocytes recognize an antigen that is present in both the thyroid and the retrobulbar fibroblasts (Fig. 2). These T cells then secrete various cytokines, facilitating an amplification of the immune response by inducing adhesion molecules such as ICAM-1 on retrobulbar fibroblasts, which direct other immune cells to the target tissues. T-cell-derived cytokines may also activate B lymphocytes to differentiate into plasma cells capable of producing autoantibodies against unknown autoantigens. In addition, several cytokines possess the ability to stimulate glycosaminoglycan (GAG) production by fibroblasts and fibroblast proliferation. This chain of events leads to swelling and active inflammation of the retrobulbar tissues. As for the nature of the responsible autoantigen, one might suggest the TSH receptor given that this protein is also expressed on retrobulbar fibroblasts at certain stages of their differentiation.

Figure 2 Schematic representation of the pathogenesis of Graves' ophthalmopathy. T lymphocytes recognize and process an antigen on the thyroid gland and mount an antithyroidal autoimmune attack, resulting in hyperthyroidism. These T cells circulate throughout the body and may become attracted to the orbit, where retrobulbar fibroblasts express homing molecules. There, the T cells recognize an antigen similar (or even identical) to the thyroidal antigen and start an autoimmune attack against the fibroblasts. The cells will produce several cytokines, which stimulate the production of glycosaminoglycans by the retrobulbar fibroblasts.

RELATIONSHIP WITH GRAVES' HYPERTHYROIDISM

Graves' ophthalmopathy is usually seen in patients in whom a diagnosis of Graves' hyperthyroidism is well established. In the majority of patients, the eye disease develops concomitantly with or some months after the onset of the thyroid disease. However, in 25% of patients, the eye disease precedes a diagnosis of hyperthyroidism by a number of months. Sometimes, there is considerable delay between the onset of the two manifestations that in rare cases may even be several years. In these circumstances, it can be difficult to make the correct diagnosis. In a small minority (5%), patients with ophthalmopathy present with primary hypothyroidism instead of hyperthyroidism. The pathogenesis of this thyroid failure is unclear but may be due to so-called TSH-blocking autoantibodies against the TSH receptor. These antibodies render the thyroid gland devoid of the stimulating effect of TSH, resulting in atrophy and hypothyroidism.

CLINICAL MANIFESTATIONS

Graves' ophthalmopathy causes a plethora of signs and symptoms that are summarized in [Table I](#), the so-called NO SPECS classification. This classification system was first developed in 1969, was subsequently revised on a number of occasions, and now serves as a good memory aid. The various signs and symptoms might seem complex ([Fig. 3](#)), but all can be explained from a mechanical point of view.

Class 1: Only Signs, No Symptoms

This refers to the upper eyelid retraction frequently observed in patients with Graves' hyperthyroidism.

Figure 3 A patient with severe Graves' ophthalmopathy. Note the abnormal eyeball position, resulting in double vision, swelling of the eyelids, increased lid aperture, and periorbital swelling.

The lid retraction causes stare and lid lag on downward gaze (Von Graefe's sign) and can be due to swelling of the superior levator muscle. However, thyrotoxicosis per se can also induce this sign by increasing the sympathetic tone, so Von Graefe's sign is sometimes also present in hyperthyroidism not caused by Graves' disease. Sympathetic overactivity is not the only cause of lid retraction given that upper eyelid retraction frequently remains present when ophthalmopathy patients are rendered euthyroid. If severe, lid retraction may lead to lagophthalmos, that is, incomplete closure of the eyelids at night.

Class 2: Soft Tissue Involvement

This entails chemosis (edema of the conjunctiva), conjunctival injection and redness, swelling of the

Table I NO SPECS Classification of Eye Changes in Graves' Ophthalmopathy

| Class | Description | Signs and symptoms | Cause |
|-------|--------------------------------|---|--|
| 0 | No signs or symptoms | — | — |
| 1 | Only signs, no symptoms | Lid retraction, stare, lid lag | Increased sympathetic tone |
| 2 | Soft tissue involvement | Swelling of eyelids, chemosis, photophobia, grittiness | Impaired venous drainage, herniated orbital fat |
| 3 | Proptosis | Exophthalmos | Increased retrobulbar pressure pushing globe forward |
| 4 | Extraocular muscle involvement | Restricted eyeball motility (often with diplopia) | Swollen eye muscles |
| 5 | Corneal involvement | Keratitis, corneal ulcer | Overexposure of cornea |
| 6 | Sight loss | Decreased visual acuity due to optic nerve involvement, impaired color vision, visual field defects | Pressure on optic nerve, apical crowding |

caruncle, and swelling of the upper and lower eyelids (periorbital swelling). These findings are partly explained by impaired venous drainage as a result of the increase in volume of the retrobulbar tissues. Periorbital swelling is also due to herniation of retrobulbar fatty tissues through openings in the orbital septum covering the retrobulbar cavity.

Class 3: Proptosis

Because of the confining bony surroundings, the swollen retrobulbar tissues have no other outlet than pushing the globe forward. Hence, exophthalmos may be seen as “nature’s own decompression.”

Class 4: Extraocular Muscle Involvement

One can easily imagine that swelling of the normally very thin extraocular eye muscles leads to impaired mobility. If the impairment is asymmetrical, the patient will have double vision. However, if the impairment is symmetrical, no diplopia will occur. Sometimes, the patient will keep the neck in a certain position (usually bent backward) to correct for impaired motility. This so-called ocular torticollis may lead to painful neck muscles.

Class 5: Corneal Involvement

Exophthalmos, lid retraction, lagophthalmos, and less frequent blinking all contribute to an excessive exposure of the cornea to air that can lead to inflammation of the cornea (keratitis). Early signs are photophobia, a gritty sensation, intolerance to contact lenses, and blurred vision. This phenomenon is different from diplopia in that the abnormal images disappear after blinking.

Class 6: Sight Loss

Sight loss can occur if the enlarged eye muscles compress the optic nerve. This can occur in the apex of the orbital cavity where the optic nerve leaves the orbit. On CT scanning, no room is seen between the optic nerve and the swollen muscles; this is called “apical crowding.” Early signs of optic nerve involvement are impaired color vision and visual field defects. This severe complication is more often seen in males and in patients without significant proptosis. In those patients, a tight orbital septum precludes forward displacement of the globe, causing a rise in retrobulbar pressure that is damaging to the optic nerve.

Other Signs and Symptoms

Apart from the manifestations described in the NO SPECS classification, patients in the active stages of the eye disease often complain of a dull pain or pressure on or behind the eyeball. Pain can also be felt during attempted up, side, or down gaze. Perhaps the most important complaint is the change in appearance. Bulging of the eyes, swelling of the eyelids or even only lid retraction, and an abnormal position of the globes all contribute to a sometimes very marked change in appearance. This will be better appreciated if the patient shows photographs of himself or herself taken before onset of the disease.

QUALITY OF LIFE

In view of these many and different clinical manifestations, it is not surprising that patients suffer from a diminished quality of life. The changes in appearance as a consequence of proptosis and periorbital swelling can be profound. Diplopia will hamper many activities in daily life such as reading and driving. In fact, research has established that even patients with mild to moderately severe eye disease already have a markedly decreased sense of well-being. They rate their degree of social and role functioning lower than do patients with other chronic diseases such as diabetes mellitus. Use of a disease-specific quality of life questionnaire developed with the aid of patient self-support groups has shown unequivocally that Graves' ophthalmopathy is a seriously disabling disorder. The disease leads to feelings of social isolation in as many as 40% of these patients. Half of the patients notice unpleasant reactions from others, and many do not want to appear in photographs. As a consequence, as many as 70% of patients with mild to moderately severe ophthalmopathy report a marked decrease in self-confidence.

DIAGNOSIS

In patients with clear evidence of Graves' hyperthyroidism who present with bilateral proptosis, a diagnosis of Graves' ophthalmopathy is easily made. However, this diagnosis may be less obvious in patients with unilateral disease or in patients without a thyroid disorder. Nevertheless, even in these patients, the most likely diagnosis will be Graves' eye disease. It should be noted that there is no diagnostic procedure establishing a diagnosis of thyroid-associated eye disease unequivocally, but several imaging procedures may be helpful. CT scanning of the orbits typically

will reveal swelling of the extraocular eye muscles, of the retrobulbar tissues, or of both (Fig. 1). Magnetic resonance imaging (MRI) will show the same but may also demonstrate a prolonged T2 relaxation time, suggestive of edematous swelling. Other diagnostic imaging procedures include octreotide scintigraphy, where labeled octreotide binds to somatostatin receptors on activated orbital lymphocytes, and ultrasound. However, enlargement of the eye muscles or connective tissues is not definitive proof of the existence of ophthalmopathy. Other diagnoses that should be entertained are lymphomas or metastases of carcinomas to the orbit and the rare disease entity of an orbital pseudotumor. It is the combination of various signs and symptoms of ophthalmopathy, together with evidence of an autoimmune thyroid disease, that will trigger the physician to make the correct diagnosis.

GENERAL THERAPEUTIC PRINCIPLES

The first step in the management of a patient with ophthalmopathy is adequate treatment of the underlying thyroid disorder. Restoration of the euthyroid state frequently leads to some amelioration of soft tissue involvement and sometimes even of diplopia in 2 to 3 months. Generous application of lubricants (eye drops should be applied at least six times daily) prevents corneal damage. Lagophthalmos is frequent, and application of a protective gel at night protects the exposed cornea during sleep. Further therapeutic measures depend on the severity and stage of the eye disease.

DISEASE ACTIVITY

From observations by the Australian physician, F. F. Rundle, it has become clear that the disease has a tendency toward spontaneous improvement (Fig. 4). After reaching a peak in severity, the signs and symptoms gradually ameliorate over a highly variable period of time, from several months to a number of years. However, in most patients, a complete restoration to the premorbid state is seldom reached. On histology, the active state is characterized by lymphocytic infiltration, whereas during the chronic phase, fibrotic scar tissue is found. It is conceivable that immunosuppressive therapies will be effective during the active stage only and that rehabilitative surgery is the treatment of choice when the disease is in its inactive phase. Unfortunately, reliably assessing the stage of the disease in individual patients has been difficult. Obviously, when the eye condition is rapidly

Figure 4 Rundle's curve showing the natural history of Graves' ophthalmopathy and its tendency toward spontaneous improvement over a variable period of time. Note that the x axis (time) is not defined.

deteriorating, it is in its active stage. On the other hand, when the ophthalmopathy has been stable for 6 months, it is likely to have become inactive. However, in many patients with moderately severe disease, such changes are less obvious and one prefers to assess the disease stage without having to observe symptomatic patients during several months without therapy. Therefore, various methods to assess disease activity have been developed, and the ones used most frequently are mentioned in Table II. However, none of these measures is entirely satisfactory in predicting a successful outcome of immunosuppressive therapy. If one or more of the measures from Table II indicates activity, it is reasonable to assume that the disease is still amenable to immunosuppressive therapy (if the severity of the disease warrants treatment).

MANAGEMENT DURING THE ACTIVE STAGE

One option during the initial phase of the disease is to observe the patient over the course of several months. When the disease is not severe, this is certainly a good option in view of the natural tendency toward spontaneous improvement and because of the side effects associated with the various treatment options. Adequate antithyroid treatment and lubrication of the cornea will alleviate some of the symptoms until the disease has become inactive and surgical rehabilitation is possible. In more severe cases, nonsurgical (immunosuppressive) treatment can be indicated. Both corticosteroids and retrobulbar irradiation have been used for this indication for many decades. The

Table II Commonly Used Parameters for Disease Activity and Their Cutoff Values Indicating Active Disease

| Parameter | Cutoff value |
|---|--------------|
| Duration of signs or symptoms | <18 months |
| Clinical activity score (for each sign present, 1 point is given): | |
| <i>Pain or oppressed feeling on globe</i> | ≥4 |
| <i>Pain on attempted up, side, and/or down gaze</i> | |
| <i>Redness of eyelids</i> | |
| <i>Redness of conjunctiva</i> | |
| <i>Swelling of eyelids</i> | |
| <i>Swelling of caruncle</i> | |
| <i>Chemosis</i> | |

rationale for the use of corticosteroids is their anti-inflammatory and immunosuppressive effects. Radiotherapy probably exerts its effect through the killing of infiltrating lymphocytes and activated (GAG-secreting) fibroblasts. Both therapies have an overall response rate of approximately 65% and are effective at reducing periorbital swelling and the degree of diplopia. They have very little, and clinically insignificant, effects on the degree of proptosis. A typical oral prednisone course starts with 60 mg for 2 weeks, followed by 40 mg for 2 weeks, 30 mg for 4 weeks, and 20 mg for another 4 weeks, after which the dose is tapered to zero in 1 to 2 months. Intravenous administration of large doses (500–1000 mg) of methylprednisolone for 1 to 3 days, repeated several times, is also effective and may be better tolerated. Radiotherapy is administered in 10 daily fractions of 200 cGy. Improvement of eye signs occurs earlier when corticosteroids are used (usually some effect is seen within 2–4 weeks), whereas a beneficial effect of irradiation may take 3 to 6 months. The usual prednisone dose is almost always associated with side effects, whereas radiotherapy causes no significant untoward effects and is safe in the long term. The only contraindication is diabetes mellitus because irradiation can aggravate diabetic retinopathy.

In patients with optic nerve involvement, characterized by apical crowding on CT scanning, visual field defects, and/or a decrease in visual acuity, a more aggressive approach is warranted. In those patients, methylprednisolone pulses can be administered (1000 mg intravenously on 3 consecutive days, repeated once 1 week later, followed by oral prednisone for 3–5 months), and this may even be combined

with orbital irradiation. In case of an unsuccessful outcome, acute surgical decompression of the orbits is the only option left.

Intravenously administered immunoglobulins have also been found to be beneficial, with a response rate similar to that of oral corticosteroids. Because of its high cost, the treatment is seldom used. Octreotide and other (long-acting) somatostatin analogues may cause some regression of eye signs. They are well tolerated but seem to be less effective than prednisone. Other immunosuppressive treatments used in autoimmune diseases, such as ciamexon and azathioprine, are not effective in Graves' ophthalmopathy. Cyclosporine given as monotherapy is ineffective but can be combined with oral prednisone, in which case a lower dose of prednisone can be used to achieve a similar response rate.

SURGICAL TREATMENT

Once the disease has become inactive, most patients still experience disabling and often disfiguring symptoms, even after otherwise successful immunosuppressive therapy. These remaining manifestations can be treated successfully with various targeted surgical procedures by an experienced orbital surgeon. The surgical procedures should be done in a strict order. First, an orbital decompression is performed if there is significant proptosis. During this procedure, several of the orbital walls are partly removed to increase the retrobulbar space. The degree of proptosis reduction varies with the number of walls removed. A three-wall decompression (coronal, transantral, and swinging eyelid approaches) typically results in a 6- to 8-mm reduction in proptosis. Complications include numbness of parts of the skin and worsening or even induction of diplopia. This latter complication occurs in 10 to 20% of patients and is the reason why a decompression should always be done before squint (strabismus) surgery.

Squint surgery consists of a recession of restricted extraocular eye muscles. The tendon of the muscle is severed from the eyeball and reinserted in a new position determined preoperatively during extensive orthoptic evaluations. Binocular single vision in all directions of gaze is seldom achieved, but single vision in the primary and reading positions is reached in 50 to 80% of patients after one operation. Thus, frequently two or even more procedures are required to obtain an acceptable situation.

The final step in the rehabilitation of these patients consists of eyelid surgery. Upper eyelid retraction can

be treated by recessing the levator muscle with or without a sclera interpositioning. Upper eyelid surgery is difficult, and in most patients various procedures (under local anesthesia) are needed. Lower eyelid surgery is often successful after just one attempt. Finally, redundant connective and fatty tissues can be removed by a blepharoplasty of the upper and/or lower eyelids.

prepubertal period, but there is a marked decrease in growth velocity during the years preceding puberty, and puberty is also delayed. For other conditions, such as Crohn's disease, the disease occurs during the preadolescent period, the pubertal changes stop, and the pubertal growth spurt is delayed. Besides the delayed onset of puberty, other abnormalities of puberty have been reported such as a slow clinical progression of puberty and delayed menarche in females as well as a decrease in the duration and intensity of the pubertal growth spurt, resulting in an irreversible loss of height during puberty.

Therefore, abnormal growth during puberty is the major mechanism of short stature in chronically diseased patients.

Chronic Renal Failure

When renal disease and its consequences occur early during infancy, a marked height deficit may develop due mainly to inadequate nutrition. Additional factors are water and electrolyte losses, metabolic acidosis, renal osteodystrophy, and catabolic response to infection.

During the mid-childhood period, the growth pattern of a child with congenital chronic renal failure (CRF) follows the percentile achieved at the end of infancy. In children who develop CRF after 2 years of life, growth usually follows the percentile achieved after stabilization of the disease. The degree of renal dysfunction is the principal determinant of growth during this period. Relative height tends to decrease in patients with a glomerular filtration rate (GFR) of less than 25 ml/min/1.73 m²; growth is usually stable when the GFR is above this threshold.

The onset of puberty is usually delayed in adolescents with CRF, with an average delay of approximately 2 years for the appearance of clinical signs of puberty. The degree of delay of the pubertal growth spurt (mean delay 2.5 years) correlates with the duration of CRF. The mean pubertal height gain is only 50% of that of normal late-maturing children. Hence, it appears that height potential in children with CRF is lost mainly during two developmental stages of rapid growth: infancy and puberty. These abnormal growth patterns have severe consequences for final height.

According to the Registry of the European Dialysis and Transplant Association, 50% of patients who started dialysis before 15 years of age have a final height below the 3rd percentile of the normal population. Children who had continued dialysis until

adulthood reached a slightly lower mean final height than did those with a renal transplant. Less than 25% of patients with preterminal CRF reached a final height above the 50th percentile, indicating that even moderate CRF alters the genetic growth potential. Despite general improvements in renal replacement therapy, the mean final height in adolescents with CRF did not increase during the past decade.

Modern treatment of children with CRF and short stature nowadays includes growth hormone (GH) administration. This has changed the height prognosis of these children, who may reach a normal adult height provided that the GH treatment is administered early in the course of their disease (Fig. 1).

Juvenile Idiopathic Arthritis

Growth retardation is a prominent feature of children with idiopathic arthritis (JIA). It is present in patients given glucocorticoids, but short stature was described long before the era of modern treatment. In 1887, Sir George Still wrote the following about JIA:

A remarkable feature in these cases is the general arrest of development that occurs when the disease begins before the second dentition. A child of 12 and a half years would easily have been mistaken for 6 or 7 years, which another of 4 years looked more like 2 and a half or 3 years.

Although growth retardation was described a long time ago, few precise studies are available on cohorts of patients treated with corticoids. We have studied linear growth and final height in a large group of patients who were followed until final height (Fig. 2). Mean age at onset of the disease was 3.4 ± 2.4 years, and prednisone therapy was initiated at disease onset for a mean duration of 13.6 ± 5.0 years. A significant loss of height of -2.7 ± 1.5 SDS (standard deviation score) occurred during the first 4 years of the disease and was correlated with prednisone therapy duration. Consequently, mean height for chronological age (approximately 12 years) at prednisone discontinuation was significantly lower than mean target height (-2.6 ± 1.4 vs -0.3 ± 0.9 SDS). After prednisone discontinuation, 17 patients (70%) had catch-up growth, but 7 patients (30%) had a persistent loss of height. Consequently, mean final height was significantly different between these two groups (-3.6 ± 1.2 SDS in the group without catch-up growth vs -1.5 ± 1.6 SDS in the group with catch-up growth). Overall, mean final height was -2.0 ± 1.8 SDS and was strongly correlated with mean height at prednisone discontinuation.

Figure 1 Change from initially predicted adult height at baseline in 38 children (32 boys and 6 girls) with chronic renal failure who received growth hormone treatment, as compared with 50 control children with chronic renal failure who did not receive growth hormone, according to gender. Values are means \pm standard deviations. Asterisks indicate significant differences from the previous period ($P < 0.001$); daggers indicate significant differences from the children who were not treated with growth hormone ($P < 0.001$). Reproduced from Haffner, D., Schaefer, F., Nissel, R., Wühl, E., Tönshoff, B., and Mehls, O., for the German Study Group for Growth Hormone Treatment in Chronic Renal Failure. (2000). Effect of growth hormone treatment on the adult height of children with chronic renal failure. *N. Engl. J. Med.* **343**, 923–930, © 2000 Massachusetts Medical Society. All rights reserved.

Altogether, two periods had a critical influence on final height in these patients: the active phase of the disease characterized by a significant loss of height and the period following prednisone discontinuation, during which catch-up growth occurred in most, but not all, of the patients. Earlier studies reported that linear growth retardation during the active phase of JIA was dependent mainly on disease severity and duration but was worsened by high-dose glucocorticoid therapy. In fact, it has been established that glucocorticoid therapy slows growth when the dose is at least 0.25 mg/kg/day prednisone equivalent. Moreover, many patients with JIA, particularly younger ones, experience partial catch-up growth when their disease becomes inactive. Catch-up growth is less common in patients with longer disease duration.

Few studies have reported final height in patients with a history of JIA. In a study of 65 patients with various forms of JIA, Zak and co-workers found that final height SDS was less than -2 SDS in 11% of patients, all of whom had had polyarticular disease treated with glucocorticoid therapy, and that polyarticular or systemic disease was associated with a final height shorter than the target height. In our study,

Figure 2 Systemic form of juvenile chronic arthritis: growth and final height. Reproduced from Simon, D., Lucidarme, N., Prieur, A. M., Ruiz, J-C., and Czernichow, P. (2002). Treatment of growth failure in juvenile chronic arthritis. *Horm. Res.* **58**(Suppl. 1), 28–32, by permission of Karger, Basel.

41% of patients suffering from systemic forms of JIA had a final height less than -2 SDS and that 87% of patients had a final height below their target height. Altogether, these data suggest that polyarticular or systemic JIA treated with glucocorticoids is associated with an increased risk of reduced final height. The final height of these patients may vary from one patient to another, depending mainly on severity of the disease and on their linear growth during and after prednisone therapy.

Crohn's Disease

Approximately 30 to 40% of patients under 18 years of age with Crohn's disease (CD) suffer from impaired linear growth, lack of weight gain, retarded bone development, and delayed onset of sexual maturation. It is not uncommon to find that growth failure precedes any clinical evidence of bowel disease, often by years. Decreased growth rate has been recorded in 40% of patients before symptoms were noted and in 60% of patients at the time of diagnosis. At least one-third of these patients had decreased height velocity before any weight loss. Thus, both abnormal linear growth and abnormal ponderal growth are significant presenting features of inflammatory bowel disease (IBD) in children and may be the earliest indicators of the disease.

A prospective 3-year study, carried out during the early 1990s on pediatric CD patients, found a linear growth delay in 40% of the patients; their actual height was less than 95% of the expected median for their age, and 10% of them had severe growth

impairment below the 5th percentile (Z score < -1.64). A similar percentage (37%) had bone age that was more than 2 SDS below normal and retarded sexual maturation. During the follow-up, 24% had retarded linear growth velocity.

A more recent multicenter prospective 2-year study (1996–1999) of 82 pediatric CD patients indicated that severe growth failure (height ≤ -2 SDS) was initially present in 12 (15%) of the cases, with significant retardation of bone age and sexual maturation. Of these, 11 remained less than -2 SDS after 2 years of follow-up. In addition, 6 (8%) of the patients who were initially within the normal range showed impaired growth velocity during the follow-up, leading to a total of 17 (21%) of the patients less than -2 SDS at 2 years follow-up. No differences in the sex, age at diagnosis, age at inclusion, and parental height for this group were found.

During the 1970s, a retrospective study analyzed the long-term growth of patients from adolescence into adulthood and found that a population suffering from IBD during infancy was significantly shorter than the normal population at diagnosis (12.2 years) and after reaching adulthood (follow-up at 8 years). Similar data were reported during the 1990s, with persistent stunting into adulthood of 15 and 31%, respectively.

Modern treatments, including nutrition, have improved the height prognosis of children with CD. More studies are needed to identify those children who remain at risk for short stature.

Celiac Disease

Childhood celiac disease (CCD) is caused by an intolerance to gluten, leading to damage of the small intestinal mucosa and resulting in malabsorption of nutrients. Usually, CCD is clinically characterized by abdominal complaints and weight loss, but failure of statural growth may also be a prominent symptom, especially when diagnosed beyond a toddler's age. The hormonal status of these patients resembles that observed in malnutrition, with elevated GH secretion and low insulin-like growth factor-1 (IGF-1). Withdrawal of gluten from the diet constitutes removal of the pathogenetic factor and is an effective treatment for CCD. After institution of a gluten-free diet, the symptoms usually disappear quite rapidly, and most patients exhibit complete catch-up. IGF-1 will return to normal values very rapidly during the course of the treatment. If the compliance to treatment is correct and nutrition is adequate, the final height of these patients should be normal.

Thalassemia

Growth retardation is still present in thalassemia despite efforts to prevent iron overload. In 2000, an Italian series showed that short stature (height < 3 rd percentile) was present in 34% of the patients.

The mechanism of growth retardation is complex and has been attributed mainly to iron overload in the tissues and, more specifically, the endocrine glands. A direct role of chronic anemia, folic acid deficiency, has also been suggested. Failure of pubertal development has been observed in 43% of patients over 16 years of age. In some patients, a direct effect of a gonadal lesion was the main cause, whereas in other cases, pituitary insufficiency or a combination of both primary and secondary hypogonadism was demonstrated.

Cystic Fibrosis

Growth retardation is present in cystic fibrosis (CF) and for a long time was thought to be due to malnutrition. In a large survey of approximately 5000 patients from Boston and Toronto, the population of CF patients from Toronto was taller than the population from Boston. The only difference was a better nutritional status in the Canadian cohort, a result suggesting that nutritional status was a key component of growth in this population. In fact, it has been demonstrated that by improving nutritional support, the difference in height between these U.S. and Canadian populations disappeared.

Malnutrition is frequent at diagnosis, and early nutritional intervention can improve growth velocity, height, and weight. However, nutrition is not the only factor affecting growth in CF. For example, in Denmark, despite improvement in nutritional status of CF patients, growth velocity and height did not change in the patients from 1960 to 1990 and the only parameter that improved was the body mass index (BMI). It is evident that there are other causes in growth retardation besides malnutrition per se. Chronic inflammation is probably another key factor that influences growth in these patients, as it is in many other chronic diseases. Whether systematic antibiotic courses and anti-inflammatory drugs, in addition to nutritional support, will improve final height remains to be determined.

Insufficient insulin secretion and diabetes is another cause of short stature in these patients. Abnormal growth velocity or lower BMI has been shown before the onset of diabetes. Because the anabolic action of insulin is essential in normal growth, especially

during puberty, it has been suggested that insulin insufficiency is responsible for poor growth in these patients. Controlled trials with insulin injection during the early prediabetic stage are necessary to demonstrate the effect of insulin supplementation on growth and nutrition.

Diabetes

In the past, abnormal growth and a decrease in final stature were common in patients with uncontrolled diabetes and were components of Mauriac syndrome. A study of identical twins, discordant for diabetes prior to puberty, found that the diabetic twin was on average 5.8 cm shorter than the control twin.

Improvements in the management of diabetes have eliminated severe growth alterations. However, growth impairment has been reported in children with poorly controlled disease or improved growth after a period of better metabolic control. Longer disease duration and poorer metabolic control were associated with a shorter final stature. To a large extent, the decreased final height is related to a decrease in the pubertal growth spurt, particularly in girls. It should be kept in mind that hypothyroidism and celiac disease should be looked for in diabetic children with slow statural growth.

Growth in Other Glucocorticoid-Treated Diseases

Information on several chronic diseases treated by glucocorticoids is not available. This is the case for Blackfan Diamond disease, dermatomyositis, Lupus, and the like. In children with asthma, inhaled corticosteroids might have a short-term effect on growth velocity. However, long-term follow-up seems to indicate that adult height is normal.

MECHANISMS OF ABNORMAL GROWTH VELOCITY AND ADULT SHORT STATURE

Primary Organ Lesion

Abnormal organ function is one of the major causes of growth retardation. This is the case for chronic anemia observed in children suffering from congenital anomalies of red cells, for enteric losses and malabsorption in IBD, and for reduced lung capacity and function in CF. In renal disease, growth retardation is mediated

by predominant tubular abnormalities, resulting in excessive loss of growth-promoting substances. Urinary losses of water and electrolytes are present in many congenital renal diseases. Urinary losses of amino acids, bicarbonate potassium, phosphate, or calcium are observed in complex tubular disorders such as Fanconi syndrome and cystinosis.

Malnutrition

Energy malnutrition contributes to growth failure in children with chronic disease. Dietary intake may be inadequate because of chronic anorexia, which is often observed in these patients. Protein-calorie malnutrition is observed in protein-losing enteropathy and is present in 70% of child and adult patients with CD. Bleeding and extensive damage to intestinal cells due to chronic inflammation and ulceration tend to increase nitrogen losses and result in hypoalbuminemia. This is accompanied by malabsorption, notably of fat, due to the damage to the ileum, with bile salt malabsorption in approximately 30% of children. It is associated with the malabsorption of fat-soluble vitamins (A, D, and E). The plasma concentrations of minerals (Ca and Mg) and trace elements (notably zinc) are also low (20–30%), as are those of folic acid and vitamin B12, a consequence of steatorrhea, malabsorption, and/or protein-losing enteropathy. However, the malnutrition should be taken in a broad sense and include, for example, metabolic acidosis (observed in patients with CRF) and chronic anemia in thalassemia.

Chronic Inflammation

Several early clinical observations suggest a direct link between factor(s) produced during chronic inflammation and growth failure. In systemic JIA, for example, impairment of linear growth is seen during periods of disease activity, with subsequent normalization of growth rate during remission. In addition, in patients with systemic JIA and growth retardation treated with GH, growth velocity during treatment appears to be inversely correlated with the intensity of inflammation. In CD, the growth defect seems to be related to the degree of disease activity rather than to steroid treatment. In CF, growth retardation appears to be related to the severity and number of episodes of pulmonary infection and not to the degree of pancreatic failure.

During the past few years, the progress in our understanding of inflammation, and especially of the

role of cytokines, has opened up new fields of investigation. Three cytokines—interleukin-1 (IL-1), tumor necrosis factor- α (TNF- α), and IL-6—possess a particularly intense proinflammatory activity and have, for this reason, been investigated extensively within various inflammatory diseases, both acute and chronic. In CD, for example, large amount of cytokines, notably TNF- α and IL-1, are produced. Experimental work was carried out by de Benedetti on a murine transgenic model in which an overexpression of the IL-6 gene could be observed. As a consequence, these animals had high circulating levels of IL-6 and, interestingly, an important growth defect. The reduction in the growth rate led to an adult size that was about 30 to 50% smaller than that of nontransgenic litter mates. Interestingly, the growth defect was completely abolished by immunoneutralization of IL-6, demonstrating the direct role of IL-6 overexpression in the growth defect. The exact mechanism remains to be determined, although a role of IGF-1-binding protein 3 has been shown in transgenic animals that could result in decreased half-life and clearance of IGF-1.

Altogether, chronic inflammation plays an important role, probably variable from one disease to another (e.g., prominent in JIA and secondary in CF), but this role is now well recognized and will introduce interesting therapeutic options in the future.

Glucocorticoids

Glucocorticoids have a general antianabolic and catabolic influence on bone and cartilage. Therefore, they have a direct action on the growth plate, suppressing multiple-gene expression. Glucocorticoids interfere with chondrocyte proliferation and matrix proteoglycans synthesis, and they increase the apoptotic rate of hypertrophic cells. In the tissues adjacent to the growth plate, glucocorticoids enhance osteoclastic activity and suppress osteoblast development and function. Thus, glucocorticoid therapy started during childhood induces severe bone loss, which may increase the risk of osteoporosis and fracture during early adulthood.

In addition, glucocorticoids interfere with the GH-IGF-1 axis and so influence growth. However, in chronic disease, several factors influence the GH-IGF-1 axis; therefore, it is difficult to dissociate the responsibility of glucocorticoid administration from other causes, such as malnutrition and chronic inflammation, that also have distinct action on growth factor synthesis or secretion.

The GH-IGF-1 Axis

Several animal studies and *in vitro* experiments showed that chronic disease and glucocorticoid administration may influence the GH-IGF-1 axis. However, there are no major anomalies in GH secretion in patients with chronic diseases. For instance, in JIA, pharmacological stimulation of GH and sleep-related GH secretion are normal (Fig. 3), as are IGF-1 plasma concentrations and circulating IGF-binding protein. However, there is a wide heterogeneity among the patients, with some having clearly abnormal values. A similar observation was made with patients suffering from CRF.

Although glucocorticoids do not consistently reduce circulating immunoreactive IGF-1, they do inhibit IGF bioactivity in children with chronic diseases such as in nephrotic syndrome. There is some experimental evidence that glucocorticoids suppress GH receptor expression. Moreover, in JIA, circulating GH-binding protein has been found to be subnormal (Fig. 3). A similar observation has been made in patients suffering from CRF. Moreover, GH administration increases IGF-1 plasma values in both diseases. Therefore, even though glucocorticoids may induce a certain degree of GH resistance through their action on the GH receptor, GH administration at therapeutic dose can overcome this resistance. Altogether, changes in GH, GH-binding protein, IGF-1, and IGF-binding protein are minor. However, recent studies have shown that the local effect of the disease and, more important, the local effect of glucocorticoids on the growth plate seem to play a major role. The general message is that glucocorticoids lower local production of IGF-1 via IGF-1 transcription inhibitors. Unfortunately, it is impossible to study the mechanisms involved in humans, and most of the available information is from animal models.

TREATMENT

The dramatic improvement in the metabolic conditions of several diseases has played a key role in the growth and development of chronically ill children, particularly those with CRF, CD, diabetes, and CF. However, better nutrition has not been sufficient to normalize the height of children suffering from CRF and JIA.

The important role of glucocorticoids in growth limitation and bone formation has been discussed previously. Therefore, careful administration of glucocorticoids in chronic disease is of utmost importance

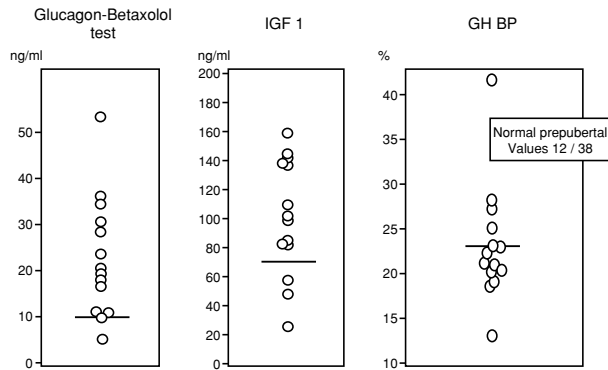

Figure 3 Plasma growth hormone (GH) after pharmacological stimulation, insulin-like growth factor-1 (IGF-1), and GH-binding protein (GH BP) in 14 children with juvenile idiopathic arthritis. Although mean plasma values are normal, there are large interindividual variations and some patients have extremely low values. Reproduced from Touati, G., Prieur, A. M., Ruiz, J. C., *et al.* (1998). Beneficial effects of one-year growth hormone administration to children with juvenile chronic arthritis on chronic steroid therapy: I. Effects on growth velocity and body composition. *J. Clin. Endocrinol. Metab.* **83**, 403–409.

in the prevention of short stature. Alternate-day steroid therapy has also been efficient in the attenuation of corticoid-induced impairment of linear growth.

The role of GH as a growth-promoting agent in several chronic diseases has been studied extensively. Significant research has been done in CRF, and this indication for GH is now recognized in a number of countries. Not only does long-term GH treatment of these children induce persistent catch-up growth, but if the treatment duration is sufficiently long, it is now recognized that patients will achieve a normal adult height (Fig. 1).

Concomitant administration of glucocorticoids in nephrotic syndrome, for example, is certainly a limitation to the anabolic action of GH when the prednisone dose is greater than 0.3 mg/kg/day.

The use of GH in several other conditions is under investigation. In JIA, for example, short-term GH treatment can improve growth velocity and body composition. Long-term studies are needed to confirm these results. The available data regarding GH therapy in chronic illness are encouraging and should be extended to other conditions where chronic disease and glucocorticoids have a serious impact on growth.

Table I Commonly Used Glucocorticoid Preparations

| Oral | Equivalent adult dose (mg) | Potency | | Relative affinity for glucocorticoid receptor | Half-life (h) |
|--------------------|----------------------------|-------------------|------------------|---|---------------|
| | | Anti-inflammatory | Sodium retaining | | |
| Cortisone | 25.0 | 0.8 | 0.8 | 0.01 | 8–12 |
| Cortisol | 20 | 1 | 1 | 1 | 8–12 |
| Prednisone | 7.5 | 4 | 0.8 | 0.05 | 12–36 |
| Prednisolone | 5 | 4 | 0.8 | 2.2 | 12–36 |
| Methylprednisolone | 4 | 5 | 0 | 11.9 | 12–36 |
| Triamcinolone | 4 | 5 | 0 | 1.9 | 12–36 |
| Betamethasone | 0.75 | 30 | 0 | 5.4 | 36–54 |
| Dexamethasone | 0.75 | 35 | 0 | 7.1 | 36–54 |

| Inhaled/Nasal | Relative vasoconstrictor potency | Half-life (h) | Licensed dose limit ($\mu\text{g}/\text{d}$) | |
|-----------------------------|----------------------------------|---------------|--|-------|
| | | | Inhaled | Nasal |
| Fluticasone propionate | 1.2 | 14.4 | 200 | 200 |
| Budesonide | 1.0 | 2.3 | 800 | — |
| Flunisolide | 0.3 | 2.0 | — | 100 |
| Beclomethasone dipropionate | 0.6 | 15.0 | 400 | — |
| Triamcinolone acetonide | 0.4 | 3.1 | — | 55 |

GENERAL CONSIDERATIONS

Variability in Glucocorticoid Sensitivity

Variability in the sensitivity to glucocorticoids across individuals is illustrated physiologically by the wide range in basal early-morning plasma cortisol concentrations in the normal population and pharmacologically by the response of patients treated with glucocorticoids regarding both efficacy and side effects.

General Influence of Glucocorticoids on the Growth Rate, Bone Maturation, and Final Height

Excess endogenous cortisol and exogenous synthetic glucocorticoids over several weeks or more will lead to impairment of linear growth along with weight gain. The greatest detriment is likely to occur when growth is normally most rapid during the infancy and pubertal phases. The growth impairment is associated with a variable delay in skeletal maturation, and final height attained is influenced by the rate of growth relative to the rate of skeletal maturation. A transient period of impaired linear growth and comparable retardation in bone age favors good “catch-up” growth and attainment of normal predicted adult height. However, a blunted pubertal growth spurt and

permanent stunting may occur with long-term treatment (6 months or longer).

Growth impairment in glucocorticoid-treated children and the potential for catch-up growth are influenced by the duration of treatment, dose, administration regimen, and potency of the glucocorticoid preparation (Table II). In addition, the effects of glucocorticoids may be difficult to distinguish from the natural history of the underlying disease and other disease factors that might adversely affect growth, especially considering that those most severely affected are more likely to receive glucocorticoids.

Table II Approaches to Minimize Adverse Effects of Nonphysiological Doses of Systemic Glucocorticoid Treatment

- Use only for well-established indications.
- Use the lowest possible dose that will control the primary symptoms.
- Avoid prolonged treatment (>3 months).
- Give alternate-day regimen if prolonged systemic treatment is required (growth suppression is likely with cortisone $\geq 30\text{ mg}/\text{m}^2$ daily, prednisone $\geq 4\text{ mg}/\text{m}^2$ daily, betamethasone $\geq 0.6\text{ mg}/\text{m}^2$ daily).
- Use concomitantly with glucocorticoid-sparing agents (e.g., cyclosporin-A for nephrotic syndrome).
- Avoid during infancy and/or puberty.

Concomitant Effects on the Hypothalamic–Pituitary–Adrenal Axis, Body Composition, and Bone Metabolism

In addition to inhibiting linear growth, supraphysiological doses of oral glucocorticoids and high doses of locally administered glucocorticoids can suppress hypothalamic–pituitary–adrenal (HPA) function and may reduce bone mass. It is not clear exactly how these major side effects relate to each other in terms of dose–response and whether different glucocorticoid preparations have the same hierarchy of systemic effects.

GLUCOCORTICOID THERAPY IN SPECIFIC DISEASES

Glucocorticoid Replacement for Abnormal Hypothalamic–Pituitary–Adrenal Axis

Congenital Adrenal Hyperplasia and Glucocorticoid Substitution Treatment

Substitution treatment with glucocorticoids is essential in the management of congenital adrenal hyperplasia (CAH) to suppress excessive hypothalamic corticotropin-releasing hormone (CRH) and pituitary adrenocorticotropic hormone (ACTH) secretion, reduce circulating levels of adrenal androgens, and provide physiological replacement. This is achieved with hydrocortisone (10–15 mg/m²/day in two or three doses, i.e., above the physiological cortisol production rate). Overtreatment, especially during the first 2 years of life, and undertreatment can result in abnormal growth during childhood and in failure to reach adult height potential. Potential future approaches with a reduced hydrocortisone dose or alternative glucocorticoid preparations along with other treatments, such as an antiandrogen (flutamide) or an aromatase inhibitor (testolactone) and luteinizing hormone-releasing hormone (LHRH) agonist with or without growth hormone (GH), may improve growth and adult height in patients with CAH.

Primary Adrenal Insufficiency

The most common cause of primary adrenal insufficiency during childhood is autoimmune disease. Height is below average but not usually less than the 3rd percentile. Growth is normal with adequate replacement, and although the onset of puberty may be delayed, pubertal development is normal.

Familial Glucocorticoid Deficiency (ACTH Resistance)

These autosomal-recessive disorders are characterized by a failure of the adrenal cortex to respond to ACTH but normal mineralocorticoid secretion. Tall stature and advanced skeletal maturation have been described despite glucocorticoid deficiency. Physiological replacement with glucocorticoids allows normal growth.

Hypopituitarism

Deficiency of GH, ACTH, TSH, and gonadotropins contribute to the growth failure and the delayed or lack of pubertal development seen in hypopituitarism. As with other glucocorticoid-deficient states, the lowest dose of hydrocortisone necessary to prevent the symptoms of adrenal failure should be used to avoid suppression of growth.

Pharmacotherapy in Diseases That Do Not Primarily Involve the Hypothalamic–Pituitary–Adrenal Axis

Atopic Diseases

Asthma and Inhaled Glucocorticoid Treatment

Impaired growth and a higher prevalence of short stature in children with atopic disease were reported well before the availability of glucocorticoids (8–25% of children with asthma not treated with glucocorticoids and up to 45% of those treated with daily oral glucocorticoids had a height standard deviation score [SDS] ≤ −2). Independent of glucocorticoid treatment, short stature in children with asthma is associated with delayed bone age, delay in the onset of puberty, and delay in the pubertal growth spurt by approximately 1.3 years. Although the mean adult height attained is normal, up to 20% of those with severe unremitting asthma have final height less than the 10th percentile. The degree of growth impairment is greater in those with more severe asthma and with onset of asthma before 3 years of age.

Inhaled glucocorticoids are the treatment of choice for childhood asthma, and dose–response studies suggest that doses of less than 400 μg/d of any inhaled glucocorticoid are beneficial in controlling symptoms. Higher doses confer little added advantage, but the potential for adverse effects increases dramatically. Lower leg length assessed by knemometry is a highly sensitive measure of the dose-dependent systemic effects of inhaled glucocorticoids over days to weeks (short term) but does not predict longer term growth or final adult height. The potential for linear

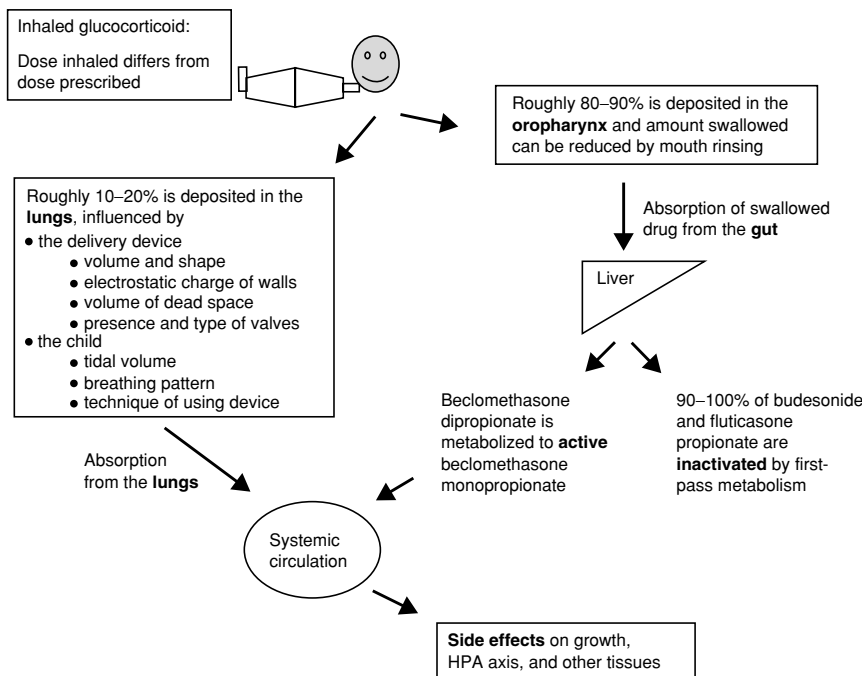

Figure 1 The pharmacokinetics of inhaled glucocorticoids.

growth impairment with inhaled glucocorticoid treatment depends on systemic bioavailability (Fig. 1), which in turn is influenced by the delivery device, inhalation technique, prescribed dose, lipophilicity, pharmacokinetics of the glucocorticoid preparation, and severity of asthma. Randomized controlled trials help to distinguish the effects on linear growth of inhaled glucocorticoid treatment from those of the asthma itself. At doses of at least 400 $\mu\text{g}/\text{day}$, beclomethasone dipropionate suppresses linear growth by approximately 1.5 cm/year but does not necessarily suppress the HPA axis. Although it is advisable to use the minimum dose necessary to control symptoms, undertreatment that compromises asthma control may also impair linear growth. In addition, there is no evidence of impairment in final adult height with prolonged inhaled or intranasal glucocorticoids in recommended doses.

Growth failure associated with increased body fat with centripetal distribution and reduced lean mass indicative of iatrogenic Cushing's syndrome has been reported in patients on high doses of inhaled glucocorticoids. Paradoxically, poor linear growth and poor weight gain associated with endogenous cortisol insufficiency but without these well-known peripheral effects of excess exogenous glucocorticoids have also been described in a small number of children treated with inhaled glucocorticoids.

Chronic Rhinitis and Intranasal Glucocorticoid Treatment

Intranasal glucocorticoids are increasingly being used as a first-line treatment for conditions associated with chronic mucosal inflammation. Systemic effects, including growth impairment, can occur and depend on the dose and duration of treatment. As with inhaled treatment, growth suppression may occur without adverse effects on the HPA axis. It has been observed for lower leg growth and linear growth, for example, with budesonide nasal spray (400 $\mu\text{g}/\text{day}$) and beclomethasone dipropionate (>160 $\mu\text{g}/\text{day}$ for 6 weeks to 12 months) but not with mometasone furoate (100 $\mu\text{g}/\text{day}$). Like fluticasone propionate, mometasone furoate has reduced systemic bioavailability when absorbed from the gut, owing to complete first-pass hepatic metabolism. There are no long-term studies of growth in children treated with intranasal glucocorticoids.

Atopic Dermatitis and Topically Applied Glucocorticoid Treatment

A number of factors influence percutaneous absorption of topically applied glucocorticoids and the potential for systemic effects such as the formulation, method of application, sites treated, and severity of dermatitis. Growth retardation in association with Cushing's syndrome and HPA suppression, with catch-up growth when treatment was stopped or

reduced, has been reported in isolated cases treated with topical glucocorticoids. There are no randomized controlled trials on the systemic effects of topical glucocorticoid treatment in children and, thus, no studies that clearly separate the contribution made by such treatment from other disease factors that might adversely affect growth. Impaired growth in children with atopic dermatitis and a higher prevalence of atopic dermatitis among children with shorter stature than those with normal stature have been reported (up to 10% of children with atopic dermatitis have height <3rd percentile). It is likely that growth in children with atopic dermatitis may follow a pattern consistent with constitutional delay independent of glucocorticoid treatment, as observed in asthma and other chronic diseases. This is supported by observations of deviation of linear growth from normal in prepubertal children with atopic dermatitis, a greater delay in bone age as these children approach the teenage years, and attainment of adult height within the normal range (mean heights of males and females 162 and 175 cm, respectively).

Inflammatory Conditions

Growth failure, influenced by complex disease-related factors, is common in inflammatory conditions such as Crohn's disease and juvenile chronic arthritis. By controlling the inflammatory process in Crohn's disease, glucocorticoid treatment may facilitate growth, and height velocity has been found to increase during treatment and follow-up (from mean -0.8 to 1.0 SDS). However, prolonged systemic glucocorticoid treatment can exacerbate linear growth inhibition, reduce final adult height attained, and alter body composition. For localized disease, topical treatment offers the potential for minimizing adverse effects (e.g., rectal budesonide or hydrocortisone for Crohn's disease, intra-articular triamcinolone hexacetonide for mono or oligoarticular arthritis).

Conditions Requiring Immunosuppression

Prednisolone is the most widely used treatment for nephrotic syndrome. Children with frequently relapsing or steroid-dependent nephrotic syndrome are most likely to have impaired linear growth. Catch-up growth occurs after stopping prednisolone, and final height attained is satisfactory provided that high-dose prolonged maintenance therapy is avoided.

STRATEGIES TO OVERCOME GLUCOCORTICOID-INDUCED GROWTH FAILURE

Short-term trials of recombinant human growth hormone (hGH, 0.32 – 0.47 mg/kg/week for 1–10 years) in children with nephrotic syndrome and juvenile chronic arthritis reveal catch-up growth in the former (mean height SDS -1.4 before treatment and -0.3 after treatment) and prevention of further decline in height in the latter (mean height SDS -4.1 before treatment, with height velocity increasing from 1.9 to 5.4 cm/year during treatment). Serum insulin-like growth factor-I (IGF-I) and IGF binding proteins-3 (BP-3) levels increase during hGH treatment but fall to pretreatment values when treatment is stopped. Treatment with hGH improves growth and final height in chronic renal failure as well as posttransplantation (mean adult height SDS -1.7 in males and -1.3 in females vs pre-hGH treatment height SDS of -3.2 in males and -2.5 in females). For other conditions, long-term studies are required to determine whether pubertal maturation is influenced by hGH or interferes with the growth-promoting effect of hGH and final adult height.

INTERACTIONS BETWEEN GLUCOCORTICOID AND THE GROWTH HORMONE AXIS

The mechanisms that underpin glucocorticoid-induced growth suppression are complex, involving interactions at multiple levels with those hormones that mediate growth. The actions of glucocorticoids are delineated in terms of their effects at the hypothalamic–pituitary level as well as their actions in peripheral growing tissues.

The Growth Hormone Axis

Growth Hormone Secretion

The principal hormonal regulators of childhood growth are GH and thyroxine, with a contribution from sex steroids during puberty. The secretion of GH from pituitary somatotrophs is under complex control, not only from hypothalamic factors (themselves regulated by input from higher cortical centers) but also from negative feedback. GH production and release are regulated positively by GH-releasing hormone from neurons in the arcuate nucleus and negatively by somatostatin from the periventricular

nucleus. A third stimulatory factor has recently been recognized, namely Ghrelin, the endogenous ligand for GH secretagogue receptors, located in the hypothalamus and pituitary. The interplay among these factors leads to the generation of a pulsatile pattern of GH secretion. Approximately half of the GH released into the circulation is bound to a high affinity-binding protein that is homologous to the extracellular domain of the GH receptor. This binding protein appears to be generated by proteolytic cleavage at the cell membrane of the extracellular domain of the GH receptor. The role of GH binding protein (GHBP) to GH action is not clear, but it prolongs the half-life of GH.

GH and IGF-I in Peripheral Tissues

To exert its cellular actions, GH must bind sequentially to two GH receptors to form a trimeric complex. GH receptors are found in high concentration in the liver but are also present in many tissues throughout the body. Of particular relevance to growth are the GH receptors located on growth plate chondrocytes. Activation of GH receptors leads to changes in expression of a range of genes, regulating growth, cell differentiation, and metabolism. One such gene is IGF-I. It is the local production of IGF-I in the growth plate that is most significant to growth. IGF-I binds to its receptor and, like GH, activates signaling pathways that lead to changes in gene expression and ultimately to growth. IGF-I is also present in the circulation, secreted primarily from the liver. Here it associates with a number of specific binding proteins (IGFBPs), most commonly IGFBP-3. It can be transported into tissues, where the local IGFBP milieu is specific to that tissue. Binding proteins can act to enhance or inhibit IGF-I actions.

Glucocorticoid Effects on the GH Axis

The interactions between glucocorticoids and this GH-IGFBP-IGF-I axis are complex. Glucocorticoids can affect all levels of the axis—at the hypothalamus, pituitary, liver, and growth plate—influencing individual components such as the GH receptor, intracellular signaling, the IGF-I gene, the IGF-I receptor, and IGFBP expression. In children treated with potent high doses of glucocorticoids, the net effect is to inhibit growth, generating a state of GH/IGF-I insensitivity. However, not all of these interactions are negative.

Positive Effects of Glucocorticoids

Time of exposure to glucocorticoids is most important in that acute administration can enhance GH secretion. Dexamethasone can also increase liver and growth plate GH receptor expression *in vivo*. Glucocorticoid response elements are found in the promoter region of the GH gene along with thyroid hormone response elements. In fact, glucocorticoids enhance the thyroid hormone effect on GH gene expression. Transgenic mice, overexpressing the GH gene, secrete more GH when treated with glucocorticoids. In addition, the intracellular glucocorticoid-receptor complex interacts with one of a family of signal transducers and activators of transcription (STAT-5) proteins that is activated by GH to enhance the GH effect on STAT-5-dependent gene expression. Therefore, there is an important synergy between glucocorticoids and the GH axis. Glucocorticoids in physiological amounts are important to normal growth, and it is the failure of these positive interactions that may contribute to the growth failure of children with glucocorticoid deficiency.

Inhibitory Effects of Glucocorticoids

However, the dominant clinical effect of high-dose, long-term glucocorticoids is growth suppression. At the hypothalamic level, glucocorticoids increase somatostatin tone. At low concentrations, they enhance GHRH secretion; however, at higher concentrations, they cause inhibition. The overall effect is a reduction in GH release following stimulation with, for instance, GH-releasing hormone or clonidine and attenuation of GH pulse amplitude in physiological GH secretion profiles. At the peripheral level, using rat chondrocytes *in vitro*, dexamethasone reduces GH receptor number and, hence, GH binding. GHBP is also reduced in those chronically treated with glucocorticoids. Growth of rat chondrocytes, both basally and in response to GH or IGF-I, is reduced by dexamethasone. Local IGF-I production in response to GH is lowered by dexamethasone, and a further reduction in the effectiveness of local IGF-I results from a decrease in IGF-I receptor expression.

In the circulation, IGF-I levels do not appear to be consistently altered; however, changes in binding proteins have been identified. In Cushing's syndrome, IGFBP-3 is slightly increased, IGFBP-1 is unchanged, and IGFBP-2 is elevated. In osteoblast cultures, expression of IGFBP-1, -3, -4, and -5 is reduced by glucocorticoid. IGFBP-5 can potentiate IGF-I action in bone; therefore, its reduction may inhibit IGF-I action.

Table III Possible Effects of Chronic Exposure to High-Dose Glucocorticoids on the GH-IGF-I Axis

- GH release from the pituitary gland is reduced, primarily by an increase in somatostatin.
- Chondrocyte GH receptor number is decreased, but a possible increase in hepatic GH receptor may occur.
- GH-binding protein, released into the circulation from proteolysis of membrane-bound GH receptors, is reduced.
- Local tissue IGF-I production is reduced, although circulating levels do not consistently change.
- IGF-BPs in the circulation can be altered.
- IGF-I receptor expression in chondrocytes is reduced.

Glucocorticoids, when present in excess, are acting throughout the GH-IGF axis to suppress growth-promoting activity (see summary of effects in [Table III](#)). Other mechanisms may be contributing. For instance, glucocorticoids down-regulate type I collagen gene expression and up-regulate collagenase 3 expression. Thus, the synthesis of important matrix proteins, necessary for normal skeletal growth and mineralization, and their degradation by proteases are facilitated by glucocorticoids. In addition, effects of glucocorticoids on other local growth factors in bone may contribute to growth failure. Nevertheless, despite this multilevel inhibition, exogenous GH has been used successfully to reverse steroid-induced growth failure.

receptor gene transcription via protein–DNA and protein–protein interactions.

TRANSCRIPTIONAL REGULATORY REGIONS OF GROWTH FACTOR RECEPTOR GENES

Transcription initiation is a key regulatory step in the control of gene expression. Formation of a pre-initiation complex on GC-rich TATA-less promoters involves the interplay of many transcription factors and a combinatorial array of *cis*-regulatory DNA elements. A number of growth factor receptor gene promoter regions have been cloned and sequenced to identify potential transcription factor-binding motifs. Most of them lack consensus TATA- and CCAAT-boxes and are GC-rich in their upstream regulatory region. The rat epidermal growth factor receptor (EGFR), rat transforming growth factor- β type III (TGF- β RIII), and human FGFR3 promoters are 64, 69, and 82% GC-rich, respectively. Structural analyses of the promoters of the human and rat IGF-IR and human TGF- β RIII genes revealed a lack of consensus TATA and CCAAT motifs in the proximal promoter regions. Similarly, the human EGFR, hepatocyte growth factor receptor (HGFR), FGFR1, and FGFR3 gene promoters also lack TATA elements. Some growth factor receptors that lack a TATA-box do contain a functional CCAAT-box. For example, the platelet-derived growth factor β receptor (PDGF β R) promoter contains a functional CCAAT motif located 60 bp upstream from the start of transcription. Similarly, the TGF- β RII promoter contains two CCAAT-boxes at –440 to –444 bp and at –423 to –427 bp.

Many growth factor receptor promoters, whether they contain functional or nonfunctional CCAAT sequences, do contain multiple Sp transcription factor-binding sites in the GC-rich region upstream of their major transcription start sites. Sp transcription factors constitute a family of zinc-finger DNA-binding proteins that regulate a variety of genes involved in cell growth and differentiation. Sp factors bind to the consensus GC-boxes (GGGCGG), which are often located near the transcriptional start site. The human TGF- β RII promoter contains two Sp-binding sites located 25 and 143 bp upstream from the start of transcription. The human and rat IGF-IR promoters contain at least five Sp-binding sites within the proximal 450 bp. Similarly, the human FGFR4 and mouse FGFR3 regulatory regions contain at least five

Sp-binding sites, the majority of which are located within the proximal 100 bp.

In addition to the canonical Sp factor-binding site or GC-box, additional Sp factor-binding sequences have been identified in promoters of growth factor receptor genes. Typically, these sequences are composed of a “GT motif” (GGGTTGTGGC) or they have a homopurine/homopyrimidine motif (CCTCCTCCTCCTCGGCCTCCTCCCC) and constitute a “CT element.” These latter motifs have been identified in IGF-I, EGF, and vascular endothelial growth factor (VEGF) receptor promoters. Such CT elements are also located in the chicken FGFR1 promoter, which is structurally and functionally divided into proximal and distal regions. The distal region is located more than 1 kb upstream from the start of the transcription initiation site. The proximal region contains three Sp1 sites and the distal region contains two Sp1 sites. Mutation of the FGFR1 sequence, CTCCCCTC, located 23 bp upstream from the start of transcription reduced FGFR1 promoter activity in proliferating skeletal myoblasts to basal levels. Electromobility shift and Southwestern blot analyses have confirmed that this site binds the Sp1 transcription factor. In addition, another four Sp factor-binding sites with the sequence, CTGCCC, are also required for maximal FGFR1 promoter activity. Mutation of the two proximal CTGCCC sites at –42 and –54 bp reduced promoter activity by 50 and 79%, respectively. Interestingly, deletion or mutation of either of the two CTGCCC sites located more than 1 kb upstream from the proximal sites also fully abrogated promoter activity. These studies indicate that Sp1 is a key regulatory factor of the chicken FGFR1 promoter.

Several other promoters, such as human TGF- β RII and rat TGF- β RIII, contain CT elements located within 500 bp of the transcription initiation site. Similarly, mouse FGFR2, human IGF-IR, and HGFR promoters also contain these elements within the proximal 25 bp regulatory region. It is likely that the CT elements in these promoters have a function similar to that observed in the chicken FGFR1.

In addition to the multiple Sp sites, activator protein 1 (AP-1) and AP-2 consensus binding sites are also present in the GC-rich region of almost all growth factor receptor promoters, suggesting that these sites are of functional significance. AP-1 and AP-2 factors, composed of *c-fos* and *Jun* subunits, often direct transcription in proliferative cellular response to extracellular signals. For example, the rat TGF- β RIII promoter contains two AP-1-binding sites located at –511 to –480 and –464 to –434 bp and these sites are necessary for activation of the promoter. Nonetheless,

overexpression of AP-2 by transfection did not further stimulate TGF- β RIII promoter activity, suggesting that the endogenous AP-2 may be sufficient for TGF- β RIII expression or that the complex interactions between AP-2 and Sp1 (which is located in close proximity) may govern overall TGF- β RIII expression. Interestingly, human TGF- β RII, chicken FGFR1, VEGFR2, human IGF-IR, HGFR, and mouse and human FGFR3 and FGFR4 promoters also contain AP-1- and AP-2-binding sites in close proximity to Sp-binding sites but their functional importance is poorly understood. Therefore, it seems reasonable to expect that AP-1 and AP-2 may be activators of other growth factor receptor promoters as well and that AP-1/AP-2-mediated promoter activation acts in concert with Sp factor transcriptional activation.

TRANSCRIPTIONAL ACTIVATION OF GROWTH FACTOR RECEPTOR GENES

Transcriptional activation is one of the means of regulating gene expression in many cell types and is governed by complexes of transcription factors. The lack of consensus TATA- and CCAAT-boxes in the majority of analyzed growth factor receptor gene promoters suggests that other DNA-binding sites present in the promoter region and their interactions with site-specific transcription factors are required for basal as well as heightened transcriptional activity. For the few growth factor receptor promoters that do contain consensus CCAAT-boxes, most notably PDGFR α and PDGFR β , these sites bind positive transcription factors. The PDGFR α CCAAT element binds the CCAAT/enhancer-binding protein δ and the TGF- β R CCAAT element binds the nuclear factor Y (NFY) transcription factor. Numerous studies have implicated Sp transcription factors in the positive regulation of promoter activities for these growth factor receptor genes. It has been proposed that such multiple Sp-binding sites and associated protein(s) may stabilize the transcriptional machinery and establish a site of transcription initiation in promoters without TATA elements. Sp1 activates the promoters of TGF- β RI, TGF- β RII, TGF- β RIII, FGFR1–4, IGF-IR, EGFR, and HGFR. Most of these promoters contain 1 to 11 Sp sites in their regulatory region.

Positive transcriptional activity is conferred to the FGFR1 promoter during skeletal myoblast proliferation. Occupancy of an increasing number of Sp sites in the FGFR1 promoter additively increases transcriptional activity. However, the order of

Sp-binding sites in relation to the start of transcription does not necessarily correlate with activity in regulating transcription. The chicken FGFR1 promoter contains three Sp sites in the proximal region, between –60 to –23 bp from the start of transcription. Mutation in the most proximal region (–23 Sp site) abolished promoter activity, indicating that this site confers most of the promoter activity. Mutation of the other two sites also reduced promoter activity to a lesser extent. Moreover, two additional Sp sites located 1 kb upstream from these proximal sites are also required for transcriptional activity of the FGFR1 gene promoter in proliferating myoblasts. These results suggest that Sp1–Sp1 protein interactions may induce looping of the intervening promoter sequences to create protein–protein complexes formed by distant *cis*-elements.

Other members of the Sp family, such as Sp2, Sp3, and Sp4, are also involved in the regulation of growth factor receptor genes. Like Sp1, both Sp3 and Sp4 can bind to GC-box or GT motifs, whereas Sp2 has a much weaker binding affinity for GT motifs. Sp2 and Sp4 often function as transcription activators, whereas the function of Sp3 is highly variable. Sp3 is a bifunctional transcription factor that can either activate or repress transcription. It has discrete domains for both activation and repression and therefore either activates or represses gene transcription depending on the cellular context. For instance, Sp3 augmented Sp1-mediated transcription of the FGFR1 gene promoter in chicken myoblasts. However, Sp3 itself was not able to activate the FGFR1 promoter. Therefore, Sp3 may function as a transcriptional coactivator of growth factor receptor promoters, in particular molecular and cellular contexts defined by the presence and activity of other interacting activators.

In many cases, Sp1 interacts with transcriptional factors other than Sp family members and synergistically activates growth factor receptor gene expression. The mouse TGF- β RIII promoter has been cloned and its sequence showed putative binding sites for Sp1, Smad3, Smad4, myogenic transcriptional regulators such as MyoD and myocyte enhancer factor 2 (MEF2), and retinoic acid receptor within a 2100 bp segment. All these factors are involved in the up-regulation of TGF- β RII gene expression in the mouse myogenic cell line, C₂C₁₂.

Other transcription factors are also involved in the transcriptional activation of growth factor receptor genes and they are mostly found in cancer cells. For instance, the murine TGF- β RII gene promoter contains two conserved Ets-binding sites and mE1f-3, a member of the Ets family, plays a key role in the activation of the promoter in mouse embryonal

carcinoma cells. Similarly, AP-1 binds to at least seven sites in the EGFR promoter region and activates expression of the EGFR gene, which may contribute to cancer cell progression. Transcription factor Pax1 also acts as a transcriptional activator of the PDGFR α gene in differentiated Tera-2 human embryonic carcinoma cells. Many growth factor receptor gene promoters have been analyzed for interactions with Sp1 by site-specific binding assays and functional assays of expressed protein. However, the functional importance of transcription factors other than Sp factors binding to these promoters is poorly understood.

TRANSCRIPTIONAL REPRESSION OF GROWTH FACTOR RECEPTOR GENES

Negative transcriptional regulators also control the expression of growth factor receptor genes for normal cellular function. Identification of negative regulators of growth factor receptor gene promoters has been more elusive than that of positive regulators. Nevertheless, several direct repressors of growth factor receptor promoters have been identified. The transcription factor GC factor (GCF) and its close relative GCF2 have been shown to function as transcriptional repressors of EGFR and IGF-IR promoters. GCF was initially identified as a factor that binds GC-rich elements. Since most of the growth factor receptor promoters are GC-rich, it is possible that GCF-binding sites would exist and repress their gene expression in a variety of cellular contexts.

Most growth factor receptor genes are transcriptionally activated by the Sp1 transcription factor and therefore down-regulation of these genes may occur by direct inhibition of Sp1. In many cancer cells, tumor suppressor genes may act as direct negative regulators by binding to promoter regions of these growth factor receptor genes and reduce transcription, thereby controlling receptor-specific cell signaling and/or cell proliferation. For instance, in prostate cancer cells, Wilm's tumor suppressor 1, a member of the Egr transcription family, directly binds to the IGF-IR promoter region to down-regulate its activity. In addition, Egr-1 itself interacts with an Sp-binding site in the TGF- β RII promoter, causing transcriptional repression, possibly by interfering with Sp1 binding to DNA.

Given the number of Sp transcription factor-binding sites typically located in growth factor receptor promoters, whether GC or CT elements, negative as well as positive regulation may be mediated via these sites. Sp3 is a likely candidate as a transcriptional repressor

interacting with the Sp sites. Though Sp1 and Sp3 share very similar structural features, opposing functions were observed in the regulation of growth factor receptor genes. For example, Sp3 was first considered to be a transcriptional repressor as it interfered with Sp1 binding to the promoter region of TGF- β R. However, other evidence indicates that Sp3 can function as a coactivator with Sp1 in the regulation of the FGFR1 promoter. This dual regulatory capability of Sp3 is due to the presence of a broad activation domain and a more narrowly defined repressor domain, both of which are likely to be selectively functional based on the molecular and cellular contexts of promoter activity. Careful analysis of protein-DNA interactions of Sp-binding sites in other growth factor receptor promoters may further elucidate the role of Sp family members in such dual regulation of transcription.

Other Sp-like transcription factors that bind Sp-binding sites include basic transcriptional elements (BTEB1, BTEB2, and BTEB3), core promoter-binding protein, Krüppel-like factors, and TGF- β -inducible early genes (TIEG1 and TIEG2). These factors compete with Sp factors in binding to the Sp sites of the promoters and either synergistically activate or repress Sp-mediated transcription of many genes involved in cell growth and differentiation. Therefore, further sequence analysis and functional interactions with Sp-like factors involving canonical and noncanonical Sp sites will likely reveal important molecular mechanisms by which growth factor receptor promoters are regulated.

REGULATORY CONTROL OF GROWTH FACTOR RECEPTOR GENES VIA PROTEIN-PROTEIN INTERACTIONS

In normal and cancer cells, growth factor receptor genes are positively and negatively regulated via protein-protein interactions among transcription factors. Positive transcription of the PDGFR β gene occurs via the nuclear factor NFY, which binds to a CCAAT-box located 60 bp upstream of the initiation site. In addition, two Sp1 sites located in close proximity to the CCAAT-box are also essential for synergistic activation of this promoter. Deletion of the two Sp1 sites resulted in 50% reduction of promoter activity and Sp1 overexpression did not increase promoter activity. Furthermore, transfection of NFY failed to enhance transcriptional activity when the Sp1 sites were deleted from the promoter, suggesting an important role for Sp1 sites in NFY-controlled transcription. In contrast, negative regulation of the PDGF β R promoter

also occurs via the NFY transcription factor. C-Myc interacts with NFY and interferes with its binding to the promoter. Other evidence also suggests that the transcription factor p73 (a p53 homologue) represses transcription of the PDGF β R gene by interaction with NFY. Therefore, combinatorial interactions between positive and negative regulatory factors regulate the expression of the PDGF β R gene.

In cancer cells, several transcription factors possessing tumor suppressor activity negatively modulate Sp1-mediated transcription through protein-protein interactions. For instance, BRCA1 (breast cancer 1) repressed the activity of the IGF-IR promoter in a number of breast cancer-derived cell lines. Electromobility shift assay results indicated that BRCA1 did not exhibit any specific DNA binding to the IGF-IR promoter. However, it repressed promoter activity by preventing Sp1 from binding to the promoter. Similarly, promyelocytic leukemia protein interfered with Sp1 binding to DNA and suppressed EGFR promoter activity. In another instance, p53 also repressed Sp1-mediated transcription of IGF-IR in Saos-2 osteosarcoma cells.

Decreased promoter activity of growth factor receptor genes may also be regulated by a reduction in transcriptional activators as cells cease proliferation. As skeletal muscle myoblasts exit the cell cycle and differentiate into multinucleated muscle fibers, FGFR1 gene expression and signaling decline. Simultaneously with cell differentiation, Sp1 and Sp3 protein levels also decline, indicating that regulation of this promoter is highly dependent on the expression and availability of both Sp1 and Sp3. Similar mechanisms of Sp factor deficiency appear to repress growth factor receptor gene expression in several human cancer cell lines. The TGF- β RI promoter in the GEO human colon carcinoma cell line is inactivated due to reduced Sp transcription factors. Therefore, developmentally regulated and cell type-specific expression of these factors can significantly affect growth factor receptor promoter activity and ultimately affect the capacity of cells to proliferate and differentiate.

In conclusion, most studies have indicated that Sp1 is the key regulator of many growth factor receptor genes. Though other Sp-like proteins bind to the same *cis*-elements, how these proteins exert their functions

is not understood. At one level, specificity can follow from tissue-restricted expression. However, not only are a number of these factors expressed in multiple tissues, most cells express more than one factor at a time. As a result, the second level of specificity may occur via differential affinity in DNA binding or via their distinct activation and repression domains that mediate protein-protein interactions. Future studies in the involvement of transcription factors other than Sp1 in the regulation of growth factor receptor genes will provide more insight into the molecular mechanisms that govern the normal expression of these factors and provide potential therapeutic means to prevent disease.

following: (1) in combined pituitary hormone deficiency (CPHD), defects in the genes HESX1, LHX3, PROP1, and PIT1 are found; (2) in isolated GH deficiency (IGHD), there are defects in GH1 and GHRHR; and (3) in GH resistance, there are defects in the genes GHR and IGF-I.

ISOLATED GH DEFICIENCY

Estimates of the frequency of GH deficiency (GHD) range from 1/4000 to 1/10,000 in various studies. The causes of GHD include central nervous system (CNS) insults or defects such as cerebral edema, chromosome anomalies, histiocytosis, infections, radiation, septo-optic dysplasia, and trauma or tumors that affect the hypothalamus or pituitary. Whereas most GHD patients are the only member of their families to be affected, estimates of the proportion of cases that have an affected parent, sibling, or child range from 3 to 30% in different studies. This familial clustering suggests that having a close relative affected conveys substantial relative risk and that a significant proportion of GHD cases may have a genetic basis. The genetic contributions to a series of familial

defects in the GH pathway are discussed in the following sections.

Clinical Features

An intact GH pathway is needed throughout childhood to maintain normal growth. Concomitant or combined deficiencies of other pituitary hormones [luteinizing hormone (LH), follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH), and/or adrenocorticotrophic hormone (ACTH)] in addition to GH deficiency constitute combined pituitary hormone deficiency or panhypopituitary dwarfism. The combination of GH and these additional hormone deficiencies often causes more severe retardation of growth, and skeletal maturation and spontaneous puberty may not occur.

Diagnosis

Short stature, delayed growth, and delayed skeletal maturation occur with GH pathway defects. Since these signs can also be associated with systemic illnesses, individuals suspected of having GHD should be evaluated for systemic diseases before

Figure 1 The growth hormone (GH) biosynthetic pathway (for details, see text).

having complicated tests to detect GHD. Provocative tests for GHD include GH stimulation tests. Deficient GH peak responses range from 7 to 10 ng/ml. Testing for concomitant deficiencies of LH, FSH, TSH, and/or ACTH should be performed on GHD patients to detect CPHD to provide a complete diagnosis and enable planning of optimal treatment.

Types of Familial IGHD

Several types of familial IGHD are associated with at least six different Mendelian disorders. These include four autosomal-recessive disorders (IGHD 1A, IGHD 1B, bioinactive GH defects, and GHRHR defects, OMIM Nos. 262400, 139250, 262650, and 139191, respectively). In addition, there is an autosomal-dominant form (IGHD II, OMIM No. 173100) and an X-linked form of IGHD (IGHD III, OMIM No. 307200; see [Table I](#)).

IGHD 1A

The most severe form of IGHD, called IGHD 1A (OMIM Nos. 262400 and 139250), has an autosomal-recessive mode of inheritance. Affected neonates occasionally have mildly decreased birth lengths and hypoglycemia in infancy. All develop severe dwarfism

by 6 months of age. Although replacement therapy with exogenous GH gives a good initial growth response in individuals with IGHD 1A, this response is often temporary because GH resistance develops due to anti-GH antibodies. IGHD 1A is usually caused by a deletion of the GH1 genes. At a molecular level, these DNA deletions are 6.7, 7.0, or 7.6 kb in length, with approximately three-quarters of the deletions measuring 6.7 kb. DNA sequence analysis of the fusion fragments associated with these recurring deletions has shown that the deletions arise from homologous recombination between repeated sequences that flank the GH1 gene. Multiple studies indicate that ~15% of individuals with severe IGHD (>4.5 SD in height) have GH1 gene deletions. Since gene deletions as well as frameshift and nonsense mutations have been found to cause the IGHD 1A phenotype, this disorder is best described as complete GHD due to heterogeneous GH1 gene defects, rather than gene deletions alone (see [Table I](#)).

IGHD 1B

A milder form of IGHD, IGHD 1B, also has an autosomal-recessive mode of inheritance. These cases differ clinically from IGHD 1A in their having low but detectable levels of GH and a continued growth response due to immunological tolerance to treatment with exogenous GH. IGHD 1B cases are caused by GH gene defects that result in a mutant GH protein that may not be detected by radioimmunoassay (RIA). The presence of these mutant GH protein molecules may explain the good responses that are seen with GH therapy because their presence mitigates against the production of anti-GH antibodies. IGHD 1B is caused by mutations that affect splicing of the GH1 gene. This altered splicing causes loss of amino acids that affect the stability and biological activity and reduce the secretion of the mutant GH protein.

IGHD II

IGHD II has an autosomal-dominant mode of inheritance due to dominant-negative mutations of the GH1 gene and patients respond well to GH treatment. Almost all the GH1 gene defects reported in IGHD II are mutations that alter the splicing of GH mRNA and cause skipping or deletion of exon 3. The mechanism by which these dominant-negative mutations prevent expression of GH protein from the other, normal GH1 gene is poorly understood. Other IGHD II mutations cause skipping of exon 3 by disrupting splicing enhancer sequences (SEs) that regulate the splicing pattern of GH mRNA and, when these SEs are perturbed, exon 3 skipping occurs. An

IGHD II mutation that does not cause abnormal splicing is a G-to-A transition that results in an Arg to His substitution at residue 183 (Arg183His) of the GH molecule. This substitution is thought to alter the intracellular processing of the GH molecule by binding to zinc, thereby deranging the zinc-associated presecretory packaging of GH.

IGHD III

A third form of IGHD called IGHD III (OMIM No. 307200) has an X-linked mode of inheritance and there have been distinct clinical findings in different families. In some families, all cases have agammaglobulinemia associated with their IGHD, whereas in other families, all cases have only IGHD. This suggests that contiguous gene defects on the long arm of the X chromosome may cause some IGHD III cases. Duriez *et al.* reported that X-linked agammaglobulinemia and IGHD are caused by a mutation in the Bruton's tyrosine kinase (BTK) gene.

Laumonier *et al.* studied the SOX3 gene in families with X-linked mental retardation, where the causative gene had been mapped to Xq26-q27. They showed that the SOX3 gene maps to Xq26.3 and was involved in a large family in which affected individuals had mental retardation and IGHD (OMIM Nos. 300123 and 313430; Table I). The mutation was an in-frame duplication of 33 bp encoding 11 alanines in a polyalanine tract of the SOX3 gene. The expression pattern during neural and pituitary development suggested that dysfunction of the SOX3 gene caused by this polyalanine expansion might disturb transcription pathways and the regulation of genes involved in pituitary development.

Biodefective GH

There have been a number of reports of patients with the clinical features of IGHD who achieved normal plasma immunoactive GH levels following GH provocative or stimulation tests, but low levels of somatomedin (OMIM No. 139250; Table I). Less GH was detected by radioreceptor assay than by RIA analysis in some studies. In view of these patients' clinical syndrome of IGHD, their apparently normal plasma concentrations of GH, their low basal somatomedin levels, and their normal response to exogenous GH, individuals with bioinactive GH are thought to secrete a biologically inert GH. Takahashi *et al.* identified a C-to-T transition at codon 77, which results in an Arg to Cys substitution in the GH1 gene of a subject diagnosed with bioinactive GH.

GHRH Receptor Defects

A variety of mutations have been detected in the human GHRHR gene in individuals with IGHD (OMIM No. 139191). In a kindred with a nonsense mutation, affected family members had poor growth since infancy and were extremely short. They failed to produce GH in response to standard provocative tests and had good responses to GH replacement. Cases were homozygous for a G-to-T transversion that caused a premature termination mutation (Glu72Stop). Salvatori *et al.* described a large Brazilian family with many family members with IGHD due to an intronic G-to-T transition that destroys the 5' splice site of IVS1 of the GHRHR gene.

COMBINED PITUITARY HORMONE DEFICIENCY

Cases with CPHD vary in their clinical findings because they have deficiencies of varying severity of one or more of the other pituitary tropic hormones (ACTH, FSH, LH, or TSH) in addition to GHD (OMIM No. 262600). Whereas most cases of CPHD are sporadic, a variety of familial forms that can have autosomal-recessive, autosomal-dominant, or X-linked modes of inheritance are known.

HESX1 Mutations

HESX1 is expressed in the thickened layer of oral ectoderm that gives rise to Rathke's pouch, the primordium of the anterior pituitary. Down-regulation of HESX1 coincides with the differentiation of pituitary-specific cell types. Dattani *et al.* found a missense HESX1 mutation (Arg53Cys) in a homozygous state in a brother and sister with septo-optic dysplasia, agenesis of the corpus callosum, and CPHD (OMIM No. 182230).

LHX3 Mutations

Murine Lhx3 mRNA accumulates in Rathke's pouch, the primordium of the pituitary, and may be involved in the differentiation of pituitary cells. Netchine *et al.* identified two families with CPHD (OMIM No. 262600) caused by mutations in the LHX3 gene. The phenotype associated with these mutations included the following: (1) severe growth retardation, (2) complete deficiency of all but one of the anterior pituitary hormones (ACTH), (3) elevated and anteverted shoulders with a short neck associated with severe restriction of rotation of the cervical spine, and (4) an

enlarged anterior pituitary. The authors concluded that LHX3 is required for the proper development of all anterior pituitary cell types except corticotropes and that the rigid cervical spine phenotype is consistent with a function of LHX3 in the proper development of extrapituitary structures as well.

PIT1 Mutations

Defects in the PIT1 gene cause familial CPHD cases, which have a different phenotype (OMIM No. 173110). PIT1 is an anterior pituitary-specific transcription factor that regulates the expression of GH, prolactin (PRL), and TSH. PIT1 is also required for pituitary cellular differentiation and function. PIT1 has functional domains that enable the transactivation of other genes including GH, PRL, and TSH or binding to these genes. At least six different PIT1 mutations causing autosomal-recessive CPHD and two others causing autosomal-dominant CPHD have been found in humans in a subtype of panhypopituitary dwarfism associated with GH, PRL, and TSH deficiency (see [Table I](#)).

PROPI Mutations

PROPI is a pituitary-specific homeodomain factor that is required for the development of somatotropes, lactotropes, and thyrotropes of the anterior pituitary and for the expression of PIT1. Multiple PROPI gene mutations cause an autosomal-recessive CPHD that has a third phenotype in humans (OMIM No. 601538; [Table I](#)). In addition to deficiencies of GH, PRL, and TSH that are seen in those with PIT1 defects, subjects with PROPI defects also have deficiencies of LH and FSH, which prevent the onset of spontaneous puberty and, in some cases, ACTH deficiency in later life. The various PROPI mutations include (1) a C-to-T transition at codon 120, which encodes a TGC (Arg) to CGC (Cys) substitution; (2) a T-to-A transversion that encodes a TTC (Phe) to ATC (Ile) substitution at codon 117; and (3) a 2 bp AG deletion in codon 101 (101delAG) that causes a frameshift and results in a premature stop at codon 109. The resulting protein products from all three of these different PROPI mutations have greatly reduced DNA-binding and transactivation abilities. The 101delAG is a recurring mutation that is estimated to occur in 55% of familial and 12% of sporadic CPHD cases. A fourth PROPI mutation is a 2 bp GA deletion at codon 51 (51delGA). Like the 101delAG mutation, the 51delGA mutation causes a frameshift that results in a premature stop codon.

This mutation was found in 12% of familial and 21% of sporadic CPHD cases.

X-Linked CPHD

Lagerstrom-Fermer *et al.* described a family that included affected males suffering from variable degrees of CPHD (OMIM No. 312000). Some affected males who died during the first day of life had postmortem findings of hypoadrenalism, presumed to be due to CPHD. Others had variable combinations of hypothyroidism, delayed pubertal development, and short stature due to GHD. All surviving patients exhibited mild to moderate mental retardation. They found linkage with markers in the Xq25–q26 region. Furthermore, they found an apparent extra copy of the marker DXS102 in affected males and heterozygous carrier females, suggesting that a segment including this marker was duplicated.

MENDELIAN DISORDERS WITH ENDOCRINE ABNORMALITIES

A variety of Mendelian disorders have among their pleiotropic effects endocrine abnormalities. These disorders include some abnormalities, such as achondroplasia, that have a single common mutation and others, such as hemoglobinopathies, that are caused by heterogeneous mutations.

Achondroplasia with Obstructive Sleep Apnea

Achondroplasia is a common skeletal dysplasia in which the dwarfism is due to an abnormality in endochondral ossification (see OMIM No. 100800; [Table I](#)). Up to 10% of patients with achondroplasia have been reported to have serious respiratory complications. Some with achondroplasia and obstructive sleep apnea have low growth hormone secretion during sleep as a contributing cause of their growth retardation.

Borjeson-Forssman-Lehmann Syndrome

The X-linked Borjeson-Forssman-Lehmann syndrome is characterized by short stature, hypogonadism, hypotonia, severe mental deficiency, and coarse facial appearance with a prominent brow ridge and large ears in affected males (see OMIM No. 301900; [Table I](#)). Markedly deficient GH responses to arginine and L-DOPA as well as low somatomedin C levels have been documented in affected individuals.

CHARGE Association

CHARGE is an acronym that describes a nonrandom association of anomalies: *colobomas* of the eye; *heart* disease; *atresia* of the choanae; *retarded* growth and development and/or CNS anomalies; *genital* hypoplasia; and *ear* anomalies or deafness (see OMIM No. 214800; [Table I](#)). Growth retardation, which is usually of postnatal onset, and hypogonadism are prominent features of the CHARGE syndrome and may well be due to hypothalamic defects.

Fanconi Anemia

Fanconi's syndrome is an autosomal-recessive disorder characterized by chronic pancytopenia with bone marrow hypoplasia, abnormal pigmentation, upper limb malformations, kidney anomalies, growth retardation, small genitalia, and increased frequency of chromosomal breaks in cultured lymphocytes (see OMIM Nos. 227650, 227660, 227645, 227646, and 600901; [Table I](#)). A number of investigators have documented GH deficiency in patients with Fanconi anemia and administration of GH resulted in excellent short-term and long-term responses in most of these patients.

Hemochromatosis

Both male hypogonadism and pituitary hemosiderosis can occur in hemochromatosis (see OMIM Nos. 235200 and 602390; [Table I](#)) and abnormalities have also been found in gonadotropin, cortisol, GH, PRL, and TSH secretion.

Hemoglobinopathies

There are well-documented cases of acquired pituitary insufficiency occurring in adults with hemoglobinopathies, presumably secondary to infarction of the gland (see OMIM No. 141900; [Table I](#)).

Histiocytosis X

Histiocytosis X (also known as Letterer-Siwe disease, Hand-Schuller-Christian disease, or eosinophilic granuloma) is characterized by foamy histiocyte infiltration in many areas of the body, including the hypothalamus. When the histiocytic infiltration involves the hypothalamus, prepubertal growth retardation associated with GH deficiency and diabetes insipidus frequently occur (see OMIM No. 246400; [Table I](#)).

Neurofibromatosis Type I

A variety of endocrine disturbances have been reported in patients with neurofibromatosis, which has an autosomal-dominant mode of inheritance (see OMIM No. 162200; [Table I](#)). The most common associated endocrine disorder in children with neurofibromatosis type 1 (NF1) is sexual precocity, whereas the most common associated endocrine disorder in adults is pheochromocytoma. Marked growth retardation and GH deficiency have also been reported.

Pallister-Hall Syndrome

This neonatally lethal malformation syndrome consists of hypothalamic hamartoblastoma, hypopituitarism, postaxial polydactyly, and imperforate anus (see OMIM No. 146510; [Table I](#)). An anterior pituitary gland was absent in all cases. The posterior pituitary was absent in the majority of cases.

Rieger's Syndrome

Rieger's syndrome (also known as iris-dental dysplasia) is an autosomal-dominant disorder associated with malformation of the iris, pupillary anomalies, and hypoplasia of the teeth, with or without maxillary hypoplasia. A large family in which multiple individuals had both Rieger's syndrome and IGHD (see OMIM No. 180500; [Table I](#)) has been described. Siblings of the proband had Rieger's syndrome with normal pituitary function, but GHD was not found in any member of the family who did not have Rieger's syndrome. One subject who was treated with GH exhibited substantial enhancement of his rate of growth.

CHROMOSOMAL DISORDERS WITH ENDOCRINE ABNORMALITIES

A large variety of chromosomal abnormalities are associated with endocrine disorders. These chromosomal anomalies can affect a variety of autosomes as well as the sex chromosomes.

Autosomal

GH deficiency has been described with 18p- and 20p- chromosomal deletions (see OMIM No. 146390; [Table II](#)). In addition, molecular detection of deletions of 17q (i.e., the GH gene cluster region) has been documented in IGHD IA. Since the gene for

GHRH has been mapped to 20p, the GH deficiency in 20p– could result from either the deletion of the GHRH gene or a developmental anomaly of the hypothalamus. Patients with 18p– have been reported with hypopituitarism and solitary central maxillary incisor, suggesting that the pituitary insufficiency in 18p– may be due to a structural malformation of the hypothalamus. GHD has been rarely associated with 47,XXY, 49,XXXXY, and ring 5. Finally a search of the London Dysmorphology Database at <http://www.hgmp.mrc.ac.uk/DHMHHD/view.html> identifies a series of partial chromosome deletions or duplications that are associated with short stature and pituitary abnormalities (see Table II). These include the deletions del(4)pter–p16, del(7)q32–qter, del(13)q22–qter, del(14)q22–q23, del(18)p, del(18)q21–qter, and del(22)pter–q11 and the duplications dup(1)q25–q32, dup(9)p, dup(9)pter–q22, and dup(11)q23–qter.

Turner's Syndrome (45,X)

Although GH secretion has been reported to be normal, or paradoxically increased, in most patients with gonadal dysgenesis, pituitary insufficiency has been reported in several patients (see Table II). Ross *et al.* studied GH secretion in 30 patients with Turner's syndrome and found no differences in mean GH concentration or peak amplitudes throughout the day and night between patients less than 8 years of age and controls. Patients over 9 years of age had lower

mean GH levels and peak amplitudes. Reduced plasma somatomedin C levels and delayed bone age were found in patients of all ages. These abnormalities in GH secretion in Turner's syndrome are probably secondary to the absence of sex hormones during adolescence.

TREATMENT OF PITUITARY GENE MUTATIONS

Recombinant-derived GH is widely available but must be given by subcutaneous injection. To obtain an optimal outcome, children with GHD should be started on replacement therapy as soon as their diagnosis is established. The dosage increases with increasing body weight to a maximum during puberty and is usually discontinued by ~17 years of age. Disorders in which GH treatment is of proven efficacy include GHD, either isolated or in association with CPHD, and Turner's syndrome. The clinical responses of individuals with IGHD or CPHD to GH replacement therapy vary depending on (1) the severity and age at which treatment is begun, (2) the recognition and response to treatment of associated deficiencies such as thyroid hormone deficiency, and (3) whether treatment is complicated by the development of anti-GH antibodies. The outcome of Turner's syndrome subjects varies with the severity of their (1) short stature, (2) chromosomal complement, and (3) age when treatment began.

Table II Chromosomal Disorders with Growth Hormone Deficiency

| Disorder | Cytogenetic change | Endocrine features | Comments |
|-----------------|--|--|--|
| Autosomes | | | |
| Deletions | del(4)pter–p16 del(7)q32–qter del(13)q22–qter, del(14)q22–q23 del(18)p del(18)q21–qter del(20)p del(22)pter–q11 | Pituitary abnormalities with decreased GH, CPHD, or other deficiencies | Replace appropriate hormone(s) |
| Duplications | dup(1)q25–q32 dup(9)p dup(9)pter–q22 dup(11)q23–qter | Pituitary abnormalities with decreased GH, CPHD, or other deficiencies | Replace appropriate hormone(s) |
| Rings | Ring 5 | Decreased GH or CPHD | Replace appropriate hormone(s) |
| Sex chromosomes | 45,X 47,XXY 49,XXXXY | Decreased GH or CPHD | Replace appropriate hormone(s); GH & estrogen for 45,X |

GH ISOFORMS

Several molecular forms of hGH exist. The most abundant form (except during pregnancy) is pituitary GH-1, also known as GH-N or 22-kDa GH. GH-2 (also known as GH-V or placental GH) differs from pituitary GH-1 at 13 of the 191 amino acid residues. In addition, GH-2 contains an N-linked glycosylation site, and indeed, GH-2 exists as both a glycosylated and a nonglycosylated form. During pregnancy, placental GH progressively supplants pituitary GH in the maternal circulation. The *GH-1* gene also generates an internally deleted GH (lacking 15 internal amino acids and named 20-kDa GH) through alternative mRNA splicing. A secondary splice site within exon 3 is used for that purpose. This 20-kDa variant accounts for 5 to 10% of GH production. A second postulated splice variant arises from complete exon 3 skipping, owing to the relatively weak splice donor site in intron 3. Although the mRNA for this so-called 17.5-kDa GH has been demonstrated, it is not entirely clear whether the corresponding protein is produced in significant amounts in normal individuals. Additional GH molecular variants arise from posttranslational processing. These include glycosylated (especially placental GH), acetylated, deamidated, and (in some animals) phosphorylated GHs. Further molecular heterogeneity results from oligomeric GH forms (up to at least pentameric GH), with both noncovalently associated oligomers and disulfide-linked oligomers. The biological roles of the GH variants are largely unknown. They vary in biological activity, with 22-kDa GH-1 and GH-2 being the most biologically active.

REGULATION OF GH PRODUCTION AND SECRETION

Expression of the *GH-1* gene in pituitary somatotropes is positively regulated by GH-releasing hormone (GHRH), glucocorticoids, and (in rodents) thyroid hormones. It is negatively regulated by insulin-like growth factor-1 (IGF-1) and somatostatin. GHRH is also very important for normal somatotrope cell proliferation during pituitary development. GH is stored in secretory granules and released in response to GHRH; its release is inhibited by somatostatin. Ghrelin or related GH secretagogues, in pharmacological amounts, are potent releasers of GH, but the physiological role of ghrelin in GH regulation appears to be minor at best. The various GH isoforms appear to be cosecreted, and no isoform-specific stimulus has been identified.

GH secretion is under complex hypothalamic control by at least two hypophysiotropic hormones: GHRH (stimulating) and somatostatin (inhibitory). Secretion is pulsatile, with a marked ultradian rhythm of pulses of widely varying amplitude occurring every 1 to 2 h. The highest secretory pulses are linked to slow wave sleep and typically occur during the first 2 h after sleep onset. However, major pulses can also occur at other times due to stimuli such as stress, exercise, pain, and other acute events. Feedback inhibition of GH secretion is provided by IGF-1 as well as by GH itself. Daily GH production is high and largely unregulated during fetal and neonatal life, falls after birth under the regulatory influence of IGF-1, is again high during puberty, and falls progressively thereafter by about 15% per decade. Physiological and metabolic regulators of GH secretion are nutrition, estrogen (stimulatory), glucocorticoids (the inhibitory effect at the hypothalamic level predominates over the stimulatory effect at the pituitary level), and thyroid hormone (stimulatory, especially in rodents). In humans, undernutrition stimulates GH production, whereas overnutrition dampens GH production (the opposite is generally true in rodents). There is marked sexual dimorphism in the GH secretory rhythm, with women showing generally higher values, higher basal secretion, and more “noisy” circadian profiles. This difference can be largely attributed to an estrogen effect. In rats, the male secretion pattern is characterized by very high pulses interrupted by nearly complete quiescence, whereas the female secretion pattern is characterized by lower pulses but higher tonic secretion between pulses.

In contrast to this complex regulation of GH production in the pituitary gland, the expression and secretion of placental GH during pregnancy appear to be constitutive and largely unregulated.

BLOOD TRANSPORT OF GH

GH circulates in blood partly bound to two GH-binding proteins (GHBPs). The principal carrier is the high-affinity GHBP that corresponds to the soluble ectodomain of the GH receptor (GHR). In humans and many other species, the GHBP is produced by proteolytic cleavage of the GHR in its juxtamembranous stem region by a metalloproteinase(s) of the ADAM family (TACE = TNF- α -converting enzyme and perhaps other ADAMs), with shedding of the ectodomain from the cell as the GHBP. In rodents, the GHBP is generated from the GHR gene as an alternative mRNA splice product. Under basal conditions, approximately half of circulating

GH is bound to this GHBP. A minority of GH (~5%) is bound to another, low-affinity GHBP that appears to correspond to a modified form of α_2 -macroglobulin. The GHBPs prolong the plasma half-life of GH and act to provide a circulating GH reservoir. In addition, the high-affinity GHBP is a modulator of GH action at the cellular level. The plasma half-life of GH in humans is 15 to 20 min and is eliminated primarily through glomerular filtration and GHR-mediated clearance.

THE GHR AND GH SIGNAL TRANSDUCTION

The GHR is a 620-amino acid single-chain glycoprotein that belongs to the family of cytokine receptors. It has a large, 246-residue extracellular domain, a single-transmembrane domain, and a 350-amino acid cytoplasmic domain. The ectodomain is folded into two subdomains; the amino-terminal subdomain 1 contains the GH-binding site, and the carboxy-terminal subdomain 2 is involved in receptor dimerization. A short (~10 residue) linear stem region between subdomain 2 and the transmembrane domain serves as the substrate for cleavage by TACE to yield the GHBP. The cytoplasmic domain contains several features involved in hormone signaling. Among those, a membrane-proximal proline-rich region (Box 1) is most important; it serves as a docking site for Janus kinase 2 (Jak 2). Another important region in the cytoplasmic portion is the internalization domain.

The single *GHR* gene resides on the short arm of human chromosome 5 (5p13–p12), spans more than 156 kb, and consists of at least 10 exons, of which exons 2 to 10 encode the protein. The 22-residue portion encoded by exon 3 is not necessary for function, and inclusion or exclusion of exon 3 occurs as a form of *GHR* polymorphism. Several alternative exons 1 can be used to express the GHR in a tissue- or metabolic state-specific manner. They are only incompletely characterized. Two truncated splice variants of the GHR are known; they lack most of the cytoplasmic domain, represent a small part (~1–5%) of the total GHR complement, and have an unknown function. The GHR is expressed ubiquitously, although the level of expression varies among tissues. The liver is the tissue with the highest GHR content.

GH binding to the GHR results in GHR dimerization as two GHRs associate sequentially with the two binding sites on GH. (Some evidence also suggests that the GHR is predimerized and then conformationally changed by GH binding.) GHR

dimerization is followed by initiation of a signal transduction cascade by recruitment of Jak 2 to the GHR cytoplasmic domain and phosphorylation of both Jak 2 and the GHR. Following this initial step, several downstream signal transduction pathways are activated. They include, most prominently, the Jak–Stat (especially Stat 5b) pathway, but also the mitogen-activated protein (MAP) kinase pathway, the insulin receptor substrate (IRS)/phosphatidylinositol 3-kinase (PI3K) pathway, the phospholipase C (PLC)/protein kinase C (PKC) pathway, and probably other signaling pathways. A detailed discussion of these signaling cascades is beyond the scope of this article. The various pathways may subserve different components of the GH bioactivity spectrum. For example, the growth-promoting/IGF-1-generating action is principally mediated by signaling through the Jak–Stat pathway, whereas some metabolic activities are mediated by signaling through PI3K. A whole host of genes are activated in response to GH signaling. Among those best recognized are serine protease inhibitor 2.1 (Spi 2.1), c-Fos, and IGF-1. GH signaling also has nongenomic effects in the cell, such as enhanced glucose transport.

GH signaling is negatively regulated by several mechanisms to prevent runaway cellular stimulation, with some acting in a classic feedback loop. Among the factors inhibiting GH signaling once it has started are induction of SOCS (suppressors of cytokine signaling) proteins and CIS (cytokine-inducible SH2 protein), activation of phosphatases, GHR down-regulation through GHR internalization, and perhaps GHR inactivation by proteolytic GHR decapitation/GHBP shedding.

The GHBP, in addition to its role in the circulation, acts as a local modulator of GH action by competing with GHRs for ligand and probably by forming biologically unproductive GHR/GHBP dimers at the cell surface. Thus, at the local tissue level, GHBP acts primarily as an inhibitor of GH action.

BIOLOGICAL ACTIONS OF GH

Many, but not all, of the activities of GH are mediated by its second messenger, IGF-1. IGF-1 is generated in response to GH in liver and many other target tissues. It is primarily responsible for the growth-promoting action, serving as both a mitogen and a metabolically active hormone. For some GH actions, it is still not clear whether they are mediated by IGF-1, by GH directly, or by both. [Table I](#) lists the principal bioactivities of GH. The protean and diverse manifestations of GH action are evident from the table. All

Table 1 Biological Activities of GH

| |
|--|
| A. Direct GH effects |
| Lipolysis |
| Prechondrocyte differentiation |
| Preadipocyte differentiation |
| Amino acid transport in muscle |
| Glucose transport (acute hypoglycemic effect, so-called “insulin-like effect”) |
| IGF-1 generation, IGFBP3 and ALS generation |
| Hypothalamic somatostatin secretion (short-loop feed back) |
| Milk production (human GH only) |
| B. IGF-1 mediated effects |
| Sulphate and thymidine incorporation into growth cartilage |
| Clonal expansion of chondrocytes |
| Linear bone growth |
| DNA and RNA synthesis |

| C. Unknown or combined GH/IGF-1 effects |
| Nitrogen retention |
| Somatic growth ^a |
| Insulin antagonism |
| Beta cell hyperplasia |
| Erythropoiesis |
| Immune system stimulation |

^aSomatic growth involves not only bone elongation, but also concomitant muscle and organ growth. Somatic growth is possible with IGF-1 alone, but differs both quantitatively and qualitatively from that induced by GH.

tissues and organs are targets for GH action; hence, the term “somatotropin” describes this hormone more aptly than does the term “growth hormone.” The most prominent net effects of GH actions *in vivo* are somatic growth, loss or maintenance of fat mass, muscle anabolism, increase or maintenance of bone mineral density, and insulin antagonism.

IGF-1 AND IGF-BINDING PROTEINS

IGF-1 and the related IGF-2 are 70- and 67-amino acid, proinsulin-like polypeptides of about 7.5 kDa, respectively, that are induced by GH (IGF-1 and IGF-2) and mediate many of the GH actions. IGF-1, rather than IGF-2, is the principal player in the GH-IGF axis. Circulating IGFs are bound to six IGF-binding proteins (IGFBPs). Foremost among those is IGFBP3, which complexes the great majority of IGFs in a 150-kDa ternary complex composed of IGF, IGFBP3, and another protein called acid-labile subunit (ALS). Both IGFBP3 and ALS are GH inducible and GH dependent. The ternary complex acts to

retain IGFs in the circulation, thereby prolonging their half-life (~20 h) and modulating their access to tissues and *in vivo* bioactivity. The other IGFBPs bind smaller amounts of IGFs and are of lesser importance as IGF transport proteins. They play a role in local regulation of IGF action in tissues. IGFBP1 is inversely regulated by insulin (i.e., insulin down-regulates IGFBP1) and acts as a circulating inhibitor of IGF action by complexing IGFs. IGF-1 acts through its own receptor (the type 1 IGF receptor), which is structurally related to the insulin receptor and expressed widely.

DISEASE STATES WITH ABNORMALITIES IN THE GH-IGF AXIS

GH Deficiency

GH deficiency can result from a variety of causes such as genetic defects, birth trauma, and organic lesions affecting the pituitary or the hypothalamus. The most common cause is a pituitary or hypothalamic tumor resulting in destruction of somatotropes or GHRH-producing neurons as well as interruption of hypothalamo-pituitary communication. In patients with pituitary tumors, GH deficiency usually develops before the other pituitary hormones are compromised. Genetic causes include inactivating mutations in the *GH-1* gene, the *GHRH receptor* gene, or genes involved in pituitary development such as *PROP-1*, *PIT-1*, *HESX1*, *PITX2*, *LHX3*, and *LHX4*. One relatively common type of GH deficiency is called “idiopathic,” meaning that no cause is evident. In general, this is a diagnosis of exclusion in a child with poor growth and subnormal serum GH levels. The delineation between this entity and normal variation of growth patterns is difficult.

The clinical manifestations of GH deficiency depend, in part, on whether it develops during childhood or during adult life. Childhood GH deficiency is characterized by growth retardation, a feature that does not apply to adults. Other clinical manifestations of GH deficiency include moderately delayed puberty, childhood hypoglycemia, increased adiposity (especially visceral fat), osteopenia, decreased lean body mass, low exercise tolerance and stamina, extracellular volume depletion, impaired psychosocial functioning, and decreased quality of life. In humans, immune function is not sufficiently affected to be clinically relevant. Except for growth retardation and hypoglycemia, the manifestations of GH deficiency are relatively subtle and not readily recognized unless sought out specifically. Diagnosis is suspected in the proper

clinical setting and is confirmed by the failure of serum GH to rise in response to standard pharmacological stimuli. Typical biochemical features include low levels of serum IGF-1, IGFBP3, and ALS as well as an elevated level of IGFBP2. Treatment consists of replacement therapy with recombinant GH.

Deficiency of the placental GH appears to have no adverse effects on either mother or fetus, as has been learned from naturally occurring cases with a deletion of the *GH-2* gene.

GH Insensitivity

GH insensitivity or resistance shows a clinical picture that is similar, although not identical, to GH deficiency. There is no shortage of GH; rather, there is inability of GH to act. In its most extreme form, GH insensitivity is a genetic syndrome (Laron syndrome) caused by inactivating mutations in the *GHR* gene. Patients show all of the physical manifestations of GH deficiency, but serum GH levels are high, while IGF-1, IGFBP3, and ALS levels are low. In most, but not all, cases, the serum GHBP level is low or undetectable (the type of mutation in the GHR determines the presence or absence of GHBP). The phenotype is one of complete absence of GH activity and resembles that of patients with the most severe degrees of GH deficiency. Diagnosis is suspected in the proper familial setting by measuring serum GH, IGF-1, and GHBP; it is usually confirmed by genetic analysis. A unique form of GH insensitivity was reported in a single patient who carried a partial deletion of the *IGF-1* gene. Treatment consists of IGF-1 replacement therapy.

A mild to moderate form of acquired GH resistance is frequently seen in catabolic states. This appears to be an adaptive response, with low serum IGF-1 and elevated GH levels. The nutritional deprivation that frequently accompanies such conditions explains part, but not all, of this phenomenon. This is a reversible derangement in the GH-IGF axis that returns to normal when the underlying disease process is corrected. Treatment with GH is not recommended because GH therapy, in severe cases of illness, has been associated with increased mortality. However, one partially GH-resistant condition where GH treatment is beneficial is chronic renal failure.

GH Excess

Overabundance of GH secretion leads to a condition called acromegaly in adults. When it occurs during

childhood, it leads to gigantism. In the latter case, overall somatic growth is accelerated; in the former case, there is only acral overgrowth in hands, feet, and facial structures. The condition is typically caused by a GH-producing pituitary adenoma. At least half of these adenomas have somatic mutations in the $G_s\alpha$ -subunit of the signal-transducing G protein. (GHRH normally signals through this pathway.) The mutation renders the G protein constitutively active and leads to tumor formation and unchecked GH production. A germ line variant of this type of G-protein activation is seen in McCune-Albright syndrome, which has as one of its manifestations the occurrence of acromegaly. In rare cases, acromegaly can be caused by overproduction of GHRH, either by a eutopic source (e.g., a hypothalamic lesion) or (more frequently) in an ectopic site by tumors of neuroendocrine lineage (e.g., carcinoids, islet cell tumors). The high levels of systemic unregulated GHRH lead to somatotrope hyperplasia and GH overproduction. Only one convincing case of ectopic production of GH itself—by an islet cell tumor—has been reported. The clinical aspects of acromegaly include soft tissue swelling and bony overgrowth in hands and feet, prognathia and frontal bossing, dental malocclusion, a general coarsening of facial features and body habitus, general organomegaly, hypertension, carbohydrate intolerance or diabetes mellitus, and increased cardiovascular morbidity and mortality. The diagnosis is typically delayed because of the insidious onset of clinical signs. Biochemical findings include increased serum GH and IGF-1 levels. The diagnosis is supported by demonstrating a pituitary tumor and confirmed by showing that serum GH is not normally suppressible by administration of glucose (an oral or intravenous glucose tolerance test). In cases of ectopic GHRH production, a high GHRH level in peripheral blood is diagnostic. Treatment of acromegaly consists of surgical removal of the pituitary adenoma (or, rarely, the ectopic tumor). Surgical resection is frequently not curative, especially when the adenoma exceeds the confines of the sella turcica. In such cases, radiation or medical therapy can be used. Medical treatment in the form of the long-acting somatostatin analogue octreotide (or lanreotide) is often effective in reducing GH secretion toward or into the normal range. Another form of medical treatment is available in the form of the GH antagonist pegvisomant, which blocks GH action at the GHR by preventing receptor dimerization. The aim of therapy is to lower serum IGF-1 levels to the normal range. Effective treatment of acromegaly is successful in reversing the soft tissue changes and metabolic

derangements but is only partially effective in reversing the bony changes. Thus, early diagnosis and curative intervention are of paramount importance. Early diagnosis is linked to cure rate because the size of the pituitary tumor largely determines the chance for a surgical cure.

DIAGNOSTICS

GH deficiency is diagnosed by pituitary stimulation test because a random serum GH level is largely uninformative due to the normally pulsatile nature of GH secretion. Standard and reliable pharmacological tests used for stimulation of GH secretion are: insulin hypoglycemia, GHRH-arginine infusion, and possibly GHRH-ghrelin or GHRH-hexarelin injection. Other useful but less reliable tests include arginine alone, GHRH alone, L-dopa, glucagon, and clonidine. Clonidine appears to be a more potent secretagogue in children than in adults, where it is considered a weak stimulus. The absolute GH response to these provocative stimuli (in terms of serum GH levels achieved) varies depending on the GH assay used. Typically, monoclonal immunoassays yield lower GH values than do polyclonal assays. Diagnostic guidelines have been published by the GH Research Society and by the American Association of Clinical Endocrinologists.

Acromegaly is readily diagnosed in the right clinical setting by an elevated serum IGF-1 level and a high GH level. (The latter is not diagnostic by itself due to the normally pulsatile GH secretion.) The confirmatory test, both in overt acromegaly and especially after surgical treatment, is the glucose tolerance test. Serum GH should fall below 1 ng/ml after glucose. In addition, IGF-1 should be within the normal age-adjusted range. Frequently, evidence for low-grade acromegaly persists even in cases where these criteria are met as GH secretory dynamics remain disordered when examined carefully. For practical clinical purposes, an IGF-1 level in the mid-normal range is a reasonable criterion for a cure.

GH AS A THERAPEUTIC AGENT

Human GH was extracted from cadaveric human pituitaries until the mid-1980s because there was no other source of GH that was biologically active in humans. Only children were recipients of this GH because supplies were limited by necessity. The occurrence of cases of Creutzfeldt-Jacob disease attributed to hGH contaminated with prions and the

simultaneous arrival of recombinant hGH in unlimited quantities resulted in a universal switch to recombinant hGH. Supplies became sufficient to treat adult patients with GH deficiency as well as conditions not associated with GH deficiency (e.g., chronic renal failure, Turner syndrome). Several pharmaceutical companies manufacture 22-kDa hGH, which is highly effective despite lacking all the other GH isoforms that are normally produced by the pituitary. Indications for GH continue to expand beyond classical GH deficiency, and much has been learned about GH biology from the availability of large quantities of chemically defined, highly pure GH preparations as well as from clinical trials and more intense scrutiny of the manifestations of GH deficiency and the effects of GH replacement therapy.

–10 SD. In the large series of Laron syndrome patients from the Middle East reported by Laron's group, final height ranged from –4 to –8 SD. In the series reported from Ecuador studied by Guevara-Aguirre and Rosenfeld's group, final height ranged from –6.8 to –9.6 SD.

GH secretion is increased and is associated with extremely low or undetectable levels of the GH-dependent peptides IGF-1, IGF-binding protein-3 (IGFBP-3), and acid labile subunit (ALS). The IGF-1 generation test, designed originally to predict growth response to GH therapy, shows a notable absence of increase in the preceding three peptides, confirming the presence of insensitivity to both endogenous and exogenous GH. A score of criteria for the diagnosis of GH insensitivity were proposed by Blum and colleagues (Table II).

PARTIAL GH INSENSITIVITY

During the early 1990s, the availability of recombinant IGF-1 for treatment led to the collection and central

Table II Scoring System for the Diagnosis of GHIS

| Test | Parameter | Criterion | Score |
|------------------|---------------------|------------|-------|
| Auxology | Height | <–3 SDS | 1 |
| Basal GH | GH | >2.5 ng/ml | 1 |
| Basal IGFs | IGF-1 | <50 µg/L | 1 |
| | IGFBP-3 | <–2 SDS | 1 |
| IGF-1 Generation | Change in IGF-1 | <15 µg/L | 1 |
| | Change in IGFBP-3 | <0.4 mg/L | 1 |
| GH Binding | Percentage GH bound | <10% | 1 |

Note. A total of ≥ 5 points indicates GHIS.

analysis of a large, predominantly European population of patients with GH insensitivity. This series consisted of 82 patients, each with the diagnostic criteria of GH insensitivity (Table I) but with varying degrees of phenotypic and biochemical abnormality. It became clear that GH insensitivity was not a homogenous state but rather a highly heterogeneous clinical state. Height in this population ranged from –2.2 to –10.4 SDS, and serum IGFBP-3 ranged from –1.4 to –14.7 SDS.

One analysis of the European population of GH insensitivity patients classified the patients into those with classical Laron syndrome features and those with atypical features such as normal facial appearance. Clinical and biochemical details of the atypical and classical patients are shown in Tables III and IV, respectively. It can be concluded that the disorder of atypical or partial GH insensitivity does exist. Such patients might not have the typical clinical features of Laron syndrome and, hence, may present as idiopathic short stature (ISS).

There have been several reports of children with ISS having clinical, biochemical, and molecular evidence of GH insensitivity. However, it appears likely that mild GH insensitivity is only a rare cause of ISS. Nevertheless, the IGF-1 generation test, using either the standard dose of GH (0.033 mg/kg/day \times 4) or a lower dose, with measurement of IGF-1 and IGFBP-3, may be of value in identifying such patients.

Table III Clinical Details of Atypical and Classical GHIS Patients

| | n | Age (years) | Sex (M/F) | Height | Body weight (g) | Body length (cm) |
|----------------|----|---------------|-----------|----------------|-----------------|------------------|
| Atypical GHIS | 9 | 7.8 \pm 4.1 | 7/2 | –4.0 \pm 1.4 | 3445 \pm 245 | 51.8 \pm 2.5 |
| Classical GHIS | 50 | 8.6 \pm 4.6 | 24/26 | –6.7 \pm 1.4 | 3290 \pm 374 | 48.3 \pm 1.7 |
| | | | | P<0.001 | n.s. | P<0.001 |

Table IV Biochemical Details of Patients with Atypical and Classical GHIS

| | Basal GH (ng/ml) | Basal IGF-1 (μ g/L) | IGF-1 post-GH (μ g/L) | IGFBP-3 (μ g/L) | Normal GHBP (>10%) | IGF-2 (μ g/L) | IGFBP-1 (μ g/L) |
|-----------|---------------------|-----------------------------|-------------------------------|-------------------------|-----------------------|-----------------------|-------------------------|
| Atypical | 18 (1.1–69.5) | 22 (<20–53) | 26 (<20–82) | 776 (213–1670) | 28 (4–52) | 148 (39–283) | 165 (28–521) |
| Classical | 36 (1–135) | <20 (<20–135) | <20 (<20–62) | 334 (95–170) | 0 (0–46) | 84 (26–205) | 153 (39–489) |

Note. Values are expressed as means and ranges (in parentheses). Levels of IGF-1, IGFBP-3, IGF-1, and IGFBP-1 are age dependent. Standard deviation scores for IGFBP-3 are outlined in the text.

MOLECULAR BASIS OF GH INSENSITIVITY

The demonstration by the group of Laron that the basic defect in Laron syndrome, an autosomal recessively inherited disorder, was situated at the level of the GH receptor orientated scientists to characterize the molecular basis of GHR dysfunction. It is now established that the majority of GHR mutations are situated in exons coding for the extracellular domain of the receptor. This was confirmed in the genetic analysis of the European GH insensitivity population (Fig. 1). More recently, new mutations are being described, extending the mechanism of GH receptor dysfunction. Examples of these are splice site mutations affecting receptor dimerization, intronic mutations associated with pseudoexon formation, and dominantly inherited heterozygous mutations with dominant negative action on GHR function. Most recently, a mutation of the STAT5 gene, causing impaired intracellular signal transduction, was identified by Rosenfeld's group.

IGF-1 GENE DELETION

An example of IGF-1 deficiency, not linked to the GHR, was reported by Woods and colleagues in

1996. The patient had severe intrauterine growth retardation and postnatal growth failure. He also had a dysmorphic phenotype with microcephaly, sensorineural deafness, and mild mental retardation. Serum IGF-1 was undetectable, IGFBP-3 was normal, and GH was increased. Molecular analysis revealed partial deletion of the IGF-1 gene, with absence of exons 4 and 5. This patient also has severe insulin resistance, secondary to high GH levels, acting through an intact GH receptor. Treatment with recombinant IGF-1 suppressed GH and corrected the insulin resistance.

ACQUIRED GH INSENSITIVITY

GH insensitivity is seen in association with a number of chronic disorders that have mostly been studied in adults. Predominant among these are disorders of acute illness such as patients receiving intensive care or undergoing major surgery. Serum levels of IGF-1 are reduced and GH is elevated, indicating GH insensitivity. Other examples are chronic liver disease, where there may be impaired synthesis of IGF-1, and malnutrition, where IGF-1 generation is sensitive to calorie intake. Two chronic disorders

Figure 1 GHR mutations in 21 families with GH insensitivity from the European series. From Woods, K. A., Dastot, F., Preece, M. A., Clark, A. J. L., Postel-Vinay, M.-C., Chatelain, P. G., Ranke, M. Metab.* 82, 3529–3535, © The Endocrine Society, with permission.

affecting children and adolescents, both associated with GH insensitivity, are type 1 diabetes mellitus and Crohn's disease. In diabetes, GH secretion is elevated, particularly during adolescence, contributing to the insulin resistance, which is well recognized in adolescent patients. Dunger and colleagues showed effective reduction of insulin resistance and improvement in glycemic control during treatment with recombinant IGF-1.

In Crohn's disease, there is usually a combination of chronic malnutrition and inflammation. The malnutrition causes IGF-1 deficiency, and the inflammation, mediated through the effect of cytokines (which also impair IGF-1 production), exacerbates the GH insensitive state. A similar situation is seen in the chronic inflammatory state of patients with juvenile chronic arthritis.

TREATMENT OF GH INSENSITIVITY WITH IGF-1

GH insensitivity is associated with deficiency of IGF-1 and IGFBP-3. Because GH treatment is ineffective, IGF-1 is the only available therapy for

this group of disorders. Early trials during the late 1980s demonstrated a clear growth-promoting effect of recombinant IGF-1 given by subcutaneous injection in twice-daily doses of 40 to 120 $\mu\text{g}/\text{kg}$. Laron showed similar responses using IGF-1 (150 $\mu\text{g}/\text{kg}$) once daily. A compilation of results of treatment trials from 1993 to 1997 showed an increase in mean growth velocity during the first year of treatment, from 3.6 cm/year (range = 2.9–4.7) to 8.4 cm/year (range = 7.2–9.3).

IGF-1 does not increase growth in GH insensitivity to the same extent as does GH therapy in severely GH-deficient children. This may be related to rapid clearance of free IGF-1 because of the preexisting IGFBP-3 deficiency. A potential solution to this problem would be the use of the IGF-1/IGFBP-3 complex, an equimolar preparation that has been shown to be effective in the treatment of the GH insensitivity of adolescent diabetes mellitus.

However, Ranke and colleagues demonstrated the long-term benefit of IGF-1 therapy on growth in children with GH insensitivity (Fig. 2). IGF-1 has been in short supply, resulting in limited opportunity to establish the optimal treatment regimens. The

BIOCHEMICAL AND MOLECULAR CHARACTERIZATION

Binding studies using radioactively labeled GH coupled with a variety of chromatographic and immunological techniques have reported significant heterogeneity (number and size) in GHBP isoforms present in the sera of many different vertebrates. A number of these isoforms are of low abundance, low specificity, and (often) low affinity, and their physiological importance, if any, is currently unknown. By far, the major focus of attention has been on the characteristic high (nanomolar)-affinity GHBP that, in most species, has a molecular mass of approximately 60 kDa. In rodents, it appears to be smaller in size (35–45 kDa), probably due to lower levels of glycosylation. This high-affinity GHBP is, structurally, closely related to the extracellular GH-binding domain of the cellular receptor for GH (GHR) and is generated by two distinct, apparently species-specific, mechanisms (Fig. 1).

There is a single GHR gene in all species, and it consists of a number of coding exons (numbered 2–10) for which exon 2 represents the signal peptide, exons 3 to 7 represent the extracellular (ecto)domain (with exons 4–6 being involved in the GH-binding site), exon 8 represents the transmembrane-spanning domain, and exon 9 and part of exon 10 represent the

intracellular (cytoplasmic) signaling domain. In rodents, but no other species known to date, an additional small exon (8a) has been identified, situated between exons 7 and 8. Transcription of the GHR gene leads to a single primary mRNA transcript in humans and other nonrodent species, constituting exons 2 to 10. However, in rodents, because of alternative splicing mechanisms, two distinct mRNAs are produced. The first is comparable to that in other species (exons 2–10) and codes for the full-length GHR. The second is a truncated form that codes for a shorter protein, the GHBP, which has an identical extracellular GH-binding domain (exons 2–7) but no GHR transmembrane (hydrophobic) domain (exon 8) or intracellular signaling domain (exon 9 and part of exon 10). Instead, exons 8 to 10 are replaced with exon 8a, which codes for a short 17- to 25-amino acid hydrophilic sequence, commonly referred to as the “hydrophilic tail.” The absence of the hydrophobic transmembrane domain and the substitution of the hydrophilic tail provide a mechanism for the rodent GHBP to be secreted directly from the cell of synthesis. No equivalent mechanism has been identified in human or other species despite considerable effort on the part of a number of researchers. There have been various alternatively spliced GHR mRNA transcripts reported in human cells, some of which lead to truncated membrane-bound GHR isoforms (e.g., exon 3

Figure 1 Diagrammatic representation of the GHR gene and the alternative mechanisms for generation of full-length GHR and the soluble truncated GHBP in both rodents and humans (and other species). The rodent GHR gene differs from the human gene essentially due to inclusion of an additional coding exon (8a, ▨). The classical transmembrane domain of the full-length GHR is denoted by exon 8 (■).

deleted forms and exon 9/10 truncations), but none of these leads to direct expression of a unique GHBP mRNA.

Given the absence of a specific GHBP mRNA in humans and species other than rodents, a quite distinct mechanism has been identified to account for the production of GHBP in these species. The GHBP is produced as a result of a specific posttranslational proteolytic cleavage of the ectodomain of the cell membrane-embedded GHR. There is some evidence that cleavage may be influenced by intracellular mechanisms such as endosomal proteases, but generally it is thought to be an extracellular event. Cleavage occurs through the action of one or more metalloproteinases, and recent evidence indicates that TNF α -converting enzyme (TACE), the enzyme responsible for membrane cleavage of the growth factor TNF α , is also involved in GHBP generation. TACE (also known as ADAM-17) is a member of the large ADAM family of zinc-dependent metalloproteinases or "shedases." The cleavage site in the extracellular domain of the GHR, and therefore the precise C-terminal sequence of the GHBP, is currently not known, but it is almost certainly very close to the transmembrane insertion site.

Like the GHR, the human GHBP is quite heavily glycosylated, although there is little evidence to suggest that glycosylation is necessary for GH binding. The GHBP is immunologically identical to the extracellular domain of the GHR and so can be immunoprecipitated and/or detected using N-terminally directed GHR antisera. Therefore, several immunologically based assay systems have been developed for the direct measurement of both "free" (unoccupied by GH) and "total" human GHBP.

Based on studies primarily in rodents and rabbits, it is known that most epithelial, endothelial, and mesenchymal cell types express the GHR and also produce GHBP. Although first identified and primarily studied in serum, the GHBP is found in secretions other than serum such as milk, urine, and follicular fluid. Liver is perhaps the major source of circulating GHBP, but tissues such as adipose, kidney, placenta, breast, ovary, brain, muscle, and bone all are significant producers. In adipose tissue, significant amounts of GHBP remain attached via an unknown linkage mechanism to the adipocyte cell membrane. The functional implications of this are not clear but may facilitate modulation of GH action on adipose tissue. A major store of GHBP is also found within the cytosolic compartment of several rodent (and rabbit) tissues, and this may arise from *de novo* synthesis and/or via internalization and intracellular processing of

externalized GHR/GHBP. Of particular interest is the observation that GHBP has also been detected, by direct binding studies and immunohistological examination, in the nucleus of several cell types. The mechanism for nuclear localization is unknown, but it is likely to be via facilitated transport in association with another nuclear-targeting protein. The GHBP itself has no recognizable nuclear localization motif. Nonetheless, there is emerging evidence to suggest that the GHBP may have the capacity to bind to nuclear DNA and thereby influence nuclear transcriptional activity. If this is proven, it will revolutionize our thinking about the potential physiological role and importance of the GHBP.

FUNCTIONAL ROLES AND IMPLICATIONS FOR GH ACTION

In addition to the hypothesis proposed earlier regarding potential nuclear roles for GHBP, there is strong evidence to indicate that the GHBP is functionally important and has quite varied roles. Indirect evidence for physiological relevance and roles distinct from those of the GHR comes from the now quite extensive work demonstrating in rodents, at least, that there is differential regulation of the GHBP and GHR mRNA expression. Given that both are independently synthesized from distinct mRNAs, the differential regulation is not surprising. Several studies primarily, but not exclusively, examining hepatic GHBP production have indicated its sex, pregnancy, GH, steroid, and ontogenic dependence. In humans, of course, such definitive studies are more difficult to conduct (due to tissue availability) and interpret because there is a much closer link between regulation and, therefore, levels of GHBP and its parent or precursor molecule, the GHR. Indeed, one of the indicated advantages of being able to readily measure GHBP in serum is that it may well reflect closely the status (abundance and binding affinity/capacity) of the generally nonaccessible human tissue GHR. In this context, numerous studies have measured the levels of GHBP in various physiological and pathophysiological states and have drawn conclusions about GHR status and the likely impact on tissue GH responsiveness. However, it is important to keep in mind that indirect regulatory mechanisms, such as those that modulate abundance and/or activity of the GHR cleavage enzyme TACE, may lead to differential regulation of tissue GHR and soluble GHBP in humans.

The roles of GHBP can be classified into two primary groups: endocrine roles in the circulation

and paracrine/autocrine roles in the immediate extracellular environment of GH-responsive cells. In the circulation, the high-affinity GHBP binds approximately 50% of circulating GH under normal conditions. There is significant unoccupied GHBP in the serum under these conditions, but this can be readily saturated in the face of high levels of GH such as in acromegaly. The effect of binding GH in serum is to increase the half-life of circulating GH via modulation of GH clearance and/or degradation and to influence its capacity for transcapillary transfer out of the vasculature and into the extracellular environment of target cells. Both of these roles would have a subsequent influence on the responsiveness of tissue to GH by regulating the availability of GH to its target cell receptors. Overall, the GHBP provides a circulating reservoir of GH that can serve as a readily releasable pool of GH in the face of diminished supply. Hence, one would expect the endocrine effects of GHBP to be a positive regulator of GH action.

However, the GHBP is also known to have a distinct and influential paracrine/autocrine role in the immediate extracellular environment of secreting cells. Studies *in vitro* have shown that addition of exogenous purified GHBP to cells in culture can inhibit the effects of added GH on those cells. This may be due in part to binding and sequestration of GH away from interaction with the cell's GHR. On the other hand, an additional and more important explanation is now known as a result of detailed understanding of the mechanisms involved in GH activation of its tissue GHR (Fig. 2). When GH binds to its receptor, it results in dimerization of the

Figure 2 Diagrammatic representation of the sequential GH-induced dimerization of the GHR, the recruitment of the cytoplasmic tyrosine kinase JAK2, the activation of GHR through phosphorylation reactions, and the initiation of various cytoplasmic signaling pathways. For GH, the primary signaling pathways involve phosphorylation cascades using the classical phospholipase C (PLC), insulin receptor substrate-1 (IRS-1), signal transducer and activator of transcription (STAT), and the small G-protein RAS/mitogen activated protein kinase (MAPK) pathways.

Figure 3 Models for the formation of homo- and heterodimers resulting from the GH-induced dimerization of mixed populations of full-length membrane-bound GHR and truncated soluble GHBP. Based on experimental evidence, only the GHR homodimer is likely to initiate GH-induced intracellular signaling reactions.

GHR in a $1 \times \text{GH}:2 \times \text{GHR}$ stoichiometry. Dimerization is essential for the activation of the GHR. This activation occurs through the recruitment of the intracellular tyrosine kinase JAK2, the cross-phosphorylation of the twin cytoplasmic domains of the GHR dimer, and the subsequent docking and activation of additional SH2- and SH3-containing cytoplasmic kinases, which then initiate an intracellular phosphorylation cascade leading to expression of a multitude of GH actions. In the presence of GHBP, which binds GH but clearly lacks any cytoplasmic “activation” domains, the obvious possibility exists that a variety of homo- and hetero-GHR/GHBP dimers may form (Fig. 3), depending on the relative available concentrations of each component. Formation of GHBP homodimers or GHBP/GHR heterodimers, with no or only one GHR cytoplasmic domain present, will not be sufficient to recruit and activate JAK2. Hence, one would predict a reduction or blockade of GH action in these circumstances. Experimental evidence indeed shows that overexpression of GHBP in wild-type, GHR-containing cell lines can act as a dominant negative influence on GH action due to the formation of inactive GHBP:GH:GHR (short:long) heterodimers. Thus, the GHBP adds another dimension to the already complex and varied mechanisms employed in the regulation of GH action.

RELATIONSHIP OF GHBP WITH GH RESPONSIVENESS IN HUMAN DISEASE STATES

As indicated previously, in humans, the general consensus is that circulating levels and binding ability of GHBP reflect the abundance and function of the tissue GHR. In turn, this often reflects the degree of responsiveness or resistance to GH action in particular clinical settings.

GH treatment is now used widely in a variety of clinical conditions, and numerous studies have investigated the possible predictive nature of GHBP with respect to correlation with GH responsiveness. In GH deficiency, there is a general positive correlation between serum GHBP and GH response as measured by change in growth rate or, acutely, changes in IGF-I levels. Growth responses to GH therapy may be influenced by the frequency of GH injection such that more frequent, smaller doses (mimicking the natural pulsatility of GH secretion) lead to better growth responses than do larger, more infrequent doses. A few studies have examined in some detail whether this increased GH response is associated with a corresponding change in GHBP based on the knowledge that, at least in rodents, GHBP expression is regulated by GH. However, there is little consensus as to whether the increased growth responses due to the mode of GH delivery are reflected or predicted by similar changes in serum GHBP activity.

Children with idiopathic short stature often have slightly reduced levels of GHBP, reflecting a subtle endogenous resistance to GH. Similarly, African pygmies also show reduced GHBP together with apparent GH resistance during puberty. However, perhaps the most clear-cut correlation between GHBP and GH responsiveness occurs in cases of GH insensitivity syndrome (GHIS or Laron dwarfism). These children are severely growth retarded due to genetic mutations in the GHR. Most are completely resistant to GH treatment. The majority of mutations occur in the extracellular binding domain of the GHR and prevent the binding of GH to the receptor. Hence, the same defect occurs within the proteolytically cleaved GHBP, which exhibits complete failure to bind GH and so is undetectable by “functional” assays, although the inactive protein can be detected immunologically in many GHIS sera. In a few reported cases of GHIS, however, active GHBP was detected in serum, and this led researchers to examine and identify additional mutations in the GHR that occurred not in the GH-binding domain but rather in other domains such as the cytoplasmic signaling domain and the region required for stabilization of receptor dimerization. Thus, although these GHRs and the GHBP would still bind GH normally, the receptor itself would be nonfunctional and would result in severe GH resistance.

There are a host of other pathophysiological states that exhibit various degrees of GH responsiveness. With respect to decreased responsiveness, such states include metabolic disturbances such as malnutrition

and poorly controlled diabetes as well as thyroid, renal, and liver disease. In each of these cases, there are many studies indicating that levels of GHBP are low, consistent with the degree of GH resistance. Conversely, in obesity, one of the rather less common situations of increased GH responsiveness, GHBP levels are reported to be significantly higher than normal. Again, each of these examples supports the argument that the levels of circulating GHBP in general reflect the abundance and activity of the tissue GHR and, hence, GH responsiveness.

This is not always the case, however, as illustrated by the rare GHIS example cited earlier and perhaps by observations in pregnancy. Although pregnancy in the rat shows a quite dramatic increase in expression of the GHBP, the situation is somewhat less marked and more varied in human pregnancy. Indeed, a rather complex biphasic effect on maternal GHBP levels is seen during human pregnancy—an initial rise followed by a decrease as gestational age advances. This pattern is particularly in contrast to that of placental GH, which shows a rather dramatic rise across the final two trimesters. The precise role of placental GH during pregnancy is not known; however, it is likely to play a significant metabolic role in the delivery and regulation of nutrients and metabolites to the placenta and the growing fetus, and in this context one might expect the sensitivity of the system to GH to rise. It is not known whether the decrease in maternal GHBP reflects a concomitant change in the expression and activity levels of the placental GHR; however, this may represent one situation, compounded by the complex milieu of interacting systems (e.g., maternal, fetal, placental) and pregnancy-related regulatory factors, where a tight linkage between GHBP and GHR expression is lost.

Clearly, there is still much to learn about the clinical relevance of the GHBP and whether it is a useful and effective marker of tissue GHR status in humans. Nonetheless, evidence to date suggests that the GHBP has potentially very important physiological sequelae with respect to GH action in both normal and abnormal clinical conditions. Continued exploration of the endocrine and paracrine/autocrine effects of GHBP is paramount to gaining a full understanding of the complex and diverse mechanisms involved in regulating GH action *in vivo*.

Many of the hormonal components of growth are controlled via the hypothalamic–pituitary axis. Thus, the secretion of GH, leading to the secretion of IGFs, is under the control of hypothalamic neuropeptide hormones known as growth hormone-releasing factor (GRF) and somatostatin or somatotropin release-inhibiting factor (SRIF). Similarly, the secretion of thyrotropin-simulating hormone (TSH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), and adrenocorticotrophic hormone (ACTH), all of which play major roles in the control of growth, is itself under the control of hypothalamic neurohormones. In addition, the secretion of insulin, which is not directly under pituitary control, also plays an important role in the control of cellular growth. Of course, many nonhormonal factors play major roles in the control of growth. Foremost among these is nutrition given that no cell could grow or divide without substrates. There are also underlying genetic factors that determine the potential for growth, not only for the whole organism but also for each organ and tissue. In addition, there are a host of tissue growth factors, such as epidermal growth factor (EGF) and nerve growth factor (NGF), whose roles in the overall control of growth are only beginning to be understood. The interaction of these hormonal and nonhormonal factors leads to the normal growth and development of children, and abnormalities of these mechanisms lead to disorders in growth that present themselves to a physician. A thorough understanding of the factors controlling growth is crucial for a rational approach to the diagnosis and management of growth disorders.

Growth Hormone

GH is a 191-amino acid polypeptide secreted by special cells in the anterior pituitary gland called somatotropes. Neurohormones control these cells through the hypophyseal portal system, and both positive effectors of GH secretion and an inhibitor of GH secretion exist. Current data indicate that the combination of GRF and ghrelin (growth hormone-releasing peptide [GHRP]) is responsible for the rapid pulses of GH secretion seen mainly during the nighttime hours and in response to meals and exercise, whereas the inhibitor of GH secretion, somatostatin (SRIF), appears to be responsible for the underlying tone of GH secretion. There are two major forms of GH synthesized, stored, and secreted by the somatotropes. The most abundant form (approximately 90%) is the 22-kDa molecular weight form. In addition, there is an alternative splicing of the GH messenger RNA

that leads to a minor 20-kDa form of GH whose physiological role is unknown.

The secretion of GH is followed by a complex chain of events that ultimately leads to the stimulation of growth at the endocrine level. After GH is released into the bloodstream, a large proportion of it binds to a specific GH-binding protein. It is now clear that the human GH-binding protein represents the extracellular portion of the GH receptor site. Like many receptors for polypeptide hormones, the receptor site for GH consists of three polypeptide domains: an extracellular domain that contains the three-dimensional structure necessary for the recognition of the hormone, a transmembrane domain that is highly hydrophobic, and an intracellular domain that contains the three-dimensional structure necessary to lead to the biological action within the cell. In humans, it appears that there is proteolytic cleavage of the extracellular domain of the GH receptor that leads to a soluble circulating polypeptide that plays a major role in protein binding of GH in the serum. The exact biological role of this binding protein is unclear; however, it does serve as a useful index to the level of GH receptors in the body. GH receptors are widely distributed throughout tissues in the body, and it is the binding of the GH ligand to these GH receptors that leads to the biological events within the cells themselves. Of the many direct biological events that are ascribed to GH action, one of the most important ones is clearly control of the production of yet another polypeptide hormone known as IGF-1.

Insulin-like Growth Factors

IGF mRNA is widely distributed throughout the body and is under GH control not only in the liver but also in other tissues. IGFs circulate tightly bound to proteins known as insulin-like growth factor-binding proteins (IGFBPs). In most normal circumstances, there are few or no free IGF polypeptides circulating. It is now known that a total of six distinct but homologous IGFBPs exist. By far the most abundant form of IGFBP in normal serum is IGFBP-3. This is a glycosylated protein of approximately 40 kDa molecular weight. The combined IGF-peptide/IGFBP-3 complex binds to yet another protein known as the acid labile subunit (ALS) to form a 150-kDa, three-subunit protein complex that is the major circulating form of the IGFs. This 150-kDa complex contains well over 90% of the total IGF in the serum in most circumstances. A smaller proportion of the IGFs in serum circulate bound to the other forms of IGFBPs (IGFBP-1,-2,-4,-5, and-6). In addition, these other

IGFBPs are major components in certain bodily fluids such as IGFBP-1 in amniotic fluid, IGFBP-2 in joint fluid, and IGFBP-5 in cerebrospinal fluid. The exact biological purpose of this complex system of controlling the amount and distribution of IGF in the serum and extracellular fluid spaces is unclear. However, it does result in the prolongation of the circulating time of IGFs in plasma and may play a major role in modulating the delivery of the IGF peptides to the receptor sites on cells. Most of the observed biological actions of GH on the control of growth appear to be subserved by the chain of action initiated by GH. This leads to the production of IGF-1 and its delivery to the IGF type 1 receptor sites in the tissues. It is this chain of action that has been most clearly linked to the anabolic and growth-promoting events that we associate with GH in the whole organism. Any abnormality in this complex chain of events can lead to growth failure.

Thyroid Hormone

Thyroid hormone also plays an extremely important role in the control of growth. Like the GH-IGF axis, there is a hypothalamic mechanism of control with the neurohormone thyrotropin-releasing hormone (TRH) being secreted by specialized neurons into the hypophyseal portal system leading to the release of the pituitary hormone TSH. TSH then leads to the production and release of the final hormone in the chain: thyroid hormone (thyroxine [T_4] and triiodothyronine [T_3]). Like the IGFs, the thyroid hormones are nearly totally bound to plasma proteins that control the half-life and tissue delivery of the thyroid hormones. The thyroid hormone receptor site that is widely distributed throughout cells in the body subserves thyroid hormone action. This receptor site is located intracellularly, similar to that of steroid hormones, and the ligand- T_3 complex binds to chromatin and DNA to initiate mRNA synthesis. Without thyroid hormone action through its receptor sites, GH and IGFs are unable to stimulate anabolic and growth responses. Furthermore, there is a close interaction of thyroid hormone with GH secretion. In the presence of hypothyroidism, GH secretion from the pituitary gland is decreased in response to both pharmacological and physiological stimulation. Therefore, the normality of thyroid hormone secretion must be proven before any attempt to assess GH secretion in a short patient.

Sex Hormones

The sex hormones, estrogens and androgens, play an extremely important role in the control of growth

during puberty. The secretion of these hormones is relatively low after the fetal and perinatal periods of life until there is an increase in the gonadotropins (LH and FSH) prior to the clinical onset of puberty. It is the increased secretion of estrogens and androgens under the control of the pituitary gonadotropins that leads to the development of the secondary sex characteristics that are so closely associated with the events of puberty. Estrogens and androgens have been associated with growth-stimulating actions directly as well as indirectly. Both androgens and estrogens have been shown to influence the secretion of GH at the time of puberty. This increase in GH secretion at the time of puberty is thought to play a major part in the pubertal growth spurt. In addition to the direct and indirect roles that androgens and estrogens play in the stimulation of growth, estrogens play a major role in the maturation of bones and the ultimate disappearance of the epiphyseal centers. It is this event that results in the cessation of linear growth at the end of puberty. Like the thyroid hormones, the sex hormones appear to act by diffusing into the cell and binding to the specific receptor sites of the steroid/TSH category. The binding of androgens and estrogens to their respective receptor sites initiates changes in the three-dimensional structure that allow the interaction of these activated receptors with chromatin and the chromosomal DNA. This interaction leads to the production of specific mRNA and the secretion of specific proteins, leading to the biological action observed. The evaluation of sex hormone secretion plays an important part in the evaluation of disorders of size, particularly during the peripubertal period.

Adrenal Hormones

In addition to the other hormonal factors reviewed, it is clear that adrenal hormones play a role in the control of growth. Adrenal androgens appear to have an important adjunctive role in the events of puberty and act in concert with androgens from the testes and ovary to lead to growth stimulation, by both direct and indirect means, and the maturation of the bones. In addition, the adrenal glucocorticoids appear to have a bimodal action in the control of growth. A minimal level of glucocorticoids is necessary for cells to function, grow, and divide. On the other hand, many observations have shown that even a slight excess of glucocorticoids makes cells in the body unresponsive to the other hormonal growth-stimulating agents and leads to slowing of linear growth.

Other Factors

There are many extremely important nonhumoral factors controlling growth. Without adequate food intake, and therefore without adequate substrates for cells, no effective growth can occur. This is clearly seen in the clinical disorders of kwashiorkor and marasmus as well as in more subtle clinical disorders in nutrition. Genetics also has an extremely important role in determining the potential for growth. The differences in stature among humans depend to a large extent on differing genetic constitutions. The best, but a relatively crude, way in which to determine these underlying genetic factors is parental and familial heights. Tissue growth factors such as EGF play a critical role in the control of growth in the organism. This is best illustrated by achondroplasia, which is now known to be caused by a defect in the gene for the EGF receptor. Finally, the role of systemic disease in the growth of children and adolescents cannot be overemphasized. Even in the presence of normal hormonal, nutritional, and genetic factors, underlying systemic disease such as inflammatory bowel disease can interfere with growth potential. The existence of short stature in a patient is an important clue to the physician as to the underlying condition of the patient.

SECULAR TRENDS IN MATURATION AND FINAL HEIGHT

The expected range of the growth rate for infants and children, timing of puberty, and final adult height is commonly thought to be immutable. However, an examination of the past history of growth and development shows that there have been very large variations in the rate of “normal” growth, puberty, and final height that must have been due to environmental changes, not genetics. These are known as the secular trends. There is a large body of data establishing that in many regions of the world, the average age of menses for women has decreased markedly over the past two centuries at the same time as the adult height of women has been increasing. In addition to these data in females, there are less well-known data in boys, including data as disparate as those from a royal boys school in 18th-century Germany and height records of male slaves in the American South in the 19th century, illustrating that a similar process of earlier puberty and taller final stature has occurred over the past two centuries in men. The environmental reasons for this appear to be a combination of better nutrition and sanitation, particularly during infancy, and control of infectious diseases. One of the most remarkable

illustrations of a secular trend occurred in Japan after World War II. Coincident with the introduction of more protein and calories in the Japanese diet, especially during infancy, the average adult height of Japanese men has increased by more than 25 cm, and a similar phenomenon has occurred in Japanese women. This fact can be vividly illustrated by a ride on a Tokyo subway, where often the older passengers are much shorter than the younger passengers. In some areas of the world such as the United States, this process has slowed down or even ceased. In other parts of the world, the secular trend in growth and development is continuing today, or in some areas may even be going backward toward slower maturation and shorter adult height, due to deteriorating health and nutrition. The absolute worst time to grow up in England, as judged by the height of army recruits, was during the early stages of the Industrial Revolution and the Napoleonic Wars. Children we now consider to have CDG would have been average or even tall in another time and place. The syndrome of constitutional delay is the perfect example of the relativity of human development; it depends on the standard of comparison. Most of the children who present with CGD do not have an underlying hormonal or genetic disease. However, hidden within this large number of the basically normal children are a few who have clinically important disorders that the physician must search for diligently.

DISTINCTION FROM PATHOLOGICAL CAUSES OF SHORT STATURE

The pathological causes of short stature are outlined in [Table I](#). Clinical abnormalities of GH secretion or action are clearly associated with short stature. The most apparent of these is GH deficiency, in which there is either a disorder of the hypothalamic control of GH secretion or an inability of the pituitary itself to secrete GH. The consequences of classical GH deficiency are reflected not only in low levels of circulating GH, as assessed by both physiological and pharmacological stimulation, but also in extremely low levels of IGF-1 and a consequent decrease in the growth rate. These children almost invariably respond to GH treatment with a marked increase in growth rates. An interesting but rare disorder of the chain of GH action is Laron syndrome (also known as GH insensitivity syndrome). This disorder, originally described in Ashkenazi Jews, is now known to be more widely distributed both ethnically and geographically. Laron syndrome is a group of genetic disorders of the

GH receptor that make the GH receptor unable to bind GH. This results in an increase in circulating GH levels (due to lack of IGF feedback), a decrease in the level of circulating GH-binding protein derived from the GH receptor, markedly decreased levels of IGF-1, and extremely poor growth rates. Children with Laron syndrome will respond to treatment with synthetic IGF-1 with an increased rate of growth, thereby validating the somatomedin hypothesis. It is possible that more subtle abnormalities of the GH-binding protein or GH receptor are underlying causes in some of the undiagnosed cases of poor growth.

Because of the important role of thyroid hormone in both the secretion and endocrine actions of GH, it is clear that any level of hypothyroidism would lead to a decrease in growth rate and eventually to short stature. There is a remarkable decrease in growth rate seen with severe hypothyroidism, and a rapid increase in growth rate is seen after thyroid therapy is instituted. Some patients with severe hypothyroidism will actually present with a peculiar form of precocious puberty known as "overlap syndrome," in which there is a premature activation of gonadotropins apparently associated with the high levels of TRH secretion by the hypothalamus. On the other hand, the treatment for hypothyroidism can lead to the rapid onset of true

puberty, which in turn leads to an accelerated advance in bone age and may compromise final height despite the institution of thyroid therapy.

Short stature relative to that expected for age can also occur as a result of inadequate sex hormone secretion. This is most commonly seen in boys who have delayed puberty, but some girls will also have a significant delay in puberty. Treatment with short courses of androgen has been used in boys with severely delayed puberty. Many times, this delay in puberty is physiological; however, it can also be associated with hypogonadotropic hypogonadism in both boys and girls. These patients may present at the early pubertal age with short stature that is due to the lack of sex hormone secretion and pubertal growth spurt, even though their final adult height might not be short. A relatively common form of hypogonadotropic hypogonadism in both boys and girls is Kallmann's syndrome, in which the hypogonadotropic hypogonadism is associated with anosmia. These patients can be treated with androgens or estrogens as appropriate.

Short stature can also be associated with hypersecretion of glucocorticoids caused by an increase in ACTH secretion (Cushing's disease) or the hypersecretion of glucocorticoids by a functioning adrenal tumor. These patients need to be treated by the control of their excess glucocorticoid secretion. The most common cause of glucocorticoid excess leading to growth failure is in association with the treatment of steroid-responsive diseases with pharmacological doses of glucocorticoids. In these patients, the obvious treatment of decreasing or stopping the glucocorticoid therapy may in practice be very difficult to accomplish because of exacerbation of the underlying disease state.

In girls, the most common genetic disorder leading to short stature is Turner syndrome. The mechanism by which Turner syndrome leads to short stature is not yet clear, but it does not appear to be directly GH related. These girls have relatively poor growth rates during childhood, leading to a progressive decrease in their average height when compared with normal girls of the same age. In addition, they fail to enter puberty due to the ovarian failure associated with Turner syndrome and, therefore, achieve very short adult stature with an average height of approximately 140 cm. The use of GH treatment has seen some success in increasing growth rates and final height in girls with Turner syndrome. Although the vast majority of these children will have delayed puberty, a significant percentage of them do have enough estrogen secretion from their ovaries to develop secondary sex characteristics and even to menstruate. Thus, any
