The field of endocrinology is inextricably linked to physiology. The specialty was initially founded when it became clear that various glands produced hormones that exerted characteristic physiologic effects on growth, reproduction, and metabolism. Early descriptions of hormone deficiency syndromes such as Addison's disease and myxedema were soon followed by hormone replacement strategies, often resulting in dramatic clinical effects. These observations unleashed intensive efforts to isolate and characterize the steroid and peptide hormones produced by the adrenal, thyroid, parathyroid, pituitary, and pancreatic islets, and other glands. The success of this era was epitomized by the isolation of insulin and the successful treatment of children with type 1 diabetes mellitus in 1922. The development of radioimmunoassays (RIAs) was a monumental advance that allowed hormones to be measured in various physiologic conditions. RIAs transformed endocrinology more than any other field. The ability to measure hormone levels during stimulation and suppression tests firmly established the principles of feedback regulation and formed the basis for many current diagnostic algorithms. RIAs also revealed the natural patterns of hormone secretion, including circadian rhythms and reproductive cycles, as well as hormonal responses to sleep, meals, stress, exercise, and other daily life events. Our understanding of hormone action has been accelerated by studies of their membrane and nuclear receptors, which convey hormone specificity in target tissues. The signaling pathways elicited by these receptors constitute intricate and complex networks that inform the cell about its external environment. Recombinant DNA technology has been essential for cloning the genes and cDNAs that encode large families of hormones and receptors. Growth hormone, chorionic gonadotropin, and

somatostatin were among the first mammalian cDNAs to be cloned. With completion of the human genome project, all of the genes that encode hormones and their receptors have, in principle, been identified. However, many of these receptors remain "orphans" with still-unknown ligands and incompletely defined functions. Not surprisingly, genetic advances have revealed remarkable insight into inherited endocrine disorders.

Most physicians are attracted to the field of endocrinology because it so beautifully integrates physiology, biochemistry, and cell signaling with patient care. Clinical manifestations of endocrine disorders can usually be explained by understanding the physiologic role of hormones—whether deficient or excessive. The conceptual framework for understanding hormone secretion, hormone action, and principles of feedback control provides the clinician with a logical diagnostic approach that typically employs appropriate laboratory testing and/or imaging studies. The fact that many endocrine disorders are amenable to cure or effective treatment also makes the practice of endocrinology especially satisfying. Because most glands are inaccessible to physical examination, endocrinologists are trained to detect key features of the medical history and subtle physical signs that point toward true endocrine disease. Increasingly, the challenge is to identify endocrine disorders at their earliest stages rather than when the clinical manifestations are obvious. Terms such as subclinical hypothyroidism, impaired glucose tolerance, and incidental adrenal or pituitary adenoma have crept into our vocabulary and have changed our approach to patients. Laboratory testing takes on added importance as we attempt to diagnose more subtle forms of disease.

Building on this strong foundation of basic science, the knowledge base in endocrinology continues to change rapidly. In addition to the dramatic advances

generated from genetics and molecular biology, the field has benefited from the introduction of an unprecedented number of new drugs, particularly for the management of diabetes and osteoporosis. Common diseases such as diabetes, hypertension, obesity, and osteoporosis have also been the subject of numerous large-scale clinical trials that provide a powerful evidence base for medical decision-making.

The rapid changes in medicine mandate that physicians continuously update their knowledge base and clinical skills. The *Encyclopedia of Endocrine Diseases* recognizes this challenge and provides a remarkable compilation of current knowledge in basic and clinical endocrinology. This ambitious four-volume set provides nearly 500 articles on basic and clinical endocrinology. The topics range from classic endocrine subjects such as hypothyroidism and acromegaly to new dimensions of the field including adipocytokines, ghrelin, and the role of the aldosterone receptor in cardiovascular disease. The international group of authors are experts in their topics, which have been subdivided to provide in-depth coverage. Thus, acromegaly is separated into articles on clinical features, diagnosis, and therapy to provide the level of detail needed to manage the most challenging cases. The standardized format and clear illustrations help to quickly offer answers. It is difficult to imagine an endocrine topic not covered in this encyclopedia, which provides a new, comprehensive reference for the daunting body of knowledge in endocrinology.

With a four-volume *Encyclopedia of Endocrine Diseases* in hand, it is interesting to speculate about

the remaining big questions and future discoveries in endocrinology. What are the genetic and adaptive elements that cause such a broad normal range for hormone values? It is humbling to recognize that we still have an incomplete understanding of the hormonal control of fundamental processes such as the onset of puberty, appetite control, gonadal differentiation into testes or ovaries, islet cell regeneration, insulin resistance, and causes of autoimmune endocrine disease. We still have much to learn about the optimal way to deliver many hormone therapies to mimic normal physiology. This topic is prominent in our efforts to provide intensive insulin replacement, or to replace growth hormone or cortisol, such that the beneficial effects outweigh complications. New therapies, such as intermittent PTH for osteoporosis, will be subjected to additional clinical trials, and one can easily imagine emerging questions about how to cycle the therapy and how to use it in relation to other treatments that alter osteoblast and osteoclast function. Gene transfer and stem cell strategies provide promising treatments for disorders such as diabetes and osteoporosis. The *Encyclopedia of Endocrine Diseases* can help to foster these discoveries by keeping researchers and clinicians at the cutting edge of endocrinology.

J. Larry Jameson, M.D., Ph.D.
Irving S. Cutter Professor and Chairman
Department of Medicine

Chicago, Illinois, United States

Among the most complex constructs in the body, the endocrine system comprises a group of glands that secrete hormones directly into the bloodstream, together with the receptors for these hormones and the intracellular signaling pathways they invoke. The endocrine system maintains and regulates stable functioning by using hormones to control metabolism, temperature, biological cycles, internal fluid volume, reproduction, growth, and development. Fortunately, the system is a marvel when functioning optimally. However, the ways in which its processes, actions, and functions may go awry are myriad.

The *Encyclopedia of Endocrine Diseases* is not meant as a primer on the subject of endocrinology, but instead is intended to provide a comprehensive reference work on the extensive spectrum of diseases and disorders that can occur within the endocrine system. This groundbreaking encyclopedia is especially timely, as there have been dramatic discoveries in the field of endocrinology over the past 10 to 20 years, particularly with respect to diagnosis techniques and treatment methods. Indeed, during the time since the encyclopedia was conceived, new hormones have been named.

To bring a major reference work of such broad scope from initial conception to final publication involved a great deal of planning, staging, and organization, together with the efforts of innumerable individuals. At the start, the broadest possible list of topics was compiled and a distinguished multinational panel of 14 associate editors was assembled. Throughout the editorial process, the editors supervised their subject area of expertise, recommended and corresponded with article contributors, reviewed the subsequent manuscripts, and continuously helped to refine the topics list.

The encyclopedia is intended to serve as a useful and comprehensive source of information spanning

the many and varied aspects of the endocrine system. It consists of nearly 500 topics explored by some 800 eminent clinicians and scientists from around the world, a veritable who's who of endocrine research. Here the interested reader can find articles on newly discovered hormones such as ghrelin and leptin; articles about such maladies as hypertension, hypoglycemia, diabetes, cancer, osteoporosis, kidney stones, Graves' disease, Paget's disease, Alzheimer's disease, Noonan syndrome, Langerhans cell disease, Cushing's syndrome, thyroid and pituitary disorders; and articles dealing with subjects ranging from the evolution of the endocrine systems, the mechanisms of hormone action, and the endocrine failure in aging to the integration between the nervous and the endocrine systems.

Written to be accessible to both the clinical and nonclinical reader, all of the articles are formatted in similar fashion and each is intended as a stand-alone presentation. Beginning each article is a glossary list defining key terms that may be unfamiliar to the reader and are important to an understanding of the article. The body of the article begins with a brief introduction to the subject under discussion, bold headings lead the reader through the text, and figures and tables explain and illuminate most articles. Following the article are reference citations to provide the reader with access to further in-depth considerations of the topic and cross-references to related entries in the encyclopedia. A compilation of all glossary terms appearing in the complete four-volume work is presented in the final volume as a dictionary of subject matter relevant to the endocrine system and its disorders.

It is my hope that the *Encyclopedia of Endocrine Diseases* proves to be a valuable resource to a deservedly diverse readership, and particularly to students, many of whom it may well attract to the rewarding field of

endocrinology. The project would not have been possible without cooperation, coordination, and reliance on e-mail among the key people, who were located in Japan, The Netherlands, Denmark, Switzerland, Italy, and the United States. I am greatly indebted to the dedicated and unstinting efforts of my associate editors, as well as the diligence and generosity of spirit of the Elsevier/Academic Press personnel who shepherded the project: Tari Paschall, Chris Morris, Carolan Gladden, and Joanna Dinsmore. To all of our

contributors go profound thanks for investing time and energy to produce their articles, which together have made the encyclopedia.

ABCA1 Defects

Gerd Schmitz and Wolfgang Drobnik
University of Regensburg, Regensburg, Germany

Glossary

ATP-binding cassette (ABC) transporters A family of multispan transmembrane proteins that mediate the active uptake or efflux of specific substrates across biological membrane systems.

high-density lipoproteins Plasma lipoprotein subclass mediating reverse cholesterol transport.

lipid microdomain Plasma membrane compartments with a specific lipid composition characterized by a distinct physical state and insolubility in certain nonionic detergents.

ABCA1 belongs to the family of ATP-binding cassette transporters, which represent one of the biggest multispan membrane protein families described by the early 21st century.

INTRODUCTION

ATP-binding cassette (ABC) transporters have attracted much attention because mutations in these molecules are the cause of various human inherited diseases. Functional ABC transporters usually consist of two transmembrane domains (TMDs) and two nucleotide-binding domains (NBDs) or ABCs that are present either in one polypeptide chain (full-size transporter) or in two polypeptides (half-size transporter). A signature motif located between both ABCs is characteristic of each of the seven ABC subfamilies (ABCA–ABCG) described by the early 21st century. The majority of these proteins mediate the active uptake or efflux of specific substrates across various biological membrane systems, whereby two different groups of ABC proteins can be distinguished by their mode of action. The one group of ABC transporters (e.g., ABCB1 (MDR1), ABCC1 (MRP1)) has strong ATPase activity, and the resulting free energy is directly coupled to the movement of molecules across membranes, whereas the other group (e.g., ABCC7 (CFTR), ABCC9 (SUR2), ABCA1) is characterized by very low

ATP hydrolysis but conformational change subsequent to ATP binding, which is linked to regulatory processes rather than direct transport-pump activity. A multitude of substrates is transported by the various ABC family members, including glutathione, glucuronate, or sulphate conjugates; xenobiotics; peptides; nucleotides; ions; and various lipid species. Members of the ABCA family especially are involved in the transport of steroids and various phospholipid and sphingolipid species, and the transcriptional control of at least seven ABCA members is controlled or influenced by lipids. These data indicate an important role of the whole ABCA subfamily in cellular lipid transport processes.

ABCA1 DEFECTS

ABC defects cause high-density lipoprotein (HDL) deficiency syndromes. Lipid-rich α -HDL originates from lipid-poor discoidal apolipoprotein–phospholipid complexes, with apo AI being the main apolipoprotein (Fig. 1A). Apo AI binds to cells and promotes vesicle transport and exocytosis of cholesterol and phospholipids. Cholesterol acquisition followed by lecithin:cholesterol-acyltransferase (LCAT)-mediated esterification results in the formation of lipid-rich spherical α -HDL. The cholesteryl esters associated with these mature HDL particles could be removed from the circulation by a scavenger receptor BI-mediated selective uptake into hepatocytes. Disorders of HDL metabolism could result from mutations in various genes along this metabolic pathway, including LCAT, apo AI, and ABCA1. ABCA1 is a 2261 amino acid protein with a molecular weight of 220 kDa that is expressed in a multitude of human organs, including liver, adrenal tissues, placenta, and spleen. Mutations in the ABCA1 gene have been identified as a cause for Tangier disease and other HDL deficiencies. Tangier disease is a rare inherited disorder of HDL metabolism. It was initially described by D. S. Fredrickson in 1961 and has since been diagnosed in at least 70 patients from 60 families. The patients are characterized by a complete deficiency of α -HDL and a severe

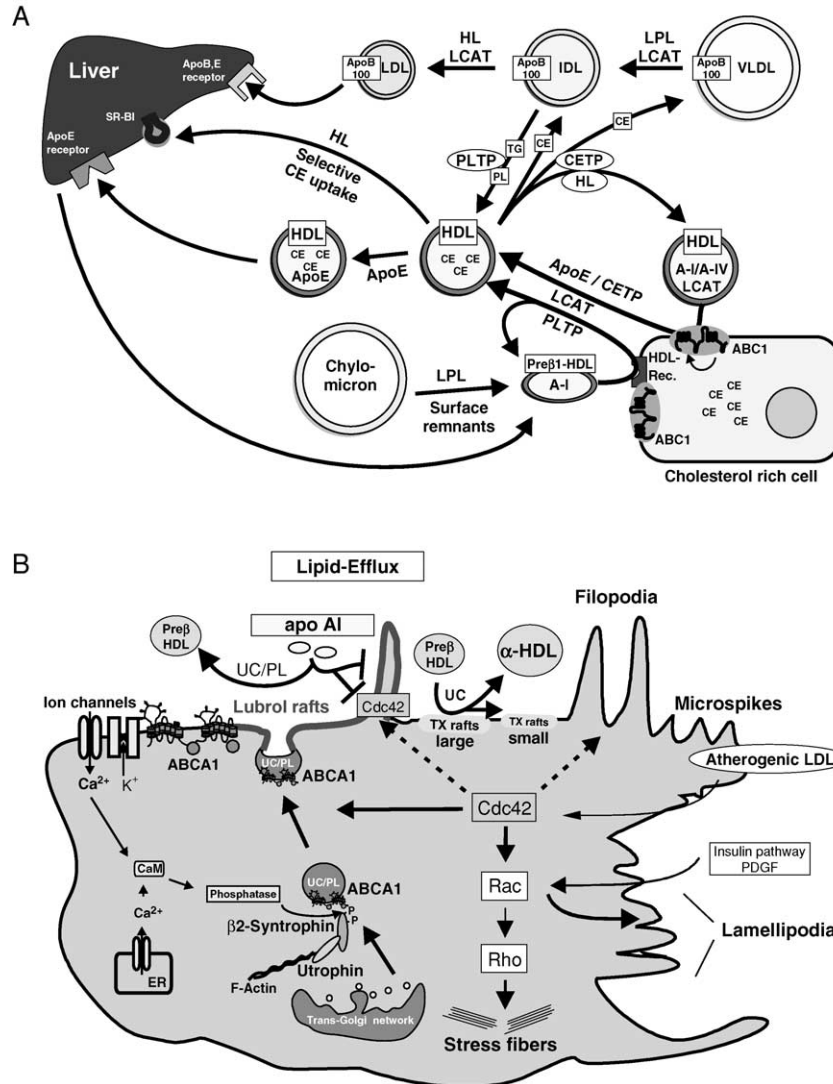

Figure 1 (A) High-density lipoprotein metabolism. (B) ABCA1: A regulator of lipid rafts, vesicular transport, and filipodia formation.

reduction of apo AI to 1 to 3% of normal, accompanied by low plasma cholesterol and normal or elevated triglycerides. The main clinical signs include the accumulation of cholesteryl esters in various tissues, hyperplastic orange tonsils, splenomegaly, and relapsing neuropathy. In addition, some Tangier patients have premature coronary artery disease (CAD), whereas others, even those over 60 years of age, are without any clinical symptoms of CAD. The clinical phenotype of Tangier disease and the biochemical features (e.g., low HDL) are inherited in an autosomal recessive mode and a co-dominant mode, respectively. In 1998, the genetic defect in Tangier disease was confined to chromosome 9q31, followed by the

demonstration that ABCA1 that is contained within this candidate region is subject to sterol-dependent regulation. Subsequent studies have shown that homozygous mutations in ABCA1 are the underlying defect in Tangier disease, whereas heterozygous mutations are found in patients with the more frequent and less severe familial HDL deficiency, which is inherited in a dominant mode and lacks clinical features of Tangier disease (i.e., at least a subgroup of familial HDL deficiency patients are Tangier heterozygotes). The essential role of ABCA1 in the regulation of HDL metabolism was further supported by demonstrating that targeted disruption of the ABCA1 gene in mice produces a phenotype similar to human Tangier

disease, whereas overexpression of ABCA1 increased HDL cholesterol levels. ABCA1-deficient cells are characterized by a complete loss of apo AI-mediated cholesterol and phospholipid efflux, indicating that ABCA1 is critically involved in the first step of reverse cholesterol transport. Without the initial ABCA1-dependent lipidation, apo AI undergoes rapid degradation, explaining the extremely low apo AI levels in Tangier patients and the increased catabolism of apo AI and HDL in Tangier patients infused with radiolabeled normal HDL. In BAC transgenic mice overexpressing ABCA1, a highly significant correlation was observed between the increase in cholesterol efflux from various tissues and the elevation of plasma HDL. Similarly, in patients with heterozygote ABCA1 mutations, the reductions in cholesterol efflux and plasma HDL were closely correlated. Together, these data provided direct evidence that ABCA1-dependent cholesterol efflux is a major determinant of plasma HDL cholesterol levels.

ABCA1: A REGULATOR OF APO AI-MEDIATED LIPID EFFLUX

The exact cellular processes facilitating and regulating ABCA1-dependent lipid efflux are the subject of intense investigation. Data suggest that apo AI interacts either directly with ABCA1 or with lipid domains in close proximity to ABCA1. This interaction stimulates a Golgi- and energy-dependent vesicular transport process, resulting in the translocation of intracellular cholesterol and phospholipids to sites accessible to the apolipoprotein. Data also suggest that this apo AI-mediated lipid efflux is a two-step mechanism, with an initial ABCA1-dependent efflux of phospholipids and a subsequent ABCA1-independent efflux of cholesterol to the newly formed apo AI-phospholipid complex. Moreover, it has been shown that ABCA1 rapidly recycles between the cell surface and the intracellular compartments, although it is currently unclear whether this recycling is involved in the lipid transport process or instead regulates synthesis and degradation of ABCA1. Regarding the direct function of ABCA1, it was initially assumed that ABCA1 functions as an active pump translocating cholesterol from the inner leaflet of the plasma membrane to the outer leaflet, where it is accessible to the uptake by apo AI. However, in contrast to ABC transporters that exert bona fide pump function (e.g., MDR-1), ABCA1, similar to the ABC regulator proteins CFTR and SUR, shows only marginal intrinsic ATPase activity. Thus, ABCA1 may act as a transport

facilitator rather than as an active pump. Interestingly, both the C terminus of CFTR and ABCA1 contain a PDZ domain-binding sequence. By using the yeast-two-hybrid system, we demonstrated a direct interaction of ABCA1 with the PDZ domain-containing protein β 2-syntrophin. Immunoprecipitation confirmed these results and identified utrophin as an ABCA1 interaction partner. In analogy to the function of β 2-syntrophin-utrophin complexes in anchoring insulin-containing secretory granules, it is tempting to speculate that the interaction of ABCA1 with β 2-syntrophin-utrophin regulates the availability of ABCA1 at the cell surface. Additional ABCA1 interacting proteins include components of t-SNARE complexes, which are involved in targeted vesicle transport and are also known to interact with the N terminus of CFTR.

REGULATION OF ABCA1 EXPRESSION AND FUNCTION

Several factors have been shown to control the expression of ABCA1. Since the initial finding that cholesterol influx into the cell potentially induces ABCA1 expression, a number of transcriptional control elements have been characterized. Tissue-specific regulation of ABCA1 is controlled by the transcription factors Sp1/3, USF1/2, and HNF-1 α , and considerable attention has been paid to nuclear liver X receptors (LXR) as inducers of ABCA1 expression in response to lipid loading. In addition, the zinc finger protein ZNF202 appears to function as a major repressor of ABCA1 transcription, and the oncostatin M-induced ABCA1 transcription provides a new concept for how members of the IL6 family of cytokines may regulate lipid transport proteins. Additional regulators of the ABCA1-dependent lipid efflux pathway include cAMP, phospholipase C, phospholipase D, and bioactive sphingolipids such as ceramide, sphingosine, and sphingosine-1-phosphate. The effects of these signaling pathways are probably cell type dependent, and further work is necessary to determine the exact mechanisms by which they control ABCA1-dependent cell function.

ABCA1 AND SUSCEPTIBILITY TO ATHEROSCLEROSIS

Considering the known reverse relationship between HDL cholesterol levels and the risk of premature CAD, several groups have investigated the role of ABCA1 in atherogenesis. Thus, it has been reported

that homozygote and heterozygote mutations in ABCA1 are associated with an increased prevalence of premature CAD that correlates to the reduction in HDL cholesterol. Furthermore, it has been demonstrated that diet-induced development of atherosclerotic lesions is significantly reduced in transgenic mice overexpressing ABCA1. In contrast, complete inactivation of ABCA1 in apo E^{-/-} and LDL^{-/-} mice had no effect on the development of atherosclerotic lesions, although it markedly reduced HDL cholesterol. It was suggested that the proposed atherogenic effect of complete ABCA1 deficiency may be compensated by a less atherogenic lipid profile, a hypothesis that may also partially explain the lack of premature atherosclerosis in a significant number of Tangier patients. Importantly, two independent studies showed that targeted disruption of ABCA1 in leukocytes of LDL^{-/-} or apo E^{-/-} mice resulted in the development of more advanced atherosclerotic lesions without significantly affecting HDL levels. Together, these data indicate that ABCA1 clearly serves an anti-atherogenic function, although this may involve properties of ABCA1 that are independent of plasma lipids and HDL levels.

Several factors may account for the protective effect of ABCA1 in atherogenesis. First, ABCA1-mediated cholesterol efflux may significantly compensate excessive cholesterol uptake by macrophages in the vessel wall without significantly influencing plasma HDL levels. Second, ABCA1 has been implicated in the engulfment of apoptotic cells by macrophages. Thus, it is conceivable that the ABCA1-mediated phagocytic activity of lesion macrophages may counteract excessive accumulation of apoptotic material that, in return, may stimulate the inflammatory response within the vascular wall. Finally, we have previously hypothesized that ABCA1 function regulates the differentiation, lineage commitment (phagocytic vs dendritic cells), and targeting of monocytes into the vascular wall or the RES. This concept has been substantiated by recent work from our laboratory demonstrating accumulation of macrophages in liver and spleen in LDL receptor-deficient mouse chimeras that selectively lack ABCA1 in their blood cells. The fact that the absence of ABCA1 from leukocytes is sufficient to induce aberrant monocyte recruitment into specific tissues identifies ABCA1 as a critical leukocyte factor in the control of monocyte targeting. An interesting clue as to how ABCA1 may be implicated in the control of monocyte/macrophage trafficking at the cellular level comes from the observation that apo AI-mediated lipid efflux is paralleled by the down-regulation of the protein Cdc42 and filipodia formation, which may mitigate monocyte recruitment to the artery wall.

ABCA1: A REGULATOR OF MEMBRANE PROTRUSIONS AND LIPID MICRODOMAINS

CDC42 is a member of the family of small GTP-binding proteins that controls a wide range of cellular functions, including cytoskeletal modulation, formation of filipodia, and vesicular processing. Similar to ABCA1, the protein expression of CDC42 is increased by cholesterol loading of monocytes, whereas deloading by apo AI and HDL has the opposite effect. These changes in CDC42 expression are paralleled by alterations in M-CSF-induced filipodia formation and fMLP-induced chemotaxis, with an increase on E-LDL-mediated cholesterol loading and a decrease in response to apo AI and HDL. ABCA1-deficient monocytes from Tangier patients showed reduced filipodia formation and decreased CDC42 expression. Thus, the ABCA1 pathway is linked to the formation of membrane protrusions, which may be of significant relevance for the anti-atherogenic effects of apo AI and HDL. Further evidence for this functional link was provided by Matsuzawa and colleagues, who demonstrated that overexpression of ABCA1 in HEK293 cells induces formation of filipodia and long membrane protrusions. These ABCA1 effects and the apo AI-mediated lipid efflux in MDCK cells were significantly reduced by a dominant negative form of CDC42. Together with the finding that ABCA1 co-immunoprecipitated with CDC42, the data suggest a role for CDC42 as a downstream mediator of ABCA1 function. Moreover, it could be imagined that the principal function of ABCA1 is to facilitate the supply of choline-phospholipids and cholesterol for newly emerging plasma membrane extensions, which in the presence of apo AI are transferred to the extracellular acceptor rather than being used for the formation of new membrane areas (Fig. 1B). This hypothesis would be in accordance with the slightly impaired intestinal cholesterol absorption observed in *Abca1*^{-/-} mice, a process that involves the microvilli of the enterocyte brush boarder membrane. Further support is derived from findings that apo AI preferentially depletes cholesterol and phospholipids from a novel type of cholesterol-based microdomain called Lubrol raft. Röper and colleagues showed that these lipid microdomains are building units for different forms of plasma membrane protrusions and that CDC42 and ABCA1 were partially localized to these domains. In fibroblasts, apo AI-induced lipid efflux also involved classical Triton X-100 rafts, and independent of the cell type, these domains were also modified by spherical HDL₃ (Fig. 1B). Because Triton rafts are recognized as

platforms of signal transduction and cell regulation, the observed effect may be of major importance for the role of HDL in atherogenesis.

Abetalipoproteinemia

John R. Wetterau and Richard E. Gregg
Bristol-Myers Squibb, Princeton, New Jersey, United States

Glossary

chylomicron Triglyceride-rich lipoprotein made in the intestine that transports dietary lipid to various tissues throughout the body.

microsomal triglyceride transfer protein (MTP) Heterodimeric lipid transfer protein found within the lumen of the endoplasmic reticulum of enterocytes and hepatocytes that promotes the transport of triglyceride and cholesteryl ester between phospholipid membranes in *in vitro* lipid transfer assays.

protein disulfide isomerase Multifunctional redox chaperone protein found within the lumen of the endoplasmic reticulum that promotes the proper folding of newly synthesized secretory proteins that contain disulfide bonds.

very low-density lipoprotein (VLDL) Triglyceride-rich lipoprotein made in the liver and intestine that transports lipid to peripheral tissues.

Abetalipoproteinemia is an autosomal recessive disease caused by mutations in the gene encoding the microsomal triglyceride transfer protein. Affected individuals have defects in the production of plasma lipoproteins that contain apolipoprotein B: chylomicrons, very low-density lipoproteins, and low-density lipoproteins. As a result of the defect, subjects have plasma cholesterol and triglyceride levels of approximately 40 and 10mg/dl, respectively. Neuromuscular and retinal degeneration occurs due to a secondary deficiency in vitamin E, a fat-soluble vitamin that depends on lipoproteins for its absorption and transport throughout the body.

INTRODUCTION

In 1950, F. A. Bassen and A. L. Kornzweig diagnosed a patient with retinitis pigmentosa, malformed erythrocytes, celiac disease, and ataxia. This disease was later named abetalipoproteinemia when H. B. Salt and colleagues associated a similar syndrome with an absence of plasma lipoproteins with beta electrophoretic

mobility. Subsequently, it was found that many of the pathological consequences of the disease, particularly the neurological findings, were related to vitamin E deficiency. In the 1990s, the molecular basis of the disease was elucidated when a link between mutations in the gene encoding the microsomal triglyceride transfer protein [MTP; a lipid transfer protein located at the sites of chylomicron and very low-density lipoprotein (VLDL) assembly], a defect in lipoprotein assembly, and abetalipoproteinemia was established, thus demonstrating that the proximal cause of abetalipoproteinemia is a mutation in the MTP gene.

ABETALIPOPROTEINEMIA IS CAUSED BY MUTATIONS IN THE MTP GENE

Overview of Lipoprotein Metabolism

Plasma lipids are transported throughout the body in lipid-protein complexes. Chylomicrons and VLDL are triglyceride-rich emulsions surrounded by a monolayer of phospholipid, free cholesterol, and protein. They transport dietary and endogenously synthesized triglyceride, respectively, to peripheral tissues, where it is hydrolyzed to produce free fatty acids that can be used as an energy source or stored as fat in adipocytes. Following lipolysis, chylomicron remnants are rapidly cleared from plasma. Some VLDL remnants are cleared directly from plasma, but a portion are converted to cholesterol and cholesteryl ester-rich LDLs, which are subsequently removed from plasma by a receptor-mediated process. The primary protein component of VLDL is apolipoprotein B (apoB)-100 (4536 amino acids). The primary protein component of chylomicrons is apoB-48 (2152 amino acids), which is encoded by an edited version of the mRNA that encodes apoB-100.

High-density lipoproteins (HDLs) are small, dense particles secreted directly from the liver or made from excess surface components of chylomicrons and VLDL following hydrolysis of their triglyceride

core. HDLs play an important role in the transport of cholesterol from peripheral tissues to the liver, where it can be processed and transported out of the body.

Genetic Link between a Defect in MTP, a Defect in Lipoprotein Assembly, and Abetalipoproteinemia

The MTP is a heterodimeric lipid transfer protein found in the lumen of the endoplasmic reticulum and Golgi apparatus. One subunit is protein disulfide isomerase, a 58-kDa multifunctional redox chaperone protein that catalyzes the proper folding of newly synthesized proteins that contain disulfide bonds within the endoplasmic reticulum. The second subunit is a novel 97-kDa subunit that confers the lipid transfer activity to the protein complex. In lipid transfer assays utilizing synthetic membrane substrates, MTP accelerates the transfer of triglyceride, cholesteryl ester, and, to a lesser extent, phospholipid between membranes.

Intestinal biopsies from abetalipoproteinemic subjects were found to be devoid of MTP activity and the unique large subunit of MTP. Following the cloning of the MTP large subunit, various missense, nonsense, frameshift, and splice site mutations were identified in the gene encoding the MTP large subunit in the patients studied. All mutations were either homozygous or compound heterozygous and explained the complete absence of functional MTP protein, consistent with the autosomal recessive transmission of the disease. These and subsequent studies of specific inhibitors of MTP lipid transfer activity established that MTP is required for the assembly of apoB-containing lipoproteins, and that defects in MTP are the proximal cause of abetalipoproteinemia.

PATHOLOGICAL CONSEQUENCES OF A DEFECT IN MTP

Clinical Description of Abetalipoproteinemia

Abetalipoproteinemic subjects have fat malabsorption that results in abdominal discomfort, diarrhea, and steatorrhea following a meal with a normal fat content. Intestinal enterocytes are fat laden. Subjects also have malabsorption of fat-soluble vitamins—vitamins E, A, K, and, to a lesser extent, D. Plasma cholesterol and triglyceride levels are very low (approximately 40 and 10mg/dl, respectively), and plasma triglyceride levels do not increase following a meal. Apolipoprotein B,

the major protein component of VLDL and chylomicrons, is virtually absent. Although HDL levels may be only moderately decreased, they have an abnormal composition, including an elevated total cholesterol, free cholesterol/esterified cholesterol ratio, and sphingomyelin content.

Half or more of the erythrocytes in abetalipoproteinemic subjects have irregular cytoplasmic projections. These abnormal erythrocytes, referred to as acanthocytes, are thought to arise from an altered membrane composition. A moderate anemia may occur due to hemolysis and a shortening of the red blood cell resident time in the circulation. Coagulation abnormalities secondary to a deficiency of vitamin K may occur. Liver biopsies show evidence of steatosis. Elevated transaminase levels and fibrosis have been reported. There are also rare reports of serious liver pathology, including cirrhosis.

The neurological abnormalities are usually the most severe consequence of the syndrome and include spinal–cerebellar degeneration and peripheral neuropathies, which can lead to a loss of reflexes, altered sensation, muscle weakness, and ataxia that can progress to a point at which the affected individual is unable to walk. Degenerative pigmentary retinopathy, retinitis pigmentosa, leads to decreased night and color vision. If left untreated, this will progress to blindness.

Treatment

The gastrointestinal side effects of the disease can be controlled by avoiding high-fat meals. This is particularly important early in life, when severe gastrointestinal side effects and malabsorption can result in a failure to thrive. Therapy for abetalipoproteinemic subjects includes fat-soluble vitamin supplements, including massive levels of vitamin E (up to 20,000mg/day) and more usual replacement doses of vitamins A and K. Vitamin D does not usually need to be supplemented. The neurological and ophthalmological manifestations of abetalipoproteinemia are similar to those found in animals with vitamin E deficiency. Vitamin E, which plays an important role in preventing lipid peroxidation, requires chylomicrons and VLDL for efficient absorption and transport throughout the body. Although plasma vitamin E levels remain far below normal following vitamin E therapy, tissue levels may increase to near normal levels. Vitamin E and A therapy may slow the progression or even stabilize the neurological and retinal consequences of the disease.

Acetylation

Paolo Portaleone
University of Turin, Turin, Italy

Glossary

arylalkylamine Ammonia (NH₃) derivative with aromatic (aryl) and aliphatic (alkyl) radicals.

choline Alcoholic molecule derived from phosphatidylcholine (or lecithine) supplied by food.

enzyme A protein or proteinaceous substance produced by a living cell that catalyzes a specific reaction.

histone Eight proteic sequences (octamer) constituting the core of the nucleosome (chromatin unit) around which the DNA double helix is wrapped.

peptide hormone Proteic endocrine messenger with low molecular weight, from 2 to several 10s of amino acid sequence linked by amino acid bond.

Acetylation is a biochemical reaction, catalyzed by specific enzymes (acetyltransferases), that consists in the transfer of an acetyl radical (CH₃-CO-) from a donor (e.g., acetyl coenzyme A) to an acceptor molecule.

INTRODUCTION

Acetylation is a general metabolic reaction common to both the plant and animal kingdoms. Nevertheless, acetyltransferase enzyme systems are involved not only in the biotransformation of xenobiotics but also in activating–deactivating processes of endogenous active agents such as proteins (e.g., histones, peptide hormones), alcohols, amino acids, and amines (e.g., choline, 5-hydroxy-tryptamine).

In this regulatory function, it is evident that acetylation holds a crucial role in basic processes of cellular life, from DNA transcription, replication, and repair to the control of selective messenger information through neurohormones and neurotransmitters. For the relevance of the acetyltransferase regulatory role, its involvement in several pathologies, from functional or degenerative diseases (e.g., headache, depression,

Parkinson's disease, Alzheimer's disease) to neoplastic growth, has been suggested.

HISTONE ACETYLATION

The nucleosome, the fundamental unit of chromatin in eukaryotic cells, holds a core particle consisting of a proteic histone octamer, two copies each of H2A, H2B, H3, and H4, around which 146 bp of DNA is wrapped. The whole chromatin components are responsible for DNA dynamic behavior, but histone modifications have the main influence on DNA transcription, repair, and replication. Histones are modified by means of the addition of several chemical radicals such as phosphate, methyl, acetyl, ribosyl, and ubiquitin groups.

Acetylation of core histones is associated with transcriptional activation. In contrast to cotranslational N-terminal α -acetylation of many proteins, histone acetylation occurs posttranslationally and reversibly on the ϵ -NH₃⁺ groups of highly conserved lysine residues of the N-terminal tails of core histones.

The enzymes catalyzing reversible histone acetylation are histone acetyltransferases (HATs) and deacetylases (HDACs). HATs catalyze the transfer of the acetyl moiety from acetyl coenzyme A (Ac-CoA) to the ϵ -NH₃⁺ of lysine residues, whereas in the opposing deacetylation reaction, HDACs remove the acetyl groups and thereby reestablish the positive charge in the histones. Thus, acetylation neutralizes the positive charge increasing the hydrophobicity of the histones, leading to “opening up” the chromatin complex through a reduced affinity of acetylated N-terminal domains of histones to DNA. Therefore, the modification in nucleosomal structure is considered to play a causative role in activating transcription. Another possibility, or rather an additional effect, has been suggested: histone acetylation could represent a signal “flag” recognized by other molecules linked to transcriptional activation.

Two different classes of HATs have been described: type A and type B. Type A HATs are localized in the

nuclei and acetylate nucleosomal histones leading to transcriptional activation, whereas type B HATs can be found in cytoplasmic fractions and acetylate newly synthesized histones before chromatin assembly during DNA replication.

Several known transcriptional regulators in mammals have been found to possess intrinsic type A HAT activity, and among them the best understood family is the Gcn5-related N-acetyltransferase (GNAT) family. No type B HAT has been identified and characterized in mammals.

Not only nuclear histones are substrates for the acetyltransferase, but also numerous nonhistone proteins involved in transcription regulation, such as p53, E2F1, EKLF, TFIIE β , TFIIF, TCF, GATA1, HMGI(Y), and ACTR, or even non-nuclear proteins, such as α -tubulin, are substrates for the acetyltransferase. There are three possible consequences of the acetylation processes, depending on where acetylation takes place within the protein: increased or decreased DNA binding, protein-protein interaction regulation, and protein stability.

If there has been an explosion of studies on HAT activity during the past decade or so, only a few lines of evidence indicate the regulation of the enzymatic activity of acetylases. A bromodomain (a specific HAT protein structure) is present in many transcriptional activators with HAT activity, and it seems to be a requisite for targeting the enzyme to the substrate. The regulation of HAT activity is carried out by proliferation and differentiation signals by means of phosphorylation or hormonal signaling.

Because acetylation can regulate such wide and different cellular functions, both nuclear and cytoplasmic (including the circadian clock in DNA transcription), it is obvious that its dysfunctioning could be at the origin of the different pathologies.

PEPTIDE HORMONE ACETYLATION

N-terminal acetylation is a nearly selective posttranslational processing event among peptide hormones, and among the end products of the pro-opiomelanocortin (POMC) biosynthetic pathway, only α -melanocyte-stimulating hormone (α -MSH) and β -endorphin undergo this posttranslational modification. The relevance of the POMC-derived peptide N-acetylating mechanism, under a phylogenetic point of view, is supported by its persistence as an "ancestral" mechanism throughout vertebrate evolution. In mammals, α -MSH and β -endorphin, as final products of a set of cleavage reactions of POMC, were found not only in

secretory granules of pituitary neurointermediate lobe but also in anterior pituitary lobe and in neurons, mainly of the hypothalamic arcuate nucleus.

The N-acetylation reaction, which requires acetyl-CoA as a coenzyme, occurs on the serine-NH₂ terminal for α -MSH and on the tyrosine-NH₂ terminal for β -endorphin. On the basis of the various amino-terminal targets of N-acetyltransferase (NAT) and its different regional distributions in the pituitary and brain, two distinct enzymes, an α -MSH-acetyltransferase (MAT) and a β -endorphin-acetyltransferase (EAT), have been proposed. Actually, two forms of NAT have been found. One enzyme, specifically localized in secretory granules of the neurointermediate lobe (NIL) of the pituitary gland with an optimal pH of 6.0 to 6.6, is inhibited by several solubilizing detergents and possesses similar characteristics in the acetylation process of both the serine of α -MSH and the tyrosine of β -endorphin. Therefore, this single NAT capable of acetylating the opioid and melanotropic peptides has been termed opiomelanotropin acetyltransferase (OMAT). A second enzyme, with an optimal pH of 7.4, is inhibited by Mg²⁺, shows different anatomical and subcellular (cytosol) distribution, and has a more general acetyltransferase activity (GAT).

The POMC-derived peptide NAT is coexpressed with the POMC gene and undergoes the same regulatory control of POMC synthesis by inhibitors and activators (e.g., glucocorticoids, sex steroids, and dopamine as inhibitors; adrenalectomy, castration, and dopamine receptor antagonists as activators).

The N-acetylation of des-acetyl- α -MSH and β -endorphin substantially alters the physiological responses produced by both peptides. The acetylated form of α -MSH, in fact, is about 10 to 100 times more effective than its des-acetylated form in increasing arousal, memory, and attention in the Y-maze visual discrimination task and in eliciting excessive grooming. Moreover, the *in vitro* lipolytic activity on rabbit adipose tissue slices and the *in vitro* melanotropic activity in frog skin are markedly reduced after removing the acetyl group from monoacetyl- α -MSH. Conversely, the acetylation of β -endorphin completely eliminates the opiate analgesic activity of the peptide and markedly reduces its affinity in binding to opiate receptors. Furthermore, a substantial decrease of NAT activity has been observed during the lifetime, fitting in with the decreased concentrations of α -MSH found in rat aged brain.

The physiological role of POMC-derived peptide NAT, with its ambivalent effects, activating des-acetyl- α -MSH, and deactivating β -endorphin, is very difficult to interpret, and the lacking characterization of the

enzyme, very unstable and ubiquitous, makes the task arduous. Considering that the POMC-derived peptides (adrenocorticotropin hormone [ACTH], α -MSH, and β -endorphin) are the main effectors in the “organized stress response” coordinating the biological and behavioral adaptive effects, we suggest that the deactivating–activating N-acetylation regulates the chronology of the adaptive response sequence with a rapid inactivation of ACTH and β -endorphin effects and with a potentiation of the α -MSH long-lasting adaptive activity. The progressively lower synthesis and activating–deactivating NAT activity of POMC-derived peptides during aging could be related to the reduced adaptive capabilities of aged individuals.

CHOLINE ACETYLATION

Acetylcholine (ACh) is the neurotransmitter of the parasympathetic nervous system and is synthesized from choline and Ac-CoA in a single-step reaction catalyzed by the enzyme choline acetyltransferase (ChAT) that is expressed selectively in cholinergic neurons, where it serves as a phenotypic marker. The substrate choline, derived from phospholipids and the ACh hydrolysis, is taken up by the high-affinity sodium (Na^+)-dependent choline transporter. The newly synthesized neurotransmitter is accumulated in synaptic vesicles by means of a specific vesicular acetylcholine transporter (VACHT), a 12-transmembrane domain protein that uses the electrochemical gradient generated by a proton ATPase to exchange two protons by one ACh molecule.

ChAT is encoded by a single gene and is coexpressed with VACHT. The gene of VACHT is embedded in the first intron of the ChAT gene. This unique organization was named “cholinergic gene locus,” suggesting reciprocal posttranslational regulation between the two proteins. In humans, four of the six identified transcripts translate to the same 69-kDa protein. The fifth and sixth transcripts yield 82- and 74-kDa forms of ChAT. Until now, the mechanisms regulating production of these different transcripts and their physiological roles have not been elucidated.

ChAT exists in two forms in cholinergic nerve terminals: a soluble form (80–90% of the total enzyme activity) and a membrane-bound form (10–20%). Moreover, the 82-kDa ChAT has been localized to the nucleus, whereas the 69-kDa enzyme is largely cytosolic. Because it is unclear whether ACh synthesis occurs in the nucleus, different functional roles for 82-kDa ChAT must be considered. The 69-kDa ChAT is the form more represented and responsible for the majority of ACh biosynthesis.

The fact that ChAT is not saturated at the substrate concentrations in *in vitro* kinetic studies means that the enzyme would be in kinetic excess. Based on these *in vitro* data, it is accepted that the neuronal ChAT levels might not be rate limiting in ACh synthesis; therefore, the availability of the substrates would regulate ACh production. On the other hand, some data support the regulatory role of ChAT to maintain the homeostatic levels of ACh under some conditions of neuronal activity and demand for ACh synthesis.

Short- and long-term regulation of ChAT activity has been described. Thomas Dobransky and R. Jane Rylett reviewed the role of phosphorylation in ChAT short-term regulation, showing that ChAT is phosphorylated by several protein kinases at various sites of ChAT primary structure in response to different functional states of neurons. Taken together, these lines of evidence indicate that phosphorylation of ChAT is physiologically significant and could serve as a regulatory mechanism. Neurotrophic factors (neurotrophins) such as nerve growth factor (NGF) are responsible for long-term ChAT regulation, enhancing the enzyme expression and/or its activity. Clarifying the molecular mechanisms of ChAT regulation and its dysfunctions may be helpful in explaining the possible cellular mechanisms responsible for the loss of cognitive attributes associated with cholinergic deficit in Alzheimer’s disease.

ARYLALKYLAMINE N-ACETYLATION

The acetylation of serotonin (5-hydroxy-tryptamine [5-HT]) in the pineal gland is another acetylation reaction essential to regulating the biological circadian rhythms in vertebrates by means of the production of the pineal hormone melatonin.

Melatonin is synthesized from serotonin, which is acetylated into N-acetylserotonin (NAS) by the arylalkylamine N-acetyltransferase (AA-NAT) and then is methylated by the hydroxyindole-O-methyltransferase enzyme (HIOMT). The rate of O-methylation is largely a function of substrate availability, whereas the N-acetylation step is regulated by the amount and activation of AA-NAT protein. Melatonin synthesis occurs in darkness under the control of norepinephrine (NE) that is released from sympathetic fibers originating in the superior cervical ganglia and that is regulated, through a polysynaptic neuronal pathway, by a circadian oscillator located in the suprachiasmatic nuclei (SCN). NE activates pinealocytes acting on α_1 - and β_1 -adrenergic receptors and subsequent increases in the intracellular concentration of calcium ions ($[\text{Ca}^{2+}]_i$) and cyclic AMP (cAMP), respectively, leading

a strong AA-NAT activation at both the transcriptional and posttranscriptional levels. cAMP-increased levels induce the phosphorylation protein kinase A-dependent of the stimulatory transcription factor cAMP response element-binding protein (CREB). Phosphorylated CREB binds to a cAMP response element (CRE) element in the AA-NAT gene, resulting in increased transcription and accumulation of AA-NAT mRNA and then in increased expression and activity of the AA-NAT enzyme. The activation of α_1 -adrenergic receptors induces increased concentrations of Ca^{2+} and diacylglycerol (DAG), leading to activation of protein kinase C (PKC) potentiating β_1 -adrenergic receptor stimulation of adenylate cyclase (AC) through a postreceptor mechanism.

Furthermore, there is posttranslational regulation of AA-NAT protein levels by means of cAMP-dependent inhibition of proteosomal proteolysis. This mechanism involves phosphorylation-dependent binding of AA-NAT to 14-3-3 proteins, shielding the enzyme from proteolysis. In rodents, cAMP stimulation causes AA-NAT mRNA to increase more than 150-fold at night, whereas in ungulates and primates, the night/day ratio is approximately 1.5. This difference may be explained by the fact that in ungulates and primates, AA-NAT protein levels are regulated primarily at the posttranslational level by controlled proteosomal proteolysis.

AA-NAT is a member of a large superfamily of proteins referred to as the GNAT family and acts through catalysis of the transacetylation of serotonin to N-acetylserotonin with Ac-CoA as a donor. AA-NAT is a globular protein with a molecular weight of 23 kDa and consisting of eight stranded β -sheets containing Ac-CoA-binding sites. It is described in two different conformational states influencing its functional efficiency.

In addition to NE-induced activation of the melatonin-generating system, several other neuroactive substances have been shown to influence melatonin synthesis. These include vasoactive intestinal peptide (VIP), pituitary adenylate cyclase-activating polypeptide (PACAP), and ACh acting on AA-NAT

mRNA expression and/or on second messenger-induced AA-NAT stimulation.

It has been hypothesized that alterations in AA-NAT synthesis and/or activity can represent the pathophysiological basis not only of circadian rhythm disturbances but also of several pathologies such as migraine, depression, and insomnia.

Acromegaly, Clinical Features of

Ariel L. Barkan

University of Michigan, Ann Arbor, Michigan, United States

Glossary

arthropathy Abnormality in the condition of a joint of the body; enlargement, swelling, degeneration, or other such disturbance in a joint.

growth hormone (GH) A polypeptide hormone that is secreted mainly by the pituitary gland, although it is also produced by other cell types, such as lymphoid cells. Its actions are related mainly to growth (soft tissues, long bones, etc.) and to metabolism. It belongs to a family of hormones that includes prolactin and placental lactogens as well as other placental factors. Acromegaly results from GH hypersecretion.

insulin-like growth factor (IGF) One of a class of hormones structurally related to insulin, but exhibiting proliferative and differentiative, rather than metabolic, effects. IGF-1 overproduction is associated with acromegaly.

multiple endocrine neoplasia (MEN) syndromes A group of genetically distinct familial diseases in which two or more endocrine glands develop excess normal tissue (hyperplasia) and/or adenoma (tumor).

sleep apnea A sleep disorder in which the subject has intermittent periods of a failure to automatically control respiration; these involuntary pauses in breathing may occur repeatedly during a given period of sleep.

From the purely clinical perspective, acromegaly is the most spectacular endocrine disease. Humanity has always been fascinated with giants, and from the biblical Goliath to James Bond's foe, Jaws, they populate the lore of virtually every era and culture.

INTRODUCTION

Acromegaly is due to growth hormone (GH) hypersecretion and the resultant secondary overproduction of insulin-like growth factor-1 (IGF-1). In virtually all cases (>99%), the source of excessive GH is a benign pituitary tumor of purely somatotroph or mixed cellular origin. Rarely, somatotroph tumors arise in an ectopic pituitary, a remnant of the primitive

Rathke's pouch, and are found in the posterior pharynx, sphenoid bone, or sphenoid sinus or even within the sella, separate from the normal pituitary gland. Ectopic production of GH-releasing hormone (GHRH) leads to pituitary somatotroph hyperplasia with subsequent adenoma formation. Carcinoids and islet cell tumors are the most frequent sources of ectopic GHRH. Hypothalamic/pituitary gangliocytomas or choristomas, or in one case the pituitary adenoma itself, were shown to be a source of excessive GHRH production. Ectopic GH secretion was documented in only two cases: one by a malignant islet cell tumor and another by a non-Hodgkin's lymphoma. Acromegaly may be a part of well-defined MEN syndromes such as MEN-1 (parathyroid, pituitary, pancreas), McCune-Albright, and Carney syndromes. In some instances, the clinical syndrome of acromegaly may be overshadowed by other manifestations of a malignant or polyglandular disease.

Clinical manifestations of acromegaly correlate better with the prevailing levels of IGF-1 than with GH, and the duration of GH/IGF-1 excess may play a major role. A clinical and biochemical syndrome of acromegaly may be transiently expressed during normal puberty or pregnancy. This is due to physiological overproduction of GH by the normal pituitary gland during sexual maturation or by the placental synthesis of the GH variant.

In most cases, acromegaly is an insidious disease, and its early clinical manifestations usually go unnoticed by the patient, the patient's family, and/or the patient's family physician. Retrospective questionnaires and the inspection of old photographs usually set the clinical onset of disease at 5 to 10 years prior to the diagnosis.

Clinical presentation of acromegaly consists of the mass effects of the tumor itself, the manifestations of the abnormal growth affecting virtually all organs and tissues, and the metabolic derangements effected by GH itself. Despite the seemingly straightforward pathophysiological mechanisms, the clinical picture of acromegaly is often protean, and the correct

and timely diagnosis requires significant clinical acumen.

MASS EFFECTS OF THE TUMOR

Most pituitary somatotropinomas (60–80%) are large at the time of diagnosis (macroadenoma, >10 mm in the largest diameter) and are often invasive. Visual field defects were present at diagnosis in 90% of patients in the past, but this figure decreased to ~10 to 20% due to earlier recognition of the disease. Ophthalmoplegia (III, IV, VI, and V₁, V₂ nerves) is rare and, if present, suggests recent rapid expansion of the tumor by a hemorrhage. Headache is present in 50 to 60% of patients and may be severe in about half of them. Headache may be present even in patients with relatively small tumors, where mass effect is unlikely to provide an explanation. Hypopituitarism (ACTH and TSH deficiency) in acromegaly occurs less frequently than in patients with nonfunctioning tumors of similar size. However, hypogonadism is frequent (~50%), likely as a consequence of coexisting hyperprolactinemia and inherent lactogenic effect of GH itself. Symptomatic pituitary hemorrhage occurs in less than 5% of patients, but asymptomatic events may occur in 30 to 40% of the cases.

ABNORMAL GROWTH

Onset of pathological GH hypersecretion before puberty results in an augmented statural growth. Concomitant hypogonadism prevents epiphyseal closures, and gigantism ensues. Postpubertal onset of disease leads to disproportionate growth and dysmorphic features, that is, true acromegaly (“large extremities”). Eventually, even pituitary giants develop an acromegalic appearance.

Face

A combination of bone and soft tissue overgrowth leads to a typical “acromegalic” face: large nose, thick lips, exaggerated nasolabial and frontal skin furrows, mandibular overgrowth and prognathism, teeth separation, and frontal bossing. These features are seen in 98 to 100% of patients (see Fig. 1).

Extremities

Hands and feet become very “fleshy.” An increase in finger circumference and a widening of the hands and feet develop in 98 to 100% of patients. Patients

Figure 1 Appearance of a patient with florid acromegaly. Courtesy of Professor Stefan S. Fajans.

routinely recall repeat resizing of rings and changes in shoe size (mostly widening).

Skin and Appendages

Skin is characteristically thickened because of excessive deposition of the glycosoaminglycans, hyaluronic acid, chondroitin sulfate, and dermatan sulfate in the papillary and upper reticular dermis. These compounds are very hydrophylic, causing the appearance of a nonpitting edema. Skin thickening at the vertex

causes a peculiar appearance of cutis verticis gyrata (skin folds at the top of the head). Hair growth is increased, and women complain of hirsutism. As opposed to the androgen-related hirsutism, this is pronounced even on the forearms and forelegs. Many women with acromegaly have exceedingly thick scalp hair growth. Hair loss after successful therapy is often a cause of concern but is essentially a physiological return to normalcy.

The functional capacity of sweat and sebaceous glands is increased, resulting in excessive perspiration, often with offensive odor, and in oily skin. Skin tags are frequently present, particularly on the neck. Whether their presence and number can be a marker for colonic neoplasia is uncertain.

Neuromuscular

The muscle mass is increased, but this is primarily due to increased intracellular water, so that muscle strength is either normal or low. In fact, many patients have clinically obvious proximal myopathy. Muscle biopsy often shows hypertrophy of type I and/or atrophy of type II fibers.

Compression neuropathies are common (30–50%); the median nerve is most often affected. It was believed that carpal tunnel syndrome was due to external compression by the components of the wrist compartment, but MRI data showed that the nerve itself is swollen. Occasionally, distal symmetric polyneuropathy may be present.

Oral

Prognathism and widening of the interdental spaces have already been mentioned. Importantly, the size of the tongue is usually enlarged and contributes to the obstruction of the pharynx, with the resultant sleep apnea and impaired mastication. The abnormal oral anatomy often results in speech disturbances. The diameter of the trachea is increased, and the vocal cords are thickened. Together with grossly enlarged sinus cavities, this results in a low and hollow voice pitch. Salivary glands are typically enlarged, and their size is a convenient measure of the GH effect on parenchymatous organs.

Articular

GH receptors are present on all major cell types comprising the skeletal system: fibroblasts, chondrocytes, and osteoblasts. These cells readily produce IGF-1 and are targets for both endocrine and autocrine IGF-1

effects. Thus, arthropathy is a frequent (60–80%) symptom of acromegaly, affecting both axial and appendicular skeleton. The degree and severity of arthropathy best correlate with the duration of disease. Joint pain and low back pain may be experienced soon after the clinical onset of acromegaly but are often fully reversible with successful therapy. However, clinical duration of acromegaly in excess of 10 years is often associated with clinical and radiographical joint deformities that are only minimally affected by the GH-lowering therapy.

Appendicular Arthropathy

The knee is the joint most frequently affected, followed by the shoulder, hip, ankle, elbow, and small hand joints. Radiographic changes are usually seen even in clinically unaffected joints. Initially, GH excess causes cartilage hypertrophy and laxity of the ligaments. The combination of altered geometry of the joint and its instability leads to repeat trauma to the cartilage. The ensuing cartilage fissures are filled by regenerative fibrocartilage, with the subsequent calcification, formation of osteophytes, and exposure of the subchondral bone. Eventually, the articular cartilage becomes thinned and the joint space narrows. The end-stage acromegalic arthropathy looks essentially like degenerative osteoarthritis. Clinical and radiological reversibility of arthropathy can be seen after successful therapy in the joints exhibiting cartilage thickening, but late stages may require joint prosthesis for relief of pain and functional mobility.

Axial Arthropathy

Lumbar involvement is most common, followed by thoracic and cervical arthropathy. Overall, approximately 50% of patients complain of back pain and limitation of movements. Thickened intervertebral discs and lax paraspinal ligaments contribute to abnormal joint mobility. End-stage arthropathy is characterized by the narrowing of the intervertebral space. Ossification of the anterior aspect of the vertebral bodies with exuberant osteophyte formation often bridges the disc space, mimicking diffuse idiopathic skeletal hyperostosis (DISH). Vertebral deformities often lead to kyphosis that may become almost grotesque in some patients.

Bone Metabolism

Biochemical markers of bone remodeling are increased in patients with acromegaly, but histomorphometric data are conflicting; cortical bone shows predominance of bone formation over resorption, whereas trabecular bone has the opposite pattern. Because most patients

with acromegaly have concomitant hypogonadism, these data should be interpreted with caution.

Bone density studies are equally controversial, but overall it appears that cortical bone mineral density may be normal or even increased, whereas trabecular bone mineral density is normal or decreased. The "normalcy" of the latter is questionable because of the interference by osteophytes. In any case, patients with acromegaly do not have altered fracture rates, and the assessment of bone mineral density in acromegaly may be of academic interest only.

Cardiovascular

Increased mortality of untreated or poorly treated acromegaly is almost completely attributable to cardiovascular disease. Hypertension is seen in 20% of patients and does not appear to be reversible by GH/IGF-1-lowering therapy. Concentric left ventricular hypertrophy is seen in approximately two-thirds of patients, and its occurrence is best related to the duration of disease. Hypertrophy frequently occurs even in normotensive patients. Early stages of acromegaly, typical of young patients with short disease duration, are characterized by tachycardia and increased systolic output (hyperkinetic syndrome). Progressively, cardiac hypertrophy and diastolic dysfunction ensue, and end-stage disease is characterized by impaired systolic function and heart failure. The development of hemodynamic abnormalities is augmented by valvular involvement in approximately 20% of patients. Normalization of GH and IGF-1 can reduce the degree of left ventricular hypertrophy within 2 to 4 weeks.

Rhythm abnormalities, occurring in 40% of patients, are more ominous. Ectopic beats, paroxysmal atrial fibrillation, paroxysmal supraventricular tachycardia, sick sinus syndrome, ventricular tachycardia, and bundle branch blocks all are seen with increased frequencies in patients with acromegaly and are exacerbated by physical exercise. Disturbingly, biochemical control of acromegaly might not improve conduction abnormalities. Late ventricular potentials (low-amplitude, high-frequency waves in the terminal phase of QRS complexes) are strong predictors of future arrhythmic events and are seen in 50% of patients with active acromegaly.

Sleep Apnea

Sleep apnea occurs in 75% of patients. In most, it is of an obstructive nature due to soft tissue hypertrophy of the pharynx. Interestingly, in approximately one-third

of patients, there is a central component of sleep apnea with decreased ventilatory drive. The pathogenesis of central sleep apnea in acromegaly is unknown, but both subtypes may be ameliorated by GH-lowering therapy. Sleep apnea is manifested as snoring, daytime sleepiness, fatigue, and headache. It is a strong predictor of future cardiovascular events, hypertension, or stroke. Many patients are unaware of their snoring; family members provide markedly more reliable information.

Renal

Kidney size and glomerular filtration rate are characteristically increased. Hypercalciuria may lead to kidney stone formation (in approximately 10% of patients).

Gastrointestinal

Liver and spleen sizes are normal. Hepatomegaly in patients with acromegaly always should be assumed to result from another disease process and should be vigorously investigated. Similarly, the incidence of cholelithiasis is not increased relative to that in the general population. Patients with acromegaly often suffer from constipation due to long and tortuous colon. The incidence of colonic polyps appears to be increased.

METABOLIC

Impaired glucose tolerance is present in 40% of patients, and frank diabetes (DM-2) is present in 30% of patients. These often improve or vanish altogether after successful GH-lowering therapy. Other metabolic abnormalities include hypertriglyceridemia, hypercalciuria, and hyperphosphatemia. Hypercalcemia is not a feature of acromegaly per se, and its presence should suggest another pathological process.

NEUROPSYCHIATRIC

Similar to any chronic disease associated with physical discomfort and lifelong therapy, acromegaly is associated with decreased quality of life. However, there are no specific neuropsychiatric features attributable to the disease.

CANCER

Because patients with acromegaly have increased incidence of colonic polyps, some investigators assumed that the incidence of colonic carcinoma will also be increased. This was supported by the data from several small studies. Large-scale data, however, failed to

document increased incidence of colon cancer in acromegaly. Similarly, the incidence of breast and prostate cancers was not increased. This, of course, does not apply to patients with genetic forms of acromegaly, such as MEN-1, in which there is a predictable component of coexisting neoplastic diseases.

Acromegaly, Diagnosis of

Klaus von Werder

Humboldt University, Berlin, Germany

Glossary

acromegaly Clinical consequence of growth hormone hypersecretion.

growth hormone (GH) Hormone of the anterior pituitary lobe that is essential for normal growth in children. GH is also an important metabolic hormone in adults.

insulin-like growth factor-I (IGF-I) Peptide hormone produced in the liver and other tissues following activation of the GH-receptor.

Endocrinological investigation using hormone measurements and function tests to document active acromegaly is indicated whenever symptoms and clinical stigmata suggestive for the disease are present. Thus, the diagnosis of acromegaly is made by measuring elevated, often glucose nonsuppressible, growth hormone levels and elevated insulin-like growth factor-I levels.

MEASUREMENT OF GROWTH HORMONE LEVELS

Growth hormone (GH) levels are measured by immunoassay or immunoradiometric assay. Most centers use polyclonal antibodies in their assay systems which measure higher GH levels compared to assay systems that use oligo- or monoclonal antibodies. Cutoff values that differentiate between normal and abnormally elevated GH levels are based on polyclonal assay systems according to the consensus conference on diagnostic aspects of acromegaly held in Cortina d'Ampezzo in 1999. Using these systems, fasting morning or random GH levels are usually clearly elevated in patients with acromegaly of at least more than 0.4 ng/ml (Fig. 1). Using the more sensitive and better standardized assay system with oligo- or monoclonal antibodies, these cutoff values will have to be redefined in the future. Since GH is episodically secreted in normal subjects, GH levels considerably

higher than the cutoff levels are not indicative for acromegaly unless the insulin-like growth factor-1 (IGF-1) level is also elevated. Because of the spontaneous fluctuation of GH levels in nonacromegalic subjects, many investigators recommend an oral glucose tolerance test as a suppression test for GH secretion.

Acromegaly is documented in patients in whom GH levels are higher than 1.0 ng/ml and who have elevated IGF-1 levels simultaneously. Blood sugar measurements during the oral glucose tolerance test demonstrate the different degrees of carbohydrate intolerance that are observed in active acromegalics. Measurement of insulin levels demonstrating insulin antagonism in active acromegalics is not required for making the diagnosis. Furthermore, the cumbersome measurement of GH 24-h profiles is not necessary, nor is it helpful to document the inappropriate stimulation of GH after thyrotropin releasing hormone (TRH) or gonadotropin releasing hormone (GnRH) injection that occurs in 70 and 40% of all active acromegalics, respectively. Measurement of urinary GH is also not useful for documentation of a GH hypersecretory state.

MEASUREMENT OF IGF-I LEVELS

Serum IGF-1 levels are invariably elevated in active acromegaly, showing a certain degree of correlation with GH levels. Since IGF-1 levels are also elevated during puberty and pregnancy, they are specific for active acromegaly in the nonpregnant adult. Since IGFBP-3 is concomitantly produced and secreted with IGF-1, IGFBP-3 levels are also elevated in acromegalic patients. Measurement of the binding protein, however, does not add to the accuracy of the diagnosis. This pertains also to the acid labile subunit (ALS), which is also elevated as part of the ternary complex consisting of IGF-1, IGFBP-3, and ALS. In addition, measurement of free IGF-1, which is only possible in some laboratories, is not required for making the diagnosis of active acromegaly.

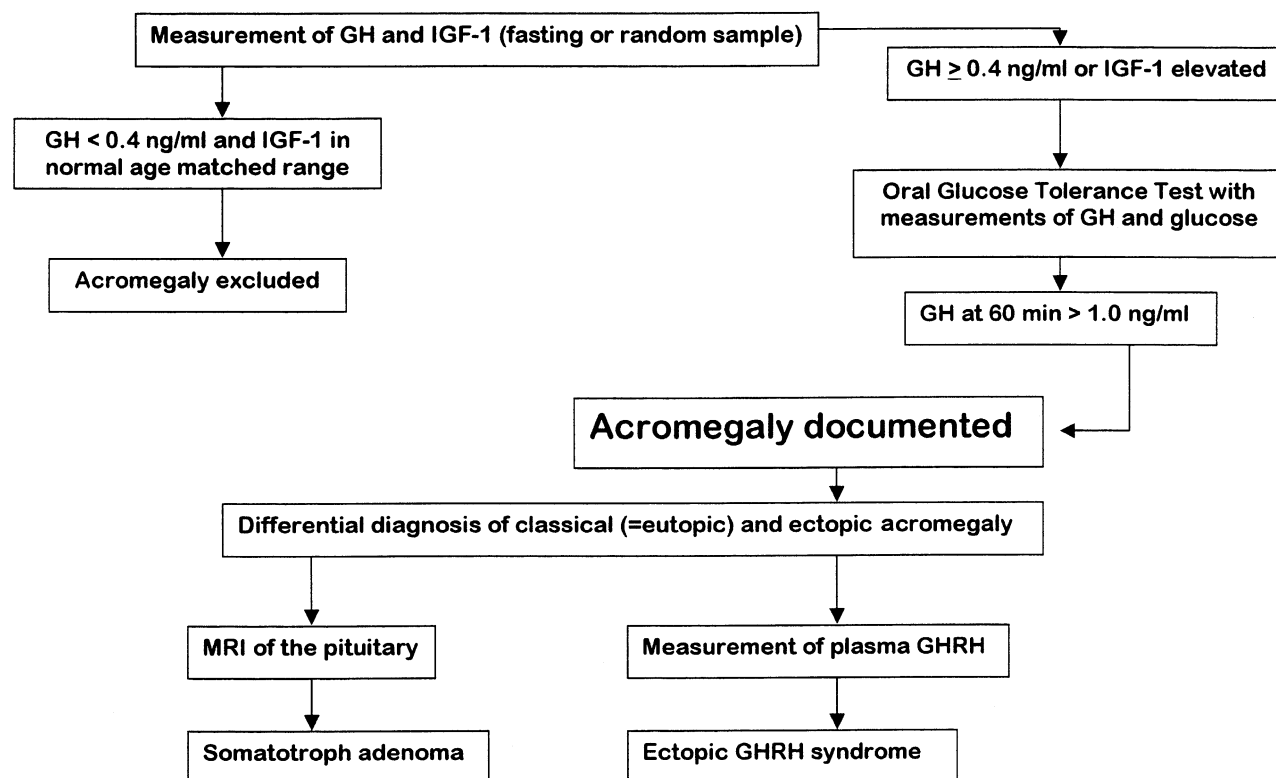

Figure 1 Algorithm for the diagnostic workup of a suspected acromegalic patient. According to the consensus statement (Giustina *et al.*, 2000.)

MEASUREMENT OF PROLACTIN AND OTHER ANTERIOR PITUITARY HORMONES

Since some GH-producing tumors also produce and secrete prolactin (PRL), basal PRL should be measured in all acromegalics. PRL levels higher than 200 $\mu\text{g}/\text{liter}$ are usually indicative of a somatomammotrophic adenoma. The identification of a somatomammotrophic tumor may be important with regard to medical therapy since the PRL-cosecreting adenomas respond particularly well to dopamine agonists.

Slightly elevated PRL levels can result from impingement of the somatotroph tumor on the pituitary stalk leading to unrestrained PRL release from the nontumorous pituitary. Tests to evaluate the other pituitary functions—the gonadal, adrenal, and thyroid axis—are also indicated.

DIFFERENTIAL DIAGNOSIS OF ACROMEGALY

In more than 99% of all patients with acromegaly, a monoclonal GH-producing tumor is the cause of the

disease (Fig. 2). The imaging method of choice is magnetic resonance imaging (MRI), which in most cases allows visualization of a macroadenoma and, less frequently, a microadenoma. This situation has been referred to by Losa and von Werder as classical acromegaly. In contrast to classical acromegaly, there are rare cases who have extra pituitary lesions causing GH hypersecretion, leading to the clinical picture of acromegaly. The ectopic growth hormone-releasing hormone (GHRH) syndrome is most common (Fig. 2). In this syndrome, GHRH is secreted from benign or malignant, often neuroendocrine, tumors, leading to somatotroph hyperplasia with consecutive GH hypersecretion. GH and IGF-1 levels are not different from those of classical acromegaly. On MRI, no pituitary adenoma can be demonstrated, although sometimes these patients have suprasellarly extending lesions due to somatotroph hyperplasia.

The diagnosis of ectopic GHRH syndrome cannot be made using function tests, although many of these patients do not respond to exogenous GHRH administration but show hypersecretion of GH after TRH. The diagnosis of ectopic GHRH secretion is made by the measurement of elevated peripheral GHRH levels (Fig. 1), which are in the nanogram range, in contrast

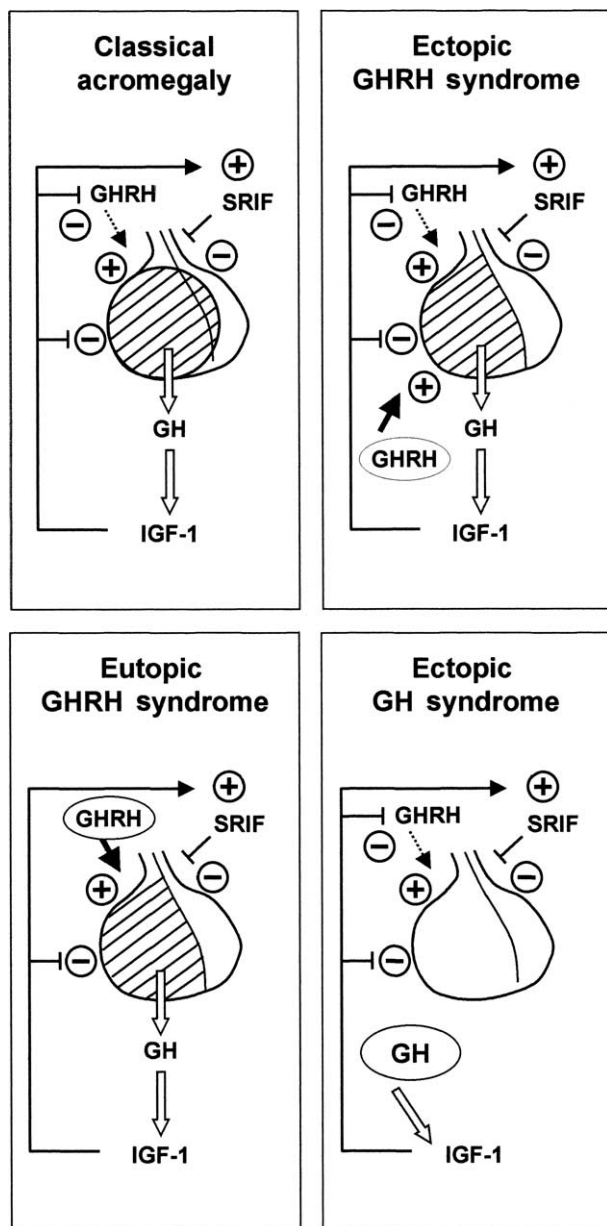

Figure 2 Different causes of acromegaly. In more than 99% of all cases, a monoclonal pituitary tumor can be demonstrated (classical acromegaly). The ectopic GHRH syndrome is the second most common cause of GH hypersecretion. Eutopic GHRH secretion from hypothalamic lesions cannot be differentiated from classical acromegaly before operative therapy. The extremely rare ectopic GH syndrome has been demonstrated unequivocally in only two cases. SRIF, somatotrophic hormone release inhibiting factor.

to classical acromegaly, in which GHRH levels do not exceed 100 pg/ml. Often, the ectopic GHRH source can be localized by somatostatin receptor scintigraphy since these tumors seem to express somatostatin receptor types 2 and 5.

In contrast, patients with hypothalamic GHRH-secreting tumors, so-called eutopic GHRH syndrome, do not have elevated GHRH levels in the periphery (Fig. 2). This diagnosis is usually made after transphenoidal operative therapy. In these cases, no tumors which are separated from the anterior pituitary lobe, but in which somatotroph hyperplasia is found, are sometimes intermingled with neuroendocrine tissue expressing GHRH. Occasionally, GHRH-producing cells are found in the pituitary specimen interspersed within the somatotroph cells.

The ectopic GH syndrome is extremely rare. Only two cases, one with pancreatic cancer and the other with non-Hodgkin lymphoma (both shown to produce and secrete GH), have been reported. The diagnosis can be suspected when GH levels are elevated, there is no evidence of a pituitary lesion (either adenoma or somatotroph hyperplasia), and GHRH levels are normal.

When there is a family history of acromegaly, one has to consider familial acromegaly or multiple endocrine neoplasia type 1. In the latter case, one needs to exclude primary hyperparathyroidism and islet cell tumors.

Occasionally, acromegaly occurs as part of the McCune-Albright syndrome, with very severe bone deformations caused by acromegaly accompanied by osteofibrotic bone disease, which is the hallmark of this rare syndrome.

Acromegaly, Therapy for

Anat Ben-Shlomo and Shlomo Melmed

University of California, Los Angeles School of Medicine, Cedars-Sinai Research Institute, Los Angeles, California, United States

Glossary

arthralgia Pain in a joint.

bradycardia A slower than normal contraction of the heart muscle causing a pulse of less than 60 beats per minute.

dopamine A hormone-like substance that is an important neurotransmitter in both the central and peripheral nervous systems; occurs as an intermediate in epinephrine and norepinephrine biosynthesis.

gallstone An amalgamous concretion, commonly of cholesterol crystals, bilirubin, and protein, that is formed in the gallbladder or bile duct.

A cromegaly, a somatic growth and proportion disorder, is a rare and insidious disease caused by growth hormone (GH)-secreting pituitary tumors or (rarely) extrapituitary disorders. Elevated levels of GH and insulin-like growth factor-1 (IGF-1) are the hallmarks of this syndrome. Clinical manifestations include skeletal and soft tissue growth and deformations as well as cardiac, respiratory, neuromuscular, endocrine, and metabolic complications. Early diagnosis and aggressive control of the disease significantly attenuate or even abolish the increased morbidity and mortality from the disease. Although transsphenoidal surgery is considered the primary treatment of choice, it is apparent that complete macroadenoma resection, especially if invasive, is difficult even for skilled surgeons, hence their low rate of biochemical control.

INTRODUCTION

When using strict criteria for disease control to define a cure for acromegaly (e.g., random serum growth hormone [GH] levels < 2.5 ng/ml, GH levels after oral glucose tolerance test [OGTT] < 1 ng/ml, gender- and age-matched insulin-like growth factor-1 [IGF-1] levels in the normal range), approximately 70% of patients were in remission during the short period after surgical intervention alone and 40% were in remission up to 16 years postsurgery. Radiotherapy,

either conventional external deep X-ray or heavy-particle (proton-beam) irradiation, is reserved mainly as adjuvant therapy for patients who have failed surgical or medical treatment. Therefore, pharmacological treatment has assumed more importance in managing patients with acromegaly. This article briefly discusses the pharmacotherapy available for acromegaly, including somatostatin analogues, GH receptor antagonists, and dopamine agonists.

SOMATOSTATIN AND ITS SYNTHETIC ANALOGUES

Somatostatin, a peptide that suppresses GH secretion, was discovered in the hypothalamus some 30 years ago and was shown to reduce GH serum levels. The two major somatostatins that are enzymatically cleaved from the large preprosomatostatin precursor molecule are somatostatin-18 and somatostatin-28. These are produced in multiple tissues and induce their variable actions through a family of five major receptors, SSTR1 to SSTR5. Because GH cell pituitary adenomas express SSTRs (mainly SSTR5 and SSTR2 subtypes) that regulate GH secretion, the pharmacological use of somatostatin binding to these receptors has been employed for treating these tumors. Endogenous somatostatin-14 has a high affinity to all SSTRs, produced locally and rapidly degraded to prevent systemic effects. Exogenous administration of the peptide is not applicable for prolonged treatment of acromegaly due to an extremely short half-life and multiple side effects. The synthetic compounds octreotide (SMS201-995) and lanreotide (BIM23014) offer a greater metabolic stability and subtype specificity for the treatment of acromegaly (e.g., high affinity to SSTR2 and SSTR5 and moderate affinity to SSTR3 vs somatostatin-14).

Octreotide is a short-acting molecule, with a half-life of 2 h, that binds with high affinity to SSTR2 and, to a lesser extent, to SSTR5. This analogue was the first to be used clinically and has been proved safe and effective for medical therapy of acromegaly.

Reduction of GH levels is achieved with octreotide doses ranging from 50 to 500 μg given subcutaneously every 8 h (in most patients, 100 μg trice daily). The drug will achieve its maximal suppressive effect on GH levels 2 to 6 h after injection. With continuous treatment, the extent by which GH levels rise between injections is reduced. After 6 months of octreotide treatment, integrated mean GH levels decreased to less than 5 ng/ml in 53% of 115 patients with acromegaly, and IGF-1 levels were normalized in 68% of the patients. After 30 months of treatment, GH levels were reduced to less than 5 ng/ml in 65% and to less than 2 ng/ml in 40% of 97 patients. In a summary of 11 studies, serum IGF-1 levels were normalized in 53% (range 42–80%) of 417 patients with acromegaly treated with 100 to 1500 μg octreotide daily for a period of 3 to 57 months. Improved clinical symptoms, including headache, perspiration, fatigue, arthralgia, and cystic acne, were observed in up to 78% of 115 patients treated with 750 μg octreotide for 6 months and in up to 95% of 103 patients in another study. Adverse drug effects include diarrhea (60%), abdominal discomfort (45%), loose stool (32%), nausea, headache, dizziness, flatulence, and constipation. These symptoms usually subside after 1 to 3 weeks of treatment. Clinically nonsignificant bradycardia develops in approximately 25% of treated patients. Asymptomatic cholesterol gallstones form in approximately 25% of treated patients, usually during the first 2 years of therapy.

Octreotide LAR is a depot intramuscular preparation (D,L-lactide-coglycolide-glucose) that provides sustained slow release of the drug peaking at 28 days.

Injections of 20 to 30 mg octreotide LAR at 28-day intervals suppresses GH levels and generally achieves steady-state drug levels after two or three injections. As demonstrated in Table I, GH levels are reduced to less than 2.5 ng/ml in 70 to 90% of patients, and IGF-1 levels are normalized in approximately 65% or even as many as 88% of patients treated with 20 to 40 mg octreotide LAR monthly injections for 12 to 30 months. Octreotide responders respond well to the LAR form. Moreover, reduction of GH levels to less than 5 ng/ml was observed in more patients treated with octreotide LAR (94%) than in those having received subcutaneous octreotide (82%). IGF-1 levels were normalized in 65% of patients treated with octreotide LAR, as compared with 50% of those treated with subcutaneous octreotide. Marked improvement of carpal tunnel syndrome, paresthesias, perspiration, arthralgia, headache, and fatigue was reported, as was approximately 20% tumor shrinkage. Adverse effects are mostly mild, last for 1 to 2 days, and include diarrhea (45%), abdominal pain (32%), and flatulence (35%). These effects are transient, and their frequency decreases with treatment extension to 11, 3, and 8% of patients, respectively. Gallbladder abnormalities that were apparent in 26% of patients treated for 30 months included asymptomatic cholelithiasis, sediment, sludge, and biliary or gallbladder dilatation. More recently, a case of probable partial tachyphylaxis to both depot preparations of somatostatin was reported along with demonstration of antisomatostatin analogue antibodies.

Slow-release lanreotide is a cyclic octapeptide somatostatin analogue administered intramuscularly

Table I Summary of Prospective Open-Label Studies on the Effects of Long-Term Treatment (3–89 months) of Patients with Acromegaly with Octreotide LAR, Lanreotide SR, and Pegvisomant on Serum GH and/or IGF-1 Levels

| | Number of patients | Treatment outcome | | |
|----------------|--------------------|-------------------|----------------|------------------|
| | | GH < 5 ng/ml | GH < 2.5 ng/ml | Normalized IGF-1 |
| Lanreotide SR | 298 ^a | 225 (76) | 197 (53) | 297 (55) |
| | 369 ^b | | | |
| | 538 ^c | | | |
| Octreotide LAR | 360 ^a | 337 (94) | 260 (59) | 308 (69) |
| | 439 ^b | | | |
| | 449 ^c | | | |
| Pegvisomant | 208 | | | 193 (93) |

Note. Percentages are in parentheses.

^aTotal number of patients who achieved GH levels of < 5 ng/ml.

^bTotal number of patients who achieved GH levels of < 2.5 ng/ml.

^cTotal number of patients who achieved normal IGF-1 levels.

at a dose of 30 mg every 10 or 14 days. To summarize 10 open-labeled prospective studies, 71% of patients treated with lanreotide for at least 1 year exhibited GH levels less than 5 ng/ml (43% < 2.5 ng/ml) and 58% exhibited normal IGF-1 levels. Of 23 newly diagnosed, nonoperated or irradiated patients treated with lanreotide SR, 5 (22%) had significant tumor shrinkage (> 20%) after 6 months of therapy. Clinical improvement of perspiration, headache, and tissue swelling was reported in 4 of 13, 4 of 6, and 5 of 5 patients, respectively, after 1 month of treatment. Arthralgia improved in 3 of 5 patients after 9 months of therapy. Patients treated with long-term subcutaneous octreotide and then subsequently with lanreotide reported similar improvement with both therapies, including improved headache (81% of 22 patients), paresthesia (73%), and soft tissue swelling (61%). Lanreotide Autogel, a new delivery formulation of lanreotide administered by deep subcutaneous injection at a dose of 60 to 120 mg every 28 days, was introduced recently. Studied in 107 patients with acromegaly for 3 months, lanreotide Autogel proved to be at least as efficacious and well tolerated as 30 mg lanreotide. Improvement of clinical symptoms, including headache (30%), night sweats (20%), and joint pain (40%), was reported after 3 months of treatment with both preparations. Similar clinical improvement was reported with lanreotide SR during long-term treatment. Side effects include mainly diarrhea (38%), abdominal pain (22%), gallbladder lithiasis or sludge (27%), and sludge (11%).

GROWTH HORMONE RECEPTOR ANTAGONIST

Pegvisomant (B2036-PEG) is a genetically engineered analogue of human GH. This mutated GH not only prevents the homodimerization of the two GH receptors, thereby preventing signaling, but it also has a higher affinity to growth hormone-binding protein (GHBP), thereby prolonging its circulating half-life. This GH receptor antagonist is not yet approved for clinical use in the United States. Subcutaneous daily injection of up to 40 mg normalized serum IGF-1 levels in 89% of 80 patients treated for 12 weeks and in 97% of 152 patients treated for 12 to 18 months. The biochemical improvement was accompanied by a clinical alleviation of soft tissue swelling, excessive perspiration, and fatigue. Serum GH levels were increased nearly twofold in the treated patients, and serum anti-GH antibodies were detected in 8% of the patients after 12 weeks of therapy and in 17%

after longer treatment. Adverse effects included headache (26%); infection (mainly upper respiratory tract infection) (33%); injection site reaction (11%); pain in scalp, neck, shoulders, arms, and/or legs (23%); diarrhea (13%); asthenia (13%); arthralgia (12%); sinusitis (10%); and hypercholesterolemia (14%). In addition, one patient exhibited a significant increase in transaminases levels. No tumor shrinkage was observed; moreover, two patients had an increase in tumor size under treatment (1.6- and 1.8-fold increases). Despite being the most effective of all drugs at reducing IGF-1, and despite the promising results when used as adjunct therapy, there is insufficient data supporting the use of pegvisomant as primary pharmacotherapy for acromegaly and safety for long-term treatment.

DOPAMINE AGONISTS

Dopamine agonists decrease GH levels in some patients with acromegaly in contrast to those in normal individuals. Bromocriptine, long-acting bromocriptine LAR, pergolide, and cabergoline are ergot derivative dopamine agonists, whereas quinagolide is a nonergot derivative. Only bromocriptine and quinagolide are approved for clinical use in the United States. In contrast to their dramatic effect on prolactinomas, their effect on GH-secreting adenomas is limited and largely less effective than somatostatin analogues. GH levels decreased in 20% and IGF-1 levels decreased in 5 to 10% of patients treated with high doses of bromocriptine (up to 60 mg daily) and in 34 and 43% of those receiving cabergoline (up to 7 mg weekly) and quinagolide (up to 0.6 mg daily), respectively. Because of high drug doses required to achieve hormone reductions, the incidence of adverse effects is high and often unacceptable to patients. Side effects include gastrointestinal discomfort, including transient nausea and vomiting, dizziness (due to postural hypotension), headache, nasal congestion, and mood disorders. Addition of dopamine agonists, especially longer acting ones, may improve therapeutic efficacy of other modes of therapy for the treatment of acromegaly.

CONCLUSION

The main goal of acromegaly therapy is tight control of GH and IGF-1 levels, hence reducing GH serum levels to less than 1 ng/ml after OGTT, normalizing age- and gender-matched IGF-1 levels, and reducing tumor mass as much as possible. Treatment of the disease's complications is also of great importance.

The preferred primary treatment is transsphenoidal surgery by an experienced surgeon. Patients who were not cured by surgery, or who cannot or do not wish to be operated on, may be controlled by pharmacotherapy. First choice for medical treatment is the long-acting somatostatin analogues octreotide LAR and lanreotide SR. Other somatostatin analogues, such as SOM203, are at different stages of development and are not yet in clinical use. Dopamine agonists can be added, especially if the patient has coexisting hyperprolactinemia. Until side effects and efficiency of GH receptor antagonist are better established, this treatment is reserved for patients who cannot be cured by surgery and/or somatostatin and dopamine agonists.

ACTH (Adrenocorticotropin Hormone)

George Mastorakos

University of Athens, Athens, Greece

Evangelia Zapanti

Alexandra Hospital, Athens, Greece

Glossary

adrenocorticotropin hormone (ACTH) A 39-amino-acid peptide hormone (MW 45,000) that is part of the proopiomelanocortin precursor molecule. It controls the function of the adrenal cortex.

proopiomelanocortin (POMC) A precursor molecule (MW 28,500) that, in the anterior lobe of the pituitary, is processed to adrenocorticotropin hormone and β -lipotropin and further processed to β -endorphin, an endogenous opioid peptide of 31 amino acids.

Adrenocorticotropin is the hypophyseal hormone that controls the function of the adrenal cortex.

BIOCHEMISTRY

Adrenocorticotropin hormone (ACTH) is a 39-amino-acid peptide hormone (MW 45,000) that is part of the proopiomelanocortin (POMC) precursor molecule (MW 28,500). The POMC gene is located on chromosome 2. Proopiomelanocortin is expressed in the brain, skin, and immune system and in the anterior and intermediate lobes of the pituitary gland. In the anterior lobe, POMC is processed to ACTH and β -lipotropin (β -LPH), which is further processed to β -endorphin, an endogenous opioid peptide of 31 amino acids (Fig. 1). In the intermediate lobe, ACTH is processed to α -melanocyte-stimulating hormone (α -MSH) (ACTH 1-13) and corticotropin-like intermediate lobe peptide (CLIP) (ACTH 18-39). In species with developed intermediate lobes (rat and sheep), these fragments are secreted, whereas in humans they are normally found only during fetal life. The NH_2 -terminal amino acids of ACTH are identical in all species thus far studied, but there are species differences in the COOH terminus of the molecule.

Interestingly, only the first 18 amino acids beginning with the NH_2 -terminal amino acids of ACTH are required for biological activity. In the brain, POMC is expressed in the arcuate nucleus of the hypothalamus and the nucleus tractus solitarius of the caudal medulla. In the brain, POMC generates a range of bioactive peptides, including ACTH, β -endorphin, and α -, β -, and γ -MSH. β -Lipotropin, a fragment with 91 amino acids, which contains β -MSH (41-58), γ -LPH (1-58), and β -endorphin, is secreted in equimolar quantities with ACTH. The endogenous opioid peptides α -, β -, and γ -endorphin are derived from POMC and are composed of amino acids 61-76, 61-91, and 61-77 of β -LPH, respectively.

The biological effects of POMC-derived peptides are diverse and are largely mediated through melanocortin (MC) receptors (R), five of which have been described. MC1R, MC2R, and MC5R have established roles in the pigmentation in the skin, adrenal steroidogenesis, and thermoregulation, respectively. Proopiomelanocortin-derived peptides are also found in the placenta, pancreas, testes, and gastric antrum.

PATHOLOGY AND EMBRYOLOGY

The synthesis and processing of POMC to ACTH and to the other POMC derivatives are executed within the corticotroph cells of the anterior pituitary lobe. This cell type was originally considered chromophobic and later was shown by light microscopic studies to be basophilic (Fig. 2). Corticotrophs represent 15-20% of adenohypophyseal cells. The embryological origin of corticotrophs is the intermediate lobe, but groups of cells migrate during development into regions of the anterior and posterior lobes. Ultrastructural studies have shown different morphologies in these two groups of cells, reflecting differences in the processing enzymes responsible for the production of the above-mentioned hormones. The cells in the anterior lobe appear irregularly shaped with

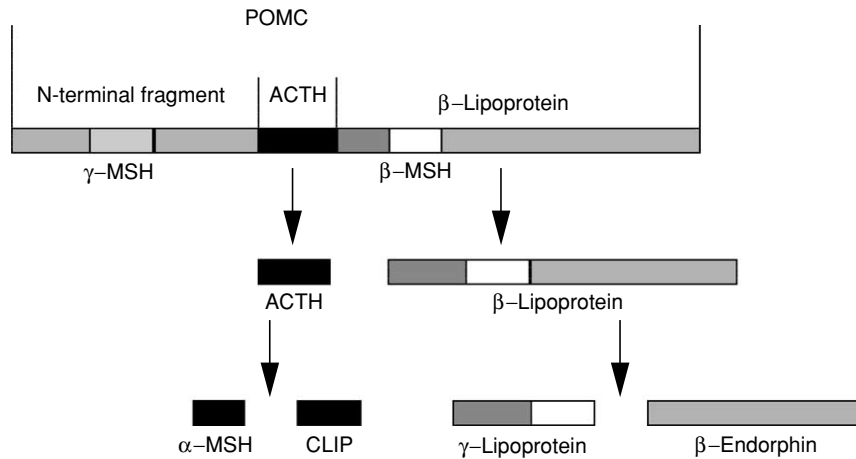

Figure 1 Enzymatic process of POMC in the pituitary.

sparse secretory granules and poor staining, whereas those of the intermediate and posterior lobes exhibit dense granulation. In states of glucocorticoid excess (endogenous or exogenous), corticotrophs undergo degranulation and microtubular hyalinization, known as Crooke's hyaline degeneration. In adrenal insufficiency, the corticotroph cells in the anterior lobe increase in number and the densely granulated cells of the intermediate and posterior lobes decrease in number.

Figure 2 Corticotroph cells in the anterior pituitary, positively stained immunohistochemically with a basophilic stain.

MEASUREMENT OF ACTH

The radioimmunoassay for the measurement of plasma ACTH is a highly sensitive and reliable assay for clinical use. Assays using other methodologies are also widely employed (i.e., enzyme-linked immunosorbent assay, chemiluminescence). The basal morning concentration of ACTH ranges from 9 to 80 pg/ml. The episodic secretion of ACTH causes fluctuations in plasma ACTH and cortisol levels. ACTH secretion has a distinct diurnal rhythm, with peak levels in the early morning and the lowest levels at approximately midnight. The interpretation of ACTH values requires a simultaneous cortisol determination. Provided that adrenocortical function is intact, plasma cortisol measurements, from a practical viewpoint, are a reliable index of ACTH secretion. There are other assays available for measuring ACTH (bioassays, radioreceptor assays, cytochemical assays), but measurement of ACTH by these techniques is performed only for research purposes, because of complexity and cost. The half-life of ACTH depends on the assay used for its measurement. Bioactive ACTH disappears from the circulation more rapidly (half-life of 3–9 min) than does immunoreactive ACTH (half-life of 7–12 min).

PHYSIOLOGY

Control of ACTH Secretion

The secretion of ACTH is controlled by an inherent diurnal rhythmicity; it is augmented by noxious stimuli that are neurally, hormonally, and biochemically

mediated, which is termed stress (open-loop component), and is inhibited by glucocorticoids (closed-loop, negative feedback). In normal circumstances, the daily secretion of ACTH and cortisol is episodic and variable. The highest burst of activity is observed in the early morning hours. Thereafter, the release of both ACTH and cortisol occurs only in 7–15 episodes per day and the levels of both hormones gradually decrease, reaching a nadir at approximately midnight.

Diurnal Rhythmicity

The basis of the diurnal rhythm is poorly understood. There is evidence for the involvement of at least three factors in the regulation of the diurnal rhythmicity of ACTH: (1) intrinsic rhythmicity of the secretion of the corticotropin-releasing factor (CRH) as well as vasopressin (AVP); (2) light–dark exposure; and (3) feeding times. Diurnal variation frequently disappears during periods of stress and depression and is also changed by conditions that affect cortisol metabolism (liver disease, chronic renal failure, alcoholism).

Intrinsic Rhythmicity of Hypothalamic CRH and AVP

Tests for the evaluation of the CRH secretion pattern have shown a diurnal intrinsic rhythmicity that persists even in hypophysectomized animals that are deprived of ACTH and glucocorticoid feedback. This hypothalamic rhythmicity appears to be neuronal but not hormonal. On the other hand, the presence of diurnal rhythmicity of ACTH in women during pregnancy when the increased circulating levels of placenta-derived CRH do not show a nycthemeral rhythm strongly suggests that hypothalamic AVP secretion plays a role in this diurnal regulation.

Light–Dark Cycles

Secretory episodes of ACTH increase between the third and fifth hours of sleep and peak in the morning during the first several hours of wakefulness. This rhythm usually appears after the first year of life but may not be established until the age of 8 years. Reversal of the normal asleep–awake patterns, as occurs when an individual moves to a distant time zone, is followed by a corresponding change in the diurnal pattern of ACTH secretion over the course of 2 to 3 weeks.

Feeding Cycles

Experiments in rats have shown that feeding schedule is more important than the light–dark cycle in determining the glucocorticoid diurnal secretory pattern. It appears that glucocorticoids tend to be released during fasting and decrease with feeding. Less is

known about the effects of feeding schedule on ACTH release in humans.

Open-Loop Control (Stress)

The open-loop component of ACTH control may be initiated by noxious stimuli of various sorts, all of which represent types of physical or emotional stress, such as pain, fever, trauma, hypoglycemia, hypoxia, surgery, anxiety, and depression. All of these stimuli stimulate the secretion of ACTH via the release of CRH. Corticotropin-releasing hormone and AVP are probably the two major physiologic secretagogues of hypophyseal ACTH. Immunoreactive CRH is found in the human hypothalamus in the paraventricular, supraoptic, and infundibular nuclei and also in the human thalamus, cortex, cerebellum, and pons. However, most human CRH-secreting neurons are located in the anterior portion of the paraventricular nucleus and their nerve endings project to the external layer of the median eminence, where CRH is released into the portal hypophyseal circulation. The same neuronal bodies in the paraventricular nucleus also produce AVP. These AVP neurons are probably the most important in vasopressin control of ACTH release, but the major site of vasopressin neurons is the supraoptic nucleus. These vasopressin neurons are usually of the magnocellular type and most of them project to the neural lobe.

There is strong evidence that both α - and β -adrenergic stimuli, cytokines, angiotensin II, and opiates are involved in the regulation of ACTH secretion. During infection, autoimmune processes, or trauma, a complex cascade of events ensues, characterized by fever, circulation of cytokines, and alterations in acute-phase proteins in plasma that are important to initiate, propagate, and terminate host defense mechanisms. In addition, it has been known for several decades that activation of the hypothalamic–pituitary–adrenal (HPA) axis occurs in parallel. It has become apparent that several mediators of inflammation play a major role in this phenomenon. Among all cytokines, three [tumor necrosis factor α (TNF α), interleukin-1 (IL-1), and interleukin-6 (IL-6)] are responsible for most of the stimulation of the HPA axis that is associated with the immune/inflammatory response. These three cytokines are produced at inflammatory sites and elsewhere in response to inflammation. Tumor necrosis factor α , which has a tumoricidal activity and is responsible for cachexia, is the first to appear in the inflammatory cascade of the events and stimulates both IL-1 and IL-6; similarly, IL-1 stimulates both TNF α and IL-6. In contrast, IL-6, which participates in a major fashion in the

acute-phase reaction, inhibits the secretion of both of the other cytokines. All three inflammatory cytokines have been shown to activate the HPA axis, i.e., ACTH secretion *in vivo*, alone or in synergy with one another. This effect can be blocked significantly with CRH-neutralizing antibodies, glucocorticoids, and prostanoïd synthesis inhibitors. When administered to humans, both IL-1 and TNF α have significant toxicity, including fever, general malaise, and hypotension, at the doses needed to activate the HPA axis. In the past, it has been demonstrated that IL-6, with its ability to inhibit the two other inflammatory cytokines and its modest toxicity in experimental animals, was a potent stimulator of the HPA axis in humans, causing an impressively marked and prolonged elevation of plasma ACTH and cortisol when administered either subcutaneously or intravenously. The elevations of ACTH and cortisol attained after stimulation with IL-6 were well above those observed with maximal stimulatory doses of CRH, suggesting that parvocellular AVP and other ACTH secretagogues were also stimulated by this cytokine. In a dose-response study, maximal levels of ACTH were seen at doses at which no peripheral AVP levels were increased. At higher doses, however, IL-6 stimulated peripheral elevations of AVP, indicating that this cytokine might also be able to activate magnocellular AVP-secreting neurons. This suggested that IL-6 might be involved in the genesis of the syndrome of inappropriate secretion of antidiuretic hormone, which is observed in the course of infectious or inflammatory diseases or during trauma. It has been shown that IL-6, in patients with head trauma (an aseptic inflammatory state) and a syndrome of inappropriate secretion of antidiuretic hormone, is quantitatively correlated with AVP.

In addition to their hypothalamic effects, the inflammatory cytokines can apparently directly stimulate pituitary ACTH and adrenal cortisol secretion. This may be related to the chronicity of the elevation of the inflammatory cytokines or may be a dose-related phenomenon. It is noteworthy that IL-1 and IL-6 are themselves produced in the anterior pituitary and adrenal glands, where they may have autocrine/paracrine effects.

Closed-Loop Feedback

The negative feedback control of ACTH secretion is mediated by cortisol, which exerts inhibitory effects on both the central nervous system and the pituitary. Negative feedback occurs via three mechanisms: (1) fast feedback, which is sensitive to changes in the levels of circulating cortisol, (2) intermediate

feedback, and (3) slow feedback, which is sensitive to the absolute cortisol level. Increased concentrations of glucocorticoids accelerate the progression from fast to slow feedback. Both fast feedback and intermediate feedback appear to be mediated by inhibition of the release of the existing CRH and ACTH rather than by inhibition of their synthesis. Slow feedback is characterized by decreased synthesis of ACTH, complete suppression of POMC gene transcription, and a lack of responsiveness of the corticotroph to the administration of CRH. The last result is mediated by the direct inhibitory effect of cortisol on the pituitary and there is evidence suggesting that this inhibitory effect of cortisol at the level of the pituitary constitutes the most important cortisol negative feedback in the physiological regulation of ACTH secretion. Glucocorticoids decrease the hypothalamic content of CRH and AVP and also decrease AVP mRNA content, but they have only a minimal effect on CRH mRNA. Electrophysiological studies have shown that there are hypothalamic as well as extrahypothalamic sites of cortisol feedback, which serve to suppress the release of CRH.

Action of ACTH

The adrenal cortex is the principal target organ for ACTH. ACTH stimulates the synthesis and release of steroids by binding to high-affinity plasma membrane receptors of adrenocortical cells. The ACTH-receptor interaction then activates adenyl cyclase and therefore stimulates the production of intracellular cyclic AMP (cAMP). The cAMP formed activates a number of intracellular phosphoprotein kinases that mediate both acute and chronic effects on steroidogenesis.

Acute and Chronic Actions of ACTH

ACTH stimulates the synthesis and release of cortisol within 2 to 3 min by increasing free cholesterol formation as a consequence of increased cholesterol esterase activity and decreased cholesteryl ester synthetase activity. ACTH rapidly promotes the transport of cholesterol across the mitochondrial membranes, facilitates the binding of cholesterol to the cytochrome P450_{scc}, and facilitates the release of newly synthesized pregnenolone from the mitochondria. ACTH also stimulates the release of adrenal mineralocorticoids and androgens, as well as the release of various intermediate products. Chronic actions of ACTH are exerted on both adrenal architecture and steroidogenesis. ACTH chronically stimulates low-density lipoprotein (LDL) uptake and metabolism and the synthesis of the LDL receptor and of other factors, so

it has tropic effects on all known early steps in steroidogenesis. Chronic effects of ACTH on steroidogenesis occur mainly by promoting the transcription of the genes that encode steroidogenic enzymes and other factors. ACTH increases the transcription of the genes for P450scc, P450c17, P450c21, and P450c11 and stimulates the accumulation of human P450scc mRNA and human P450scc activity. The exact mechanisms of ACTH stimulation of the side-chain cleavage enzyme P450scc remain to be elucidated. ACTH promotes both adrenal cellular hypertrophy and hyperplasia. ACTH at physiologic concentrations can promote the synthesis of insulin-like growth factor-II (IGF-II) and also the synthesis of basic fibroblast growth factor and epidermal growth factor, which may act with IGF-II to stimulate adrenal growth.

ACTH, α -MSH, and POMC, Evolution of

Robert M. Dores and Phillip B. Danielson
University of Denver, Denver, Colorado, United States

Glossary

adrenocorticotropin (ACTH) An anterior pituitary polypeptide hormone that induces the production of cortisol by cells of the adrenal cortex.

β -lipotropin (β -LPH) A biosynthetic intermediate derived from the proopiomelanocortin precursor that contains the sequence of β -melanocyte-stimulating hormone and β -endorphin.

melanocortins Adrenocorticotropin, α -melanocyte-stimulating hormone (MSH), β -MSH, γ -MSH, and δ -MSH.

α -melanocyte-stimulating hormone (α -MSH), β -MSH, γ -MSH, δ -MSH Polypeptide hormones produced in the intermediate pituitary that share the melanocortin core sequence HFRW.

proopiomelanocortin (POMC) The common precursor for melanocyte-stimulating hormone-related polypeptides and β -endorphin.

Proopiomelanocortin is the common precursor for the melanocortins and β -endorphin. This gene is expressed in corticotropic cells of the anterior pituitary and melanotropic cells of the intermediate pituitary. As a result of differential post-translational processing, these two regions of the pituitary will yield distinct sets of melanocortin-related and β -endorphin-related end products.

INTRODUCTION

During the middle portion of the 20th century, prior to the implementation of immunocytochemistry and subsequent molecular biology procedures to analyze endocrine cells, several pituitary polypeptide hormones were biochemically characterized from extracts of the anterior and intermediate pituitary. These analyses revealed the surprising observation that adrenocorticotropin (ACTH) and β -lipotropin (β -LPH), polypeptides characterized from the anterior pituitary, shared the amino acid sequence motif HFRW with

α -melanocyte-stimulating hormone (α -MSH) and β -melanocyte-stimulating hormone (β -MSH), polypeptides characterized from the intermediate pituitary. The fact that ACTH contained the complete sequence of α -MSH and that β -LPH contained the complete sequence of β -MSH led to the hypothesis that all of these polypeptides had a common origin. Later immunocytochemical studies would show that ACTH-related immunoreactivity and β -LPH-related immunoreactivity were colocalized in the corticotropic cells of the anterior pituitary, whereas α -MSH-related immunoreactivity and β -MSH-related immunoreactivity were colocalized in the melanotropic cells of the intermediate pituitary. From these observations, several research groups in the 1970s arrived at two conclusions: (1) ACTH, β -LPH, α -MSH, and β -MSH must be derived from a common precursor and (2) the common precursor must undergo differential posttranslational processing to yield distinct sets of end products in the anterior pituitary and intermediate pituitary. The cloning and characterization of proopiomelanocortin (POMC) mRNA from the bovine pituitary by Nakanishi and colleagues in 1979 confirmed the common precursor hypothesis. In addition, that study revealed the presence of a third MSH sequence (γ -MSH) in the precursor. Since that time, the POMC gene has been analyzed in representative species from nearly every major group of vertebrate. This article focuses on the changes that have occurred in the POMC gene during the evolutionary radiation of the vertebrates.

ORGANIZATION OF POMC IN TETRAPODS

The organization of the POMC precursor is remarkably conserved in tetrapods as diverse as amphibians and mammals. Tetrapod POMC can serve as a good model to illustrate the distribution of biologically active sequences and spacer regions within this precursor and to outline the major issues with respect to the origin and evolution of the POMC gene within

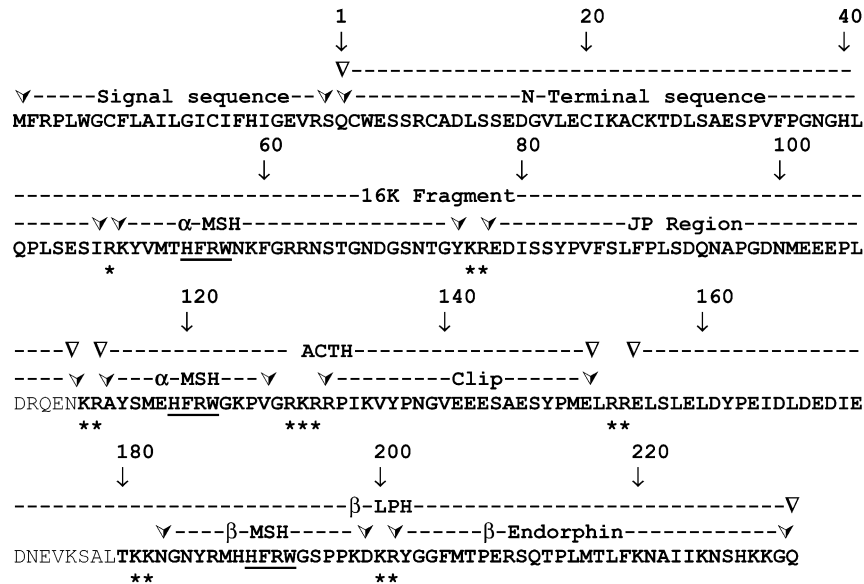

Figure 1 The amino acid sequence of *Xenopus laevis* POMC. The deduced amino acid sequence for the pre-pro form of POMC (Accession No. X59370) is presented. Proposed endoproteolytic cleavage sites are marked by asterisks. MSH core sequences are underlined. The opioid core sequence for β -endorphin is Y²⁰²G²⁰³G²⁰⁴F²⁰⁵. NTS, N-terminal sequence; JP, joining peptide.

the phylum Chordata. Tetrapod POMC can be divided into three major regions: the 16K fragment region, the ACTH region, and the β -LPH region (Fig. 1). The 16K fragment is located in the N-terminal region of POMC immediately following the signal sequence. This region can be subdivided into the N-terminal sequence (NTS), the γ -MSH sequence, and the joining peptide sequence. The NTS (Q¹-I⁴⁷) contains four cysteine residues at positions 2, 8, 20, and 24. The number and location of these cysteine residues represent a feature common to all gnathostome POMC sequences and undoubtedly play a role in influencing the three-dimensional structure of the precursor. *In vitro* studies on developing mammalian pituitary cells indicate that the NTS can serve as a maturation factor to promote the development of prolactin-producing cells. Studies have not been performed *in vivo* to verify this activity. However, it is coincidental that in teleosts, vertebrates in which the anterior pituitary cell types segregate into zones, ACTH-producing cells are found in close proximity to prolactin-producing cells. The joining peptide region (E⁷⁹-N¹¹¹) is one of the most variable regions in POMC and is one of the spacer regions found in this precursor. No function has been found for this sequence. Located between the NTS and the joining peptide is the sequence of γ -MSH (K⁴⁹-Y⁷⁵). γ -MSH is one of three sequences within POMC that contains the MSH core sequence HFRW. Bioassay studies indicate that γ -MSH has weak

melanocyte-stimulating activity at nonphysiological concentrations. However, studies on rats indicate that this peptide may be involved in regulating blood pressure at sites outside of the central nervous system. The γ -MSH sequence is flanked by paired basic amino acids (R⁴⁸K⁴⁹ and K⁷⁶R⁷⁷), and these sites undergo endoproteolytic cleavage in the intermediate pituitary but not in the anterior pituitary. In both mammals and anuran amphibians, the R⁴⁸K⁴⁹ site is a functional monobasic cleavage site. Hence, for the *Xenopus laevis* POMC sequence presented in Fig. 1, the first residue in the γ -MSH sequence is K⁴⁹. The reason for this particular cleavage event is not clear. Often, the presence of a proline residue C-terminal to a basic amino acid prevents the removal of the basic amino acid. However, for the R⁴⁸K⁴⁹ sequence, the position C-terminal to K⁴⁹ is a tyrosine residue. In fact, as seen in Fig. 2, the tyrosine residue is conserved at this position in the γ -MSH sequences of vertebrates as diverse as sharks and amphibians. In contrast to the R⁴⁸K⁴⁹ site, proteolytic cleavage at K⁷⁶R⁷⁷ follows the conventional endoproteolytic mechanism and both amino acids are removed. Many gnathostome γ -MSH sequences have a potential internal cleavage site at R⁶²R⁶³ that can be cleaved to yield an amidated form of γ -MSH that would correspond to K⁴⁹-F⁶⁰.

The ACTH region in the *X. laevis* POMC sequence extends from A¹¹³ to L¹⁵². ACTH is a potent stimulator of cortisol production by adrenal cortical cells. This hormone plays a critical role in

found in all vertebrates at this position, apparently prevents cleavage at R¹³¹. The result of these proteolytic cleavage events yields ACTH(1–13) amide (A¹¹³–V¹²⁶) and corticotropin-like intermediate lobe peptide (R¹³¹–L¹⁵²) (CLIP) as products. ACTH(1–13) amide will undergo N-terminal acetylation to form α -MSH, the second polypeptide sequence in amphibian POMC that has the MSH core sequence (H¹¹⁹F¹²⁰R¹²¹W¹²²). α -MSH is a potent stimulator of physiological color change in several species of amphibians and reptiles. The function of CLIP is still an enigma.

The final major region of the POMC precursor is the β -LPH region (Fig. 1). Located in the C-terminal portion of POMC, this sequence has traditionally been divided into the γ -LPH sequence (E¹⁵⁴–D¹⁹⁹) and the β -endorphin sequence (Y²⁰²–Q²³²). The former sequence contains the β -MSH sequence (N¹⁸³–D¹⁹⁹), the third polypeptide with a MSH core sequence (H¹⁹⁰F¹⁹¹R¹⁹²W¹⁹³) in tetrapod POMC. β -MSH has melanocyte-stimulating activity and appears to work in concert with α -MSH to promote physiological color change in amphibians and reptiles. In all vertebrates in which MSH has been studied, β -MSH is an end product of the intermediate pituitary, but not of the anterior pituitary.

The other major product derived from β -LPH is β -endorphin. This polypeptide is an endogenous opiate-like chemical signal that functions as an inhibitory neurotransmitter when released from neurons located in the central nervous system. In the mammalian anterior pituitary, β -LPH is a major end product and β -endorphin is a minor end product. In the mammalian intermediate pituitary, just the opposite result is observed. In this tissue, β -LPH serves as a biosynthetic intermediate that is processed to yield N-terminally acetylated, C-terminally truncated forms of β -endorphin. The later peptides lack opiate receptor-binding activity.

The organization of tetrapod POMC is interesting for a number of reasons. This precursor contains three polypeptide sequences that have very distinct functions (ACTH, α -MSH, and β -endorphin). The repeat of the MSH core sequence appears to be the result of a series of domain duplication events likely resulting from unequal crossover. This feature is not unique to POMC. Several neuropeptide precursors, such as proTRH or proenkephalin, contain repeats of a biologically important sequence. However, the presence of three MSH sequences in tetrapod POMC leads to the questions of when these sequences appeared and which of the polypeptides was the ancestral MSH sequence. To address these questions, a phylogenetic comparison of POMC sequences is required.

PHYLOGENETIC ANALYSIS OF POMC SEQUENCES

The POMC gene has been analyzed in a jawless fish, two cartilaginous fishes, several ray-finned fishes, two lobe-finned fishes, several amphibians, and several mammals. Figure 2 provides a comparison of a few representative species. These species were selected because they represent five major taxonomic groups of vertebrates (i.e., jawless fish, cartilaginous fish, ray-finned fishes, lobe-finned fish, and tetrapods). The jawless fish were well established over 500 million years ago (mya) and are represented today by lamprey and hagfish. In the lamprey, *Petromyzon marinus*, two distinct POMC genes are expressed. The POM form of POMC, a gene expressed in the intermediate pituitary of this species, is presented in Fig. 2. The jawed vertebrates (gnathostomes) appear in the fossil record approximately 420 mya and two distinct groups were established by 400 million years ago: the cartilaginous fish, represented in Fig. 2 by the dogfish, and the bony fish. The bony fish radiated into two major groups: the ray-finned fish, represented by the gar and sockeye salmon, and the lobe-finned fish, represented by the Australian lungfish. The lungfish lineage can be traced back in the fossil record to 390 mya. Approximately 20 million years later, the first tetrapods were clearly present in the fossil record. *X. laevis* was included in Fig. 2 to provide a representative tetrapod POMC sequence. Two ray-finned fish POMC sequences are also included in Fig. 2 to illustrate some unique features associated with the radiation of the POMC gene in this group. The gar belongs to an older lineage of ray-finned fish that can be traced in the fossil record back to the Jurassic era. The sockeye salmon is a teleost, a relatively recent group of bony fish that first appears in the fossil record during the Cretaceous period.

A striking feature of the sequences presented in Fig. 2 is the presence of α -MSH-like, β -MSH-like, and β -endorphin sequences in all taxa. There has been considerable divergence of the POMC sequence in vertebrates and without these conserved sites it would have been very difficult to align the agnathan POMC sequence to the gnathostome POMC sequences. Even with these conserved sites, it was still necessary to insert 11 gaps to facilitate the alignment of the sequences. The presence of α -MSH-like, β -MSH-like sequences in the lamprey precursor indicates that the POMC gene must have been in the ancestral chordate. Indeed, this gene may have been in the ancestral eucoelomates. Based on this data set, it is not possible to ascertain when the α -MSH/ β -MSH duplication event occurred. One hypothesis would be

that the ACTH sequence appeared early in eucoelomate evolution and that β -MSH is the result of the duplication of the α -MSH sequence. In the case of the lamprey, nucleotide insertions occurred in both the α -MSH- and the β -MSH-coding regions of the lamprey POM gene. The gnathostome α -MSH and β -MSH sequences are highly conserved in the taxa presented in Fig. 2. In addition, the β -endorphin region contains a remarkable number of conserved sites in all taxa. There must be selection pressure to retain certain features of the β -endorphin sequence that is not being exerted on other regions of the gene.

A sequence that is conspicuously absent from the lamprey POM sequence is γ -MSH. Based on this observation, it is reasonable to propose that the duplication event that yielded the γ -MSH sequence must have occurred in the ancestral gnathostomes. Although a γ -MSH-like sequence can be detected in dogfish, gar, and Australian lungfish POMC, this sequence is shorter than the tetrapod γ -MSH sequence. In addition, paired basic proteolytic cleavage sites are not found C-terminal to the γ -MSH sequence in the gar or lungfish sequences. In addition, the gar γ -MSH-like sequence does not have an intact MSH core sequence and the entire γ -MSH sequence is absent in teleost POMC. Apparently during the radiation of the ray-finned fish, selection pressures favored the gradual degeneration and eventual loss of the γ -MSH sequence.

Whereas the presence of α -, β -, and γ -MSH is a feature common to many tetrapods, the dogfish POMC sequence has a fourth MSH sequence: δ -MSH (D²²³-P²³⁷; Fig. 2). This sequence is located in a large insertion (V²⁰⁴-A²⁴²; Fig. 2) that appears to have occurred during the radiation of the cartilaginous fish and hence is limited to this group of gnathostomes.

The uniqueness of the δ -MSH sequence is balanced by the high degree of primary sequence conservation observed for ACTH among the gnathostome taxa. For the gnathostome species presented in Fig. 2, 66% of the positions are identical in the ACTH sequence. In fact, 88% of the first 25 positions in gnathostome ACTH are

identical. For the β -endorphin region, 45% of the positions are identical in all taxa. This percentage rises to 67% when all gnathostome fish sequences are compared. Clearly, ACTH and β -endorphin must be physiologically important in all vertebrates.

ORIGIN OF POMC

POMC is a member of the opioid/orphanin gene family that includes the proenkephalin gene, the prodynorphin gene, and the proorphanin gene. A unifying feature of this family is the presence of at least one Y(F)GGF sequence in each precursor. To date, members of this gene family have not been found in any prokaryotes and it appears that these genes are not found in pseudocoelomates such as *Caenorhabditis elegans*. Hence, the gene family appears to have evolved in the eucoelomates. Although POMC is clearly a member of this family because of the β -endorphin sequence, the presence of the melanocortin sequences (ACTH, α -MSH, β -MSH, γ -MSH, and δ -MSH) is a feature that is unique to the POMC gene. Since POMC is found in all vertebrate groups and perhaps is common to all chordates, the origin of the melanocortin sequences may provide the key to deciphering the genesis of this opioid/orphanin gene family.

Adenylyl Cyclase

Ferenc A. Antoni

University of Edinburgh, Edinburgh, United Kingdom

Glossary

cyclic nucleotide phosphodiesterases (PDEs)

Enzymes that break down cyclic nucleotides into nucleotide monophosphates.

guanosine-5'-triphosphate (GTP) Required for the activity of G proteins to modulate effectors such as adenylyl cyclase; hydrolyzed by G proteins into guanosine-5'-diphosphate (GDP) before the GDP is released and new GTP is bound and effector activation is resumed ("GTP-ase switch").

heterotrimeric G proteins A group of proteins that consist of three subunits (α , β , γ .) and couple cell surface receptors to their effector enzymes; on activation of cell surface receptors by their ligands, heterotrimeric G proteins dissociate into the α -subunit and the $\beta\gamma$ -complex, both of which regulate the activity of effector enzymes such as adenylyl cyclase in the cell membrane.

protein kinases Enzymes that tag proteins with phosphoryl residues derived from ATP; activity may be regulated by a variety of intracellular messengers, protein-protein interactions, or phosphorylation by other protein kinases.

protein phosphatases Reverse the action of protein kinase and remove phosphoryl groups from proteins.

second messengers Generated by extracellular stimuli arriving at the cell surface; transduce the extracellular signal toward the interior of the cell.

Adenylyl cyclases (EC 4.6.1.1) are enzymes that generate the second messenger adenosine-3'/5'-monophosphate from ATP.

INTRODUCTION

Adenosine-3'/5'-monophosphate (cAMP) was the first "second messenger" to be discovered in 1956 by Earl Sutherland. As a prototype and, for a long time, as the only identified intracellular signaling pathway, the

cAMP cascade was the subject of a large number of studies until the mid-1980s, when interest shifted toward novel signaling mechanisms such as polyphosphoinositides and receptor tyrosine kinases. The fact remains, however, that cAMP is a ubiquitous second messenger from gametogenesis to cognition. The application of molecular genetics to the field has highlighted the molecular diversity in the biosynthetic and catabolic arms (cyclic nucleotide phosphodiesterase, PDE) of cAMP metabolism. Ten adenylyl cyclase (AC) genes have been identified in mammals. Diversification of AC genes is already apparent in *Drosophila melanogaster* and *Caenorhabditis elegans*, indicating a distinct adaptational advantage of this feature. Taking into account the currently known molecular variants of AC and PDE, the turnover of cAMP in a mammalian cell may occur in up to 500 different ways. The biological significance of this diversity is only slowly becoming apparent and is currently under investigation in numerous biological systems.

ADENYLYL CYCLASE GENE AND PROTEIN STRUCTURE

Two types of ACs have been identified in mammals: a membrane-bound species representing 9 of the 10 known ACs and a soluble enzyme. All of the membrane-bound ACs have the same predicted structure (Fig. 1), resembling that of ion channel/transporter proteins. The N-terminal end is cytoplasmic and continues in the M1 intramembrane segment consisting of six membrane-spanning helices. This is followed by a large cytoplasmic loop (C1), which can be subdivided into C1a and C1b on the basis of the conservation of the C1a segment in other ACs as well as a corresponding region (C2a) in the second cytoplasmic domain. The C1b portion of the cytoplasmic loop is a nonconserved isotype-specific segment. The second half of the molecule is analogous to the first half. The six transmembrane helices of the M2

Figure 1 Schematic representation of mammalian ACs. N: N-terminal cytoplasmic loop; M1 and M2: intramembrane domains; C1a and C2a: homologous catalytic domains (thick lines); C1b and C2b: nonhomologous regulatory domains (thin lines). The C1a and C2a domains must come into physical contact to form the catalytic core. This is facilitated by $G\alpha$ that binds to the C2a domain. Most ACs are inhibited by $G\alpha$ that binds to a site on the C1a domain.

intramembrane segment are followed by a cytoplasmic tail designated C2, which is usefully divisible into C2a and C2b because C2a is relatively well conserved in all known ACs and also shows significant homology to C1a. Both intramembrane domains are predicted to be glycosylated on the extracellular surface.

The C1 and C2 segments of ACs also show highly significant homology to guanylyl cyclases. In fact, a point mutation in the C1a region is sufficient to change an AC into a guanylyl cyclase enzyme. Note that for historical reasons, the sequence motif corresponding to the conserved catalytic core in ACs is called guanylyl cyclase motif in protein structure databases. Mini-protein heterodimers consisting of the C1a and C2b domains of ACs are catalytically active and retain numerous regulatory properties of the holoenzyme. Furthermore, high-resolution X-ray crystallographic maps of the secondary structure of C1a and C2a heterodimers have been reported. The results concur that the catalytic core of the enzyme, including the substrate binding site, requires both domains. The heterodimer C1a:C2a is a symmetrical array; guanosine-5'-triphosphate (GTP)- $G\alpha$ is bound by the C1a domain, whereas forskolin, an alkaloid known to stimulate ACs, binds to C1a and C2a in the vicinity of the $G\alpha$ binding site in C1a (Fig. 2). The C1-C2 complex also contains two metal-binding sites, which under physiological circumstances are occupied by Mg^{2+} . One of these sites attracts Mg^{2+}

in complex with ATP, whereas the other site binds Mg^{2+} and has a preference for Mn^{2+} , explaining early observations on the stimulatory action of Mn^{2+} on ACs.

The 10th mammalian AC is a soluble enzyme that is structurally more closely related to cyanobacterial ACs than to the membrane-spanning family of mammalian ACs. The crystal structure of this enzyme was not yet published at the time of this writing.

REGULATION OF ADENYLYL CYCLASE

General Considerations

There are currently 10 mammalian AC genes, each of which encodes a different protein. These are differentially controlled by heterotrimeric G proteins, intracellular Ca^{2+} , and protein phosphorylation (Table I). In addition, ACX is uniquely controlled by bicarbonate ions. Hence, several signaling pathways converge on ACs, which act as molecular signal integrators. In a further aspect, AC isotypes have distinct tissue distributions, indicating nonredundant physiological roles. At the single-cell level, expression of multiple AC isotypes is the rule rather than the exception. Thus, polarized distribution of ACs within cellular microdomains or compartments is yet another element of functional diversity in the cAMP signaling cascade.

Figure 2 The structure of the AC catalytic core. The C1a and C2a domains of dog ACV (VC1) and rat ACII (IIC2) in complex with GTP-Gs α are shown. Note the pseudo-symmetrical arrangement of α -helices (represented by cylinders) numbered 1 to 7 and β strands (represented by arrows) of the C1a and C2a domains. ATP and forskolin (FSK) are drawn as stick models; Gs α is represented as a cylinder. The S and T denote serine and threonine residues that are putative phosphorylation sites in ACIII and ACII, respectively. Note that residues from both polypeptide chains are required to form the substrate-binding site. Reproduced from Tesmer, J. J., and Sprang, S. R. (1998). The structure, catalytic mechanism, and regulation of adenylyl cyclase. *Curr. Opin. Struct. Biol.* 8, 714, Elsevier.

G Proteins

The activity of all transmembrane ACs is stimulated by Gs α combined with GTP. The structure-activity analysis of the AC catalytic core by various methods has identified the site of interaction with GTP-Gs α (Fig. 2) in the cytosolic C2a domain. The binding of GTP-Gs α to C2a is thought to facilitate the association of C1 and C2. The activity of some but not all ACs is inhibited by Gi α (Table I), thereby opposing the stimulation by Gs α .

In addition to G protein alpha subunits, G $\beta\gamma$ subunits have a direct influence on the activity of some ACs. Above all, in the presence of Gs α , activity of ACII and ACIV is enhanced further by G $\beta\gamma$. Thus, ACII and ACIV are coincidence detectors for receptors coupled to Gs and Gi/o, respectively. It is important to note that G $\beta\gamma$ derived from Gs or Gq is unlikely to exert this type of effect given that the EC₅₀ of G $\beta\gamma$ for this action is approximately 100 nmol/L, whereas the stimulatory effect of Gs α is already maximal at approximately 10 nmol/L and the tissue levels of this G protein are low compared with those of Gi and Go. The potential for G $\beta\gamma$ to stimulate ACs is remarkable because it shows that the direction as well

as the magnitude of the effects of hormones on cAMP synthesis can be dependent on the context of the stimulus applied. In contrast to ACII and ACIV, G $\beta\gamma$ subunits reportedly inhibit the activation of ACI by Gs α . A summary of the actions of G proteins is shown in Fig. 3.

Calcium

ACI was the first AC protein to be purified and the first AC cDNA to be cloned. It is an enzyme stimulated by Ca²⁺-calmodulin and is highly abundant in the brain. The calmodulin modulatory site is in the C1b domain of ACI. The Ca²⁺-calmodulin complex and GTP-Gs α produce synergistic stimulation of ACI. ACVIII is also activated by Ca²⁺-calmodulin, but apparently through a different, IQ-type, calmodulin-binding domain, and no synergy with Gs α has been reported. Thus, these enzymes are capable of directly responding to a rise of intracellular-free Ca²⁺ from a variety of sources, especially plasma membrane calcium channels. Another mode of regulation by Ca²⁺ is an apparently direct inhibition of activity. ACVI is the best characterized example of

Table I Mammalian AC Genes

| Cyclase | G proteins | Calcium-Calmodulin | Phosphorylation | Facets of tissue distribution | Human chromosomal localization | Other |
|---------------|---|---|--|--|--------------------------------|---|
| ACI | G α stimulates, G $\beta\gamma$ inhibits | Calmodulin-dependent stimulation, synergy with G α | Inhibition by CaMKIV | Mainly in the brain | 7p13-p12 | Participates in synaptic plasticity |
| ACII | G α stimulates, G $\beta\gamma$ synergizes with G α | | Stimulation by protein kinase C in synergy with G α | Brain, lung, uterus pituitary | 5p15.3 | |
| ACIII | G α stimulates | | Inhibition by CaMKII | Brain, kidney, testis, vasculature, pancreas beta cells | 2p24-p22 | Important for olfaction, involved in insulin release |
| ACIV | G α stimulates | | Inhibition by protein kinase C | Lungs | 14q11.2 | Very little known about this enzyme |
| ACV | G α stimulates, G α inhibits | Direct inhibition by Ca ²⁺ | Stimulation by protein kinase C | Brain, heart | 3q13.2-q21 | Effect of protein kinase C not dramatic in vivo, has splice variant, required for EGF stimulation of cAMP |
| ACVI | G α stimulates, G α inhibits | Direct inhibition by Ca ²⁺ | Inhibition by protein kinase A and C, enhancement by tyrosine kinase | Widespread, including pituitary, adrenal cortex | 12q12-q13 | |
| ACVII | G α stimulates | | Not known | Brain, retina, pituitary, hematopoietic system | 16q12-q13 | Has splice variant |
| ACVIII | G α stimulates | Calmodulin-dependent stimulation | | Brain specific | 8q24.2 | Has splice variants |
| ACIX | G α stimulates, G α inhibits | | Inhibited by dephosphorylation pathway involving calcineurin | Widespread, including major endocrine glands, prostate, uterus | 16p13.3 | Participates in adrenal corticosteroid feedback |
| ACX (soluble) | N/A | Not known | Not known | Testis, also present in other tissues | 1q24 | Modulated by bicarbonate, highly expressed in spermatogonia |

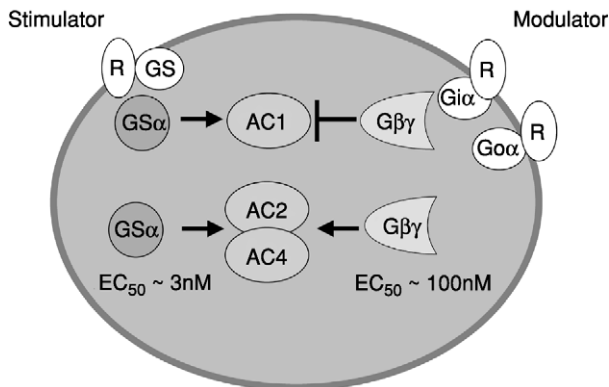

Figure 3 Summary of the control of AC isotypes by G proteins. Arrows indicate stimulation; T bars indicate inhibition; R indicates G-protein-coupled receptor.

this control. The inhibition is apparent between sub-micromolar (>100 nmol/L) to low-micromolar concentrations of Ca^{2+} . The structural requirements for direct inhibition of ACs by Ca^{2+} are not known.

Protein Phosphorylation

Typically, ACs contain a multitude of potential consensus phosphorylation sites for a variety of protein kinases. Because these are large molecules that cannot be assayed reliably in single-cell assays, the characterization of control by phosphorylation has been very slow to appear. The most striking effects have been reported for ACII and ACVII. The activity of both enzymes is markedly stimulated by protein kinase C. Whether protein kinase C phosphorylation alone is sufficient to activate the enzymes in normal cells is unclear, but synergistic stimulation by GTP-Gs α and

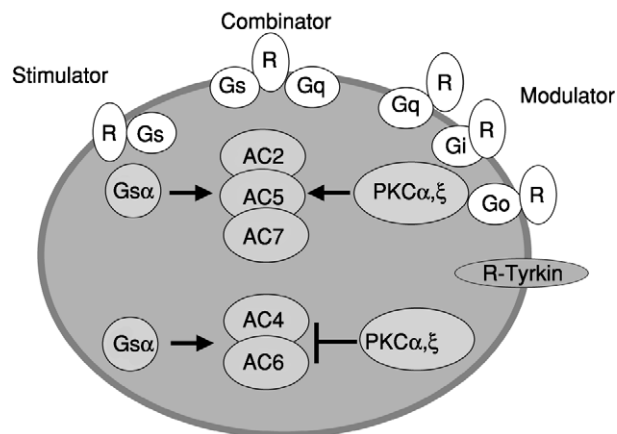

Figure 4 Summary of the modulation of AC activity by protein kinase C. The α and ξ variants of protein kinase C have been implicated in the control of ACs.

Figure 5 Distribution of mRNAs for cytochrome CYP11B2, which is responsible for the synthesis of aldosterone in the zona glomerulosa, cytochrome CYP11B1, which in turn is responsible for the synthesis of corticosterone in the zona fasciculata-reticularis and various ACs in the rat adrenal gland detected by *in situ* hybridization histochemistry. Animals were treated with vehicle or ACTH for 10 days before processing of the adrenal gland to *in situ* analysis. Reproduced from *Endocrinology* (1997), Vol. 138, p. 4596, with permission of The Endocrine Society, Bethesda, MD.

activators of protein kinase C is well established. In the case of ACII, the site of phosphorylation has been localized to the C2b domain. Inhibition of ACVI by protein kinase C has also been reported; here there are multiple sites of phosphorylation, one of which is in the N-terminal segment of the protein. The effects of protein kinase C activation on ACs are summarized in Fig. 4. ACVI is also inhibited by protein kinase A (cAMP-dependent protein kinase), and mutagenesis studies indicated that the site of phosphorylation is in the C1b segment. Thus, ACVI is inhibited by

cAMP-dependent negative feedback. In a similar vein, ACI is inhibited by calmodulin-dependent protein kinase IV. Calmodulin-dependent protein kinase II is inhibitory to ACIII, which appears to be important in the olfactory system of rodents where very rapid restoration of cellular responsiveness is vital. Yet another mode of Ca^{2+} -mediated inhibition is apparent in the case of ACIX, which is inhibited by a pathway involving the Ca^{2+} -calmodulin-dependent protein kinase calcineurin (protein phosphatase 2B). The nature of the presumed stimulatory phosphorylation is not known.

ADENYLYL CYCLASES IN ENDOCRINE SYSTEMS

It is quite clear that without ACs, hormonal control would simply not function. Several hypothalamic-releasing hormones exert their actions through cAMP, and the effects of the majority of pituitary-tropic hormones that regulate the peripheral endocrine glands are mediated, at least in part, by cAMP. Interestingly, no obvious endocrine abnormalities have emerged from the three gene deletion studies published as of this writing that targeted ACI, ACIII, and ACVIII, respectively. This is plausibly due to the fact that these ACs are found mainly in the central nervous system or that, as in the cases of ACI and ACVIII, a double gene deletion was necessary to demonstrate a clear behavioral phenotype.

Data on the role of AC isotypes in endocrine systems are very limited indeed. The rat adrenal gland is the best explored tissue (Fig. 5) from this respect. There is striking compartmentalization of the ACs in the medulla and cortex. Furthermore, within the cortex, there are differences between the

aldosterone-synthesizing zona glomerulosa, which expresses mainly ACVI and the zona fasciculata, where the predominant AC appears to be ACIX. These characteristics are retained and accentuated after treatment of the animals with adrenocorticotrophic hormone. It was also shown that sodium restriction causes a marked increase of ACVI mRNA expression in the zona glomerulosa. Other studies of AC expression in endocrine tissues have not been consistent; however, there is little doubt that similar segregation of functionally distinct ACs is not restricted to the adrenal gland.

Adipocytokines

Tohru Funahashi and Ichihiro Shimomura

Osaka University Graduate School of Medicine, Osaka, Japan

Yuji Matsuzawa

Osaka University Graduate School of Medicine, Sumitomo Hospital, Osaka, Japan

Glossary

adipovascular axis Adipose tissue secretes various vasoactive substances. Dysregulation of these adipocyte-derived vasoactive molecules in obesity directly contributes to the development of vascular diseases.

lipodystrophy A disease in which there is disturbed differentiation of adipocytes. Human generalized lipodystrophy and bioengineered mice lacking fully differentiated adipocytes exhibit phenotypes resembling that of obesity, such as insulin resistance, dyslipidemia, and fatty liver.

metabolic syndrome The condition characterized by upper body obesity, insulin resistance, dyslipidemia, and hypertension. The metabolic syndrome is a common cause of atherosclerotic vascular diseases.

visceral fat Adipose (fat) tissue located in the omentum and mesenterium. Accumulation of visceral fat is a common cause of the metabolic syndrome.

Obesity is a common risk factor for type 2 diabetes and cardiovascular diseases, and it is a major health problem in industrialized countries; however, the molecular basis for the link between obesity and obesity-related diseases has been unclear. Traditionally, adipose tissue has been regarded as an organ passively storing excess energy. However, research on adipocyte biology has found that adipocytes produce and secrete a variety of biologically active molecules, including growth factors, cytokines, and complement factors, in the immune system.

INTRODUCTION

The adipocyte-derived factors (Fig. 1) affect the function of adipocyte in an autocrine and a paracrine fashion and affect whole body homeostasis through the bloodstream. These findings indicate that adipose tissue is an endocrine organ and the adipocyte-derived bioactive substances are adipocytokines. Because these adipocyte-derived substances include the molecules belonging to

the strict cytokines, they are also called adipokines. Every cell type secretes various cytokines and bioactive substances to the surrounding milieu to maintain normal functions. The importance of adipocytokines is highlighted by the fact that adipose tissue is the largest organ in the body. Although the amount of adipocytokines produced by a single adipocyte is small, the total amount in the body greatly affects whole body functions. Another notable feature is that adipose tissue is supplied by the bloodstream, and adipocytokines released from adipocytes easily flow into the systemic circulation. Findings obtained from bioengineered mice with undifferentiated adipose tissue revealed the importance of adipocytokines in maintaining metabolic homeostasis. Adipocytokines play a significant role in the self-defense system against metabolic overload and probably also in the immune system.

There is substantial evidence that dysregulated production of adipocytokines is involved in the development of obesity-related diseases. Tumor necrosis factor- α (TNF- α), leptin, and resistin affect insulin sensitivity in the whole body. Overproduction of TNF- α has been suggested to contribute at least in part to the development of insulin resistance, which is a major clinical feature of obesity. Furthermore, adipose tissue also produces various vasoactive substances, such as plasminogen activator inhibitor

Figure 1 Adipocytokines.

(PAI-1), an inhibitor of the fibrinolytic system, and heparin-binding epidermal growth factor-like growth factor (HB-EGF), a potent growth factor for vascular smooth muscle cells. These factors are also overproduced in obesity. These findings suggest the existence of an adipovascular axis in which adipocyte-derived factors affect vascular functions independent of the coronary risk factors frequently associated with obesity.

Although the total amount of adipose tissue is increased in obesity, not all adipocytokines are overproduced. For example, adiponectin is factor D of the complement system. The expression of adiponectin in adipose tissue is severely impaired in obesity and results in the reduction of plasma concentration. The physiological meaning of the decreased plasma adiponectin in obesity is unclear. Next, adiponectin belongs to the soluble defense collagen superfamily. Although the protein possesses antiatherogenic and antidiabetic properties, its plasma concentration is decreased in obesity. The proteome analysis proved that there is impaired secretion of various molecules from the adipocytes of obese subjects. Not only hypersecretion of offense adipocytokines but also hyposecretion of defense adipocytokines affects the development of obesity-related disorders.

LEPTIN

Leptin is a 16-kDa protein secreted primarily from adipocytes. Rodents defective in leptin synthesis (*ob/ob* mice) or leptin receptor function (*db/db* mice, Zucker *fa/fa* rats, and Koletsky rats) are obese and develop hyperinsulinemia and insulin resistance. Leptin suppresses food intake and increases energy expenditure by enhancing thermogenesis and metabolic rate. These functions seem to be mediated mainly by the central nervous system because intracerebroventricular injection of leptin produced significant effects with much smaller amounts than those required by systemic injection.

Leptin receptors (OB-R) are single membrane-spanning receptors with homology to members of the cytokine receptor superfamily. Seven different leptin receptors, produced by alternative splicing, have been identified. The receptors containing transmembrane domains can be divided into two groups. One group has a short amino acid residue intracellular domain (OB-Ra, OB-Rc, OB-Rd, and OB-Rf). The other group has a long intracellular domain (OB-Rb). OB-Rb is mainly expressed in hypothalamus, whereas the short forms are expressed in a variety of tissues.

The long form of the receptor has two Janus kinase sites in the intracellular domain and the short form has one. Only the long form can activate the signal transducers and activators of the transcription family (STAT). C57B1/Ks *db/db* mice, which lack the long form of the receptor and have intact short forms, exhibited almost identical phenotype to *ob/ob* mice, which lack leptin.

There is accumulating evidence indicating that leptin mimics some of the insulin actions in liver, adipose tissue, and muscle. In diabetic rats, leptin increased glucose uptake in muscle and brown adipose tissue and normalized hyperglycemia. In liver and hepatocytes, leptin lowered hepatic glucose production by decreasing glycogenolysis and increasing glycogen synthesis.

The physiological significance of leptin was emphasized by the successful administration of leptin to treat the metabolic disorders of lipodystrophy in mice and humans. Generalized lipodystrophy is a disorder characterized by a paucity of adipose (fat) tissue accompanied by a severe resistance to insulin, leading to hyperinsulinemia, hyperglycemia, and an enlarged fatty liver. In the two genetically engineered mouse models of lipodystrophy, the plasma concentration of leptin was very low due to the loss of mature adipose tissues. Leptin supplementation overcame insulin resistance, diabetes, hyperlipidemia, and fatty liver in both models. These effects were not observed with chronic food restriction. The results support the theory that leptin exerts favorable effects on glucose and lipid metabolism independently of its effect on food intake. Based on these observations, human lipodystrophy patients were recently treated with leptin, resulting in an improvement in metabolic disorders and fatty liver.

TNF- α

It has been shown that the adipose TNF- α mRNA and plasma TNF- α protein are increased in most animal models and human subjects with obesity and insulin resistance. Neutralizing the blood TNF- α in obese rats with a soluble TNF- α receptor-IgG fusion protein markedly improved insulin resistance. These results indicated that the higher production of TNF- α in accumulated adipose tissue was causative for obesity-associated insulin resistance.

TNF- α treatment reduced insulin-stimulated autophosphorylation of the insulin receptor and IRS-1 phosphorylation in various tissue cultured cells, including adipocytes, fibroblasts, and hepatoma cells. These disturbances of insulin signaling were also

observed in the muscle and adipose tissues of the obese and insulin-resistant *fa/fa* rats. It has been reported that TNF- α induces serine phosphorylation of IRS-1 in cultured adipocytes and hepatocytes. The serine phosphorylated form of IRS-1 was also increased in the muscle and adipose tissues of *fa/fa* rats. The modified IRS-1 inhibited the autokinase activity of the insulin receptor, resulting in the deterioration of insulin signaling.

Hotamisligil and colleagues fed wild-type and TNF- α knockout mice with a high-fat diet. Both types of mice became similarly obese, but obese TNF- α (-/-) mice maintained high insulin sensitivity. These results demonstrated that TNF- α deficiency blocked the development of insulin resistance associated with diet-induced obesity. In the *ob/ob* mice with targeted mutations in both p55 and p75 TNF- α receptors, the signaling and function of TNF- α were completely abolished. Without the changes in body weight, the *ob/ob* mice with null mutations of TNF- α receptors showed higher insulin sensitivity than the *ob/ob* mice with normal TNF- α receptors. These results further support the theory that the enhanced TNF- α protein and TNF- α signaling are involved in obesity-associated insulin resistance.

RESISTIN

Resistin is a 12.5-kDa, cysteine-rich protein identified by screening for the genes that were induced during the differentiation of the adipocytes but were down-regulated in mature adipocytes exposed to glitazone, an insulin-sensitizing drug. Mouse resistin contains 114 amino acids and circulates as a homodimer of two peptides. Administration of resistin to mice impaired glucose tolerance and insulin action. Plasma concentrations of resistin were higher in genetic and diet-induced obese mice with insulin resistance. Administration of the neutralizing antibody against resistin increased insulin sensitivity in obese mice. These results suggest that resistin is a fat-derived factor causing insulin resistance in obesity and that the insulin-sensitizing effect of glitazone can be attributed to its inhibition of resistin expression.

One study, however, showed contradictory results. It was reported that resistin expression was decreased in obese mice and increased in response to glitazone.

The human homologue of resistin is located on chromosome 19p13.3, a region not previously implicated in the susceptibility to obesity, insulin resistance, or diabetes. Its significance in humans remains to be clarified.

PAI-1

PAI-1 is an inhibitor of plasminogen activators and fibrinolytic activity. Although PAI-1 is synthesized in endothelial cells and liver, adipose tissue is also a main source of plasma PAI-1. Expression of PAI-1 is augmented in adipose tissue, especially intraabdominal visceral fat in obesity. The amount of visceral fat is positively correlated with the plasma level of PAI-1 and is one of major determinants of plasma PAI-1. It is well-known that the plasma concentration of PAI-1 is elevated in subjects with type 2 diabetes and hypertriglyceridemia, although the precise mechanism is unclear. Type 2 diabetes and hypertriglyceridemia are often associated with visceral fat accumulation. PAI-1 produced by accumulated visceral fat may explain the high plasma PAI-1 in these conditions. The reason why adipocytes secrete PAI-1 has not been clarified. Adipocytes dramatically change cell size in response to nutritional conditions. Plasmin works to destroy the basement membrane to facilitate cell expansion. PAI-1 may control the activity of plasminogen activators to prevent the overproduction of plasmin.

ADIPONECTIN

Adiponectin is an adipocyte-derived factor identified through the extensive search of adipose tissue transcripts in the human genome project. The expression of adiponectin mRNA is exclusive in adipose tissue. The protein is composed of two structurally distinct domains—the C-terminal collagen-like fibrous domain and the complement C1q-like globular domain. Adiponectin is abundant in the circulating plasma in a multimeric form. Interestingly, plasma concentrations of adiponectin are decreased in obese subjects despite its restricted expression in adipocytes. Plasma adiponectin levels are also lower in patients with coronary artery disease and type 2 diabetes than those in body mass index-matched subjects. Physiologically, adiponectin inhibits the differentiation of adipocytes in a paracrine manner via the COX-2 pathway. When the endothelial barrier is injured, adiponectin accumulates in the subendothelial space of the vascular walls. The protein has anti-atherogenic properties, such as suppression of monocyte attachment to vascular endothelial cells via the reduced expression of adhesion molecules, suppression of foam cell formation and TNF- α secretion of macrophages, and suppression of the growth factor-induced proliferation of vascular smooth muscle cells. Administration of adiponectin also improves fatty

oxidation and insulin resistance in dietary-induced and genetically obese animals. Adiponectin is cleaved between fibrous and globular domains. The globular form of adiponectin has more potent activity for insulin sensitization than the whole protein. Thus, adiponectin has a dual function on insulin sensitivity and vascular functions. Hypoadiponectinemia in obesity may be a key factor in the metabolic syndrome, which is often accompanied by insulin resistance and cardiovascular diseases. Interestingly, patients with genetic hypoadiponectinemia caused by a missense mutation in the adiponectin gene also exhibit the clinical phenotype of the metabolic syndrome. Studies of mice genetically lacking adiponectin confirmed the significance of adiponectin in the metabolic syndrome. Two cohort studies of a specialized population report that hypoadiponectinemia is a risk for cardiac death or the developments of type 2 diabetes. The genetic variation in the adiponectin gene is also associated with an increased risk of type 2 diabetes in the Japanese population. Further

studies are necessary to verify the significance of adiponectin in the metabolic syndrome and obesity-related diseases.

Adrenal Androgens

Lucia Ghizzoni and Alessandra Vottero
University of Parma, Parma, Italy

Glossary

adrenal gland Triangular, endocrine, hormone-secreting gland located on top of each kidney.

androgens Sex hormones that stimulate the development of secondary masculine characteristics (i.e., deep voice, facial hair).

receptor Molecule on the cell surface or inside the cell that recognizes a specific antigen or hormone.

The adrenal androgens (AAs), normally secreted by the fetal adrenal zone or the zona reticularis, are steroid hormones with weak androgenic activity. Although AAs do not appear to play a major role in the fully androgenized adult man, they seem to play a role in the adult woman and in both sexes before puberty. Girls, women, and prepubertal boys may be negatively affected by AA hypersecretion, in contrast to adult men. This article discusses AA biosynthesis, regulation, physiology, and biological action.

ADRENAL ANATOMY AND ANDROGEN BIOSYNTHESIS

Adrenal Gland Anatomy

The adrenal glands, consisting of the cortex and medulla, have a roughly pyramidal shape and lie above the upper poles of the kidneys. The two zones receive their blood supply from branches of the phrenic arteries, aorta, and renal arteries. Arterial blood enters from the outer cortex, flows through fenestrated capillaries between the cords of cells, and drains into venules in the medulla. On the right, the adrenal vein directly enters the inferior vena cava; on the left, it usually drains into the left renal vein. The adrenal cortex is divided into three histologic and functional zones: the outer, aldosterone-secreting zona glomerulosa; the intermediate, cortisol-secreting zona fasciculata; and the inner, androgen-secreting zona reticularis. Whereas the zona glomerulosa is primarily

regulated by angiotensin II, both the zona fasciculata and the zona reticularis are regulated by adrenocorticotrophic hormone (ACTH).

Fetal Adrenal and Development

The fetal adrenal cortex arises from mesodermal cells migrating from the celomic epithelium very early in the embryonic period. It consists of both the adult adrenal zona glomerulosa and zona fasciculata and an inner large adrenal zone, which virtually disappears within weeks after birth. The active secretion of steroids occurs by week 6 from the provisional zone, which represents the functional cortex in the fetal period. Remaining cell foci from the fetal adrenal zone presumably give rise to the adrenal zona reticularis, starting at the age of 4 to 5 years in both sexes. This zone continues to grow until young adulthood (20 to 25 years), remains at a plateau for 5 to 10 years, and regresses gradually after the age of 35 years. Aging results in a reduction in the size of the zona reticularis and a relative increase in the outer cortical zones with no significant difference in the total width of the cortex.

Biosynthesis

Like all human steroid hormones, AAs are derived from cholesterol, which can be synthesized within the adrenal from acetyl coenzyme A, but mainly (80%) is derived from circulating plasma lipoproteins (low-density lipoproteins). The major androgens secreted by the adrenals are dehydroepiandrosterone (DHEA), DHEA sulfate (DHEAS), and androstenedione (Δ^4 -A) (Fig. 1). Production of testosterone (T) by these glands is minimal. DHEA and DHEAS are mainly products of the zona reticularis; Δ^4 -A and T are secreted by both the zona reticularis and the zona fasciculata. The enzymes responsible for the synthesis are hydroxylases, dehydrogenases, isomerases, and desmolases (Fig. 1), most of which require NADPH or NAD^+ as

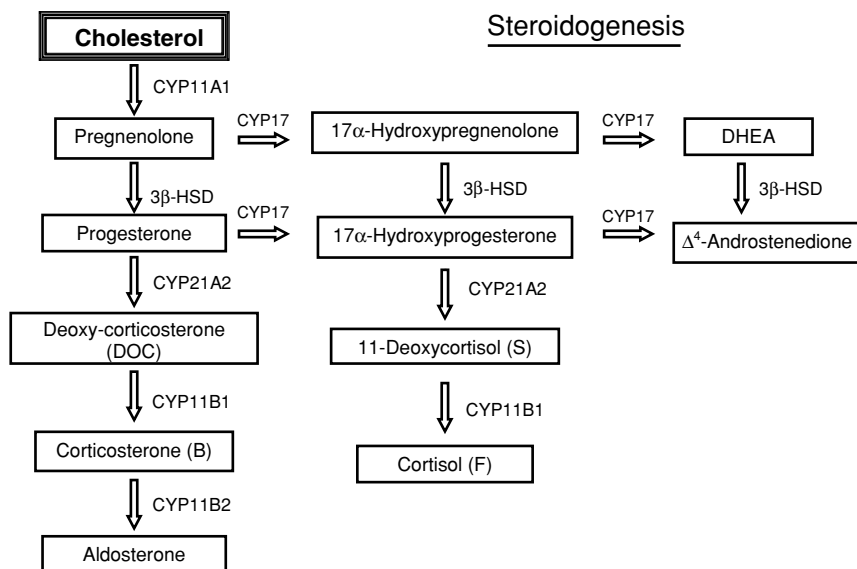

Figure 1 Adrenal androgen biosynthetic pathway. CYP11A1, cholesterol side-chain cleavage enzyme; desmolase; CYP17, 17 α -hydroxylase/17,20-lyase; 3 β -HSD, 3 β -hydroxysteroid dehydrogenase; CYP21A2, 21-hydroxylase; CYP11B1, 11 β -hydroxylase; CYP11B2, aldosterone synthase, corticosterone 18-methylcorticosterone oxidase/lyase.

cofactors. The anatomical alterations of the adrenal cortex, occurring mainly in the age groups of 20–30 years and 50–60 years, result in a marked decline in circulating adrenal C₁₉ steroids and their metabolites.

BIOCHEMISTRY

The steroid hormones produced by the adrenal cortex are members of a large family of compounds derived from the cyclopentanoperhydrophenanthrene ring structure that comprises three cyclohexane rings and one cyclopentane ring. Three 19-carbon compounds are the principal androgens secreted by the adrenals: DHEA, DHEAS, and Δ^4 -A.

ADRENAL ANDROGEN REGULATION AND PHYSIOLOGY

Regulation

Adrenal androgens are secreted by the adrenal glands in response to ACTH. ACTH is a 39-amino-acid peptide derived from proopiomelanocortin, synthesized and secreted by the anterior pituitary under the regulation of corticotropin-releasing hormone (CRH) and arginine-vasopressin (AVP) (Fig. 2). Both CRH and AVP are produced by parvocellular neurons of the paraventricular nucleus of the hypothalamus and act in synergy with each other (Fig. 2). Under ACTH regulation, adrenal androgens such as DHEA, Δ^4 -A,

and T are secreted synchronously with cortisol both in secretory episodes and in a circadian pattern. The levels of plasma DHEAS do not exhibit a circadian rhythm because of its much longer circulating half-life.

Numerous other endocrine signals were proposed as regulators of adrenal androgen secretion. Glasgow *et al.* reported the presence of prolactin (PRL) receptors in the human adrenal gland and suggested a direct effect of PRL on adrenal steroidogenesis that may be of particular relevance in clinical disorders characterized by hyperprolactinemia. Interestingly, adults with

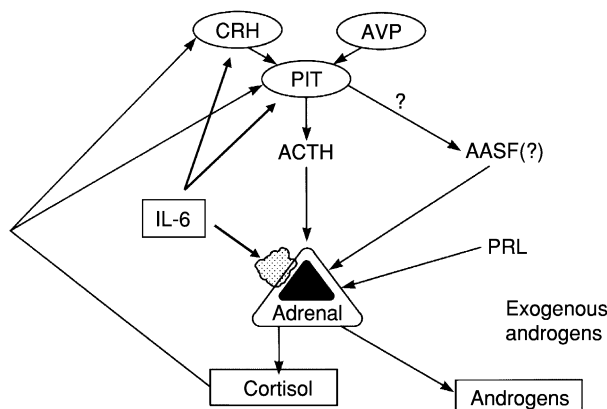

Figure 2 Schematic representation of adrenal androgen regulation.

hyperprolactinemia have increased secretion of AAs by the zona reticularis, which is corrected by reduction of PRL secretion with bromocriptine. In women with PRL-secreting tumors, there is a correlation between PRL levels and DHEAS.

Together with ACTH and/or PRL, other factors including estrogen, epidermal growth factor, prostaglandins, angiotensin, growth hormone, gonadotropins, β -lipotropin, and β -endorphin may act as stimulators of androgen secretion. Interleukin-6 (IL-6) is also known to stimulate mineralocorticoid, glucocorticoid, and androgen production by acting through specific receptors expressed in the adrenals, mainly in the zona fasciculata and reticularis, but also to a lesser extent in the zona glomerulosa. The ability of IL-6 to stimulate mineralocorticoid, glucocorticoid, and androgen production suggests that IL-6 might play a role in coordinating the responses of all adrenocortical zones and the interaction of the adrenal function with the immune system.

Both ACTH and PRL stimulate AA secretion by the fetal adrenal zone. Placental CRH production, which rises exponentially during human pregnancy, may also play a key role in promoting DHEAS production by the fetal adrenals, leading to an increase in placental estrogen synthesis and contributing to the process of parturition in humans.

Physiology

AAs are secreted in small amounts during infancy and early childhood and their secretion gradually increases with age, paralleling the growth of the zona reticularis. Adrenarche is the appearance of pubic hair (pubarche) resulting from a rise in adrenal androgen levels. The mechanisms by which the zona reticularis develops with age and by which adrenarche is regulated are not fully known. It was shown that children with premature pubarche have hormonal responses to a CRH stimulation test that are similar in magnitude to those of prepubertal children of comparable age, ruling out a prominent role for CRH in premature pubarche. Gell *et al.* suggested that as children mature, a decrease in 3β -hydroxysteroid dehydrogenase activity in the adrenal reticularis occurs, resulting in the shift of pregnenolone through the 17α -hydroxylase/ $17,20$ -lyase pathway, leading to increased production of DHEA and DHEAS, as seen during adrenarche. Locally produced insulin-like growth factor type II (IGF-II) modulates fetal adrenocortical cell function by increasing responsiveness to ACTH via activation of the IGF type I receptor and increases the capacity of those cells for androgen synthesis by directly

augmenting the expression of P450c17. Thus, IGF-II may play a pivotal role in AA production, both physiologically *in utero* and at adrenarche, as well as under conditions of hyperandrogenemia.

Experiments by Miller and co-workers suggested that an increased serine phosphorylation of human P450c17 might play a role in the development of both human adrenarche and hyperandrogenism of polycystic ovary syndrome (PCOS), resulting in a substantial increase in $17,20$ -lyase activity. P450c17 is the key enzyme that regulates androgen synthesis. It is the only enzyme known to have the ability to convert C_{21} precursors to the androgen prehormones, the 17 -ketosteroids. It is a single enzyme with two activities, 17 -hydroxylase and $17,20$ -lyase, and serine phosphorylation appears to modulate its activity. In particular, it promotes $17,20$ -lyase activity and at the same time inhibits the activity of the insulin receptor. It was postulated that a single abnormal serine kinase might hyperphosphorylate both P450c17 and the insulin receptor, accounting for the hyperandrogenism and the hyperinsulinism responsible for both the premature pubarche and later in life for PCOS. *In vitro* studies, however, failed to find evidence for hyperphosphorylation of insulin receptor- β and P450c17 in PCOS.

CIRCULATION

Circulating steroid hormones are largely bound to plasma proteins (binding globulins and albumin). Approximately 90% of DHEA, DHEAS, and Δ^4 -A is bound to albumin and 3% is bound to sex hormone-binding globulin. The binding globulins have high affinity and low capacity, whereas albumin has a low affinity and high capacity for steroids.

ANDROGEN RECEPTOR

The inactive androgen precursors secreted by the adrenal, after conversion to T and 5α -dihydrotestosterone (DHT), exert their effects in most peripheral tissues by interacting with high-affinity receptor proteins. The androgen receptor (AR), encoded by the AR gene on the X chromosome, is a member of the steroid receptor superfamily. This gene contains a polymorphic CAG microsatellite repeat within exon 1, which codes for a variable length of polyglutamine chain at the amino terminus, the transactivation domain of the AR protein. Triplet-repeat DNA sequences can be sites of genetic instability and their expansion in a variety of genes has been associated with human genetic diseases, such as

fragile X syndrome and myotonic dystrophy. In the case of the AR gene, an inverse correlation between the number of CAG repeats and the risk for prostate cancer was described and its expansion was documented in Kennedy's disease (spinal and bulbar muscular atrophy), a disorder associated with primary hypogonadism. *In vitro* studies showed that progressive expansion of the repeat length in the AR is associated with a linear decrease in its transactivation function. These observations support the idea that there is an optimal number of repeats that varies in the population from 11 to 31 (average size: 21 ± 2 repeats).

Methylation of deoxycytosine residues is another factor involved in the modulation of gene expression. Belmont *et al.* showed that the methylation of *HpaII* and *HhaI* sites near the polymorphic CAG repeats in the first exon of the human AR (HUMARA) locus correlated with X inactivation. Patients with idiopathic hirsutism were shown to have a normal number of CAG repeats but with a preponderance of the shortest and most active alleles. These patients also had a preferential methylation of the longer AR allele compared to normal subjects, leading to inactivation of the functionally weaker gene. This skewing could allow the shorter, more active AR allele to be preferentially expressed, explaining the peripheral hypersensitivity to androgens in hirsute patients.

Multiple coactivators that enhance the transcription of the AR gene have been identified, including AP-1, Smad3, nuclear factor κ B, sex-determining region Y, and the Ets family of transcription factors. The relative importance of these coactivators for any particular cell type remains unclear, since a putative coregulator that can alter transcriptional activity is typically included in transient transfection experiments. Although AR is normally thought to function as a homodimer, it was also shown to heterodimerize with other nuclear receptors including the estrogen receptor, glucocorticoid receptor, and testicular orphan receptor 4. One of the major mechanisms through which coregulators might function is by forming a bridge between the DNA-bound nuclear receptor and the basal transcriptional machinery (type I regulators). Coactivators may also facilitate ligand binding, promote receptor nuclear translocation, or mediate signal transduction (type II coregulators).

The role of corepressors in AR function is poorly defined. Three corepressors of androgen-bound AR have been identified thus far: cyclin D1, calreticulin, and HBO1 [histone acetyltransferase binding to ORC (origin recognition complex)]. However, relatively little is known about the mechanism(s) of their repressive effects.

PERIPHERAL CONVERSION AND METABOLISM

DHEA, DHEAS, and Δ^4 -A are converted to the potent androgens T and DHT in peripheral tissues. Major conversions are those of Δ^4 -A to T and of T to DHT as carried out by the enzymes 17-hydroxysteroid dehydrogenase (17 β -HSD) and 5 α -reductase, respectively. Major peripheral sites of androgen conversion are the hair follicles, the sebaceous glands, the prostate, and the external genitalia.

The active uptake of androgens and *in situ* estrogen synthesis occur in peripheral adipose tissue and are carried out by the enzymes 17 β -HSD and aromatase, respectively. Peripheral conversion contributes significantly to circulating T levels in women, but not in men, in whom T is largely produced by the testis.

The AAs and their metabolites are inactivated or degraded in various tissues, including the liver and kidneys. Major biochemical routes for inactivation and excretion are conjugation of androgens to glucuronate or sulfate residues to produce hydrophilic glucuronides or sulfates that are excreted in the urine.

BIOLOGICAL EFFECTS

In adult men, the conversion of adrenal Δ^4 -A to testosterone accounts for less than 5% of the production rate of the latter; thus, its role in the physiological androgenization of the male is negligible. Excessive AA secretion appears to have no major clinical consequences in the adult man, although this may be a matter of debate. AA hypersecretion in prepubertal boys, on the other hand, has clearly been associated with isosexual precocious puberty.

In adult women, adrenal Δ^4 -A and Δ^4 -A generated from the peripheral conversion of DHEA contribute substantially to total androgen production and its effect. In the follicular phase of the menstrual cycle, adrenal precursors account for two-thirds of testosterone production and one-half of dihydrotestosterone production. At midcycle, the ovarian contribution increases and the adrenal precursors account for 40% of testosterone production. In women, increased AA production may be manifested as cystic acne, hirsutism, male type baldness, menstrual irregularities, oligo-ovulation or anovulation, infertility, and/or frank virilization. Excessive adrenal androgen secretion in prepubertal or pubertal girls can cause heterosexual precocious puberty.

Adrenal Cortex Development, Regulation of

Michel Grino

Université de la Méditerranée, Marseille, France

Glossary

adrenocorticotrophic hormone (ACTH) A 39-amino acid peptide secreted by the anterior pituitary that acts primarily on the adrenal cortex, stimulating its growth and its secretion of corticosteroids.

corticotropin-releasing hormone (CRH) A 41-amino acid peptide secreted by the hypothalamus and the placenta; hypothalamic CRH acts primarily on the anterior pituitary to stimulate adrenocorticotrophic hormone (ACTH) synthesis and secretion, whereas placental CRH acts on the fetal adrenals to regulate corticosteroid secretion and on the reproductive tract to regulate the processes of parturition.

estrogens Female sex hormones that are responsible for the development of the female secondary sex characteristics, the regulation of the menstrual cycle, the production of an environment suitable for the implantation of the early embryo, the maintenance of pregnancy, and the development of fetal and maternal tissues.

growth factors Secreted proteins that exert diverse effects on cell growth, metabolism, and differentiation.

Steroids synthesized by the adrenal cortex, in particular glucocorticoids, play an important role in the maintenance of pregnancy and the maturation of maternal and fetal tissues during fetal life and in the adaptation to extrauterine life after birth. An adequate exposure to glucocorticoids relies on coordinate regulation of adrenal growth, maturation, and steroid biosynthesis. Anterior pituitary adrenocorticotrophic hormone (ACTH) is believed to be the major trophic regulator of adrenal development and glucocorticoid synthesis and secretion. However, because ACTH is not a mitogen per se, it is now generally accepted that some of the trophic actions of ACTH on the fetal adrenal cortex are mediated indirectly via tissue growth factors. In addition, other hormonal factors originating from the placenta, such as corticotropin-releasing hormone (CRH) and estrogens, are important for fetal adrenal maturation.

HORMONAL REGULATION OF ADRENAL GROWTH AND STEROID BIOSYNTHESIS

Adrenocorticotrophic Hormone

Adrenocorticotrophic hormone (ACTH) is the main stimulator of glucocorticoid synthesis and secretion in the adult. Exposure to robust ACTH secretion is required for normal adrenal growth and maturation. Indeed, disruption of the hypothalamo-pituitary-adrenal (HPA) function in the human fetus, experimental anencephaly in the fetal rhesus monkey or the fetal rat, or fetal hypophysectomy in sheep inhibits growth of the fetal adrenal cortex.

ACTH acts through a specific adrenal cortical cell surface G protein-coupled receptor that activates adenylate cyclase, leading to an increase in intracellular cyclic adenosine monophosphate (cAMP) that in turn activates protein kinase A and initiates the cascade of intracellular signaling events. In midgestation human fetal adrenals, ACTH receptor mRNA is localized in cells from all cortical zones; abundance is higher in the definitive zone than in the fetal zone. The effect of ACTH on adrenal growth and/or metabolism is zone specific. In anencephalic fetuses, the definitive zone appears to be normal. In fetal monkeys, blockade of endogenous fetal ACTH secretion by glucocorticoid treatment decreases expression of 3β -hydroxysteroid dehydrogenase (3β -HSD) and eliminates the transitional zone but has no effect on the size of the definitive zone. Conversely, ACTH administration or stimulation of endogenous ACTH secretion by metyrapone treatment results in stimulation of 3β -HSD expression and in an increase of the width of the transitional zone but not of the size of the definitive zone. The growth and the steroidogenic activity of the fetal zone are also controlled by ACTH. In fetuses with congenital adrenal hyperplasia, the fetal zone is hypertrophied and adrenal androgen concentrations are stimulated dramatically. In monkeys, inhibition of

endogenous ACTH decreases adrenal 17 α -hydroxylase/17 \rightarrow 20 lyase (P450c17) expression, whereas metyrapone-induced stimulation of ACTH secretion results in stimulation of P450c17 gene transcription in the fetal zone.

The stimulatory effect of ACTH on adrenal growth and steroid biosynthetic capacities seems to depend both on the circulating levels of the hormone and on the sensitivity of the adrenal gland. In addition, these phenomena could be associated given that it is established that ACTH up-regulates the expression of its own receptor gene in both adult and fetal adrenocortical cells.

In human fetuses, the maximal rate of adrenal growth occurs during the time the plasma ACTH concentration is the lowest. In baboons, there is a temporal parallelism between ACTH receptor mRNA expression in the fetal zone and ACTH-stimulable dehydroepiandrosterone (DHEA) formation. It has been suggested that the increase in 3 β -HSD expression and cortisol production observed during late gestation results from the ACTH receptor-mediated development and enhanced functional capacity of the transitional/definitive zone.

In sheep, between embryonic day 90 (E90) and E120, adrenal growth and adrenal cell division occurs at the lowest rate compared with any other time during gestation, and there is a decreased expression of steroidogenic enzymes. Between E130 and postnatal day 2 (P2), there is a phase of rapid adrenal growth and functional maturation. Circulating ACTH increases steadily between E110 and E145, whereas plasma cortisol concentrations are low between E110 and E130 and increase abruptly between E130 and E145. Interestingly, the lowest level of adrenal expression of the ACTH receptor occurs at E90, whereas there is increased ACTH receptor mRNA, ACTH binding, and ACTH-induced adenylate cyclase activity after E125. The ACTH sensitivity of fetal adrenal cells incubated *in vitro* parallels the evolution of the density of ACTH binding sites. Ovine fetuses that have undergone hypothalamo-pituitary disconnection at E115 show decreased ACTH and cortisol secretion at E126 but normal ACTH and decreased cortisol secretion at E145. Hypophysectomy in ovine fetuses induces a decrease in adrenal expression of the side-chain cleavage enzyme (P450ssc), 3 β -HSD, and P450c17 mRNAs that is reversed by ACTH₁₋₂₄ infusion. Other pro-opiomelanocortin (POMC)-derived peptides can participate in adrenal maturation because, in fetal sheep, infusion of N-POMC 1-77 stimulates adrenal growth and 21-hydroxylase (P450c21) mRNA expression.

In fetal rats, plasma corticosterone levels rise progressively from E16 to E19. The pattern of plasma ACTH levels parallels that of corticosterone, indicating that the observed adrenal hyperactivity during late gestation is driven by increased ACTH secretion from the corticotropes. In newborn rats, circulating ACTH levels are low during the first 10 days after birth, the so-called stress hyporesponsive period, and the density of adrenal ACTH-binding sites and basal and ACTH-stimulated adenylate cyclase activity are decreased in the adrenals of P7 rats. Chronic administration of ACTH or POMC-derived peptides (e.g., Lys- γ ₃-melanocyte-stimulating hormone) during this period has a trophic effect on the adrenal and potentiates the subsequent corticosterone response to stress or to ACTH injection.

Angiotensin II

In adults, angiotensin II, acting through membrane G protein-coupled receptors, is one of the most important factors involved in the regulation of aldosterone biosynthesis and secretion. Two subtypes of angiotensin II receptors have been described: AT₁ and AT₂.

AT₁ and AT₂ receptors are present on human gestational week 16 (W16) to W18 fetal adrenocortical cells. AT₁ receptors, which mediate most of the known actions of angiotensin II, are located in the definitive zone, whereas AT₂ receptors are present throughout the gland, with a predominant labeling in the fetal zone. It has been proposed that AT₂ receptors are involved in the apoptotic process observed in the human fetal adrenal gland and could participate, after birth, in the involution of the fetal zone.

In sheep, isolated adrenal cells obtained from E40 to E90 fetuses secrete aldosterone and respond to relatively high doses of angiotensin II. At E100 to E130, adrenal glands become unresponsive to angiotensin II. *In vivo*, during late gestation, fetuses are less responsive to infused angiotensin II, in terms of aldosterone secretion, than are adult sheep. In addition, *in vitro*, angiotensin II inhibits ACTH-induced cortisol secretion and P450c17 expression. This phenomenon may be mediated via AT₁ receptors. The mRNA coding for the AT₁ receptor is first detected in the unzoned gland as early as E40 and is present at high levels in the zona glomerulosa and, to a lesser extent, in the zona fasciculata at E60 to E105. During late gestation (E120–E135), the AT₁ receptor hybridization signal decreases before showing a further increase to reach adult values by P2. The fall in AT₁ receptor expression during late gestation could allow ACTH to override angiotensin

II-induced inhibition of cortisol secretion and P450c17 expression. The mRNA for the AT₂ receptor is present in the same location from E40 to E130 and declines to extremely low levels after E140.

In the rat adrenal zona glomerulosa, angiotensin II receptor content decreases from very high levels at birth to adult levels by P20. This decrease is due to a decline in AT₂ receptors. In P7 rats, aldosterone secretion is more sensitive to the stimulatory effect of ACTH than of angiotensin II.

Placental Factors

Functional interactions exist between the placenta and the fetal adrenals. The placenta synthesizes corticotropin-releasing hormone (CRH), the major hypothalamic neuropeptide that stimulates anterior pituitary POMC synthesis and ACTH secretion. Estrogens, which originate mainly from the placental conversion of fetal DHEA sulfate (DHEA-S), have a direct effect on fetal adrenal activity and regulate placental metabolism of maternal glucocorticoids (Fig. 1).

Corticotropin-Releasing Hormone

In primates, CRH and POMC synthesized in the placenta are released in both the maternal and fetal circulations. Plasma CRH increases exponentially during gestation, peaking at labor. The role of placental CRH in the regulation of fetal adrenal function is not clear. A circulating binding protein is present in the human fetal circulation and is capable of inactivating a large amount of CRH. CRH may modulate fetal adrenal function indirectly by stimulating placental or fetal anterior pituitary ACTH and POMC-derived peptide release, or it may do so directly by regulating the fetal adrenal cortex. Indeed, human midgestation fetal adrenals express CRH receptor mRNA. CRH stimulates DHEA-S and cortisol production, stimulates P450ssc and P450c17 expression, and increases ACTH responsiveness in cultured human fetal adrenocortical cells.

Estrogens

Estrogens play an important role in regulating, either directly or indirectly, cortisol and DHEA synthesis and secretion. The primate fetal adrenal begins to synthesize cortisol *de novo* from cholesterol between mid- and late gestation. As a consequence, at midgestation, most if not all of the glucocorticoids in the fetal circulation originate from the mother. Maternal glucocorticoids are metabolized in the placenta, which

Figure 1 Hormonal regulation of fetal adrenal growth and steroid biosynthesis. It is proposed that fetal anterior pituitary adrenocorticotropic hormone (ACTH), either directly or mediated by growth factors, and pro-opiomelanocortin (POMC)-derived peptides have a stimulatory effect on fetal adrenal growth and steroid biosynthesis. Placental estrogens, originating from local conversion of the fetal adrenal androgen precursor dehydroepiandrosterone (DHEA), can regulate fetal adrenal metabolism directly or can act through a modulation of placental 11 β -hydroxysteroid dehydrogenase (11 β -HSD) activity. Between early and midgestation, 11 β -HSD shows preferential reduction of cortisone to cortisol, leading to decreased pituitary ACTH secretion and subsequent reduced adrenal maturation and cortisol biosynthesis. With advancing gestation, the increase in estrogen production enhances placental 11 β -HSD oxidation of cortisol to cortisone, leading to decreased cortisol feedback at the fetal pituitary level and acceleration of adrenal maturation and stimulation of cortisol and DHEA secretion, thereby creating a positive feedback loop. Placental corticotropin-releasing hormone (CRH) may modulate fetal adrenal function indirectly by stimulating fetal anterior pituitary ACTH and POMC-derived peptide release or directly by regulating fetal adrenal cortex. synthesizes the two isoforms of 11 β -hydroxysteroid dehydrogenase (11 β -HSD). 11 β -HSD-1, which is expressed in placental intermediate trophoblast cells and in the vascular endothelium, has both oxidase (active cortisol-to-inactive cortisone) and reductase (cortisone-to-cortisol) activities. 11 β -HSD-2, which is present in placental syncytiotrophoblast cells, exhibits only oxidase activity. Because 11 β -HSD activity

Table I Main Characteristics of the Major Growth Factors Involved in Fetal Adrenal Growth and Steroidogenesis

| Growth factor | Site of synthesis | Receptors location | Role in growth | Role in steroidogenesis | Regulated by |

shows preferential reduction of cortisone to cortisol between early and midgestation, increased circulating fetal cortisol leads to decreased pituitary ACTH synthesis and secretion and to subsequent reduced adrenal maturation and cortisol biosynthesis capacity. With advancing gestation, the increase in estrogen production enhances placental 11 β -HSD oxidation of cortisol to cortisone, leading to decreased cortisol feedback at the fetal pituitary level. The subsequent increase in anterior pituitary ACTH synthesis and secretion induces acceleration of adrenal maturation and stimulation of cortisol secretion by the definitive zone and of DHEA production by the fetal zone, creating a positive feedback loop. In addition to their effects on placental glucocorticoid metabolism, estrogens can act directly at the adrenal level. Indeed, the primate fetal adrenal contains estrogen receptors β . Also, *in vivo*, estrogen treatment increases the responsiveness of the fetal adrenal gland to ACTH, presumably through stimulation of protein kinase A activity.

In sheep, during late gestation, estrogens also have a stimulatory effect on fetal ACTH and cortisol secretion. However, unlike in primates, the stimulatory effect of estrogens on the HPA axis takes place at the central nervous system level, that is, on the hypothalamic ACTH secretagogues arginine vasopressin and CRH.

ROLE OF GROWTH FACTORS

As mentioned previously, ACTH is the primary regulator of adrenal growth and steroid biosynthesis. However, because ACTH is not a mitogen per se, it is now generally accepted that some of the trophic actions of ACTH on the fetal adrenal cortex are mediated indirectly via tissue growth factors such as insulin-like growth factors (IGF-I and IGF-II), epidermal growth factor (EGF), vascular endothelial growth factor (VEGF), fibroblast growth factor-2 (FGF-2), members of the transforming growth factor- β (TGF- β) family, and adrenomedullin (Table I).

Insulin-like Growth Factors

IGF-I and IGF-II are mitogenic peptides, structurally related to proinsulin, that affect growth and function in a wide variety of cell types and can act as autocrine, paracrine, or endocrine factors. The biological actions of IGF-I and IGF-II are modulated by insulin-like growth factor-binding proteins (IGFBPs). IGF-I mediates many of the somatotrophic actions of growth hormone, whereas IGF-II is important in the regulation of fetal development. The effect of IGFs on adrenal cortical cells is most likely mediated through

IGF type 1 receptors because this subtype has been identified in both adult human and fetal nonhuman primate adrenal glands and because IGF type 2 receptor does not bind IGF-II.

Circulating concentrations of IGF-II are high during fetal life in several species (e.g., primates, sheep, rodents) and decrease after delivery. IGF-I and IGF-II mRNAs are present in adrenals from mid-gestation human fetuses. IGF-I mRNA is detected only in the capsule and not in the cortical zones, whereas IGF-II mRNA is detected in the definitive and fetal zones as well as in the capsule. The IGF-II mRNA is present in high abundance in human fetal adrenals and is barely detectable in adult adrenals, whereas the mRNA encoding IGF-I is expressed at low levels in fetus adrenals and at high levels in adult adrenal glands. In adrenals obtained from nonhuman primates, IGF-II mRNA is abundant from early (E60) to late (E165) gestation and is localized in the definitive, transitional, and fetal zones. The mRNAs coding for IGFBP-2 and IGFBP-6, which have been shown to bind preferentially IGF-II, are expressed in adrenals obtained from monkey fetuses in the definitive, transitional, and fetal zones. In the developing ovine adrenal, IGF-II mRNA is highest in E60 fetuses, decreases slightly between E60 and E100, remains relatively constant until term, and decreases significantly after birth, with IGF-I mRNA being expressed at very low levels. At all gestational ages, IGF-II mRNA and protein are localized in the capsule and mesenchymal cells surrounding the gland and in the steroidogenic cells of the zona glomerulosa and zona fasciculata.

IGFs have profound effects on adrenal growth. Transgenic mice that are IGF-I, IGF-II, or IGF type 1 receptor-deficient have intrauterine growth retardation. However, IGF-II-deficient mice have near-normal postnatal growth due to IGF-I. In ovine fetuses, chronic infusion of either IGF-I or IGF-II between E120 and E130 results in an increase in adrenal growth. *In vitro*, IGF-I and/or IGF-II stimulate proliferation of fetal adrenocortical cells obtained from sheep or human fetuses. As mentioned previously, IGF-II may mediate the trophic actions of ACTH on the fetal adrenal gland. Treatment of rhesus monkey fetuses with metyrapone, which likely increases pituitary ACTH secretion, induces in the adrenals hypertrophy of all cortical zones together with an increase in the concentrations of IGF-II and IGF type 1 receptor mRNAs. *In vitro*, in human fetal adrenal cells in culture, ACTH increases IGF-II mRNA levels. In addition to its effects on adrenal growth,

IGF-II regulates adrenal steroidogenesis. It has been demonstrated, using primary cultures of adrenal cortical cells obtained from human mid-gestation fetuses, that IGF-I and IGF-II stimulate basal and ACTH-, forskolin-, or cAMP-induced cortisol and DHEA production. Under the same experimental conditions, IGF-II increases adrenocortical responsiveness to ACTH without any effect on ACTH receptor mRNA, suggesting that IGF-II modulates ACTH sensitivity in fetuses by increasing ACTH signal transduction at some point distal to the ACTH receptor. In addition, IGF-II increases ACTH-stimulated abundance of P450_{ssc} and P450_{c17} mRNAs, thereby augmenting the potential for adrenal androgen synthesis.

Epidermal Growth Factor

Human cord blood EGF levels have been shown to increase with progressive gestation, suggesting a functional role for EGF during the perinatal period. Knockout mice for the EGF receptor have intrauterine growth retardation. However, EGF and EGF precursor mRNA are expressed as low levels, and tissue EGF immunoreactivity appears late in rodent fetuses. Therefore, it has been proposed that TGF- α , a member of the EGF family, is the ligand for the fetal EGF receptor. TGF- β has been identified in steroidogenic cells of adult adrenal cortex. EGF receptor concentrations increase steadily from E15 until birth in several mouse tissues. EGF receptors have been identified in both the definitive and fetal zones from mid-gestation human adrenal fetuses. EGF has been shown to stimulate the proliferation of human fetal adrenal cells *in vitro* and to act cooperatively with IGF-I and IGF-II. Late-gestation EGF-treated monkey fetuses show an increase in adrenal weight due to a hypertrophy of the definitive zone and stimulation of 3 β -HSD immunoreactivity in the definitive and transitional zones. In EGF-infused fetal sheep, adrenal cortical hypertrophy is accompanied by increased cortisol and aldosterone secretion. EGF may act directly at the adrenal level or indirectly through stimulation of the hypothalamo-pituitary axis because EGF increases the secretion of CRH from the hypothalamus and of ACTH from the anterior pituitary. It has been demonstrated that, in fetal monkeys, EGF acts on the hypothalamic-pituitary axis to modulate adrenal cortical growth and functional maturation of the transitional zone, whereas EGF can act independently of the hypothalamic-pituitary axis to stimulate functional maturation of the definitive zone.

Vascular Endothelial Growth Factor

VEGFs are a family of direct-acting endothelial cell mitogens and angiogenic factors that derive from a single gene by alternative splicing. The mRNAs coding for the four isoforms of VEGF and for the two VEGF receptors have been identified in the adult mouse adrenal gland. VEGF mRNA and protein have been detected in the adrenal cortex from midgestation human fetuses, predominantly in the fetal zone. The predominant staining for VEGF in the fetal zone correlates with the extensive vasculature of this zone. In primary cultures of human fetal adrenal cortical cells, ACTH and forskolin increase both VEGF mRNA levels and VEGF protein secretion.

Fibroblast Growth Factor-2

FGF-2 (also called basic FGF) is a potent angiogenic molecule that belongs to the family of the FGF and interacts with four cell surface receptor subtypes. FGF-2 is synthesized by human W16 fetal adrenal cortex and is stimulated by ACTH and cAMP. FGF-2 mRNA increases steadily during gestation in adrenal glands obtained from nonhuman primate fetuses. *In vitro*, FGF-2 stimulates the proliferation of human fetal adrenal cells from the definitive or fetal zone, with its effect being additive to those of IGF-I and IGF-II.

Transforming Growth Factor- β

TGF- β s are a family of potent multifunctional cytokines that modulate a wide variety of cellular activities. Members of the superfamily include TGF β -1, activin, and inhibin.

TGF- β 1

TGF- β 1 immunoreactivity has been detected in the adrenal cortex from adult and neonatal mice. However, expression of TGF- β 1 in human adrenals during development remains to be determined. TGF- β 1-binding sites have been identified in fetal human cortical cells. Several reports indicate that TGF- β 1 inhibits basal and EGF-stimulated growth of human fetal cortical cells, in both the definitive and fetal zones, possibly through a stimulation of apoptosis. This inhibitory effect is significantly blunted by ACTH. TGF- β 1 is also a potent inhibitor of adrenal steroidogenesis. Incubation of primary cultures of human fetal cortical cells with TGF- β 1 results in a decrease of both basal and ACTH-induced DHEA secretion and P450c17 gene expression. In fetal sheep, adrenal TGF- β 1 has an inhibitory effect on

basal P450ssc expression and on ACTH-induced cortisol secretion and P450c17 activity. The interplay between TGF- β 1 and ACTH in regulating adrenal growth and steroid production does not involve mutual control of their respective receptors because TGF- β 1 does not influence ACTH receptor gene expression and because ACTH increases TGF- β 1 binding in the fetal adrenal cortex.

Inhibins

Inhibins are dimers of an α -subunit and either a β_A - or a β_B -subunit, whereas activins are homo- or heterodimers of either a β_A - or a β_B -subunit. α -, β_A -, or β_B -subunit immunoreactivity and mRNAs, as well as activin type I/II receptor and inhibin receptor mRNAs, have been detected in the definitive and fetal zone of adrenals from midgestation human fetuses. *In vitro*, activin A inhibits basal and EGF-stimulated fetal zone proliferation, possibly through enhanced apoptosis, whereas inhibin A has no apparent mitogenic effect. The inhibitory effect of activin A on fetal adrenal cell proliferation is additive to that of TGF- β . In addition, ACTH has a stimulatory effect on α and β_A subunit mRNA levels and inhibin A/B secretion from primary cultures of human fetal adrenal cells.

Adrenomedullin

Adrenomedullin is a multifunctional peptide, initially purified from an adrenal tumor of the medulla, that shows structural homology with calcitonin gene-related peptide (CGRP). In mice, adrenomedullin mRNA and protein are present in the adrenal primordia as early as E12. The observations that antagonism of adrenomedullin function during rat pregnancy causes fetal growth restriction, and that proadrenomedullin N-terminal 20 peptide enhances proliferation of adult rat zona glomerulosa cells by acting through CGRP1 receptors, suggest that proadrenomedullin-derived peptides may be important in regulating adrenal growth during development.

Glossary

adrenal cortex The outer portion of the adrenal gland. It produces glucocorticoid and mineralocorticoid hormones and adrenal androgens.

adrenal gland A pair of small glands, each of which is located on top of one of the kidneys.

cortisol The major natural glucocorticoid in humans and the primary stress hormone.

The adrenal gland was first described by Bartholomeus Eustachius in 1563. However, it was Thomas Addison in 1855 who first recognized the importance of the adrenal glands, and in 1856 Charles Edward Brown-Séquard showed by bilateral adrenalectomy in experimental animals that the function of these glands was necessary for life. Using histochemical techniques developed in the mid-19th century, it was demonstrated that the adrenal medulla and the adrenal cortex have divergent cellular and functional properties.

HISTOLOGY

Whereas the fetal cortex mainly consists of the zona fetalis, the adult adrenal cortex consists of at least three anatomically distinct zones: the outer zona glomerulosa, which is the site of mineralocorticoid production (e.g., aldosterone); the central zona fasciculata, which is predominantly responsible for glucocorticoid production; and the inner zona reticularis, where adrenal androgens [predominantly dehydroepiandrosterone (DHEA), DHEA sulfate, and androstenedione] are located and some glucocorticoid synthesis (cortisol and corticosterone) occurs (Fig. 1). In rats, a fourth zone, the zona intermedia, can be discerned that is believed to contain adrenocortical stem cells and to be the region in which adrenocyte differentiation begins.

The adrenal cortex synthesizes exclusively steroid hormones, which are derived from various

modifications of the precursor cholesterol. Glucocorticoids are secreted during the course of stress regulation and act mainly on intermediary metabolism and the immune system. Mineralocorticoids exert their main action on salt and water homeostasis. Adrenal androgens show a testosterone-like effect but can also be precursors for aromatization to estrogens. The human adrenal cortex is able to synthesize more than 50 steroids, but not all of them are secreted into the blood circulation or are biologically active. In addition, adrenocortical cells can secrete active peptides, cytokines, and other hormones.

At the ultrastructural level, cells of the zona glomerulosa are rounded and smaller than the polyhedral cells of the zona fasciculata, which gradually extend into the zona reticularis. The latter zone consists of cells that appear identical to those of the zona fasciculata and also those of another type of smaller cells with a dark-staining nucleus. The cells of the adrenal cortex are arranged in a cord-like manner, extending from the adrenal capsule to the medulla and are surrounded by a capillary network. In adrenocortical cells, the mitochondria are particularly numerous, and the smooth endoplasmic reticulum is especially

abundant and forms a network of anastomosing tubules.

The classic view of a strict separation between the steroid-producing adrenal cortex and the catecholamine-producing medulla has been shown to be an oversimplification; displaced chromaffin cells have been found in all zones of the adult adrenal cortex and, similarly, cortical cells are found in the medulla (Fig. 2). The close anatomic colocalization of the cortical and medullary cells has been suggested to be a prerequisite for paracrine interactions.

BLOOD SUPPLY

Relative to its small size, the adrenal gland is one of the most extensively vascularized organs in the body, with an estimated flow rate of 5 ml per minute. Each gland may be supplied by as many as 50 arterial branches, or arterioles, that arise directly from the aorta, the renal arteries, and the inferior phrenic arteries. The subcapsular arteriolar plexus receives this blood supply and distributes it via two types of vessels. Through the sinusoids, both the adrenal cortex and medulla are supplied, and through the medullary arteries there is a direct blood supply to the medulla. Blood converges at the corticomedullary junction, and through the

Figure 3 Adrenocortical endothelial cells (arrow) immunostained for CD31.

central adrenal vein it is drained directly or indirectly (via the renal vein) into the inferior vena cava (Fig. 3).

INNERVATION

The adrenal cortex receives extensive afferent innervation, with evidence of direct contact between nerve terminals and cortical cells. A possible efferent innervation has been reported, with the presence of baroreceptors and chemoreceptors in the adrenal cortex.

Adrenal innervation influences compensatory adrenal hypertrophy and has been implicated in the regulation of the diurnal variation of cortisol secretion. Moreover, splanchnic nerve activation has been demonstrated to regulate adrenal steroid release (Fig. 4).

Figure 4 Nerve cells and fibers (arrow) silver stained.

Figure 5 Lymphocytes (arrows) immunostained for CD45.

IMMUNE CELLS

Macrophages are found within the adrenal cortex. Not only do they possess the ability to act as phagocytic cells but also they are able to produce and secrete a variety of different compounds, such as cytokines [interleukin-1 (IL-1), IL-6, and tumor necrosis factor- α] and neuropeptides (VIP), that influence adrenocortical function. It has been demonstrated that lymphocytes infiltrate the adrenal cortex and have the ability to produce ACTH-like substances (Fig. 5). In addition, a cytokine-independent cell-cell-mediated regulation of adrenal androgen release has been demonstrated.

Adrenal Cortex, Development

Michel Grino

Université de la Méditerranée, Marseille, France

Glossary

embryogenesis Differentiation of the fertilized ovum during the period of most rapid development, i.e., after the long axis appears until all major structures are represented.

nuclear receptor Ligand-inducible transcription factor that specifically regulates the expression of target genes involved in metabolism, development, and reproduction.

pregnancy or gestation The condition of having a developing embryo or fetus in the body. Duration of pregnancy is 266 days in women, 184 days in baboons, 165 days in rhesus monkeys, 145–150 days in sheep, 21 days in rats, and 18.5 days in mice.

steroid hormones Lipophilic molecules, having a C₁₇ ring as the basis of their chemical structure, that freely cross the cell membrane and interact with nuclear receptors.

transcription factor Protein that directly affects the initiation of transcription of specific genes.

Maturation of the hypothalamic–pituitary–adrenal (HPA) axis, which is characterized by increased activity during late gestation, is essential for the development of the fetus and plays a critical role in preparing for its transition to extrauterine life. The fetal adrenal cortex synthesizes and secretes androgens and glucocorticoids. In primates, androgens are necessary for placental conversion to estradiol, a hormone that is crucial for the maintenance of pregnancy, the maturation of the fetal and maternal tissues, and immunosuppression, leading to implantation of the placenta and the fetus. Glucocorticoids are essential for the maturation of brain, lung, liver, gut, kidney, and the adrenal itself. In some species, a surge in fetal glucocorticoid secretion has been suggested as being integral to the cascade of events leading to the onset of parturition. However, premature or abnormal exposure of fetuses or newborns to high levels of glucocorticoids permanently programs the HPA axis, leading to an increased prevalence of metabolic and cardiovascular disease. This article details both morphological and functional aspects of adrenal cortex development in several types of

mammals, including primates, ruminants, and rodents. In particular, the role of nuclear receptors and transcription factors in the regulation of adrenocortical organogenesis and steroidogenesis is examined.

EMBRYOGENESIS, DEVELOPMENT AND GROWTH

Figure 1 depicts the major milestones of adrenal cortex development in primates, sheep, and rodents.

In Primates

Human adrenal development begins at approximately the fourth week of gestation and continues into adult life. Adrenocortical cells derive from a single cell lineage that originates in the celomic epithelium in the notch between the primitive urogenital ridge and the dorsal mesentery. These cells are also the origin of gonadal and kidney structures. Five landmark phases have been described:

- Condensation of the celomic epithelium (3–4 weeks of gestation).
- Proliferation and migration of celomic epithelial cells (weeks 4–6) that stream medially and cranially, accumulating at the cranial end of the mesonephros, forming the adrenal blastema.
- Morphological differentiation of fetal adrenal cortical cells into two distinct zones (weeks 8–10): the fetal zone and the definitive zone. The fetal zone is an inner cluster of large, eosinophilic cells and represents the largest part (80–90%) of the adrenal cortex. The definitive zone is a thin outer band of small basophilic cells, densely packed, showing structural characteristics of proliferative cells that appear to function as a reservoir of progenitor cells that may populate the remainder of the gland. A third zone, located between the fetal and definitive zones, has been called the transitional zone. By week 30 of gestation, the definitive and transitional zones resemble the adult zona glomerulosa and the zona fasciculata,

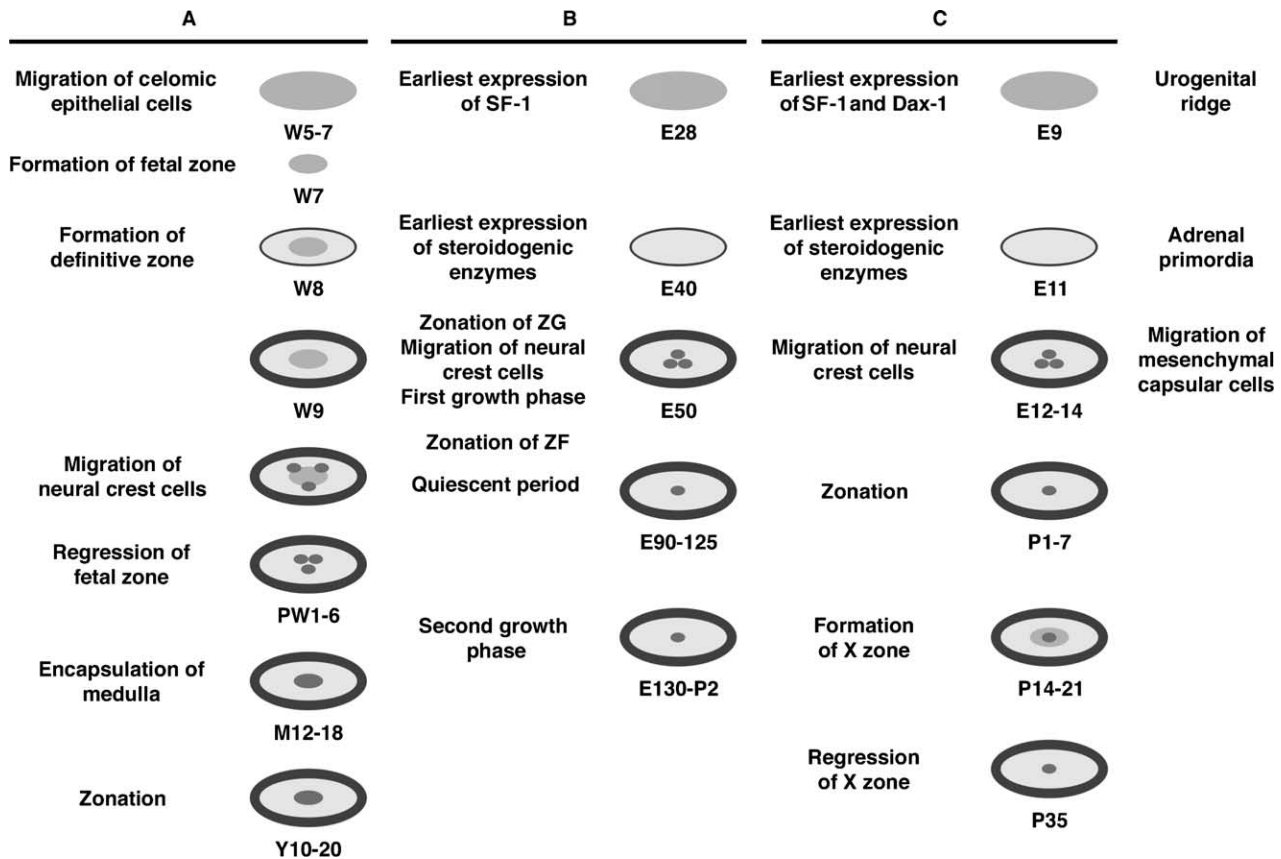

Figure 1 The adrenocortical development cascade in human (A), sheep (B), and mouse (C), showing progression from the urogenital ridge to final zonation. W, week of gestation; PW, postnatal week; M, month; Y, year; E, day of gestation; P, postnatal day; ZG, zona glomerulosa; ZF, zona fasciculata. Adapted from *Trends in Endocrinology and Metabolism* 13, Keegan, C. E., and Hammer, G. D. Recent insights into organogenesis of the adrenal cortex, pp. 200–208, copyright 2002, with permission from Elsevier.

respectively. A period of rapid growth begins at approximately week 10 and continues to term. The fetal zone grows by hypertrophy and limited proliferation, whereas growth in the definitive zone occurs mainly by hyperplasia. Several lines of morphological evidence indicate that the human fetal adrenal gland is a dynamic organ, in which proliferating cells located at the periphery migrate, differentiate, and finally undergo senescence in the central part of the gland.

- Decline and disappearance of the fetal zone (first 3 postnatal months); by this period, the primate adrenal cortex remodeling involves apoptosis of the fetal zone and expansion of the preexisting zona glomerulosa and zona fasciculata. Following the involution of the fetal zone, chromaffin elements, derived from the fetal ectoderm, begin to cluster around the central vein. The medulla acquires an adult-like pattern by 12–18 months.

- Establishment and stabilization of the adult zonal pattern (10–20 years of age); this leads to individualization of the three distinct cell layers: the outer zona glomerulosa, the central zona fasciculata, and the inner zona reticularis.

In Sheep

In the ovine fetus, the adrenal gland can be identified as early as embryonic day (E) 28. Its development occurs during three phases, reflecting the interactions of the cellular kinetic phenomena of hyperplasia and hypertrophy:

- Establishment of functional zonation (E50–E90): this first growth phase is characterized by the separation of the medullary and cortical portions and the presence of a well-defined zona glomerulosa at

approximately E50 and zona fasciculata at approximately E90. During this period, the zona fasciculata grows mainly by hyperplasia.

- Quiescence and reactivation (E90–E125): during this period, adrenal growth and adrenal cell division occur at the lowest rate compared to any other time in gestation.

- Structural and functional maturation [E130 to postnatal day 2 (P2)]: this second growth phase is characterized by an increase in the rate of cell growth and cell division of the zona fasciculata, with the rate of increase in the volume of steroidogenic cells becoming greater than at any other stage. Cellular hypertrophy precedes cellular hyperplasia. The zona reticularis does not become apparent before 1 month of life.

In Rodents

In mice, the adrenal gland starts to develop on E11 from the celomic epithelium, when the anlage of the adrenal cortex is formed. On E12, the cortical cells are found close to the adrenal medulla sympathoblasts. The capsule and the cortical capillaries have completed their development by E15, when the adrenal gland has become a morphologically distinct structure. The individualization of the different layers of the adrenal cortex is nearly completed by birth. The

mouse adrenal possesses a transient developmental zone between the cortical zones and the adrenal medulla: the X zone, which becomes histologically distinct at P10–P14 and enlarges until P21. The X zone subsequently degenerates. The function of the rodent X zone remains unclear.

ONTOGENY OF STEROID BIOSYNTHESIS

The adrenals synthesize several classes of steroids: androgens, glucocorticoids, and mineralocorticoids. The major human adrenal steroidogenic pathways are summarized in Fig. 2. Schematically, the process of adrenal steroidogenesis has two major components. The first is quantitative; i.e., it regulates how much steroid can be made at a given moment. The second is qualitative; i.e. it regulates which particular steroid is made.

- First step: Conversion of cholesterol to pregnenolone. This step involves the delivery of the substrate cholesterol to the inner mitochondrial membrane, driven by steroid acute regulatory protein (StAR), and the conversion of cholesterol to pregnenolone, catalyzed by P450 steroid chain cleavage (P450ssc), adrenodoxin, and adrenodoxin reductase.

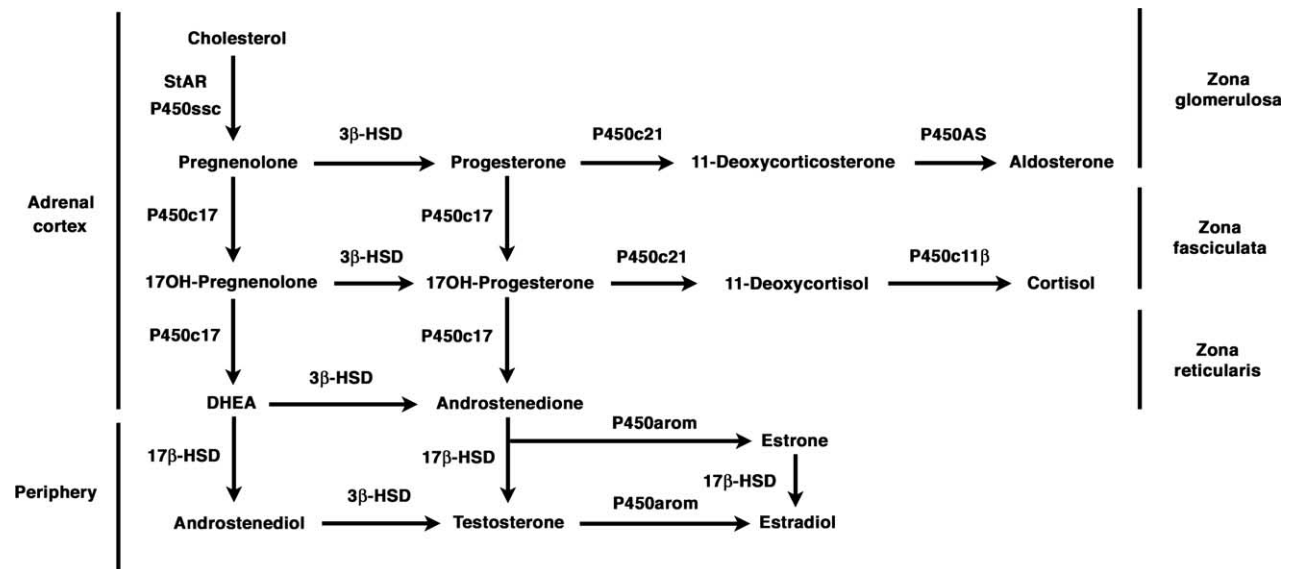

Figure 2 Schematic view of human adult adrenal and peripheral steroidogenic pathways. StAR, steroid acute regulatory protein; P450ssc, side-chain cleavage enzyme; P450c17, enzyme complex having 17 α -hydroxylase and 17,20-lyase activities; 17 β -HSD, 17 β -hydroxysteroid dehydrogenase; 3 β -HSD, 3 β -hydroxysteroid dehydrogenase; P450c21, 21-hydroxylase; P450AS, aldosterone synthase (contains 11 β -hydroxylase, 18-hydroxylase, and 18 β -hydroxysteroid dehydrogenase activities); P450c11 β , 11 β -hydroxylase; P450arom, aromatase.

Table I Localization and Relative Expression of the Enzymes Involved in Fetal Adrenal Steroid Biosynthesis

| Human | < Week 25 | | | > Week 25 | | |
|----------------|--------------|-------|-----|-----------|------|-----|
| | DZ | TZ | FZ | DZ | TZ | FZ |
| P450ssc | + | + | + | + | + | + |
| 3 β -HSD | - | - | - | ++ | ++ | - |
| P450c17 | - | +++ | ++ | - | +++ | ++ |

| P45011 β | ND | + | ++ | + | ++ | +++ |

Note. E, day of gestation; P, postnatal day; DZ, definitive zone; TZ, transitional zone; FZ, fetal zone; P450ssc, side-chain cleavage enzyme; 3 β -HSD, 3 β -hydroxysteroid dehydrogenase; P450c17, enzyme complex having 17 α -hydroxylase and 17,20-lyase activities; P450c21, 21-hydroxylase; P450c11 β , 11 β -hydroxylase; ND, not determined.

- Second step: Transformation of pregnenolone to active hormones. The coordinate regulation of several enzymes will direct the transformation of pregnenolone toward a given class of steroid hormone—androgens, glucocorticoids, and mineralocorticoids. During adrenal cortex development, the synthesis of these various steroids is not temporally coordinated, is zone-dependent, and is species-specific. [Table I](#) summarizes the localization and relative expression of the enzymes involved in fetal adrenal steroid biosynthesis.

Androgens

The conversion of cholesterol to pregnenolone is mature in the fetal zone during early pregnancy in humans. High levels of 17 α -hydroxylase/17,20-lyase (P450c17) are present in the fetal zone very early (as soon as 44 days postconception). As a consequence,

the fetal zone produces dihydroepiandrosterone (DHEA), the bulk of which appears to be secreted as a 3-sulfoconjugate DHEA sulfate (DHEAS) that is formed by the action of DHEA sulfotransferase and the cofactor 3'-phosphoadenosine 5'-phosphosulfonate. DHEAS is used by the placenta for conversion to estrogens. By term, the fetal zone produces approximately 200 mg DHEA per day. In fetal sheep and rodents, the adrenals do not synthesize DHEA.

Glucocorticoids

In Primates

Assays of steroids in cord blood have suggested that human fetus can synthesize cortisol as early as the 10th week of gestation. This hypothesis is supported by clinical and biological observations in patients with congenital adrenal hyperplasia (CAH) caused by deficiency of 21-hydroxylase (P450c21), 3 β -hydroxysteroid dehydrogenase (3 β -HSD), or 11 β -hydroxylase (P450c11 β). Patients with this disorder have impaired glucocorticoid production with a compensatory increase in pituitary adrenocorticotrophic hormone (ACTH) secretion and subsequent stimulation of DHEA synthesis. Interestingly, female infants with CAH have ambiguous external genital development, indicating that, in unaffected female fetuses, cortisol is synthesized by the adrenal by the time of external genital differentiation, a process that is sensitive to androgens and begins at approximately week 10. These observations do not necessarily indicate that the week 10 fetal adrenal is able to synthesize cortisol *de novo* from cholesterol. Although StAR and P450ssc immunoreactivities are expressed in the cytoplasm of human fetal adrenocortical parenchymal cells of the transitional zone as soon as week 14, in early gestation the fetal adrenal can synthesize cortisol using placental progesterone as substrate, since high levels of progesterone are present in the fetal circulation. P450c21 and P450c11 β immunoreactivities have been detected in the transitional zone of human fetal adrenals as soon as weeks 13–14 and P450c17 mRNA is present in the transitional zone of week 22 human fetal adrenal. This is consistent with the observation that progesterone infusion into human fetuses between weeks 16 and 18 results in cortisol synthesis. As a consequence, the key enzyme for the production of cortisol *de novo* from cholesterol during early gestation is 3 β -HSD. It has been reported that 3 β -HSD immunoreactivity and mRNA could not be detected in human adrenals before weeks 22–24, suggesting that the transitional zone of human fetus adrenals is

able to synthesize *de novo* cortisol beginning at week 24. Similarly, in nonhuman primates, 3 β -HSD mRNA is undetectable during early gestation, starts to increase at midgestation, and is further stimulated at late gestation. 3 β -HSD protein expression in the transitional zone of adrenals from fetal rhesus monkeys follows a comparable developmental pattern.

In Sheep

Adrenal cortisol synthesis and secretion in ovine fetuses follow a triphasic pattern. P450ssc and P450c17 are expressed at a relatively high level in the whole adrenal cortex as early as E40–E60. In the zona fasciculata, the levels of P450ssc and P450c17 decrease between E90 and E120 before showing a further elevation between E130 and P2. At E90, P450c17 expression is confined to the zona fasciculata. 3 β -HSD is present at uniformly moderate levels in the zona fasciculata at mid and late gestation. P450c21 mRNA shows a steady increase throughout gestation. Intense P450c11 β immunoreactivity is consistently detected throughout the adrenal cortex as early as E90 and remains constant until birth. Cortisol is secreted from adrenal cells from E50 fetuses. Basal cortisol secretion decreases at E100 and increases subsequently, between E130 and E145.

In Rodents

Adult mouse and rat adrenal cortex, which lack P450c17, produce mainly corticosterone. P450ssc and adrenodoxin are expressed at midgestation in the rodent adrenal cortex (E15–E16). 3 β -HSD mRNA and protein have been detected in the fetal rat adrenal as early as E16; their labeling in the reticular and fascicular zones is at a higher level than in the glomerular zone at E18. P450c21 and P450c11 β immunoreactivity and mRNA are present in the fetal rat adrenal at E18. P450c17 mRNA and activity are detectable in the adrenals of mouse fetuses at E12.5, increase in abundance from E12.5 to E14.5, and are then lost between E16.5 and E18.5, suggesting that the fetal mouse adrenal is able to synthesize cortisol during late gestation. Although the ontogeny of StAR expression in the rodent embryonic adrenal remains to be elucidated, it is known that fetal rat adrenals synthesize and secrete corticosterone as early as E13. The corticosterone contents of the fetal rat adrenal are high from E16 to E20 and plasma corticosterone concentrations rise progressively from E16 to E19. This phenomenon occurs following activation of pituitary ACTH and the hypothalamic neuropeptides that control ACTH synthesis and secretion.

During the first 10 days after birth, there is a marked decrease in adrenal corticosterone contents

and both basal and stress-induced circulating corticosterone levels. This period has been called the “stress hyporesponsive period” (SHRP). These low-circulating glucocorticoid levels are believed to be essential for normal brain and behavioral development. A decrease in the steroidogenic capacity of the newborn adrenal cortex may account, at least in part, for the SHRP. It has been demonstrated that StAR mRNA and protein are highly expressed in the adrenals at birth, decrease subsequently until P14, and increase thereafter. The level of expression of P450ssc is comparable to that of P1 in adults. At birth, adrenal 3 β -HSD activity is low at P1, increases at P10, and remains stable until adulthood. P450c21 activity is low (approximately half of the adult values) on P1 and P10. P450c11 β immunoreactivity has been detected in the adrenals of newborn rats and did not change during neonatal development. In P7 rats, P450c11 β mRNA is present at high levels only in the zonae fasciculata and reticularis.

Mineralocorticoids

In Primates

Regarding the ontogeny of aldosterone secretion, assays of steroids in cord blood have suggested that human fetus can synthesize aldosterone as early as weeks 16–20. However, *in vitro* experiments have demonstrated that at midgestation human fetal adrenal tissues do not produce detectable levels of aldosterone, under basal or stimulated conditions. The primary steps in aldosterone synthesis, i.e., those driven by StAR, P450ssc, 3 β -HSD, and p450c21, are mature in the definitive zone in human fetal adrenals at the end of the midgestation period. However, in human fetal adrenals obtained from second-trimester abortuses, aldosterone synthase (P450AS) immunoreactivity is absent in the definitive zone and P450AS mRNA is weakly detectable in the whole cortical zone. Similarly, P450AS immunoreactivity is absent in the definitive zone of fetal rhesus monkey adrenal until near term. Activation of the late gestation fetal rhesus monkey HPA axis (obtained after treatment with metyrapone, a compound that inhibits P450c11 β) was able to induce P450AS expression. Taken together, these data indicate that in the primate fetal adrenal gland, the definitive zone has the capacity to synthesize aldosterone, but not until term.

In Sheep

In the fetal sheep, levels of aldosterone synthesis and secretion are very low until the final part of gestation.

Although P450AS is expressed as early as E90 in the fetal zona glomerulosa, there is weak 3 β -HSD staining until term.

In Rodents

In rats, P450AS immunoreactivity is detected in E16 adrenals, in small clusters of cells, dispersed throughout the gland. By E18–E19, the number of P450AS-labeled cells increases and these cells become localized in the outer cortex. P1 adrenals have a pattern of P450AS staining comparable to that of the adult gland. In P7, rats, P450AS mRNA is confined to the subcapsular zona glomerulosa. Aldosterone content in fetal adrenal homogenates increases between E17 and P1 and remains stable thereafter.

ROLE OF NUCLEAR RECEPTORS AND TRANSCRIPTION FACTORS

The complex cascade of the development and differentiation of the adrenal cortex, from the formation of the urogenital ridge to the zonation of the fetal adrenal, involves several nuclear receptors and transcription factors (Table II).

WT1 and WNT4

Two genes are crucial for the development of the urogenital ridge: WT1 (Wilm's tumor suppressor gene 1), which encodes a protein having many characteristics of a transcription factor, and WNT4 (wingless-related mouse mammary tumor virus integration site 4), a member of the WNT family of developmentally regulated signaling molecules. WT1 is developmentally one of the earliest known genes that specifies kidney, gonadal, and adrenal cell lineages. Mice fetuses knocked out for *Wt1* and rescued with a YAC (yeast artificial chromosome) construct spanning the *Wt1* locus have adrenal-like structures that are greatly reduced in size and express lower levels of P450ssc mRNA than wild-type mice. WNT4 is involved in the development of the kidney, pituitary gland, female reproductive system, and mammary gland. Wnt4 is expressed next to the anterior site of the mouse mesonephros on E11.5 and in the developing adrenal cortex from E12.5 onward. Adrenals of Wnt4 knockout mice are morphologically comparable to those of wild-type animals. However, Wnt4 knockout animals have reduced adrenal P450c21 and P450AS mRNA concentrations and decreased aldosterone production.

Table II Transcription Factors and Nuclear Receptors Involved in Adrenal Differentiation and Steroidogenesis

| Transcription factor or nuclear receptor | First detected on | Phenotype of rodent KO | Genes that are regulated in adrenal cells |
|--|--------------------------|---|---|
| WT1 | Mouse: E9 | Lethal: lacks adrenals, kidneys, and gonads | DAX-1 |
| Wnt4 | Mouse: E11.5; human: E33 | Abnormal kidney and adrenal development | P450c21 P450AS |
| SF-1 | Mouse: E11; human: E33 | Lethal: lacks adrenals and gonads | StAR P450ssc 3 β -HSD P450c17 P450c21 P450AS P450c11 β ACTH-R DAX-1 |
| DAX-1 | Mouse: E10.5 | Lack of X zone regression | StAR P450c17 P450c21 ACTH-R |

Note. WT-1, Wilm's tumor suppressor gene 1; Wnt4, wingless-related mouse mammary tumor virus integration site 4; SF-1, steroidogenic factor-1; DAX-1, dosage-sensitive sex reversal adrenal hypoplasia congenita critical region on the X chromosome, gene 1; E, day of gestation; StAR, steroid acute regulatory protein; P450ssc, side-chain cleavage enzyme; P450c17, enzyme complex having 17 α -hydrolase and 17,20-lyase activities; 17 β -HSD, 17 β -hydroxysteroid dehydrogenase; 3 β -HSD, 3 β -hydroxysteroid dehydrogenase; P450c21, 21-hydroxylase; P450AS, aldosterone synthase; P450c11 β , 11 β -hydroxylase; ACTH-R, adrenocorticotropic hormone receptor.

SF-1, DAX-1, and GATA Proteins

Several transcription factors, such as steroidogenic factor-1 (SF-1), dosage-sensitive sex-reversal adrenal hypoplasia congenita critical region on the X chromosome, gene 1 (DAX-1), and GATA proteins, play major roles in the development of the adrenal primordium, its functional zonation, and the regulation of fetal adrenal steroidogenic capacities.

SF-1

SF-1, also called Ad4BP or NR5A1, belongs to the orphan receptor class of nuclear receptors. It has been proposed that SF-1 acts through recruitment of cofactors, including both coactivators (CREB-binding protein, WT1, and nuclear receptor coactivator 1) and corepressors (nuclear receptor corepressor, DEAD/H box polypeptide 20, COP9 constitutive photomorphogenic subunit 2, nuclear receptor-interacting protein 1, and DAX-1). In mouse, Sf-1 mRNA was detected in the adrenal primordium from E11. From E14–E14.5 onward, Sf-1 mRNA is restricted to the steroidogenic cells in the cortex. In humans, SF-1 was expressed as early as E33 in the presumptive adrenal primordium. Newborn Sf-1 knockout mice are devoid of adrenals and die from adrenocortical insufficiency shortly after birth. However, Sf-1 heterozygous mice (SF-1^{+/-}) are viable but show adrenal disorganization (reduced adrenal size and hypoplastic zona fasciculata and adrenal medulla), altered adrenal gene expression (increased StAR mRNA and decreased ACTH receptor mRNA), and impaired basal and stress-induced glucocorticoid secretion. Studies of SF-1 gene mutations in humans demonstrated that SF-1 regulates adrenal development in a dose-dependent manner. A number of studies have demonstrated that SF-1 acts a global regulator of the proteins involved in adrenal steroidogenesis (StAR, P450_{ssc}, 3β-HSD, P450c21, P450AS, P45011β, and P450c17). In addition, Sf-1 regulates adrenal ACTH sensitivity through a cell-specific modulation of both constitutive and cyclic AMP-induced expression of the ACTH receptor gene. In the late-gestation ovine fetus, Sf-1 mRNA is present in adrenal extracts; its expression is positively regulated by a pituitary-dependent factor, which is not ACTH.

DAX-1

DAX-1 is an orphan nuclear receptor that regulates both adrenal development and functional zonation. Mutations in the DAX-1 gene are responsible for X-linked adrenal hypoplasia congenita, an inherited disorder in humans that is characterized by hypoplasia

of the fetal adrenal glands with absence of the definitive zone and persistence of the fetal zone. DAX-1 has been postulated to bind to hairpin loops of the StAR promoter and/or to function as an RNA-binding protein. In human fetuses, DAX-1 is expressed in the adrenal primordium as early as E33. In mouse, it has been shown that Dax-1 is colocalized with Sf-1 in the developing adrenal and that Sf-1 expression precedes or coincides with expression of Dax-1, suggesting that these two molecules could cooperate in regulating adrenal development. *In vitro*, Dax-1 inhibited Sf-1-induced stimulation of transcription of the adrenal promoter of StAR, P450c17, Dax-1 itself, possibly through interactions with Sf-1, and transcriptional corepressors such as NcoR and Alien, whereas Sf-1 stimulated expression of the Dax-1 promoter. *In vivo*, male mice with a single Dax-1-deleted allele (Dax-1^{-/-}) have normal zona glomerulosa, but the zona fasciculata is less well developed and shows decreased staining for 3β-HSD and the X zone fails to regress. Dax-1^{-/-} animals have increased stress-induced corticosterone secretion and enhanced adrenal responsiveness to exogenous ACTH stimulation, most probably following increased adrenal P450c21 and ACTH receptor expression. Dax-1^{-/-} animals have normal expression of Sf-1 and expression of Dax-1 is maintained in Sf-1^{+/-} mice. The absence of Dax-1 partially reverses adrenal growth defects in Sf-1^{+/-} mice. However, the precise mechanisms governing the interplay between Sf-1 and Dax-1 in regulating adrenal development and steroidogenesis are not known.

GATA Proteins

GATA proteins are transcription factors that bind to the consensus sequence (A/T)GATA(A/G) in the promoter and enhancer regions of their target genes. GATA-4 is present in human adrenocortical carcinoma and in a transgenic mouse model developing adrenocortical tumors. GATA-4 and GATA-6 are detectable from E14 and week 19 onward in the mouse and human adrenal cortex, respectively. After birth, GATA-4 expression decreases, whereas GATA-6 continues to be expressed. Studies in chimeric mouse embryos demonstrated that GATA-4 is not essential for early adrenocortical differentiation. The exact role of GATA-6 in adrenal development remains to be determined.

Glossary

adrenocorticotropic hormone or corticotropin (ACTH) Synthesized as part of a 241-amino acid precursor, proopiomelanocortin. Usually, ACTH derives from the pituitary gland to stimulate the adrenal glands through the melanocortin-2 receptor (rarely, ACTH is produced ectopically, i.e., in ectopic Cushing's syndrome).

corticotropin-releasing hormone (CRH) Hypothalamic 41-amino acid peptide that usually stimulates the pituitary to release ACTH.

hypothalamic–pituitary–adrenal (HPA) axis Hypothalamic-releasing factors including CRH are influenced by central nervous system afferents. For instance, stress can trigger CRH release. The major secretagogue of CRH is ACTH, which subsequently stimulates the adrenals to produce and release cortisol. Cortisol, on the other hand, can inhibit further release of CRH and ACTH in a negative feedback loop.

steroids Hormones produced by the adrenal gland. Members of a large family of compounds that are derived from the cyclopentanperhydrophenanthrene ring structure that consists of three cyclohexane rings and one cyclopentane ring. The nomenclature denotes rings by a letter and the individual carbon atoms by a number. Gonane is the unsaturated 17-carbon ring structure. Estranes are steroids with 18 carbons (C18 steroids) by adding a methyl group at C13. Androstane is a C19 steroid with two methyl groups. Pregnane is a C21 steroid with methyl and ethyl groups. The ending-ene denotes a double bond of the parent compound.

The *Tabulae Anatomicae* mention Bartholomeo Eustachius, who apparently first described the anatomy of the adrenal glands in 1563. A central physiologic role for the adrenals was presented in 1849 by Thomas Addison, and today Addison's disease refers to adrenal insufficiency, a life-threatening condition. To better understand pathophysiologic states of the adrenal glands, one must recall their normal anatomy and physiology. The adrenal glands are divided into cortex and medulla. The adrenal cortex is composed of three zones—the glomerulosa, fasciculata, and reticularis. The largest and

most important zone is the fasciculata, where glucocorticoids including cortisol are produced. Extracellular volume status is influenced by aldosterone, the hormone of the zona glomerulosa. Androgens such as dehydroepiandrosterone are produced by the zona reticularis, which starts to grow at approximately age 4, shortly before adrenarche occurs. Corticotropin, usually coming from the pituitary, is the principal stimulus for cortisol secretion and is released under stress and other stimuli through hypothalamic corticotropin-releasing hormone (CRH) secretion. Corticotropin can also stimulate the zona glomerulosa (to a minor extent) and reticularis to secrete aldosterone and adrenal androgens. A feedback loop exists between the hypothalamus (H), pituitary (P), and adrenal gland (A)—the HPA axis. High peripheral cortisol levels inhibit further release of CRH and corticotropin. At the extreme (e.g., in conditions of supraphysiologic exogenous glucocorticoid administration), the secretion of hypothalamic CRH and pituitary corticotropin becomes severely suppressed, with subsequent atrophy of the adrenal glands due to the lacking stimulus corticotropin. The adrenal medulla forms postnatally and exerts effects on the adrenal cortex and vice versa. Adrenomedullary chromaffin cells are intermingled with the adrenal cortex, facilitating an interaction between the two.

FETAL ADRENAL GLAND

Fetal Adrenal Steroidogenesis

The fetal adrenal cortex plays a critical role in regulating intrauterine homeostasis and the maturation of fetal organ systems that are necessary for extrauterine life. The important mediators for these functions are steroid hormones from the fetal adrenal. Throughout gestation and postnatally, the fetal adrenal gland undergoes morphological and functional changes during its transformation to the adult adrenal gland. The progenitor cells of the adrenal cortex stem from a cell lineage that also leads to steroid-secreting cells of the gonads. By week 8 of gestation, the adrenal cortex-forming progenitor cells build an inner cluster (the fetal zone) consisting of large eosinophilic steroid-secreting cells that express high levels of steroid 17 α -hydroxylase (CYP17) and an outer zone (the definitive zone) consisting of cells that do not express

CYP17. Between the fetal and definitive zone lies the transitional zone, which is composed of cells similar to those of the zona fasciculata of the adult adrenal gland. At gestational week 8, chromaffin cells enter the rudimentary adrenal gland and remain there as discrete islands until day 8 postnatally, before they form a rudimentary adrenal medulla. During gestation, the fetal zone represents 85% of the cortical volume and produces large amounts of dehydroepiandrosterone (DHEA) sulfate, a hormone that serves as a precursor for other androgens synthesized in the periphery. Before birth, DHEAS is used by the placenta to synthesize estrogen. Placental estrogen, on the other hand, supports the fetal adrenal to synthesize cortisol. Several endocrine, paracrine, and autocrine factors influence the steroidogenesis of the fetal adrenal cortex. Within the first postnatal year, the fetal zone degenerates. During the third trimester, aldosterone production starts by the zona glomerulosa, derived from the outer zone of the fetal adrenal cortex (without CYP17). A transitional area between the inner and outer zones gives rise to the zonae fasciculata and reticularis, which secrete glucocorticoids and DHEA sulfate under stimulation and control by corticotropin. Certain transcription factors (e.g., steroidogenic factor 1, DAX1, and WT1) are essential in adrenal development. Adrenal dys- or agenesis with subsequent adrenal insufficiency and death can result from nonfunction of these factors, for instance, by mutations in the steroidogenic factor 1.

Growth Factors

During the first trimester of pregnancy, human chorionic gonadotropin (HCG) regulates the growth of the fetal adrenal. Adrenocorticotrophic hormone (ACTH) is critical for growth, steroidogenesis, and differentiation of the fetal adrenal gland and becomes the main force for further growth after the fifth month of gestation. ACTH deficiency leads to increased apoptosis and subsequent atrophy of the adrenal glands, whereas ACTH excess (e.g., in Cushing's syndrome or congenital adrenal hyperplasia) can cause hyperplastic adrenal glands. In addition to HCG, ACTH, and its receptor ACTHR, local growth factors are important for steroidogenesis, growth, and development of the adrenal gland.

Insulin-like growth factors 1 and 2 (IGF-1 and IGF-2), their receptors, and binding proteins are all expressed in the fetal adrenal. IGF-1 not only amplifies the effect of ACTH on the adrenal but also enhances steroid production of the adrenal gland by increasing

the activities of 17α , 21-, and 11β -hydroxylase. Similarly, IGF-2 promotes ACTH action. In addition, IGF-2 helps the fetal adrenal to synthesize cortisol and androgen by regulating the enzymes p450scc, p450c17, and 3β -hydroxysteroid dehydrogenase.

Basic fibroblast growth factor is a mitogenic protein and is more effective (stimulating proliferation) on adrenal cells of the definitive zone than those of the fetal zone. Epidermal growth factor (EGF) and transforming growth factor- α (TGF- α) are growth factors with sequence homology that both activate the EGF receptor. This may lead to hypertrophy of the fetal adrenal. Although EGF stimulates hypothalamic corticotropin-releasing hormone (CRH) release, it does not cause subsequent ACTH secretion from the pituitary. The TGF- β family of growth factors, including activin, inhibin, and TGF- β_1 , are paracrine/autocrine regulators of growth and steroidogenesis in the fetal adrenal cortex. Activin increases ACTH-stimulated cortisol production but not DHEAS production in fetal zone cells. In the adult adrenal cortex, activin has no effect on growth or steroidogenesis. In fact, activin may lead to apoptosis and involution of the fetal adrenal cortex postnatally. TGF- β_1 appears to decrease fetal and definitive zone cell proliferation and steroidogenesis.

Nuclear Receptors

Steroidogenic factor 1 (SF-1), DAX-1, and the estrogen receptor (ER) belong to the nuclear receptor superfamily. Members of this family are transcription factors that are important for regulating expression of genes involved in cellular growth control and differentiation. SF-1 is classified as an orphan receptor because its ligand is unknown. The human cDNA sequence of SF-1 is highly homologous (>95%) to murine and bovine sequences. Human adrenal cortex, ovaries, testes, and spleen show high SF-1 mRNA expression. In human placenta, SF-1 is not or only minimally expressed. SF-1 plays an essential role in the organogenesis of the fetal adrenal gland and also in regulating genes that code for steroidogenic enzymes. SF-1 stimulates the promoter activities of genes encoding steroidogenic acute regulatory (StAR) protein, the scavenger receptor-type class BI (SR-BI), and the ACTH receptor. StAR protein is critical in the translocation process of cholesterol from the outer to the inner mitochondrial membrane. In contrast to the adult adrenal gland, the fetal adrenal uses low-density lipoprotein (LDL) rather than high-density lipoprotein cholesterol as the main source for steroid

biosynthesis. It appears that SR-BI binds to LDL with high affinity. SF-1 influences the constitutive activity of the human ACTH receptor gene promoter and regulates steroid hydroxylase enzymes. In addition, SF-1 regulates the genes coding for the β -subunit of luteinizing hormone, the α -subunit of the glycoprotein hormones, gonadotropin-releasing hormone receptor, prolactin receptor, oxytocin, Mullerian inhibiting substance, and aromatase. Furthermore, SF-1 interacts with other proteins and cofactors.

Gene deletions at Xp21/22, where the DAX-1 gene is located, may lead to X-linked adrenal hypoplasia congenita, glycerol kinase deficiency, hypogonadotropic hypogonadism, and/or Duchenne's muscular atrophy. DAX-1 (dosage-sensitive sex reversal, adrenal hypoplasia congenita, X-linked) is highly expressed in the fetal and adult adrenal gland, hypothalamus, pituitary, testes, and ovaries. Together with SF-1, it may coregulate steroidogenesis as well as adrenal and gonadal organogenesis. DAX-1 can block steroidogenesis by inhibiting the activity of StAR and the expression of p450scc and 3β -hydroxysteroid dehydrogenase.

Estrogens are important in cell differentiation, growth, and function of various tissues. Estrogen receptors are members of the steroid receptor superfamily

and mediate the action of estrogens. ER β is highly expressed in the fetal adrenal gland, in contrast to ER α . As mentioned previously, estrogen is critical in fetal steroidogenesis and organogenesis.

ADULT ADRENAL CORTEX

Steroid Biosynthesis and Regulation of Cortisol Production

The normal adult human adrenal gland weighs approximately 5 g. Ninety percent of this weight is due to the adrenal cortex, which is composed of three zones (from outside to inside): the zona glomerulosa, the zona fasciculata, and the zona reticularis. The adrenal medulla forms postnatally and is composed of chromaffin cells, some of which may still be intermingled and spread within the adrenal cortex. The adult adrenal cortex produces glucocorticoids, mineralocorticoids, and adrenal androgens (Fig. 1 and Table I). The blood flow in the adrenal gland is centripetal (from outside to inside), which exposes the inner zones and the adrenal medulla to increasing concentrations of adrenal steroids. High cortisol levels in the medulla are needed to induce enzymes for epinephrine biosynthesis. Seventy-five percent

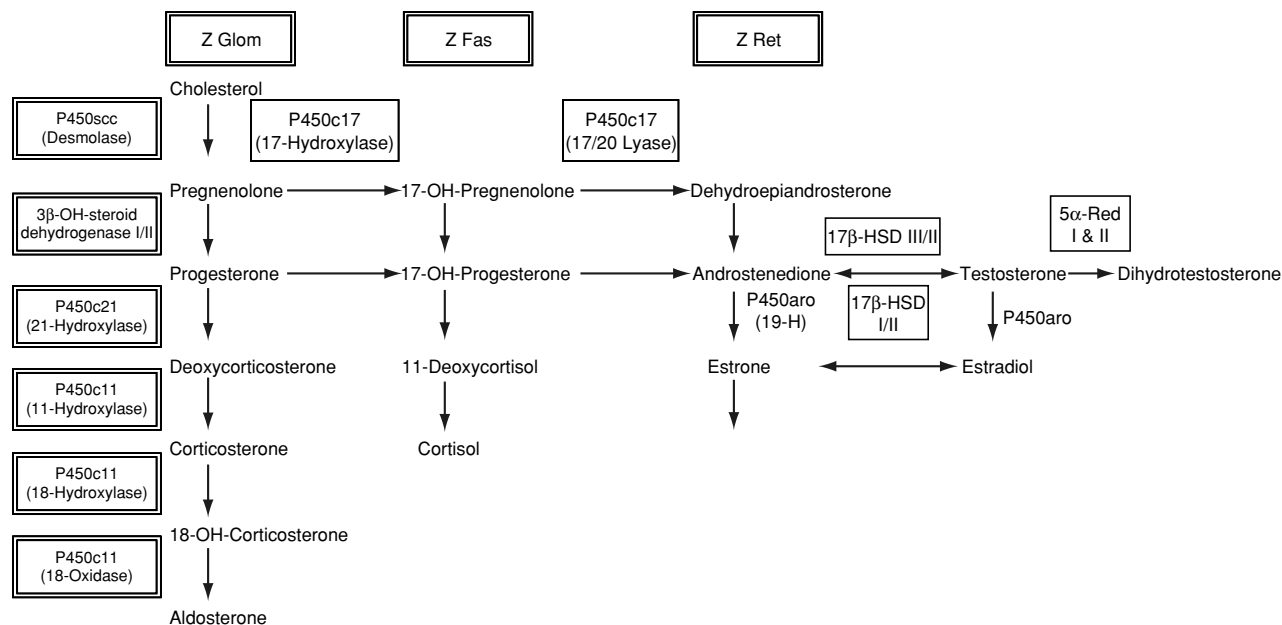

Figure 1 Adrenal steroidogenesis. Z Glom, zona glomerulosa; Z Fas, zona fasciculata; Z Ret, zona reticularis; 19-H = 19-hydroxylase; HSD, hydroxysteroid dehydrogenase; P450aro, aromatase; 5 α -Red, 5 α -reductase. The three adrenal cortex zones Z Glom, Z Fas, and Z Ret are listed above the hormones that are produced in the respective zones. The steroidogenic enzymes on the left, starting with P450scc (desmolase), are listed in order of vertical and horizontal reading—that is, desmolase converts cholesterol to pregnenolone, 3 β -OH-steroid dehydrogenase I/II convert pregnenolone to progesterone, 17-OH-pregnenolone converts progesterone to 17-OH-progesterone, P450c11 converts deoxycorticosterone to 18-OH-corticosterone and 11-deoxycortisol to cortisol, etc.

Table I Key Human Steroidogenic Enzymes and Cofactor Proteins^a

| Protein | Gene | Chromosomal locus | Substrate | Activities |
|---------------------------|----------------|-------------------|---|---|
| StAR | <i>STAR</i> | 8p11.2 | Cholesterol flux within mitochondria | Sterol delivery to P450 _{scc} |
| P450-OR | <i>CPR</i> | 7p15-q35 | Microsomal P450s | Electron transfer |
| Cytochrome b ₅ | <i>CYB5</i> | 18q23 | Aids P450c17 | Augments 17,20-lyase activity |
| Adrenodoxin reductase | <i>ADR</i> | 17q24–25 | Mitochondrial P450s | Electron transfer |
| Adrenodoxin | <i>ADX</i> | 11q22 | Mitochondrial P450s | Electron transfer |

of the adrenal gland weight is due to the zona fasciculata, the largest zone and the one that synthesizes glucocorticoids. The zona fasciculata also produces DHEA and DHEAS, whereas the zona reticularis also produces cortisol. In contrast to the zona fasciculata, the zona reticularis is small and not very involved in adrenal androgen production until adrenarche (approximately 6 years of age). The precursor for glucocorticoid production is cholesterol, which in a first step is converted to pregnenolone in the adrenal cortex. Steroids derive from the cyclopentanoperhydrophenanthrene four-ring hydrocarbon nucleus, a relatively inert structure. Depending on the presence

of several enzymes in the respective adrenal cortex zone, several steroid hormones can then be synthesized. Cytochromes P450 are categorized into two classes: type 1 enzymes that reside in the mitochondria and type 2 enzymes located at the smooth endoplasmic reticulum (Table II).

The secretion and synthesis of cortisol are regulated by the hypothalamic–pituitary–adrenal (HPA) axis. Certain stimuli including stress lead to the release of CRH in the hypothalamus. CRH then stimulates ACTH release from the pituitary (Fig. 2). ACTH binds to ACTH receptors located on adrenocortical cells and stimulates them to release cortisol

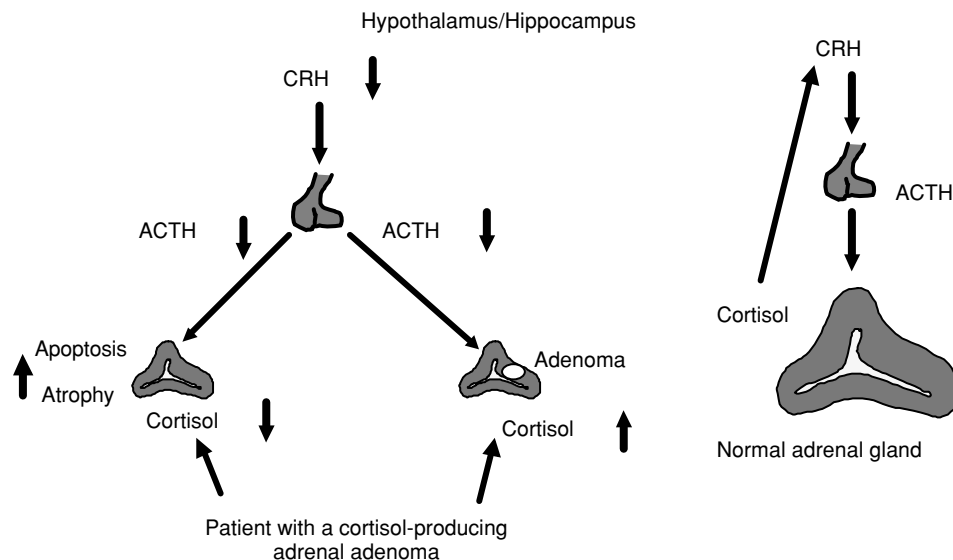

Figure 2 The HPA axis. Modified from Koch and Chrousos (2001).

through cAMP. Cortisol can then increase energy-providing compounds, including glucose, free fatty acids, and free amino acids. As mentioned previously, ACTH is also growth promoting on the adrenal cortex; that is, continuous stimulation by ACTH may cause adrenal hypertrophy, whereas a lack of ACTH may lead to adrenal atrophy. The HPA axis is very sensitive to exogenous glucocorticoid administration, which can easily lead to ACTH suppression through a negative feedback loop on CRH. In normal individuals who are not working in (night) shifts, there is a diurnal variation of cortisol production, with serum cortisol being highest in the morning and lowest at midnight. In patients with Cushing's syndrome (hypercortisolism), these normal physiologic circuits are disturbed (i.e., there is no suppression of

the HPA axis and cortisol production by administration of exogenous glucocorticoids such as dexamethasone). Prolonged (7–48 h) increases in ACTH lead to an increased synthesis of all the steroidogenic enzymes, especially P450_{scc}, as well as an increased uptake of cholesterol from the circulation. Chronic lack of ACTH (e.g., through exogenous glucocorticoid administration) leads to adrenal atrophy. Therefore, the exogenous glucocorticoid has to be tapered to allow the pituitary and adrenal gland to recover in order to synthesize normal levels of cortisol on its own. Depending on the level of suppression, this may take weeks or months.

Biosynthesis and Regulation of Aldosterone Production

Aldosterone, the major human mineralocorticoid, is produced in the zona glomerulosa of the adrenal cortex. Its secretion is stimulated mainly by angiotensin II (and III) through the renin–angiotensin–aldosterone system and, to a lesser extent, by ACTH. Chronic infusion of ACTH stimulates aldosterone secretion for only 24 h. Less potent stimulators of aldosterone secretion are endothelin and serotonin. Also, increases in potassium concentrations stimulate aldosterone production. An increase in serum potassium of 0.1 mmol/liter can elevate plasma aldosterone by 35%. On the other hand, a decrease in serum potassium of 0.3 mmol/liter can reduce plasma aldosterone by 46%. Aldosterone decreases the absorption

Table II Locations of Steroidogenic Proteins

| Endoplasmic reticulum | Cytoplasm | Mitochondria |
|--------------------------------|-------------------|---------------------------------------|
| 11 β -HSD I and II | 3 α -HSD | 3 β -HSD II |
| 5 α -Reductase I and II | 17 β -HSD V | StAR |
| 17 β -HSD I–III | 17 β -HSD I | Adrenodoxin reductase |
| 3 β -HSD II | 3 β -HSD II | P450 _{c11AS} |
| Cytochrome b ₅ | StAR | P450 _{c11β} |
| P450 oxidoreductase | Adrenodoxin | P450 _{scc} |

| P450 _{c21} | | |
| P450 _{c17} | | |

Modified from Auchus and Miller (2001).

of potassium and promotes sodium reabsorption and fluid retention, thereby increasing the extracellular fluid volume. However, after a few days of extracellular fluid expansion by increased aldosterone levels, the individual will be protected from continuous expansion through a so-called “escape” mechanism that denotes attaining a new sodium balance and the formation of a new steady state.

Target tissues of aldosterone, including kidney (distal tubules and cortical collecting ducts), colon, and salivary glands, have mineralocorticoid receptors that bind aldosterone. In the distal nephron, cortisol is a potent agonist at the mineralocorticoid receptor. Among inhibitors of aldosterone secretion are atrial natriuretic peptide (ANP) and dopamine. ANP strongly inhibits stimulated (e.g., low sodium intake) aldosterone secretion, with much less effect on basal (e.g., normal or high sodium intake) activity. Chronic sodium restriction leads to increased activity of aldosterone synthase and a higher content of this enzyme in the zona glomerulosa. The first steps of aldosterone biosynthesis are identical to those of cortisol biosynthesis (Fig. 1). The synthesis of cortisol, however, depends on 17α -hydroxylation of pregnenolone by 17α -hydroxylase (P450c17), which is exclusively expressed in the zona fasciculata. On the other hand, aldosterone synthase is normally expressed only in the zona glomerulosa.

Regulation of Adrenal Androgen Production

At approximately 4 years of age, in both sexes the zona reticularis forms and continues to grow until the mid-20s. After age 40, this zone gradually regresses. Corticotropin and prolactin stimulate adrenal androgen secretion in the fetal adrenal zone. Postnatally, the zona reticularis responds to ACTH, as exemplified in congenital adrenal hyperplasia in which ACTH and androgen hypersecretion can occur. During infancy, only small amounts of androgens are secreted, and it is unknown how adrenarche, the time point at which a slight amount of pubic hair develops, is regulated. Seventy percent of circulating testosterone in women with normal menstrual cycles derives from the conversion of adrenal DHEA. The principal androgens secreted by the adrenals are DHEA, DHEAS, androstenedione, and (minimally) testosterone. DHEAS per se has only weak androgenic effects. Peripheral conversion of the aforementioned precursors leads to more potent androgens, such as testosterone and dihydrotestosterone. Major conversion sites include

the hair follicles, sebaceous glands, external genitalia, and prostate. Peripheral adipose tissue can convert androgens into estrogens by the highly active enzymes aromatase and 17 -ketosteroid reductase. Glucocorticoids stimulate aromatase. Inactivation or degradation of androgens and their metabolites occur at different sites, including the liver and kidneys. Exogenous adrenal androgen administration can suppress gonadotropin secretion. Excess endogenous androgen production can be caused by several conditions, including congenital adrenal hyperplasia and adrenal tumors.

Impact of the Sympathoadrenal System on the Regulation of Adrenocortical Function

Adrenocortical steroid hormones influence the differentiation and hormone production of adrenal chromaffin cells. On the other hand, the sympathoadrenomedullary system modulates diurnal variations of steroidogenesis in the adrenal cortex. The adrenal cortex is innervated by neurons originating in cell bodies within the adrenal medulla and by nerves that have cell bodies outside the adrenal, reaching the cortex via blood vessels. Adrenal chromaffin cells contain many neuropeptides that regulate adrenocortical steroid production in many species. Adrenomedullary cells are found throughout the adrenal cortex, which facilitates the paracrine action of their products. Another avenue for adrenomedullary secretory products reaching the adrenal cortex is the lymphatics.

CONCLUSION

The adrenal cortex fulfills important functions before and after birth. Prenatally, the fetal adrenal cortex is large and mainly consists of the fetal zone, which produces high amounts of DHEAS, a hormone that serves as a precursor for other androgens. DHEAS is used by the placenta to synthesize estriol and to regulate intrauterine homeostasis as well as maturation of fetal organ systems that are necessary for life after birth. Postnatally, the adrenal cortex becomes a three-zoned structure, with the largest zone being the zona fasciculata. From outside to inside, the three zones are the zona glomerulosa, the zona fasciculata, and the zona reticularis. The zona glomerulosa produces aldosterone. Production of this hormone is stimulated by angiotensin II and, to a lesser extent, ACTH, potassium, endothelin, and serotonin. Aldosterone secretion is inhibited by dopamine and atrial natriuretic peptide. The zona fasciculata produces mainly cortisol, the stress hormone.

Secretion of this hormone is regulated by the HPA axis. Chronic stress can overstimulate the HPA axis, leading to depression. The zona reticularis produces adrenal androgens and can be stimulated by ACTH. All three zones gradually regress during the life span. Interaction between the adrenal cortex and the adrenal medulla exists and is facilitated by the intermingling of adrenomedullary chromaffin cell islets with the adrenal cortex. The adrenal medulla matures within the first 18 months postnatally and produces the stress hormones epinephrine and norepinephrine as well as other catecholamines.

Adrenal Insufficiency

Evangelia Charmandari and George P. Chrousos

NIH/National Institute of Child Health and Human Development, Bethesda, Maryland, United States

Glossary

Cushing's syndrome A condition caused by increased adrenocortical secretion of cortisol resulting from adrenocortical hyperplasia or tumor and characterized by obesity, acne, amenorrhea, hypertension, abdominal pain, and weakness.

HIV infection Human immunodeficiency virus, the causative agent of AIDS.

thrombosis The formation, development, or presence of a thrombus, or blood clot, in a blood vessel or the heart.

Adrenal insufficiency is a disorder characterized by impaired adrenocortical function and decreased production of mineralocorticoids, glucocorticoids, and/or adrenal androgens.

INTRODUCTION

Adrenal insufficiency can be caused by diseases affecting the adrenal cortex (primary), the pituitary gland and the secretion of adrenocorticotrophic hormone (ACTH) (secondary), or the hypothalamus and the secretion of corticotrophic-releasing hormone (CRH) (tertiary). This article provides a brief overview of the etiology, clinical manifestations, diagnosis, and treatment of adrenal insufficiency.

CAUSES OF ADRENAL INSUFFICIENCY

Primary Adrenal Insufficiency

Autoimmune Adrenitis

This condition is the result of an autoimmune process that destroys the adrenal cortex. Both humoral and cell-mediated immune mechanisms directed at the adrenal cortex are involved. Antibodies that react with several steroidogenic enzymes as well as all three zones of the adrenal cortex are detected in 60–75%

of patients with autoimmune primary adrenal insufficiency but only rarely in patients with other causes of adrenal insufficiency or normal subjects. Approximately 50% of patients with autoimmune adrenal insufficiency have one or more other autoimmune endocrine disorders, whereas patients with the more common autoimmune endocrine disorders, such as type 1 diabetes mellitus, chronic autoimmune thyroiditis, or Graves' disease, rarely develop adrenal insufficiency. The combination of autoimmune adrenal insufficiency with other autoimmune endocrine disorders is referred to as the polyglandular autoimmune syndromes types I and II (Table I).

Infectious Adrenitis

Many infectious agents may affect the adrenal gland and result in adrenal insufficiency, including tuberculosis, disseminated fungal infections, and HIV infection.

Hemorrhagic Infarction

Bilateral adrenal infarction caused by hemorrhage or adrenal vein thrombosis may lead to adrenal insufficiency. Adrenal hemorrhage has been mostly associated with meningococemia (Waterhouse–Friderichsen syndrome) and *Pseudomonas aeruginosa* infection.

Drugs

Drugs may cause adrenal insufficiency by inhibiting cortisol biosynthesis, particularly in individuals with limited pituitary and/or adrenal reserve, or by accelerating the metabolism of cortisol and most synthetic glucocorticoids following induction of hepatic mixed function oxygenase enzymes.

Secondary and Tertiary Adrenal Insufficiency

Secondary adrenal insufficiency may be caused by any disease process that affects the anterior pituitary and

Table I Etiology of Adrenal Insufficiency

interferes with ACTH secretion. The ACTH deficiency may be isolated or occur in association with other pituitary hormone deficits (Table I). On the other hand, tertiary adrenal insufficiency can be caused by any process that involves the hypothalamus and interferes with CRH secretion. The most common causes of tertiary adrenal insufficiency are abrupt cessation of high-dose glucocorticoid therapy and treatment of Cushing's syndrome.

CLINICAL MANIFESTATIONS OF ADRENAL INSUFFICIENCY

The clinical manifestations of adrenal insufficiency depend on the extent of loss of adrenal function and

whether mineralocorticoid production is preserved. The onset of adrenal insufficiency is often gradual and may go undetected until an illness or other stress precipitates an adrenal crisis.

Adrenal Crisis

Adrenal crisis or acute adrenal insufficiency may complicate the course of chronic primary adrenal insufficiency and may be precipitated by a serious infection, acute stress, bilateral adrenal infarction, or hemorrhage. It is rare in patients with secondary or tertiary adrenal insufficiency. The main clinical manifestation of adrenal crisis is shock, but patients may also have nonspecific symptoms, such as anorexia, nausea, vomiting, abdominal pain, weakness, fatigue, lethargy, confusion, or coma. Hypoglycemia is rare in acute adrenal insufficiency but more common in secondary adrenal insufficiency. Hypoglycemia is a common manifestation in children and thin women with the disorder. Hyperpigmentation due to chronic ACTH hypersecretion and weight loss are indicative of long-standing adrenal insufficiency, and additional symptoms and signs relating to the primary cause of adrenal insufficiency may also be present.

The major factor precipitating an adrenal crisis is mineralocorticoid deficiency and the main clinical problem is hypotension. Adrenal crisis can occur in patients receiving appropriate doses of glucocorticoid if their mineralocorticoid requirements are not met, whereas patients with secondary adrenal insufficiency and normal aldosterone secretion rarely present in adrenal crisis.

Chronic Primary Adrenal Insufficiency

Patients with chronic primary adrenal insufficiency may have symptoms and signs of glucocorticoid, mineralocorticoid, and androgen deficiency. In contrast, patients with secondary or tertiary adrenal insufficiency usually have normal mineralocorticoid function. The onset of chronic adrenal insufficiency is often insidious and the diagnosis may be difficult in the early stages of the disease.

The most common clinical manifestations of chronic primary adrenal insufficiency include general malaise, fatigue, weakness, anorexia, weight loss, nausea, vomiting, abdominal pain, diarrhea that may alternate with constipation, hypotension, electrolyte abnormalities (hyponatremia, hyperkalemia, or metabolic acidosis), hyperpigmentation, autoimmune manifestations (vitiligo), decreased axillary and pubic hair, and loss of libido and amenorrhea in women.

Secondary or Tertiary Adrenal Insufficiency

The clinical features of secondary or tertiary adrenal insufficiency are similar to those of primary adrenal insufficiency. However, hyperpigmentation is not present because ACTH secretion is not increased. Also, because the production of mineralocorticoids by the zona glomerulosa is mostly preserved, dehydration and hyperkalemia are not present, and hypotension is less prominent. Hyponatremia and increased intravascular volume may be the result of an “inappropriate” increase in vasopressin secretion. Hypoglycemia is more common in secondary adrenal insufficiency, possibly due to concomitant growth hormone insufficiency, and in isolated ACTH deficiency. Clinical manifestations of a pituitary or hypothalamic tumor, such as symptoms and signs of deficiency of other anterior pituitary hormones, headache, or visual field defects, may also be present.

DIAGNOSIS

The clinical diagnosis of adrenal insufficiency can be confirmed by demonstrating inappropriately low cortisol secretion, determining whether the cortisol deficiency is secondary or primary and, hence, dependent or independent of ACTH deficiency, and detecting the cause of the disorder.

Cortisol Secretion

The diagnosis of adrenal insufficiency depends on the demonstration of inappropriately low cortisol secretion. Serum cortisol concentrations are normally highest in the early morning hours (4:00–8:00 AM) and increase further with stress. Serum cortisol concentrations of less than 3 $\mu\text{g}/\text{dl}$ (80 nmol/liter) at 8:00 AM are strongly suggestive of adrenal insufficiency, whereas values less than 10 $\mu\text{g}/\text{dl}$ (275 nmol/liter) make the diagnosis likely. Basal urinary cortisol and 17-hydroxycorticosteroid excretion is low in patients with severe adrenal insufficiency but may be low-normal in patients with partial adrenal insufficiency. Generally, baseline urinary measurements are not recommended for the diagnosis of adrenal insufficiency.

ACTH Secretion

Inappropriately low serum cortisol concentrations in association with increased plasma ACTH concentrations determined simultaneously are suggestive of

primary adrenal insufficiency. On the other hand, inappropriately low baseline morning cortisol and ACTH concentrations indicate secondary or tertiary disease. Given that plasma ACTH measurements depend on proper preparation of the sample and may not be readily available, confirmation of the diagnosis requires stimulation of the adrenal glands with exogenous ACTH.

Short ACTH Stimulation Tests

A short ACTH stimulation test should be performed in all patients suspected of having adrenal insufficiency. It involves the intravenous administration of synthetic ACTH(1–24) (cosyntropin), which has the full biologic potency of native ACTH(1–39), and subsequent measurement of serum cortisol concentrations at regular intervals for up to 1 h (usually at 0, 30, and 60 min).

High-Dose ACTH Stimulation Test

This test consists of determining serum cortisol responses immediately before and 30 and 60 min after intravenous administration of 250 μg of cosyntropin. This dose of cosyntropin results in pharmacologic plasma ACTH concentrations for the 60-min duration of the test, which may be too high to detect cases of chronic partial and mild pituitary ACTH deficiency. Therefore, this test may miss mild cases of adrenal insufficiency. Also, in early acute secondary or tertiary adrenal insufficiency, as in Sheehan syndrome, the test is not reliable because it takes several days for the adrenal cortex to atrophy. The advantage of the high-dose test is that the cosyntropin can be injected intravenously or intramuscularly since pharmacologic plasma ACTH concentrations can be achieved by either route.

An increase in serum cortisol concentration after 30 or 60 min to a peak of 18–20 $\mu\text{g}/\text{dl}$ (500–550 nmol/liter) or more is considered a normal response to the high-dose ACTH stimulation test and excludes the diagnosis of primary adrenal insufficiency and almost all cases of secondary adrenal insufficiency. However, if secondary adrenal insufficiency is of recent onset, the adrenal glands will have not yet atrophied and will still be capable of responding to ACTH stimulation normally. In these cases, a low-dose ACTH test or insulin-induced hypoglycemia may be required to confirm the diagnosis.

Low-Dose ACTH Stimulation Test

This test theoretically provides a more sensitive index of adrenocortical responsiveness because it

results in physiologic plasma ACTH concentrations. It is performed by measuring serum cortisol concentrations immediately before and 30 min after intravenous injection of cosyntropin in a dose of 1.0 μg (160 mIU) per 1.73 m^2 . This dose stimulates maximal adrenocortical secretion up to 30 min postinjection and, in normal subjects, results in a peak plasma ACTH concentration approximately twice that of insulin-induced hypoglycemia. A value of 18 $\mu\text{g}/\text{dl}$ (500 nmol/liter) or more at any time during the test is indicative of normal adrenal function. The advantage of this test is that it can detect partial adrenal insufficiency that may be missed by the standard high-dose test. The low-dose test is also preferred for patients with secondary or tertiary adrenal insufficiency.

Prolonged ACTH Stimulation Tests

Prolonged ACTH stimulation tests are rarely performed because the history and physical examination, the CRH test, and/or determination of cortisol and ACTH concentrations in association with the low-dose ACTH test may provide all necessary information. Prolonged stimulation with exogenous ACTH is used to differentiate between primary and secondary or tertiary adrenal insufficiency. In secondary or tertiary adrenal insufficiency, the adrenal glands display cortisol secretory capacity following prolonged stimulation with ACTH, whereas in primary adrenal insufficiency, the adrenal glands are partially or completely destroyed and do not respond to ACTH.

Eight-Hour ACTH Stimulation Test

This test consists of administering 250 μg (40 IU) of cosyntropin intravenously as an infusion for 8 h and determining serum cortisol and 24-h urinary cortisol and 17-hydroxycorticoid (17-OHCS) concentrations before and after the infusion. In normal subjects, the 24-h urinary 17-OHCS excretion increases three- to fivefold above the baseline. Serum cortisol concentrations reach 20 $\mu\text{g}/\text{dl}$ (550 nmol/liter) at 30–60 min and exceed 25 $\mu\text{g}/\text{dl}$ (690 nmol/liter) 6–8 h after initiation of the infusion.

Two-Day ACTH Stimulation Test

The 2-day ACTH stimulation test is similar to the 8-h infusion test, except that 250 μg of ACTH(1–24) is infused for more than 24 h on 2 (or 3) consecutive days. This test may be helpful in distinguishing primary from secondary/tertiary adrenal insufficiency. In primary adrenal insufficiency there is no or a minimal response of plasma or urinary cortisol and urinary

17-OHCS. Increases in these values during the 2 or 3 days of the test are indicative of a secondary/tertiary cause of adrenal insufficiency.

CRH Stimulation Test

This test is used to differentiate between secondary and tertiary adrenal insufficiency. In both conditions, cortisol levels are low at baseline and remain low after CRH. In patients with secondary adrenal insufficiency, there is little or no ACTH response, whereas in patients with tertiary disease there is an exaggerated and prolonged response of ACTH to CRH stimulation, which is not followed by an appropriate cortisol response.

Additional methods to identify the cause of adrenal insufficiency vary depending on whether the disease is primary, secondary, or tertiary.

TREATMENT

Adrenal insufficiency is a potentially life-threatening condition. Treatment should be initiated as soon as the diagnosis is confirmed or sooner if the patient presents in adrenal crisis.

Adrenal Crisis

Adrenal crisis is a life-threatening emergency that requires immediate treatment. If the diagnosis is suspected but not known, blood samples should be obtained for measurement of cortisol concentrations.

Initial Treatment

The aim of initial management in adrenal crisis is to treat hypotension (i.e., to correct hypovolemia) and to reverse the electrolyte abnormalities and cortisol deficiency. Large volumes of normal saline solution should be given intravenously. The glucocorticoid deficiency should be treated by immediate intravenous administration of dexamethasone sodium phosphate or hydrocortisone sodium succinate. Dexamethasone may be preferred because it has a long duration of action and does not interfere with the measurements of serum or urinary steroids during subsequent ACTH stimulation tests. After the initial treatment is provided, the cause of the adrenal crisis should be sought and treated.

Subsequent Treatment

Once the patient's condition is stable and the diagnosis has been confirmed, parenteral glucocorticoid

therapy should be tapered over 3 or 4 days and converted to an oral maintenance dose. Patients with primary adrenal insufficiency require life-long glucocorticoid and mineralocorticoid replacement therapy.

Chronic Adrenal Insufficiency

One of the important aspects of the management of chronic primary adrenal insufficiency is patient and family education. Patients should understand the reason for life-long replacement therapy and the need to increase the dose of glucocorticoid during minor or major stress and to inject hydrocortisone, methylprednisolone, or dexamethasone in emergencies.

Emergency Precautions

Patients should wear a medical alert (Medic Alert) bracelet or necklace and carry the Emergency Medical Information Card, which should provide information on the diagnosis, medications and daily doses, and the physician involved in the patient's management. Patients should also have supplies of dexamethasone sodium phosphate and should be educated about how and when to administer them.

Glucocorticoid Replacement Therapy

Patients with adrenal insufficiency should be treated with hydrocortisone, the natural glucocorticoid. The hydrocortisone daily dose is 25–30 mg (10–15 mg/m² body surface area) and can be given in two or three divided doses. A longer acting synthetic glucocorticoid, such as prednisolone, prednisone, or dexamethasone, may be employed but should be avoided because their longer duration of action may produce manifestations of chronic glucocorticoid excess, such as loss of lean body mass and bone density and gain of visceral fat. The usual oral replacement dosages are 5–7.5 mg of prednisolone or prednisone or 0.25–0.75 mg of dexamethasone once daily.

Glucocorticoid Replacement during Minor Illness or Surgery

During minor illness or surgical procedures, the dosage of glucocorticoid can be increased up to three times the usual maintenance dosage for 3 days. Depending on the nature and severity of the illness, additional treatment may be required.

Glucocorticoid Replacement during Major Illness or Surgery

During major illness or surgery, high doses of glucocorticoid up to 10 times the daily production rate are required to avoid an adrenal crisis. A continuous infusion of 10 mg of hydrocortisone per hour or the equivalent amount of dexamethasone or prednisolone eliminates the possibility of glucocorticoid deficiency. This dose can be halved on postoperative day 2, and the maintenance dose can be resumed on postoperative day 3.

Mineralocorticoid Replacement Therapy

Mineralocorticoid replacement therapy is required to prevent sodium loss, intravascular volume depletion, and hyperkalemia. It is given in the form of fludrocortisone (9 α -fluorohydrocortisone) in a dose of 0.1 mg daily. The dose of fludrocortisone is titrated individually based on the findings of clinical examination (mainly body weight and arterial blood pressure) and the levels of plasma renin activity. Patients receiving prednisone or dexamethasone may require higher doses of fludrocortisone to lower their plasma renin activity to the upper normal range, whereas patients receiving hydrocortisone, which has some mineralocorticoid activity, may require lower doses. The mineralocorticoid dose may have to be increased during the summer, particularly if patients are exposed to temperatures higher than 29°C (85°F).

Androgen Replacement

In women, the adrenal cortex is the primary source of androgen in the form of dehydroepiandrosterone and dehydroepiandrosterone sulfate. Although the physiologic role of these androgens in women has not been fully elucidated, their replacement is being increasingly considered in the treatment of adrenal insufficiency.

Chronic Secondary and Tertiary Adrenal Insufficiency

Glucocorticoid replacement in chronic secondary or tertiary adrenal insufficiency is similar to that in primary adrenal insufficiency. However, measurement of plasma ACTH concentration cannot be used to titrate the optimal glucocorticoid dose. Mineralocorticoid replacement is rarely required, whereas replacement of other anterior pituitary deficits may be necessary.

Glossary

ACTH (adrenocorticotropic hormone) A hormone synthesized and secreted by the anterior pituitary that is primarily responsible for the regulation of cortisol and adrenal androgen secretion.

adrenal crisis A medical emergency in which the subject is affected by an extreme state of adrenal insufficiency, with symptoms resembling shock or coma; considered to be life-threatening and requiring immediate administration of fluids, electrolytes, glucose, and intravenous glucocorticoids. May occur in situations of extreme stress or after the abrupt cessation of a period of glucocorticoid therapy.

Cushing's syndrome A metabolic disorder relating to the chronic oversecretion of adrenal glucocorticoids (mainly cortisol); may be associated with the long-term administration of pharmacological amounts of synthetic glucocorticoids. A condition first described by U.S. neurosurgeon Harvey Cushing in 1912.

HPA axis An anatomical complex consisting of the hypothalamus, the pituitary gland, and the adrenal cortex; ultimately controls the secretion of glucocorticoids from the adrenal cortex and thus plays a key role in various neuroendocrine, behavioral, autonomic, and immune responses to alterations in homeostasis.

Glucocorticoids are produced by the cortices of the adrenal glands and secreted into the systemic circulation in a circadian fashion and in response to stressful stimuli. These steroid hormones play pivotal roles in the regulation of intermediary metabolism, maintenance of cardiovascular function, stimulation of behavior, and control of the immune inflammatory reaction.

INTRODUCTION

The major endogenous glucocorticoid in humans is cortisol, the synthetic form of which has traditionally

been called hydrocortisone. Cortisone, the 2-keto form of cortisol, was first used therapeutically in the management of rheumatoid arthritis by Hench and coworkers in 1949. Since then, a large number of synthetic compounds with glucocorticoid activity have been developed, and glucocorticoids (administered systemically or in a compartmental fashion) have been used in the therapy of a broad spectrum of nonendocrine and endocrine diseases.

One of the adverse effects of long-term glucocorticoid therapy in supraphysiologic doses is suppression of the hypothalamic–pituitary–adrenal (HPA) axis, which can render the adrenal glands unable to generate sufficient cortisol if glucocorticoid treatment is abruptly stopped, and the patient may develop glucocorticoid deficiency manifestations. The true prevalence of clinically significant adrenal insufficiency is not known since physicians usually discontinue high glucocorticoids gradually to allow recovery of the HPA axis.

Some of the risk factors for HPA axis suppression are clearly defined, whereas others are less certain. Systemic glucocorticoid therapy is more likely to suppress the HPA axis than compartmentalized use of glucocorticoids, with the possible exception of intra-articular steroids. Systemic glucocorticoid potency is also known to correlate with risk for adrenal insufficiency.

Glucocorticoid treatment in endocrine and none-endocrine disorders, the side effects of these medications, their concomitant use and interactions with other drugs, adrenal suppression, and the glucocorticoid withdrawal syndrome are discussed in detail in this article.

PHYSIOLOGY OF THE HPA AXIS

The adrenal cortex consists of three anatomic zones: the outer zona glomerulosa, the intermediate zona fasciculata, and the inner zona reticularis. The zona

glomerulosa is responsible for the production of aldosterone, the zona fasciculata for the production of cortisol, and the zona reticularis for the production of adrenal androgens. Corticotropin (ACTH), synthesized and secreted by the corticotropes of the anterior pituitary, is the primary regulator of cortisol and adrenal androgen secretion. Hypothalamic control of ACTH secretion is exerted primarily by corticotropin-releasing hormone (CRH), a 41-amino acid peptide produced by parvocellular neurons of the paraventricular nucleus and secreted into the hypophyseal portal system.

There are several regulatory negative feedback loops that function to constrain the activity of the HPA axis. Prominent negative feedback loops are those exerted by glucocorticoids on CRH and ACTH secretion. The adrenal cortisol secretion rate under basal conditions is 12–15 mg/m²/day. In normal individuals, the highest plasma cortisol levels occur between 6:00 and 8:00 AM and the lowest at approximately midnight. Cortisol secretion increases two- to fourfold under stress. Plasma cortisol concentrations are elevated during physical and/or emotional stress, including illness, trauma, surgery, and starvation.

ADRENAL INSUFFICIENCY

Adrenal insufficiency results from inadequate adrenocortical function, which may be due to destruction of the adrenal cortex (primary adrenal insufficiency; Addison's disease), deficient pituitary ACTH secretion (secondary adrenal insufficiency), or deficient hypothalamic secretion of CRH or other ACTH secretagogues (tertiary adrenal insufficiency). Primary and secondary adrenal insufficiency related to natural causes are uncommon, whereas iatrogenic, tertiary adrenal insufficiency caused by suppression of HPA function by glucocorticoid administration is common.

PATHOGENESIS OF GLUCOCORTICOID-INDUCED ADRENAL SUPPRESSION

Glucocorticoid treatment may not suppress the HPA axis at all, or it may cause central suppression or complete adrenal gland atrophy. Supraphysiologic glucocorticoid doses inhibit both CRH production in the hypothalamus and ACTH production in the pituitary gland. When this inhibition lasts longer than the duration of the glucocorticoid exposure, it is called adrenal suppression.

The most severely affected glucocorticoid-treated patients have complete HPA axis suppression, characterized by functional adrenal gland atrophy. Cortisol production seems to depend on intermittent but consistent exposure to circulating ACTH. In states of profound or prolonged ACTH deficiency, the adrenal glands atrophy and are unable to generate cortisol in response to exogenous ACTH. However, in reality, adrenal suppression is a central nervous system problem. The rate-limiting step in HPA axis recovery from suppression is located in the brain. Thus, chronic administration of ACTH does not accelerate recovery, even though it may return cortisol production to normal while administered.

SYNTHETIC GLUCOCORTICOIDS

Since the introduction of glucocorticoids in the treatment of rheumatoid arthritis in 1949, intense efforts have been made by science and industry to maximize the beneficial effects and to minimize the side effects of glucocorticoids. Thus, many synthetic compounds with glucocorticoid activity have been manufactured and tested. The pharmacologic differences among these chemicals result from structure alterations of their basic steroid nucleus and its side groups. These changes may affect the bioavailability of these compounds (including their gastrointestinal or parenteral absorption, plasma half-life, and metabolism in the liver, fat, or target tissues) and their abilities to interact with the glucocorticoid receptor and to modulate the transcription of glucocorticoid-responsive genes. In addition, structural modifications diminish the natural cross-reactivity of glucocorticoids with the mineralocorticoid receptor, eliminating their undesirable salt-retaining activity. Other modifications increase glucocorticoids' water solubility for parenteral administration or decrease their water solubility to enhance topical potency.

Thus, prednisolone has the structure of cortisol with an additional double bond between C1 and C2, which increases its glucocorticoid and decreases its mineralocorticoid activity. Introduction of an α -fluoro group at C9, on the other hand, enhances both glucocorticoid and mineralocorticoid activity, whereas addition of a hydroxyl or methyl group at C16 practically eliminates mineralocorticoid activity. Dexamethasone, a potent synthetic glucocorticoid that has a double bond at C1 and C2, a fluoro group at C9, and an α -methyl group at C16, has 25–50 times the glucocorticoid potency of cortisol and a minimal mineralocorticoid effect. A double bond between C2

and C3 and methylation at the C2 or C16 positions significantly prolong the plasma half-life of a compound. A keto group at C11 is normally reduced by liver enzymes to an 11 β -hydroxyl group, which is necessary for glucocorticoid activity. In contrast, a C11 hydroxyl group is oxidized to a keto group in the kidney, minimizing the access of the compound to the mineralocorticoid receptor, and thus its salt-retaining effect.

Most synthetic glucocorticoids (e.g., methylprednisolone and dexamethasone) are minimally bound to cortisol-binding globulin (transcortin) and circulate mostly bound to albumin or in the free form. The percentage of such glucocorticoids bound to plasma proteins is relatively constant, and because binding is concentration independent, the metabolic clearance rate of glucocorticoids remains constant regardless of dose. Table I shows the relative glucocorticoid and mineralocorticoid potencies of commonly used systemic glucocorticoids and their approximate plasma and biologic effect half-lives. Glucocorticoid activity has been mostly defined in rat bioassays and may not always pertain to human responses, especially the growth-suppressing properties of synthetic glucocorticoids, which have been markedly underestimated. Based on the biologic effect half-life of glucocorticoids, they are classified as short, intermediate, or long acting based on the duration of corticotropin suppression after a single dose of the compound.

SYSTEMIC GLUCOCORTICOID ADMINISTRATION

Therapeutic Indications

Glucocorticoids may be administered as replacement therapy in patients with primary or secondary adrenal insufficiency, as adrenal suppression therapy in congenital adrenal hyperplasia and glucocorticoid resistance, and as anti-inflammatory or immunosuppressant therapy in a broad range of mostly nonendocrine disorders affecting many different systems. Thus, glucocorticoids are used in endocrine, autoimmune, collagen, renal, gastrointestinal, respiratory, nervous, hematologic, and ophthalmic diseases and are used in the suppression of the host versus graft and graft versus host reaction in cases of organ transplantation. Neoplastic disorders of the lymphoid system, such as leukemia and lymphomas, are also treated with glucocorticoids, along with the appropriate chemotherapy.

Acute administration of pharmacologic doses of glucocorticoids is necessary in a small number of nonendocrine diseases, such as malignant hyperthermia, and in patients with craniospinal trauma or brain tumors or in those who are undergoing major neurosurgical operations to decrease the temperature and prevent destruction of neural tissue from the local edema and inflammatory reaction, respectively. In addition, glucocorticoids have been used in the

Table I Glucocorticoid Equivalencies^a

| | Equivalent dose (mg) | Glucocorticoid potency | Mineralocorticoid potency | Plasma half-life (min) | Biologic half-life (h) |
|------------------------------|----------------------|------------------------|---------------------------|------------------------|------------------------|
| Glucocorticoids | | | | | |

^aFrom Liapi and Chrousos (1992).

prevention of the respiratory distress syndrome in the premature neonate, when delivery is anticipated before week 34 of gestation. In this case, treatment of the pregnant woman with 12 mg of betamethasone, followed by 12 mg 18–24 h later, stimulates the production of pulmonary surfactant and the maturation of the fetal lungs.

Recently, glucocorticoid therapy has been re-introduced in the treatment of adult acute respiratory distress syndrome. The recommended methylprednisolone doses are moderate and treatment is given continuously during the course of the disease. Significantly improved morbidity and mortality have been observed. Similar glucocorticoid treatment is being studied in patients with systemic inflammation syndrome, septic shock, and multiple organ dysfunction with promising results.

Side Effects

Side effects occur only with supraphysiologic doses of glucocorticoids and not with proper replacement, which is equivalent to 12–15 mg of hydrocortisone/m² body surface area/day. Major complications are unlikely for short-term treatment (<2 weeks) with high doses of glucocorticoids, although sleep disturbances and gastric irritation are common complaints, and depression, mania, or psychosis may be infrequently precipitated. On the other hand, many side effects are associated with long-term daily administration of pharmacologic amounts of glucocorticoids (Table II), including the development of varying degrees of Cushing's syndrome manifestations during therapy and secondary adrenal insufficiency (adrenal suppression) after discontinuation of treatment. Growth retardation is one of the major side effects of long-term daily glucocorticoid therapy in children.

The degree of cushingoid features and the severity and length of adrenal suppression depend on the type and dose of the specific compound used, the duration of treatment, the idiosyncrasy, and the stress status of the patient. Most complications of glucocorticoid treatment are totally or partially reversible after discontinuation of glucocorticoid administration, with the exception of posterior subcapsular cataracts and advanced bone necrosis.

High doses of glucocorticoids suppress the immune defenses of the organism. Thus, individuals on glucocorticoid therapy are particularly susceptible to viral diseases against which they have not been vaccinated or naturally immunized (e.g., varicella, which can be devastating). Also, such individuals are

susceptible to contract or to sustain activation of dormant tuberculosis. Individuals treated with massive doses of glucocorticoids can also develop saprophytic, fungal, or protozoan infections such as those seen in patients with severe immunodeficiency.

Nonfluorinated glucocorticoids (cortisone, cortisol, prednisone, and prednisolone) cross the placenta poorly. Fluorinated steroids, on the other hand, cross the placenta readily and should be given cautiously to women during pregnancy. The ratio of maternal–fetal plasma concentration gradients is approximately 10:1 for cortisol and prednisolone and approximately 2.5:1 for betamethasone and dexamethasone. Newborns exposed to high doses of synthetic fluorinated corticosteroids *in utero* should be checked for signs of adrenal insufficiency, and a Cortrosyn stimulation test should be performed to assess the need for glucocorticoid replacement. Special precautions should be taken for premature infants because some glucocorticoid preparations containing benzyl alcohol have been associated with a fatal “gasping” syndrome.

To avoid complications, alternate-day administration of intermediate-acting glucocorticoids should be used, when possible, if long-term therapy is necessary. Frequently, such a regimen can control the activity of the disease under therapy without causing Cushing’s syndrome, growth retardation, or adrenal suppression. Termination of long-term daily therapy (>2 weeks) should be gradual to prevent development of acute adrenal insufficiency and to avoid reactivation of the disease under therapy. Switching to daily hydrocortisone replacement or to alternate-day administration of intermediate-acting glucocorticoids is an acceptable method for weaning patients from glucocorticoid therapy.

COMPARTMENTAL GLUCOCORTICOID ADMINISTRATION

Topical Glucocorticoids

Glucocorticoids are quite effective when applied topically and are nontoxic to the skin in the short term. The factors that determine local penetration are the structure of the compound employed, the vehicle, the basic additives, occlusion versus open use, normal skin versus diseased skin, and small areas versus large areas of application. Fluorinated steroids (e.g., dexamethasone, triamcinolone acetonide, betamethasone, and beclomethasone) penetrate the skin better than nonfluorinated steroids, such as hydrocortisone. However, fluorinated steroids also cause more local

complications and may be associated with systemic absorption and side effects.

The complications of chronic topical skin use of glucocorticoids are mostly local (e.g., epidermal atrophy and hypopigmentation, telangiectasia, or acne and folliculitis) or infrequently systemic, with the classic manifestations of Cushing’s syndrome, growth retardation in children, and adrenal suppression. The frequency of systemic effects by topical corticosteroids is increased in newborns and small children compared to adolescents and adults because glucocorticoids penetrate the skin of newborns and small children more easily and in larger amounts. Systemic effects may also be observed in patients with hepatic disease or idiosyncratically because of decreased drug metabolism. Although most types of dermatitis are generally responsive to topical glucocorticoids, there are rare cases in which intralesional injections might be considered (e.g., hypertrophic scars, acne cysts, or prurigo nodularis).

Ophthalmic Glucocorticoids

Patients with autoimmune or idiopathic inflammation of the anterior segment of the eye (e.g., iritis and uveitis) may benefit from local administration of glucocorticoids. Also, patients with postsurgical or traumatic inflammation are given topical glucocorticoids to prevent local destruction from edema. Special care should be taken to avoid treating patients with herpes simplex conjunctivitis or keratitis during the infectious stage of the disease because major spread of the infection may be precipitated.

Inhaled Glucocorticoids

Glucocorticoid inhalation therapy is widely used in patients with bronchial asthma and croup. The existing preparations at the recommended doses have a remarkable therapeutic effect without causing manifestations of Cushing’s syndrome, growth retardation, or clinically significant adrenal suppression. Systemic effects may be observed, however, as a result of increased intake of such preparations or altered steroid metabolism.

Inhaled glucocorticoids have also been used in ventilator-dependent preterm infants to reduce the severity of respiratory distress syndrome and to facilitate weaning from mechanical ventilation of infants with bronchopulmonary dysplasia. Their effect on the function of the immature HPA axis of these preterm neonates is unclear.

Nasal Glucocorticoids

Aerosols containing glucocorticoids are available for the treatment of allergic rhinitis. Frequent and chronic use should be avoided to prevent local and systemic complications.

Intra-articular Glucocorticoids

The intra-articular injection of glucocorticoids may be of value in carefully selected patients if strict aseptic techniques are used and repeated and frequent injections are avoided.

MONITORING OF PATIENTS RECEIVING GLUCOCORTICOID TREATMENT

Patients receiving long-term treatment with glucocorticoids should adhere to a high-protein, calorie-restricted diet. The diet should also be rich in potassium and calcium and low in sodium. Adequate ambulation or exercise should be recommended to prevent muscular atrophy and osteopenia. Patients should concurrently take antacids or histamine antagonists to prevent gastric irritation or peptic ulcers. Young children should have their growth monitored every 3 months (until age 5), and older children should have their growth monitored every 6 months. For all patients, body weight, length or height, blood pressure, fasting and 2-hpostprandial blood glucose, serum electrolytes, and bone maturation and density should be measured. Because glucocorticoids decrease the organism's response to infection, care should be taken to determine whether latent infections, such as mycobacterial disease, are present before treatment begins.

CONCOMITANT USE OF GLUCOCORTICOID WITH OTHER DRUGS

Special attention is required for the concomitant use of glucocorticoids with other drugs because of potential interactions and because some drugs may affect the metabolism of the steroids, which may lead to a decreased or increased glucocorticoid effect on their target tissues. Such interactions and effects are shown in [Tables III–V](#).

PREDICTING GLUCOCORTICOID-INDUCED HPA AXIS SUPPRESSION

Several predictors of glucocorticoid-induced HPA axis suppression have been discussed. The following are the most important:

1. Kind of steroid used and glucocorticoid potency: The synthetic analogs of glucocorticoids are much better tolerated as anti-inflammatory agents because they cause significantly less sodium retention at supraphysiologic doses than hydrocortisone and cortisone acetate. Glucocorticoid potency ([Table I](#)) correlates positively with risk for adrenal insufficiency. Thus, hydrocortisone and cortisone acetate are the least potent and, therefore, least suppressive agents. Prednisone, prednisolone, methylprednisolone, and triamcinolone are moderately suppressive, and dexamethasone suppresses ACTH the longest.
2. Systemic vs compartmental therapy: Systemic glucocorticoid therapy is more likely to suppress the HPA axis than are intra-articular, inhalational, or topical glucocorticoids.
3. Alternate-day therapy: There is evidence that patients are at lower risk for adrenal insufficiency if they can take glucocorticoids on alternate days from the outset or if they can convert to alternate-day therapy before the HPA axis is suppressed.

Table III Interactions of Glucocorticoids with Other Drugs^a

| Drug | Side effect | Comment |
|---------------------------------------|-------------------------------|-------------------------------------|
| Amphotericin B | Hypokalemia | Monitor potassium levels frequently |
| Digitalis glycosides | Digitalis toxicity | Monitor potassium levels frequently |
| | Hypokalemia | |
| Growth hormone | Ineffective | — |
| Potassium-depleting diuretics | Hypokalemia | Monitor potassium levels frequently |
| Vaccines from live attenuated viruses | Severe generalized infections | — |

^aFrom Liapi and Chrousos (1992).

Table IV Effects of Glucocorticoids on Blood Levels of Other Drugs^a

| Drug | Drug blood levels | Comments |
|--------------------------|-------------------|---|
| Aspirin | Decreased | Increased metabolism or clearance; monitor salicylate levels |
| Coumarin anticoagulants | Decreased | Frequent control of prothrombin levels |
| Cyclophosphamide | Increased | Inhibition of hepatic metabolism; adjust the dosage of the drug |
| Cyclosporine | Increased | Inhibition of hepatic metabolism |
| Insulin | Decreased | Adjust the dosage of the drug |
| Isoniazid | Decreased | Increased metabolism and clearance |
| Oral hypoglycemic agents | Decreased | Adjust the dosage of the drug |

^aFrom Liapi and Chrousos (1992).

4. Once-a-day dosing in the morning or mimicking normal diurnal cortisol rhythms: Since evening doses of glucocorticoids tend to suppress the normal early morning surge of ACTH secretion, it is better, whenever possible, to cure patients with a single morning dose. Once-a-day dosing is usually feasible for prednisone, triamcinolone, and dexamethasone. The short-acting hydrocortisone and cortisone acetate are usually given twice a day, at waking and at approximately 5 P.M. To mimic normal diurnal cortisol rhythms, the morning dose is two-thirds and the afternoon dose is one-third of the total daily dose.

5. Duration and cumulative dose of glucocorticoid treatment: Although traditionally the duration of glucocorticoid therapy and the cumulative dose of glucocorticoid received have been considered as predictive of the likelihood of HPA axis suppression, several studies suggest that they only roughly predict HPA axis suppression. Adrenal insufficiency is extremely rare in patients treated for 1 week or less.

Perhaps the best predictor of HPA axis suppression is the patient's current glucocorticoid dosage. A strong correlation has been found between prednisone maintenance doses >5 mg/day and a subnormal ACTH stimulation test result.

WEANING PATIENTS FROM GLUCOCORTICOID THERAPY

Termination of long-term daily glucocorticoid therapy (>2 weeks) should be gradual to prevent development of adrenal insufficiency and to avoid reactivation of the disease under therapy. The likelihood of the latter depends on the activity and natural history of the disorder. When there is a chance that the underlying illness may recur, the glucocorticoids should be withdrawn slowly over a period of weeks to months, with frequent reassessment of the patient's condition. Daily hydrocortisone replacement or double or triple replacement of intermediate-acting glucocorticoids

Table V Effect of Drugs on Plasma Glucocorticoid Concentrations^a

| Drug | Glucocorticoid blood levels | Comments |
|---------------------|--------------------------------------|---|
| Antacids | Decreased | Possible physical adsorption to antacid |
| Carbamazepine | Decreased | Increased cytochrome P450 activity |
| Cholestyramine | Decreased | Decreased gastrointestinal absorption of glucocorticoids |
| Colestipol | Decreased | Decreased gastrointestinal absorption of glucocorticoids |
| Cyclosporine | Increased | Inhibition of hepatic metabolism |
| Ephedrine | Decreased | Probably increased metabolism |
| Erythromycin | Increased | Impaired elimination |
| Mitotane | Decreased, with elevated transcortin | Total plasma cortisol unreliable; adjust glucocorticoid levels |
| Oral contraceptives | Increased | Impaired elimination, increased protein binding |
| Phenobarbital | Decreased | Increased cytochrome P450 activity; adjust glucocorticoid dosage |
| Phenytoin | Decreased | Increased cytochrome P450 activity; adjust glucocorticoid dosage |
| Rifampin | Decreased | Increased cytochrome P450 activity(?); adjust glucocorticoid dosage |
| Troleandomycin | Increased | Partially resulting from impaired elimination |

^aFrom Liapi and Chrousos (1992).

given on alternate days are acceptable methods for weaning patients from glucocorticoid therapy.

ACUTE ADRENAL CRISIS

Recovery of the HPA axis can take 12 months or longer. Abrupt cessation of glucocorticoid treatment or quick tapering can precipitate an acute adrenal insufficiency crisis. The main symptoms range from anorexia, fatigue, nausea, vomiting, dyspnea, fever, arthralgia, myalgia, and orthostatic hypotension to dizziness, fainting, and circulatory collapse. Hypoglycemia is occasionally observed in children and very thin adults. The diagnosis is a medical emergency, and treatment should consist of immediate administration of fluids, electrolytes, glucose, and parenteral glucocorticoids.

GLUCOCORTICOID WITHDRAWAL SYNDROME

Glucocorticoid withdrawal can present as an acute adrenal crisis or with symptoms of chronic glucocorticoid deficiency. Thus, patients may suffer from anorexia, myalgia, nausea, emesis, lethargy, headache, fever, skin desquamation, arthralgias, weight loss, and postural hypotension. In addition, they may experience exacerbation of a previously present autoimmune disease (e.g., rheumatoid arthritis, atopic dermatitis, and asthma) or develop a new autoimmune disease (e.g., Hashimoto's thyroiditis and Graves' disease). Amatruda *et al.* first defined the steroid withdrawal syndrome as a symptom complex resembling true adrenal insufficiency, with nonspecific symptoms such as weakness, nausea, and arthralgias, occurring in patients who have completed a dosage reduction of glucocorticoid therapy and who respond normally to HPA axis testing.

The occurrence of the subjective component of the steroid withdrawal syndrome does not depend on the absence of cortisol from the circulation or an impairment of the HPA axis because these symptoms may occur while the patient is on proper glucocorticoid replacement or when the patient has a normal cortisol response to Cortrosyn. In this instance, the steroid withdrawal syndrome may be a result of difficulties in withdrawing from the high levels of glucocorticoids—a phenomenon that appears to be idiosyncratic.

However, when patients become ill after a dosage reduction, the physician should consider a differential diagnosis that includes true adrenal insufficiency, a

flare of the disease being treated, and steroid withdrawal syndrome. All three conditions resolve after patients are restarted on the glucocorticoid regimen that previously controlled their symptoms.

BIOCHEMICAL DIAGNOSIS OF ADRENAL INSUFFICIENCY

As previously mentioned, glucocorticoid treatment may not suppress the HPA axis at all, or it may cause central suppression and adrenal gland atrophy of varying degrees. The insulin tolerance test and the metyrapone test have been employed in the diagnosis of adrenal suppression and are quite sensitive. However, the risks involved with both tests do not justify their use when a rapid ACTH stimulation test can distinguish clinically significant adrenal suppression.

To evaluate the adequacy of HPA axis recovery, the rapid Cortrosyn (or high-dose ACTH stimulation test) is most commonly used. An intravenous bolus of 250 μg of corticotropin 1-24 is administered, and cortisol is measured after 30 or 60 min or both. A plasma cortisol concentration $>18\text{--}20$ $\mu\text{g/dL}$ at these times indicates adequate recovery of the HPA axis. This test can also be done intramuscularly.

A modified Cortrosyn test has been recommended in lieu of the standard test. Only 1 μg of corticotropin 1-24 is administered instead of 250 μg . This test is fraught with technical errors as a result of multiple dilutions of the Cortrosyn preparations and adhesion of Cortrosyn to the tubing system. Its purported increased sensitivity may not necessarily signify a greater clinical prediction of adrenal suppression.

Glossary

adrenocorticotrophic hormone or corticotropin (ACTH) Stimulates the adrenal gland.

first hit According to Knudson's two-hit model of tumorigenesis, in tumor suppressor gene-related tumors, the first hit is the germ-line mutation of the defective tumor suppressor gene. The second hit consists most commonly of a deletion of the wild-type allele of the tumor suppressor gene in question and can cause biallelic inactivation of this gene with subsequent tumor formation in the affected cell and organ.

hyperaldosteronism State of aldosterone excess. The most common cause in primary hyperaldosteronism is an aldosterone-oversecreting adrenocortical mass that can lead to secondary hypertension in the affected patient.

incidentaloma Mass (e.g., in the adrenal gland) detected by chance during radiologic imaging workup.

loss of heterozygosity (LOH) This can occur through deletion of the wild-type allele of a gene that has a germ-line mutation in hereditary tumor syndromes or through deletion of a gene that has a somatic mutation in sporadic tumors. This will move the affected cell into the homozygous state for the respective gene.

Adrenal tumors are found in up to 9% of autopsy studies. Modern imaging modalities facilitate better detection of adrenal masses than in the past but also detect adrenal incidentalomas in patients who are not evaluated for adrenal tumors. Assessing such patients for the presence of subclinical disease caused by adrenal incidentalomas and the potential for malignancy is challenging. Although there are radiological (e.g., intratumor necrosis, irregular margins, and local metastases), histopathological (e.g., Weiss criteria), and genetic (e.g., overexpression of *IGF2* and loss of heterozygosity at 17p13) criteria to predict malignancy, no absolute specific marker and feature exist to reliably distinguish benign and malignant adrenal lesions, excluding pure adrenal ganglioneuroma, which by definition is

always benign. Although adrenal tumors have been observed in several familial syndromes, the majority of these lesions occur sporadically. If the gene defect in familial syndromes is known, timely identification of family members already affected by or at risk for the development of an adrenal tumor is possible by genetic screening tools including germ-line mutation analysis. Despite these molecular advances and tools, the pathogenesis of adrenal tumors remains widely unknown. The elucidation of adrenal tumorigenesis may be facilitated by studying adrenal tumors of patients with hereditary syndromes since in these tumors at least one hit, the inherited gene defect, is known and presumably represents the "first hit" in tumor evolution. In contrast, sporadic tumors have an unknown first hit, making it more difficult to determine the sequence of genetic events or hits. In this article, we discuss the molecular pathogenesis in hereditary and sporadic adrenal tumors.

ADRENOMEDULLARY TUMORS

Pheochromocytoma

Von Hippel–Lindau Syndrome

Von Hippel–Lindau (VHL) syndrome consists of a variety of masses, including renal carcinomas, hemangioblastomas, and pheochromocytomas. It affects approximately 1 in 36,000 individuals and is caused by mutations in the VHL tumor suppressor gene located at chromosome 3p25–26. Less than 26% of patients with a *VHL* germ-line mutation develop a pheochromocytoma, and up to one-third of these patients do not suffer from symptoms of catecholamine excess since they may have "silent" (not catecholamine-oversecreting) pheochromocytomas. Most VHL-associated pheochromocytomas have loss of function (LOH) at 3p25–26, leading to biallelic inactivation of the VHL gene, thereby following Knudson's two-hit model of tumorigenesis. A small subset of VHL pheochromocytomas have LOH at 1p or chromosome 11. VHL protein leads to degradation of certain proteins, most in the 26S proteasome complex (Table I).

Table 1 Gene Alterations in Pheochromocytoma^a

| Gene | Chromosomal location | Gene alteration | Prevalence |
|-------------------------------|------------------------|--|-----------------------------------|
| Tumor suppressor genes | | | |
| <i>VHL</i> | 3p25.5 | LOH of the wild-type allele in VHL tumors | 33/46 |
| | | LOH in MEN2 tumors | 10/18 |
| | | Somatic mutations in MEN2 tumors | 3/21 |
| | | Somatic mutations in VHL tumors | 0/36 |
| | | Somatic mutations in sporadic tumors | 1/20 |
| | | LOH in sporadic tumors | 35/102 benign, 3/10 malignant |
| <i>NF1</i> | 17q11.2 | LOH of the wild-type allele | 3/7 |
| | | LOH in sporadic tumors | 1/6 |
| | | Absent neurofibromin expression | 6/6 |
| | | Reduced or absent neurofibromin expression | 1/4 sporadic, 5/14 MEN-2, 1/2 VHL |
| <i>SDHD</i> | 11q23 | LOH in sporadic tumors | 13/18 |
| | | Somatic mutations | 1/18 |
| <i>p53</i> | 17p13 | Somatic mutations | 6/55 |
| | | LOH | 10/46 |
| <i>MEN1</i> | 11q13 | LOH of the wild-type allele | 2/2 |
| <i>RASSF1A</i> | 3p21 | Somatic mutations | 0/23 |
| | | Hypermethylation | 5/23 |
| <i>p16</i> | 9p21 | LOH | 0/26 |
| Oncogenes | | | |
| <i>RET</i> | 10q11.2 | Duplication of the mutant <i>RET</i> allele in trisomy 10 or loss of the wild-type allele in MEN2 tumors | 7/9 |
| | | LOH in MEN2 tumors | 0/13 |
| | | Gain at 10q or 10 in sporadic tumors | 2/10 malignant, 3/42 benign |
| | | LOH in sporadic tumors | 2/38 benign, 1/10 malignant |
| | | Somatic mutations in MEN2 tumors | 1/3 |
| | | Somatic mutations in VHL tumors | 0/41 |
| | | Somatic mutations in sporadic tumors | 17/149 benign, 1/29 malignant |
| | | | |
| <i>Ras</i> | 11p15 (<i>H-ras</i>) | Somatic mutations | 0/8 |
| | 12p11 (<i>K-ras</i>) | Somatic mutations | 0/8 |
| <i>GNAS1</i> | 20q13.2 | Somatic mutations | 0/10 |
| <i>EGFR</i> | 7p12 | Overexpression | 4/7 |

^aModified from Koch, Pacak, and Chrousos (2002).

Multiple Endocrine Neoplasia Types 1 and 2

Multiple endocrine neoplasia type 1 (MEN1) is an autosomal dominant tumor syndrome caused by germ-line mutations in the gene *menin* located at chromosome 11q13. Characteristic endocrine tumors occur in the pituitary, parathyroid gland, and pancreas. Genotype–phenotype correlations in patients with germ-line mutations in the MEN1 gene do not exist. Adrenal nodules occur in patients with MEN1 approximately four times more often than in individuals without MEN1, suggesting a pathogenetic link. Pheochromocytomas in patients with MEN1 germ-line mutations have rarely been reported. LOH

at 11q13 in these tumors has been observed in pheochromocytomas.

Multiple endocrine neoplasia type 2 (MEN2) is caused by germ-line mutations in the *RET* protooncogene located at chromosome 10q11.2. It is an autosomal dominantly inherited cancer syndrome and affects approximately 1 in 40,000 individuals. MEN2 is characterized by the presence of medullary thyroid carcinoma, pheochromocytoma, and parathyroid hyperplasia. Approximately 50% of patients with germ-line mutations in *RET* develop a pheochromocytoma during their lifetime. There is a clear genotype–phenotype correlation in patients with MEN2.

Figure 1 Model for tumorigenesis in MEN2-associated pheochromocytomas. In an individual with MEN2, each cell of the target organs (e.g., adrenal medulla) carries a *RET* germ-line mutation in the heterozygous state with one intact wild-type *RET* allele. Selected chromaffin cells undergo a second hit through duplication of the mutant *RET* allele in trisomy 10 or loss of the wild-type allele, giving these cells overrepresentation of mutant *RET* and a growth advantage with subsequent tumor formation. M, mutant *RET* allele; WT, wild-type *RET* allele; C10, chromosome 10. Modified from Koch, Pacak, and Chrousos (2002).

The same germ-line mutation in *RET* may lead to the development of a pheochromocytoma in one patient but not in another patient. Similarly, one patient with MEN2 may develop medullary thyroid carcinoma in the first month of life, whereas another patient with the same germ-line mutation in *RET* may develop medullary thyroid carcinoma at his or her 83rd birthday. It is therefore puzzling how germ-line mutations in *RET* lead to tumor formation in patients with MEN2. Recently, the model of a “second hit” in such patients was introduced. Selected cells in the target organs, such as the chromaffin cells and the C cells of the thyroid gland, may gain a growth advantage by overrepresentation of mutant *RET* by duplication of mutant *RET* in trisomy 10, loss of wild-type *RET*, or tandem amplification (Fig. 1). A subset of MEN2-related pheochromocytomas have somatic *VHL* gene alterations, possibly leading to an overrepresentation of *RET*. LOH at 1p has been reported in some MEN2-related pheochromocytomas, highlighting the developmental relationship between pheochromocytoma and neuroblastoma (neuroblastomas frequently have LOH at 1p). Also, reduced neurofibromatosis type 1 (*NF1*) expression occurs in a subset of MEN2 pheochromocytomas, suggesting a role for the *ras* pathway in tumor formation.

Neurofibromatosis Type 1

Although this inherited tumor syndrome affects 1 in 4000 individuals, pheochromocytomas occur in less than 2% of patients with *NF1*. The *NF1* gene maps

to chromosome 17q11.2 and encodes neurofibromin, which is involved in controlling the *ras* signaling pathway. Mice heterozygous for one mutant *NF1* allele develop pheochromocytoma in 50% of cases. LOH at 17q11 has been observed in a subset of *NF1* pheochromocytomas. Because of the rarity of *NF1*-related pheochromocytomas, there is a lack of larger genetic studies and the molecular pathogenesis of *NF1* pheochromocytomas is largely unknown.

SDHX Syndromes

Pheochromocytomas are also referred to as adrenal paragangliomas (“next to the ganglia”). Paragangliomas can be of sympathetic and parasympathetic origin. Sympathetic paragangliomas are mainly located in the retroperitoneum. Parasympathetic paragangliomas are often located in the neck from the skull base down to the aortic arch. Head and neck paragangliomas usually do not oversecrete catecholamines, whereas those below the neck commonly do. Carotid body paragangliomas develop from the carotid body, a structure that serves as an oxygen-sensing organ. Chronic hypoxia has been shown to be associated with enlargement of the carotid bodies, an observation that drew the attention of investigators to possible genetic defects of the oxygen-sensing and oxygen-signaling pathways. Subsequently, germ-line mutations in the succinate-ubiquinone oxidoreductase subunit D gene (*SDHD*), a gene belonging to the mitochondrial complex II that is involved in the Krebs cycle and in the aerobic electron transport chain, have been identified in extraadrenal pheochromocytomas. Researchers have also analyzed adrenal pheochromocytomas for mutations in *SDHD*. Subsequent investigations on genes encoding for the other three subunits of mitochondrial complex II led to the detection of germ-line mutations in *SDHB* and *SDHC* in patients with hereditary pheochromocytomas. To date, germ-line mutations in *SDHA*, the gene encoding for the flavoprotein, have not been found in adrenal pheochromocytomas or in “paragangliomas.” Of the five mitochondrial complexes (I–V), complex II is the only one with no subunits encoded by the mitochondrial genome. The *SDHD* gene is located at 11q23 and consists of four exons. Mutation analysis in pheochromocytomas has revealed missense and nonsense mutations. *SDHD* encodes for the small (cybS) subunit of cytochrome b in the succinate-ubiquinone oxidoreductase (complex II). Functional analysis revealed that inactivation of cybS by a nonsense mutation (R22X) abolishes the enzymatic activity of mitochondrial complex II and activates the hypoxia pathway (e.g., through increased expression of

VEGF). The *SDHB* gene is located at 1p35–36 and consists of eight exons. Mutation analysis showed inactivating mutations in hereditary pheochromocytomas and paragangliomas. *SDHB* encodes for the iron sulfur protein in the succinate–ubiquinone oxidoreductase (complex II). The *SDHC* gene is located at 1q21 and consists of six exons. Mutation analysis revealed a G-to-A transition in exon 1 in one family with paragangliomas. *SDHC* encodes for the large (cybL) subunit of cytochrome b in the succinate–ubiquinone oxidoreductase (complex II).

Sporadic Pheochromocytomas

Allele losses at 1p, 3p, 3q, 17p, and 22q are commonly found in pheochromocytomas. Their role in tumorigenesis and tumor progression, however, remains unclear. Less than 10% of sporadic pheochromocytomas have somatic mutations in *RET*, *VHL*, *SDHD*, or *SDHB*. Among 91 sporadic pheochromocytomas investigated for *SDHD* mutations, only 1 carried a somatic mutation. Mutation analysis of *SDHB* in 24 sporadic pheochromocytomas revealed only 1 with a germ-line mutation. Mutations in *SDHC* have not been identified.

Notably, apparently sporadic pheochromocytomas may be part of a familial syndrome with germ-line mutations in *VHL*, *RET*, *SDHD*, or *SDHB*. In a recent study of 271 patients, Neumann *et al.* reported up to 24% of such cases. This may justify screening all patients presenting with a pheochromocytoma for germ-line mutations in the previously mentioned genes. Somatic mutations and genetic alterations in other genes, such as *p53*, *NF1*, *RASSF1A*, *c-erbB-2*, and *EGFR*, have been observed in sporadic pheochromocytomas, suggesting a role in the pathogenesis of these tumors. No markers reliably distinguish benign and malignant pheochromocytomas. The only criterion is clinical: the presence of metastases at locations at which there is usually no chromaffin tissue (e.g., liver, bone, and lung). Telomerase expression does not predict malignancy. Clonal analyses of adrenomedullary nodules in patients with a *RET* germ-line mutation suggest that these nodules are monoclonal.

Ganglioneuromas and Ganglioneuroblastomas

Ganglioneuromas are neuroectodermal tumors related to neuroblastoma. Rarely, these tumors occur in the adrenal gland and are entirely benign except for mixed or so-called composite tumors, such as ganglioneuroblastomas. Most neuroblastomas show LOH at 1p36

and have a less favorable prognosis. Ganglioneuromas as mature tumors are not expected to reveal LOH at 1p36. A few tumors have low p53 content. The pathogenesis of these adrenal lesions is unclear.

ADRENOCORTICAL TUMORS

Li–Fraumeni Syndrome

This autosomal dominant familial cancer syndrome is associated with breast cancer, brain tumors, soft tissue sarcomas, leukemia, and adrenocortical carcinoma. Adrenal cancer occurs in approximately 1% of patients with the classic Li–Fraumeni syndrome. Germ-line mutations in *p53* at chromosome 17p13 are responsible for this syndrome and can lead to adrenocortical tumors as the sole manifestation. Frequently, adrenal tumors of patients with germ-line mutations in *p53* show LOH at 17p13 and, therefore, evidence of biallelic inactivation of this tumor suppressor gene (Table II).

Beckwith–Wiedemann Syndrome

This syndrome shows variable expressivity and occurs sporadically. Affected patients are at increased risk for developing adrenal cancer. The gene locus is at 11p15.5, a chromosomal region that includes the *IGF2* and the *p57/KIP2* genes. p57 is a negative regulator of cell proliferation and inhibits G1 cyclin/cyclin-dependent kinase (CDK) complexes. Adrenocortical tumors in this syndrome show overexpression of *IGF2*, probably related to uniparental paternal isodisomy for the *IGF2* locus. Duplication of the paternal 11p15 allele containing the *IGF2* gene locus and/or loss of the maternal allele are frequently found in adrenal cancer. This is in contrast to adrenocortical lesions that are classified as benign and frequently do not demonstrate overexpression of *IGF2*.

Carney Complex

First described in 1980, this autosomal dominant hereditary syndrome comprises primary pigmented nodular adrenocortical disease, growth hormone-secreting pituitary tumors, spotty skin pigmentations, atrial and peripheral myxomas, and psammomatous melanotic schwannomas. Adrenocortical disease occurs in approximately 26% of patients with this complex. At least two chromosomal loci have been identified: 2p16 and 17q22–24. A subset of patients with Carney complex have germ-line mutations in

Table II Genetic Alterations in Adrenocortical Tumors^a

| Gene | Chromosomal location | Gene alteration | Prevalence (tumors) |

^aModified from Koch, Pacak, and Chrousos (2002).

PRKARIA, a gene that encodes protein kinase A regulatory subunit 1 α .

Multiple Endocrine Neoplasia Type I

Approximately 35% of patients with MEN1 have adrenal nodules, most of which are adrenocortical. LOH at 11q13, the *menin* locus, has been identified in some adrenocortical tumors, but the precise pathogenesis of adrenal lesions in patients with MEN1 remains obscure.

Familial Hyperaldosteronism

Hyperaldosteronism can occur in at least two familial syndromes: familial hyperaldosteronism type 1, caused by the formation of a hybrid gene with fusion of the corticotropin-regulated promoter of the 11 β -hydroxylase gene and the angiotensin II-regulated aldosterone synthase gene at 8q24, and familial hyperaldosteronism type 2, which does not respond to dexamethasone administration by decreasing corticotropin (ACTH) secretion and whose responsible gene is linked to chromosomal subband 7p22 but is still unidentified. The molecular pathogenesis of adrenal nodule development in patients with hyperaldosteronism is unknown.

Congenital Adrenal Hyperplasia

Almost all patients with this autosomal recessive disorder have germ-line mutations in the gene coding for 21-hydroxylase at 6p21.3. This genetic defect leads to impaired cortisol secretion with subsequent elevation of ACTH. Almost half of heterozygous carriers have macronodular adrenal disease, the rationale basis for investigators to search for mutations in the 21-hydroxylase gene in patients with apparently sporadic adrenal tumors. How these adrenal nodules develop remains unknown.

McCune–Albright Syndrome

This syndrome is a sporadic postzygotic genetic disease that includes growth hormone-secreting pituitary adenomas and nodular adrenocortical disease. Somatic mutations in the α chain of the stimulatory G protein *GNAS1* at 20q13.2 are responsible for this syndrome and result in stimulation of cAMP. Mutations in the cAMP inhibitory *GNAI2* gene occur in only a few adrenocortical tumors. The precise

mechanisms of adrenal nodule formation are unknown.

Ectopic G Protein-Coupled Receptors

Aberrant expression of ectopic membrane hormone receptors, including gastric inhibitory polypeptide, β -adrenergic agonists, luteinizing hormone, vasopressin, and interleukin-1, has been found in some adrenal adenomas but not in adrenal cancer.

Sporadic Tumors

Cell replication errors may lead to numerical changes of chromosomes, chromosomal translocations, amplification and/or loss of genes, somatic sequence alterations in specific genes including DNA repair genes, and other genomic changes. An important step in analyzing adrenal and other tumors is to determine whether they are mono- or polyclonal. The cellular origin of adrenocortical tumors is unknown, although clonal analyses of adrenal cortex lesions have helped better define the nature of these tumors. Usually, the development of cancer and tumors in general is regarded as a multistep process. One tumor-initiating mutation in a single cell may equip the cell with a selective growth advantage, enabling it to become a tumor. This tumor would then be called monoclonal since it derived from a single genetically aberrant cell. In contrast, a polyclonal tumor would develop from a group of aberrant cells arising in parallel. Only one of three studies on the clonal analysis of adrenocortical tumors noted the duration of follow-up for patients with benign adrenal adenomas/hyperplasias, even though this feature is important because differences in the rate of growth may distinguish benign from malignant adrenocortical tumors. It appears that adrenocortical carcinomas are monoclonal, whereas the majority of benign adrenocortical lesions are polyclonal. It can be speculated that tumorigenesis develops from polyclonal adrenocortical cell aggregates, some of which gain a selective growth advantage, giving rise to a monoclonal tumor. However, considering the issues of clonality interpretation, it is unclear whether a clonality assay helps differentiate benign and malignant adrenocortical lesions.

Comparative genomic hybridization (CGH) studies and allele typing using microsatellite markers to detect involvement of genes with tumor suppressor or oncogenic function may help in elucidating the pathogenesis of adrenocortical tumors. Studies on adrenocortical tumors must be considered carefully because

many investigators do not refer to a specific follow-up time; the natural history is important in classifying an adrenocortical tumor as benign or malignant. Sidhu *et al.* reported an equal distribution of chromosomal gains and losses in benign and malignant adrenocortical tumors, although the genetic events in both groups were quite different. Limitations of this study are the classification of benign vs malignant tumors, which was not based on the presence of metastases but rather on modified Weiss histologic criteria, and the variable follow-up period for the group of benign tumors, which was up to 41 months. These investigators analyzed 18 benign and 13 malignant adrenocortical tumors. Benign adrenal masses <5 cm frequently had gains in chromosome 4, whereas malignant (>5 cm) adrenal tumors had gains in chromosomes 5, 12, and 19. Losses in the benign group were limited to chromosome 3q, whereas they occurred at chromosomes 1p, 11, 17p, and 22 in the malignant group. This is in contrast to earlier CGH studies showing gains at chromosome 4 mainly or exclusively in malignant tumors. Sidhu *et al.* proposed activation of a protooncogene on chromosome 4 as an early event in adrenocortical tumorigenesis and that the presence of four or more CGH alterations in one tumor is suggestive of the malignant phenotype.

To elucidate the pathogenesis of adrenocortical tumors, the precise definition of adenoma vs carcinoma is of utmost importance, as is the identification of precursor lesions. Without this critical information, it is difficult to determine the sequence of events from tumor initiation to progression. The assumption that putative oncogenes at regions of chromosomal gain represent the first step in tumor development, and regions of chromosomal loss represent putative tumor suppressor genes allowing subsequent steps of tumor progression, may seem plausible to many investigators but it is speculative.

Candidate genes believed to be involved in tumor formation of sporadic adrenal tumors are those that are known to be associated with hereditary tumor syndromes, such as *p53*, *GNAS1*, *MEN1*, and *IGF2*, and genes and receptors involved in signal transduction systems. Mutations or other genetic alterations in the angiotensin II type 1 receptor and corticotropin receptor gene have rarely been found. Biallelic inactivation of the *MEN1* gene in sporadic adrenocortical tumors has not been identified, although either somatic mutation in *MEN1* or LOH at its locus 11q13 have been reported.

The roles of *IGF2*, *H19*, and *p57/KIP2*, all located at 11p15, in the pathogenesis of adrenocortical tumors were previously mentioned. Overexpression

of *IGF2* is frequently found in malignant sporadic adrenocortical tumors. Genetic alterations in *p57/KIP2* (CDK inhibitor 1C) were sought in adrenocortical tumors because adrenal cancers frequently showed allelic loss at 11p15. However, no somatic mutations were found in this gene in 75 sporadic adrenocortical tumors, but low *p57/KIP2* expression was demonstrated in 3 of 10 adrenal adenomas and 6 of 6 carcinomas. Reduced or absent function of this gene seems to lead to enhanced activity of G1 CDK complexes with possibly subsequent promotion of cell proliferation. Consequently, investigators examined adrenocortical tumors for abnormalities in other inhibitors of CDKs. One such protein, P16, whose gene is located at 9p21, is an inhibitor of the *CDK 2A* gene. One of 7 benign and 3 of 7 malignant adrenocortical tumors showed loss of one *p16* allele and absent p16 protein by immunohistochemistry. P21, a CDK inhibitor that can be induced by p53, was overexpressed in 70% (25/38) of adrenocortical cancer samples. Downregulation of *p21*, however, did not affect the prognosis of patients with adrenal cancer. This suggests a role for these CDK inhibitors in only a small subset of adrenocortical cancers.

In addition to IGF2, epidermal growth factor (EGF) is very important. Its receptor, EGFR, has been studied in a small number of adrenal tumors. By immunohistochemistry, EGFR was overexpressed in benign and malignant adrenocortical tumors, whereas EGF was not detected. Instead, transforming growth factor- α (TGF- α) was overexpressed in adrenal cancer. TGF- α is a natural ligand for EGFR.

The *p53* gene has been studied in many tumors, including adrenocortical tumors, because of its frequent mutation in cancers and its known role in regulating the cell cycle. *p53* has been classified as a tumor suppressor gene and is mutated in the germ line of most patients with Li-Fraumeni syndrome. Since this syndrome is associated with adrenocortical tumors, it is conceivable that *p53* may also play a role in the pathogenesis of sporadic adrenal tumors. Although allelic loss at 17p13, the locus for the *p53* gene, and somatic *p53* mutations frequently occur in adrenal cancer, they are uncommon in benign adrenocortical tumors, suggesting that genetic alterations in *p53* are involved in tumor progression rather than initiation. Only one study from Taiwan reported *p53* mutations in adrenocortical adenomas, but the classification of benign vs malignant adrenal tumors, including the follow-up period of the affected Taiwanese patients, remains unclear. In contrast, *p53* mutations (predominantly in exons 5–8) were reported in up to 70% of adrenal cancers. However, it is unknown whether

biallelic inactivation of *p53* occurred in these tumors since investigators reported either allelic loss at 17p13 or somatic *p53* mutations and not whether both events (biallelic inactivation of *p53*) took place in the respective tumor. Nevertheless, LOH at 17p13 has been suggested as a molecular prognostic marker for sporadic adrenocortical tumors.

The *ras* gene family encodes G proteins, which are involved in signaling pathways through modification of intracellular cAMP concentrations. Overexpression of *ras* may lead to constitutive signal transduction and/or cell proliferation. *ras* mutations were first identified in 12.5% of adrenocortical tumors with an equal prevalence in benign and malignant tumors. A subsequent study reported somatic *K-ras* mutations and an overexpression of *K-ras* in 33% of benign adrenocortical tumors, whereas somatic *H-ras* mutations were not detected. However, previous studies did not find this prevalence rate of *ras* mutations.

The *RET* protooncogene at chromosome 10q11.2 encodes a tyrosine kinase receptor that is involved in the control of cell differentiation and proliferation. Germ-line mutations in *RET* are found in almost all patients with MEN2. Importantly, *RET* is only expressed in certain tissues, such as the neural crest-derived parafollicular C cells in the thyroid gland and extra- and intraadrenal chromaffin cells. Overrepresentation of mutant *RET* may initiate tumorigenesis of medullary thyroid carcinoma and pheochromocytoma. Although adrenocortical tumors are not part of MEN2, they may have genetic alterations involving *RET*. Analysis of 21 sporadic adrenocortical tumors revealed 1 aldosterone-producing tumor with a point mutation in *RET* and *RET/PTC1* rearrangements in 2 tumors—one cortisol-producing and one aldosterone-producing.

Telomerase is the ribonucleoprotein enzyme that elongates telomeres (i.e., chromosomal DNA ends). In most normal somatic cells, telomerase is repressed, whereas this enzyme is reactivated in transformed cells. Recently, a considerable amount of data have been obtained on telomerase activity in human cancers, including endocrine tumors. In general, the presence or absence of telomerase activity in adrenocortical tumors does not seem to be a prognostic marker, although some studies suggest that malignant adrenal tumors have increased telomerase activity.

CONCLUSION

Most adrenal tumors are sporadic and associated with numerous somatic genetic alterations. The exact

order and time frame of these genetic events are difficult to determine. Therefore, one cannot make precise statements about the pathogenesis of tumor initiation and tumor progression. Identifying reliable genetic prognostic markers is also a challenge and strongly depends on the follow-up period of patients with adrenal tumors that are classified as benign or malignant. Focusing on adrenal tumors that occur in hereditary syndromes may facilitate the determination of their pathogenesis since in these adrenal masses at least one genetic hit, the inherited gene defect, is known. Subsequent genetic alterations may then be easier to place into context. In MEN2-associated pheochromocytomas, a second hit model leading to overrepresentation of mutant *RET* as a possible tumor-initiating event has been proposed. Somatic mutations in genes that are known to be involved in hereditary syndromes, such as *p53*, *VHL*, and *RET*, are rarely found in sporadic adrenal tumors. Future studies should focus not only on single genes and genetic alterations but also on the interaction of their encoded protein products.

Adrenarche, Premature

Catherine Dacou-Voutetakis, Sarantis Livadas, Antony Voutetakis, and Maria Dracopoulou
Athens University Medical School, Aghia Sophia Children's Hospital, Athens, Greece

Glossary

adrenarche Initiation of function of the reticular zone of the adrenal gland.

congenital adrenal hyperplasia A disorder resulting from enzymatic defects in the pathway of cortisol synthesis.

CYP21 A gene encoding the steroidogenic enzyme 21-hydroxylase.

gonadarche Initiation of function of the hypothalamic-pituitary-gonadal axis.

premature pubarche The appearance of pubic hair, with or without axillary hair growth or increased apocrine odor, in the absence of other secondary sexual characteristics, occurring prior to age 8 in girls and age 9 in boys.

Premature adrenarche refers to the premature activation of the zona reticularis of the adrenal gland, clinically manifested by pubic hair development.

INTRODUCTION

Although more than 60 years have elapsed since the endocrinologist F. Albright coined the term adrenarche, the mystery of the mechanisms involved in its development has not yet been unraveled. In studying girls with gonadal dysgenesis, a natural experimental model of gonadism, Albright observed that pubic hair can develop under the influence of adrenal androgens and in the absence of gonadal hormones. He was thus the first to distinguish between gonadal and adrenal puberty (gonadarche and adrenarche, respectively). Subsequent studies of other clinical prototypes, including hypogonadotropic hypogonadism and isolated premature thelarche, confirmed his observation. Dissociation between adrenal androgens and cortisol secretion has also been documented by demonstrating that a rise in dehydroepiandrosterone

sulfate (DHEAS) during puberty is not accompanied by a rise in cortisol. Moreover, the rise in adrenocorticotropic hormone (ACTH) and cortisol in Cushing's syndrome occurs without an analogous increase in DHEAS.

ADRENARCHE

Definition

Adrenarche refers to the activation of the zona reticularis (ZR) of the adrenal gland, biochemically marked by a rise in dehydroepiandrosterone (DHEA) and DHEAS but not in other androgens. The clinical manifestation of adrenarche is termed pubarche and is characterized by the development of pubic hair with or without axillary hair growth or apocrine odor. The decline in the function of the ZR, later in life, is termed adrenopause.

Phylogenetic Data on Adrenarche

Adrenarche and adrenopause appear to be phenomena that are unique to the highest order of primates and, therefore, represent a recent evolutionary development. The serum levels of DHEA, DHEAS and Δ_4 -adrostenedione (Δ_4 A) remain unchanged during sexual maturation in rats, hamsters, guinea pigs, sheep, pigs, goats, horses, and cows. Modest (twofold) changes in DHEA are observed in rabbits and dogs only after their sexual maturation. In primates, the phenomenon of adrenarche is observed only in the chimpanzee and not in other types (e.g., the rhesus monkey).

Ontogenetic Data on Adrenarche

During the fifth gestational week, cells from the celomic epithelium migrate to the cephalic part of the mesonephros and form the distinct adrenal primordium. The central part of this primordium consists of large, eosinophilic cells that constitute the so-called

fetal zone, whereas the outer zone consists of densely packed cells that form the definitive zone. By the second trimester of pregnancy, the fetal zone of the human adrenal cortex represents approximately 80–90% of the fetal adrenal. In the fetal zone, CYP11A and CYP17 [but not 3 β -hydroxysteroid dehydrogenase (3 β -HSD)] and dehydroepiandrosterone sulfotransferase are expressed. The adult ZR, which also lacks 3 β -HSD and expresses dehydroepiandrosterone sulfotransferase activity, is considered the equivalent of the fetal adrenal zone (Fig. 1). During the third trimester of pregnancy, the definitive zone of the fetal adrenal forms two, functionally separate units: the outer unit is the zona glomerulosa and the inner unit comprises the zona fasciculata and the ZR (Fig. 1). It must be underscored that the cortisol- and androgen-producing parts of the adrenal and the adrenal medulla are related ontogenetically, anatomically, and functionally, suggesting a possible link between adrenomedullary function and adrenarche.

Postnatal Development of the Reticular Zone

During the first postnatal months in humans, the fetal zone regresses and almost disappears. Focal islands of the ZR are noted in the adrenals at the age of 3 years and a continuous ZR starts to develop at the age of 6, an age at which adrenal C₁₉ steroids begin to rise. Adrenarche is initiated at approximately age 6 in girls and approximately age 7 in boys and this is reflected in a gradual rise of the adrenal androgens DHEA and DHEAS. The driving force of these evolutionary events has not been determined.

The serum levels of DHEA and DHEAS start to rise approximately 2 years prior to the gonadal

activation (gonadarche), reaching their peak values at 20–25 years. Thereafter, the serum concentrations of the adrenal androgens gradually decline and in elderly people are 10–20% of those encountered in young adults (adrenopause). The DHEAS reduction in the elderly is coupled with a decrease in the width of the ZR without any impact on the size of the rest of the adrenal cortex. The values of cortisol and aldosterone do not show analogous changes. This observation strongly indicates that the events described are unique to the ZR. Some of the mechanisms involved in these alterations of the ZR are outlined herein. A histological study of adrenal samples from individuals between the ages of 4 months and 56 years showed a decrease in the enzymatic activity of 3 β -HSD in the ZR, beginning at the age of 8–13 months with a further progressive decline up to the age of 25–26 years. Longitudinal clinical data obtained from subjects aged 2.9 to 12.3 years have demonstrated a progressive, age-related increase in the DHEAS values (approximately 22% per year) in parallel with an increased activity in 17,20-lyase and a decreased activity in 3 β -HSD (an enzymatic profile encountered in both the fetal and the adult reticular zones). These changes are already evident at the pre-adrenarcheal stage of development. It can thus be deduced from this study that adrenarche is not the result of a sudden change in the activity of adrenal enzymes, at a particular period of time; it rather reflects a gradual maturational process that begins in early childhood. When controlled for chronological age, no association between weight, body mass index (BMI), and DHEAS (a marker of adrenarche) was evident. Nevertheless, changes in the nutritional status, measurable by changes in BMI, have been suggested as an important physiological regulator of adrenarche.

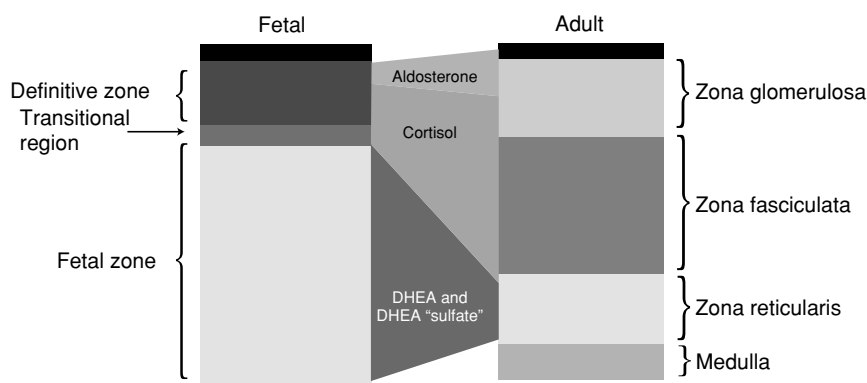

Figure 1 The zones in the fetal and adult adrenal gland. Modified from *Topical Endocrinology* 21, p. 18, with permission of the publisher.

Origin, Regulation, and Biological Significance of Adrenarche

Origin and Regulation

The extra- or intra-adrenal factors involved in the development and function of the ZR have not yet been fully elucidated. It has long been postulated that a distinct pituitary factor [adrenal androgen-stimulating hormone (AASH)] conducts the development and function of the ZR, but this factor has not been isolated.

Studies of natural human models have provided valid data on the putative developmental and/or functional factors that influence the ZR. Among these models are anencephalic fetuses, patients with congenital adrenal hypoplasia (ACTH receptor defect), combined pituitary hormone deficiency, hypogonadotropic hypogonadism, or isolated premature thelarche, and subjects with precocious gonadarche on gonadotropin-releasing hormone analogue (GnRH_a) suppression. The study of adrenal androgens in these models suggests that DHEA and DHEAS synthesis and secretion are dependent on an intact corticotropin-releasing hormone (CRH)–ACTH axis, not only later in life but also in the latter part of pregnancy. It is most probable that the CRH–ACTH complex exerts a permissive effect and acts in synergy with a putative extra-adrenal factor to successfully orchestrate the development and function of the ZR.

An interesting model in which low DHEAS levels have been detected, despite the normal ACTH–adrenal axis, is the pituitary insufficiency associated with the Prop1 gene defect. The low level of DHEAS in these patients may indicate that the pituitary transcription factor Prop1 is necessary for the normal synthesis of the putative factor (AASH) that initiates adrenarche. Alternatively, the low DHEAS level in patients with the Prop1 gene defect could simply represent an early marker of incipient ACTH insufficiency, which is known to occur later in life in a number of these patients.

In addition to CRH–ACTH and the putative AASH, other extra-adrenal factors have been implicated in the development and function of the ZR: prolactin, estrogens, the epidermal growth factor, angiotensin, gonadotropins, proopiomelanocortin-related peptides, growth hormone (GH), insulin growth factor-I (IGF-I), insulin, and possibly adipose tissue factors. None of these factors, however, have been conclusively shown to regulate androgen secretion by the adrenal gland.

Age-related alterations in the expression of the adrenal enzymes have also been proposed as a mechanism

for the development and function of the ZR (intra-adrenal factors). These changes not only refer to the relative activity of the adrenal enzymes but also to their responsiveness to ACTH. Specifically, the increase in 17-hydroxylase and 17,20-lyase activity occurs along with a decrease in 3 β -HSD activity, primarily evident in the developing ZR. It must be stressed, however, that these biochemical changes alone cannot fully explain the initiation of adrenarche.

Biological Significance of Adrenarche

Since a human model of isolated absence of the ZR has not thus far been identified, the exact biological role of the ZR and the implications of its absence or insufficiency still remain enigmatic.

A small, transient increase in growth rate occurring at approximately age 7 (midchildhood growth spurt) has been attributed to the initiation of adrenarche. However, a cause and effect relationship between adrenarche and the midchildhood growth spurt has been disputed. It has also been shown that adrenarche is not a sine qua non for gonadarche since gonadal puberty proceeds normally in clinical entities in which adrenarche is absent.

The decline of DHEA coincides with signs of aging and has therefore been interpreted to indicate that aging is, at least in part, a DHEA deficiency syndrome. This observation has prompted studies on the effect of DHEAS replacement in the elderly and in young subjects with DHEAS deficiency of various etiologies, with equivocal results.

PREMATURE ADRENARCHE–PUBARCHE

Definitions

Premature adrenarche (PA) and premature pubarche (PP) are frequently used interchangeably. Nevertheless, they are not synonymous. PA refers to premature activation of the ZR of the adrenals and is marked by levels of DHEA and DHEAS that are high for the chronological age (CA) but appropriate for the stage of pubic hair development. PP is the term applied to characterize the clinical expression of PA, namely, the appearance of pubic hair, usually at the labiae, with or without axillary hair growth or increased apocrine odor, in the absence of other secondary sexual characteristics, prior to age 8 in girls and 9 in boys. This age cut-off point has been called into question but is still accepted. PP occurs more frequently in girls than in boys, with a male to female ratio of 1/5 to 1/10, for no apparent reason.

The term “exaggerated adrenarche” has been coined to describe a form of PP in which androgen levels, basal or post-ACTH stimulation, are above those expected for the stage of pubic hair development.

Etiology of Premature Pubarche

Premature pubarche may be caused by: (1) premature activation of the ZR without any apparent pathological condition (idiopathic), (2) congenital adrenal hyperplasia (CAH), (3) virilizing adrenal or ovarian tumor, and (4) increased end-organ sensitivity to androgens.

In idiopathic PP, increased BMI or a sudden rise in BMI may constitute a trigger factor for its induction. Nevertheless, BMI and leptin levels only partially explain the increased DHEAS values. The GH-IGF-I axis and especially hyperinsulinism, as a consequence of insulin resistance, have been implicated in androgen production by the ZR and generally in the mechanism of PP initiation.

The most frequent pathological condition underlying PP, and the one usually creating diagnostic dilemmas, is defective adrenal steroidogenesis and, in particular, nonclassical CAH (NC CAH). This aspect of PP has been quite controversial. Based on the determination of basal and ACTH-stimulated adrenal androgen levels, defective steroidogenesis, indicative of the NC CAH (caused by 21-hydroxylase or 3 β -HSD deficiency), ranges from 0 to 54% in the various published series. These huge differences are probably due to the variety of criteria used for recruitment and evaluation of the subjects participating and, most important, in the lack of confirmation by molecular analysis. In a study by Dacou-Voutetakis and Dracopoulou, 48 consecutive cases of PP were evaluated by molecular analysis of the CYP21 gene as well as by basal and ACTH-stimulated 17-OH progesterone (17OHP) values. A significantly increased incidence of mutations in the CYP21 gene was detected in PP children in comparison to the general population (heterozygous 37.5% and homozygous 8.3%). The 17OHP values on the ACTH test showed an overlap between carriers and noncarriers. The application of the receiver operating curve (ROC) curve in this study showed that the sum of the basal plus 60 min value of 17OHP was the best indicator of heterozygosity. For children over the cut-off point of 5 ng/ml (15 nmol/liter), there is a 76.5% certainty of heterozygosity for a CYP21 mutation. By using the nomogram proposed by New *et al.*, the heterozygote's values fell in the expected area, but this was also the case for the majority of normal values. A value of 17OHP 60 min post-ACTH stimulation equal to or greater than 10 ng/ml

(30 nmol/liter) was indicative of a homozygous mutation and occurred in 8.3% of the cases. The latter finding is accepted by most investigators. An increased incidence of CYP21 heterozygosity in either PP or functional hyperandrogenism in adolescents has also been reported by Witcell *et al.* and has been postulated by Knorr *et al.*, based on hormonal evaluation. Contrary to these findings, Potau *et al.* did not find higher incidence of CYP21 carriers in Spanish subjects with a history of PP. It is not possible to determine whether or not PP CYP21 heterozygote subjects have a higher probability of manifesting hyperandrogenism and the clinical syndrome related to this entity than PP girls who are not CYP21 carriers. Only a long-term follow-up study of such cases will provide a definitive answer to these important questions. Mutations in the 3 β -HSD gene have also been detected in girls with PP, though infrequently. The new hormonal criteria for the diagnosis of 3 β HSD deficiency in children with PP are as follows: (1) baseline 17OH pregnenolone (17P) and 17P/cortisol ratio >29 nmol/liter and >103, respectively, and (2) ACTH-stimulated 17P and 17P/cortisol ratio >294 nmol/liter and >363, respectively.

Androgen-producing tumors of the adrenals or ovaries are rarely a cause of PP, but they should be considered in the differential diagnosis.

Finally, in some children with PP, no androgen excess for either CA or pubertal stage is detected and the pubic hair growth is attributed to increased end-organ sensitivity to androgens.

Long-Term Consequences of Premature Adrenarche–Pubarche

Growth and Pubertal Development

At presentation, children with PP show an acceleration of linear growth and skeletal maturation. In some children, the difference between their bone age (BA) and CA (Δ BA–CA) can be up to 2 years, whereas in others the BA is comparable to CA. Long-term follow-up of children with PP has not shown impaired growth potentials: the final height (FH) attained is comparable to target height (TH). It seems that the linear growth pattern in children with PP is modified in that height velocity in the period preceding PP diagnosis is higher than that of controls, peak height velocity occurs at an earlier age, and growth during puberty is compromised. Despite reports indicating good FH prognosis, the physician must individualize the approach for each child with PP and closely watch patients with so-called “exaggerated adrenarche” and/or those who have BA advancement greater than 1

year, for the possibility of an unfavorable effect of PP on growth potentials, namely, a predicted height below the TH. The age of gonadarche and menarche in children with PP is not different than in the general population.

Functional Ovarian Hyperandrogenism and Polycystic Ovary Syndrome

In a percentage of girls with PP, functional ovarian hyperandrogenism (FOH) (excessive response of androgens to GnRH α), along with an increased incidence of anovulation, hirsutism, and menstrual irregularities [characteristics of polycystic ovary syndrome (PCOS)], has been reported to occur already in late adolescence. It seems that girls with an exaggerated response of 17OHP to ACTH at the time of PP diagnosis are more likely to develop FOH and/or PCOS.

Insulin Resistance, Hyperinsulinism, and the Metabolic Syndrome

Acanthosis nigricans, decreased insulin sensitivity and consequent hyperinsulinism, and dyslipidemia have been found in a number of girls with PA. Pertinent data in boys are inconsistent. In certain studies, the hyperinsulinemia is already evident at the prepubertal stage, possibly conferring a higher risk for later development of diabetes mellitus type 2 (DM2). Contrary to the above findings, other investigators found no differences in glucose tolerance, insulin resistance indices, or lipid values between PP girls and control girls studied 5 years after menarche. It is quite possible that the stated differences reflect differences in the population (ethnic) groups studied and this must be seriously considered in the study and follow-up of PP girls. The contribution of intrauterine growth retardation to the occurrence of later adverse consequences, and especially FOH in girls with PP, is highly controversial and most authors have not found such an association.

Does PA Represent a Pathologic Condition?

The question of whether or not PP is a benign condition, simply reflecting premature activation of the ZR without long-term adverse consequences, cannot be convincingly answered yet. A number of girls with PP later present insulin resistance and hyperinsulinism, low sex hormone-binding globulin (SHBG), FOH, increased hirsutism, acne, or polycystic ovary-like syndrome with possible later occurrence of DM2 or the metabolic syndrome. Pertinent data in boys are not consistent.

No specific features at PP diagnosis have yet been identified to predict the child at risk of developing these pathological entities. Nevertheless, it seems that some of the late consequences are, to a large extent, restricted to certain population (ethnic) groups. In addition to ethnic group, other factors, such as obesity and a family history of DM2, might contribute to the occurrence of adverse consequences. Exaggerated adrenarche as well as low SHBG (an index of insulin resistance and free androgen levels) and glucose/insulin ratio <4.5 at the time of PP diagnosis might confer a higher risk for the later development of FOH and/or the metabolic syndrome in children with PP.

Evaluation, Management, and Follow-up of the Child with PP

Clinical Evaluation

The clinical evaluation of the child with PP at presentation should include measurements of height, weight, waist circumference, BMI estimation, BA determination, and recording of relevant family history. Predicted height, TH, and the stage of pubertal development should also be assessed. The presence of acne, hirsutism, or virilization (clitoral enlargement) should be noted. If $\Delta\text{BA}-\text{CA}$ is less than 1 year and the predicted height falls within the height range expected from parental height (TH), the possibility of isolated premature activation of the ZR is quite high (Fig. 2).

Hormonal Determinations

If basal values of 17OHP, Δ_4 -androstenedione, testosterone, and DHEAS taken at 8 AM fall into the range expected for the pubic hair developmental stage, the diagnosis of idiopathic PP is fairly well confirmed. If basal adrenal androgen levels are higher than the levels for the corresponding pubertal stage and are accompanied by advanced BA ($\Delta\text{BA}-\text{CA} > 1$), the main possibilities are as follows: (1) exaggerated adrenarche, (2) defective adrenal steroidogenesis, or (3) virilizing tumor (adrenal or ovarian). In such cases, an intravenous Synacthen test (ACTH) is carried out (250 μg , 150 $\mu\text{g}/\text{m}^2$, or 10 $\mu\text{g}/\text{m}^2$, the last dose being infrequently used). Blood samples, primarily for 17OHP determination, are obtained at 0 and 60 min. A 60 min value of 17OHP >10 ng/ml strongly suggests a homozygous mutation of the CYP21 gene (NC form) and CYP21 gene analysis should be considered (Fig. 3). There is a 75% probability of existence of heterozygosity if the sum value of 0 and 60 min post-Synacthen is >5 ng/ml (15 nmol/liter). Obviously, the latter information is of no immediate practical significance and may be of value only for genetic

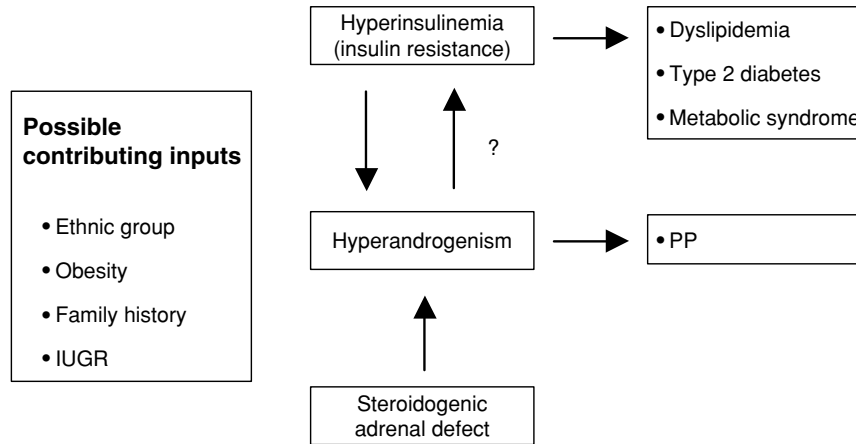

Figure 2 Possible pathogenetic mechanisms of premature pubarche (PP). IUGR, intrauterine growth retardation.

counseling. Determination of glucose/insulin value, SHBG, and ovarian sonography might constitute a good baseline record but should not be regarded as necessary diagnostic tools. It must be stated that an increased prevalence of sonographic findings of PCOS has been reported in girls with PP at the prepubertal stage, but the diagnostic and prognostic value of such a finding remains unclear. The dexamethasone suppression test or some form of imaging

study is rarely indicated for the remote possibility of a virilizing tumor. This latter possibility is much higher if pubarche occurs very early and there is an increased level of serum testosterone.

Management and Follow-up

The therapeutic approach for children with PP will be determined by the pathogenetic mechanism involved and the clinical findings. In most cases, however, drug

Clinical and laboratory data

Diagnostic possibilities

$\Delta BA-CA < 1$ year
 Predicted height within target → High probability of idiopathic PP

DHEAS, $\Delta 4A$, testosterone, 17OHP: Basal values

- Within normal limits for CA → Increased end-organ sensitivity
- Within the range of pubertal stage → Idiopathic PP

- Above the values for pubertal stage and $\Delta BA-CA > 1$

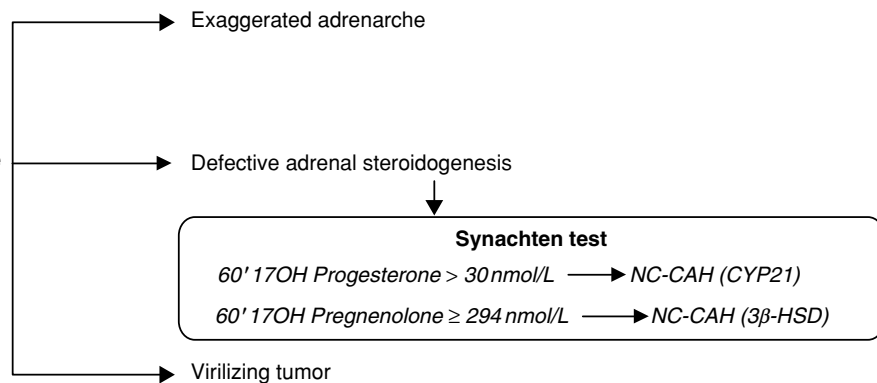

Figure 3 Premature pubarche (pp): diagnostic steps.

intervention is not required. A follow-up of children with PP must be assured, especially during puberty and the immediate postpubertal years. In general, both the child and the parents should be made aware of the good prognosis of most patients. Instructions concerning dietary habits and exercise should be given in cases with borderline or elevated BMI or a positive family history of DM2.

The physician should be aware of the possible long-term consequences of PP and should individualize the care and follow-up, keeping in mind that PP, in certain cases, might not represent an innocent temporal deviation of sexual maturation but, possibly, an early manifestation of a complex metabolic abnormality. Fasting glucose/insulin ratio <4.5, low SHBG values, and exaggerated adrenarche might constitute early markers conferring an increased risk for later development of FOH, PCOS, DM2, or the metabolic syndrome. However, it must be underscored that such recommendations are not strictly evidence based; rather, they constitute extrapolation from still controversial published data. Moreover, data related to long-term consequences seem to apply to certain population (ethnic) groups. The physician in charge, being aware of the trends concerning prognosis of PP, will determine the diagnostic studies necessary at presentation of the patient, as well as the frequency and duration of the follow-up visits.

Adrenergic Mechanisms

José Marino-Neto, Marcelo Sabi, and Marta Aparecida Paschoalini
Federal University of Santa Catarina, Florianópolis, Brazil

Glossary

energy balance A dynamic matching of bodily demands and supplies of metabolic fuels (e.g., glucose [GLU], free fatty acids [FFAs]); this balance is accomplished by a variety of internally and externally generated signals processed by numerous, redundant, and widely distributed central and peripheral circuits controlling feeding behavior, cellular energy metabolism, and the stored and circulating GLU/FFA levels.

glucoprivic state A state of diminished intracellular metabolism of glucose [GLU] that may be produced by (1) a reduction in circulating GLU levels, (2) reduced access of circulating GLU to the intracellular metabolic machinery, or (3) agents that compete with GLU metabolic pathways (thereby inhibiting cellular GLU use) such as 2-deoxy-glucose (2-DG) and 5-thio-D-glucose (5-TG); systemic or central injections of these agents produce glucoregulatory responses (hyperglycemia and feeding) in mammals.

Adrenergic systems (ASs) are neural and endocrine circuits that use epinephrine (adrenaline [EPI]) and/or norepinephrine (noradrenaline [NE]) as neurotransmitters. The ASs include (1) EPI- and NE-producing neurons in the central nervous system (CNS-AS), (2) NEergic postganglionic sympathetic neurons, and (3) EPI- and NE-producing cells of the adrenal medulla. These systems play critical roles in mechanisms coordinating homeostatic responses to environmentally and systemically generated challenges.

INTRODUCTION

The catecholamines norepinephrine (noradrenaline [NE]) and epinephrine (adrenaline [EPI]) have been identified as neurotransmitters crucially involved in the control of cognitive, emotional, arousal, and memory processes. In addition, they have a role in reproductive, aggressive, and ingestive activities; in pain regulation; and in thermal, energetic, cardiovascular, and osmoregulatory functions. The

postganglionic sympathetic neurons and adrenal adrenergic systems (ASs) constitute the major effector mechanisms that elicit rapid visceral/metabolic adjustments in response to homeostatic challenges, originated internally or externally, that prepare the organism to engage in energetically demanding behaviors. Central nervous system (CNS)-ASs are crucially involved in the integration of viscerosensory information and in the coordination of neuroendocrine, autonomic, and behavioral responses to these challenges. This article concentrates on some of the neuroanatomical and neurophysiological information relevant to the role of CNS-ASs in mechanisms controlling energy balance.

CENTRAL ADRENERGIC PATHWAYS: NEUROANATOMICAL OUTLINE

Simultaneous immunoreactivity for tyrosine hydroxylase (TH), the first and rate-limiting enzyme in the catecholamine synthetic pathway, and for phenylethanolamine-N-methyltransferase (PNMT), the enzyme that converts NE into EPI, has been used to identify EPI-synthesizing cells, whereas the absence of PNMT in cells that express TH and dopamine β -hydroxylase (DBH, which converts dopamine into NE) identifies NE-synthesizing neurons. During the past two decades or so, P. E. Sawchenko and colleagues have shown that important adrenergic influences on neuroendocrine/autonomic functions are originated in (1) brainstem NE-synthesizing cell groups referred to as A1, A2, and A5, located in the caudal ventrolateral medulla (cVLM), the nucleus of the solitary tract (NTS), and the ventrolateral pons, respectively, and (2) in EPI-synthesizing neurons that are found in the C1, C2, and C3 groups, located in the rostral VLM (rVLM), the NTS, and the rostral dorsomedial medulla, respectively. The A2/C2 neurons are innervated by primary viscerosensitive afferents carried by the vagus and the glossopharyngeal nerves that convey information from mechano- and chemoreceptors

Figure 1 Schematic representation of the adrenergic mechanisms and circuitry involved in energy balance control systems. In the hypothalamus, a plus sign (+) indicates sites where NE and/or EPI infusions evoke increased feeding (F), hyperglycemia (g), or increased plasma FFA (fa) levels, whereas a minus sign (-) indicates sites where AS activation produces decreased feeding or FFA levels. In the medulla, the same symbols indicate that injections of the glucoprivic agent 5-thio-D-glucose into A1/C1 and A2/C2 evoke feeding and hyperglycemia. 3V and 4V, third and fourth ventricles, respectively; Amb, nucleus ambiguus; fx, fornix; pc and mc, parvo- and magnocellular cell groups of the PVH, respectively; PAG, periaqueductal gray matter; PBN, parabrachial nuclei. related to cardiovascular, pulmonary, and gastrointestinal systems (Fig. 1). NTS neurons receiving visceral afferents in turn project to A1 and C1 neurons. Descending projections from C1 cells to the spinal cord innervate sympathetic preganglionic neurons and so can directly activate catecholaminergically mediated responses to visceral changes.

Ascending projections from A1/C1 and A2/C2 cells travel through the ventral adrenergic bundle and terminate in several limbic nuclei and hypothalamic areas. AS terminals are found in the ventromedial (VMH), arcuate (ARH), dorsomedial (DMH), and lateral (LHA) hypothalamic nuclei, and a particularly dense innervation reaches the paraventricular nucleus (PVH). Neurons in these nuclei (particularly in the PVH and LHA) are in turn connected to (1) endocrine (pituitary) mechanisms (e.g., driving pituitary–adrenal and pituitary–thyroid activities), (2) mesencephalic and prosencephalic limbic nuclei (thereby influencing the expression of behavioral, learning/memory, and emotional responses), (3) premotor and preganglionic autonomic neurons (thereby controlling autonomic outflow), and (4) A1/C1/A2/C2 neurons (where they can modulate visceral reflexes mediated by these cells). These relationships are summarized in Fig. 1.

Other hypothalamic hypophysiotropic (somatostatin- and luteinizing hormone-releasing hormone [LHRH]-synthesizing) and neurosecretory (arginine vasopressin [AVP]- and oxytocin [OT]-containing) neurons are also innervated by EPI/NE terminals. These terminals provide the substrate for relevant adrenergic control of pituitary secretion of growth hormone/somatomedins (deeply affecting the balance between energy mobilization and storage in peripheral tissues in addition to the thyroid-stimulating hormone [TSH]- and adrenocorticotrophic hormone [ACTH]-related mechanisms mentioned previously) as well as of the plasmatic levels of luteinizing hormone/follicle-stimulating hormone (LH/FSH), AVP, and OT. Also important to point out is that although terminals from A6 (the locus ceruleus) NE-synthesizing neurons are ubiquitous in the CNS, these neurons have limited direct input to the hypothalamic circuitry. The locus ceruleus receives a major, essentially inhibitory innervation from EPI- and NE-producing medullary neurons, through which the latter ASs gain access to a “brain-wide web” of NE-mediated modulation of cognitive and arousal functions as well as to indirect influences on neuroendocrine mechanisms through prosencephalic limbic nuclei.

CENTRAL ADRENERGIC SYSTEM MECHANISMS CONTROLLING FEEDING AND FUEL HOMEOSTASIS

Brainstem EPI- and NE-Synthesizing Cells Manifest Glucoreceptive Mechanisms

Sue Ritter, Kadhija Yettefti, and their colleagues have independently gathered convincing evidence for glucoreceptive activity in medullary EPI/NE cells. Single-unit recording studies have identified neurons sensitive to peripheral or local changes of glucose (GLU) levels in A1/C1 and A2/C2 cell groups, whose responses are depressed by locally applied clonidine (an α_2 -adrenoceptor agonist). Both feeding and blood GLU increases were observed after local GLU deficits evoked by injections of 5-thio-D-glucose (5-TG), a glucoprivic agent, into the C1 and C2 areas. Systemic injections of 2-deoxy-glucose (2-DG), another glucoprivic agent, provoked feeding, hyperglycemia, and Fos expression predominantly in C1 and C2 (but also in A1 and A2) cells. Thus, these neurons are in a position to mediate metabolic and behavioral responses to central or systemic changes in GLU levels. A1/C1 and A2/C2 cells are also activated by other stressful situations such as hemorrhage, immune challenge, noise, restraint, and forced swim. In each case, activation of medullary ASs occurs either directly through visceral afferents or subsequent to higher level processing of the stressful stimulus and may recruit different, possibly stressor-specific A1/C1 and A2/C2 cell subpopulations. Thus, these circuits may be of importance under different conditions of stress and energy demand.

NE and EPI Influences on Hypothalamic Circuits Regulating Fuel Homeostasis

Feeding Behavior

After the pioneering work by S. P. Grossman during the early 1960s, and thanks mainly to the systematic efforts of Sara Leibowitz, Paul Wellman, and their colleagues over the past 20 years or so, CNS-AS inputs to the hypothalamus were established as crucial to the control of feeding behavior and fuel metabolism. The PVH is by far the most sensitive (and the most studied) area with regard to feeding-related AS activity. Injections of NE or EPI, as well as injections of NE reuptake blockers (which increase local extracellular NE levels), into the PVH promptly elicit feeding. These effects are mediated by α_2 -adrenoceptors,

whereas activation of α_1 receptors suppresses food intake. NE release within the PVH reaches a maximum immediately before the active (dark) period and is positively correlated with the intense feeding that occurs at this time. The reactivity to exogenous NE and the number of α_2 -adrenoceptors in the PVH also increase at the beginning of the dark period. Furthermore, extracellular NE increases into the PVH were positively correlated with meal size and with the carbohydrate content of the meal. Conversely, decreases in NE release into the medial hypothalamus were observed after intraduodenal nutrient infusions. Thus, it is possible that endogenous NE acts in an α_2 -receptor-enriched PVH mainly to increase carbohydrate intake and restore bodily reserves of this macronutrient.

Ritter and her colleagues suggested that these medullary ASs may represent the main origin of NE/EPI inputs to the PVH that provoke feeding in response to glucoprivic situations. They showed that injections into the PVH of the toxin saporin conjugated to an antibody against DBH, DSAP (which is retrogradely transported to cell bodies and selectively destroys NE/EPI terminals and perikaria), dramatically reduced the number of TH-containing neurons in the A1, C1, A2, C2, and C3 groups and abolished 2-DG-induced feeding and Fos expression in the PVH. Neurons of the A1 group project mainly to hypothalamic magnocellular neurosecretory cell groups (which produce AVP and OT) either within or outside the PVH, whereas C1, C2, and A2 neurons project densely to parvocellular PVH neurons (whose terminals release corticotropin-releasing hormone [CRH] and thyrotropin-releasing hormone [TRH] into the median eminence and into premotor and preganglionic autonomic neurons). Thus, this circuit is in a position to regulate autonomic outflow as well as neuro- and adrenergic activities related to energy balance (as well as to other functional domains).

NE injections into the VMH acutely induce hyperphagia, and chronic infusions of NE into this nucleus provoke weight gain associated with a GLU-intolerant, diabetic-like state in normal rats. Furthermore, increases in NE levels and/or activity have been observed in this nucleus in a variety of animal models of insulin-resistant obesity. Extracellular NE increases into the VMH were observed after systemic 2-DG injections, suggesting a role for NE-mediated VMH circuits in behavioral and humoral responses to glucoprivic situations. Grossman's seminal study pointed to the DMH as a site where NE injections also increase food intake. Push-pull cannula studies revealed

substantial increases in the DMH content of EPI (and, to a lesser extent, of NE) during intense feeding episodes but not during other maintenance behaviors. NE/EPI neurons densely innervate the ARH, which is populated by neurons producing the orexigenic agents agouti gene-related protein (AGRP) and neuropeptide Y (NPY) and which is rich in leptin receptors. Systemic 2-DG injections induce activation of these AGRP and NPY neurons of the ARH, and 2-DG-induced increases in AGRP expression are inhibited by DSAP lesions in this nucleus, pointing to an important role for ASs in the control of feeding-related functions of the ARH.

Contrary to what is observed in medial hypothalamic nuclei, CNS-AS inputs to the LHA have hypophagic effects. NE and EPI injected into the perifornical nucleus (PF) of the LHA inhibit food intake, a response that is mediated by β_2 -adrenoceptors. On the other hand, activation of α -adrenoceptors in this area enhances feeding responses. The amphetamine-induced hypophagic effect is strongly associated with increases in extracellular levels of NE in the PF. Increases in NE release in the LHA appear to be associated with satiation signals brought about by a meal. NE release in the LHA increase after intraduodenal nutrient infusions, whereas food deprivation and systemic injections of 2-DG evoke a decrease in extracellular levels of NE. It is important to note that many LHA neurons have shown to express peptide systems involved in feeding behavior, including the melanin-concentrating hormone (MCH), the cocaine-amphetamine-regulated transcript (CART), dynorphin (Dyn), and orexins (Orx). These LHA neurons give rise to afferents to limbic, basal ganglia, and cortical structures and represent major output mechanisms by which AS-mediated inputs are translated into feeding/metabolic responses in addition to the pituitary- and autonomic-directed PVH outputs (Fig. 1).

Blood Glucose and Free Fatty Acids

Data obtained by A. J. Scheurink and colleagues, as well as by Leibowitz's group, suggest an important role for CNS-AS-mediated circuits in the hypothalamic integration of blood levels of metabolic fuels to feeding responses. EPI or NE administration into the PVH (as well as into the DMH and preoptic area) has been shown to induce a potent hyperglycemic response in resting rats. Furthermore, injections of an α -adrenoceptor blocker in the PVH and VMH suppress the exercise-induced increase in blood GLU levels. Physiological evidence for a catecholaminergic mechanism in the hypothalamic circuitry controlling

lipolysis in rats has also been described. Intracerebroventricular (ICV) administration of NE, as well as infusion of EPI or NE into the VMH or DMH, evokes an increase in plasma free fatty acid (FFA) concentration. In contrast, infusion of EPI or NE into the LHA decreased or left unchanged plasma FFAs, respectively. The increase in plasma FFAs evoked by swimming is potentiated by injections of an α -adrenoceptor antagonist (phentolamine) into the VMH, whereas the infusion of a β -adrenoceptor antagonist (timolol) provoked a delay in this response. These data suggest the existence of an extensive hypothalamic catecholaminergic circuitry involved in an integrated control of fuel homeostasis.

However, AS-originated inputs to PVH might not be essential for 2-DG-induced hyperglycemia. Injections of DSAP into the PVH, which abolished 2-DG-induced feeding, failed to affect 2-DG-evoked hyperglycemia. DSAP injections into the spinal cord abolished 2-DG-induced hyperglycemia (but not feeding responses) and also deleted TH-containing cells in the A5, A6, A7, C1, and C3 neurons, indicating that glucoprivic-induced feeding and the glycemic response are mediated by different subpopulations of hindbrain catecholamine neurons. An important participation of ASs in VMH mechanisms of fuel control has been shown by A. Cincotta and colleagues. Chronic infusions of NE in the VMH increased plasma insulin, glucagon, leptin, triglyceride, abdominal fat, and lipogenic/lipolytic activities and also evoked insulin resistance and glucose intolerance. Furthermore, extracellular concentrations of NE in the VMH increased during insulin-induced hypoglycemia.

Are There Functional Central Pathways That Use EPI as a Neurotransmitter?

The studies on central AS roles in neuroendocrine/autonomic mechanisms have focused on NE-mediated pathways rather than EPI-mediated pathways. Such a disregard for EPI central mechanisms may be related to the intimate neurochemical, neuroanatomical, and pharmacological correspondence between these catecholamines. EPI and NE systems (1) share most of their synthetic pathways, pre- and postsynaptic fates, and receptor mechanisms, (2) show considerable anatomical overlap in the brainstem and hypothalamus, and (3) have their central actions poorly differentiated by the available pharmacological tools. Furthermore, the presence of PNMT in a

neuron does not necessarily mean that it uses EPI as neurotransmitter. For example, A. F. Sved found very low EPI levels in the thoracic cord, which is densely innervated by TH-, DBH- and PNMT-containing C1 neurons. However, C. Routledge and C. A. Marsden showed that stimulation of the C1 region increases extracellular EPI (but not NE, as observed by intracerebral microdialysis with high-performance liquid chromatography [HPLC] detection) in the posterior hypothalamus of adrenalectomized animals. Leibowitz and colleagues showed that, at maximally effective doses, the hyperphagic and hyperglycemic effects of EPI injections into the PVH are twice those of NE, and EPI is even more potent than NPY in eliciting an increase in food intake. Ritter and colleagues demonstrated that 2-DG-evoked Fos expression affects predominantly EPI neurons. Although these data support the existence of functional pathways innervating the hypothalamus that use EPI as a neurotransmitter, the functional attributes of AS actions in central circuits actually attributable to EPI or NE systems are poorly understood.

A Comparative Note

A role for CNS-ASs in feeding and fuel homeostasis is also evident in nonmammalian vertebrates with disparate feeding habits and metabolic demands. Research by our group, as well as by others, has indicated remarkable parallels between avian and mammalian AS-mediated energy balance mechanisms. The existence of medullary NE and EPI cell groups anatomically comparable to mammalian A1/C1 and A2/C2 with ascending projections to a hypothalamic paraventricular nucleus (PVN) corresponding to the mammalian PVH was observed in pigeons. Injections of NE or EPI into the PVN of pigeons evoke intense, α -adrenoceptor-mediated feeding responses. Similar to what was observed in rats, hyperphagic responses after intra-PVN EPI injections in pigeons are significantly higher than those observed after injections of equimolar doses of NE. Also in pigeons, ICV or intra-PVN injections of EPI evoke a β -adrenoceptor-mediated increase in blood glucose (with no effect on FFA levels), whereas ICV injections of NE raise plasma FFA levels. These responses are mediated by both autonomic and pituitary mechanisms. These functional and anatomical attributes may represent a mechanism highly conserved during amniote (reptiles, birds, and mammals) evolution, possibly present in the last common ancestor of these vertebrate classes and probably still playing a fundamental role in the control of fuel homeostasis.

Glossary

α -adrenoceptor Membrane-bound G protein-coupled receptor that mediates physiological and neurophysiological responses to epinephrine and norepinephrine; characterized by order of agonist potencies for stimulation: epinephrine \rightarrow norepinephrine \rightarrow isoproterenol.

β -adrenoceptor Membrane-bound G protein-coupled receptor that mediates physiological and neurophysiological responses to epinephrine and norepinephrine; characterized by order of agonist potencies for stimulation: isoproterenol \rightarrow epinephrine \rightarrow norepinephrine.

arrestin Intracellular protein that, when bound to an adrenoceptor, promotes the receptor uncoupling from G proteins and receptor desensitization.

autonomic nervous system A component of the nervous system that is primarily involved in internal body functions and behavior.

Adrenergic receptors are membrane-bound proteins that mediate the peripheral and central actions of norepinephrine and epinephrine. By virtue of their location, either presynaptically or postsynaptically on neurons or effector organs such as the heart, vasculature, and adipose tissue, this class of receptors mediates a wide range of important homeostatic responses. Adrenergic receptors were originally divided into two major groups: α - and β -adrenoceptors (ARs). α -ARs demonstrate weak responses to the synthetic agonist isoproterenol but are very responsive to epinephrine and norepinephrine. In contrast, β -ARs respond potently to isoproterenol and are less sensitive to epinephrine and norepinephrine. During more recent years, both new pharmacological tools and the cloning of genes have revealed nine different AR subtypes: three α 1-ARs (α 1A, α 1B, and α 1D), three α 2-ARs (α 2A/D, α 2B, and α 2c), and three β -ARs (β 1, β 2, and β 3).

β -ADRENOCEPTORS

Peripherally, β 1-adrenoceptors (ARs) are localized to cardiac and adipose tissue, whereas β 2-ARs are found primarily in smooth muscle, liver, and human white cells but have also been localized on cardiac tissue. In the rat central nervous system (CNS), both β 1- and β 2-ARs are found with high densities in the cerebral cortex, caudate, and cerebellum. In amphibian and rat brains, β -ARs are located primarily on the postsynaptic membrane. β 3-ARs were not cloned until 1989, and receptor density appears to vary among species. Immunohistochemical and radioligand-binding studies suggest that β 3-AR mRNA is localized in both white and brown adipose cells as well as in skeletal muscle. Activation of this class of β -ARs is thought to mediate lipolysis and play a role in thermogenesis in these tissues. There is also evidence that β 3-ARs can be expressed in human atrial and ventricular cardiomyocytes under certain conditions.

β 1- and β 2-Adrenoceptors

The postsynaptic mechanisms of β 1- and β 2-ARs have been studied the most extensively. β 1 receptors have approximately equal affinities for epinephrine and norepinephrine. Conversely, β 2 receptors have a higher affinity for epinephrine than for norepinephrine, suggesting that tissues with a predominance of β 2 receptors respond quickly to circulating epinephrine. β -AR stimulation leads to activation of adenylate cyclase and elevation of intracellular cyclic AMP (cAMP). This receptor effector system consists of three components: the β -AR, a guanine nucleotide regulatory protein that links the receptor to adenylate cyclase, and adenylate cyclase. When the G protein is in the stimulatory configuration, the binding of a neurotransmitter to the β -AR results in increased production of cAMP from adenosine triphosphate (ATP). In cardiac muscle, increased levels of cAMP

in turn activate protein kinase A (PKA), calcium channels are phosphorylated, and calcium entry increases through the sarcolemma, promoting a positive inotropic effect. Phospholamban is phosphorylated, promoting an increased rate of calcium reuptake into the sarcoplasmic reticulum and increasing the rate of myocardial relaxation (lusitropic effect). In addition, there is an increased rate of sinus node depolarization or a positive chronotropic effect. Cardiac β_2 -ARs may also interact with an inhibitory G protein and may possibly modulate several G protein-independent pathways, including a possible link to a phosphatidylinositol 3' kinase pathway that has been linked with antiapoptotic mechanisms. In smooth muscle, the β -AR-stimulated increase in intracellular cAMP promotes relaxation through increased calcium reuptake into the sarcoplasmic reticulum and calcium extrusion to the extracellular space. β -receptor stimulation of smooth muscle also triggers activation of calcium-dependent potassium channels that hyperpolarize the membrane.

Prolonged agonist exposure to β -AR stimulation leads to receptor internalization and diminished response to subsequent stimulation. This process of down-regulation of the receptor primarily affects β_1 -ARs and is mediated by increased activity of β_1 -adrenergic kinase (β_1 -ARK) during prolonged β_1 agonist activity. β_1 -ARK in turn phosphorylates the β_1 -receptor. In the presence of β_1 -arrestin, the receptor becomes uncoupled from the stimulatory G protein and is internalized. In failing human ventricles, β_1 -ARK levels are elevated and the ratio of β_1 : β_2 receptors decreases as β_1 -receptors are internalized. In addition, there may be a functional uncoupling of remaining receptors. Although this mechanism of down-regulation is thought to be protective against the adverse effects of prolonged increased intracellular levels of cAMP and calcium, including apoptosis, the net outcome is a reduced response to β -receptor stimulation and systolic dysfunction. Transgenic mice with overexpression of human β_1 - or β_2 -ARs develop cardiomyopathic phenotype, including systolic dysfunction and chamber dilation, suggesting that overactivation of either receptor subtype can trigger internal pathways involved in receptor desensitization. The link between prolonged β -receptor stimulation and up-regulation of β_1 -ARK also appears to be critical to the development of heart failure. Inhibition of β_1 -ARK activity with a peptide inhibitor both enhances contractility in the normal heart and prevents the development of cardiomyopathy in a murine model of heart failure.

β_3 -Adrenoceptors

β_3 -ARs have also been linked to cardiac function. In β_3 -knockout mice, the inotropic response to isoproterenol is greater than that observed in wild-type controls. Alternatively, cardiac-specific overexpression of β_3 -ARs results in a reduction in left ventricular function. Evidence suggests that β_3 -ARs are up-regulated in human heart failure, whereas β_1 -ARs are down-regulated, suggesting that β_3 -ARs may constitute an opposing role to the excitatory effects of the other two β -ARs. The postsynaptic mechanisms of β_3 -AR stimulation in cardiovascular tissue remains to be fully defined, yet there is evidence of coupling to both stimulatory and inhibitory G proteins as well as activation of nitric oxide synthase. It does not appear that β_3 -ARs are targeted for intracellular phosphorylation or that they bind β -arrestin. As a result, β_3 -ARs are relatively resistant to long-term down-regulation, although this resistance may be tissue specific.

β -ARs are also extremely important in thermogenesis and lipolysis in adipocytes and possibly skeletal muscle. All three β -ARs appear to be present on brown and white adipocytes. Activation of β -ARs produces biphasic changes in intracellular cAMP (reflecting the coupling of the β_2 and β_3 -ARs to both stimulatory and inhibitory G proteins) and activates a mitochondrial uncoupling protein (UPC-1 in brown adipose tissue) that is important for the purpose of heat generation (thermogenesis) at the expense of coupled ATP production. In animals, stimulation of β_3 -ARs has antiobesity and antidiabetic properties by decreasing fat content, increasing muscle glucose uptake, and decreasing hepatic glucose output. There is also a link between β_3 -AR activation and decreased leptin expression and secretion from white adipose tissue. The mechanism underlying interaction between β_3 -AR stimulation and leptin has yet to be fully determined but may involve β -AR activation of cAMP-dependent protein kinases. Alternatively, in animal models of obesity such as the *ob/ob* mouse and Zucker fatty (*fa/fa*) rat, where leptin release or receptor binding is dysfunctional, there is a decrease in both β_3 - and β_1 -AR expression. The mismatch between leptin levels and β -AR function may be related to sympathetically mediated β -AR down-regulation. However, in humans, the profound effect of β -AR down-regulation in obesity has yet to be linked specifically to β_3 -AR deletion. The relative numbers of β_3 -ARs in metabolically active tissues of rodents versus humans may explain these differences. Furthermore, there is evidence of significant

redundancy in the system given that deletion of all three β -AR subtypes is necessary to generate mice that are intolerant to cold exposure.

α -ADRENOCEPTORS

α -ARs mediate most (but not all) of the excitatory effects of catecholamines, including contraction of vascular smooth muscle, contraction of uterine muscle, contraction of the urethra, and pupillary dilation. In general, α 1-ARs are involved in mediating responses at effector organs. The α 2-ARs are located primarily on the presynaptic terminal and modulate transmitter release, although they also are present postsynaptically and contribute to effector organ responses. Responses at many effector organs are mediated by more than one AR subtype. For example, several α -AR subtypes are expressed in the vasculature and mediate different aspects of vascular function. Moreover, the relative roles of these subtypes vary among different vascular beds, at different levels of individual blood vessels, and are species dependent.

α 1-Adrenoceptors

The α 1-ARs are distributed in various organs and tissues, including the vasculature, heart, lung, kidney, liver, and brain. Within the brain, radioligand binding and autoradiographic techniques have indicated rich localization of α 1-ARs in the rat cerebral cortex, hippocampus, certain thalamic nuclei (dorsal lateral geniculate), and dorsal raphe nucleus. Peripherally, this class of receptors is thought to be involved importantly in the control of vascular tone. The three different subtypes (α 1A, α 1B, and α 1D) all have been implicated in vascular smooth muscle contraction, with varied roles depending on the species and the vascular bed. It appears that the α 1A subtype may be involved more in the maintenance of basal tone, whereas the α 1B subtype may participate more in the response to exogenous agonists. Different physiological conditions can influence the response to activation of these receptors, and expression of the different subtypes can be affected independently under different physiological and pathophysiological situations. It appears that expression of the α 1B subtype may be especially subject to changes in level of expression. Thus, it is possible that this receptor may be involved in altered responses under different physiological and pathophysiological conditions.

The α 1-ARs are G protein-coupled receptors, coupled primarily to Gq/11. Activation of this system

stimulates activity of phospholipase C, resulting in the formation of 1,4,5-trisphosphate and diacylglycerol. These molecules subsequently stimulate an increase in cytosolic Ca^{2+} and activation of protein kinase C. Although this is the primary coupling system for most α 1-AR-mediated responses, evidence suggests that these receptors can also be coupled to other G proteins. Thus, it is likely that activation of α 1-ARs is capable of influencing a number of different signaling pathways and of modulating many different types of responses.

An important aspect of α 1-AR function, similar to β -ARs, is that they are highly subject to desensitization. Prolonged exposure to an agonist results in reduced responsiveness to subsequent stimulation of the receptor. The reduction in response to agonist stimulation appears to be due to binding of arrestin proteins to the receptor, which favors its uncoupling from the G protein. In addition, receptors are internalized within the cell, also contributing to decreased receptor activity. Phosphorylation of the receptor via activation of G protein receptor kinases is a primary event in the process of desensitization/internalization of these receptors.

α 2-Adrenoceptors

α 2-ARs generally are considered to be located presynaptically, modulating neurotransmitter release. However, they also are present postsynaptically and on non-neuronal tissues. Like the α 1-ARs, they are located both peripherally and throughout the central nervous system. The α 2-ARs are important in a wide variety of responses, including inhibition of neurotransmitter release, control of vascular tone, regulation of renin release, inhibition of insulin secretion, inhibition of lipolysis, and platelet aggregation. Within the central nervous system, α 2-ARs influence the control of arterial pressure, modulation of growth hormone release, sedation, analgesia, and a variety of effects on behavior and cognition. Prominent locations within the CNS are in cardiovascular regions such as the nucleus tractus solitarius and rostral ventrolateral medulla as well as the locus coeruleus. Central stimulation of α 2-ARs can result in hyperpolarization and neuronal inhibition.

Peripherally, it is clear that the α 2-ARs, like the α 1-receptors, mediate vasoconstriction. The primary subtype involved in vasoconstrictor responses is the α 2A/D receptor, although there are contributions from the other subtypes as well, in particular α 2B receptors. Interestingly, the α 2B-AR also appears to

be the dominant subtype that mediates the central hypotensive response to $\alpha 2$ -AR agonists. Thus, the same receptor subtype appears to mediate vasoconstriction peripherally and hypotension centrally; however, the hypotensive response predominates. An interesting aspect of the vasoconstrictor effects of $\alpha 2$ -ARs is that they appear to be the primary AR involved in the contraction of veins. Depending on the species and vascular bed, this venous constriction is mediated by different subtypes, primarily the $\alpha 2A/D$ -ARs and the $\alpha 2C$ -ARs.

The presynaptic effects of $\alpha 2$ -ARs appear to be mediated predominantly by the $\alpha 2A/D$ subtype, although some studies suggest that the $\alpha 2C$ subtype also may be involved. These receptors act as autoreceptors, primarily mediating inhibition of transmitter release. They are present widely in the brain as well as in peripheral tissues, including the heart, kidney, and vasculature. These presynaptic receptors are thought to contribute, at least in part, to the hypotensive, sedative, and analgesic effects of $\alpha 2$ -AR agonists.

The $\alpha 2$ -ARs primarily are negatively coupled to adenylate cyclase. In addition, cellular effects of $\alpha 2$ -ARs may be mediated through inhibition of voltage gated Ca^{2+} channels, activation of inwardly rectifying K^{+} channels, activation of phospholipase C, increased Ca^{2+} release from intracellular sources, and stimulation of mitogen-activated protein kinase (MAP kinase). Thus, activation of $\alpha 2$ -ARs has the capacity to influence a number of signaling pathways, providing a modulatory effect on a variety of cellular functions.

Aging and Longevity of Human Populations

Kenneth G. Manton

Duke University, Durham, North Carolina, United States

Glossary

antioxidant A substance that chemically inhibits oxidation reactions.

caloric restriction Eating fewer calories than *ad libitum* while achieving adequate or optimal nutrition. This has extended both mean and maximum life span in various animal models.

Gompertz function A mathematical model developed by B. Gompertz in 1825 of the age-related increase in mortality during the adult life span.

juvenile hormone An insect hormone that is secreted by the corpora allata and plays a role in reproduction, gene expression, and metabolism.

mitochondria Any of various round or long cellular organelles of most eukaryotes that are found outside the nucleus, produce energy for the cell through oxidative processes, and are rich in fats, proteins, and enzymes.

nuclear DNA DNA found within the nucleus of the cell.

oxidative theory of aging The theory that declines in physiological function with age are due to damage accumulated from reactive oxygen species.

superoxide dismutase (SOD) A potent intracellular antioxidant.

telomere The natural end sequence of a eukaryotic chromosome.

Aging and longevity are fundamental characteristics of human populations. Aging typically means the loss with increased chronological age of the functional capability of different organs of the body due to the operation of a general process of biological senescence. Aging, or senescence, is usually viewed as distinct from major chronic diseases, such as cancer or cardiovascular diseases, although there may be shared exposure factors or mechanisms (e.g., oxidative processes causing mutations in DNA). Often, aging is defined at the cellular level, such as the replicative senescence of cells whose telomere reaches a critical length, or related to

mitochondrial dysfunction in energy production due to the accumulated damage of reactive oxygen species. Longevity, the number of years lived, is generally viewed as being determined by senescent processes reaching their end stage. However, it is clear that there are multiple determinants of longevity, and the correlation of life span with the progression of the different dimensions of senescence is more complex and plastic than had been previously thought and is not well understood.

CELL-BASED SENESENCE

Biological models of human aging and longevity have often focused on the senescence and death of the individual cell—the fundamental building block of the human organism. For example, one model of senescent-limited longevity is based on a model of genetic restrictions on the number of cell replications that can occur under the so-called Hayflick limit. The physical basis for this phenomena is believed to be the telomere, the end sequence of the chromosome that tends to decrease in length with each replication of the cell. These cell-based models tend to underplay the significance of endocrine and growth factors.

One problem with this perspective is that an experimental analysis of the decline in the number of replications that a cell can perform (often estimated at 50–60) per year of age *in vitro* was estimated to be 0.2/year in humans aged 30–80, implying that this mechanism limited the human life span to 250–300 years. The highest reliable age reported at death is currently that of Madame J. Calment, who died at age 122. A second problem is that although the Hayflick limit may explain longevity bounds, it does not explain loss of function with age.

A recent analysis showed that in healthy human subjects, and controlling for the biopsy site, there was no significant negative correlation between the cell's replicative capacity in a given tissue and subjects' age *in vitro*. As a consequence, questions are raised about the importance and exact role of the loss of cell replicative capacity as a limiting factor in human longevity. Additionally, studies have found the correlation

of telomere length with replicative senescence to be complex because it varies across tissue types and because the telomere may have additional cellular functions, such as monitoring oxidative cell damage.

Further complicating analysis of the mechanisms controlling longevity is the fact that most tissues, including the brain, are now thought to have a small proportion of stem cells from which new cells can generate. It has been demonstrated that new neurons are generated in the human brain at all ages. Aerobic exercise may stimulate production of new cells in the hippocampus. One specific interesting stem cell is the SHED stem cell found in teeth. This stem cell has been shown to have the potential to form cells of a variety of tissue types. The intrinsic potential for regeneration of each tissue type and the tissue-specific hormonal and growth factor triggers that may cause new cell growth (or may restrict growth, e.g., the myostatin gene discovered in 1995) are not well understood with respect to their role in regulating senescence and determining human longevity.

OXIDATIVE STRESS AND MITOCHONDRIAL INFLUENCES ON AGING

Another promising model of the cellular mechanisms limiting the human life span is the senescence of the human mitochondria. This is a specific form of the general theory of an oxidative basis for aging originally proposed by Harman. Mitochondrial DNA (mtDNA) has fewer error monitoring and correcting mechanisms than does nuclear DNA (nDNA). Furthermore, since the mitochondria is the primary center of energy production in cells, the organelle is thought to be especially vulnerable to the oxidative stress of reactive oxygen species (ROS), which are produced in the respiratory processes centered in the mitochondria.

Because the mutation rate of mtDNA is much greater (approximately 10-fold) than that of nDNA, in a variant of the oxidative theory of aging, “aging” of the mitochondria has been suggested to be the physiological process limiting human longevity to a maximum of 130 years. This is a more plausible limit than that derived from the Hayflick limit in *in vitro* studies focusing on the loss of replicative capacity of the cell and its correlation with the age of the cell donor.

Of interest is that the production of many mitochondrial proteins in humans has been taken over by nDNA, with 47 of 60 mitochondrial proteins produced in the nucleus, in which error monitoring and corrective mechanisms are more complete. An interesting corollary of

this model is that as aging degrades the efficiency of energy production, the physical activity of the organism is degraded, inducing a correlation of functional loss and longevity. Cell-specific failure can be communicated systematically by cytokines such as interleukin-8, which is increased by stress due to ROS, and interleukin-6, which is a proinflammatory cytokine.

EXOGENOUS MODULATORS OF MITOCHONDRIAL FUNCTION

Problems arise with this model of longevity and senescence when one considers how “external” factors affect the process of mitochondrial senescence and functional degeneration. A common model for life-expectancy extension is caloric restriction. In this case, the lowering of caloric consumption is thought to decrease basal metabolism, reduce oxidative stress, and retard age-related degeneration. Since this involves energy production and metabolism, it is reasonable to consider the mitochondria as the focal point of these processes. Such an intervention has been shown to increase life expectancy in experimental models of rodents and other lower organisms. Additionally, several genetic mutations in *Caenorhabditis elegans* and *Drosophila* have shown that slowing metabolism, and reducing growth and reproduction, can significantly extend the life span. It is believed that longevity-extending mutations in these organisms either protect against ROS species (e.g., genes controlling SOD2 production) or alter insulin and insulin growth factor-1 pathways and signaling.

A significant counterexample to these experimental models is *Apis mellifera*, the common honeybee. Both bee workers and queens have identical genotypes. Their polyphenotypic differentiation occurs due to differences in larval nutrition whereby larva destined to become queens are fed royal jelly, which contains juvenile hormone that alters the developmental trajectory, increases body size and respiration/metabolic rate, increases life expectancy 15- to 30-fold over that of the worker bee, and increases the level of royal jelly produced in queens.

Juvenile hormone seems to affect basal metabolic rate by increasing the production of mitochondrial transcription factors and certain mitochondrial enzymes (Cox-1 and CytC) involved in the respiratory process. Thus, juvenile hormone in bees appears to play roles similar to those of thyroid hormones in humans, which can also affect the developmental process as well as the mitochondrial energy production function. Of interest is that the nuclear receptors

for thyroid hormone T_3 also code for the type of mitochondrial translation proteins elevated in queen bees. One of the crucial findings of experimental studies of the queen bee was that the increases in respiration rate were due to enhanced mitochondrial function and not to increased numbers of mitochondrial organelles. The queen bee model raises the question of how thyroid hormones in humans might regulate senescence and affect longevity by controlling mitochondrial behavior and function (a process not extensively studied), especially regarding how nutritional and physical activity (energy expenditure) factors may affect mitochondrial function.

There is significant evidence that nutritional or dietary factors can alter mitochondrial function and, indeed, changes in mitochondrial functions with age in animal models. Studies of mitochondrial efficiency in experimental animal models suggest that oral ingestion of acetyl-L-carnitine (a substrate for fatty acid membrane transport in mitochondria) and α -lipoic acid (a fat-soluble antioxidant) increased oxidative efficiency of the mitochondria in elderly experimental animals, increased their physical activity level, and improved memory. Thus, the age-related level of accumulated oxidative stress and degradation of mitochondrial function may be partly reversed by appropriate nutritional supplementation in these model systems. It is not known how such interventions perform in humans.

TISSUE INTERDEPENDENCE AND HORMONAL CONTROL IN LONGEVITY

Any model that attempts to explain human longevity and senescence solely at a cellular or molecular level is likely to fail as an oversimplified representation of the physiological and molecular mechanisms involved. The fact is that the molecular functioning of a cell is important not only for its internal maintenance but also for the functioning of the organism. Thus, part of the question of the relation of senescence and longevity concerns the biological complexity of the organism due to the functional differentiation of tissue and organs and the hormonal synchronization of the wide variety of heterogeneous physiological functions that need to be performed.

One way to model such biological complexity is to explicitly introduce the effects of the endocrine system into a model of human aging and longevity. Although certain hormonal factors have been studied in experimental models of aging, they have not explicitly been

introduced in mathematical models of human aging and longevity in populations.

To illustrate, the two hazard functions most often used to describe the age trajectory of mortality in humans are the Gompertz and Weibull. One theoretical justification for these functions is that they may describe increases in the risk of death as a function of the thermodynamics of protein denaturation. As a consequence, the lowering of body temperature is thought to significantly increase human longevity; for example, a several-degree (centigrade) decline in body temperature is projected to increase longevity by approximately 20 years. Not specified in these models are the physiological mechanisms controlling core body temperature (possibly the thyroid gland), its effects on thermogenesis, and its regulation by feedback through other endocrine organs. Thyroid hormone (T_3) effects energy production by regulating mitochondrial respiratory function and proliferation.

The hormone and signaling pathways studied most intensively for their effects on longevity and aging are insulin, insulin-like growth factor 1 (IGF-1), and growth hormone (GH) because of the experimental observation of increases in longevity due to caloric restriction. Among the experimental models most frequently used in such studies are *C. elegans*, *Drosophila melanogaster*, yeast, and rodents. IGF-1 and GH have been intensively studied because of the conceptual attractiveness of the oxidative theory of aging and because of the effects of caloric restriction on life span in experimental models (e.g., rodents), which are believed to be mediated, in part, by IGF-1, insulin, and/or GH. The logic of the relation is that caloric restriction slowed metabolism, the production of ROS, the accumulation of oxidative damage, and thus the aging rate. Genetic mutations that increased the production of antioxidants, such as catalase or SOD2, were also associated with significant increases in longevity in various experimental models.

It is unclear, however, whether such interventions work in the same way in humans because of their greater histological (especially hormonal) complexity. Genetic mutations that altered IGF-1 and GH production and reduced metabolic functions, although associated in simple experimental models with increased longevity, have been associated in humans with a number of adverse conditions, such as obesity and lipid dysfunction, resulting in a higher risk of death from circulatory disease and cancer.

An additional rationale for this line of research is reasoning based on evolutionary models that there is a trade-off of energy expended in growth and reproductive function and somatic maintenance. Reduced

somatic maintenance during periods of scarce food supplies causes metabolism in *C. elegans* to decrease and reduces the requirement for energy and may cause organisms to enter a quiescent, or dauer, state. This quiescent, low-energy consumption state is often associated with reduced oxidative stress and increased longevity but a lower rate of reproduction and less growth.

Hormonal control, however, is more complex in humans than in these experimental models. The IGF-1/insulin effect in the fly and the worm may favor localized hormonal actions. In worms and flies, there was a single receptor that favored local system actions of insulin and IGF peptides, permitting aging regulation to be dominated by a single tissue type (e.g., the neuroendocrine tissue of *C. elegans*). In tetrapods, in contrast, there are four candidate receptors—IGF-1, IGF-2, IR, and RR. This may have led to the developmental differentiation of insulin to control metabolic factors and IGF-1 to control mechanisms of growth in humans. As a consequence, in humans, caloric restriction may have become dissociated from factors controlling longevity, with factors linked to human longevity (e.g., DHEA, insulin, and body temperature) no longer simply associated with caloric restriction. Indeed, recent animal studies show that intermittent starvation, as opposed to caloric restriction, leads to preservation of growth while having even greater effects on insulin and insulin sensitivity and, consequently, on longevity. Another recent experiment in mice is also of interest. Mice were raised without a gene for the insulin receptor in adipose tissue. These mice were found to have greater longevity (+18%) than control mice. In addition, the gene knockout mice were lighter and much leaner than the control mice, even though they consumed more food. This suggests that they had a higher rate of respiration along with their greater average and maximal longevity. This study suggests the primary effect of caloric restriction in rodents is not in reducing oxidative processes but in reducing body fat. Indeed, increasing the efficiency of mitochondrial function and energy production appears to increase longevity. Thus, both insulin regulation and thyroid function appear to be factors that can strongly regulate human longevity and perhaps senescence, suggesting systematic multiorgan regulation of longevity rather than simple, universal cellular “clocks.”

Whereas insulin, IGF-1, and GH have been extensively studied, one endocrine system's effects on aging and longevity that has not been well studied is that of the thyroid. Thus, an interesting future focus of hormonal research on human longevity and aging is on

the effects of thyroid hormone, T_3 , on energy production in the mitochondria. A recent review suggested it has at least three effects. The first, occurring within 30 min, is up-regulation of the energy production of the mitochondria by altering their membrane structure and enhancing their efficiency in energy production. A second change, occurring within 12 h, stimulated production of proteins in the mitochondria to further enhance energy production (e.g., by altering the lipid composition of the inner membrane of the mitochondria). The third effect, not evident for at least 24 h, was the stimulation of nuclear and mitochondrial DNA to produce necessary protein for mitochondriogenesis. Thus, there are fundamental interactions between mitochondrial performance and growth and T_3 hormone. The action of T_3 also seems to be involved in tissue differentiation so that there is a direct linkage of metabolic level and thyroid hormone and the energy demands of organism development. The relation of these factors in controlling human longevity and development/senescence needs extensive study.

Also significantly involved in senescence and longevity is the endocrine control of immune function during aging by the hypothalamic–pituitary–adrenal axis. Hormones play many roles in cytokine production, and cytokines perform a number of important tasks. It is thought that the level of interleukin-6 (IL-6) increases with age. IL-6 controls inflammatory processes in part by stimulating C-reactive protein production in the liver. However, this mechanism is controversial as a model of aging, disability, and longevity because IL-6 is not clearly elevated in centenarians. It appears that in the age range 85–96 years, mortality selection on genetic factors eliminates persons predisposed to certain types of immunosenescence. There is interest in IL-6 because it causes dysfunction of muscle tissue by catabolism, promoting a direct linkage of functional loss and mortality. IL-6 is also implicated in the neurodegenerative process of Alzheimer's disease. It is of interest that anti-inflammatory compounds such as NSAIDs (especially ibuprofen) and statins seem to be highly effective in reducing the risk of neurodegenerative processes (e.g., Alzheimer's disease) through multiple pathways, as may certain steroid hormones (e.g., testosterone).

A MODEL LINKING HUMAN REPRODUCTION AND GROWTH WITH SENESCENCE AND MORTALITY

To adequately model the physiology of such complex hormonal effects and interactions, more sophisticated

quantitative population models of human survival and physiological function are necessary. Based on evolutionary arguments, much of the linkage of senescence and development and reproduction is due to the need to compromise between the energy demands of growth and reproduction, on the one hand, and somatic maintenance, on the other hand, both of which require considerable expenditure of energy. No current model of aging and longevity/human mortality effectively links the age-changing linkage of these processes over the life span, and it is likely in the complex linkage of these processes that endocrine control systems are involved in complex ways.

One candidate model uses a series of three random walk equations for an individual in a state variable space of j dimensions, where each state variable is denoted by x_j . The first describes the temporal trajectory of a person progressing/developing through j dimensions due to both deterministic forces and stochastic influences (modeled as the process w):

$$d(x, t) = \beta(x, t)w(x) \quad (1)$$

where t is the age or time, d is change, and β is the position-specific rate of change.

The second describes the change in the probability of mortality conditional on the position in the state space and stochastic factors:

$$M(x, t) = P_m(x, t)w(x) \quad (2)$$

The third describes the probability of a birth for a female at that position in the state space:

$$B(x, t) = P_b(x, t)w(x) \quad (3)$$

The advantage of this model is that the energy devoted to reproduction is correlated with the risk of death for a person of a given age and physical state through the state dynamic process in x_t (Eq. 1). The stochastic process, $x_1(t)$, linking fertility and mortality is the system through which hormonal control factors may work as indexed by physiological measurements x .

To apply this model, we need to generate equations for the change in the state space distribution of a population of such individuals. For change in the state variables over time, we need a second-order dynamic equation, or

$$x_{t+1} = u_0 + R_{x1} + C(x_t^I \cdot x_t) + e \quad (4)$$

This includes not only the cross-temporal dependency of factors but also interaction terms, which suggests that the effects of risk factors over time are functions of the values on other variables. This reflects various

“field” effects in which trajectories are affected by multiple variables. The e term reflects stochasticity in these cross-temporal relations.

To model mortality and its dependence on state variables, we use an age-dependent quadratic form, or

$$\mu_T(x_1t) = (x_t^T M x_t) e^{\theta t} \quad (5)$$

The risk of death is a function of age, t , and risk factor values. The matrix M are hazard coefficients. The term $e^{\theta t}$ reflects the effects of unobserved factors correlated with age of mortality. To the extent that measured factors reflect age dependence, the value of θ will decrease.

From Eq. (5), we can estimate cause-specific functions, μ_C , to reflect the different relation of risk factors to each of a set of C distinct causes of death. All cause-specific mortality functions, and the birth function, will be related through the stochastic dynamic process x_t .

The next component of the model is the birth function. This is modeled as a quadratic function of the same set of risk factors (where B are the birth probability coefficients),

$$b(x_1t) = (x_t^T B x_t) e^{\delta t}$$

where the values of x_t reflect the physiological state of the mother prior to birth. Thus, both mortality and birth are linked to a common multidimensional state variable process with age functions δ and θ that reflect different latent states affecting the potential for survival and reproduction. The measurable cross-age effects of endocrinological factors are represented in the stochastic process x_t .

To understand how this model could be applied, we use as an example our analysis of the 46-year follow-up of the Framingham Heart Study, in which every 2 years a number of factors were measured, including systolic and diastolic blood pressure, left ventricular hypertrophy, pulse rate, body mass index (BMI), vital capacity index, smoking or nonsmoking, serum cholesterol, and blood glucose, as well as demographic variables such as gender and chronological age.

These factors describe a wide range of physiological effects. Blood glucose is connected to diabetes and hence insulin function. This effect is modulated by BMI, which is related to thyroid function and leptin as well as other hormonal factors. Blood pressure indicates, among other things, how hormonal factors affect arterial endothelium and renal function. Implicit in the interrelation of the variables is the interaction of a wide range of endocrinological factors. For example, blood glucose, hypertension, and cholesterol have been jointly implicated in Reaven’s metabolic syndrome X.

Other patterns of change may reflect features of endocrine control of multiple variables.

Obviously, in the model it would be best to have direct sequential hormonal measures (e.g., corticosteroid, T₃, T₄, insulin, GH, and leptin), but using the data that are usually available on large, representative human populations, we must infer their effects on aging and longevity from their joint temporal pathways and evolution. The more detailed measures may be obtained in the future for large, longitudinally representative populations, such as the 2004 National Long Term Care Survey, as the technology for protein assays improves. One of the critical hypotheses suggested by the previously mentioned model is that longevity and fertility are correlated through the state variables. Such a model could be evaluated in, for example, the Framingham Heart Study, in which two offspring cohorts have been assessed in addition to the original cohort. The age, timing and number of births may be factors in determining longevity, as demonstrated by Promislow in British aristocratic families. Effective intervention should take into account how various profiles of risk factor relations are changed.

CONCLUSION

As the biological complexity of organisms increases, hormonal factors increase in importance as determinants of the correlation of senescence and mortality. Since no single organ dominates survival, the coordination and communication between organ systems becomes more crucial to survival and successful functioning. Because of the increased biological complexity of humans, the linkage of GH, IGF-1, and insulin observed in many studies of simple organisms likely does not function in the same way in humans. The role of thyroid hormones, especially their ability to cause the cell nucleus to produce mitochondrial proteins, must be further studied as a fundamental factor in senescence and longevity. It is reasonable to assume hormonal factors significantly affect human longevity and related aging processes in a variety of complex ways, that these are altered by exogenous factors such as nutrition, physical activity, by genetic polymorphisms, and that, if understood, could indicate how to better control senescent loss of function and overall survival.

Aging and the Male Reproductive System

David A. Gruenewald

University of Washington School of Medicine and VA Puget Sound Health Care System, Puget Sound, Washington, United States

Glossary

andropause An age-related decline in serum testosterone in older men to levels below the normal range for young men; associated with symptoms and signs consistent with androgen deficiency.

erectile dysfunction Difficulty obtaining an erection of sufficient quality to allow for sexual intercourse.

hypogonadism Failure of testicular production of testosterone, spermatozoa, or both.

libido Sexual desire.

Compared to women, men experience a more variable, gradual, and progressive decline in reproductive function as they age. Male reproductive system aging is notable for reductions in testicular secretion of testosterone; alterations in hypothalamic/pituitary regulation of testicular function; structural changes in the testis, penis, and accessory sexual glands; and alterations in sexual function, spermatogenesis, and fertility. The significance of most of these age-related changes in male reproductive physiology is unclear, although erectile dysfunction and some consequences of the age-related decline in testosterone levels may have a major negative impact on quality of life in aging men.

INTRODUCTION

Variability is a hallmark of male reproductive system aging and the aging process in general. Whereas some older men exhibit relatively normal reproductive function, others develop significant impairments in testosterone production, spermatogenesis, or erectile function with aging. Age-associated interindividual variability has important implications for the study and management of male reproductive aging.

PHYSIOLOGY OF AGING

Decline in Serum Testosterone Levels with Aging

In longitudinal studies, serum testosterone levels decline progressively with aging in healthy men beginning in the third decade, and approximately 20% of men older than 60 years of age and half of men older than 80 years of age have total testosterone levels below the normal range for young men. However, even higher percentages of older men have bioavailable testosterone levels below normal levels for young men. This is because levels of sex hormone-binding globulin (SHBG; the major serum-binding protein for testosterone) increase with aging, and SHBG binds testosterone with high affinity. Therefore, bioavailable non-SHBG-bound testosterone, comprising free testosterone and testosterone weakly bound to serum albumin, declines more than total testosterone with aging.

Testosterone is metabolized to estradiol and 5 α -dihydrotestosterone (DHT) (Fig. 1). Like testosterone, bioavailable estradiol levels decline with aging in men, reflecting both the decline in its substrate, testosterone, and the increase in serum SHBG levels with aging. Serum total DHT levels are unchanged or slightly decreased with aging, but bioavailable DHT appears to decrease as a consequence of the age-related increase in SHBG.

In many older men, the age-related decline in testosterone levels is exacerbated by the effects of comorbid illnesses (e.g., diabetes mellitus, renal failure, and alcohol abuse), malnutrition, and medications (e.g., psychoactive medications and glucocorticoids) that further suppress testosterone levels. Elderly men with serious chronic illnesses, residents in nursing homes, and patients in inpatient rehabilitation units have significantly lower testosterone levels than healthy older men and a higher prevalence of testosterone levels below the normal range for young men.

Figure 1 Schematic diagram of age-related changes in hypothalamic-pituitary-testicular axis function. Dashed lines denote negative feedback effects. Arrows denote aging effects on hormone levels or spermatogenesis, large arrowheads denote increased androgen feedback sensitivity, and arrows in parentheses denote age-related changes in bioavailable but not total hormone levels. Note that although luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels may be normal or increased with aging, they are inappropriately low in comparison to those of young men with similar reductions in testosterone levels. Also note that the effect of aging on gonadotropin-releasing hormone (GnRH) secretion is inferred from observation of peripheral hormone levels. N, unchanged; T, testosterone; E2, estradiol; DHT, 5 α -dihydrotestosterone.

Decline in Testicular and Hypothalamic Regulation

The age-related decline in testosterone levels is a consequence of both primary testicular failure and impaired hypothalamic secretion of gonadotropin-releasing hormone (GnRH) that results in relatively suppressed pituitary secretion of luteinizing hormone (LH) (Fig. 1). Age-related primary testicular dysfunction is manifested by decreases in the number and volume of Leydig cells (testosterone-producing cells) in the aging testis, in basal testosterone secretion rates, and in maximal testosterone secretion after administration of human chorionic gonadotropin (an LH-like hormone). Metabolic clearance of testosterone is also decreased with aging, partially offsetting the decrease in testosterone production.

Spermatogenesis is also adversely affected by aging. Histologic studies show a decrease in spermatogenesis

with advancing age, although sperm concentration in ejaculated semen is unchanged or increased as a result of longer periods of abstinence compared with that of younger men. In addition, the number of Sertoli cells that support spermatogenesis in the seminiferous tubules is decreased with aging. There is a corresponding age-associated decrease in serum levels of inhibin B, which is secreted by Sertoli cells and mediates feedback inhibition of pituitary follicle-stimulating hormone (FSH) secretion. This decline in inhibin B is thought to reflect changes in spermatogenesis in the aging testis. However, most of the decline in inhibin B levels occurs by middle age, with little additional decline in late life. Functionally, sperm fertilizing capacity as determined by *in vitro* sperm penetration is well preserved with aging, although the percentage of sperm with normal morphology and motility is decreased. Fertility rates decrease with aging, but this is due primarily to a decrease in sexual activity.

Impairment of hypothalamic GnRH secretion with aging is thought to lead to a relative decrease in pituitary gonadotropin secretion and to contribute to impairment in testicular function. In turn, the age-related decline in serum testosterone levels is associated with a gradual increase in serum FSH and, to a lesser degree, LH levels as a result of diminishing testosterone negative feedback. However, gonadotropin levels often remain within normal limits for younger men. Even when levels of LH and FSH are elevated, they may remain inappropriately low in comparison to those of younger men with similar reductions in testosterone levels, suggesting hypothalamic-pituitary dysfunction (secondary hypogonadism).

Although hypothalamic GnRH secretion cannot be assessed directly in man, several lines of evidence indicate that age-related secondary hypogonadism is due to a defect at the level of the hypothalamus. First, although gonadotropin responses to acute GnRH administration are mildly impaired with aging, older men exhibit intact LH and FSH responses to prolonged pulsatile administration of GnRH, suggesting unimpaired pituitary gonadotropin secretion with aging. Second, the frequency of pulsatile LH secretion (an indicator of hypothalamic GnRH pulse generator activity) is decreased in healthy elderly men. Third, the circadian variation of serum testosterone levels with highest levels in the morning is attenuated in older compared to young men, suggesting an age-related impairment in the hypothalamic circadian pacemaker mechanism. Finally, the sensitivity of gonadotropin suppression to testosterone negative feedback is increased with aging. Taken together, these findings suggest that the decline in testicular

function with aging is due to both primary testicular failure and impaired hypothalamic GnRH regulation of gonadotropin secretion.

POSSIBLE CONSEQUENCES OF AGING-ASSOCIATED ANDROGEN DEFICIENCY

The term andropause has been coined to denote an age-related decline in circulating testosterone to levels below normal for young men, associated with symptoms and signs consistent with androgen deficiency. Many of the physiological changes associated with advancing age are similar to the symptoms associated with hypogonadism in younger men, including decreases in muscle mass and strength, bone mass, libido, sexual activity, body hair, and hematopoiesis and increased fat mass. In young hypogonadal men, these symptoms improve with testosterone replacement. It has been hypothesized that in aging men, these problems are due at least in part to declining testosterone levels.

Epidemiological Studies

Descriptive studies involving older men provide some support for this hypothesis. Testosterone levels and total or abdominal fat mass are inversely related in most studies of elderly men, and some studies report a positive correlation between testosterone levels and lean body or muscle mass and strength. In addition, low testosterone levels are associated with depressed mood and reduced performance on spatial cognition and some memory tasks in older men. Some longitudinal studies in healthy older men report a modest correlation between testosterone levels and sexual activity, whereas other studies find no association. Based on the observation that men have a higher incidence of coronary heart disease than women of similar age, it has been suggested that testosterone predisposes to coronary heart disease. However, most studies report a favorable or neutral correlation between testosterone levels and coronary heart disease in men.

Many of the peripheral effects of testosterone are mediated at least in part by its active metabolites estradiol and DHT (Fig. 1). As noted previously, bioavailable estradiol and DHT levels decline with aging. In older men, decreased bone mineral density and fracture risk are more strongly correlated with low estradiol than with low testosterone levels, suggesting an important role of estradiol in developing

and maintaining normal bone mass in men. Local production of the androgen DHT in the skin and prostate plays an important role in the development of male pattern baldness and prostate disorders, including benign prostatic hyperplasia with aging, but the significance of age-related changes in circulating DHT levels is unclear.

Controlled Clinical Studies of Testosterone Treatment in Older Men

Potentially Beneficial Effects

Changes in lean body mass and fat mass are among the most consistently reported effects of testosterone supplementation. In trials of up to 3 years, lean body mass increased and total body and visceral fat mass decreased in healthy older men with low-normal or mildly decreased testosterone levels. Bone mineral density of the lumbar spine and hip increased in older men with low testosterone levels but not in men with testosterone levels in the normal range. However, fracture rates have not been reported to decrease in older men receiving testosterone.

Total and low-density lipoprotein cholesterol levels generally decreased with testosterone supplementation, whereas high-density lipoprotein cholesterol levels were unchanged. Most trials involving older men with coronary heart disease have reported decreased exercise-induced coronary ischemia with acute or chronic testosterone administration, although effects on angina were variable. The long-term effects of testosterone treatment on cardiovascular disease risk in older men are unknown.

Libido, sexual activity, energy, and subjective well-being improved with testosterone treatment in some studies but were unchanged in others. Studies in small numbers of subjects reported improvements in some aspects of cognition, including spatial ability and spatial, working, and verbal memory. However, in another trial testosterone appeared to impair verbal fluency. Testosterone therapy had no effect on clinical depression in one study.

Testosterone's effects on strength and functional status in older men were variable. In healthy older men, testosterone increased upper and lower extremity strength in some studies but not in others. Performance on functional tasks was unchanged in healthy men treated for 3 years, although testosterone appeared to prevent a decline in self-assessed physical function in these men. In frail older men undergoing inpatient rehabilitation, testosterone improved some measures of strength and functional status. However,

the effects of testosterone treatment in the prevention and treatment of frailty, and on health-related quality of life, remain largely unexplored.

Adverse Effects

Testosterone supplementation was generally well tolerated by older men treated for up to 3 years. The most consistently reported adverse effect of testosterone was the development of hematocrit elevations above the normal range in 6–25% of older men. In most studies, the mean hematocrit increased 2.5–5% over baseline values during treatment. Erythrocytosis occurred during both parenteral and transdermal testosterone supplementation, although it was less common with transdermal administration.

Voiding symptoms and prostate examination abnormalities did not increase during treatment, although prostate size increased slightly in one study. Although most studies found no significant change in prostate-specific antigen (PSA), in a few studies PSA levels increased slightly during testosterone treatment, mostly within the normal range. However, the long-term risks of clinically significant prostatism or overt prostate cancer in men receiving testosterone therapy are unknown.

Sleep apnea has been reported as a potential complication of testosterone therapy in younger hypogonadal men, but it has not been observed in controlled studies of testosterone treatment.

CONCLUSION

The foregoing evidence suggests that the age-related decline in testosterone levels contributes to some of the physiological changes associated with aging in men.

However, the available data are insufficient to assess the long-term benefits and risks of testosterone supplementation. Furthermore, age-associated physiological alterations such as altered body composition and sexual dysfunction are usually multifactorial in origin. Therefore, clinicians must identify and treat all potentially treatable or reversible contributory factors.

Aging, Animal Models for

George A. Kuchel, Qing Zhu, Blanka Rogina, and Stephen H. Clark
University of Connecticut Health Center, Farmington, Connecticut, United States

Glossary

DNA sequencing Technique used to determine the sequence of nucleotide bases present in a DNA molecule or fragment.

epithelial Layers of cells forming the outer surface of the body and also lining its internal cavities.

mutagenesis Causing a permanent heritable change in the nucleotide sequence of a chromosome.

phenotype Observable characteristics of a cell or an organism.

transgenesis The stable introduction of a cloned gene into a plant or an animal, allowing its transmission to future generations.

Scientists interested in exploring fundamental mechanisms of aging need to judiciously choose animal models of aging most appropriate for their area of research. Similarly, great care must be taken when using animal models for the study of disease processes that tend to occur in late life. The establishment of funding agencies devoted to aging research (e.g., U.S. National Institute on Aging [NIA] in 1974) and a growing general interest in aging have led to an unprecedented increase in the use of aging models and in resulting publications. Although researchers are now able to choose from a broad variety of vertebrate and invertebrate models, most such research is still conducted using a very limited number of rat or mouse strains. Because no one single species or strain is optimal for all aging questions and studies, care must be given to the choice of the most appropriate animal aging model. Moreover, other animal-related issues, such as the presence of confounding disease, genetic background, diet, housing, husbandry, microbial status, and exercise, all can greatly influence experimental results. Thus, when designing aging studies, these factors must be given the same considerations as is the determination of an outcome measure of primary interest to investigators. Fortunately, although important issues still remain unresolved, researchers are now able to base their decisions on a reasonable body of experience and knowledge.

GENERAL PRINCIPLES OF AGING RESEARCH

As described by Weindruch, animal models have been used in five general categories of aging studies. Many investigators have used cross-sectional and (less commonly) longitudinal study designs to examine the influence of normal aging on parameters that are thought to either cause aging or be the consequence of aging processes. One major pitfall of this type of study is attributing observed differences to normal aging without taking into account the presence of confounding disease processes. Other difficulties arise from an inappropriate choice of ages. For example, an investigator comparing very young (e.g., newborn) rats with older adult (e.g., middle-aged) rats may be studying maturational rather than aging processes, and a failure to include intermediate ages between young and old may cause the investigator to miss important changes that may herald the aging process. Interestingly, the absence of appropriate life tables for the determination of survival curves has been the limiting factor in the use of some potentially useful aging models.

Other, more comparative studies examine species with widely different longevity to identify factors associated with longevity and aging. Similarly, different strains within the same species (e.g., congenic mice) may possess major differences in longevity. Finally, animal models of accelerated aging (e.g., senescence accelerated mouse) and models of decelerated aging (e.g., *Drosophila* overexpressing catalase or superoxide dismutase) both have proved to be useful in aging studies.

THE LABORATORY RAT

NIA's decision to provide the Fischer 344 (F344) rat strain to the scientific community has played a major

role in its great popularity for aging studies. Many investigators also welcomed this inbred strain because the commonly used outbred Sprague–Dawley strain tended to become grossly obese in old age and exhibited tremendous variability when purchased from different suppliers. Unfortunately, although inbred F344 rats have the advantage of being genetically identical, this also results in their frequent development of tumors (testicular interstitial cell and pituitary) as well as renal failure from nephropathy. Although these tumors are rarely metastatic or secretory, screening is important because both the tumors and renal failure could confound research data. Fortunately, the NIA also offers the inbred Brown Norway (BN) rat, as well as an F1 hybrid (F344/BN), through a contractual arrangement. Caloric restriction still remains the best validated and most robust means of extending longevity in rodents while also decreasing their burden of disease (including F344 nephropathy), and all three rat strains provided by the NIA are also available from a caloric-restricted colony. Many investigators have argued for the use of rodents that have undergone modest caloric restriction because such animals tend to be healthier in old age, minimizing the confounding effect of illness and disability. Interestingly, some investigators have used the heterogeneity present in other outbred strains (e.g., Wistar, Long–Evans) to great advantage in aging studies. For example, Long–Evans rats remain relatively healthy into old age and exhibit great variability in their spatial memory performance on a Morris water maze test.

The rat is a popular model for examining endocrine and reproductive issues in old age. Although this has resulted in the availability of considerable information regarding this model, great caution must be exercised when extrapolating from these studies to human conditions. For example, unlike women whose ovaries cease to produce estrogens past menopause, rat ovaries appear to be capable of normal or near-normal function throughout their life span. In contrast to human menopause, reproductive senescence in rats is associated with the development of irregular cycles. This is followed by a period constant estrus in nearly one-half of the animals, which then proceed to a state of persistent diestrus, whereas the other half proceeds immediately to persistent diestrus. As a result, approximately one-half of 2-year-old rats will be in a state of constant estrus with a minimum of three consecutive epithelial vaginal smear cycles, whereas the other half will proceed to a state of persistent diestrus with a minimum of three leucocytic smears. Interestingly, estrogen levels are only slightly higher in the former group. As discussed previously,

a high prevalence of pituitary and testicular tumors, particularly in aged F344 rats, also needs to be considered when using this strain in aging studies.

THE LABORATORY MOUSE

Being smaller than rats, mice provide investigators with smaller amounts of tissue, and systemic physiological studies can sometimes be difficult. However, mouse genetics are extremely well known, and the ability to create genetically modified mice has become an important tool for studying aging and age-related processes. The presentation of a phenotype in any organism is a composite of the interactions between its genetic complement and the environment in which it is placed. Although the process of aging is a complex phenotype, it is no exception to this generally accepted biological principle. In contemporary biomedical research, the laboratory mouse has become a premier model organism to study processes important to human biology. This surge in mouse-related research has been driven largely by the ability to develop genetically engineered mice both by transgenesis via pronuclear injection and with gene targeting using embryonic stem (ES) cells. In addition, large mutagenesis programs have been initiated to isolate new mutations associated with a wide variety of biological processes. These activities have been complemented with other technological advances, including the initiation of a DNA sequencing effort to completely sequence the mouse genome and the development of microarray technology. Although the promise of these efforts in contributing to the genetic dissection of complex biological processes is extraordinary, having the appropriate model to which one can apply these emerging technologies is paramount to a successful and productive outcome.

Although the mouse has many advantages, it is not without its disadvantages. It must be recognized that not all discoveries or observations made with the mouse will have direct parallels in the human. Furthermore, with a life span of many months as compared with days in a species such as *Drosophila*, another powerful genetic model, data collection is inherently slower. Finally, housing costs and the operation of a barrier facility is a major consideration in the selection of this model.

The mouse model provides an opportunity for investigators to control both the nutrition and housing environments for their experiment animals. It has been well documented that caloric restriction can substantially lengthen the life span of laboratory mice. This

principle seems to be true not only for mice and other rodents but also for insects, worms, and nonhuman primates, with possible implications for humans. Clearly, continued work with genetic models such as *Drosophila* and the mouse will ultimately reveal the genetic basis for this phenomenon. In the design of an aging study, the program for housing animals should be evaluated carefully. Caging style, light–dark cycle, ambient temperature, and the number of mice housed per cage all are obvious concerns. Other factors for consideration include extraneous noise and consistency in caretaker handling of the animals. Careful training of caretakers for uniformity in handling of the mice during cage-changing activities should not be underestimated.

Infectious diseases have long been known to have a potential impact on experimental analyses in mice. It is important to be able to determine whether the onset of a disease state is a function of the aging process or the result of a pathogen infection in the colony. In this context, the development and maintenance of specific pathogen-free (SPF) colonies for aging studies is essential. A researcher is also aided in this area by the existence of a large literature base on diseases in mice and on variations in susceptibility to diseases in specific lines or strains. The SPF status of study animals should be defined and maintained by careful husbandry practices. Frequently, an SPF barrier facility equipped with micro-isolator caging is employed to minimize the risk of an unwanted pathogen entering the colony. Access to such barriers is limited, and strict protocols for entry and animal-handling practices are mandated for staff working in such areas. A carefully designed sentinel program is essential for monitoring the health status of the colony and should be associated with a careful plan to respond if a break in the SPF status should occur.

Many inbred strains of mice have been developed and maintained by brother–sister matings for numerous generations. One major advantage of an inbred strain is genetic uniformity from one generation to the next. This feature permits an experiment to be repeated in both time and space with an identical or nearly identical genetic environment. In addition, a wealth of information on individual strain characteristics has been accumulated through years of research with these lines. Several inbred strains have been used in aging studies and can be obtained from a variety of sources. Inbred mice currently available through the NIA include BALB/cBy, CBA, C57BL/6, and DBA/2. Hybrids and calorically restricted mice will be increasingly available in future years. However, genetic uniformity of the inbred strain does not come without a

price in that certain lines come with their own particular set of problems that can affect an aging study. In the selection of a particular strain for analysis, previous work with that strain, the nature of the aging question being addressed, and potential strain idiosyncrasies must be evaluated. Fortunately, databases that allow rapid electronic access to much of this information have been developed to assist investigators with strain selection.

One approach to reduce the potential problems associated with the use of inbred strains is the production of an F1 hybrid mouse that is created by mating individuals from two different inbred strains. These F1 animals have the virtue of being genetically identical as well as being potentially heterozygous at most loci (F1 mice will be homozygous only for loci that happened to be identical in their inbred parents), reducing the impact of certain idiosyncrasies found in their inbred parents.

The number of variants at individual genetic loci has grown precipitously as a function of genetic engineering and focused mutagenesis programs that have been initiated relatively recently. Because designer variants and many spontaneous mutations are often isolated on different or mixed genetic backgrounds, breeding programs are frequently conducted to place each variant in a defined genetic background. This is accomplished by a series of back-crosses of the variant locus to a selected inbred strain such as C57BL/6. Lines established in this fashion are referred to as congenic strains. To avoid the complications of studying a variant in an inbred setting, a second congenic line in a different inbred strain can be created. By crossing these two congenic strains, a particular variant can be analyzed in an F1 hybrid and compared with the phenotype in the inbred strain.

Although the inbred strains and F1 hybrids allow rigid control of the genetic environment in a set of experimental animals, not all researchers agree with this approach. Concerns about the lack of genetic variance in these experimental paradigms (inbred lines and F1 hybrid) has led some researchers to favor experimental systems that provide more genetic heterogeneity. One experimental paradigm involves F2 hybrids. In this model, experimental mice are obtained by mating two F1 mice of the same type (e.g., F1 mice produced by crossing C57BL/6 mice with C3H mice). Alternatively, F2 animals can be developed using the four-way breeding scheme. This breeding program involves the mating of two different F1 parents. In this type of mating system, the resulting F2 animals have four different grandparents, whereas they have only two different grandparents if the F1 parents are

of the same type. In either system, the F2 mice are genetically heterogeneous, yet the genetic makeup of the population is defined and reproducible from laboratory to laboratory.

INVERTEBRATE MODEL SYSTEMS IN AGING

Saccharomyces cerevisiae (yeast), *Caenorhabditis elegans* (nematode), and *Drosophila melanogaster* (fruit fly) are the leading invertebrate model systems used in aging research. Their great advantages include ease of maintenance, short life spans, advanced molecular and genetic tools, and availability of their complete genomic sequences. Genetic screens have already identified a number of genes that appear to be involved in the aging process. Genetic and molecular characterization of these genes has provided valuable information about the physiological pathways that may be important in the aging process. Furthermore, the molecular conservation that has been so widely observed among yeast, *C. elegans*, *Drosophila*, and mammalian model systems such as mice and rats suggests that information obtained in these “simpler” systems is certain to facilitate our understanding of aging.

The budding yeast, *S. cerevisiae* (a single-cell organism), has been used in aging research since 1959, when Mortimer and Johnson described an increase in volume and number of scars as an aging phenotype. Aging of the yeast is measured as the average number of cell divisions that a mother cell can undergo or as the survival of nondividing cells during the stationary phase. The asymmetric cell divisions result in a larger mother cell and smaller daughter cells that can be easily separated, leaving behind the scar. Average cell divisions can range from 15 to 30 generations, depending on the strain. During the past decade, more than 16 longevity genes have been discovered in yeast, many of which are now being found to be important in the aging process of other invertebrates and mammals.

The nematode, *C. elegans*, is a very valuable tool in aging research. Some of the specific advantages of nematodes are their easy maintenance; small size (~1 mm as adult), short life span (~15 days at 20°C), and ability to be frozen indefinitely in liquid nitrogen and revived. Moreover, this relatively simple transparent organism is the only multicellular animal whose developmental anatomy has been described in great detail. The exact lineage of every cell in the body has been fully mapped out by direct observation of the developing animal from a single-cell egg to a

multicellular adult. Its genome has been completely sequenced. Recently developed microsurgical and genetic approaches can be applied to dissect the genetic control of specific developmental mechanisms.

C. elegans is a hermaphrodite, allowing for self-fertilization. As a result, a single heterozygous worm can produce homozygous progeny, an important feature that helps to make this organism exceptionally convenient for genetic studies. Meanwhile, genetic crosses are also possible given that the nematode can be mated with males. During normal development, *C. elegans* hatches from the egg as a first-stage larvae L1. After three more larval stages, it becomes sexually mature. Crowding, high level of pheromones, and food limitation induce entering of L2 to the dauer larval stage, an alternative L3 form that allows nematodes to survive difficult conditions. Dauer is a developmentally arrested form characterized by a lower metabolic rate, accumulations of fat, an increased level of antioxidant enzymes, and a longer life span. A nematode can survive during the dauer stage for up to 6 months. When conditions improve, the nematode develops into an L4 stage with a normal life span. Mutations in several genes extend the life span and affect dauer formation. Molecular and genetic characterizations of these genes reveal that some of them are components of the insulin-signaling pathway regulating both dauer formation and life span.

D. melanogaster or closely related species have been used to study aging since at least since 1915. There are numerous advantages such as the fact that fruit flies are not expensive to breed, are easy to maintain, and have a relatively short life span. *D. melanogaster* live about 2 months at 25°C. There are a number of environmental and genetic manipulations that can alter the life span of *Drosophila*. For instance, flies live about 3 months at 18°C and live only 1 month at 29°C. Also of interest is that a majority of the cells of adult fruit flies are postmitotic, with exceptions of some gut cells and gonads. Finally, the molecular genetic tools that have been developed over the past 90 years or so of *Drosophila* research have reached a point where experimenters have great control over the molecular genetic life of the fly. Through a combination of various already available techniques, it is possible to alter, increase, or decrease the level of expression of any gene or set of genes in any cell or group of cells at any time in life, from development to old age.

Reproduction has a strong negative effect on longevity in *D. melanogaster*. Both virgin female and male flies live significantly longer than do fully mated ones. The costs of reproduction in flies include energy

allocation for courtship and mating, egg production and egg laying, and direct toxic effects of mating. Although egg production does not play a role in aging in *C. elegans*, a signal from the germ line is involved in limiting life span such that removal of this signal results in an increase in life span. In addition to the reproductive system, other hormones, such as the insulin/insulin-like growth factor-1 (IGF-1) signaling pathways, have been shown to affect life span in nematodes and flies as well as in mice. Mutations in components of the highly conserved insulin pathway in *C. elegans* and *Drosophila* result in life-span extension.

NONHUMAN PRIMATES

The high cost and small availability of aged nonhuman primates have limited their use to selected research centers. Further compounding the difficulties in conducting research with these animals is their long life span and a lack of good survival data. At the same time, the phylogenetic proximity of these primates to humans makes these highly attractive, and in some cases even indispensable, models for the study of human aging and disease. For example, true menstruation occurs only among some primate species, making some nonhuman primates invaluable models for the study of female human menopause. Another area is brain structure, where only nonhuman primates represent adequate models for the study of many aspects of higher cortical structure and physiology.

Aging, Immunology and

Victor Appay

Institute of Molecular Medicine, John Radcliffe Hospital, London, United Kingdom

Glossary

antigen A substance that can elicit an immune response following recognition by T cells or B cells. Antigens can be proteins, carbohydrates, nucleic acids, lipids, or hormones. The immune system usually responds only against foreign antigens (e.g., from pathogens), but it can also react against self-antigens as if they were foreign, which can result in autoimmune diseases.

B cells A population of white blood lymphocytes found in bone marrow, lymph nodes, and blood circulation. B cells are generated and mature in the bone marrow; their role is to produce antibodies to bind and neutralize pathogens and toxins. Each antibody is strictly specific to only one antigen.

cytokines Proteins synthesized by cells of the immune system. Cytokines include an extensive range of mediators (interleukins, interferons, chemokines, and growth factors) with various functions (e.g., immunostimulatory or immunosuppressive).

immunosenescence Deterioration of the immune system or its function with time.

T cells A population of white blood lymphocytes found in the thymus, lymph nodes, and blood circulation. T-cell precursors are generated in the bone marrow; following their maturation in the thymus, naive T cells are exposed to foreign antigens and produce memory T cells, which are long-lived antigen-experienced cells that respond rapidly to a subsequent exposure with the same antigen. T cells have many functions, including the elimination of foreign pathogens or infected cells and the regulation of the immune response by assisting or suppressing other cells of the immune system.

Immunology is the study of the immune system or immunity, a range of defenses developed by humans, for example, to protect against infection by surrounding microorganisms (viruses, bacteria, fungi, and other parasites) and related dangerous pathologies. Immunogerontology is the study of the immune system in the context of aging (i.e., in the elderly).

INTRODUCTION

The study of our native immunity began in the late 18th century and has led to incredible discoveries regarding the role of our immune system and the mechanisms through which pathogens attempt to penetrate our defenses. In comparison, immunogerontology is a relatively new field that is gradually becoming more relevant because the older population is increasing at an unprecedented rate due to progress in health care, especially in developed countries, where life expectancy has nearly doubled during the past century. The aging of the human population represents a considerable challenge to public health authorities, raising both health care-related and socioeconomic issues.

The functional capacity of the immune system gradually declines with age so that the immune system cannot respond as quickly or as efficiently to stimuli, particularly new antigens. This deterioration, referred to as immunosenescence, is reflected by deregulation of the immune system, including changes in cellular phenotype and function, and alterations of whole organs. These changes are believed to contribute to the increased susceptibility to and severity of infectious disease, cancer, and autoimmune disease, which characterize individuals of advanced age. Research on the immunology of aging is needed to increase our understanding of the immunosenescence process and potentially to develop therapeutic intervention.

IMMUNE ALTERATIONS ASSOCIATED WITH AGING

Hayflick Limit

In 1961, Hayflick and Moorhead showed that cultures of fetal human fibroblasts could reach an irreversible state of growth arrest—the first evidence for replicative senescence. Accumulating evidence suggests that the so-called Hayflick limit is not restricted to cultured human fibroblasts but applies also to the cells of the immune system, which may have a limited replicative life span *in vivo*. The concept of limited replicative life

span is important in the context of aging and immunosenescence. The occurrence of replicative senescence is primarily related to the number of cell divisions, varying according to cell type and cellular environment. A commonly used marker of replicative history is the length of the telomeres (DNA repeats at the end of chromosomes), which is reduced after each cell division. Cells that have reached a state of replicative senescence have short telomeres.

Hematopoiesis

All the cells that constitute our immune system originate from hematopoietic stem cells (in the bone marrow) that differentiate and commit themselves to a specific cellular lineage (e.g., myeloid or lymphoid) to continuously generate new granulocytes or naive lymphocytes. Aging appears to result in a deregulation of hematopoiesis: Progenitor cells in elderly individuals are present in lower numbers and exhibit a decline in their ability to generate new cells. Hematopoietic stem cell telomeres appear to be shorter in adults than in the cord blood of newborns. Moreover, granulocytes and naive T cells show a shortening in telomere length associated with age, suggesting that this also applies to stem cells. Increasing evidence supports the hypothesis that stem cells have a limited replicative potential so that their capacity to replenish the cell population of the immune system is restricted. Although there is debate regarding whether this phenomenon has a real consequence on the immune function in aging, it implies that the capacity of the immune system is not unlimited and can reach exhaustion over time.

T Cells

During the past two decades, Graham Pawelec, Rita Effros, and others have provided strong evidence that aging results in important alterations of the T-cell function.

Thymus Involution

The thymus is the organ in which T-cell precursors mature into naive T cells capable of mounting an immune response against foreign antigens. With aging, the thymus naturally atrophies, a process called thymic involution. At birth, the thymus is involved in massive generation of T cells to fill the immunological space and provide the elements necessary to protect the host against pathogens. T cells are produced continuously throughout life; however, over time progressive decay of the thymus results in decreased

production of T cells and a lower number of naive T cells in the elderly.

Post-Thymic Development

When encountering a foreign antigen, naive T cells become activated and differentiate into antigen-experienced T cells that exhibit direct effector functions and can expand greatly to eliminate foreign antigens from the body. The ratio of naive to antigen-experienced T cells differs substantially in young and old subjects; it is high in newborns but decreases with age. Aging is also associated with a variety of changes in the characteristics and function of antigen-experienced T cells: (i) changes in T-cell receptor signal transduction and in the expression of cell surface receptors, including the loss of costimulatory receptors (e.g., CD27 and CD28) involved in activation; (ii) changes in the profile of cytokine expression (e.g., decreased production of interleukin-2, which is necessary for proliferation); (iii) reduced capacity to expand upon stimulation, associated with shorter telomere length, and increased susceptibility to undergo activation-induced cell death; and (iv) restricted T-cell repertoire so that T cells recognize a narrower range of antigens. All these functional changes have been postulated to play a role in the decreased immunocompetence associated with age. Interestingly, these characteristics may reflect a change in the T-cell subset composition, with a shift toward more differentiated antigen-experienced T cells that exhibit these characteristics (Fig. 1).

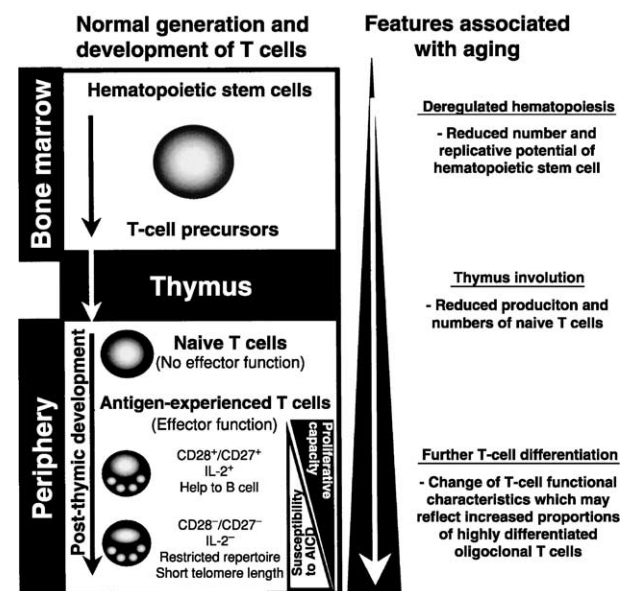

Figure 1 Alterations in the T-cell compartment associated with aging.

Other Alterations

The T-cell compartment is clearly the most affected during the process of aging. However, aging also affects the quantity and quality of protective antibodies produced by B cells, or humoral immunity. These alterations reflect a change in the B-cell repertoire and include a decline in the production and activity of T-cell-dependent B₂ cells compared to T-cell-independent B₁ cells, associated with a reduction in the diversity and quantity of serum antibodies specific for foreign antigens and a shift in specificity toward autologous antigens (with production of auto-antibodies). Other cell types (including natural killer cells, macrophages, monocytes, neutrophils, and eosinophils) may also be affected by aging. However, there are few data available and results have been contradictory. More research is needed to resolve these discrepancies.

IMPLICATIONS OF IMMUNOSENESCENCE

Onset of Immunosenescence

The precise mechanisms involved in the development of immunosenescence are not completely understood; however, the following hypothesis has been developed from the available evidence. In adults, the ratio of naive to antigen-experienced T cells is progressively reversed as naive T cells are increasingly exposed to antigens, which also drives T cells to differentiate toward stages of replicative senescence. However, with age, the naive T-cell population is not replenished, likely a consequence of the gradual deterioration of the thymus, and highly differentiated oligoclonal senescent antigen-experienced cells accumulate. The very old individual may become practically devoid of naive T cells. Immunosenescence may therefore be the result of the continuous challenge by a variety of antigens (e.g., pathogens) to which the immune system is exposed throughout a lifetime. The maintenance of a protective immunity over time may cause the eventual exhaustion of the finite capacity of the adaptive immune system. The reduced function of T cells in the elderly may affect B-cell function because T cells play a role in the regulation of B cells and the production of antibodies. Although further investigation is required, the potential reduction in the replicative capacity of the hematopoietic stem cells might have a significant impact on thymus involution and the decline in the production of

naive T cells as well as on the overall alteration of homeostasis.

Consequences of Immunosenescence

T cells play a prominent role in immunity, and alteration of their function has profound effects on the entire immune system and the host defense against pathogens. The age-associated decline in immunocompetence results in an increase in the incidence and/or severity of many infectious diseases (e.g., influenza, pneumonia, meningitis, sepsis, varicella zoster virus, and HIV), particularly in developing countries, in which health care is not optimum. Similarly, this decline may also be related to the prevalence of cancers in the elderly. In addition, deregulation of immune function may be involved in the onset of noninfectious diseases such as autoimmune disorders (e.g., diabetes, multiple sclerosis, and atherosclerosis) due to a decrease in the ability to discriminate between “self” and “nonself” and possibly neurodegenerative disorders such as Alzheimer’s disease. It is also well documented that the elderly do not respond to vaccinations as well as young individuals, as exemplified by influenza vaccination. In the elderly, T-cell and antibody responses to vaccines are slower and not as strong as in younger people, which makes the development of vaccines targeted for older adults a particular challenge. Interestingly, many of the immune characteristics associated with aging are also common to other conditions, independent of age, but result in a decline in immunocompetence (e.g., HIV infection and the genetic disorder ataxia telangiectasia). These observations link immunosenescence with the development of some degree of immunodeficiency. In the context of HIV infection, the virus is thought to cause elevated and chronic immune activation that may lead to premature exhaustion or aging of the immune resources, increasing the progression toward AIDS.

Aging: Muscle

Blake B. Rasmussen and Elena Volpi
University of Southern California, Los Angeles, California, United States

Glossary

adrenopause The gradual decrease in DHEA that normally occurs with aging.

andropause The decrease in androgens (primarily testosterone) that gradually occurs in men during the normal aging process.

menopause The termination of ovulation resulting in an abrupt decrease in circulating estrogens in women.

muscle plasticity An inherent property of skeletal muscle that allows muscle cells to adapt to external and internal stimuli.

sarcopenia The involuntary loss of muscle mass and function with aging that slowly develops over decades and becomes a significant contributor to disability in the older population.

somatopause The gradual decrease in circulating growth hormone and insulin-like growth factor-I that normally occurs with aging.

Aging is associated with a number of changes in muscle mass and function that may be caused at least in part by age-related endocrine changes and, conversely, may also be responsible for changes in the effects of some hormones. The most prominent effect of age is the involuntary loss of muscle mass, strength, and function called sarcopenia. Sarcopenia increases the risk of falls and vulnerability to injury and, consequently, can lead to functional dependence and disability. A decrease in muscle mass is also accompanied by changes in body composition and bone density, and it is associated with an increased incidence of insulin resistance in the elderly. A reduction in endocrine function, physical activity, and appropriate nutrition all play important roles in regulating muscle mass during aging.

INTRODUCTION

Muscle is profoundly affected by age. Muscle mass decreases approximately 3–8% per decade after age 30, and this rate of decline is even higher after age 60. The involuntary loss of muscle mass, strength, and

function is a fundamental cause of and contributor to disability in older people. This has been called sarcopenia. Sarcopenia may lead to a reduction in physical activity, which may have possible metabolic effects, including decreased bone density, obesity, and impaired glucose tolerance.

The etiology of sarcopenia is not clearly understood, but several mechanisms have been proposed, including irreversible fiber damage or permanent denervation resulting in a loss of contact between the nerve and muscle, mitochondrial DNA deletion mutations subsequent to oxidative damage, changes in satellite cell recruitment, altered endocrine function (e.g., changes in hormone, growth factor, and/or cytokine release) and/or impaired muscle responsiveness to the hormonal stimuli, changes in muscle response to nutrients and/or malnutrition, and disuse (e.g., sedentary lifestyle). Most likely, sarcopenia is a multifactorial problem. This article examines the last three possibilities that are directly or indirectly related to the endocrine system: endocrine dysfunction, nutrition, and disuse.

MUSCLE CHANGES WITH AGING

A variety of morphological and biochemical changes are detected in the aged human body and in skeletal muscle. Here, the alterations in body composition, skeletal muscle tissue, and muscle metabolism are discussed.

Body Composition

There is a progressive decrease in fat-free mass and a progressive increase in fat mass as a person ages. Furthermore, bone density decreases, joint stiffness increases, and there is a small reduction in stature (kyphosis). These changes in body composition have probable implications for several conditions, including type 2 diabetes, obesity, heart disease, and osteoporosis.

Muscle Tissue

The primary alteration is a reduction in total skeletal muscle mass. After age 30, the average person will lose approximately 3–8% of their muscle mass with each passing decade of life. Specific cellular alterations include reductions in muscle cell number, muscle twitch time and twitch force, sarcoplasmic reticulum volume, and calcium pumping capacity. Sarcomere spacing becomes disorganized, muscle nuclei become centralized along the muscle fiber, the plasma membrane of muscle becomes less excitable, and there is a significant increase in fat accumulation within and around the muscle cells. Neuromuscular alterations include a decrease in the nervous firing rate to muscle, the number of motor neurons, and the regenerative abilities of the nervous tissue. Motor unit size also increases.

Muscle Metabolism

Biochemical changes are also associated with the aging process and include a reduction in glycolytic and oxidative enzyme activities, creatine phosphate and ATP stores within the muscle cell, mitochondrial volume, and a slight reduction in overall metabolic rate (~10%). These metabolic changes in muscle contribute to the overall physical fitness capacity of the elderly and are an important component of the ~30% reduction in ability to use oxygen during exercise (i.e., $\dot{V}O_{2max}$). Initial studies on a small number of elderly subjects suggested that aging is associated with a reduction in basal muscle protein synthesis, which might be responsible for the progressive reduction in muscle mass. However, recent data obtained by our group from the largest cohort of healthy older men did not confirm the results of earlier reports, leading to the conclusion that differences in basal muscle protein turnover between elderly and young men cannot explain muscle loss with age and suggesting that future research should focus on responses to specific stimuli, such as nutrition, exercise, or disease.

AGE-RELATED ENDOCRINE CHANGES RELEVANT TO MUSCLE

A variety of hormonal changes are seen during the aging process. We have selected the most important ones in relation to their effect on skeletal muscle.

Andropause

The primary and most potent androgen is testosterone. In approximately 60% of men older than age 65,

testosterone levels decrease below normal levels of younger men. Testosterone levels gradually decrease throughout the aging process (unlike the immediate decrease in estradiol seen with menopause). It has been proposed that the decrease in testosterone may cause a decrease in muscle protein synthesis and result in a loss of muscle mass. With this in mind, several studies have examined the effect of testosterone replacement therapy in men with overt hypogonadism or testosterone concentrations at the lower normal range. Testosterone was administered via injection, transdermal patch, or dermal gel. From these studies, it was shown that testosterone replacement to mid-normal levels resulted in a significant increase in muscle mass, muscle strength, muscle protein synthesis, and bone density. The results are positive and may lead to a reversal or attenuation of sarcopenia. However, testosterone is currently not recommended for the treatment of sarcopenia, and a careful evaluation of the potential benefits compared to the potential risks (e.g., increased prostate-specific antigen, hematocrit, and cardiovascular risk) should be performed before initiating testosterone replacement therapy for sarcopenia.

Menopause

Estradiol levels abruptly decrease during menopause. Very little information is available regarding the role of menopause in sarcopenia. It appears that muscle mass is not affected by the decrease in estrogens. Cross-sectional studies evaluating the effects of age on lean body mass and appendicular muscle mass have shown that the rate of decline of muscle mass in women does not increase after menopause, suggesting a marginal role, if any, of this event in the development of sarcopenia in women. On the other hand, hormone replacement therapy can significantly increase serum steroid hormone-binding globulin, which leads to a significant decrease in serum free testosterone levels in women. Low serum free testosterone levels in women are associated with a lower muscle mass. Therefore, hormone replacement therapy may play a role in further reducing, rather than increasing, muscle mass in older women.

Somatopause

The growth hormone (GH)/insulin-like growth factor-1 (IGF-1) axis also exhibits a gradual decline during normal aging. Although providing GH replacement therapy to GH-deficient adults resulted in

an increase in muscle mass and strength, recent studies in which GH replacement therapy was given to aged individuals have shown no effect on muscle strength. Therefore, GH replacement therapy in the elderly may be beneficial for lowering fat mass, improving blood lipid profiles, and increasing lean body mass, but these changes do not lead to an increase in muscle strength and function. In fact, muscle strength increased only when GH was given to elderly men undergoing a weight-training program compared to GH replacement therapy alone. It is also important to note that the methodologies used to measure body composition may be affected by water retention. Thus, an increase in muscle mass with no change in strength following GH therapy should be interpreted with caution because GH is notorious for increasing water retention, which can be misinterpreted as an increase in lean body mass. Regarding testosterone, GH replacement is not currently recommended for the treatment of sarcopenia due to both the unclear efficacy on muscle strength and function and the potentially serious side effects (arthralgia, edema, insulin resistance, cardiovascular risk, etc.).

Adrenopause

The concentrations of DHEA in the blood also decrease gradually with normal aging. In fact, levels may be up to five times lower in very old men compared to younger men. Oral supplementation of DHEA restores DHEA levels in older persons to younger values, increases IGF-1 levels in men and women, increases estrogens in men, and increases testosterone in women. Unfortunately, no changes in lean body mass were detected and high-density lipoprotein-cholesterol levels were significantly decreased. However, in one study muscle strength was increased in older men (but not women) by DHEA supplementation. Recently, a very large study of older subjects showed that DHEA replacement therapy has no effect on muscle size, strength, or function.

Insulin Resistance

The ability of muscle tissue to respond to insulin is an important aspect of overall insulin sensitivity. The incidence of insulin resistance and type 2 diabetes increases with aging, and sarcopenia may play an important role. It is unclear whether the increase in insulin resistance observed with aging is due to age per se or whether it is secondarily due to the reduction in metabolically active lean body mass. Some studies have

reported that when using the oral glucose tolerance test to compare insulin resistance between cohorts of young and older subjects, the prevalence of glucose intolerance is higher in older subjects when the data are reported per unit of body mass, but these differences disappear if the data are corrected by lean body mass. This suggests that the changes in body composition may drive the increase in insulin resistance with age. Although insulin is usually considered in the context of its ability to increase glucose uptake into cells, there is evidence that insulin resistance of muscle protein metabolism in the elderly may be an important contributor to sarcopenia. For example, when glucose is ingested with a regular meal, the subsequent increase in insulin concentrations has a negative effect on muscle protein synthesis. This implies that with normal aging, the ability of muscle cells to properly respond to circulating insulin (by increasing muscle protein synthesis) is impaired.

AGING AND MUSCLE PLASTICITY

Human skeletal muscle is one of the most adaptable tissues in the body. The ability of muscle cells to respond to external and internal stimuli is often called muscle plasticity. We examine how two common physiological stimuli (exercise and nutrition) of skeletal muscle anabolism may be involved in the development of sarcopenia and may be used to counteract muscle loss with age.

Exercise

Inactivity reduces muscle mass, even over a short period. Typical examples are the reduction of muscle mass observed in bed-ridden patients, following immobilization for fractures, or in weightlessness (space flight). Resistance exercise and aerobic exercise have a significant influence on skeletal muscle mass, strength, plasticity, and metabolism. Resistance exercise training results in hypertrophy of muscle cells and large increases in strength. Aerobic exercise training does not alter muscle cell size but has significant effects on the aerobic capacity of muscle cells (i.e., increases in oxidative enzymes and mitochondrial volume) with minimal effects on muscle strength. Resistance exercise acutely stimulates muscle protein synthesis in both young and older people. Both types of exercise reduce insulin resistance and increase glucose and fat oxidation. The elderly respond very well to resistance exercise training by increasing muscle mass and strength, and their aerobic capacity increases

following aerobic exercise training. Recent data also suggest that aerobic exercise may acutely increase muscle protein synthesis in older subjects. Thus, both types of exercise can be very useful to counteract sarcopenia and the associated metabolic alterations of the aging muscle.

Nutrition

Malnutrition leads to muscle wasting. Several studies have shown that the caloric intake of many elderly individuals is too low and may be an important factor in the development of sarcopenia. Recent data also suggest that the recommended protein daily intake for the elderly (0.8 g/kg/day) might be insufficient to maintain a neutral nitrogen balance. Additionally, older people may voluntarily reduce their protein intake to comply with reduced fat and cholesterol diets. Amino acids from ingested protein directly stimulate muscle protein synthesis. Interestingly, healthy elderly subjects respond to an amino acid stimulus with an increase in muscle protein synthesis that is not significantly different from the effect observed in their younger counterparts. Unfortunately, high-protein diets given to older subjects have not proven to be effective on muscle size or strength. This may be explained by the fact that in these trials, the additional protein was given in combination with carbohydrate, which stimulated insulin secretion. Our recent data indicate that when carbohydrates are included in a protein meal for the elderly, the positive effect of amino acids on muscle protein synthesis is blunted, possibly due to the negative effect that insulin exerts on muscle proteins in the elderly. However, there are no long-term studies in which older subjects have been given only amino acids or proteins with no carbohydrate to stimulate muscle protein synthesis and provide additional energy.

CONCLUSION

Sarcopenia is a multifactorial process. Reductions in endocrine function and physical activity and inadequate nutrition all play an important role in the reduction of muscle mass with normal aging. Testosterone replacement therapy may be a useful intervention in hypogonadal older men for increasing muscle mass and strength, although it is not currently recommended. Hormone replacement therapy for menopause, adrenopause, or somatopause appears to

have marginal or no positive effect on muscle mass and strength.

Exercise training and proper nutrition can have dramatic effects on muscle mass and strength. An optimal intervention program may include an exercise-training schedule that incorporates both resistance and aerobic exercise with adequate intake of total calories and protein. This would not only improve muscle mass and strength but also reduce insulin resistance, which is more prevalent in the elderly. Providing a nutritional supplement of only amino acids or protein might also be beneficial to promote muscle growth by stimulating muscle protein synthesis and increasing the total daily caloric intake; however, further investigation is needed.

Fortunately, aged muscle is still very plastic and can respond to anabolic stimuli by increasing its mass and strength. This knowledge is vital for designing interventions to reverse and/or attenuate the loss of muscle mass with aging and to improve metabolism and functional abilities in the elderly.

Agonadism, Male and Female

Marco A. Rivarola and Alicia Belgorosky
Garrahan Pediatric Hospital, Buenos Aires, Argentina

Glossary

estradiol Main female sex hormone secreted by the ovary; synthesized from ovarian male sex hormones by the action of the enzyme aromatase, localized in the granulosa cells.

gonadotropin-releasing hormone (GnRH) Small polypeptide hormone (10 amino acids) secreted by hypothalamic interconnected neurosecretory cells in a pulsatile fashion; reaches the pituitary gland via a local circulatory system to stimulate pituitary gonadotropins (gonadotrope cells).

gonadotropins Protein hormones synthesized and secreted into the blood by the pituitary gland or the placenta; stimulate the gonads.

ovarian follicle Main cellular structure of the ovary, containing one oocyte (germ cell) surrounded by many granulosa and theca cells; synthesizes female sex hormones.

seminiferous tubules Tubular structure of the testis containing the germ cells that are supported by a layer of Sertoli cells.

testosterone Main male sex hormone secreted by the testis; a small molecule belonging to the steroid family of chemicals.

Congenital agonadism is the absence of both gonads in a newborn baby. The gonads (testes and ovaries) are formed during embryonic life under genetic control.

INTRODUCTION

There is a sexual dimorphism in the genetic material that is evident under microscopic observation of the sex chromosome constitution. In humans, the two sexes have 46 chromosomes, but whereas females have two X chromosomes (46,XX), males have one

X chromosome and a Y chromosome (46,XY). The Y chromosome has fundamental genetic information necessary for the differentiation of the testis, even though genes located in other chromosomes (the X chromosome and the autosomes) are also necessary.

In the case of males, the function of the fetal testis is essential for the formation of male external genitalia (penis and scrotum); therefore, testes had to be present at the time of differentiation of the genitalia, during the first trimester of pregnancy. Indeed, in the absence of gonads, external genitalia (vulva and lower third of the vagina) as well as internal genitalia (fallopian tubes, uterus, and the upper third of the vagina) are female, regardless of genetic sex. For some reason, usually spontaneous testicular torsion that blocks vascular supply, testes might “vanish” after the time of genitalia differentiation and no longer be present at birth. This event is very rare; therefore, male agonadism is seen only infrequently. In a broader sense, partial loss of testicular function, properly called hypogonadism, is discussed in this article.

In the case of females, fetal ovaries are not necessary for the formation of female external genitalia. Girls with Turner’s syndrome, a condition secondary to an absence or abnormality of one chromosome X, have atrophic or hypotrophic ovaries but normal external and internal genitalia. These girls are short and usually have other physical problems.

The function of the gonads is under tropic control of the hypothalamo–pituitary axis by two pituitary hormones called gonadotropins. Even though gonadotropins are the same molecules in the two sexes, they take their name from their effects in females: follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Hypogonadism is defined as “primary” when the defect is primarily of the gonads and as “secondary” when the defect is secondary to hypothalamo–pituitary deficiency.

MALE AGONADISM

The Testis: Two Compartments, Two Functions, Two Gonadotropic Controls

There are two distinct compartments in the testis with two different functions. First, the seminiferous tubules are multiple rolled-up microscopic tubules wrapped up in a capsule, within which millions of germ cells are produced daily (in adults) and released into a lumen along with a specific seminal fluid. These tubules end up in a common reservoir, and their contents leave the testis through a single duct. Germ cells are supported by Sertoli cells, which provide them with nutrition and functional modulation. Sertoli cells have receptors for the FSH gonadotropin in the cell membrane. Receptors for protein hormones, such as FSH, are specialized proteins that can recognize, bind, and retain a specific hormone arriving via the blood supply. After binding the hormone, receptors send a signal inside the cell that triggers a specific response. Sertoli cells also secrete a hormone, inhibin B, for pituitary FSH regulation. Second, the interstitial tissue surrounds the seminiferous tubules. This compartment contains capillary blood vessels and various specialized cells, among which the Leydig cells are in charge of synthesizing and secreting testosterone, the main male hormone. Testosterone is secreted into the blood for peripheral androgen stimulation, but it is also diffused locally to the seminiferous tubules in large concentrations. It is essential for proper development of spermatogenesis. Therefore, the close proximity of Leydig cells to seminiferous tubules serves a useful purpose. Leydig cells have receptors for the LH gonadotropin in the cell membrane. Testosterone also regulates pituitary LH secretion. Peripheral androgen stimulation induced by testosterone includes enlargement of the penis and contributes to sustaining penile erection and sexual potency. It also has many other actions, including central nervous system effects in sexual conduct.

Testes are located in the scrotum, outside the abdominal cavity, because spermatogenesis cannot proceed normally at 37° Celcius, the normal body temperature. This is so important that the scrotum has its own refrigeration system. The cooled venous blood returns from the scrotal tissues inside multiple small veins, which surround the arterial vessels, cooling off the incoming warmer arterial blood.

Testicular Differentiation and Development

From Embryonic Life to Late Prepuberty

Because the underdeveloped seminiferous tubules do not have a lumen, they are named seminiferous cords. The reason why males do not have a uterus is that the embryonic and fetal Sertoli cells of these cords have the function of inducing regression of the embryonic Müllerian ducts, the precursors of fallopian tubes and uterus. For these purpose, they secrete anti-Müllerian hormone (AMH), also known as Müllerian-inhibiting substance (MIS). Secretion of AMH continues for a few years after birth for reasons that are not well understood. Seminiferous cords remained immature throughout childhood and become mature at adolescence along with maturation of spermatogenesis. The immature Sertoli cells have the capacity to proliferate (pre-Sertoli cells) during childhood. Maturation of germ cells during fetal life is halted at the stage of gonocytes and spermatogonia. Spermatogonia remain the most mature germ cells up to puberty.

Germ cells are unique in their modes of division. They can divide by mitosis, like any other cell, but can also divide by meiosis, a complex process that includes chromatin interchange (gene mixing) and ends up with a reduction of gene material to one half (one allele). In males, the first meiosis takes place during adolescence, and it goes on throughout adult life.

Leydig cell development in humans is a triphasic phenomenon: testosterone production has peaks at 14 to 18 weeks of fetal life, 2 to 3 months after birth, and from puberty throughout adult life. Testosterone secretion by the fetal testes is essential for species existence because it induces differentiation of male external genitalia. At the critical period of male differentiation, it is stimulated by a placental gonadotropin called chorionic gonadotropin (CG). For final penile enlargement, the contribution of fetal pituitary LH is also necessary. The function of the early postnatal peak of testosterone secretion is unknown. It is a matter of controversy whether testosterone secretion during the fetal and postnatal phases may play a role on the central nervous system, programming hypothalamic gonadotropic modulation and/or adult male sexual orientation and behavior.

Pubertal Maturation

At puberty, dramatic changes take place in the testes. The initiation of testicular growth is the first sign of

male puberty taking place at approximately 11 to 13 years of age, but this event goes unnoticed by most boys. The process actually had started earlier by the activation of the gonadotropin-releasing hormone (GnRH) pulse generator, a neurosecretory structure located in the hypothalamus. The GnRH pulses reach the pituitary through a local portal vein system to induce a pulsatile secretion of LH and FSH, which in turn reach the gonads through the general blood circulation to stimulate Leydig and Sertoli cells, respectively. Initial testosterone production has a local effect on seminiferous tubules growth in combination with the direct FSH stimulation of Sertoli cells (Fig. 1). Secretion of testosterone increases gradually and, as mentioned previously, has effects in multiple organs. Those more obviously responsive are the growth of male external genitalia and pubic hair and a deepening of the voice, but many other tissues

Figure 1 Interactions among the components of the hypothalamo–pituitary–testicular axis in males. The GnRH pulse generator of the hypothalamus exerts the overall control of the system. The GnRH hormone is delivered directly to the pituitary gland via a specialized local blood supply. The gonadotropic cells respond to GnRH by secreting the LH and FSH gonadotropins. They reach the testis through the general circulation. LH stimulates the secretion of testosterone by the Leydig cells of the interstitial compartment, whereas FSH stimulates the function of Sertoli cells to sustain spermatogenesis (along with testosterone). Testosterone, in turn, controls its own secretion by inhibiting an excess of gonadotropins (mainly LH) and also controls the GnRH pulse generator. This is known as the feedback system. Similarly, inhibin B, secreted by Sertoli cells, inhibits FSH secretion, a second feedback system.

respond as well. There is a simultaneous spurt in growth velocity, increases in muscle strength and bone mineral density, and important changes in the central nervous system function that affect general behavior and sexual interest.

Inside the seminiferous tubules, spermatogonia, the germ cell reserve, initiate a complex process of very active replication and maturation to produce spermatozoa. This process goes on continuously until senescence. Billions of spermatozoa are produced daily as a reassurance for the conservation of the species. Spermatozoa leaving the testes are immature, but they mature during their passage through the epididymis, a convoluted and unique tubule contributing to the seminal plasma and carrying the spermatozoa toward the deferent duct. Other exocrine glands, such as the prostate, also contribute to the seminal plasma. The semen is stored in the seminal vesicles, ready to be expelled during ejaculation.

Testosterone reaches most androgen-responsive organs via the blood supply. Cells of these organs have an intracellular receptor for androgens. Receptors for sex hormones do not need to be located in the external cell membrane because sex hormones have free access through the cell membrane. In some organs such as the prostate, testosterone is converted into a more potent androgen, dihydrotestosterone, before interacting with the androgen receptor. This is a protein with high affinity for androgens. The complex is then carried inside the cell nucleus to interact with androgen-responsive genes in the genomic DNA.

Puberty takes approximately 4 years to be completed. There are large variations in the onset of puberty in the two sexes. In males, age limits are conventionally set to diagnose early and late alterations in the onset of puberty. Normal variations are early puberty, when the onset is observed between 9 and 10 years of age, and delayed puberty, when it has not started by 14 years of age. An abnormality, and sometimes a serious problem, has to be suspected in boys when the onset of puberty is precocious (before 9 years of age) or very much delayed (after 15 years of age).

Delayed Puberty

Those normal boys who undergo a delay in the initiation of puberty are frequently upset when they compare themselves with most other boys who are already in the process of sexual development, height velocity increments, and gains in physical strength. They have

difficulties in competing with their peers and might suffer from psychological problems. This is a relatively common complaint to pediatricians, who have to make the differential diagnosis between a normal variation of sexual development and hypogonadism, a disease affecting primarily the testis or, as already defined, secondary to hypothalamo–pituitary dysfunction.

The diagnosis of primary hypogonadism in males is much easier than in females because testes are outside the abdomen and, therefore, can be examined directly. In this respect, the position, size, and consistency of the pubertal testes should be evaluated. The progress of sexual maturation can be followed clinically; stages of sexual maturation for the two sexes were defined by James M. Tanner in 1962, and they are used universally in the follow-up of normal adolescence. Finally, an important clinical tool to evaluate the progress of body maturation is the determination of “bone age.” Normal maturational changes in the ossification of the hand and wrist in normal boys and girls are used to assess maturational bone age. In a single individual, bone age does not necessarily correspond to chronological age. It is a useful marker for whole body maturation as well as for sexual maturation. When necessary, imaging studies and hormonal tests can be used to establish a diagnosis.

In most instances, delayed puberty is associated with constitutional delay of growth, with the two expressing a delay in general body maturation. Frequently, there is a familiar trend. Because this is a variation of normality, the prognosis is good and no treatment is indicated. In exceptional instances, serious psychological problems might arise, and puberty can then be induced by transient administration of sex hormones.

Undescended Testis (Cryptorchidism)

The embryonic differentiation and most of the fetal development of the testis take place in the abdomen. During the final trimester of pregnancy, the testis descends from the abdomen to the scrotum via the inguinal canal. Cryptorchidism is defined as the failure of this descent. It is observed quite often. Sometimes (2–5% of male newborns), and particularly in premature babies (up to 30%), testicular descent is not complete at birth, but the testis goes down spontaneously during the first 3 months of life. Cryptorchidism can be unilateral or bilateral. Bilateral cryptorchidism is more often associated with hormonal or genetic abnormalities than is unilateral cryptorchidism. Development of spermatogenesis, beginning at adolescence, requires that the testis

be located in the scrotum. However, the consensus among pediatricians and urologists is that the testis should be in the scrotum much earlier, around the first year of life.

Advances in the mechanism of testicular descent have been reported. However, this new information can explain only a few cases of undescended testis.

The incidence of testicular tumors is higher in adults who had had cryptorchidism during childhood than in the general population. However, early surgical correction does not change this incidence. In general, fertility during adult life is much higher in unilateral cryptorchidism than in bilateral cryptorchidism. A point of controversy is whether early correction of cryptorchidism is able to improve fertility in adult life. There is some weak evidence that this might be the case. Therefore, early correction of this condition (between 1 and 2 years of age) is recommended. This can be done with hormone stimulation (human CG [hCG]) for a few weeks followed by surgical correction in case of lack of descent.

Primary (Hypergonadotropic) Hypogonadism

Klinefelter's Syndrome

One of the frequent causes of hypergonadotropic hypogonadism is Klinefelter's syndrome. In 1942, H. F. Klinefelter described a syndrome of small testes, sterility, excessive gonadotropins, and bilateral breast development (gynecomastia). Different degrees of mental deficiency are frequently observed. In most patients, an extra X chromosome is found (47,XXY), but variants can be present. A defect in cell division of paternal or maternal germ cells, or during the first cell divisions after fertilization, is responsible for the sex chromosome excess. Frequency of the syndrome has been estimated to be between 1/500 and 1/1000 males—certainly a high proportion.

In most cases, these boys remain undiagnosed before puberty, even though school difficulties are common. Diagnosis is made at puberty because sexual development proceeds in the presence of small testes and gynecomastia becomes apparent. Soon after the initiation of spermatogenesis, germ cells start to die and the seminiferous tubules do not grow. Deficiencies in the secretion of inhibin B by Sertoli cells and testosterone by Leydig cells stimulate the secretion of FSH and LH, respectively. Even though testosterone secretion is subnormal, it is sufficient to induce sexual development; however, fertility is impaired. Mental deficiency and behavioral problems might be serious difficulties in these boys.

Anorchia

Anorchia, or congenital agonadism, is the absence of testes in a newborn with male external genitalia and 46,XY chromosomal constitution. Androgen action is needed at a critical time of embryonic development to masculinize the external genitalia. Independently of the chromosomal constitution when there is a failure in the differentiation of the gonads, external genitalia are female. If there is partial differentiation of the testes, external genitalia undergo incomplete masculinization and the baby is born with ambiguous genitalia. The problem of human intersex is very complex and is not dealt with in this article. If, for some reason, testes become atrophic before birth but after formation of external genitalia, a male baby is born without palpable testes. True anorchia must be differentiated from intra-abdominal bilateral cryptorchidism. Monorchia is the presence of only one testis. In rare occasions, a 46,XX female with congenital adrenal hyperplasia has complete virilization of the external genitalia induced by an abnormal excess of adrenal androgens. These babies have a uterus and two ovaries that might go unnoticed. Therefore, it is important to establish the correct diagnosis at birth.

To detect the presence of nonpalpable intra-abdominal testes, some hormonal tests can be used. For many years, stimulation of testosterone secretion with hCG for 1 week has been the most useful test. Nowadays, a single blood sample determination of inhibin B or AHM, two products of Sertoli cells, can also detect the presence of intra-abdominal testes.

The lack of testes results in the absence of restraint to gonadotropin secretion. This is more marked than in Klinefelter's syndrome and becomes evident during late prepuberty, particularly for FSH.

Treatment of anorchia presents two problems. On the one hand, it is necessary to replace the function of the testes to induce puberty and to maintain appropriate androgen stimulation throughout adult life. On the other hand, the patient or parents often request that a testicular prosthesis be put in place to replenish the empty scrotum. If the boy is too small, the prosthesis will have to be replaced by a bigger one at adolescence. The induction and maintenance of testosterone function is relatively easy to accomplish using intramuscular long-acting preparations of testosterone (usually one shot per month) or dermal testosterone patches. The replacement of the second testicular function, the production of sperm, is not possible at this point. However, the astonishing advances in the techniques of human fertilization might bring solutions to this problem in the future.

Other Causes

Other causes of hypergonadotropic hypogonadism include infections, trauma, and medications that are toxic for the testes. For instance, an unwanted side effect of the survival of boys with malignant diseases requiring chemotherapy is the destruction of the germinal epithelium. Radiation to the testes is also deleterious for germ cells. Before chemotherapy, there is the possibility of collecting sperm for storage for the purpose of using it to achieve fertility in the future.

Secondary (Hypogonadotropic) Hypogonadism

In secondary hypogonadism, there is a deficiency in the secretion of the two gonadotropins: LH and FSH. In most instances, it is secondary to a failure in the function of the hypothalamic GnRH pulse generator.

It is interesting that the ontogeny of GnRH cells is closely associated with that of the olfactory neurons. Indeed, in the embryo, the two types of cells arise from the olfactory placode in the encephalon. They migrate together for some time and become separated later, with the GnRH neurons reaching the hypothalamus. This common biological origin might be associated with the known role of odors in sexual attraction in many animal species as well as in humans.

Kallman's syndrome is a relatively frequent type of hypogonadotropic hypogonadism that associates lack of sexual function and loss of sense of smell. The cause of Kallman's syndrome is heterogeneous. Loss of function mutations of at least two genes is responsible for the alteration. Because one of these genes is located in the X chromosome and the other one is present in an autosome, familiar transmission is different. Kallman's syndrome in boys might be suspected before puberty because of the association of small testes, cryptorchidism, and hyposmia or anosmia.

When lack of sexual development at puberty is the only symptom, differential diagnosis with pubertal delay might be difficult. Several hormonal tests have been devised for this purpose, but sometimes only the evolution of the signs and symptoms will define the diagnosis. In the meantime, patients can be treated temporarily.

Hypogonadotropic hypogonadism may be congenital or acquired, secondary to a lesion of the hypothalamo-pituitary axis. Such a lesion might be the consequence of the development of a tumor in this area. Even though these tumors are "benign,"

they might be life-threatening because of their location. Frequently, neurological or visual problems are the main concern. Other hormonal functions of the pituitary gland might be affected. Some of these tumors require surgery, but others respond to chemotherapy or hormonal treatment, depending on the tumor cell type. Unfortunately, surgery in the hypothalamic area frequently produces important invalidating sequelae. Paradoxically, tumors in this area can induce an opposite alteration: precocious puberty in small children.

Treatment of hypogonadotropic hypogonadism is needed for induction of sexual development at adolescence, maintenance of sexual function during adulthood, and stimulation of spermatogenesis when paternity is desired. When the pituitary gland is intact, the ideal treatment would be to replace the deficient secretion of the GnRH pulse generator. For this purpose, a portable pump that generates secretory pulses at the appropriate frequency (every 2 h) has been used. For practical reasons, this treatment is discontinued after completing sexual development in approximately 2 years. An alternative approach is to administer LH and FSH in adequate combinations. Finally, the most practical treatment is to administer replacement doses of testosterone as in boys with anorchia.

FEMALE AGONADISM

The Ovaries: Two Functions, Two Gonadotropic Controls

Similar to the testes but with multiple differences, ovaries have two separate functions (synthesis of female hormones [estrogens] and ovulation) and two gonadotropic controls (LH and FSH). However, compartmentalization is less evident. In the two sexes, during early embryogenesis, primitive germ cells migrate to the bisexual embryonic gonads. However, testes in males differentiate much earlier than do ovaries in females. Female germ cells, called oogonia, intermingle with surrounding somatic cells, called granulosa cells, to form the primordial ovarian follicles, each consisting of a single germ cell, now developed into an oocyte, wrapped in a layer of granulosa cells. Similar to Sertoli cells of the testis, granulosa cells have receptors for FSH and secrete inhibin for pituitary FSH regulation.

The growing follicle is encircled by a layer of steroidogenic cells called theca cells. Synthesis of estrogens results from cooperative action between theca

and granulosa cells in growing follicles. Theca cells have the steroidogenic machinery to synthesize androgens under LH stimulation. These androgens are then converted into estrogens by an enzyme of the granulosa cells under FSH stimulation. Curiously, female hormones are derived from male hormones. On the other hand, some of the actions of male hormones are mediated by their conversion into female hormones at target tissues.

Ovarian Differentiation and Development

From Embryonic Life to Late Prepuberty

Different from testis, germ cells of the ovary initiate meiotic division during embryonic life. However, meiosis is already arrested at birth before completion. At birth, there are several hundred thousand primordial follicles, each one containing a single oocyte. This reserve of germ cells has to last a lifetime because there is no proliferation after birth. Ovaries are not necessary for differentiation of female internal genitalia (uterus and fallopian tubes) or external genitalia (vulva and vagina). Therefore, in the absence of ovaries, no clinical sign of the problem is evident in the external genitalia at birth.

Follicles develop continuously from the pool of primordial follicles throughout prepuberty and reproductive life. However, development during prepuberty is slow and restricted to partial growth. Therefore, estrogen secretion is minimal and there is no evidence of either secondary sexual characteristic development or ovulation.

Estrogen secretion starts to increase during late prepuberty. This minimal estrogen activity is often responsible for the increase in growth velocity observed at late prepuberty in girls. At the beginning of puberty, breast development becomes evident (thelarche). However, moderate and transient increases in breast development occasionally might be observed in girls at any time during prepuberty.

Pubertal Maturation

As is the case in males, the process of pubertal development in females is controlled by the hypothalamic GnRH pulse generator. In the ovaries, follicle development, stimulated by pituitary FSH, is morphologically characterized by the proliferation of granulosa cells and a synchronous increase in the diameter of the oocytes (Fig. 2). During the first couple of years after the onset of puberty, growing follicles of the ovaries secrete increasing amounts of estrogens to develop secondary sexual characteristics, mainly breasts,

Figure 2 Sequence of events in the cycling ovary showing interactions among the components of the preovulatory follicle. Pituitary FSH stimulates granulosa cell function. These cells, which surround the oocyte, control oocyte development; in turn, the oocyte controls granulosa cell function. Estrogen synthesis is also the result of cell cooperation. Indeed, theca cells synthesize androgens, which are converted to estrogens by granulosa cells. One of the growing follicles becomes the dominant follicle, accumulates fluid, and is the target for LH-induced ovulation. After ovulation, the oocyte is taken up by the fallopian tube. The remaining follicular cells undergo a process of change (luteinization) and form the corpus luteum. The corpus luteum secretes progesterone, an ovarian hormone that is necessary for preparing the endometrium of the uterus for egg nesting.

fallopian ducts, uterus, vagina, and vulva. Growing follicles undergo a process of regression, becoming atresic and being replaced by new growing follicles.

At one stage in the process of sexual maturation, the development of follicles (involving the recruitment of some primordial follicles from the resting pool and the continued growth of these follicles) reaches the point of selection of a dominant follicle in one of the ovaries. Active interaction between the oocyte and the granulosa cells, under LH stimulation, prepares the dominant follicle for ovulation. Two weeks later, at ovulation, the oocyte is expelled from the ovary and is taken up by the fallopian tube. Fertilization takes place in the fallopian tube after the arrival of mature spermatozoa several hours postcoitum. After ovulation, the dominant follicle undergoes an active process of cell reorganization and maturation, called luteinization, and is transformed into the corpus luteum (Fig. 2). This newly formed ovarian component secretes a different ovarian hormone called progesterone. One of the main functions of progesterone is to prepare the endometrium, the internal layer of the uterus, for possible nesting of the fertilized egg.

In the absence of fertilization, the corpus luteum regresses in approximately 2 weeks and the hormonal

activity of the ovary, both estrogens and progesterone, goes down.

These two hormones are necessary for maintaining the tropic development of the internal uterine layer. Hormonal withdrawal results in elimination of part of the endometrium along with its blood supply (menstruation). Afterward, the process of pituitary gonadotropic stimulation and follicle growth starts again. The cyclic nature of the ovarian function is in sharp contrast to the continuous functioning characteristic of the testis. The first menstruation is called menarche. As stated previously, it is usually preceded by approximately 2 years of acyclic ovarian activity that prepares the body for full sexual function. The age of menarche may vary greatly in normal girls, as much as between 10 and 15 years of age.

Primary (Hypergonadotropic) Hypogonadism

Female hypergonadotropic hypogonadism can be congenital or acquired after birth. The most frequent cause of congenital primary hypogonadism in girls is Turner's syndrome. Other causes of congenital

hypergonadotropic hypogonadism in girls are very uncommon gene defects, which are of interest to medical specialists. Acquired hypergonadotropic hypogonadism can be secondary to trauma or surgical removal of the ovaries, chemotherapy or radiotherapy, ovarian infections, autoimmunity of the ovary, and/or ovarian resistance to gonadotropins of unknown cause.

Secondary (Hypogonadotropic) Hypogonadism

Females can suffer from the same disorders of hypogonadotropic hypogonadism that have already been described for males. Complaints of delayed puberty are seen less frequently in girls than in boys. It is only a delay in the physiological activation of the GnRH pulse generator and is usually associated with a delay in stature growth. After some time, normal puberty should develop.

However, in females, a mild disorder may be limited to a loss of the cyclic function of the system. Menstrual irregularities or absent menstruation is the only complaint, with conservation of a reasonable degree of estrogen stimulation. Excessive exercise (e.g., sports, dancing) and anorexia or severe diets are well known and common causes of menstrual disorders. Finally, psychological problems can also disturb the adequate functioning of the GnRH pulse generator, showing the close linkage between the superior functions of the central nervous system and the hypothalamus. In extreme cases of anorexia, such as in the syndrome of anorexia nervosa (a profound psychological disorder), there might be a complete deficiency of gonadotropin secretion.

Hypogonadotropic hypogonadism can be isolated or associated with deficiency of other pituitary functions. Isolated hypogonadotropic hypogonadism is usually congenital and may or may not be present with olfactory dysfunction. Multiple pituitary deficiency might be congenital or acquired. Congenital multiple deficiencies are the consequence of deficiency of one of the various genes active during early pituitary embryogenesis. In these patients, symptoms vary and depend on the type of hormonal function affected.

Treatment of hypogonadotropic hypogonadism involves replacement of ovarian function with female sex hormones. In girls with sexual infantilism, estrogens are administered continuously, at increasing doses, over approximately 2 years. Then, estrogens are given in cycles of 3 weeks, with the addition of progesterone during the third week. During the week of resting, menses are expected. Estrogens should be administered under strict medical control. Periodic examination of the breasts and follow-up of uterine response by ultrasound are required. Occasionally, congenital absence of the uterus impairs menstruation.

Acquired pituitary deficiency in young girls is usually secondary to tumors of the pituitary gland or the hypothalamus. One relatively common benign tumor is a tumor of prolactin-secreting cells of the pituitary called prolactinoma. Prolactinomas produce hypogonadotropic hypogonadism (amenorrhea) and galactorrhea (abnormal milk secretion). They might grow outside the pituitary gland and produce lesions of the visual fields. When diagnosed early in their evolution, these tumors can be controlled with an oral medication and without the need for surgery.

University of Virginia Health System, Charlottesville, Virginia, United States

Glossary

café au lait spots Pigmented skin macules with irregular borders that are variable in shape, size, and age.

fibrous dysplasia A benign developmental disorder of the bone-forming mesenchymal cells resulting in replacement of spongiosa by fibrous bone.

McCune–Albright syndrome The triad of skin café au lait spots, polyostotic fibrous dysplasia, and peripheral precocious puberty.

monostotic fibrous dysplasia Involvement of a single bone by fibrous dysplasia.

polyostotic fibrous dysplasia Involvement of multiple bones by fibrous dysplasia.

MMcCune–Albright syndrome is a sporadically occurring disorder caused by a somatic postzygotic missense mutation in the *GNAS1* gene encoding the subunit of the signal-transducing guanine nucleotide-binding protein (G protein). This abnormal Gs protein constitutively activates the receptors and the adenylyl cyclase system, resulting in autonomous cell proliferation and hormonal hypersecretion responsible for corresponding clinical features.

INTRODUCTION

Fuller Albright described the triad of cutaneous café au lait spots, fibrous dysplasia and peripheral precocious puberty in 1937 after his observations of several such patients during the early 1930s. Around the same time, Donovan McCune reported a patient with the same triad and hyperthyroidism, revealing the associated endocrine abnormalities with this disease.

CLASSIC FEATURES OF McCUNE–ALBRIGHT SYNDROME

The clinical features of the classical form of McCune–Albright syndrome (MAS) are skin café au lait spots, osseous fibrous dysplasia (FD), and precocious puberty that is caused by gonadotropin-independent sex steroid secretion. The classical form of the disease is more prevalent in females. Only two of the three features are encountered in the nonclassical form.

FD of bone is a benign osseous disorder of fibro-osseous tissue, accounting for approximately 2.5% of all bone neoplasms. The monostotic form affects one bone and accounts for approximately 70% of FD cases. The polyostotic form involves multiple bones and accounts for approximately 25% of cases. The polyostotic form occurring as part of MAS accounts for approximately 3 to 5% of the reported cases of FD. Clinical manifestations of MAS can occur as early as 0.7 years to as late as 11 years of age, with 50% of patients displaying bone dysplasia by 8 years of age.

Café au lait spots are thought to represent active proliferation of melanocytes and are variable in shape, size, and age. These pigmented skin macules are of varied color, are not raised above the skin, and typically have irregular borders (comparable to the coast of Maine) in contradistinction to neurofibromatosis café au lait spots, which have smooth margination (comparable to the coast of California).

Precocious puberty can affect both sexes; however, the majority of reported cases of precocious puberty are described in young girls. It can be evaluated based on the pubic hair development according to Tanner stages and breast enlargement, menarche, and estrogenization of external genitalia before 8 years of age. The patients develop ovarian cysts that are responsible for their elevated estrogen levels. Baseline luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels, as well as gonadotropin-releasing hormone (GnRH)-stimulated LH and FSH, are below

normal. MAS manifestations of skin, bone, and endocrine abnormalities with or without precocious puberty are occasionally seen in males. Precocious puberty in males may be considered on the basis of testicular volume greater than 4 ml according to Prader's orchidometer, androgenization of genitalia, and pubic hair development as per Tanner's standards before 9 years of age.

POLYOSTOTIC FIBROUS DYSPLASIA

Polyostotic FD is the hallmark of MAS. Osseous lesions of FD are usually an incidental finding in a patient with an unrelated complaint. The radiographic appearance of FD is variable. Lesions containing larger proportions of fibrous content appear to be lucent, accounting for their typical ground glass appearance, whereas lesions with larger proportions of osseous material have a more sclerotic radiographic appearance. The disease has predilection for multiple bone involvement on one side of the body. The pelvis (Figs. 1 and 2), long bones, skull (Fig. 3), and ribs (Fig. 4) are involved in decreasing order of frequency. The expansile portion of the lesion may thin the cortex, and septations or cortical scalloping may be visualized (Fig. 2). The osseous radiographic features are a result of normal bone undergoing physiological resorption and replacement by fibrous tissue. There is an irregularity of the trabecular pattern. The osseous trabeculae in FD are composed of woven immature

Figure 1 Pelvis radiograph. Anteroposterior view shows an expansile lesion (arrows) with ground glass appearance involving the left superior pubic ramus and pubis symphysis.

Figure 2 Pelvic computed tomography. Axial image shows expansile lytic lesion (arrows) with septations involving left superior pubic ramus. The low-density matrix of the involved bone is due to fibrous tissue replacement of the marrow. Compare the density of bony trabeculae of the normal right superior pubic ramus, not involved by fibrous dysplasia.

Figure 3 Head computed tomography. Axial image shows significant involvement of the skull base and the left-sided and central facial bones. The involved bones are expanded with a mixed-density ground glass material. The nasal cavity and ethmoid sinuses are completely obliterated.

Figure 4 Left rib series showing expansion of a left posterolateral rib (black arrows) containing mixed-density lesions of fibrous dysplasia. A normal rib (white arrows) is marked for width comparison.

bone and show no osteoblastic activity (i.e., “naked trabeculae”). The lesions increase in number and size until skeletal maturation. Pathological fracture is the most frequently encountered complication of polyostotic FD. Pathological fracture of femoral neck in these patients may lead to “shepherd’s crook” deformity. The other complications include bowing deformities and length discrepancies of the extremities. There is a tendency for polyostotic FD to be of the more symptomatic than monostotic type, resulting in a higher incidence of bowing deformities and pathological fractures. Craniofacial bone dysplasia may result in hearing and visual impairment due to cranial nerve compression. Involvement of cranial and facial bones may also lead to facial deformity and a “lion face” appearance. Surgical intervention in these areas can be associated with significant complications and morbidity; therefore, it is reserved mostly for palliative treatment.

ENDOCRINOPATHIES ASSOCIATED WITH MAS

MAS has been reported in association with multiple endocrine abnormalities, including hyperthyroidism, hypercortisolism, hyperprolactinemia, and growth hormone (GH) hypersecretion. Concurrent

hypophosphatemic rickets may occur. Hepatocellular disease might not become evident without lab values. Dysfunction of several visceral organs has been reported. There is an increased risk for developing breast cancer in females with MAS, and this may be due partly to prolonged estrogen stimulation. Increased risk for osseous and thyroid malignancies has also been reported. Associated thymic dysplasia and intestinal polyps have been reported.

GH hypersecretion and acromegaly are rarely associated with MAS and result in elevated serum levels of insulin-like growth factor 1. When these individuals are subjected to an oral glucose load, their serum GH levels do not fall and may even increase. Autonomous adrenocortical hyperfunction resulting in Cushing’s syndrome has been reported as a rare complication of MAS. The majority of these cases are reported in young infants treated with bilateral adrenalectomy and subsequent hormone replacement therapy. Classic radiologic features of rickets, such as cupping, fraying, and widening of epiphysis, help to establish the diagnosis of rickets in MAS patients. These patients usually have normal calcium levels, normal or low-normal serum phosphorus levels, and normal or elevated serum alkaline phosphatase and urinary hydroxyproline levels attributable to polyostotic FD.

DIAGNOSIS

Diagnostic evaluations in MAS include, but are not limited to, a GnRH stimulation test, estradiol and testosterone level determination, and liver and renal function tests. Thyroid function tests, including thyroid-stimulating hormone (TSH) levels, thyroid hormone levels, and thyroid ultrasound, are appropriate in patients with thyroid-related symptoms or abnormal clinical exams given that 30 to 40% of MAS patients are found to have thyroid abnormalities.

A skeletal survey is the study of choice to diagnose location, distribution, and laterality of FD and to follow up on disease progression and complications. Radionuclide bone scintigraphy is sensitive at determining the lesion distribution. However, other etiologies resulting in bone scan abnormalities should be considered in the differential diagnosis, and bone scintigraphy should not be considered a specific diagnostic test for MAS. Computed tomography is useful in defining the extent of disease involvement, particularly when surgical contemplation is anticipated. Although magnetic resonance imaging (MRI) signal characteristics of FD are variable, an MRI can be a

useful diagnostic test if there is spine involvement and information about the spinal canal encroachment is desired. An MRI can also achieve evaluation of soft tissues adjacent to the involved bone to differentiate from a soft tissue sarcoma or determine malignant transformation of a preexisting FD lesion.

The radiographic features of polyostotic FD show diaphyseal involvement of long bones with widening of the medullary cavity and endosteal scalloping. The involved area of bone has a ground glass appearance with sclerotic margins. The radiographic patterns of FD can be classified into three categories: predominantly sclerotic, predominantly cystic or cyst-like, and mixed patterns. The radiographic appearance of FD lesions depends on the amount of fibrous or osseous contents present. Lesions with higher fibrous content are relatively more radiolucent than are lesions with higher osseous content, which may appear to be sclerotic. In the ribs, the expansion of bone can result in an extrapleural sign. The rib lesions in FD can be long, usually greater than 4 cm in length. Involvement of pelvic bones results in typical radiographic features. If the acetabular region is involved, "protrusio acetabuli" may result. Bone softening from other causes may also result in acetabular protrusion and should be considered in the differential diagnosis.

TREATMENT

Bone dysplasia treatment with bisphosphonates may reduce bone pain and fractures with probable retardation of bone disease progression. However, no medical treatment has been shown to alter the course of osseous disease. There is no "gold standard" treatment established for precocious puberty in MAS. The most commonly used therapies for precocious puberty include testolactone, tamoxifen, and cyproterone acetate (CPA). Testolactone is a competitive inhibitor of aromatase, the enzyme required to convert testosterone and androstenedione to estradiol and estrone. The effective treatment results in decreased frequency of menses as well as decreased growth rate and bone maturation in females with MAS. Males with MAS may occasionally demonstrate precocious puberty resulting from testicular hyperfunction. Precocious puberty in boys is treated with spironolactone, an androgen inhibitor, and testolactone. Patient monitoring, particularly for serum electrolyte levels,

is recommended for those taking spironolactone. The presence of endocrinopathies requires specific treatment aimed at the involved hormonal axis.

RISK OF MALIGNANT TRANSFORMATION

Malignant transformation of FD is reported in approximately 0.4% of cases. Malignant transformation into osteosarcoma, fibrosarcoma, and chondrosarcoma has been described in decreasing order of frequency. Sarcomatous transformation is reported more frequently after radiation treatment.

Aldosterone in Congestive Heart Failure

Karl T. Weber, Yao Sun, Ivan C. Gerling, and Robert A. Ahokas
University of Tennessee Health Science Center, Memphis, Tennessee, United States

Glossary

aldosterone A steroid hormone produced by zona glomerulosa cells of the adrenal cortex that is integral to the salt and water retention that begets the congestive heart failure syndrome with its characteristic signs and symptoms.

endothelial dysfunction An abnormality of endothelial cells that form the endothelium or internal lining of blood vessels and whose metabolic function (e.g., release of nitric oxide) is involved in regulating the vasomotor reactivity (dilatation and constriction) of these vessels.

heart failure The circumstance in which the heart does not provide for the delivery of oxygen and other nutrients to the body's tissues at a rate in keeping with their metabolic requirements.

Mg²⁺ homeostasis The balance that exists within the body's various stores of this predominantly intracellular divalent cation and that is involved in hundreds of enzymatic reactions.

neuroendocrine-immune interface The role played by various neurohormonal system effector hormones (e.g., aldosterone, angiotensin, catecholamines) in regulating the behavior of the immune system and its peripheral blood mononuclear cells (monocytes and lymphocytes).

Aldosterone (ALDO) was discovered more than 50 years ago. It is a mineralocorticoid hormone with well-known endocrine properties in epithelial cells of kidneys, colon, and sweat and salivary glands that contribute to the pathophysiology of congestive heart failure. This includes sodium (Na⁺) resorption at the expense of potassium (K⁺) excretion. Magnesium (Mg²⁺) excretion is likewise enhanced by ALDO, whereas adrenal ALDO secretion is regulated by extracellular Mg²⁺. An emerging body of information continues to identify other endocrine actions of ALDO receptor–ligand binding, including promoting an efflux of cytosolic-free Mg²⁺, in exchange for Na⁺, in nonepithelial cells such as peripheral blood mononuclear cells; endothelial cell function; and its central nervous system actions

involving regulation of cerebrospinal fluid composition produced by epithelial cells of the choroid plexus, activity of the hypothalamic paraventricular nucleus involved in Na⁺ appetite, Na⁺ and water (H₂O) excretion and sympathetic nerve activity, and the regulation of tumor necrosis factor- α (TNF- α) production from central and/or peripheral sources. The past decade or so has witnessed a revival of interest in this steroid molecule, and in years to come an even broader understanding of ALDO's contribution to the pathophysiology of congestive heart failure will undoubtedly emerge.

INTRODUCTION

Initially termed electrocortin, aldosterone (ALDO) was discovered some 50 years ago. Identification of its 18-aldehyde steroid structure and adrenal origin led Tait and Simpson to rename this steroid hormone aldosterone. Its ability to alter sodium (Na⁺) uptake in exchange for potassium (K⁺) prompted Selye to refer to ALDO as a mineralocorticoid. Sites of ALDO's action and receptor–ligand binding were found to reside within epithelial cells of the kidney, colon, and sweat and salivary glands. The importance of this circulating hormone in promoting salt and water retention at each of these target tissues was demonstrated by J. O. Davis and included edema-forming states such as congestive heart failure (CHF), nephrosis, and cirrhosis. Further confirmation of its biological importance was the efficacy of spironolactone, an ALDO receptor antagonist developed by Kagawa and introduced into clinical practice more than 40 years ago, in counteracting Na⁺ retention and alleviating edema.

The past decade or so has witnessed a resurgence of interest in this steroid molecule in CHF, prompted by several observations reviewed by Weber. These included a recognition of ALDO's broader range of actions that extended beyond classic target tissues and were associated with an adverse structural remodeling of the cardiovascular system that contributes to pathophysiological expressions and the progressive nature of CHF. In addition, the inability of angiotensin-converting enzyme (ACE) inhibition to provide

for sustained suppression of plasma ALDO in patients with CHF indicated that the regulation of its secretion by zona glomerulosa cells of the adrenal cortex is more complex than that governed by angiotensin II alone. Finally, Pitt and colleagues reported that in a controlled clinical trial (RALES), conducted in 19 countries on five continents and involving more than 1600 patients with CHF, spironolactone (*vis-à-vis* placebo), in combination with an ACE inhibitor and loop diuretic, reduced the risk of all-cause and cardiac-related mortality and cardiovascular morbidity by 30%. Pitt and colleagues also reported on results of another controlled clinical trial (EPHESUS), conducted in 674 centers in 37 countries, that further underscore the importance of ALDO and the efficacy of ALDO receptor antagonism in a large cohort of patients (>6000) with left ventricular dysfunction following myocardial infarction (MI). As contrasted with placebo, the addition of eplerenone to standard therapy with ACE inhibitors or AT₁ receptor blocker, beta blocker, aspirin, and diuretics led to a significant reduction in overall mortality and in cardiovascular morbidity and mortality.

This article provides a broader perspective of ALDO's properties that contribute to the pathophysiology of CHF and are mediated by receptor–ligand binding. They include ALDO's influence on magnesium (Mg²⁺) homeostasis and the role of extracellular Mg²⁺ ([Mg²⁺]_o) in regulating adrenal ALDO secretion, vascular remodeling and immune cell activation, endothelial cell dysfunction, and the central nervous system.

Mg²⁺ HOMEOSTASIS AND ALDOSTERONE SECRETION

The distribution of Mg²⁺ within body tissues is as follows: 53% in bone, 27% in skeletal muscle, and 19% in other soft tissues such as the heart. Less than 1% of total body Mg²⁺ is present in blood, and cytosolic-free Mg²⁺ ([Mg²⁺]_i) represents only 0.5 to 5% of total cellular Mg²⁺, with approximately 80% bound to adenosine triphosphate (ATP) and other phosphometabolites sequestered within organelles such as mitochondria and endoplasmic reticulum. [Mg²⁺]_i homeostasis is maintained by exchange with these intracellular stores, whereas [Mg²⁺]_o is held within narrow limits by Mg²⁺ efflux from tissue stores.

Epithelial Cells

In 1955, Mader and Iseri reported that a patient with adrenal adenoma had experienced spontaneous

episodes of hypomagnesemia together with enhanced Mg²⁺ excretion in urine and stool. Others would also note the presence of hypomagnesemia in patients with primary aldosteronism, suggesting that Mg²⁺ deficiency accompanies long-standing, ALDO-induced Mg²⁺ excretion. These clinical findings implicated ALDO in regulating both K⁺ and Mg²⁺ excretion in classic target tissues. In 1962, Horton and Biglieri addressed urinary K⁺ and Mg²⁺ excretion in five patients with PAL, where each patient had low normal or reduced serum Mg²⁺ levels. The influence of surgical resection of adrenal adenoma on urinary K⁺ and Mg²⁺ excretion was assessed in two patients (Fig. 1). In both patients, there was an immediate and marked fall in excretion of these monovalent and divalent cations after surgery together with a gradual normalization of plasma Mg²⁺. A lower basal excretion of Mg²⁺, comparable to values seen for normal controls on the same Mg²⁺ diet, was seen postoperatively. In another patient, spironolactone was shown to reduce both urinary K⁺ and Mg²⁺ excretion, which returned to previous increased basal levels following discontinuation of spironolactone (Fig. 2). Thus, the importance of ALDO in promoting urinary Mg²⁺ excretion was evident. In 1963, Conn, who had earlier coined the term PAL to connote autonomous adrenal ALDO production independent of plasma renin activity, concluded that hypomagnesemia, hypokalemia, hypernatremia, hypochloremia, and metabolic alkalosis were cardinal metabolic abnormalities of PAL.

The importance of the adrenal cortex in regulating Mg²⁺ and K⁺ excretion was further underscored in adrenal insufficiency or following adrenalectomy. ALDO treatment of dogs or rats with surgically induced bilateral adrenalectomy was shown to increase fecal K⁺ and Mg²⁺ excretion and to normalize their plasma concentrations. Horton and Biglieri treated an adrenalectomized patient with d-ALDO for 8 days (Fig. 3). On day 5 of this regimen, spironolactone cotreatment was initiated. Exogenous ALDO promoted a prompt elevation in urinary K⁺ and Mg⁺ excretion that was abrogated by receptor antagonist. Thus, the body of evidence is compelling that ALDO promotes both K⁺ and Mg²⁺ excretion at classic target tissue sites.

Mg²⁺ excretion is likely increased in patients with CHF, where elevated plasma ALDO levels are expected. In patients with CHF treated with a loop diuretic, there exists an independent stimulus to urinary Mg²⁺ excretion and the potential for exaggerated Mg²⁺ loss. However, its serum concentration does not reflect intracellular Mg²⁺, and methods to detect

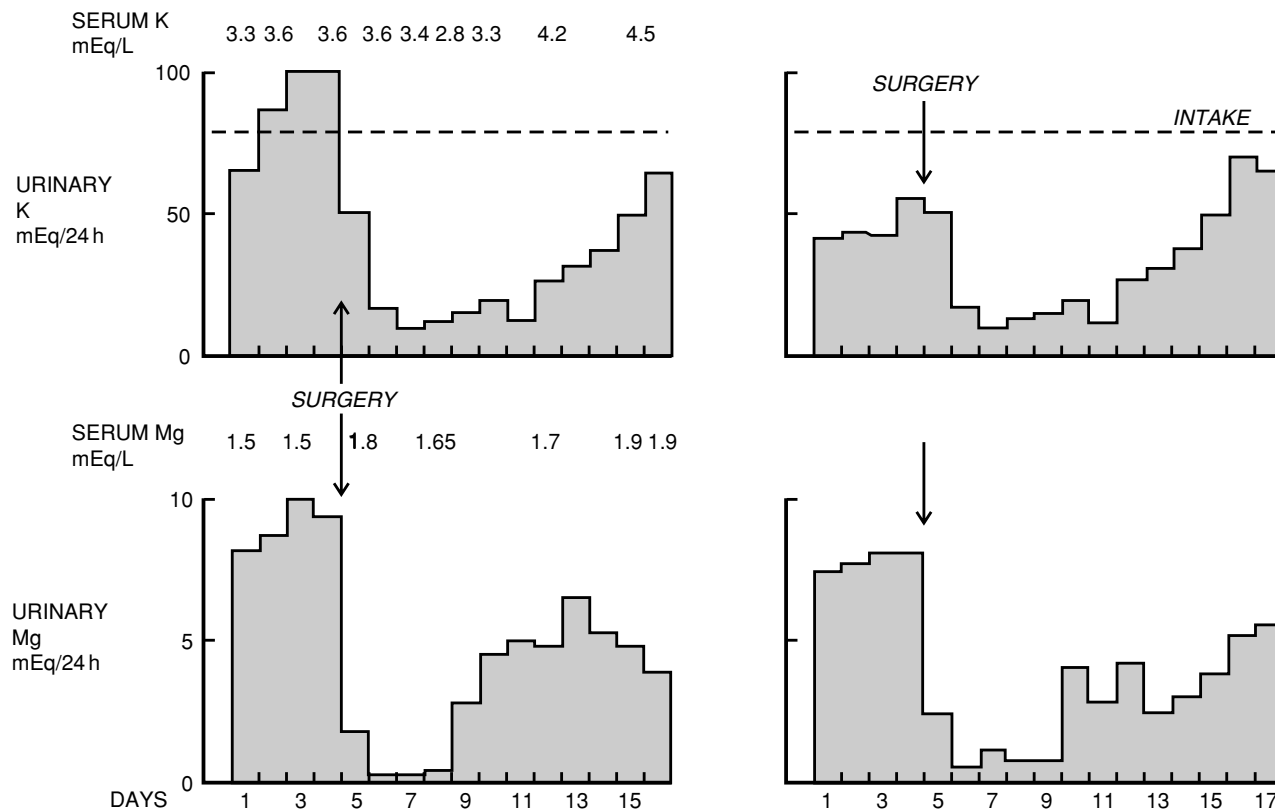

Figure 1 Urinary K^+ and Mg^{2+} excretion in two patients with primary aldosteronism before and after surgical removal of adrenal adenoma. Serum K^+ and Mg^{2+} levels are shown for one of these individuals. Reproduced from Horton and Biglieri (1962). Effects of aldosterone on the metabolism of magnesium. *J. Clin. Endocrinol. Metab.* 22, 1187–1192. © The Endocrine Society.

biologically active, cytosolic-free $[Mg^{2+}]_i$ are not widely used; therefore, the assessment of this important clinical problem remains to be defined. Intracellular Mg^{2+} deficiency may contribute to morbid and mortal events such as sudden cardiac death, which occurs in 50% of patients with CHF. The 30% reduction in risk of sudden cardiac death observed in the RALES trial may be related, in part, to spironolactone's ability to restore and preserve Mg^{2+} homeostasis.

Nonepithelial Cells

ALDO regulates Mg^{2+} exchange by nonepithelial cells, such as peripheral blood mononuclear cells (PBMCs), where it binds to a single class of cytosolic receptors. In patients with either PAL or renin-dependent secondary aldosteronism (SAL), ALDO-binding sites are reduced by 50%. Following surgical removal of adenomatous adrenal tissue, ALDO receptor binding is normalized in these cells. ALDO promotes the efflux of Mg^{2+} from cultured human

lymphocytes in exchange for Na^+ via receptor–ligand binding. This Na^+ -dependent response, measured by mag-fura-2, a fluorescent probe, involves both transcription and protein synthesis, as demonstrated by its respective abrogation by cycloheximide and actinomycin D. Lymphocyte-ionized $[Mg^{2+}]_i$ is reduced in patients with PAL secondary to either adrenal adenoma or hyperplasia. In uninephrectomized rats treated with ALDO by implanted mini-pump, PBMC $[Mg^{2+}]_i$ is significantly reduced and accompanied by immune cell activation (vide infra).

Aldosterone Secretion

$[Mg^{2+}]_o$ participates in the regulation of adrenal ALDO secretion to create a pathway of reciprocal regulation in Mg^{2+} homeostasis (Fig. 4). In healthy normotensive men and women, a 3-h intravenous infusion of magnesium sulfate ($MgSO_4$) suppresses plasma ALDO levels. On the other hand, dietary-induced Mg^{2+} deficiency with reduced $[Mg^{2+}]_o$ is accompanied by an expanded width to the adrenal

Figure 2 Urinary K^+ and Mg^{2+} excretion in a patient with primary aldosteronism before, during, and after oral spironolactone treatment. Reproduced from Horton and Biglieri (1962). zona glomerulosa together with hyperplasia of the renal juxtaglomerulosa cells, increased adrenal ALDO secretion, increased plasma ALDO, and a reduction in urinary Na^+/K^+ ratio. Dietary Mg^{2+} deficiency combined with a high- Na^+ diet attenuates, but does not abrogate, heightened ALDO secretion. In cultured zona glomerulosa cells, superfusate $[Mg^{2+}]_o$ regulates ALDO production; high $[Mg^{2+}]_o$ suppresses, whereas an $[Mg^{2+}]_o$ -free media augments, their elaboration of ALDO. The SAL that accompanies dietary Mg^{2+} deficiency is associated with a time-dependent rise in $[Na^+]_i$ and $[Ca^{2+}]_i$ in heart, skeletal muscle, kidney, and bone and is suggestive of an inhibition of Na,K -ATPase, an Mg^{2+} -dependent pump, and increased Na^+/Ca^{2+} exchange at these sites.

NEUROHORMONE-IMMUNE INTERFACE

A structural remodeling of the cardiovascular by fibrous tissue accompanies aldosteronism derived from either endogenous or exogenous sources. This fibrogenic phenotype includes intramural arteries of the heart, kidney, pancreas, mesentery, and vaso

Figure 4 Mg^{2+} balance and reciprocal regulation of adrenal ALDO secretion. Reproduced with permission from Weber, K. T. (2003). Aldosterone revisited: Perspectives on less well recognized actions of aldosterone. *J. Lab. Clin. Med.* (in press).

vasorum of the aorta and pulmonary artery. Cotreatment with a receptor antagonist (e.g., spironolactone, eplerenone), in either nondepressor or depressor doses, prevents this remodeling, indicating its independence of elevations in blood pressure. In a substudy of the RALES trial, survival benefit was associated with a reduction in circulating markers of collagen synthesis that presumably reflected an attenuation in ongoing vascular fibrosis. In this connection, urinary excretion of hydroxyproline, a marker of collagen turnover, is increased in adrenalectomized rats treated with ALDO, 1% dietary sodium chloride (NaCl), and cortisone. On the other hand, glucocorticoids reduce urinary hydroxyproline excretion, and their inhibition of collagen formation in bone is associated with osteoporosis.

In 1995, Campbell and colleagues found that the perivascular fibrosis of the coronary vasculature that ultimately appears in aldosteronism is preceded by a proinflammatory vascular phenotype that features invading monocytes/macrophages and lymphocytes and adhesion molecule expression. These findings, including their independence of blood pressure, were confirmed by others more recently. An interrogation of molecular responses involved in the invasion of coronary vessels by these inflammatory cells was addressed in animal models of PAL and SAL. In rats receiving ALDO/salt treatment (ALDOST), where plasma renin and angiotensin II both are suppressed, Sun and colleagues more recently tested the hypothesis that oxidative stress was involved in the appearance of the proinflammatory/fibrogenic cardiac phenotype. At week 3 of ALDOST, there was no evidence of cardiac pathology. However, at weeks 4 and 5, inflammatory cells (monocytes/macrophages and lymphocytes) were found to have invaded intramural coronary vessels in both ventricles. By immunohistochemistry, invading PMBCs were found to express the gp91^{phox} subunit of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, whose activation is a major source of superoxide in leukocytes, and 3-nitrotyrosine, a product of peroxynitrite with stable protein tyrosine residues and where peroxynitrite is formed by the reaction between superoxide and nitric oxide. The RelA subunit of nuclear factor- κ B (NF- κ B), a redox-sensitive transcription factor integral to inflammatory responses, was likewise activated in these cells. *In situ* hybridization localized increased mRNA expression of intercellular adhesion molecule-1 (ICAM-1), monocyte chemoattractant protein-1 (MCP-1), and proinflammatory cytokine tumor necrosis factor- α (TNF- α) at vascular sites that involved the normotensive nonhypertrophied right atrium and ventricle and left

atrium as well as the hypertensive hypertrophied left ventricle. Cotreatment with either spironolactone or an antioxidant (either pyrrolidine dithiocarbamate or N-acetylcysteine) prevented the appearance of these cells and associated molecular responses as well as the subsequent perivascular fibrosis. Thus, ALDOST induces oxi/nitrosative stress within inflammatory cells invading the intramural coronary vasculature, and it is this proinflammatory vascular phenotype that leads to intramural coronary artery pathology and the subsequent perivascular fibrosis.

What is responsible for the induction of oxi/nitrosative stress in PMBCs? Gerling and colleagues identified an ALDO-mediated reduction in $[Mg^{2+}]_i$ that appears in PMBCs at week 1 of ALDOST, long before the appearance of cardiac pathology at week 4. The early activation of these cells is evident in their transcriptome (expressed genes) and proteome (expressed proteins). The interrogation of complex molecular events that account for immune cell activation and subsequent homing of these cells to the heart may explain why cardiac pathology does not appear until week 4 of ALDOST and calls into question the prospect of an autoimmune response similar to that which can follow MI.

In rodents treated with a Mg^{2+} -deficient diet, a putative state of exaggerated aldosteronism, lymphocyte Mg^{2+} is reduced to an extent comparable to the Mg^{2+} depletion that appears in skeletal muscle and cardiac tissue. Weglicki and colleagues identified an early (week 1) induction of oxi/nitrosative stress and depletion of antioxidant defenses in PMBCs and endothelial cells. Lymphocyte activation that appears includes their production of proinflammatory cytokines and a neurogenic peptide, substance P, together with the expression of its receptors. Cardiac lesions are first seen in this model at week 3 and can be prevented by a substance P receptor antagonist.

The potential for the SAL that accompanies human CHF to likewise be accompanied by reduced $[Mg^{2+}]_i$ and immune cell activation remains unknown. The prospect does exist for an immune cell origin to the "cytokine storm" characteristic of CHF that features elevations in circulating proinflammatory cytokines such as TNF- α and interleukin-6 (IL-6). Cells of the monocyte-phagocyte system are a potent source of these cytokines. Another source of cytokine production in heart failure is the central nervous system. Irrespective of their origin, prolonged elevations in these proinflammatory cytokines contribute to the progressive systemic illness that accompanies CHF and features tissue wasting to eventuate in cardiac cachexia.

DYSFUNCTION OF THE ENDOTHELIUM

In patients with PAL or renal artery stenosis with SAL, forearm vasomotor reactivity to endothelial cell-dependent acetylcholine is diminished compared with that in normotensive controls, whereas nonendothelial cell-dependent sodium nitroprusside-induced vasodilatation is preserved. Following surgical removal of adrenal adenoma, the impairment in endothelial cell-dependent vasodilatation is restored. In the SAL that accompanies CHF, diminished forearm vasomotor reactivity to acetylcholine is normalized by spironolactone treatment. Acetylcholine-induced, nitric oxide-dependent vasorelaxation of aortic rings is reduced in rats following MI. This vasomotor dysfunction, together with increased superoxide formation by aortic tissue, is normalized by spironolactone alone or in combination with an ACE inhibitor. In cultured aortic endothelial cells, reduced Mg^{2+} concentration of culture medium is associated with increased oxidant production and reduced intracellular glutathione, an antioxidant reserve consumed in neutralizing oxidative stress. Abnormal Mg^{2+} homeostasis may account for the underlying pathophysiological basis of endothelial dysfunction seen in either PAL or SAL.

CENTRAL NERVOUS SYSTEM

ALDO receptors are found at diverse sites in the central nervous system. These include epithelial cells of the choroid plexus. A role for ALDO in the genesis of idiopathic intracranial hypertension (IIH) has been proposed given the reported association between IIH and PAL and SAL as well as the prevalence of headaches among patients with PAL. That this proposition does not apply to all patients with IIH is underscored by its appearance in patients with adrenal insufficiency unless ALDO is produced *in situ* within the central nervous system, as is now recognized to be the case for the cardiovascular system.

The choroid plexus, a site of high-affinity ALDO receptor binding, is involved in the production of cerebrospinal fluid (CSF) and is a target site for ALDO, spironolactone, and ouabain, an endogenous, digitalis-like substance released by the adrenals and the hypothalamic–pituitary axis. ALDO exerts its biological actions on epithelial cells by enhancing the activity and number of Na,K-ATPase pumps in their apical membrane. An ouabain-sensitive Na,K-ATPase is present in the microvilli of the plexus and is involved in the regulation of CSF formation and electrolyte composition (e.g., ouabain reduces CSF

production). ALDO is present in CSF, where its concentration correlates with plasma levels. Either the systemic or intracerebroventricular administration of a mineralocorticoid (ALDO or deoxycorticosterone [DOC]) is accompanied by a fall in CSF K^+ , together with a rise in arterial pressure, without changes in blood volume, cardiac output, plasma catecholamines, or vasopressin. This hypertensive response is abrogated by intracerebroventricular infusion of K^+ or a mineralocorticoid receptor antagonist. Therefore, ALDO has a central action involved in the regulation of blood pressure as well as CSF volume and composition. Produced locally within the brain, ALDO's paracrine properties may likewise contribute to blood pressure regulation.

ALDO's central actions, which may contribute to the pathophysiology of CHF, were reviewed and expanded by Felder and colleagues. The hypothalamic paraventricular nucleus (PVN), a forebrain site involved in the regulation of extracellular volume and sympathetic nerve activity, is governed by circulating neurohormones and effector signals originating from the brainstem. In rats with MI induced by coronary artery ligation, the activity of the PVN is increased. Systemic or intracerebroventricular administration of spironolactone reduces this activity, improves baroreflex regulation of renal sympathetic nerve activity (albeit in a time-dependent manner), and prevents the increase in Na^+ appetite and decline in urinary Na^+ and H_2O excretion that appear in this model. Plasma levels of TNF- α rise progressively over weeks 1 to 3 following MI, a response abrogated by intracerebroventricular infusion of spironolactone started 24 h after coronary ligation, suggesting that central ALDO receptor activation is involved in regulating the release of this proinflammatory cytokine. However, the cellular source of TNF- α remains uncertain and may include central and/or peripheral tissues.

FUTURE DIRECTIONS

Since its discovery more than 50 years ago, ALDO has had a well-established importance in clinical medicine, including its role in CHF. The past decade or so has witnessed a resurgence of interest in the adrenal's most potent mineralocorticoid as well as its *de novo* production through steroidogenesis within the cardiovascular system and brain. An ever-expanding role for this steroid molecule in the metabolism of monovalent and divalent cations by epithelial and nonepithelial cells has warranted an even broader perspective of its portfolio of actions. The many peripheral and central actions of ALDO that can contribute to the

pathophysiology of CHF syndrome remain to be defined. This is no more evident than in the adverse structural remodeling of the heart and systemic organs that accompanies chronic elevations in plasma ALDO (inappropriate relative to dietary Na^+) and that may be secondary to PBMC activation induced by $[\text{Mg}^{2+}]_i$ depletion and transduced by oxi/nitrosative stress. Molecular mechanisms involved in immune cell responses remain to be elucidated. Today's technologies will permit an assessment of ALDO's role in altering the molecular phenotype of these immune cells, specifically their transcriptome and proteome. Such insights may provide for the development of serologic biomarkers that address the risk, onset, and progression of vascular injury in CHF and could lead the way toward refined and even newer drug targets.

Aldosterone Receptors

Marc Lombès and Maria-Christina Zennaro
INSERM U 478, Xavier Bichat, Paris, France

Glossary

aldosterone A steroid hormone synthesized in the zona glomerulosa of the adrenal cortex; the major mineralocorticoid hormone in humans.

mineralocorticoid Corticosteroid hormone secreted by the adrenal gland and exerting its function through the mineralocorticoid receptor; also referred to as the hormone that affects water and electrolyte homeostasis.

Aldosterone receptors, or mineralocorticoid receptors, are defined as intracellular proteins that are able to bind aldosterone and mediate hormone action within target cells.

INTRODUCTION

The aldosterone receptor, also referred to as the mineralocorticoid receptor (MR), is a member of the nuclear receptor superfamily that acts as a ligand-dependent transcription factor mediating aldosterone effects on a variety of target tissues. These include epithelial cells in the kidney and colon but also nonepithelial cells in the cardiovascular and central nervous systems.

MECHANISM OF ALDOSTERONE ACTION

The classical model of aldosterone action is illustrated schematically in Fig. 1. Aldosterone penetrates a target cell, typically a polarized epithelial cell in the distal nephron and presumably by passive diffusion, and specifically binds to the MR. In its unliganded state, the MR resides predominantly in the cytoplasm and is complexed with various receptor-associated proteins, including a dimer of heat shock protein 90 (hsp90), heat shock protein 70 (hsp70), and other proteins such as immunophilins, cyclophilin (Cyp40), and FKBP52, which are known to bind immunosuppressive agents.

On aldosterone binding, the MR undergoes conformational change that leads to the dissociation of receptor-associated proteins. Aldosterone receptor complexes then translocate to the nuclear compartment and bind as homodimers to specific DNA sequences that are known as mineralocorticoid response elements (MREs) located in the regulatory regions of aldosterone-sensitive genes. The consensus sequence of MREs generally consists of an inverted hexameric palindrome separated by three nucleotides (AGAA-CAnnnTGGTCT). The MR is then able to recruit specific coactivators, in a sequential and/or combinatorial manner, that subsequently enhance transcriptional activation through direct interaction with the basal transcription factors and chromatin remodeling involving histone acetylation/methylation. Several aldosterone-regulated genes have been identified, including the serum- and glucocorticoid-inducible kinase (sgk1), a serine threonine kinase that is able to phosphorylate the ubiquitin ligase Nedd4-2, which in turn controls the retrieval of the subunits of the epithelial sodium channel from the apical membrane of the cell. Other aldosterone-induced proteins, such as the small monomeric GTP-binding protein Kirsten Ras (Ki-Ras), the glucocorticoid-induced leucine zipper protein (GILZ), and the N-myc down-regulated gene 2 (NDRG2), also seem to play an important role during the early phase of aldosterone responses in the renal tubule. Collectively, aldosterone stimulates the biosynthesis and activity of sodium channels and pumps, leading to an enhanced vectorial transepithelial sodium transport from the tubular lumen to the basolateral space.

Another important issue in the mechanism of aldosterone action is the apparent nonselectivity of the MR. Indeed, aldosterone and glucocorticoids such as cortisol are equally able to bind to the MR with high affinity (K_d in the nanomolar range). However, the enzyme 11 β -hydroxysteroid dehydrogenase type 2 (11 β -HSD2), by metabolizing 11 β -hydroxysteroids into 11 keto-derivatives such as cortisone, which exhibits no affinity for the MR, plays a pivotal role in

Figure 1 Schematic representation of the molecular mechanism of aldosterone action in a polarized epithelial cell. mineralocorticoid selectivity in epithelial cells, preventing permanent occupancy of the MR by the more prevalent glucocorticoid hormones.

STRUCTURE OF THE MR

The cloning of the human MR cDNA in 1987 by Ron Evans's laboratory facilitated the deduction of its primary structure and the definition of different functional domains. Like other members of the nuclear receptor superfamily of which it is a member, the MR displays a common modular structure and is composed of three distinct functional domains. A schematic representation of the MR is given in Fig. 2.

The amino terminal region, also referred to as the transactivation domain, is 602 amino acids long and so constitutes the longest domain among nuclear receptor family members. Its primary sequence bears little resemblance to that of other family members, sharing less than 15% homology with its closely related receptor, the glucocorticoid receptor. However, among all known mammalian species, more than 85%

of this MR domain is highly conserved, suggesting that it contains specific and important functions. This domain harbors two ligand-independent activation functions: AF1a located in aa 1 to 167 and AF1b spanning aa 445 to 602 and presumably an inhibitory transactivation region between aa 167 and aa 437.

The centrally located, highly conserved DNA-binding domain is responsible for the specific interaction with hormone response elements located in the promoters of aldosterone target genes. This domain has a rigid structure, is highly hydrophilic, is very rich in cysteine residues, and is composed of two zinc finger structures. It contains a P box that constitutes the interacting contact with the half-site of the response element and a D box that is responsible for weak dimerization. A nuclear export signal has also been identified between the two zinc fingers, and a weak ligand-independent nuclear localization signal, NSL1, has been shown to be located next to the C-terminal site of the DBD.

The ligand-binding domain at the carboxy-terminus part of the receptor is 250 amino acids

Figure 2 Different functional domains of the human mineralocorticoid receptor. Numbering represents the amino acids. NTD, N-terminal domain of the receptor; DBD, DNA-binding domain; LBD, ligand-binding domain; AF, activating function; NLS, nuclear localization signal; NES, nuclear export signal; D Box, dimerization box; hsp90, heat shock protein 90.

long and is separated from the DBD by a hydrophilic proline-rich hinge region. The complex C-terminal domain is responsible for ligand binding and contains a ligand-dependent nuclear localization signal (NLS2), multiple contact sites for hsp90 interaction, and a ligand-dependent activating function AF2 domain. This domain is highly structured and is composed of 12 α -helices (H1–H12) and one β antiparallel sheet on which the steroid hormone lies.

Aldosterone binds to the MR with high affinity, but glucocorticoids such as cortisol bind to the receptor with equivalent affinity. Although similar dissociation constants (K_d) have been calculated by Scatchard plot analysis, dissociation rates ($k - 1$) are much faster for glucocorticoids than for aldosterone. This intrinsic property of the MR to discriminate between aldosterone and glucocorticoids constitutes an additional molecular mechanism that ensures the mineralocorticoid selectivity of aldosterone action within target cells from a dynamic point of view. Finally, it has been shown that the aldosterone–MR complex presumably adopts conformation different from that of the glucocorticoid–MR complex, whereby distinct interaction between the N-terminal domain and the LBD occurs. This leads to the recruitment of particular coactivators resulting in a highly specific transcriptional response.

The three-dimensional structure of the MR was deduced by using an analogy of the crystal structures of the ligand-binding domain of other steroid hormone receptors. This facilitated the precise definition of the amino acid contacts with the functional groups of the steroid. Thus, the 3-ketone function of aldosterone interacts with the glutamine residue at position 776 and the arginine residue at position 817. On the other hand, the 20-ketone function contacts the cysteine residue at position 942, and the

21-hydroxyl and 18-hydroxyl groups are anchored by the asparagine residue at position 770. On ligand binding, the helix 12 within the AF2 domain rotates tightly against the LBD, and this, together with the changes in helices 3 to 5, facilitates the interaction of the receptor with coactivators of the steroid receptor coactivator (SRC) family.

CELL-SPECIFIC EXPRESSION AND SUBCELLULAR LOCALIZATION OF THE MR

The tissue-specific expression of the MR is presented in [Table I](#). The MR is essentially expressed at relatively high levels in polarized cells of sodium-transporting epithelia in the distal parts of the nephron (from the cortical part of the thick ascending limb of Henle's loop, distal tubule, and connecting tubule to the cortical and medullary collecting tubule), colon, pneumocytes, and salivary and sweat glands. It is now well established that the MR is also present in “non-classical” aldosterone target tissues, most notably neurons of the hippocampus, cardiomyocytes, adipocytes, vascular smooth muscle cells, and (presumably) other cell types. With respect to intracellular localization, initial immunocytochemical studies demonstrated that the MR is predominantly located in the cytoplasmic compartment in the absence of ligand and is translocated into the nucleus on aldosterone exposure. Experiments using green fluorescent protein–MR chimeras allowed the subcellular localization of the MR and its kinetics in living cells to be examined. As illustrated in [Fig. 3](#), on aldosterone binding, the MR rapidly translocates in the nucleus within minutes and is sequestered in specific areas within this

compartment, where transcriptionally active regions of the chromatin presumably exist.

REGULATION OF MR EXPRESSION

The human MR (hMR) gene is localized to the q31.2 region of chromosome 4 and spans approximately 450 kb. The hMR gene is composed of 10 exons, including 2 untranslated first exons referred to as exon 1 α and exon 1 β (Fig. 4). Alternative transcription of these two 5'-untranslated exons generates two mRNA isoforms: hMR α and hMR β . Given that the hMR translation initiation site, as defined by the start codon ATG, is located 2 bp downstream from the beginning of exon 2, these two isoforms give rise to the same translation product. The last 8 exons, from 2 to 9, encode the various functional domains of the protein. Exon 2 codes for the N-terminal domain of the receptor. The two small exons 3 and 4 encode each of the two zinc fingers of the DNA-binding domain, whereas the last 5 exons encode the ligand-binding domain of the receptor. However, the existence of other hMR splice variants has been demonstrated, and this seems to play a major role in modulating receptor function.

The hMR gene expression is controlled by two different promoters that differ in terms of their basal activity as well as their hormonal regulation. Experiments in transgenic mice have shown distinct tissue-specific use and activity of these two hMR regulatory regions *in vivo*. The proximal P1 promoter corresponding to the 5'-flanking region of exon 1 α is a relatively strong promoter that is transcriptionally active in all aldosterone target tissues, whereas the distal P2 promoter flanking exon 1 β is weaker and has a more restricted pattern of expression; thus, it is presumably used during specific developmental stages or physiological situations.

Figure 3 Aldosterone-dependent nuclear translocation of the hMR. RCSV3 rabbit renal cells were transfected with the expression vector encoding for a chimera protein consisting of human mineralocorticoid receptor and enhanced green fluorescent protein EGFP. The intracellular distribution of EGFP-hMR in living cells was observed directly on an inverted IRB microscope. In the absence of aldosterone, the receptor is predominantly in the cytoplasm, whereas 15 min after addition of 10^{-8} M aldosterone, the receptor is localized in the nucleus.

PATHOPHYSIOLOGICAL EFFECTS OF ALDOSTERONE

Aldosterone is primarily implicated in the maintenance of water and salt homeostasis by regulating sodium reabsorption and potassium excretion across tight epithelia. As such, aldosterone plays a key role in the regulation of blood pressure, and in turn, the dysfunctional regulation of aldosterone secretion and action is implicated in many human diseases such as hypertension and heart failure. In addition to the renal effects of aldosterone, it has become evident that aldosterone exerts direct effects on the cardiovascular system. Aldosterone excess leads to the development of cardiac hypertrophy and fibrosis, which are involved in cardiac remodeling and heart failure. Even though the molecular mechanisms remain obscure, the detrimental effects of aldosterone on cardiovascular function led to major clinical trials aimed at demonstrating beneficial effects of antimineralocorticoid compounds. Initially, the RALES study demonstrated the efficiency of spironolactone treatment by showing that it significantly reduces the morbidity and mortality (by 30%) of patients with severe congestive heart failure. A fairly new selective aldosterone antagonist, eplerenone, has been approved by the Food and Drug Administration for the treatment of high blood pressure. This antimineralocorticoid has reduced progestagenic and antiandrogenic activities more than has spironolactone. The EPHESUS study also clearly demonstrated the beneficial effects of eplerenone in patients with acute myocardial infarction complicated by left ventricular dysfunction and heart failure. It is likely that aldosterone receptor

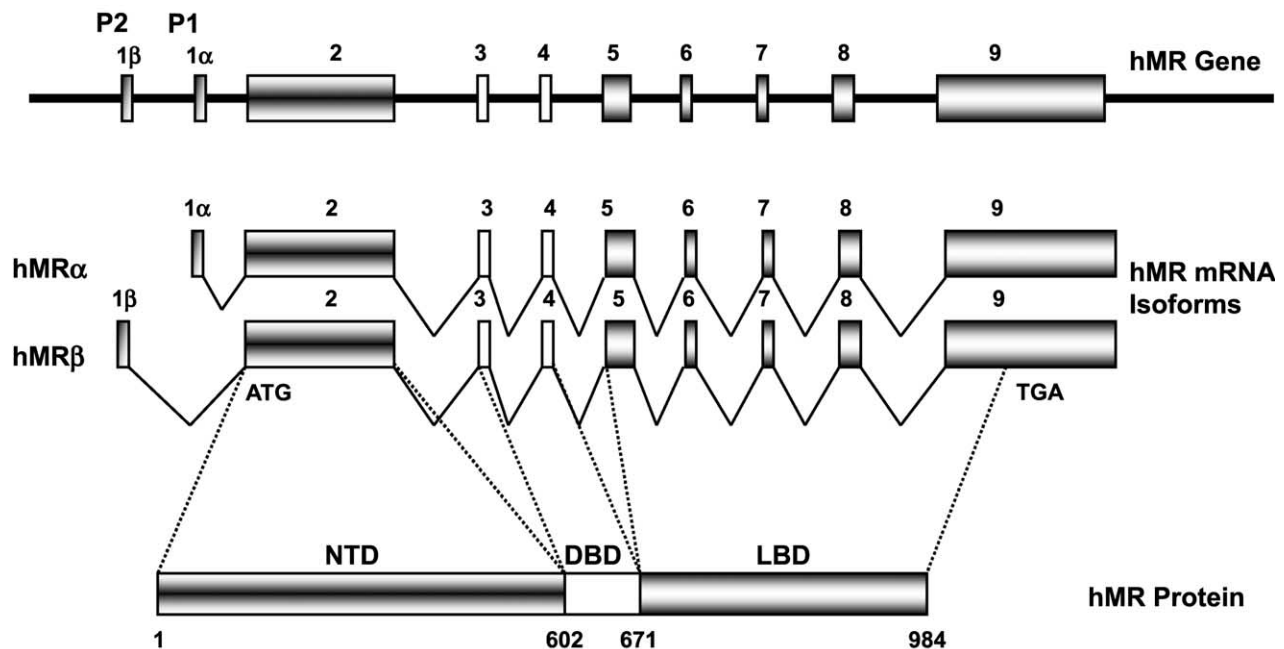

Figure 4 Structure of human mineralocorticoid receptor gene, mRNA isoforms, and hMR protein. P1 and P2 are the alternative promoters of the hMR gene. Numbering represents the exons. ATG and TGA are the starting and stop codons, respectively.

blockade preventing renal, cerebral, and vascular injuries will become increasingly important in managing hypertension, heart failure, and atherosclerosis as well as for patients during the postmyocardial infarction period.

GENETIC ALTERATIONS OF THE MR

There is now clear evidence that genetic alterations of the MR are associated with human diseases. The first MR mutations were found in patients with autosomal dominant or sporadic pseudohypoaldosteronism type I, an inherited disorder characterized by renal salt wasting during infancy and associated with failure to thrive, hyponatremia, hyperkalemia, and high plasma aldosterone levels. Therefore, these clinical and biological features are consistent with aldosterone resistance. These heterozygous frameshift, nonsense, or missense mutations occur within different functional domains of the MR receptor that, in turn, affect receptor function in different ways, generally resulting in receptor inactivity.

Conversely, a gain of function mutation in the MR has been described in a family with severe early-onset hypertension that is exacerbated by pregnancy. The mutation, a substitution of leucine for serine at codon 810, lies within the ligand-binding domain and has

been shown to drastically modify the receptor steroid specificity. Indeed, further experiments demonstrated a constitutive MR activation in the absence of ligand. In addition, progesterone, spironolactone, and even cortisone were able to fully activate the mutant receptor, consistent with the clinical presentation of gestational hypertension. Interestingly, various genetically engineered animals mimicking human disease have proven to be useful in terms of analyzing the *in vivo* function of the MR. MR gene inactivation achieved by homologous recombination leads to knockout mice developing symptoms of pseudohypoaldosteronism. In contrast, hMR overexpressing transgenic mice exhibit specific alteration in renal and cardiac function. Altogether, these animal models constitute attractive new experimental systems to further explore the widespread and pleiotropic function of aldosterone receptors *in vivo* and to decipher the molecular and cellular events underlying the aldosterone signaling pathway.

Alkaline Phosphatase

David Goltzman and Dengshun Miao
McGill University, Montreal, Quebec, Canada

Glossary

alkaline phosphatase A membrane-bound metalloenzyme that consists of a group of isoenzymes, all glycoproteins, encoded by at least four different gene loci: tissue nonspecific, intestinal, placental, and germ cell alkaline phosphatase; catalyzes the hydrolysis of a wide range of phosphomonoesters at alkaline pH.

hypophosphatasia An inheritable disorder characterized by defective bone mineralization and a deficiency of tissue nonspecific alkaline phosphatase activity.

isoenzymes Enzymes that have the same catalytic activity but differ slightly in amino acid sequence and/or posttranslational modifications.

Since its first description by Suzuki and colleagues in 1907, alkaline phosphatase (ALP) has been investigated continuously and extensively. For most of the past century, there has been widespread use of ALP activity in serum as an enzymatic signal for a variety of disease states involving, in particular, the liver and bone. Investigations directed at the molecular properties of the enzyme have been relatively recent. Quantitation of serum ALP activity has been a routine in hospital laboratories since the 1930s, and this test is perhaps the most frequently performed enzyme assay. Bone ALP became the clinically most relevant enzyme in the diagnosis of bone disease. In spite of its broad use as a clinical marker, the physiological function of this protein, which is ubiquitous in nature, is largely unknown. Identification of ALP gene mutations in hypophosphatasia, a rare heritable form of rickets, has confirmed that ALP functions importantly in skeletal mineralization in humans. Still, many questions remain.

GENETICS AND EXPRESSION

Alkaline phosphatase (ALP) is a membrane-bound metalloenzyme that consists of a group of isoenzymes. Each isoenzyme is a glycoprotein encoded by different gene loci. At least four loci have been identified: tissue nonspecific, intestinal, placental, and germ cell ALP.

It is believed that the evolution of the ALP gene family has involved the duplication of a primordial tissue nonspecific ALP (TN-ALP) gene to create the TN-ALP gene and an intermediate intestinal ALP (IAP) gene, followed by additional duplications of the latter to create intestinal, placental, and germ cell ALP genes. Only humans and great apes have placental ALP; all other mammals have IAP.

The gene encoding TN-ALP maps to the short arm of chromosome 1, bands p36.1–p34. It is expressed at its highest levels in liver, bone, and kidney (hence its alternate name L/B/K ALP) as well as at lower levels in various other tissues. Differential processing of the TN-ALP gene product occurs within the cell or during passage of the protein molecule out of its cell of origin. In this way, differential glycosylation of TN-ALP gives rise to tissue-specific isoforms.

The gene encoding IAP is a member of the gene family mapping to the long arm of chromosome 2 (q34–q37). IAP is present at high levels in intestinal tissue and at trace levels in the kidney. In contrast to the other ALP isoenzymes, the carbohydrate side chains of IAP are not terminated by sialic acid. Distinct IAPs can be isolated from fetal and adult intestinal tissue, with the fetus forming a sialylated isoenzyme in contrast to the adult. The fetal and adult forms differ not only in the carbohydrate content but also in the protein moiety itself, suggesting that a separate ALP gene locus may exist in humans during fetal development. Fetal IAP is present in amniotic fluid and in the meconium. This fetal/embryonic gene has also been identified in cancer cells and is designated the Kasahara isoenzyme.

The human placental ALP gene was also mapped to chromosome 2. It exhibits 87% homology with the IAP gene. There are, however, amino acid differences at their carboxyl-terminals. Placental ALP is a heat-stable enzyme present at high levels in the placenta. A trace amount of this isoenzyme can be detected in normal sera. Part of the serum placental-type activity originates from neutrophils. Placental ALP activity has also been detected in normal type I pneumocytes

and in the human ovary and cervix. The placental ALP gene can be reexpressed by cancer cells as the Regan isoenzyme. Placental ALP is a very polymorphic enzyme, with up to 18 identified allelozymes resulting from point mutations, in contrast to the other ALP isoenzymes.

The gene encoding germ cell ALP (GCAP) was also mapped to chromosome 2. It encodes testis/thymus ALP and can be expressed in the placenta at low levels. GCAP in testis appears to be localized to the cell membrane of immature germ cells and, like the other ALP isoenzymes, is attached to the cell membrane by means of a glycan-phosphatidylinositol (GPI) anchor. Like the intestinal and placental ALP genes, it can be reexpressed by cancer cells.

LOCALIZATION OF ALP

Localization of ALP in the cell has been performed by fractionating subcellular components by ultracentrifugation and then performing electron microscopic cytochemistry. From these studies, one can conclude that most of the ALP activity in the majority of cell types is located on the plasma membrane. Still, a small amount of enzyme activity has been shown to be present at other intracellular sites such as the nucleus, endoplasmic reticulum, and Golgi apparatus.

Histochemical techniques at the level of the electron microscope showed reaction product for ALP on the microvillar membranes, multivesicular bodies, Golgi complex, lysosomes, endoplasmic reticulum, and nuclear membranes of the absorbing epithelial cells of the intestinal mucosa. ALP in the kidneys is localized on the microvilli of the proximal tubular cells. In liver, the reaction product of ALP is present on the microvilli of the bile canaliculi. In bone, ALP activity is present on the outer surface of plasma membranes of maturing and hypertrophic chondrocytes and of preosteoblasts and osteoblasts. The reaction product is also present in chondrocyte lacunae, in matrix vesicles in cartilage matrix, as well as among uncalcified collagen fibrils of osteoid in bone. In placenta, ALP activity is found along the plasma membrane lining the microvilli and in vesicles of the syncytiotrophoblast. However, in eosinophil leukocytes, the ALP reaction product was found in only minimal amounts in the plasma membranes but was prominent on the nuclear membranes and outer compartment of mitochondria. The Golgi membranes and endoplasmic reticulum reacted but did so less intensely. The positive cytochemical reactions for ALP are confined to the cytoplasm of the more mature

neutrophilic granulocyte. ALP activity was also localized to fibroblasts, vascular smooth muscle, and endothelial cells in brain, heart, and endocrine glands.

STRUCTURE AND ANCHORING OF ALP TO THE CELL MEMBRANE

Human ALP enzymes have not yet been obtained in crystalline forms suitable for X-ray analysis. However, their active sites, and the active site of *Escherichia coli* ALP, show a high degree of homology, so that key regions of the human isoenzymes can be interpreted with reference to the corresponding regions of the bacterial enzyme. *E. coli* ALP exists as a dimer of identical subunits, each of which contains 429 amino acids. Crystallographic observations of the molecule from *E. coli* have revealed the three-dimensional structure of dimeric ALP: a bat-like figure with a metal ion triplet in each active site region. Zinc can bind to all of these sites but binds particularly strongly to four sites per dimer, with magnesium occupying two sites of the dimer.

ALP belongs to the large group of proteins attached to the outer surfaces of cells by a C-terminal GPI anchor. As such, it is an ectoenzyme expressed on the outside of the cell. The enzyme is a tetramer when it is membrane bound, but it circulates as a dimer. Phospholipase C or D, which is abundant in plasma, potentially converts the membrane-bound form to a soluble form.

IDENTIFICATION OF ALP ISOENZYMES

Total serum ALP activity remains one of the most frequently measured enzyme activities in clinical medicine. Several different substrates have been introduced for its assay. Of these, paranitrophenylphosphate (PNPP) is probably the most widely used. Many methods have been proposed to separate the various ALP isoenzymes, including heat denaturation, chemical inhibition of selective activity, gel electrophoresis, precipitation by wheat germ lectin, and immunoassay.

The heat denaturation method is based on the gradation in heat stability at 56°C of the ALP enzymes found in serum. This heat stability ranges from placental ALP, which is completely heat stable; to liver ALP, which has intermediate stability; to bone ALP, which is very labile. The mean remaining enzyme activities after 15 min at 56°C are 11, 21, 90, and 87% of the original activity for the bone,

liver, intestine, and placenta isoenzymes, respectively. Determining the tissue origin of the enzymes by employing differential heat inactivation demands precise control of the temperature during the assay.

Selective chemical inhibitors have also been used to separate ALP isoenzymes. L-phenylalanine and L-tryptophane inhibit intestinal and placental ALP, whereas levamisole and L-homoarginine inhibit TN-ALP. Each of these inhibitors is stereospecific and noncompetitive.

Another common method for distinguishing among ALP isoenzymes is polyacrylamide gel electrophoresis (PAGE). Liver ALP carries the highest net negative charge, followed by the placental, bone, and intestinal forms. Liver and bone ALP can be separated sufficiently to allow visual assessment of their relative proportions, but these methods are quite tedious and there is often overlap between the two isoenzymes, making precise quantification difficult.

Wheat germ lectin binds to N-acetylglucosamine and sialic acid residues, and it provides a method by which to separate liver and bone ALP. Based on the differing glycosylation patterns of liver and bone, wheat germ lectin selectively binds the bone form. However, proper standards and lectin concentrations are necessary for accurate resolution.

Attempts to produce tissue-specific monoclonal antibodies have resulted in antibodies with preferential recognition of the liver, intestinal, and placental ALP. A two-site immunoradiometric assay that relies on the use of two monoclonal antibodies has been developed for the bone isoform.

FUNCTION OF ALP

Biochemical Function

Three *in vitro* functions have been attributed to ALP: (1) phosphohydrolysis of organic phosphomonoesters of low molecular mass, (2) phosphotransferase activity, and (3) protein phosphatase activity. Whether any of these relate to the physiological role of the enzyme is as yet unknown. ALP has little preference for a particular substrate and will hydrolyze all phosphomonoesters (diesters are not substrates). Catalysis includes phosphorylation of a serine residue at the active site, followed by transfer of the phosphoryl group to either water (phosphohydrolysis) or an organic acceptor alcohol (phosphotransferase). However, phosphoester cleavage is faster if the transfer of phosphate is to an acceptor rather than to water, and the hydrophobic nature of plasma membrane-bound ALP might lead to a preference for organic

acceptors and, thus, principally to a transphosphorylation reaction.

Physiological Role of ALP

ALPs are widely distributed in nature; they are present in all species, from bacteria to humans. This is an indication that the enzymes are involved in fundamental biochemical processes.

Embryonal Development

Studies in amphibian embryos led to predictions concerning the expected distribution, on the embryonic flank mesoderm, of a cell surface molecule involved in guidance information for the embryonic cell migration of pronephric duct cells. An investigation of effects of disruption of the embryonic ALP gene on mouse preimplantation development revealed that the absence of the embryonic ALP gene resulted in fewer blastocysts *in vitro*, delayed parturition, and reduced litter size *in vivo*. This observation indicated that the presence of an active ALP gene is beneficial for preimplantation development.

Regulation of Lipid Transport and Intestinal and Renal Phosphate Transport

The local abundance of ALP on the membranes of cells involved in the transport of many substances (e.g., duodenal cell and small intestinal enterocytes, renal tubular cell, type I pneumocyte in the lung) suggests a role for the enzyme in complex active transport.

The evidence has been accumulating that IAP may play a role in lipid transport. Elevation of serum IAP activity has been demonstrated in rats following feeding of a high-fat diet. The magnitude of this response is dependent on fatty acid chain length. The correlation between lipid concentration and IAP activity in human lymph has led to the speculation that IAP might be involved in lipid transport.

The views concerning the role of ALP in renal inorganic phosphate (Pi) transport differ considerably. The administration of ALP inhibitors decreases Pi reabsorption in the kidney *in vivo*. Studies *in vitro*, however, showed that compounds that inhibit ALP activity did not block the uptake of Pi, suggesting that ALP is not a Pi-transporting enzyme analogous to ATPase in Na⁺ transport but rather that the role of ALP in Pi transport is indirect. In the kidney, ALP activity is highest in the early proximal tubule, which coincides with the region of the proximal luminal brush border membrane transport of Pi. Positive

correlations are found between the brush border membrane transport of Pi and the activity of ALP but not of other brush border membrane enzymes. The function of ALP in the intestinal epithelial transport of Pi (and calcium) is also a controversial subject in that inhibitors of ALP are unable to inhibit Pi transport by the intestinal cell.

Bone Formation

Another important role that has been assigned to ALP is its role in skeletal mineralization. Robison was the first to recognize the role of ALP in skeletal mineralization. The strongest evidence that TN-ALP functions in skeletal formation come with the delineation of inherited hypophosphatasia. This disorder is characterized by defective bone mineralization. The severity of hypophosphatasia is highly variable, ranging from stillbirth with almost no mineralized bone to pathological fractures first presenting during adulthood. The clinical heterogeneity of hypophosphatasia probably reflects the numerous mutations that have been described in the TN-ALP gene and that may give rise to various degrees of clinical severity.

The following roles have been postulated for bone ALP in the mineralization process: (1) hydrolysis of organic phosphate esters, resulting in high local Pi concentration and facilitating precipitation of calcium phosphate; (2) destruction of physiological crystal growth inhibitors such as inorganic pyrophosphate and adenosine triphosphate (ATP) through its hydrolyase activity; (3) action as a Pi transporter; and (4) active transport of Ca^{2+} or Pi via its ATPase activity. In bone matrix vesicles (functionally active shed plasma membrane fragments of osteoblasts) and the initial site of hydroxyapatite crystal formation, bone ALP activity can be as much as 20 times more than that on the plasma membrane surface of intact osteoblasts. ALP may be involved here in initiation of the calcification process by raising the local concentration of phosphate ions. The extracellular matrix-binding domain of TN-ALP may also be important in directing the migration of matrix vesicles along collagen fibers during the process of bone mineralization.

ALP in Liver

Although liver ALP generally represents at least half of total serum ALP activity in healthy adults, there is little evidence to support a critical hepatic function for liver ALP. It is generally assumed from its location on the sinusoidal membrane that liver ALP acts as a transport protein. Nevertheless it is doubtful that ALP fulfills a key function in liver given that gross deficiency of the liver isoenzyme in congenital

hypophosphatasia does not appear to give rise to any obvious clinical manifestation. However, one report has suggested that liver ALP may protect liver function from immunological injury by a mechanism involving neutralization of endotoxin.

ALP in Microvessels

ALP is one of the main enzymes present in brain and heart microvessels. ALP may have a role in the metabolism of pyridoxal 5'-phosphate, a cofactor of enzymes such as glutamate decarboxylase and glutamate transaminase involved in the metabolism of neural tissue, and might be a key enzyme of the blood-brain barrier regulated by insulin. Thus, insulin has been found to significantly inhibit brain ALP activity. ALP activity associated with capillary endothelial cells is also clearly affected by a hypoxic environment. ALP activity was significantly reduced or absent in areas of hypoxic skeletal and cardiac muscle, and a similar reduction was found in brain emboli associated with cardiopulmonary bypass. Focal loss of ALP activity demonstrated by histochemical methods appears to be a useful probe in identifying ischemic or hypoxic loci in these tissues. It has also been proposed that the expression of ALP in endothelia in brain and heart microvessels may contribute to the vascular hardening and calcification observed in humans. This, in turn, could be related to vascular aging, vascular disease, and the resultant weakening and/or rupture of vessel walls.

PATHOLOGICAL SIGNIFICANCE OF ALP

The major factors that affect ALP activity are age, sex, and hormonal status (puberty or menopause). From birth to 6 weeks, both bone ALP and intestinal ALP increase. No liver ALP is observed until 6 months of age. In children, a wide range of ALP activity exists and correlates with height and weight, and until puberty the bone isoenzyme represents 77 to 87% of the total. Activity increases in children around the age of puberty, with the maximum being earlier in girls than in boys, and corresponds temporally with growth spurts in both sexes. Bone ALP has been reported to increase during pregnancy; however, a gradual increase in total ALP activity is observed during the first 6 months of pregnancy, followed by a rapid increase during the final trimester. This increase is due primarily to the placental enzyme.

In healthy adults, the ratio of bone activity to liver activity is approximately 1:1. After 50 years of age,

total ALP again increases. Bone ALP activity is generally found to be higher in postmenopausal women than in premenopausal women. There is a great deal of interindividual variation in adult ALP levels, but for any one individual, values change little with time. ALP is cleared from the blood very slowly; the half-life varies from 40 h for bone to 7 days for placental isoforms. Biological daily variation of total ALP is estimated to be less than 4%.

Bone Disease

Rickets and Osteomalacia

Rickets in growing children is characterized by alterations in chondrocyte differentiation and reduced matrix mineralization in the cartilaginous growth plate, by increased osteoblastic activity, and by defective mineralization of bone matrix. The most common cause is vitamin D deficiency. Primary disorders of phosphate homeostasis and renal tubular disorders also can cause rickets in children.

A number of conditions result in vitamin D-deficient rickets, including inadequate exposure of the skin to ultraviolet radiation with inadequate dietary intake or intestinal malabsorption of this vitamin, chronic impaired renal function with insufficient production of 1,25-dihydroxy vitamin D (the metabolically active form of this vitamin), vitamin D receptor abnormalities, and an inherited deficiency of the enzyme 1 α -hydroxylase that produces 1,25-dihydroxy vitamin D. Bone ALP in these children is moderately to greatly elevated. Bone ALP activity can be further increased shortly after starting vitamin D treatment when healing begins, and it can decline progressively when therapy is effective.

X-linked hypophosphatemia due to a mutation in the enzyme PHEX and autosomal dominant hypophosphatemia due to a mutation in FGF23 are characterized by progressively severe skeletal deformities and dwarfism. Bone ALP activity is also high in these children.

Rickets can occur in a variety of disorders with impaired proximal tubular function that produce increased renal clearance of inorganic phosphate and hypophosphatemia. Glomerular filtration can be entirely normal or near normal. Because the serum concentrations of inorganic phosphate and calcium are critical for the formation of hydroxyapatite crystals and mineralization of bone, hypophosphatemia results in defective mineralization.

Osteomalacia is the adult equivalent of rickets in children. It is characterized by a defect in the

mineralization of the osteoid matrix synthesized by the osteoblasts, but because the growth plate is closed, disorders of epiphyseal cartilage do not occur and so growth abnormalities are not seen. The result is an accumulation of unmineralized bone, which in turn results in decreased bone density, as shown by X-ray or other techniques. As in children, disorders of vitamin D metabolism in adults are the most common causes of osteomalacia, and bone ALP is significantly increased in these cases.

Paget's Disease of Bone

Paget's disease of bone is a common disorder in the elderly where excessive bone turnover occurs, leading to the production of structurally abnormal bone. It is characterized during its initial phase by an increased resorption of bone, followed by an intense osteoblastic response. ALP is a very sensitive biochemical sign manifestation of Paget's disease of bone, as are indexes of bone resorption. ALP activity in Paget's disease is higher than in any other bone disease, excluding primary tumors of bone (osteosarcomas) and osteoblastic metastases from extraskeletal tumors (notably prostate cancer). Bone ALP may eventually decrease, possibly as the disease moves into a sclerotic phase. Serum ALP and indexes of bone resorption correlate well with the extent of skeletal involvement and with the response to treatment.

Congenital Hypophosphatasia

Hypophosphatasia is an inherited disorder characterized by defective bone mineralization and a deficiency of TN-ALP activity. Other ALP isoenzyme activity is unaffected. The severe homozygous form is lethal, whereas less severely affected children show generalized bone deformities due to defective mineralization of osteoid. The milder adult form is characterized by pathological fractures and precocious loss of teeth. Three phosphocompounds accumulate endogenously in hypophosphatasia—phosphoethanolamine (PEA), inorganic pyrophosphate (PPi), and pyridoxal 5'-phosphate (PLP)—indicating that these are natural substrates for TN-ALP.

Hepatobiliary Diseases

Hepatic diseases, such as acute and chronic hepatitis, cirrhosis, carcinoma of the liver, metastatic carcinoma of the liver, and acute and chronic biliary obstruction, are associated with increases in liver ALP activity.

Since the first report of elevated ALP activity in human serum in connection with obstructive jaundice,

much of the current knowledge concerning ALP in cholestasis has been obtained from experiments with bile duct-ligated rats. Studies in rats have shown that bile duct ligation or exposure of cultured explants of rat liver to bile from bile duct-ligated rats causes a marked increase in hepatic ALP synthesis in the liver, followed by an increase in serum ALP activity in the bile duct-ligated rats. Several bile acids have the capacity to stimulate ALP activity in a dose-dependent fashion in rat liver cell cultures.

In patients with liver cirrhosis, the catabolism of ALP may be reduced. Thoracic lymph flow is increased several-fold in cirrhotic patients, and the intestinal isoenzyme enriches the thoracic lymph and the serum, especially after a fatty meal. It is conceivable that these two factors (decreased clearance by the cirrhotic liver and enrichment of thoracic lymph with intestinal isoenzyme) are responsible for the frequent occurrence of the intestinal isoenzyme in the serum of cirrhotic patients.

Tumor Forms of ALP

Since the first description of ectopic production of ALP by tumor tissue, three different isoenzymes from independent gene loci have been detected in cancer patients: (1) Regan isoenzyme or term placental ALP; (2) Nagao, testicular, or placental ALP-like; and (3) Kasahara or fetal intestinal ALP.

Total serum ALP has been shown to be an effective indicator for metastatic breast cancer, with a sensitivity for metastases of 30 to 40%. Total ALP has also been suggested to be a significant prognostic factor for prostate cancer. Using various statistical methods, sensitivity, specificity, and accuracy for liver metastases in lung cancer were 71, 89, and 86%, respectively. Serum bone ALP was twice as sensitive as total enzyme activity in the diagnosis of the presence of bone metastases. Serum placental ALP has been

described as a potential marker in seminoma patients, but environmental influences have been shown to affect placental ALP levels significantly (e.g., smoking leads to a reexpression of placental ALP). Despite these environmental influences, placental ALP has been used successfully for monitoring testicular and ovarian carcinomas.

Therefore, ALP forms appear to play an important role in the diagnosis of a variety of benign and malignant clinical disorders, especially of bone and liver, and can be a useful index for monitoring therapy in these diseases.

Alternative Promoters

Erik Jansen, Torik A. Y. Ayoubi, Wim J. M. Van de Ven, and John W. M. Creemers
University of Leuven and Flanders Interuniversity Institute for Biotechnology, Belgium, The Netherlands

Glossary

promoter DNA structures containing *cis*-acting regulatory elements required for efficient initiation of transcription and for controlling expression of a gene.

transcription units Templates for RNA polymerases that encode information for the production of a single protein product (simple transcription units) or templates that produce multiple mature mRNAs that can give rise to multiple, albeit related, proteins (complex transcription units).

Alternative promoters can be defined as two or more promoters used to generate the same primary transcript or at least partially overlapping primary transcripts. Alternative promoters will always give rise to differential transcription initiation, resulting in differences in the 5' region of the mRNA isoforms.

INTRODUCTION

Probably the biggest surprise coming from the human genome sequence is the much lower than anticipated gene number. Therefore, it might be expected that complexity of the human proteome is achieved by transcriptional, translational, and posttranslational diversity. The use of alternative promoters is a frequently used way in which to generate multiple protein isoforms from a single gene. In addition, alternative promoters play an essential role in the control of transcription in a spatial and temporal fashion necessary for the proper development and differentiation of specialized cell types that define multicellular organisms.

THE NEED FOR ALTERNATIVE PROMOTERS

Expression of genes in more than one tissue or developmental stage often requires distinct combinations

of transcription factors. One single promoter might not always be sufficient to accommodate all of the required responses. Another role for alternative promoters is to be able to respond in different cell types to the same extracellular signals or to respond in the same cell to different signals. Finally, alternative transcripts can generate diversity by influencing mRNA stability, translation efficiency, and amino terminus of the encoded protein. A different amino terminus, in turn, can lead to alterations in protein levels, functions, or subcellular localization.

STRUCTURAL ORGANIZATION OF ALTERNATIVE PROMOTERS

Although there are various patterns of alternative promoter use, the two basic mechanisms are shown schematically in Fig. 1. In the first case (panel A), two tandemly arranged promoters are positioned within the same exon. In the second case (panel B), alternative promoter use will result in alternative first exons. If the start codon is located within the second exon (indicated with a black diamond), there will be no difference between the transcripts at the protein level. However, if start codons are located in the first exons (indicated with arrowheads), different protein isoforms will be generated. Another

Figure 1 Schematic representation of the organization of genes containing alternative promoters. Exons are depicted as boxes, and intervening sequences are depicted by solid lines. Dotted lines connecting exons indicate splicing patterns. Arrows indicate transcription initiation sites. Diamonds and arrowheads represent start codons, as discussed in the text.

layer of complexity can be added by additional promoters and/or exons upstream of the second promoter.

MODES OF REGULATION OF ALTERNATIVE PROMOTERS

Promoters respond to specific stimuli. In most cases, this is a direct result of the presence or absence of specific response elements in a given promoter. Alternative promoters provide the possibility of responding differentially to ubiquitous transcription activators and repressors, tissue- and developmental stage-specific regulators, and maternal or paternal allele-specific (imprinted) regulators. In combination with the generation of different protein isoforms, this will result in the differential expression and presence of, for instance, hormone receptor X_A in tissue A and its variant X_B in tissue B. This variant could display altered ligand specificity and/or altered intracellular signaling. In addition, feedback mechanisms exist in which the gene product (in)directly up- or down-regulates one or several of its alternative promoters.

SELECTED EXAMPLES

The genes encoding transcription factors CREB (cyclic AMP response element-binding protein) and CREM (cyclic AMP response element-modulatory protein) are an interesting example of regulatory mechanisms. The peculiar aspect resides in the fact that they can encode different isoforms, either activating or inhibiting gene expression, by mechanisms of alternative exon splicing, alternative promoter use, and auto-regulation of promoters. In particular, an internal promoter of the CREM gene directs the expression of a repressor isoform that auto-regulates the alternative promoter, thereby generating a negative feedback loop.

The specific regulation of expression of the cytochrome P450 aromatase gene is a good example of alternative promoter use in the context of endocrine disorders. P450 aromatase is expressed in several normal human tissues such as ovary, placenta, testis, brain, adipose, bone, and skin; in some pathological tissues such as breast and endometrial tumors; and tissues from endometriosis and myofibroma of the uterus. The regulation of expression of P450 aromatase is quite different in these tissues; follicle-stimulating hormone (FSH) stimulates the expression of P450 aromatase in ovary, phorbol esters and

ligands of retinoic acid receptors stimulate the expression in choriocarcinoma cells, and androgens stimulate the expression in the hypothalamus. It has been shown that the tissue-specific and hormonal milieu-specific expression is achieved mainly by tissue-specific alternative use of different promoters. At least nine alternative promoters and 5'-untranslated first exons have been identified. FSH increases the expression of aromatase in ovary by the use and activation of the proximal promoter II. In placenta, phorbol esters regulate the expression of the most upstream promoter I.1. And in adipose tissue, tumor necrosis factor- α stimulates the use of promoter I.4 through activation of transcription factor AP-1. The potential role of P450 aromatase promoter switching in various physiological and pathological processes is illustrated by observations that distinct transcripts are expressed in fetal versus adult human liver and in healthy versus cancerous breast adipose tissue.

A summit of complexity is represented by the GNAS1 gene encoding a stimulatory G protein that is essential for activation of intracellular signaling in response to specific hormone-receptor interactions. This gene has at least four alternative promoters. In addition, it is an imprinted gene that produces different gene products from the maternal and paternal allele through the use of oppositely imprinted alternative promoters. Moreover, abnormal imprinting of the GNAS1 gene promoters can lead to disease states such as pseudo-hypoparathyroidism and somatotrophs adenomas.

CONCLUSION

Heterogeneity in the 5' ends of mRNAs generated by alternative promoter use in a tissue- or developmental stage-specific manner is common to a large group of genes. It is obvious that the increasing complexity of the mRNA population is an appropriate means of achieving a differential and spatiotemporal expression of the corresponding gene products and their potential pleiotropic actions. There is increasing evidence for several genes that switching of gene expression from one mRNA variant to another may be a key regulatory mechanism in several physiological and pathological processes.

Alternative Splicing

Scott A. Akker, Bernard C. E. Khoo, and Shern L. Chew
St. Bartholomew's Hospital, London, United Kingdom

Glossary

exon A nucleotide sequence, separated by introns, that is included in the final mRNA.

intron A transcribed nucleotide sequence that is excised in the production of mRNA.

splicing The process by which introns are excised and exons united to form mRNA.

Alternative splicing is the process by which different mRNAs are generated from the same pre-mRNA by the selection of alternative exons.

THE SPLIT GENE, ALTERNATIVE SPLICING, AND PROTEIN DIVERSITY

“Split” genes were first recognized in 1977. It is now estimated that 95% of human genes are split, with coding exons split by noncoding introns. Splicing is the process by which the introns are excised and the exons ligated to form a translatable message. Thus, DNA is transcribed to form premessenger RNA (pre-mRNA), spliced to form messenger RNA (mRNA), and then exported from the nucleus for translation to protein.

Alternative splicing is now recognized as the major contributor to protein diversity in man. Analysis of the human genome suggests that only 1.1% of its 2.91 billion base pairs code for exons. These exons are distributed over an estimated 32,000 genes, and alternative splicing is important in generating diversity and complexity from this limited gene pool. Current estimates suggest that at least 60% of the genes can produce two or more mRNAs by alternative splicing. The potential for generating diversity is demonstrated by the *Slo* gene, which has the potential to generate more than 500 protein isoforms.

The regulation of alternative splicing provides an essential control step in post-transcriptional gene

expression, and the endocrine system is likely to be one of the key systems that directs this in a tissue- and cell-specific manner. Next, we describe the current understanding of the role, mechanisms, and control of alternative splicing, with particular reference to endocrinology.

THE SPLICING MECHANISM

Splicing is performed by a large complex of proteins and small nuclear ribonucleoproteins (snRNPs) called the spliceosome. The spliceosome must be able to recognize the exon/intron boundaries in a precise and reproducible manner. At least part of the exon/intron definition is provided by certain key intronic elements, including a 3' and 5' splice site and a branch site and polypyrimidine tract upstream of each spliced exon (Fig. 1).

Splicing occurs in close physical and temporal relationship to pre-mRNA transcription, with the C-terminal domain of RNA polymerase II helping direct splicing factors to the pre-mRNA. The snRNPs are key players in the spliceosome, and each one has a RNA component that is capable of interacting with the pre-mRNA through Watson-Crick base pairing. U1 snRNP binds the 5' splice site of the exon. U2 snRNP then associates with the polypyrimidine tract of the upstream 3' splice site and the U4/U6.U5 tri-snRNP is recruited. The spliceosome then catalyzes cleavage of the pre-mRNA at the 5' splice site, and a lariat structure with the branch site is formed (Fig. 1). Cleavage at the 3' splice site precedes exon ligation and lariat release. Splicing is followed by the addition of a poly(A) tail, which is also subject to regulation.

PATTERNS OF ALTERNATIVE SPLICING

The most primitive form of alternative splicing is intron retention; in man, however, the most commonly described form of alternative splicing is exon skipping. Several other mechanisms exist, including the use of alternative 3' and/or alternative 5' splice

Figure 1 Basic mechanisms of splice site selection and spliceosome assembly. The exons are shown as boxes and the intron as a line. The bold line in the intron, between the branch site and the 3' splice site, represents the polypyrimidine tract. The stepwise assembly of the spliceosome complexes, early (E) and subsequent (A and B), is shown. Note that only the U1, U2, and U4/U6.U5 snRNPs are depicted, and the many non-snRNP proteins are omitted for clarity. From Akker *et al.* (2001), reproduced by permission of the Society for Endocrinology.

sites (Fig. 2). Many genes in the endocrine system undergo a combination of different alternative splicing events, employing various mechanisms.

REGULATION OF ALTERNATIVE SPLICING

Splice Sites

The splice sites that flank exons are necessary but not sufficient to explain exon recognition. Splice sites have a varying degree of similarity to highly degenerate consensus sequences. In fact, splice site-like sequences that also match the consensus occur with great frequency throughout the genome and define a set of pseudosites and pseudoexons that never undergo splicing. Such pseudoexons may outnumber true exons 10 to 1. Thus, there is a spectrum of exons: those that are always spliced (constitutive exons), those that are spliced only under certain conditions (alternatively spliced exons), and those that never undergo splicing (pseudoexons). As a rule, alternatively spliced exons tend to have splice sites with a weaker match to the consensus than constitutive exons, and this allows them to be more amenable to the effects of other sequence elements and factors. Experimentally

Figure 2 Common patterns of alternative splicing. The central exons undergo alternative splicing, with one pathway represented by solid lines and the alternative with dashed lines. As seen in IGF-1, the same exon within a gene may undergo more than one form of alternative splicing.

enhancing the splice site strength of alternatively spliced exons usually causes them to be included constitutively. The splice site strength of the exons neighboring an alternatively spliced exon is also important. Strengthening the 5' splice site of the upstream exon or the 3' splice site of the downstream exon can lead to an increased degree of skipping of the middle exon.

Other RNA Sequence Elements and Their Interactions

Major advances in understanding regulated alternative splicing have occurred with the identification of primary sequence elements involved in promoting exon selection (enhancers) or repressing splicing (silencers). The factors functioning through several such regulatory sequences have been isolated. Many important non-snRNP proteins are involved in spliceosome assembly and function. A number of these also regulate splice site selection. In addition to the elements described previously, examples of elements that may function through secondary structure have been described, such as in the insulin receptor described later. Alternative splicing could be subject to regulation via RNA helicases, which function to unwind the secondary structure to allow access of the spliceosome to splice sites and regulatory elements.

Splicing Enhancers and Serine-Arginine-Rich Proteins

There are many examples of splicing enhancer elements. These are most commonly sited within exons but may also be intronic. A family of splicing factors has been shown to interact with these elements—the serine-arginine-rich (SR) proteins. SR proteins are characterized by RNA-recognition motifs and domains

containing serine and arginine repeats, which are important for protein–protein interactions. SR proteins are required for constitutive splicing and are also crucial mediators of regulated alternative splicing. SR proteins may regulate alternative splicing through other means. The SR protein SF2/ASF has been proposed to increase the stability of certain mRNAs by direct binding. Some proteins act by modulating SR protein function; for example, SRp86 directly interacts with two other SR proteins to enhance (SRp20) and repress (SC35) their actions in a dose-dependent manner.

Splicing Silencers and Heterogeneous Nuclear Ribonucleoproteins

Less well documented are examples of splicing silencers. These have also been described in both exonic and intronic contexts. It has been proposed that silencers occur frequently throughout human introns and act to repress pseudo-splice sites. The major family of proteins shown to interact with these elements is the heterogeneous nuclear ribonucleoproteins (hnRNP) family. Only a few have been characterized in terms of their function. Perhaps the best characterized hnRNP is polypyrimidine tract-binding protein (PTB; also known as hnRNP I). PTB exists as several isoforms through alternative splicing and has been associated with several types of exon skipping. PTB binding sites are often found on both upstream and downstream introns, and it has been proposed that an interaction occurs between PTBs, which can form multimers, and together they promote exon skipping. In the case of hnRNP A1, cooperative binding between several molecules occurs, starting from a high-affinity binding site. This results in the “spreading” of hnRNP binding along the pre-mRNA.

The overall picture that is emerging is that each alternatively spliced exon lies in a balance of recognition versus nonrecognition. The spliceosome makes its decision based on the splicing signal strength and the degree of signal enhancement or repression present. A major model of alternative splicing holds that the binding of SF2/ASF to a pre-mRNA is in competition with that of hnRNP A1. The binding of SF2/ASF recruits spliceosomal factors via protein–protein interactions. SF2/ASF may also function to block the propagation of hnRNP A1 binding along the pre-mRNA. Any change in the ratio of enhancing factors to silencing factors can swing the balance toward or away from splicing.

The following mechanisms may regulate enhancing/silencing factors: phosphorylation, demonstrated by STREX and insulin action on SRp40; cellular

localization/sequestration (e.g., the stress-induced cytoplasmic sequestration of hnRNP A1); and temporal regulation of factor concentrations in tissues (e.g., insulin up-regulates the expression of SRp40). A combination of all three of these mechanisms is likely to occur *in vivo*: for example, cytoplasmic sequestration of hnRNP A1 is associated with phosphorylation mediated by the MKK_{3/6}-p38 kinase pathway.

ENDOCRINE EXAMPLES OF ALTERNATIVE SPLICING

Table I provides examples of endocrine stimuli that affect alternative splicing. Here, we focus on endocrine examples that demonstrate some principles of alternative splicing regulation.

Table I Examples of Hormonally Regulated Alternative Splicing Events^a

| Alternatively spliced mRNA | Stimulus |
|-----------------------------------|--|
| Insulin receptor | Dexamethasone, glucose, insulin |
| Calcitonin/CGRP | Dexamethasone |
| Protein kinase C β | Insulin |
| IGF-1 | Growth hormone |
| Fibroblast growth factor receptor | Cytokines |
| Phosphotyrosine-1B | PDGF, EGF, bFGF |
| hPMCA2 | Calcium |
| CD44 | PDGF, IGF-1, via hnRNP A1 |
| Fibronectin EIIIB (rat) | Insulin, via HRS |
| Fibronectin ED (human) | TGF- β ₁ , vitamin D, retinoic acid |
| Kv3.1 channel | bFGF/depolarization |
| Agrin | Nerve growth factor |
| MHC-B | Nerve growth factor |
| SRp20 | Serum/cell cycle |
| Slo BK channel | Hypophysectomy/ACTH |
| Thyroid hormone receptor- β | Tri-iodothyronine |
| Tau | Tri-iodothyronine |
| Activating transcription factor-3 | TNF- α |
| SERCA3 | Retinoic acid, “hypertension” |

^aAbbreviations used: bFGF, basic fibroblast growth factor; EGF, epidermal growth factor; hPMCA2, human plasma membrane Ca-ATPase; IGF-1, insulin-like growth factor-1; Kv3.1, potassium voltage-gated channel; MHC-B, myosin heavy chain II-B; PDGF, platelet-derived growth factor; SERCA3, sarco/endoplasmic reticulum Ca-ATPase 3; TGF- β ₁, transforming growth factor- β ₁; TNF- α , tumor necrosis factor- α .

The Calcitonin/ α -Calcitonin Gene-Related Peptide Gene: Tissue-Specific Alternative Splicing Altered by a Hormonal Stimulus

The first described example of a hormonal stimulus altering splicing was in the calcitonin/ α -calcitonin gene-related peptide (α -CGRP) gene in 1986. The gene contains six exons and two polyadenylation signals. Alternative splicing leads to two proteins, distinct in both structure and function. In thyroid C cells, exon 4 is recognized and spliced with use of the exon 4 polyadenylation signal to generate calcitonin. In neuronal cells, exon 4 is skipped, and exons 5 and 6 are spliced with use of the exon 6 polyadenylation signal to generate α -CGRP (Fig. 3). Exon 4 is the key because its inclusion leads to cleavage and polyadenylation at its poly(A) site, thus preventing recognition of the downstream exons. The “constitutive” pathway is that of exon 4 inclusion, and it is only skipped in neuronal and cardiac tissue.

The important elements in and around exon 4 have been characterized. It is not surprising that exon 4 undergoes skipping because it contains weak splicing signals (non-canonical branch site and polypyrimidine tract) as well as a weak polyadenylation signal. Mutation of these signals to canonical sequences leads to exon 4 inclusion in all circumstances. Given the weak signals, it is perhaps more surprising that exon 4 is generally included. However, no fewer than three exonic splicing enhancers, one intronic splicing enhancer, and five pentanucleotide repeats, which also act as enhancers, have been described. These appear to compensate for the weak splicing signals. The intronic splicing enhancer is particularly interesting because it contains consensus sequences for both 3' and 5' splice sites that interact with U1 snRNP, PTB, and SF2/ASF. The enhancer and the factors binding it regulate both polyadenylation and terminal exon splicing.

Figure 3 Alternative splicing of the calcitonin/CGRP gene. The two potential mRNAs are schematically shown: CGRP mRNA (top) and calcitonin mRNA (bottom). A, the polyadenylation signals on the pre-mRNA.

In a medullary carcinoma-derived cell line, dexamethasone provides a stimulus that alters alternative splicing, up-regulating calcitonin production over α -CGRP production. The intermediaries between dexamethasone and the elements and factors described previously are not known.

Growth Hormone/Insulin-like Growth Factor-1 Alternative Splicing: Generation of Complexity

This system provides insight into how levels of complexity in gene expression can be established because growth hormone (GH), insulin-like growth factor-1 (IGF-1), their binding proteins, and their receptors all undergo alternative splicing.

GH is coded for by the *GH-1* gene, a five-exon gene that produces two major transcripts and at least three minor transcripts. The predominant isoform of GH is the 22-kDa form resulting from inclusion of all exons. Approximately 5–10% of human GH in the pituitary and in lymphocytes is the 20-kDa form, resulting from the use of an alternative splice site within exon 3. Use of this site is dependent on secondary structure elements and leads to a 15-amino acid deletion from the final protein. The role of this isoform is not known; somatotroph adenomas produce proportionally more 20-kDa isoform than 22-kDa isoform, and GH is carried by two GH-binding proteins that have different affinities for the 20- and 22-kDa isoforms. A small proportion of GH pre-mRNAs undergo exon 3 or exons 3 and 4 skipping, and these isoforms are believed to have a dominant negative effect, inhibiting the action of normal GH. Exon 3 inclusion has been shown to be dependent on an upstream intronic splicing enhancer. Mutations within this intronic splicing enhancer lead to exon skipping and cause isolated GH deficiency.

IGF-1 is derived from a six-exon pre-mRNA. Four of the six exons undergo alternative splicing and lead to the production of different precursor peptides but an identical mature peptide (Fig. 4). The exact roles of these different precursors are not well understood.

Figure 4 Alternative splicing of the IGF-1 gene. Alternative promoter sites are represented by the arrows of exon 1 and exon 2. Alternative splicing pathways are represented by the sloped lines.

Exon 5 splicing is dependent on tissue type and the hormonal milieu, and an exonic splicing enhancer located within exon 5 is responsive to the SR protein SF2/ASF. Increasing the activity/amount of SF2/ASF enhances exon 5 inclusion. The presence of exon 5 is linked to nuclear and nucleolar localization. The role of the precursors at different sites remains to be determined.

Insulin Receptor Alternative Splicing: A Role in Insulin Resistance?

The insulin receptor (IR) gene is a 22-exon gene. As in the calcitonin/ α -CGRP gene, there are two alternatively spliced isoforms that are generated by the inclusion or skipping of a single exon—exon 11. Exon 11 is only 36 base pairs and codes for 12 amino acids that lie in the C terminus of the α -subunit. The two receptor isoforms have been shown to differ in their tissue distribution, dimerization properties, substrate binding, and function (Table II).

In a human hepatoblastoma cell line, dexamethasone increases insulin sensitivity, and this is associated with up-regulation of the IR-B isoform. Glucose also increases IR-B splicing, and insulin levels have been linked with different IR isoform expression, independent of glucose.

Closer analysis has revealed some of the elements involved in alternative splicing of exon 11 and that ultimately mediate hormonal regulation. The weak splice sites of exons 10–12 predispose to regulation. These splice sites appear to compete for limiting splicing factors. Changing the splice sites effects the level of splicing of exon 11. Furthermore, four regulatory elements have been identified. Two elements lie in intron 10; a GA-rich region acts as an intronic

splicing enhancer that may enhance the neighboring weak splice sites. Downstream of this element lies an intronic splicing silencer, which is predicted to form a stem-loop structure with exon 11. The final two elements lie in close proximity to exon 11—one acts as an enhancer and the other as a silencer.

It is generally accepted that hyperinsulinemia is associated with relatively increased IR-A expression in muscle and that this precedes hyperglycemia. This contributes to insulin resistance, but it is not established whether hyperinsulinemia precedes the change in IR alternative splicing or vice versa. There is an additional level of complexity because both IR isoforms form heterodimers with the homologous IGF-1 receptor. Heterodimers of the IGF-1 receptor with the IR-A isoform bind IGF-1, IGF-2, and insulin, and signaling occurs along the IGF pathway. In contrast, heterodimers of the IGF-1 receptor with the IR-B isoform bind only IGF-1. Therefore, hyperinsulinemia can cause activation of both insulin and IGF pathways via IR-A homodimers and IR-A/IGF-1 receptor heterodimers, respectively. The clinical relevance is clear because heterodimers are found at higher levels in skeletal muscle and adipose tissue in type 2 diabetes.

CaRRE: The First Hormonally Responsive Splicing Regulation Element

The *Slo* gene encodes BK calcium and voltage-activated potassium channels. These channels exhibit functional diversity, partially due to alternative splicing. Two alternatively spliced stress axis-regulated exons (STREXs) have been identified that enhance repetitive firing when included. The skipping of these exons in adrenal chromaffin cells is increased

Table II Characteristics of Insulin Receptor Isoforms

| Insulin receptor isoform | IR-A (exon 11 skipping) | IR-B (exon 11 inclusion) |
|---------------------------------|--|--|
| Tissue distribution | Ubiquitous; predominant during embryonic development | Insulin-sensitive tissues: liver, muscle, adipocytes, kidney |
| Insulin binding affinity | ++ | + |
| Sensitivity to insulin action | + | ++ |
| Insulin action in β cells | Increased insulin transcription | Increased glucokinase transcription |
| IGF-1 binding affinity | ++ | \pm |
| IGF-2 binding affinity | + | \pm |
| IGF-1 receptor heterodimer | Binds insulin, IGF-1, IGF-2 | Binds IGF-1 |
| Expression in type 2 diabetes | Increased | Decreased |
| Expression in cancer cells | Increased | Decreased |

by hypophysectomy in rats. This effect is prevented by ACTH injections. Treatment of these cells with glucocorticoids increases skipping, whereas androgens decrease skipping. It is proposed that stress hormones regulate alternative splicing of STREX in adrenaline-secreting cells.

One of the sequence elements involved in this alternative splicing has been identified. Depolarization of GH₃ pituitary cells decreases STREX inclusion, and this is dependent on the action of a Ca²⁺/calmodulin-dependent protein kinase (CaMK IV). CaMK IV in turn acts via an element [CaMK IV-responsive RNA element (CaRRE)] upstream of the STREX. Transfer of this element to another exon confers CaMK IV repressibility on that exon. STREX skipping reduces the BK channel Ca²⁺ sensitivity, and this provides a feedback pathway by which chronic depolarization will reduce the Ca²⁺ sensitivity of the cell.

Hormones as Regulators of Alternative Splicing

Hormones regulate the alternative splicing of their target genes via multiple mechanisms, and many different second messenger systems mediate their effects (Fig. 5). Many of the downstream splicing factors have been identified, but the intermediaries remain elusive. Many kinases act to regulate alternative splicing, and the phosphorylation of splicing proteins is likely to be a key process. For example, terminal exon inclusion of the protein kinase C (PKC) β II pre-mRNA in skeletal muscle is up-regulated by insulin, which enhances insulin-stimulated glucose uptake. Insulin regulates the alternative splicing via the PI3K signaling pathway by phosphorylation of the SR protein, SRp40. Hormones acting via nuclear receptors may act on the C-terminal domain of RNA polymerase II to regulate the recruitment of splicing factors.

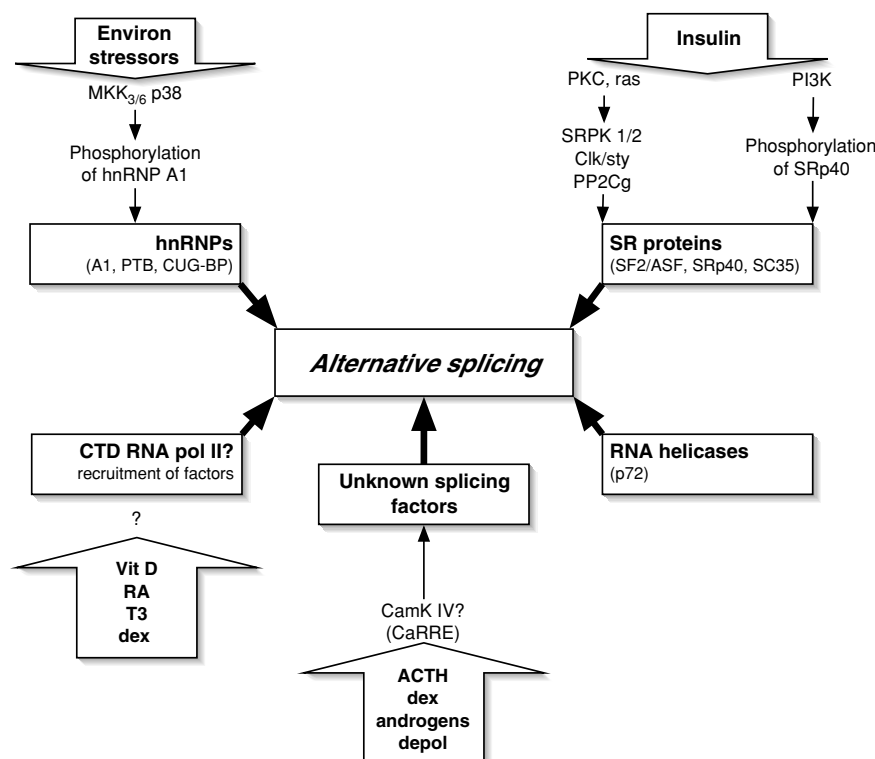

Figure 5 Possible pathways involved in the regulation of alternative splicing. Primary stimuli are indicated by the large arrows. dex, dexamethasone; depol, depolarization; environ, environmental; T3, tri-iodothyronine; RA, retinoic acid. Possible effector mechanisms are shown in boxes (examples of molecules). Second messenger molecules: Clk/sty, clk/sty kinase; MKK_{3/6} p38, p38 mitogen-activated protein kinase kinase; PP2C γ , protein phosphatase 2C gamma; CTD RNA pol II, C-terminal domain of RNA polymerase II; SRPK, SR protein kinases.

SPlicing AND ENDOCRINE DISEASE

Splicing defects are associated with an increasing array of disease processes and are particularly well represented in inherited endocrinopathies, such as congenital adrenal hyperplasia, multiple endocrine neoplasia, and neurofibromatosis type 1. Mutations that directly affect splicing may be classified into those that disrupt the splice sites and those that change non-splice site sequences. In the former class, mutations at 5' splice sites may cause activation of nearby cryptic 5' splice sites or, more commonly, skipping of the entire adjacent upstream exon. In the latter class, mutations of non-splice site sequences may disrupt regulatory elements for nearby splice sites, as previously described for isolated GH deficiency. An unusual endocrine splicing mutation occurs in the GH receptor gene, in which a deep intronic point mutation directly activates a pseudoexon, resulting in an additional 36 amino acids being included in the GH receptor, which in turn leads to GH insensitivity (Laron's syndrome). Thus, point mutations may cause disease by disrupting splicing regulatory elements.

The best described example of a disease caused by disruption of alternative splicing is myotonic dystrophy (DM1) and insulin resistance. DM1 is caused by CTG trinucleotide repeats at the 3' untranslated end of the DM protein kinase gene. In DM1 skeletal muscle, there are high levels of the hnRNP CUG-binding protein (CUG-BP), causing aberrant regulation of IR alternative splicing and a higher proportion of the IR-A isoform. Overexpression of this protein in normal cells also induces a switch to the IR-A isoform. This has been shown to occur via an intronic CUG-BP binding element upstream of the crucial exon 11. The same binding protein was previously shown to alter alternative splicing of the cardiac troponin T gene in both cardiac and skeletal muscle. Overexpression of CUG repeat RNA in normal cells appears to increase the half-life and steady-state levels of CUG-BP. Thus, a specific pathway has been proposed that leads to insulin resistance and possibly some of the other effects of this multisystem disorder.

Interestingly, higher levels of the IR-A isoform have also been demonstrated in poorly differentiated cancer cells. An autocrine loop has been proposed in anaplastic thyroid cancer in which high levels of IGF-2 have been associated with high levels of IR-A and IR-A autophosphorylation. Because IGF-2 binds IR-A and not IR-B, it may be acting as a mitogen. The presence of heterodimerization with signaling through the IGF system enhances this effect.

THERAPIES

Most attempts to alter splicing have focused on the disrupted splicing present in the cancer process, and several novel approaches to chemotherapy have been proposed. Complementary antisense oligonucleotides can switch alternative splicing but have problems with delivery and toxicity. Although suitable for cancer therapy, such approaches are less promising as long-term solutions to genetic disease caused by splicing dysregulation. However, two examples demonstrate the potential for novel therapies as our understanding increases. First, dystrophin synthesis is rescued in a Duchenne muscular dystrophy cell line by chimeric snRNAs with complementarity to exon 51 splice sites. Second, work is focusing on the development of compounds to treat human spinal muscular atrophy (SMA). Mutations in the *SMN1* gene cause SMA, but all SMA patients can produce functional SMN protein from the *SMN2* gene. This gene is identical to the *SMN1* gene except for one nucleotide in exon 7. This single nucleotide disrupts an SF2/ASF-dependent exonic splicing enhancer and leads to alternative splicing of exon 7. Exon 7 is therefore excluded from 80% of transcripts derived from the *SMN2* gene, and the 20% full SMN protein produced is not sufficient to prevent disease. Several novel splicing compounds have been identified as enhancers of exon 7 inclusion, and the search continues for a way to up-regulate exon 7 alternative splicing; however, several candidates have been found from cell culture work.

CONCLUSION

Alternative splicing is an essential means of generating diversity from a limited number of genes. Genes coding for hormones, their binding proteins, and their receptors are particularly well represented. Alternative splicing is an integral component of the endocrine system because it both regulates and is regulated by hormones.

Recent insights have shown that pre-mRNA has many sequence elements within introns and exons that regulate alternative splicing. Many factors acting directly on such elements have been described. The intermediates between a given hormone and its potential effect on a splicing factor are not known. Neither is it understood how splicing factors, many of which are ubiquitously and generously expressed, are regulated to produce subtle changes in spliceosome action.

As further knowledge of the alternative splicing process and its relation to disease processes is obtained, it is hoped that novel therapies can be

designed that divert alternative splicing to the appropriate pathway.

Alzheimer's Disease and Hormones

Sigbritt Rasmuson and Tommy Olsson
Umeå University Hospital, Umeå, Sweden

Glossary

Alzheimer's disease The most common cause of cognitive disturbance and dementia; a progressive neurodegenerative disease.

apolipoprotein E (apoE) A protein that is important for the metabolism of lipids (e.g., cholesterol); there are three different alleles coding for three isoforms of apoE, and an increased frequency of the apoE ϵ 4 allele is seen in Alzheimer's disease.

cognition The process of knowing or perceiving.

declarative memory Consists of items that are easy to verbalize and generally accessible to conscious recall; this includes both episodic and semantic memory.

entorhinal cortex A structure within the hippocampal region that provides the primary pathway by which sensory information enters and leaves the hippocampal region.

hippocampus A region of the brain that plays an important role in memory and learning and that has a high concentration of glucocorticoid receptors.

neuroendangerment Exposure that makes neurons less likely to survive neurological insults.

plaques and tangles Hallmark lesions in the brain in Alzheimer's disease; plaques are extracellular deposits consisting of the protein β -amyloid, whereas tangles are abnormalities of the neural cytoskeleton.

Alzheimer's disease is the most common form of dementia. The hallmark lesions are neurofibrillary tangles and neuritic plaques. The hippocampal formation, a key area for learning and memory processes, is affected early during the course of the disease. A number of hormones may affect the development and progression of this disease. These include hormones readily entering the brain through the blood-brain barrier as well as hormones locally produced within the brain. Potential prevention of dementia as well as treatment of this devastating disease may be achieved in the future through manipulation of hormone effects on brain cells.

ALZHEIMER'S DISEASE

In 1907, Alois Alzheimer described the first case of the most common cause of dementia. Alzheimer's disease (AD) accounts for at least 50% of all cases of dementia today. The prevalence increases with age, from approximately 2 to 3% at 70 to 74 years to 12 to 16% at 85 to 90 years. The most common cognitive symptoms in AD are impairments in explicit memory, visuospatial problems, inability to calculate, loss of judgment, and progressive loss of language. Furthermore, there are various noncognitive, behavioral, and psychological symptoms such as depression, anxiety, and aggressiveness. The definitive diagnosis of AD is based on a combination of an appropriate clinical history and a histopathological investigation. There are two hallmark pathological brain lesions: neurofibrillary tangles and neuritic plaques. The hippocampus seems to be the brain region that shows the earliest neuron loss in AD, and the pattern of neurodegeneration results in a functional isolation of the hippocampus from the cortical association areas. There are disturbances in multiple neurotransmitter systems in AD, including a profound loss of cortical and hippocampal cholinergic innervation, reduced central somatostatin levels, and changes in glutamatergic and serotonergic activity. Neurotransmitters and circulating hormones play key roles in modulating the complex neurobiological interactions that occur within the brain. Many hormones are also produced locally in the brain. There are important bidirectional links between the central nervous system and the peripheral endocrine organs. Thus, lesions in the brain of different origins may influence endocrine function.

THE LIMBIC-HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

Components of the LHPA Axis

The limbic-hypothalamic-pituitary-adrenal (LHPA) axis plays an important role in maintaining homeostasis

under basal and challenge conditions. The components of this axis function as an integrated feedback system in a hierarchic way (Fig. 1). The hippocampus, a limbic forebrain region, is an important neuroanatomical target for interactions between neurotransmitter systems and circulating hormones. The hippocampus has a high density of glucocorticoid receptors (GRs) and an inhibitory effect on cortisol release and is also important for negative feedback function.

Steroid hormones have profound effects on the central nervous system (CNS). These include effects

Figure 1 Schematic diagram of the limbic-hypothalamic-pituitary-adrenal axis. In Alzheimer's disease, there may be increased glucocorticoid production related to increased corticotropin-releasing hormone (CRH) secretion and disturbances in negative feedback. Circulating adrenal androgen levels are increased during the early phase of the disease, and this may indicate increased androgen production in the zona reticularis of the adrenal cortex or an altered metabolism of androgens. CNS, central nervous system; Ach, acetylcholine; 5-HT, serotonin; NE, norepinephrine; ACTH, adrenocorticotropic.

on mood, memory, and learning. These effects are exerted by glucocorticoids as well as by other steroid hormones such as androgens and estrogens.

Experimental Studies

Glucocorticoids have potent effects on the CNS, affecting cellular metabolism, receptor and ion channel density, neurotransmission, cell division, maturation, and cell survival. It was originally suggested that prolonged supraphysiological glucocorticoid levels with increasing age and/or stress down-regulated central GR expression. Reduced GRs in key brain areas, notably the hippocampus, might decrease the capacity for feedback, leading to further glucocorticoid hypersecretion. This would then lead to a vicious cycle in which hippocampal neuronal cell death might ensue, leading to permanently attenuated feedback and glucocorticoid hypersecretion. There are several caveats to this hypothesis. High glucocorticoid levels have only a moderate influence on GR expression. Instead, neurotransmitter influx, notably by serotonin and noradrenaline, is of major importance. Furthermore, it is not clear whether excessive glucocorticoid exposure *in vivo* per se might lead to neuron death. It seems more likely that glucocorticoids may lead to neuroendangerment. Thus, glucocorticoids make neurons less likely to survive a brain insult. The aging brain, especially the hippocampus, appears to be more susceptible than other parts of the brain to adverse effects of glucocorticoids. In combination with other insults associated with advanced age such as brain ischemia, various pathological processes might be accelerated by hypercortisolism. On a cellular level, glucocorticoids have a clear impact on neurons. Thus, increased levels of glucocorticoids seem to reduce neurogenesis within the hippocampus in close connection to excitatory amino acid efflux. Second, reversible stress-induced modeling of dendrites in hippocampal neurons is mediated by glucocorticoids along with excitatory amino acids. Finally, excitability of hippocampal neurons is influenced to a major extent. Thus, chronic excess of glucocorticoids might cause or accelerate some aspects of degenerative brain aging, notably hippocampus-associated cognitive dysfunction in rodents and humans.

Glucocorticoids and Cognition

In accordance with experimental data, several studies suggest an association between hypercortisolism, on the one hand, and hippocampal function and volume,

on the other. Healthy adults treated with low/medium doses of synthetic glucocorticoids develop a reversible decrease in both immediate and delayed recall. In patients with Cushing's syndrome with very high circulating cortisol levels, impaired declarative memory performance and mood changes are common. This is associated with reduced hippocampal volume. Notably, this volume loss seems to be a reversible phenomenon. In long-standing major depression, often associated with a moderate increase in glucocorticoid production, hippocampal volume reduction seems to be common. Interestingly, increasing serum cortisol levels in healthy elderly persons over years has been associated with decreasing hippocampal volume, with concomitant deficits in hippocampus-dependent memory tasks. In individuals with mild cognitive impairment (MCI), often preceding a later development of AD, salivary cortisol levels are inversely correlated with the result in an immediate recall task. From these data, it is not clear whether hypercortisolism is related to reversible hippocampal dysfunction or whether any association exists between hypercortisolism and future neurodegenerative disease.

Cortisol and Alzheimer's Disease

Disturbances on several different levels of the LHPA axis are present in AD. Some studies have been performed on patients in advanced stages of the disease, but it seems reasonable to assume that it is important to consider studies on mild to moderate AD, where these disturbances are early events in the disease rather than a late response to extensive CNS damage or medications.

There are several indicators of an increased central drive of the LHPA axis in AD, contributing to hypercortisolism. Postmortem studies have demonstrated increased corticotropin-releasing hormone (CRH) mRNA levels in the paraventricular nucleus of the hypothalamus. This putatively increased CRH secretion is associated with an increased cortisol but blunted adrenocorticotropin (ACTH) responsiveness to exogenous CRH in AD patients. An insensitivity to glucocorticoid feedback in AD probably also contributes to this increased activity through an inability to "shut off" temporary increases in LHPA axis activity. In line with this, increased glucocorticoid production has been reported in women with mild to moderate AD. These results show that increased glucocorticoid production is an early event in AD rather than a late response to chronic illness and/or medications. In addition, an altered cortisol metabolism is

present in mild to moderate AD, with increased excretion of A-ring-reduced metabolites in urine. This indicates that LHPA activation can be secondary to changes in cortisol clearance in AD. Alternatively, altered cortisol metabolism may be a protective mechanism that, together with down-regulation of GR expression in the periphery, can explain the absence of clinical features of hypercortisolism in peripheral tissues in AD (i.e., no increased prevalence of hypertension, diabetes mellitus, abdominal obesity, etc., as seen in Cushing's syndrome). Importantly, because of tissue-specific differences in cortisol metabolism and receptor expression, the brain may be excessively exposed to glucocorticoids. Thus, increased cortisol levels in cerebrospinal fluid (CSF) have been found in AD. Adverse effects on the brain through increased glucocorticoid exposure may be worsened via an inability of GRs in the brain to down-regulate their expression when exposed to increased glucocorticoid levels.

Thus, hypercortisolism may contribute to neuropsychiatric symptoms and accelerate neuronal damage in AD via tissue-specific alterations in pre-receptor glucocorticoid metabolism and receptor sensitivity/reactivity.

ANDROGENS

Adrenal androgens include dehydroepiandrosterone (DHEA), its sulfate (DHEAS), and androstenedione. DHEA enhances neuronal and glial survival and enhances memory retention in rodents, and placebo-controlled DHEA supplementation studies in humans have suggested that administration of DHEA may improve physical and physiological well-being.

During the more advanced phases of dementia, levels of DHEAS are clearly decreased. The latter finding has been suggested to be of importance for progression of neurodegeneration, partly through loss of a glucocorticoid-antagonistic effect by DHEA, but this is a matter of controversy. In contrast, we have found increased levels of androgens in mild to moderate AD. This indicates an increased androgen production in the zona reticularis of the adrenal cortex or an altered metabolism of androgens. Furthermore, dynamic studies show an enhanced response of androgens, including DHEA, in AD after ACTH stimulation. In one longitudinal study on AD, lower levels of DHEA were associated with superior cognitive performance.

Importantly, DHEA has no known receptor; instead, local brain metabolism of this hormone

may govern its biological activity. A cytochrome p450 enzyme, CYP7B, converts DHEA to 7 α -hydroxy-DHEA and may be responsible for putative antigluco-corticoid effects of DHEA. CYP7B mRNA is highly expressed in the human hippocampus, and this expression is significantly decreased in hippocampal neurons in patients with AD. Thus, alterations in androgen metabolism in AD might be important for tissue effects of adrenal androgens, with key interactions with glucocorticoids on a cellular level.

ESTROGEN AND OTHER FEMALE GONADAL HORMONES

Estrogens have numerous effects on the brain, including influences on development and adult brain plasticity. Beneficial effects on neuronal plasticity and blockade of neurotoxic effects may prevent or retard the development of neurodegenerative disease, including AD.

In favor of this hypothesis, estrogens regulate synaptogenesis in the rat hippocampus, notably in the CA1 subregion, which seems crucial for learning and memory functions. Synaptic spine density is related to circulating estradiol levels, and this is linked to memory function. These effects are associated with an increase in N-methyl-D-aspartate (NMDA) receptors in hippocampal neurons that relates to increased efficacy in long-term potentiation, that is, a proposed neurophysiological correlate to memory. Estrogens may also work in collaboration with neurotrophins, mainly nerve growth factor (NGF), to stimulate neuronal development, differentiation, and growth via colocalized receptors on neurons in the rodent fore-brain hippocampus and cerebral cortex. Estrogens also seem to promote neurogenesis.

In addition, estrogens influence the function in several neurotransmitter systems, including the cholinergic, serotonergic, dopaminergic, and noradrenergic systems. Estrogen-induced enhancement of cholinergic functions via increased activity of choline acetyl transferase (ChAT) in the basal fore-brain, hippocampus, and frontal cortex may be of particular relevance for AD. Related to this, the growth hormone response to pyridostigmine is increased in postmenopausal women taking estrogen replacement therapy, indicating an increased central cholinergic tone.

As evident from studies of, for example, serotonin receptor expression after manipulation of estradiol and progesterone levels, it is important to notice that estradiol may have very different effects when given

alone versus given in combination with progesterone regarding site and type of effects. This is also clear for effects on the noradrenergic system; estradiol given alone inhibits noradrenaline uptake, whereas estradiol followed by progesterone increases reuptake of this neurotransmitter. This influences the interpretation of hormone replacement studies in postmenopausal women that mainly has been done with estrogen in combination with a progestin.

In vitro, estrogens have neuroprotective effects, including inhibition of β -amyloid formation from its precursor protein. This may be due partly to reduced accumulation of reactive oxygen and nitrogen species. Importantly, estrogens seem to inhibit the production of proinflammatory cytokines, notably interleukin-6 (IL-6). Glucocorticoid-induced hippocampal neuronal damage also seems to be reduced. *In vivo* estrogens reduce damage from ischemic stroke insults, and this may be relevant for protection against development and/or progression of AD. Thus, cerebrovascular disease may affect the clinical expression of AD. In contrast, high levels of estradiol might be neurotoxic following injury, and this can be relevant for early stages of AD.

Neuroimaging studies in humans have implicated that estrogen influences the pattern of brain activation during memory processing, with regional increments in cerebral blood flow and glucose metabolism and with modulation of activity in specific brain regions affected during the early stages of AD. This may be partly related to direct effects on cerebral blood flow by estrogens.

Epidemiological studies have suggested that estrogen is protective against the development and/or progression of neurodegenerative disorders. Thus, low circulating levels of estrogen have been associated with an increased risk of AD. Some, but not all, case control studies, as well as a couple of prospective studies, have suggested that estrogen treatment may be protective against the development of AD. Importantly, there may be a protective effect of estrogen in long-term users of estrogen and/or when treatment is given during the latent preclinical stage of AD that may extend a decade or more before the onset of diagnosable dementia. Obviously, prospective randomized double-blind studies are needed for verification of these observations. Notably, circulating levels of estradiol have been reported to be slightly increased (and so not decreased) with concomitant elevated adrenal androgen hormone levels (DHEA and androstenedione) in patients with mild to moderate AD. This may reflect increased secretion and/or alterations in metabolism of these hormones during

the early phases of AD. These alterations of endogenous gonadal hormone levels during the early stages of AD imply that there may be no need for increasing estradiol levels further by supplementation in mild to moderate dementia. Indeed, increased estradiol levels may even be neurotoxic, and it might be worth exploring beneficial effects on reducing the production of adrenal androgens during the early phases of neurodegeneration/AD, thereby also reducing an excessive increase in estrogens.

The finding of a novel estrogen receptor, the estrogen β -receptor (ER β), has intensified the possibility of finding drugs that may act as neuroprotectants specifically through this receptor. The ER β has a clear role in the development of the cerebral cortex and also in survival of hippocampal neurons after exposure to excitatory neurotoxins. In contrast, ER α is the major receptor subtype expressed in basal forebrain cholinergic neurons. Thus, estrogen probably acts via ER α to enhance cognitive functions through the production of acetylcholine. On the other hand, ER β is the only estrogen receptor expressed in the dorsal raphe nucleus suggesting important effects on the serotonin system, indirectly affecting neuronal plasticity. In ER β knockout mice, spatial learning is impaired and treatment with cytotoxins causes marked apoptosis in hippocampus at doses that do not affect wild-type litter mates. Eight exon ER β knockout mice also show an increase in astroglia numbers, with a concomitant decrease in neuron number. This cell loss affects the limbic system, as well as the substantia nigra, to a major extent. Complex interactions among the subtypes of estrogen receptors is important to elucidate further, and it is not surprising that administration of estrogen compounds may induce very complex responses. Development of selective ligands for ER α and ER β may have profound effects on cognitive function and neuronal survival, notably in relationship to β -amyloid-induced neurotoxicity.

THE ROLE OF METABOLIC DYSFUNCTION

A number of recent studies have suggested an association between AD and risk markers for cardiovascular diseases. These include hypertension, diabetes mellitus, lipid abnormalities, and the presence of the apolipoprotein E (apoE) ϵ 4 allele. Related to this, antihypertensive treatment and treatment with statins may reduce the incidence of dementia. There are several explanations for these associations, including

overlapping pathophysiology and clinical features, notably metabolic dysfunction. In the "metabolic syndrome," associated with increased risk of type 2 diabetes and cardiovascular disease, hyperinsulinemia is a key element.

Insulin receptors are widely distributed in the brain, mainly in the cerebral cortex and hippocampus. Insulin receptors are localized at the synapse, where they regulate neurotransmitter release and receptor recruitment. This indicates a role for insulin in synaptic plasticity. Disruption of cerebral insulin receptor functions leads to progressive cognitive impairments in rodents, and high insulin levels may directly influence the development of neuropathological changes in AD. Thus, insulin may be involved in the formation of neurofibrillary tangles via its regulatory activity on tau phosphorylation. Insulin also seems to affect amyloid metabolism, inhibiting β -amyloid degradation.

Desensitization of the neural insulin receptor reduces transport of glucose, the major nutrient for brain cells, and so might be a crucial link between metabolic dysfunction/hyperinsulinemia and cognitive dysfunction in AD. This could be worsened through secretion of β -amyloid because this protein may influence insulin binding and action through competitive binding to the insulin receptor. Furthermore, glucocorticoid overexposure to the brain, due to either a primary increase in glucocorticoid secretion or local changes in prereceptor metabolism, can decrease insulin sensitivity.

Epidemiological studies indeed suggest a link among insulin resistance, diabetes mellitus, and AD. Ethnic factors may be of importance given that longitudinal studies of Caucasians and Japanese Americans have generated conflicting results, with clear associations between these factors found in a population-based study from Rotterdam, Netherlands. Interestingly, antidiabetic drugs may influence AD pathology. Troglitazone, a thiazolidindione antidiabetic agent acting as an "insulin sensitizer" via activation of peroxisome proliferator-activated receptor- γ (PPAR- γ) receptors, antagonizes an amyloid-stimulated proinflammatory response and neurotoxicity. This indicates a link among an inflammatory component of the metabolic syndrome, development of atherosclerosis, and pathology in AD.

Proinflammatory cytokines produced by activated microglia, especially IL-1, seem to trigger enhanced synthesis of amyloid precursor protein and production of β -amyloid. Amyloid deposits per se stimulate further cytokine production by activated microglia, leading to a vicious cycle with continuous production

of amyloid precursor protein and β -amyloid. The link between inflammatory mechanisms and AD pathology has been strengthened by the association between head trauma and later development of AD. Epidemiological studies also suggest that nonsteroidal anti-inflammatory drugs (NSAIDs) can retard the development of AD. Notably, the positive epidemiological findings with NSAIDs are reported for drugs that activate PPAR- γ receptors, lowering β -amyloid production (A β 42). This strengthens a possible link between insulin resistance and the development of β -amyloid-associated neurodegeneration.

Another potential link between insulin resistance and a later development of cardiovascular disease might be the adipocyte-derived hormone leptin. Leptin is an important regulator of satiety and energy expenditure. Based on the fact that overweight is associated with high circulating levels of leptin with associated "leptin resistance," a basic physiological function for leptin as protective against neuroendocrine consequences of starvation has been proposed. Increased leptin, strongly related to increased fat depot size, has been reported to predict the later development of myocardial infarction and stroke, independent of other risk factors. In patients with early AD, a physiological link between circulating cortisol and leptin levels over 24h seems to be lost. This suggests that leptin regulation is disturbed during the early phase of neurodegeneration, and this may be linked to abnormalities in cardiovascular risk factors as well as weight loss in patients with AD.

In summary, epidemiological and experimental data implicate that metabolic dysfunction precedes and may influence the development, progression, and symptomatology of AD.

GROWTH HORMONE

The activity of the growth hormone (GH)–insulin-like growth factor-1 (IGF-1) axis declines during aging. In humans, GH secretion takes place in a pulsatile manner, regulated by stimulatory effects of growth hormone-releasing hormone (GHRH) and inhibitory input from somatostatin. Reduced central somatostatin levels have been found in autopsy studies in AD patients. In the periphery, circulating basal GH levels have been reported to be elevated in a few studies, but the diurnal pattern of GH secretion in AD seems to be unaltered. There also seems to be a high variability in reported responsiveness to a GHRH challenge. Related to these findings, it is not clear whether peripheral IGF-1 levels are altered in AD and, if so,

whether this is a trait or a stage-dependent change in GH–IGF-1 axis function.

THYROID FUNCTION

In the Rotterdam study of aged individuals, the relative risk of AD at follow-up was increased more than three-fold for participants with reduced thyroid-stimulating hormone (TSH) concentrations at baseline. In contrast, no association was found between an increased TSH level and incident AD. Thus, the findings in the Rotterdam study are the first to suggest that subclinical hyperthyroidism among the elderly may increase the risk of AD.

CATECHOLAMINES

Noradrenergic axons arising from the locus ceruleus (LC) project to several cortical areas, including the prefrontal and entorhinal cortexes. In the brain, the levels of norepinephrine (NE) are highest in the hypothalamus, and NE plays an important role in attention, arousal, and stress reactions as well as in cognition. The level of NE in plasma is widely used as a marker of the activity of the sympathetic nervous system (SNS), and a decline in NE levels is reported in aging individuals. In AD, studies assessing the SNS are relatively few, with small numbers of patients and varying severities of the disease. Decreases in cortical NE levels are described in various degenerative diseases of the brain, including AD, and a marked LC neuronal loss is considered as a classic postmortem pathological hallmark of AD. Despite these findings, increased concentrations of NE in CSF of AD patients have been described, possibly due to a compensatory activation of remaining LC neurons in this disorder or to increased turnover. Taking into consideration the great variation between studies concerning both severity of the disease and number of patients included, the overall result of the studies on SNS in AD points to a noradrenergic dysfunction that may contribute to cognitive impairment and behavioral symptoms.

Amidation

Joseph Bell, Betty A. Eipper, and Richard E. Mains
University of Connecticut Health Center, Farmington, Connecticut, United States

Glossary

α -amidated peptide A peptide with a carboxy-terminal amide group (-CONH₂) in place of a free -COOH group.

α -amidation The enzymatic reaction that results in the presence of a carboxy-terminal α -amide group.

bioactive peptide Any peptide with a biological activity. They typically bind to receptors at nanomolar or picomolar concentrations and show very high amino acid sequence specificity. Most bioactive peptides work through G protein-coupled metabotropic receptors with seven transmembrane domains.

large dense core vesicle (LDCV) Also referred to as secretory granule. A membrane-delimited organelle formed from the trans-Golgi network that stores concentrated peptides and proteins for regulated secretion (secretion-on-demand). Standard electron microscopy preparations show an electron-dense core surrounded by a membrane.

Amidation is the process by which the -CONH₂ structure is created. The side chains of asparagine and glutamine contain this moiety, but this article discusses the process by which the carboxy terminus of a peptide acquires an α -amide.

INTRODUCTION

Endocrine cells and neurons communicate to other cells in the body (neurons, endocrine cells, muscles, glands, etc.) in part by secreting a variety of small molecules (e.g., glutamate, glycine, norepinephrine, and ATP), steroids, and peptides. Peptides are by far the most numerous class of secreted communication molecules. Bioactive peptides are normally synthesized as part of a larger inactive protein that is cotranslationally inserted into the lumen of the endoplasmic reticulum. The active peptide regions are then liberated by a small group of highly selective endo- and exoproteases. The majority of these cleavages and

other covalent modifications occur in specialized storage organelles called large dense core vesicles (LDCV). More than half of the known biologically active peptides have an α -amide group instead of a free carboxyl group on their COOH terminus (Fig. 1). Amidated fatty acids (e.g., oleamide) and other molecules have also been reported, and the formation of these α -amide groups may follow the same process established for α -amidated peptides.

For peptides, the immediate precursor of the α -amidated peptide is the corresponding peptide with an additional glycine residue at its COOH terminus. This peptidyl-glycine intermediate is formed from the initial larger precursor by the combined actions of endoproteases and carboxypeptidases; occasionally, the Gly residue is the final residue in the larger precursor. The α -amidation reaction begins with peptidyl-glycine and finishes with peptidyl-NH₂, the bioactive peptide. A single amidating enzyme can produce peptides terminating with all 20 amino acid amides.

WHY IS PEPTIDE AMIDATION IMPORTANT?

For most amidated peptides, biological potency decreases two or three orders of magnitude when the α -amide group is absent, with either the intact glycine residue remaining or the free acid exposed after the α -amide group is removed (Fig. 2). The α -amide is important because its presence means that the COOH terminus of the peptide does not change charge as a function of physiological changes in pH. Thus, the uncharged COOH terminus of the peptide can associate closely with its membrane receptor, binding to a site on the receptor at or within the transmembrane domains. This leaves the NH₂ terminus of the peptide exposed to the extracellular aqueous solution, enabling it to bind to additional portions of the peptide receptor and thus giving the peptide receptor pair more specificity and tighter binding than usually seen with smaller ligands, such as acetylcholine or glutamate.

Figure 1 The two-step α -amidation reaction.

THE α -AMIDATION REACTION

The peptide α -amidation reaction is a two-step process (Fig. 1). The first step is performed by peptidylglycine- α -hydroxylating monooxygenase (PHM; E.C. 1.14.17.3; also called peptidylglycine- α -monooxygenase). The second step is performed by peptidyl- α -hydroxyglycine- α -amidating lyase (PAL; E.C. 4.3.2.5; also known as peptidylamidoglycolate lyase).

In the α -hydroxylation reaction, ascorbate reduces the two copper ions that are bound to PHM, yielding two semidehydroascorbate molecules that leave the enzyme. Cytosolic reducing equivalents, delivered by cytochrome b_{561} , an integral membrane protein, are used to return the semidehydroascorbate to its fully reduced state. Only after the peptidyl-Gly substrate binds to PHM is molecular oxygen split, yielding peptidyl- α -hydroxy-Gly and water—soluble products that leave the enzyme. The two atoms of molecular oxygen are incorporated into the hydroxylated peptide and water. The α -hydroxylation reaction is closely analogous to the β -hydroxylation reaction performed by dopamine β -monooxygenase, which converts dopamine to norepinephrine and tyramine to octopamine. The most distinguishing features of this

reaction are its absolute dependence on copper and its use of ascorbate and molecular oxygen.

Although the second, or lyase, reaction can occur spontaneously as the pH is increased above 7.5, in cells it must be catalyzed by a separate enzyme. In LDCVs, with an internal pH of 5.0–5.5, the peptidyl- α -hydroxy-Gly product created by PHM is quite stable unless the lyase reaction is catalyzed by an enzyme. The lyase reaction, the stereospecificity of which matches that of PHM, requires enzyme-bound divalent metal, and bound zinc has been detected. It is not clear whether the zinc is catalytic or structural or both. A structural zinc could aid in the folding and stabilization of PAL, just as Ca^{2+} is thought to stabilize the prohormone convertases involved in propeptide endoproteolysis. A catalytic zinc could play a role like the one it plays in alcohol dehydrogenase, just as Zn^{2+} plays a crucial catalytic role in the carboxypeptidases.

THE PEPTIDE AMIDATING ENZYMES

The two enzymatic activities necessary to perform the peptide α -amidation reaction are initially synthesized as a single bifunctional precursor protein called peptidylglycine- α -amidating monooxygenase (PAM) (Fig. 3). Mammals have a single gene encoding PAM. Alternative splicing generates several forms of PAM that differ in important ways. Elimination of the exon encoding the transmembrane domain yields a soluble, secreted enzyme. Elimination of the flexible linker region between PHM and PAL (exon 16) greatly reduces the ability of cells to separate the two catalytic activities. In LDCVs, the same prohormone convertases that cleave propeptide precursors also cleave the PAM precursor, producing soluble PHM, soluble and membrane-anchored PAL, and soluble bifunctional PAM. In invertebrates such as *Drosophila* and *Cnidarians*, PHM and PAL are encoded by separate genes. Elimination of the *Drosophila* PHM gene is lethal, causing death in the very late embryo and young larvae stages. In snails, both catalytic functions are encoded in the same gene, but there are four copies of the PHM domain, each with a similar

Figure 2 Relative biological potency of α -amided peptides (each normalized to 100%) compared to the corresponding free acid form of each peptide.

Figure 3 Forms of the amidating enzyme as found in mammalian LDCVs.

dependence on copper and ascorbate but a unique peptide substrate specificity.

The catalytic core of PHM was defined using controlled protease digestion, and its structure was explored by assigning disulfides, examining site-directed mutants, and employing spectroscopy and X-ray crystallography. The catalytic core of PHM consists of two β -clamshell or sandwich domains. Each approximately 150-amino acid domain contains a single copper binding site. The NH_2 -terminal domain, with its three disulfide bonds, uses three His residues to bind Cu (the Cu_A or Cu_H site). The COOH -terminal domain, with its two disulfide bonds, uses two His residues and one Met residue to bind Cu (Cu_B or Cu_M). The two domains are held together by a single hydrophilic linker strand, whereas the interiors of the domains are very hydrophobic. All of the histidine and methionine residues involved in coordinating the two catalytic copper ions are conserved in all known PHM sequences. Interestingly, all the spectral and crystallography data indicate that the two copper ions are farther apart than expected for a reaction requiring both copper ions to undergo a reduction-oxidation cycle. The X-ray structure places the two copper ions 11 Å apart and separated by a solvent-filled cleft; the Gly-extended peptide substrate binds closer to Cu_B . Dopamine β -monooxygenase shares many conserved disulfide bonds and contains histidine and methionine residues that may bind to copper in a similar manner. Based on sequence similarity, two additional potential family members, monooxygenase X and dopamine- β -hydroxylase-L, have been identified; their substrate specificity has not been determined.

PAL has not been studied as extensively. However, of the amino acid residues that are conserved among species, site-directed mutagenesis has identified a subset that are candidates for involvement in maintaining the structure of PAL and additional residues that are candidates for involvement in the PAL catalytic mechanism. Unlike the copper ions in the PHM reaction, which cycle from Cu^{1+} to Cu^{2+} during each reaction cycle, transferring reducing equivalents to molecular oxygen, the catalytic zinc presumably interacts directly with the α -hydroxylated substrate. PAL remains unique, with no close homologues identified in database screens. The yeast genome lacks enzymes homologous to either PHM or PAL.

FUTURE STUDIES ON PEPTIDE AMIDATION

Future work should focus on the peculiar copper/oxygen chemistry employed by PHM and its relatives and on the unique structure of PAL and the divalent metals it binds. Cell biological studies should focus on how membrane PAM enters and leaves LDCVs and how it traverses the endocytic pathway. The role of copper transporters (e.g., ATP7A and the Menkes protein), cytochrome b_{561} , and ascorbate transporters in providing the right vesicular milieu must be elucidated. The biological consequences of disrupting amidation by interfering with copper metabolism (mottled/brindled mice) or the PAM protein (PAM knockout mice) must be explored.

Amiodarone and Thyroid

Wilmar M. Wiersinga

Academic Medical Center and University of Amsterdam, Amsterdam, The Netherlands

Glossary

action potential Changes in the plasma membrane during depolarization and the subsequent repolarization of cardiomyocytes. The duration of the action potential is reflected by the QT time of the electrocardiogram (interval between the start of the QRS-complex and the end of T-top). Class III anti-arrhythmic drugs (such as amiodarone) act via prolongation of the action potential.

colloid Proteinaceous substance in thyroid follicles, containing sizable quantities of iodine, thyroglobulin, and thyroid hormone.

deiodination Enzymatic removal of iodine atoms from organic compounds.

euthyroidism Normal thyroid function.

IC₅₀ value Concentration of a compound at which it inhibits a particular phenomenon by 50%.

lysosome A membranous bag of hydrolytic enzymes; this organelle is used for the intracellular digestion of macromolecules.

organification The incorporation of iodine atoms in organic compounds.

thionamides Class of anti-thyroid drugs (such as carbimazole, methimazole, and propylthiouracil) that inhibit thyroid hormone synthesis by interfering with organification.

thyroid hormone receptor Protein that, after binding of triiodothyronine (T₃), binds to specific DNA sequences in the promoter region of T₃-dependent genes, thereby modulating the transcription of these genes.

Wolff-Chaikoff effect Decreasing yield of organic iodine from increasing doses of inorganic iodide.

Amiodarone is a very potent anti-arrhythmic drug, which is successfully used in the treatment of atrial fibrillation and life-threatening ventricular arrhythmias. The drug, however, has many side effects. Amiodarone influences thyroid hormone secretion and metabolism in all patients taking the drug. In a

subset of patients, this results in amiodarone-induced hypothyroidism or thyrotoxicosis. Amiodarone also acts as a thyroid hormone receptor antagonist.

PHARMACOLOGY

The structural features of amiodarone are its high iodine content and its resemblance to thyroxine (Fig. 1). The drug is prescribed as amiodarone hydrochloride (MW 681.82), which contains 37.25% iodine by weight. It was originally introduced in 1962 in clinical medicine for the treatment of angina pectoris, but later was found to be very efficacious in the treatment of cardiac arrhythmias. Amiodarone is classified as a class III anti-arrhythmic agent; it lengthens the duration of the action potential and repolarization time in cardiac tissues. It also has weak anti-adrenergic effects, it causes smooth muscle relaxation resulting in a dilation of coronary arteries and an increase in coronary blood flow, and it induces peripheral arterial vasodilation and a decrease in systemic blood pressure and afterload.

Dosage forms of amiodarone (trade name Cordarone) are tablets or injections. Because of the large distribution volume, the onset of the drug's action is delayed; consequently, a loading dose to saturate the large body stores is frequently required. The highest levels of amiodarone and its major metabolite desethylamiodarone (DEA) are found in adipose tissue, liver, and lung (Table I). The slow turnover of amiodarone from deep compartments such as adipose tissue explains its exceptionally long terminal half-life of ± 10 days (half-life for DEA is 57 ± 27 days).

The major metabolic pathways of amiodarone are N-dealkylation, resulting in its main (and biologically active) metabolite DEA, and deiodination, resulting in monoiodo-, desdiiodo-, and desethyl-desdiiodo-amiodarone. A daily oral dose of 200 mg amiodarone results in a urinary iodide excretion of approximately 14,000 $\mu\text{g}/24$ liter, which is approximately 45 times higher than the optimal daily iodine intake of 150–300 μg recommended by the World Health

Figure 1 Molecular structure of amiodarone (chemical name: 2-butyl-3-[3,5-diiodo-4-(β -diethylamino-ethoxy)-benzoyl]benzofuran).

Organization. Amiodarone medication thus causes chronic iodine excess. Extensive glucuro-conjugation of amiodarone occurs and biliary excretion and fecal elimination account for 65–75% of the ingested drug. Transplacental transfer of amiodarone and DEA varies from 10 to 20%. Plasma amiodarone and DEA concentrations in the newborn are approximately fourfold lower than those in the mother. Amiodarone and DEA concentrations in breast milk are higher than in the plasma of the mother, due to their high lipid solubility.

Side effects are numerous, occurring in ~80% of patients. Most prevalent are corneal microdeposits (almost 100%), gastrointestinal symptoms such as anorexia and nausea (80%), photosensitivity and unusual blue-gray skin discoloration of exposed areas (55–75%), and neurologic symptoms such as tremor, ataxia, and peripheral neuropathy (48%). Uncommon but severe adverse effects include pulmonary toxicity, liver failure, and proarrhythmias. Most side effects develop slowly and are related to the cumulative dose of amiodarone. The mechanism of amiodarone toxicity is multifactorial, but a drug-induced phospholipidosis with disturbed lysosomal function explains many side effects. Amiodarone as an amphiphilic drug binds strongly to intralysosomal phospholipids, rendering them indigestible by phospholipases. The bound complexes form the intralysosomal multilamellar inclusion bodies, which have been found in lung,

liver, heart, skin, corneal epithelium, and nerve fibers of amiodarone-treated patients.

EFFECTS ON THYROID HORMONE SECRETION AND METABOLISM

Amiodarone treatment invariably results in changes in the plasma concentrations of thyrotropin [thyroid-stimulating hormone (TSH)] and thyroid hormones. There is an initial rise in plasma TSH starting in the first week of treatment, with a return to normal values after 3 months. This is due to a chronic iodine excess generated during biotransformation of the drug, which transiently inhibits the synthesis and release of thyroid hormones (the so-called Wolff-Chaikoff effect), explaining the rise in TSH. The thyroid usually escapes from these inhibitory effects and plasma TSH returns to normal values.

Amiodarone simultaneously affects extrathyroidal thyroid hormone metabolism; it strongly inhibits type I iodothyronine-5'-deiodinase, which catalyzes the deiodination of thyroxine (T4) into triiodothyronine (T3) and that of reverse triiodothyronine (rT3) into 3,3'-diiodothyronine. Consequently, plasma T3 decreases and plasma rT3 increases.

Plasma T4 and free thyroxine (FT4) concentrations also increase, predominantly due to a reduced metabolic clearance rate of T4 related to inhibition of T4 uptake in the liver. Inhibition of T4 entry into tissues decreases the availability of the substrate T4 for 5'-deiodination, thereby contributing to decreased production of T3 and decreased clearance of rT3. Chronic administration of amiodarone thus results in elevated plasma T4 and FT4 concentrations in the presence of a normal plasma TSH: a remarkable combination of test results.

AMIODARONE-INDUCED THYROID DISEASES

The clinical diagnosis of amiodarone-induced hypothyroidism (AIH) and amiodarone-induced thyrotoxicosis (AIT) can be made very easily if the classical symptoms and signs of thyroid hormone deficiency or excess are present, but this is not always the case. Worsening of cardiac arrhythmia can be an important clue for the diagnosis of AIT. A TSH value within the normal reference range reliably excludes AIH and AIT. An elevated TSH with a low T4 or FT4 in plasma indicates AIH. When plasma TSH is suppressed and plasma T3 is elevated, the diagnosis of AIT is straightforward. However, a normal plasma T3

Table 1 Tissue Distribution of Amiodarone (A) and Desethylamiodarone (DEA) in Human Autopsies

| Tissue | A ($\mu\text{g/g}$) | DEA ($\mu\text{g/g}$) | A/DEA |
|----------------|-----------------------|-------------------------|-------|
| Adipose tissue | 316 | 76 | 4.2 |
| Liver | 391 | 2354 | 0.12 |

Table II Incidence of Amiodarone-Induced Hypothyroidism (AIH) and Amiodarone-Induced Thyrotoxicosis (AIT) in Relation to Environmental Iodine Intake

| Iodine intake | AIH | AIT | AIH + AIT | Country |
|---------------|-------|-------|-----------|--------------------------------------|
| High | 13.2% | 1.7% | 14.9% | USA, UK |
| Intermediate | 5.7% | 7.9% | 13.6% | Spain, Australia, The Netherlands |
| Low | 6.4% | 11.9% | 18.4% | Italy, Belgium |

does not exclude AIT (in view of the decreased T₃ production due to inhibited deiodination of T₄ into T₃) and AIT may present as T₄ toxicosis.

AIH or AIT develops in 16% of amiodarone-treated patients (Table II). The incidence of AIH is higher in patients residing in areas with a high iodine intake and AIT occurs more often in regions with a low iodine intake. Amiodarone may also give rise to a small, firm goiter (induced by the iodine excess) in the presence of a normal level of TSH, but this occurs less frequently than AIH and AIT.

Amiodarone-Induced Hypothyroidism

AIH occurs more often in females than in males and most cases are seen in the first 18 months of treatment. It is caused by a failure of the thyroid gland to escape from the Wolff-Chaikoff effect, resulting in permanent inhibition of organification. This is more likely to occur in subjects with preexisting autoimmune thyroiditis. Consequently, AIH is, to a certain extent, predictable and women with preexisting thyroid peroxidase antibodies are at risk of developing AIH. Thyroidal radioiodine uptake is preserved in AIH despite the increased stable iodide pool; it is explained by the drop in organification, which normally also produces compounds (presumably iodinated lipids) that inhibit iodide uptake.

Discontinuation of amiodarone usually restores euthyroidism in 3–4 months, but permanent hypothyroidism may ensue in patients with preexistent autoimmune thyroiditis. Potassium perchlorate (which acutely inhibits thyroidal iodine uptake via the sodium–iodide symporter) may shorten the time to reach euthyroidism. Thyroxine medication is effective and allows continuation of amiodarone. Fetal hypothyroidism occurs in 11% of patients treated with amiodarone during pregnancy and should be treated at once with thyroxine.

Amiodarone-Induced Thyrotoxicosis

AIT occurs more often in males than in females and new cases continue to occur throughout the duration of treatment. Two types of AIT with a different pathogenesis have been distinguished (Table III). Type I occurs in patients with preexisting thyroid disease (Graves' disease, nodular goiter), obviously caused by increased thyroid hormone synthesis due to overrepletion of intrathyroidal iodine stores by the iodine excess. Type II is the result of destructive thyroiditis caused by the cytotoxic effects of amiodarone and DEA on thyrocytes by interference with lysosomes. Disruption of the normal thyroidal architecture allows the release of colloid contents (very rich in thyroid hormone) into the circulation, causing thyrotoxicosis. The stores of thyroid hormone in the colloid are finite, which explains the often self-limited nature of type II.

Treatment for AIT depends on its severity, which varies from mild to very severe, and on the cardiac condition, which may or may not allow discontinuation of amiodarone. In AIT type I, discontinuation of amiodarone is recommended, but patients are still thyrotoxic 6–9 months thereafter. Combination therapy using thionamides (which are less effective during iodine excess) with potassium perchlorate shortens

Table III Characteristics of Amiodarone-Induced Thyrotoxicosis Types I and II

| | Type I | Type II |
|--------------------------------|--|--|
| Underlying thyroid abnormality | Yes | No |
| Pathogenetic mechanism | Excessive thyroid hormone synthesis due to iodine excess | Excessive thyroid hormone release due to destructive thyroiditis |
| Goiter | Usually diffuse or nodular goiter | Occasionally small diffuse goiter |
| Thyroid radioiodine uptake | Low, normal, or high | Low |
| Serum interleukin-6 | Normal or slightly elevated | Markedly elevated |
| Spontaneous remission | Less likely | More likely |
| Preferred drug treatment | Potassium perchlorate plus thionamides | Glucocorticoids plus thionamides |
| Subsequent hypothyroidism | Unlikely | Possible |

Table IV Hypothyroid-like Effects of Amiodarone in Various Tissues

| Tissue effect | Hypothyroidism | Amiodarone | Amiodarone + T3 |
|--|----------------|------------|-----------------|
| Heart | | | |
| QT interval | ↑ | ↑ | N |
| Heart rate | ↓ | ↓ | N |
| β-adrenoceptor density | ↓ | ↓ | N |
| Ca ²⁺ ATPase activity of myosin | ↓ | ↓ | |
| Liver | | | |
| LDL receptor density | ↓ | ↓ | N |
| Triglyceride lipase activity | ↓ | ↓ | ↓ |
| Adipose tissue | | | |
| Lipoprotein lipase activity | (†) | ↑ | N |

Note. ↑, increase; ↓, decrease; N, return to normal; (†), increase not significant.

the period until euthyroidism to less than 3 months. ¹³¹I therapy is seldom feasible in view of the low radioiodine uptake. Total thyroidectomy has been performed successfully in resistant cases. In AIT type II, spontaneous recovery to euthyroidism is the rule within 3–5 months after stopping amiodarone. Faster improvement is usually obtained with prednisone given for 7–12 weeks in combination with thionamides. Although most authors still favor discontinuation of amiodarone in AIT type II, a favorable outcome under continuation of amiodarone is certainly possible. Despite all efforts, some patients do not respond to multidrug treatment with thionamides, potassium perchlorate, and steroids. There have been reports of fatal cases in which AIT patients have died of thyroid storm.

AMIODARONE AS A THYROID HORMONE RECEPTOR ANTAGONIST

Amiodarone is prescribed for cardiac arrhythmias and angina pectoris, the rationale being induction of bradycardia, lengthening of the cardiac action potential, and depression of myocardial oxygen consumption. Essentially similar phenomena are observed in hypothyroidism. The hypothesis has thus been put forward that one of the main mechanisms of action of amiodarone is via induction of a local hypothyroid-like condition in extrathyroidal tissues, notably the heart (Table IV). The hypothesis is quite attractive, in view of the markedly decreased tissue concentrations of T3 induced by amiodarone. However, other drugs, such as iopanoic acid (equally potent in inhibiting type I 5'-deiodination), do not induce hypothyroid-like effects. In support of the hypothesis is the finding that DEA inhibits the binding of T3 to its nuclear receptors, resulting in a dose-dependent

decrease in the expression of several T3-dependent genes. Interestingly, DEA is a competitive inhibitor of T3 binding to thyroid hormone receptor α_1 (TR α_1) (IC₅₀ value 47 μ M) but a noncompetitive inhibitor of T3 binding to TR β_1 (IC₅₀ value 27 μ M). The intracellular concentrations of DEA reached *in vivo* are high enough (50–500 μ M) for the drug to be able to interfere with T3 binding. Protein-protein binding studies with TR β_1 and the coactivator glucocorticoid receptor-interacting protein showed an inhibitory effect of DEA on the T3-dependent binding of the coactivator to TR β_1 . Further studies have indicated that residues on the outside of the TR ligand-binding domain are involved in the binding of DEA.

The available studies provide good evidence that DEA rather than amiodarone itself is responsible for the hypothyroid-like actions. The drug appears to meet the criteria of a thyroid hormone receptor antagonist.

Glossary

apolipoproteins (apo) Protein components of plasma lipoproteins, such as apoA1 and apoB. ApoB-48 corresponds to the amino-terminal 48% of apoB-100, which is produced in the intestine following RNA editing.

chylomicrons Triglyceride-rich lipoproteins secreted by the intestine after a meal.

hypocholesterolemia (hypocholesterolemic disorders) Syndromes characterized by low levels of plasma cholesterol.

lipoproteins Particles in the plasma composed of lipids (phospholipids, free and esterified cholesterol, and triglycerides) and apoproteins (e.g., apoA1, apoB, and apoC) that are responsible for lipid and lipid-soluble vitamin transport. The major lipoprotein classes are very low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs).

microsomal triglyceride transfer protein (MTP) Protein heterodimer in the endoplasmic reticulum that is necessary for the formation of apo B-containing lipoproteins, such as chylomicrons or VLDLs.

Anderson's disease and chylomicron retention disease are terms used for very similar, if not identical, rare hereditary (most likely autosomal recessive) hypocholesterolemic disorders characterized by a lipid malabsorption syndrome with steatorrhea (chronic diarrhea) and growth retardation.

INTRODUCTION

The term Anderson's disease has been used since 1970 by French medical scientists as the diagnosis for patients having manifestations similar to those of a patient described by the Australian physician

Charlotte Anderson. North American medical scientists used the term chylomicron retention disease to describe a cohort of patients with similar signs and symptoms in whom it appeared that chylomicrons were assembled but not secreted. Both terms have been used subsequently by physicians and scientists in other areas of the world as diagnoses for patients having the clinical and laboratory manifestations described in this article.

The diagnosis is made on the basis of the clinical findings (diarrhea, steatorrhea, and lipid malabsorption), endoscopy (the presence of a "white hoary" layer or *gelée blanche* on the small intestinal mucosa), the intestinal biopsy (vacuolated enterocytes that stain positively with Oil red), the levels of plasma cholesterol (hypocholesterolemia), the presence of apolipoprotein (apo)B-100 and the absence of apoB-48 in the plasma, and the absence of chylomicrons and apoB-48 in the plasma after a fat feeding. The parents of patients are asymptomatic.

CLINICAL DESCRIPTION

Three well-described, inherited hypocholesterolemic states, characterized by lipoprotein deficiency, affect apoB-containing lipoproteins: abetalipoproteinemia, familial hypobetalipoproteinemia, and Anderson's disease or chylomicron retention disease. Abetalipoproteinemia is a rare autosomal recessive disease that manifests in infancy. It is characterized by profound hypocholesterolemia, hypotriglyceridemia, lipid malabsorption, diarrhea, retinitis pigmentosa, acanthocytosis, spinocerebellar degeneration, and the complete absence of apoB-containing lipoproteins. The molecular basis of the disease is a mutation in the gene encoding the large subunit of the microsomal triglyceride transfer protein (MTP), which results in a defect in lipoprotein assembly. Familial hypobetalipoproteinemia is an autosomal codominant

disorder. Two major phenotypes have been described. Individuals who are homozygous for null alleles, in which plasma apoB is absent, are phenotypically similar to individuals who have abetalipoproteinemia. Individuals in whom truncated forms of apoB are found in the plasma, whether homozygous or heterozygous, are generally asymptomatic clinically; however, in both cases, there are decreased plasma and low-density lipoprotein (LDL) cholesterol levels. Mutations in the apoB gene form the molecular basis of the disease.

Anderson's disease is clinically distinguishable from abetalipoproteinemia and null alleles of homozygous hypobetalipoproteinemia by the absence of acanthocytosis, retinitis pigmentosa, and severe neurological symptoms and by the presence of apoB-100-containing lipoproteins. Anderson's disease is distinguishable from heterozygous familial hypobetalipoproteinemia and homozygous familial hypobetalipoproteinemia (with truncated apoB) by the presence of diarrhea, malabsorption, and steatorrhea and an autosomal recessive mode of inheritance.

At least 35 cases of Anderson's disease in 26 families have been described. Sixteen cases (10 different families) are of North African origin (Algeria, Morocco, and Tunisia). Ten cases are from 9 Canadian families. The 9 remaining cases are from six different countries (Spain, Pakistan, Turkey, England, Lebanon, and the United States). Consanguinity has been described in 9 families, no consanguinity is present in 12 families, and no information regarding consanguinity is available for the remaining 5 families.

Individuals with these disorders exhibit a malabsorption syndrome with steatorrhea and growth retardation under a normolipidemic alimentary regime. The mucosal surface of the small intestine, as observed by endoscopy, is covered with a whitish layer ("a white stippling-like hoar frosting" or *gelée blanche*). Bloating of the stomach, osteomalacia, and rickets have been observed in several cases. Hepatic steatosis has been noted in four cases but without evolution to cirrhosis. Neuroretinal manifestations occur later and are less severe than in abetalipoproteinemia. Neurological signs most frequently consist of a loss of deep tendon reflexes. There is occasional alteration of position and vibratory senses, nerve conduction velocities, and evoked auditory and visual potentials. For patients diagnosed as adults, the neurological signs are more severe and may also include areflexia, ataxia, alteration in deep and vibratory senses, myopathy (with lipofuscin deposits on muscle biopsy), and polyneuropathy. Although nystagmus and delayed dark adaptation may occur, there is no visual loss

or retinitis pigmentosa. Acanthocytosis is typically absent.

Institution of a low-fat diet supplemented with lipid-soluble vitamins (A and E) and essential fatty acids results in the resumption of normal growth and abatement of the gastrointestinal symptomatology. Departure from the low-fat diet results in recurrence of symptoms.

PLASMA LIPID AND LIPOPROTEIN AND BIOCHEMICAL ANALYSES

Plasma cholesterol levels are decreased but remain higher than 50 mg/dl. Fasting plasma triglyceride levels are normal. Postprandially, there is no increase in plasma triglycerides, and chylomicrons are not detected. However, the absorption of luminal fatty acids and their consecutive esterification by epithelial cells appear normal. Although apoB-48-containing lipoproteins are absent from the plasma, lipoproteins containing apoB-100 are present but in decreased amounts. The plasma levels of high-density lipoproteins (HDLs) and apoAI, -AIV, -E, and -C are also decreased, and there are low levels of total lipids, phospholipids, carotenoids, and lipid-soluble vitamins (particularly vitamin E) as well as vitamins A, K, and D. Lipoprotein composition is abnormal in that it has decreased amounts of cholesterol and increased amounts of phospholipid and triglyceride. Very low-density lipoproteins (VLDLs) are increased in size, whereas LDLs and HDLs are decreased in size. Analysis of mRNA synthesis in the human intestine has shown the presence of mRNA for apoAI, -AIV, -E, -CII, and -CIII. ApoB messenger RNA appeared to be correctly edited in the intestine in two cases of chylomicron retention disease in one family. Normal MTP protein and activity were detected in intestinal biopsies of several patients.

IMMUNOCHEMICAL ANALYSES

Despite the absence of apoB-48 in the plasma in this disease, this apolipoprotein as well as apoAI, -AIV, -CII, and -CIII have been detected by immunochemical techniques in the enterocytes of patients, along with the lipid components that are normally assembled into triglyceride-rich lipoproteins. Immunoprecipitation with polyclonal antibodies to apoB or apoAIV of the homogenates of organ cultures of intestinal biopsies from patients shows the presence of normal-sized apoB-48 and apoAIV in amounts three- to fivefold more abundant compared to those

found in normal individuals. Analysis of homogenates of organ cultures and of the culture media shows that the patients assemble and secrete some normal-sized apoB-48 and apoAIV, which are coimmunoprecipitated and which float like chylomicrons. No apoB-100 is detected in the biopsy or culture medium.

ULTRASTRUCTURAL ANALYSES BY LIGHT AND ELECTRON MICROSCOPY

Studies of the intestine by light microscopy have shown that villi are present in normal number and length but that the enterocytes are overloaded with fat droplets. The pattern and extent of lipid loading are variable among patients and also among biopsy sections for a given patient. In the regions of the villi that contain lipid-laden enterocytes there are always a few morphologically normal-appearing cells. The cells in the inferior approximately one-third of the villus characteristically show no accumulation of lipids.

When examined by electron microscopy, the enterocytes in some regions of biopsies have an intracellular architecture like that found in normal fasted individuals in whom intra- and intercellular lipoprotein-like particles are not readily apparent and the Golgi apparatus is flat and nondistended. In other regions, the enterocytes contain large amounts of lipid particles. Many of these are chylomicron- and VLDL-sized particles (approximately 300 nm in diameter; range, 169–580 nm) in membrane-bound compartments. When clearly identifiable, the Golgi apparatus is frequently distended and empty, although membrane-bound compartments containing particles are in close juxtaposition. These membrane-bound particles resemble lipoprotein particles seen in normal fed individuals that are situated in a membrane-bound compartment and are seen budding from the lateral aspect or located near the Golgi apparatus. The identity of the membrane-bound compartment that contains the lipoprotein-sized particles is not entirely clear, and the composition of the particles has not been carefully defined.

Other, larger particles (368–2127 nm mean diameter) appear to be lipid droplets that are free in the cytoplasm. These lipid droplets may derive from the breakdown of membrane-bound compartments that contain lipid particles unassembled with protein (putative second step triglyceride-rich particles). Large non-membrane-bound lipid droplets (presumably not assembled with protein) predominate in abetalipoproteinemia, whereas smaller membrane-bound

particles predominate in Anderson's disease. Finally, smaller particles (63 nm mean diameter) are rarely found in the intercellular spaces of affected individuals, suggesting that secretion can occur.

Even after treatment with a low-fat, lipid-soluble, vitamin-supplemented diet for at least 6 months and abatement of gastrointestinal symptoms, biopsies performed in patients after 12–15 h of fasting remained lipid laden with lipoprotein- and lipid-like particles with densities exceeding those found in the fed normal individual.

LINKAGE ANALYSES

Using an autosomal recessive mode of transmission and highly polymorphic microsatellite markers [most frequently the $(CA)_n$ type], segregation analyses of four families, excluded as a cause of the disease significant regions of the genome surrounding the genes for apoAI, -CIII, and -AIV (15 cm on chromosome 11); the apoCII gene, which includes the apoCI and apoE genes (24 cm on chromosome 19); and the genes encoding three proteins involved in intracellular lipid transport—MTP (30 cm on chromosome 4) and fatty acid-binding proteins 1 (20 cm on chromosome 2) and 2 (30 cm on chromosome 4). No evidence of linkage was found for a distance of at least 5 cm on either side of the reported location of the apoB gene (results exclude the apoB gene in 13 cases from seven families with Anderson's disease).

INTRACELLULAR PROCESSING OF APOLIPOPROTEIN B

Two basic types of asparagine-linked glycans (N-glycosylation) are found on apoB-48 present in normal enterocytes. One form contains only high-mannose oligosaccharides and represents the newly glycosylated protein in the endoplasmic reticulum. The other form contains, in addition to high-mannose glycans, complex oligosaccharides that arise by processing of some of the high-mannose glycans in the trans-Golgi apparatus. Five of six potential asparagine glycosylation sites may be used in apoB-48 based on results obtained with apoB-100, and there are probably one high-mannose chain and four complex-type oligosaccharide chains on the same molecule. The mixed glycosylation pattern (high-mannose and complex oligosaccharides on the same molecule) is apparently due to the masking of some of the oligosaccharide chains on apoB-48 to the action of Golgi

glycosyltransferases. The addition and modification of N-linked carbohydrates occur in distinct intracellular compartments. The advancement of a protein along the secretory pathway can thus be assessed by evaluating the differences in the sensitivity of the N-linked oligosaccharides to endoglycosidases. In Anderson's disease, there is a time-dependent transformation of high-mannose endoglycosidase H-sensitive oligosaccharides of endoplasmic reticulum origin to complex endoglycosidase H-resistant oligosaccharides, added in the Golgi network, as in normal individuals. The apoB-48 containing oligosaccharides only partially sensitive to endo H (high-mannose plus complex oligosaccharides) has reached the trans-Golgi and is certainly already assembled with lipids and is probably destined to be secreted. In contrast, in abetalipoproteinemic patients, there is a single intracellular population of apoB-48 containing only high-mannose and hybrid glycans, indicating that apoB-48 does not reach the Golgi apparatus since the complex glycans that are added in the medial and trans-Golgi network are absent.

CONCLUSION

Biochemical and ultrastructural analyses suggest that triglyceride-rich lipoprotein assembly takes place in enterocytes. ApoB-48 oligosaccharide processing indicates that the defect is not located between the endoplasmic reticulum and the Golgi apparatus but rather is distal to the trans-Golgi apparatus. Given that apo-AIV and apo-AI seem to be well secreted in patients, this implies a cargo-specific defect in transport between the trans-Golgi apparatus and the basolateral surface. Two independent genome-wide linkage analyses have shown that a locus on chromosome 5q31.1 segregates with affected status in several families affected with Anderson's Disease, chylomicron retention disease, or chylomicron retention disease with the neuromuscular disorder Marinesco-Sjogren syndrome. In 10 affected individuals, coding sequence variants (including two frameshift, one splice site, and five missense mutations) were identified in both alleles of the SARA2 gene, which is located in the region of apparent homozygosity. The SARA2 gene product (sar1b) belongs to the Sar1-ADP ribosylation factor family of small GTPases which are involved in COP-coated vesicle mediated intracellular transport.

Androgen Biosynthesis and Gene Defects

Mark R. Vanderwel and Richard J. Auchus
University of Texas Southwestern Medical Center, Dallas, Texas, United States

Glossary

cryptorchidism The condition in which the testes fail to descend into the scrotum and are retained within the abdomen or inguinal canal.

follicle-stimulating hormone (FSH) A gonadotropin secreted and released by the anterior pituitary. FSH stimulates the ripening of the follicles in the ovary and formation of sperm in the testes by acting on granulosa and Sertoli cells, respectively.

haploinsufficiency A mutation in only one of the two alleles for an autosomal gene, resulting in a reduced gene dosage for the protein encoded on the normal allele.

human chorionic gonadotropin (hCG) A hormone similar to the pituitary gonadotropin luteinizing hormone; it is produced by the placenta during pregnancy.

hypospadias A congenital abnormality in which the labioscrotal folds have not completely fused, so that the opening of the urethra is on the underside of the penis.

Leydig cells The cells interspersed between the seminiferous tubules of the testis. They secrete androgens in response to luteinizing hormone.

luteinizing hormone (LH) A gonadotropin secreted by the anterior pituitary. LH stimulates androgen synthesis by the Leydig cells of the testis and the theca cells of the ovary; it also stimulates the “luteinization” of ovarian cells after ovulation, forming the corpus luteum, which makes progesterone.

male pseudo-hermaphroditism A congenital abnormality in which the genitalia of a 46,XY infant are not completely masculinized, despite the presence of testes.

Müllerian structures Structures that develop from the paramesonephric duct in normal females. These include the fallopian tubes, uterus, and upper part of the vagina.

Sertoli cells Cells found in the walls of the seminiferous tubules of the testis. They anchor and nourish the developing germ cells.

Wolffian structures Structures that develop from the mesonephric duct in normal males. These include the epididymis and vas deferens.

Formation of the male external genitalia in human beings requires the production of dihydrotestosterone during the critical period of sexual differentiation at 8–12 weeks of gestation. At this time, chorionic gonadotropin (hCG) stimulates responsive Leydig cells to convert cholesterol to testosterone, which is transformed to dihydrotestosterone in target tissues. Mutations in the genes encoding the enzymes, cofactor proteins, receptors, and stimulatory hormones may disrupt this process at various steps, leading to congenital defects in androgen production and male pseudo-hermaphroditism. Defects in gonadotropin-releasing hormone will not interfere with fetal androgen production but will prevent the production of luteinizing hormone (LH) and not allow pubertal progression. This article describes the syndromes caused by mutations in these genes, focusing on the clinical and biochemical features of disorders that impair enzymatic steps in dihydrotestosterone production.

NORMAL ANDROGEN BIOSYNTHESIS

All steroid hormone production begins with the conversion of cholesterol to pregnenolone. A “mobile pool” of free cholesterol in the outer mitochondrial membrane (OMM) is physically inaccessible to the side chain cleavage enzyme (CYP11A, P450_{scc}), which resides in the inner mitochondrial membrane (IMM). Stimulation of Leydig cells with hCG or LH, both of which bind to the same LH/hCG receptor, increases intracellular cyclic AMP (cAMP). The rise in cAMP induces the expression and activation of the labile steroidogenic acute regulatory (StAR) protein, which allows the cholesterol to flow from the OMM to the IMM, where CYP11A converts the cholesterol to pregnenolone. The microsomal enzyme CYP17

(P450c17) sequentially oxygenates pregnenolone (the 17 α -hydroxylase reaction) and cleaves the C17—C20 bond (the 17,20-lyase reaction), yielding dehydroepiandrosterone (DHEA). Although human CYP17 hydroxylates pregnenolone and progesterone with comparable efficiencies, its 17,20-lyase activity is much more efficient for the Δ^5 -steroid 17 α -hydroxypregnenolone (17Preg) than for its Δ^4 -congenitor 17 α -hydroxyprogesterone (17OHP). Consequently, DHEA is the substrate for 17 β -hydroxysteroid dehydrogenase type 3 (17 β -HSD3), which reduces DHEA to Δ^5 -androstenediol, and 3 β -hydroxysteroid dehydrogenase/isomerase type 2 (3 β -HSD2) converts this Δ^5 steroid to testosterone (T). The sequence of these latter two reactions (17 β -HSD3 and 3 β -HSD2) may also proceed in reverse, with androstenedione (AD) as the intermediate. T produced by the testis diffuses into peripheral tissues and those tissues that contain the enzyme 5 α -reductase type 2 (SRD5A2) (i.e., prostate, genital skin) metabolize T to the potent androgen dihydrotestosterone (DHT). The importance of all of these steps and the lack of adequate redundancy are demonstrated by the clinical disorders caused by mutations in the genes encoding the key proteins described herein.

DISORDERS OF LEYDIG CELL STIMULATION

Hypothalamic Hypogonadism

Because fetal T synthesis during weeks 8–12 of gestation is driven primarily by placental hCG, 46,XY children with defects in gonadotropin-releasing hormone (GnRH) or gonadotropin production are born with relatively normal male external genitalia. However, T production in late gestation is driven by LH, so micropenis is often present, and these individuals fail to experience puberty. Mutations in the genes for the orphan nuclear receptors DAX1 and SF1, the homeodomain transcription factors HESX1, LH3, and PROP1, the β -subunits of LH and follicle-stimulating hormone, the GnRH receptor, or the extracellular matrix protein anosmin-1 have been identified in patients with defects in androgen production and/or infertility due to abnormalities in hypothalamus and/or pituitary development. Most of these disorders are extremely rare and variable in their manifestations, but the more common syndromes whose genetic basis has been at least partially defined are discussed below.

Kallman's Syndrome and Variants

Kallman's syndrome refers to the combination of hypogonadotropic hypogonadism and anosmia. Consequently, 46,XY patients are born with normal male genitalia except for micropenis, and they fail to initiate puberty. The diagnosis is made when LH does not rise in response to a bolus of GnRH or GnRH analogue. Magnetic resonance imaging (MRI) with attention to the olfactory bulbs and midline structures is helpful but not essential, and olfactory testing should be performed. At the time of expected puberty, sex steroid replacement appropriate for gender is commenced. Treatment with pulsatile GnRH using a programmable pump will not only induce sexual maturation but may restore fertility in individuals of both sexes.

Kallman's syndrome can be sporadic, autosomal dominant or recessive, or X-linked. The best understood form of Kallman's syndrome is the X-linked variety, which accounts for nearly half of cases and most often results from mutations in the *KAL* gene. This gene encodes an extracellular matrix protein called anosmin-1 that guides the migration of both the olfactory and GnRH-producing neurons from the olfactory placode to their proper location in the head and brain. Forms of hypothalamic hypogonadism without anosmia may result from mutations in the gene for the GnRH receptor, but these conditions are rare. In approximately half the cases of Kallman's syndrome and its variants, the molecular basis is unknown.

Septo-optic Dysplasia

Developmental defects in midline structures often ablate hypothalamic–pituitary axes, and the growth hormone and GnRH–LH axes are particularly vulnerable. Severe defects, such as holoprosencephaly, characteristically involve large portions of the brain, but milder developmental defects can involve few structures. Septo-optic dysplasia refers to the combination of optic nerve hypoplasia and hypothalamic–pituitary maldevelopment. Evaluation and management are similar to those for Kallman's syndrome, although vision testing and MRI evaluation are important for guiding follow-up and for prognosis. Mutations in the homeobox gene *HESX1* have been identified in patients with septo-optic dysplasia, and the clinical severity roughly correlates with the impairment in DNA binding by the mutant protein.

Leydig Cell Agenesis or Hypoplasia (Testicular Unresponsiveness to hCG/LH)

When a 46,XY fetus has a mutation in the LH/hCG receptor, Leydig cells fail to develop appropriately,

and T production is impaired from conception. This defect leads to varying degrees of genital anomalies at birth, depending on the amount of hCG-independent T production prior to the 10th week of gestation and the severity of the hCG/LH receptor dysfunction. Because secretion of anti-Müllerian hormone by the Sertoli cells is intact, 46,XY children with Leydig cell hypoplasia do not retain Müllerian structures. The testes lack distinct Leydig cells on biopsy, and Sertoli cells may appear at puberty. However, the seminiferous tubules, if present, often show spermatogenic arrest, and the testes degenerate progressively.

The 46,XY infants born with completely female genitalia may not be identified until puberty, when they present with failure to develop breasts and to undergo menarche. Milder forms in 46,XY infants cause undervirilization, including hypospadias, micropenis, and cryptorchidism. 46,XX females homozygous for LH receptor defects will have normal female genitalia and may experience some breast development at puberty, but with amenorrhea and infertility. The diagnosis is confirmed by low or absent T, AD, and 17OHP production in response to hCG stimulation testing. Basal and GnRH-stimulated gonadotropin values are elevated in pubertal subjects.

Management depends on the age of diagnosis and the degree of virilization. When the defects are severe enough to produce phenotypically female genitalia, assignment of the female gender, with gonadectomy and estrogen replacement therapy at the time of expected puberty, is usually recommended. For less severely affected individuals with undervirilized male genitalia, surgery may be necessary to correct hypospadias, and testosterone therapy is used to stimulate phallic development and to virilize the patient at puberty.

Leydig cell hypoplasia is an autosomal recessive condition due to mutations in the hCG/LH receptor. Several genetic defects have been reported, including missense, nonsense, and null mutations. The null mutations, such as Arg554Stop, are associated with the most severe clinical phenotypes.

VARIANTS OF CONGENITAL ADRENAL HYPERPLASIA

The most common form of congenital adrenal hyperplasia (CAH) is 21-hydroxylase (CYP21, P450c21) deficiency, but CYP21 is not expressed in the gonads and does not participate in T biosynthesis. Other, less common forms of CAH that involve enzymes or proteins expressed both in the adrenals and the gonads are discussed below.

Lipoid CAH

StAR Deficiency

Because StAR facilitates the transport of cholesterol from the OMM to the IMM, inactivating mutations in StAR block the production of pregnenolone and thus impair all steroidogenesis, both in the adrenals and in the gonads. Under the stimulation of adrenocorticotrophic hormone (ACTH) and LH, cholesterol esters massively accumulate in the adrenal glands and testes, respectively, affording the characteristic enlarged, lipid-laden adrenals from which the name lipoid CAH derives. Secondarily, sterol auto-oxidation products accumulate in the adrenals and Leydig cells, altering cell structure and ultimately provoking cell destruction.

Both 46,XY and 46,XX individuals will have female external genitalia at birth. Affected 46,XY individuals have abdominal, inguinal, or intralabial testes, a blind vaginal pouch, and no uterus or fallopian tubes. Wolffian duct remnants may be preserved in 46,XY individuals secondary to low levels of StAR-independent steroidogenesis. All reported patients are diffusely hyperpigmented from pro-opiomelanocortin excess. Because the theca cells of the ovary do not normally make steroids during fetal and neonatal life, the ovaries of 46,XX subjects do not suffer lipid accumulation and cell death during childhood. Consequently, 46,XX subjects may produce enough estrogens in early puberty to undergo some breast development and may even menstruate until lipid accumulation and auto-oxidation obliterate ovarian function as well.

The diagnosis of lipoid CAH is confirmed by low or absent glucocorticoids, mineralocorticoids, gonadal steroids, their precursors, and their metabolites in plasma and/or urine, even after stimulation. In particular, 3β -HSD2 deficiency is excluded by documenting low concentrations of not only the active Δ^4 steroids but of the Δ^5 precursors pregnenolone and 17Preg. On abdominal computed tomography scan or MRI, the lipid-laden adrenals are strikingly enlarged, displacing the kidneys caudad.

Treatment requires replacement doses of glucocorticoids and mineralocorticoids in the newborn period, which must be continued throughout life. All affected 46,XY males have been reared as females, and orchidectomy is advised. Estrogen replacement therapy for individuals of both genotypes is required at puberty to initiate female secondary sexual characteristics, and low-dose testosterone may be used to elicit a female pattern of sexual hair growth. Lipoid CAH is an autosomal recessive disease with a male/female ratio of approximately 3/1; however, this ratio may be skewed

by ascertainment bias. This condition is rare in the United States and Europe, but is the second most common form of CAH in Japan and Korea. In one series, mutation Gln258Stop accounted for 80% of the affected alleles from Japanese and Korean subjects, suggesting a founder effect that causes the relatively high incidence of lipoid CAH in these countries. Mutation Arg182Leu was found in 78% of affected alleles from Palestinian subjects in the same series.

Side Chain Cleavage Enzyme (CYP11A or P450scc) Deficiency

For many years, it was hypothesized that homozygous CYP11A deficiency caused lipoid CAH, but an absence of CYP11A would preclude placental progesterone synthesis and promote spontaneous abortion after the 8th to 10th week. However, haploinsufficiency of CYP11A has been shown to produce a milder clinical picture of lipoid CAH than in StAR deficiency. Tajima and associates described a 46,XY patient with clitoromegaly, a blind vaginal pouch, hyperpigmentation, and absent Müllerian structures. This patient was raised as a female, and testes were removed from the inguinal region. Adrenal insufficiency with hyperplasia did not occur until the child was 4 years old, and no mutation was found in the gene for StAR. Instead, one allele of the gene for CYP11A had a 6 bp in-frame insertion, adding Gly-Asp between Asp-271 and Val-272. This mutant enzyme had no activity and appeared to impair the function of wild-type CYP11A when expressed in the same cells, suggesting a partial, dominant-negative mode of action, leading to less severe disease in early childhood rather than infancy.

Treatment is similar to that for StAR protein deficiency, with gluco- and mineralocorticoid replacement to prevent life-threatening adrenal insufficiency at the time of diagnosis, plus estrogen replacement therapy at the time of puberty.

3 β -HSD2 Deficiency

The 3 β -HSD enzymes catalyze the conversion of the Δ^5 steroids pregnenolone, 17Preg, DHEA, and Δ^5 -androstenediol to their corresponding Δ^4 steroids progesterone, 17OHP, AD, and T, respectively. One of these conversions is required in the biosynthesis of all active steroid hormones, so severe 3 β -HSD deficiency will also result in a form of CAH with impaired androgen production.

46,XY individuals with 3 β -HSD deficiency most frequently exhibit male pseudo-hermaphroditism with a small phallus, hypospadias, partial labioscrotal fusion, and possibly a urogenital sinus with a blind vaginal pouch. Testes usually lie in the lower inguinal region, and Müllerian structures are absent. Paradoxically, 46, XX individuals often have trace clitoral enlargement and progressive masculinization if undertreated. Severe 3 β -HSD deficiency can present with salt-wasting crisis from glucocorticoid and mineralocorticoid insufficiency within the first week of life. Less severe forms of 3 β -HSD deficiency are usually diagnosed in genetic males because of genital abnormalities, but may be difficult to diagnose in females. Androgen production increases at puberty in both sexes but at a rate that is intermediate for males and females; consequently, girls show signs of androgen excess, but boys often develop gynecomastia. Fertility has been reported in affected individuals of both sexes.

The diagnosis of 3 β -HSD deficiency hinges on elevated ratios of Δ^5 steroids to their Δ^4 congeners. These ratios, which are already increased at baseline, are accentuated by cosyntropin stimulation and should reach >12 SD above normal. Adult females with hirsutism often have high circulating DHEA-S concentrations with high ratios of Δ^5 to Δ^4 steroids, so extremely elevated ratios are required to confidently diagnose 3 β -HSD deficiency.

Therapy includes early gluco- and mineralocorticoid replacement in salt-wasting individuals to prevent life-threatening adrenal insufficiency, and similar replacement is used in non-salt-wasting individuals to limit sexual precocity caused by increased synthesis of adrenal DHEA-S. Females require estrogen replacement, and males require testosterone supplementation to achieve full development of secondary sexual characteristics.

Two functional 3 β -HSD genes are encoded on chromosome 1p13. The type 2 enzyme is the dominant isoform expressed in the adrenals and gonads, and its gene is mutated in 3 β -HSD deficiency. Adult females who present with hirsutism, infertility, and relatively high DHEA-S concentrations do not have mutations in the 3 β -HSD genes. The type 1 enzyme is expressed in the placenta but also in liver and skin, and this enzyme accounts for the peripheral conversion of Δ^5 precursors to Δ^4 steroids in 3 β -HSD deficiency, leading to the paradoxical androgen excess in females. Mutations in the gene for the type 1 enzyme have not been reported and are probably lethal because, as with homozygous CYP11A deficiency, this disorder would compromise progesterone synthesis

by the placenta. Mutations in the type 2 gene have been found from residues Ala-10 to Gly-294, with no mutations dominating large series. Salt-wasting subjects have completely inactive alleles, and non-salt-wasting individuals can harbor mutations that retain partial activity when expressed in heterologous systems.

CYP17 (P450c17) Deficiencies

CYP17 catalyzes both the 17 α -hydroxylase and 17,20-lyase reactions. Severe mutations will ablate both activities, but milder mutations may either partially impair both activities or preferentially impair 17,20-lyase activity with 17 α -hydroxylase activity remaining relatively normal. Furthermore, the 17,20-lyase activity is particularly dependent on the interaction of CYP17 with its redox partners, cytochrome P450 oxidoreductase (CPR) and cytochrome b₅. In particular, the presence of cytochrome b₅ increases the 17,20-lyase activity 10-fold but minimally influences 17 α -hydroxylase activity. Thus, alterations in redox partners and/or their interactions with CYP17 may preferentially impair 17,20-lyase activity.

Combined 17 α -Hydroxylase/17,20-Lyase Deficiency

The classical description of severe, combined, 17 α -hydroxylase/17,20-lyase deficiency is sexual infantilism and hypokalemic hypertension in both genetic sexes. The presentation in 46,XY individuals varies from completely female external genitalia with a blind vaginal pouch to an undervirilized male genital phenotype with hypospadias and a small phallus. Testes in these subjects may be intra-abdominal, in the inguinal canal, or in labioscrotal folds. Müllerian structures are absent, and Wolffian derivatives are usually hypoplastic. Severely affected patients will fail to develop secondary sexual characteristics, including pubic and axillary hair. With milder disease, males may develop gynecomastia at puberty and females may progress to Tanner stage 5 with ovulatory menses. Based on studies with recombinant enzyme, it has been estimated that at least 25% of normal fetal CYP17 activities are required for masculinization of the external genitalia. Hypertension with hypokalemia occurs in childhood and is often severe, with myopathy and hypertensive complications at a young age.

The diagnosis should be entertained not only in male pseudo-hermaphrodites, but also in any individual with hyporeninemic hypertension, hypokalemic alkalosis, and a suppressed aldosterone. This diagnosis may be confirmed by obtaining elevated serum levels

of ACTH and the precursors that accumulate proximal to the block in 17-hydroxylation: progesterone, 11-deoxycorticosterone (DOC), corticosterone (B), 18-hydroxy-DOC, and 18-hydroxy-B. Both DOC and B have mineralocorticoid activity, leading to hypertension and hypokalemia. However, signs of adrenal insufficiency rarely develop, because the weak glucocorticoid B is present in abundance. Gonadotropins are elevated at puberty, and serum concentrations of aldosterone, 17OHP, cortisol, and sex steroids are low or absent.

Treatment includes replacement of glucocorticoids to suppress DOC and B secretion and thereby to normalize potassium homeostasis and blood pressure. Mineralocorticoid receptor antagonists, such as spironolactone, can be added to reduce the doses of glucocorticoids and to prevent iatrogenic Cushing syndrome. At puberty, sex steroid replacement is indicated, and gonadectomy should be performed in 46,XY patients assigned a female sex of rearing.

Mutations in CYP17 have been identified throughout the protein, and some missense mutations retain partial activity when expressed in heterologous systems. Most mutations that yield a completely inactive enzyme also destabilize the enzyme structure and ablate heme binding. A deletion of Phe-53 has been found in several Japanese subjects, and a CATC duplication following Ile-479 has been described in both Dutch Frieslanders and Canadian Mennonites. Recent reports suggest that 17-hydroxylase deficiency is most common in Brazil, where mutations W406R and R362C dominate.

Isolated 17,20-Lyase Deficiency

When only the 17,20-lyase activity is deficient, as has been suggested in 18 case reports, adrenal gluco- and mineralocorticoid synthesis is normal, but testosterone synthesis is impaired. Therefore, serum potassium and blood pressure are normal, but sexual development may be hampered. In 46,XY patients, the external genitalia are that of an undervirilized male, due to some residual 17,20-lyase activity. Müllerian structures are absent, Wolffian derivatives are either hypoplastic or normal, and testes may be intra-abdominal, inguinal, or in the scrotum. In 46,XX females, this condition is believed to lessen adrenarchal and pubertal development, but no confirmed cases have been studied in detail.

Cosyntropin stimulation tests yields normal or elevated 17-hydroxysteroid values, including cortisol and 17OHP, but DHEA and AD do not rise proportionately. Similarly, hCG stimulation testing will produce an increase in 17OHP concentrations, but AD and

T do not rise normally. The ratio of the rise in the C₁₉ steroids to their C₂₁, 17-hydroxy precursors is the most discriminatory parameter for diagnosing isolated 17,20-lyase deficiency.

Only six cases of isolated 17,20-lyase activity have been confirmed with molecular genetic and biochemical studies. These subjects were all 46,XY individuals homozygous for mutations Arg358Gln (one) or Arg347His (three) or heterozygous for a completely inactive allele and one copy of Arg347Cys (two). These residues, Arg-347 and Arg-358, are both located on the redox-partner-binding surface of the CYP17 enzyme. Consistent with the known dependence of the 17,20-lyase activity on the interaction of CYP17 with redox partners CPR and cytochrome b₅, these mutations at this binding surface appear to preferentially impair 17,20-lyase activity.

Gonadectomy is recommended in 46,XY subjects raised as females and gender-appropriate sex steroid replacement will be necessary at the time of puberty. Optimal management in 46,XX subjects has not been established.

DEFECTS AFFECTING ONLY TESTOSTERONE AND DIHYDROTTESTOSTERONE PRODUCTION

The final two genetic disorders discussed involve the terminal steps of T and DHT biosynthesis. These two conditions are unique in that only males (46,XY) experience clinical manifestations that are solely due to androgen deficiency *in utero*. Furthermore, other enzymes partially compensate for the genetic deficiencies, but only at puberty.

17 β -Hydroxysteroid Dehydrogenase Type 3 (17 β -HSD3) Deficiency

The human genome contains several 17 β -HSD isoforms, but 17 β -HSD3 is the enzyme that is defective in the clinical entity "17 β -HSD deficiency," also known as "17-ketosteroid reductase deficiency." The 17 β -HSD3 enzyme catalyzes the conversion of C₁₉, 17-ketosteroids to 17 β -hydroxysteroids using NADPH as cofactor: AD to T, DHEA to Δ^5 -androstenediol, 5 α -androstenedione to DHT, and 5 α -androsterone to 5 α -androstenediol. Because 17 β -HSD3 is expressed exclusively in the testes, the loss of this enzyme impairs androgen biosynthesis only in males.

Most affected 46,XY individuals with 17 β -HSD3 deficiency have predominantly female external

genitalia with a blind vaginal pouch. Surprisingly, Wolffian derivatives, such as the epididymis, vas deferens, seminal vesicles, and ejaculatory duct, are present, suggesting that an alternate pathway in these tissues enables some testosterone production, perhaps mediated by the 17 β -HSD type 5 isoform. Testes are usually located in the inguinal canal, and Müllerian structures are absent.

Most of these children are raised as females. At puberty, testicular AD production increases and significant extraglandular conversion of this AD to T elicits marked physical changes. The phallus enlarges and can reach lengths of 4 to 8 cm; the voice may deepen, male body hair develops, and muscle mass increases. Several affected individuals have changed gender role from female to male in adolescence because of the prominent physical and psychological masculinization they experience. In contrast, 17 β -HSD3 is not expressed in the human ovary, so 46,XX patients with this disorder are asymptomatic.

The diagnosis is based on markedly elevated AD concentrations in the face of low T in the neonatal period or in adolescence. The discrepancy in the AD/T ratio is accentuated with hCG stimulation. In the past, affected 46,XY males were frequently raised as females and underwent castration followed by estrogen substitution therapy at puberty, but infants with adequate phallic structures and mild hypospadias may be reared as males and undergo genitoplasty. This approach anticipates the tendency for gender reversal associated with virilization at puberty. However, even within members of a kindred with identical genotypes, affected individuals vary in their decisions about gender reversal at puberty when reared initially as females. If the patient is reared as a male, T replacement at puberty is necessary to achieve full masculinization and to prevent the development of gynecomastia. Spermatogenesis is absent because intratesticular T synthesis is blocked, and postpubertal elevations in gonadotropins may increase the risk for testicular neoplasms.

Most mutations in the gene for 17 β -HSD are located on exon 9 and impair all enzyme functions. One common mutation, identified in both Brazilian and Palestinian subjects, is R80Q, which lies in the Rossman fold area and primarily disrupts the binding of cofactor, but not of steroid.

5 α -Reductase Type 2 (SRD5A2) Deficiency

The disorder 5 α -reductase deficiency (also known as pseudo-vaginal perineoscrotal hypospadias)

Table I Clinical Manifestations in 46,XY Individuals

| | Leydig cell hypoplasia | Lipoid CAH | 3 β -HSD2 deficiency | 17-OHase deficiency | Isolated 17,20-lyase deficiency | 17 β -HSD3 deficiency | 5 α -Reductase 2 deficiency |
|----------------------------------|--------------------------------------|-----------------------------------|--|---|---|-----------------------------|--------------------------------------|
| Possible appearance of genitalia | Female/ambiguous/hypoplastic male | Female | Ambiguous/hypospadiac male | Female/ambiguous/hypospadiac male | Female/hypoplastic male \pm hypospadias | Female/ambiguous | Ambiguous hypospadias, small phallus |
| Wolffian duct derivatives | Absent/hypoplastic | Absent/hypoplastic | Normal | Absent/hypoplastic | Hypoplastic/normal | Hypoplastic | Normal |
| Müllerian duct derivatives | Absent | Absent | Absent | Absent | Absent | Absent | Absent |
| Gonads in 46,XY | Testes, no Leydig cells ^a | Testes lipid laden | Testes | Testes | Testes | Testes | Normal testes |
| Adrenal insufficiency? | No | Severe | Severe–mild | No | No | No | No |
| Virilization at puberty? | None to poor | None | Poor to mild | None to poor | Poor | Yes | Yes |
| Increased hormone concentrations | LH, FSH | LH, FSH, renin | LH, FSH, pregnenolone, 17Preg, DHEA | LH, FSH, DOC, B, Progesterone | LH, FSH | LH, FSH, Estrone, AD | T |
| Decreased hormone concentrations | T, DHT | All adrenal & gonadal steroids | Progesterone, 17OHP, AD, T, DHT | Renin, cortisol, 17OHP, DHEA, AD, T, DHT | DHEA, AD, T, DHT | T, DHT | DHT |
| Chromosomal location | 2p21 | StAR: 8p11.2 CYP11A: 15q23–q24 | 1p13 | 10q24.3 | 10q24.3 | 9q22 | 2p23 |

^aSmall undescended testes with absent or decreased numbers of Leydig cells to descended testes of normal size with decreased numbers of Leydig cells.

provides strong genetic evidence that DHT is required for complete formation of the male genitalia in human beings. The 5α -reductases catalyze the conversion of T to its 5α -reduced metabolite DHT, and the type 2 isoform executes this transformation in the prostate and genital skin. Consequently, 46,XY male infants with a deficiency in the type 2 enzyme are born with hypospadias and a phallic structure that resembles an enlarged clitoris, often bound in chordee. The urogenital sinus with a blind vaginal pouch opens on the perineum, and the scrotum is bifid, with testes located in the inguinal canal or labioscrotal folds. With the abundance of T, Wolffian structures are well differentiated, and Müllerian structures are absent. The ejaculatory ducts terminate in the blind vaginal pouch or onto the perineum next to the urethra, and the prostate is hypoplastic.

As is the case in 17β -HSD3 deficiency, masculinizing changes occur at puberty as circulating T concentrations rise into the normal adult male range. The voice deepens, muscle mass increases, the phallus grows to 4 to 8 cm, and the subject may experience erections. The testes enlarge, the scrotal structure becomes rugated and pigmented, and spermatogenesis may occur, but is often impaired from cryptorchidism. Facial hair and body hair are sparse and acne and temporal hair recession do not occur, presumably because DHT production is low. As in 46,XY infants with 17β -HSD3 deficiency, most 46,XY individuals with 5α -reductase deficiency are reared as females but reverse gender role with the masculinizing changes of puberty, and in some cultures where the disorder is endemic, this process has achieved a socially acceptable status. However, unlike 17β -HSD3 deficiency, gynecomastia does not develop. The 46,XX females with 5α -reductase deficiency are phenotypically normal at birth, but at puberty they have decreased body and sexual hair and delayed menarche yet normal fertility.

Diagnostic testing includes measurement of serum T and DHT, and a T/DHT ratio >30 confirms the diagnosis. One pitfall of testing is that after puberty, the activity of the type 1 isozyme may provide measurable levels of DHT, emphasizing the importance of the T/DHT ratio.

Treatment of 5α -reductase deficiency is DHT therapy, often applied as a cream to the genitalia, to increase phallic length and to facilitate hypospadias repair. Supraphysiologic dosing of T in adults may generate adequate DHT via a partially functional type 2 enzyme and via the type 1 isoform.

Approximately 40% of children with 5α -reductase deficiency are born to consanguineous parents; uniparental disomy has also been described. The founder mutation Arg246Trp is prevalent in the Dominican Republic, where the disease is common, but other mutations are found in other kindreds there. A 20 kb deletion that includes the *SRD5A2* gene is prevalent in Papua New Guinea, and an A insertion into amino acid 251 causes 5α -reductase deficiency in a Turkish cluster. Several mutations are found in Brazil, and Gln126Arg is the most common. The type 1 isozyme is expressed in the liver up to 2 to 3 years of age and in nongenital skin. Mutations in the type 1 isozyme have not been described.

Table I compares clinical manifestations in 46,XY children born with these disorders. Hypothalamic hypogonadism is not included, because boys with this disorder generally have normal genitalia, except for micropenis.

Androgen Biosynthesis Inhibitors and Androgen Receptor Antagonists

Stephen E. Borst, David T. Lowenthal, and George Zavros
University of Florida and Malcom Randall VA Medical Center, Gainesville, Florida, United States

Glossary

androgenetic alopecia Male-pattern baldness, requiring both a genetic predisposition and sufficient action of dihydrotestosterone.

clinical flare Temporary, but serious, side effects resulting from administration of gonadotropin-releasing hormone agonists. Includes bone pain, nerve compression, and blockage of the ureters.

gynecomastia Excessive development of male mammary glands.

hirsutism The presence of excessive facial and body hair, especially in women.

paraphilias Sexual practices that are socially prohibited.

The androgens testosterone and dihydrotestosterone (DHT) play a central role in a number of disease states, including the progression of prostate cancer, benign prostatic hyperplasia, male pattern baldness, hirsutism, acne, and virilizing syndromes in women. In adults, most of the undesirable effects of androgens are mediated specifically by DHT. This article discusses the use of drugs that produce anti-androgenic effects by the following mechanisms of action: (1) androgen receptor antagonism, (2) inhibition of the conversion of testosterone to DHT, and (3) inhibition of testosterone synthesis.

ANDROGEN RECEPTOR ANTAGONISTS

The androgen receptor, the gene of which is located near the centromere on the long arm of the X chromosome, was first described in 1969 and was cloned in 1988. It is present in highest concentrations in androgen target tissues such as the accessory organs of male reproduction. Tissues such as skeletal muscle, heart, and placenta have smaller amounts of androgen

receptor. Both testosterone and DHT bind to the androgen receptor in the cell, leading to the transcription of certain genes. The receptor's affinity is four times greater for DHT than for testosterone.

Flutamide

Flutamide is a nonsteroidal androgen receptor antagonist used in the management of metastatic prostate cancer and in the treatment of hirsutism in women. It is a pure androgen antagonist and produces no androgenic or other steroidal effects. It is metabolized in the liver to hydroxyflutamide, which is the active anti-androgen (see Fig. 1). It has a relatively short half-life of approximately 5.2 h. Side effects of flutamide treatment are gynecomastia, abnormal liver function, diarrhea, and gastrointestinal complaints. It is contraindicated in patients with severe hepatic impairment.

Nilutamide

Nilutamide is structurally related to flutamide and binds to the androgen receptor with an affinity similar to that of hydroxyflutamide. It is used in combination with surgical castration for the treatment of metastatic prostate cancer. Nilutamide has a longer half-life than flutamide, approximately 40 h, allowing once a day oral administration. The major side effects of nilutamide are diarrhea, impaired adaptation to darkness, alcohol intolerance, and the occasional serious side effect of acute interstitial pneumonitis. It is contraindicated in patients with severe respiratory insufficiency or severe hepatic impairment.

Casodex

Casodex is another nonsteroidal androgen receptor inhibitor used in the management of prostate cancer. Casodex is indicated for use in combination therapy

Figure 1 Chemical structure of flutamide and its hydroxylated active form.

with a luteinizing hormone-releasing hormone analogue for the treatment of stage D2 metastatic carcinoma of the prostate. It is generally well tolerated and the most common side effects include gynecomastia and breast pain. It should be used with caution in patients with moderate to severe hepatic impairment as hepatotoxicity has been reported during the first 3 to 4 months of treatment.

Cimetidine

Cimetidine was the first histamine-2 blocker introduced for general clinical use in the treatment of duodenal ulcers and other gastric hypersecretory conditions. It exerts anti-androgenic properties by binding to the androgen receptor, causing loss of libido, impotence, and gynecomastia. It has been used as an orphan drug for the treatment of androgenetic alopecia, hirsutism, and warts.

Cyproterone

Cyproterone acetate, a potent androgen antagonist, has been used for the treatment of acne, male pattern baldness, and hirsutism in men and for virilizing syndromes in women as well as in the treatment of the paraphilias (see Fig. 2). Its usefulness is limited by the fact that it can cross the placenta and cause male pseudo-hermaphroditism in male embryos and it has been associated with severe liver damage. It is the most widely used anti-androgen internationally. It has orphan drug status in the United States.

Figure 2 Chemical structure of cyproterone acetate.

Figure 3 Chemical structure of spironolactone.

Spironolactone

Spironolactone is a steroidal androgen receptor blocker that has been shown to be beneficial in the management of acne, hirsutism, and androgenetic alopecia (see Fig. 3). Spironolactone is a weak anti-androgen in blocking the androgen receptor but it also acts by inhibiting androgen biosynthesis. It is best known as an aldosterone receptor antagonist, it has been used traditionally as a potassium-sparing diuretic, and hyperkalemia is one of its side effects. Other side effects include menstrual irregularities, breast tenderness, fatigue, and headache.

Organophosphates

Organophosphate insecticides are widely used in agricultural and residential settings. The organophosphate insecticide fenestration has structural similarity to flutamide, a known anti-androgen, and has been identified as an androgen receptor antagonist.

ANDROGEN BIOSYNTHESIS INHIBITORS

Androgen Biosynthesis

Gonadotropin-releasing hormone (GnRH) is released from the hypothalamus in a pulsatile (on-off) manner, stimulating the anterior pituitary to produce luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH stimulates the Leydig cells of the testes to secrete testosterone. FSH stimulates the Sertoli cells of the testes, increasing spermatogenesis. Testosterone is the major circulating androgen and is converted to DHT in tissues expressing the 5α -reductase enzyme. Muscle and bone express very low levels of 5α -reductase and the anabolic actions of testosterone in these tissues are the direct result of binding of testosterone to androgen receptors. The prostate highly expresses 5α -reductase and the effects of testosterone in promoting prostate enlargement and

cancer are both mediated by DHT. Testosterone and DHT bind to the same androgen receptors, but DHT has greater potency. In addition, binding of DHT dimerizes the androgen receptor, causing additional effects. The following tissues express 5 α -reductase and exhibit androgenic effects that are dependent on DHT: hair follicles (chest, scalp, and beard), liver, kidney, adrenals, seminal vesicles, prostate, testes, foreskin, and scrotum. Virilization of the external genitalia is dependent on the conversion of testosterone to DHT and a deficiency in 5 α -reductase results in an incomplete form of male pseudohermaphroditism. However, in adults the effects of DHT are generally considered to be undesirable. The latter include increased body hair, acne, male-pattern baldness, and prostate enlargement. In contrast, the direct effects of testosterone are generally considered to be desirable. The latter include increased muscle and bone mass, deepening of the voice, increased libido and sense of well-being, spermatogenesis, penile and scrotal enlargement, and increased hematocrit (desirable in the absence of polycythemia). Blocking the effects of DHT, while preserving the direct effects of testosterone, presents an attractive therapeutic target.

Finasteride

Finasteride is a selective inhibitor of 5 α -reductase type 1 (see Fig. 4). Finasteride is effective for treating male-pattern baldness and is marketed for this

purpose as Propecia (1 mg/day). Finasteride is also effective for the treatment of benign prostatic hyperplasia (BPH) and is marketed for this purpose as Proscar (5 mg/day). Finasteride causes an approximate 20% reduction in prostate size and brings symptomatic relief of BPH within several months. In contrast, α -adrenergic receptor antagonists bring more rapid relief by decreasing urinary hesitation and spasm in the bladder neck. However, α -antagonists are less effective on a long-term basis, because they do not reduce or prevent an increase in the size of the prostate. Finasteride is less effective than other treatments for treating prostate cancer and is not indicated for this purpose. The ineffectiveness of finasteride in prostate cancer may be due to incomplete suppression of DHT or to elevation of testosterone within the prostate. Whereas 5 α -reductase type 1 predominates in the prostate, 5 α -reductase type 2 is also present and finasteride is a weak inhibitor of the latter enzyme. Finasteride reduces prostate tissue levels of DHT by approximately 70%, but the remaining DHT may be sufficient to produce a permissive effect in prostate cancer. Several compounds that are dual inhibitors of both type 1 and type 2 5 α -reductase are under evaluation. These compounds cause a near-total suppression of prostate DHT levels. Whether they have greater efficacy than finasteride in treating BPH and prostate cancer remains to be determined. By blocking the conversion of testosterone to DHT, finasteride causes an increase in prostate testosterone levels. Although testosterone promotes

Figure 4 Finasteride inhibits 5 α -reductase and thus blocks the conversion of testosterone to DHT.

prostate cancer to a much lesser degree than does DHT, 5 α -reductase inhibitors may elevate prostate testosterone levels sufficiently to promote or to maintain a permissive effect on prostate cancer.

GnRH Agonists

GnRH is a decapeptide secreted by the hypothalamus in a pulsatile manner, causing the anterior pituitary to release LH and FSH. Endogenous GnRH has a short half-life. Analogues with a D-amino acid substituted at the 6 position and with ethylamide substituted at the 10 position are GnRH agonists with greater potency and longer duration of action than endogenous GnRH (see Fig. 5). Leuprolide (Leupron) and goserelin (Zoladex) are GnRH agonists that have been used successfully to treat prostate cancer. Leupron is formulated in microspheres and Zoladex is formulated in a polymer matrix. In both cases, the slow release of the drug from an intramuscular injection site suppresses androgens for several months. GnRH agonists continuously stimulate pituitary GnRH receptors, as opposed to endogenous GnRH, which stimulates them intermittently. Continuous stimulation of GnRH receptors produces a transient "clinical flare reaction," which is caused by a surge of androgen production and which lasts 5 to 12 days. Clinical flare occurs in approximately 10% of patients with prostate cancer who are treated with GnRH agonists. The condition is dangerous and is associated with bone pain, nerve compression, and blockage of the ureters. These symptoms may be controlled with androgen receptor antagonists, such as flutamide. However, androgen antagonists also produce serious side effects. Eventually, continuous stimulation causes GnRH receptors to be down-regulated, resulting in a marked and long-lasting inhibition of LH and FSH secretion

and producing a hypogonadal state in both men and women. The GnRH agonist nafarelin (Synarel) is administered as a nasal spray for the treatment of endometriosis. Suppression of ovarian steroidogenesis and clinical effectiveness are similar to those of danazol.

GnRH Antagonists

In an effort to avoid the transient androgen surge associated with GnRH agonists, a number of GnRH antagonists have been developed. Abarelix is the first to reach clinical trials. One study has shown that abarelix causes a near-complete suppression of serum testosterone, without a transient increase. Evaluation of the effectiveness of abarelix in treating prostate cancer is under way.

Androgen Insensitivity Syndrome

Yuan-Shan Zhu and Julianne Imperato-McGinley
Weill Medical College of Cornell University, New York, New York, United States

Glossary

androgen receptor An intracellular protein that specifically binds to androgens and mediates androgen action.

coregulator A protein that interacts with nuclear receptors to enhance (coactivators) or reduce transactivation (corepressors) of target genes but does not significantly affect the basal transcription rate.

dihydrotestosterone A derivative of testosterone formed by the conversion of testosterone in the action of 5 α -reductase isozymes.

testosterone A male hormone that is produced by the testes and induces and maintains male secondary sexual characteristics.

Androgen receptor (AR), a member of the nuclear receptor superfamily and a ligand-dependent nuclear transcription factor, mediates the action of androgens. AR mutations that inactivate its function result in androgen insensitivity, classified as either complete androgen insensitivity syndrome (CAIS) or partial androgen insensitivity syndrome (PAIS). Affected 46,XY individuals with CAIS have female external genitalia, normal female breast development, absent or scanty axillary and pubic hair, and absent female internal genitalia. Testes are present, with levels of plasma testosterone, estradiol, and luteinizing hormone that are high-normal or elevated relative to those of normal males. The plasma dihydrotestosterone (DHT) level is normal or low-normal, which can sometimes result in an elevated testosterone:DHT ratio. Individuals with PAIS have a wide spectrum of phenotypic features, ranging from decreased body hair, infertility, and/or gynecomastia to severe ambiguity of the genitalia. Studies of androgen insensitivity highlight the importance of androgen-AR function in male sexual differentiation and physiology.

MALE SEXUAL DETERMINATION AND DIFFERENTIATION

Male sexual determination and differentiation is a complex process involving multiple steps, including

testes formation (sex determination) under the control of the *SRY* (sex-determining region of the Y chromosome) gene on the short arm of the Y chromosome. Other autosomal and X-chromosomal genes are also known to be involved in gonadal or testes development.

Before 6 weeks of gestation, human embryos with either a 46,XY (genetic male) or 46,XX (genetic female) karyotype develop identically, and an undifferentiated gonad is present in both genetic male and female fetuses. At approximately 6 or 7 weeks of gestation, testicular cords evolve from the primary sex cords of the indifferent gonad. The Sertoli cells within the cords enlarge, become contiguous, and engulf the germ cells. The seminiferous cords interconnect to form a network of solid cords, which connect with the mesonephric tubules and ultimately to the ductuli efferentes. Leydig cells are apparent by 8 weeks of fetal life and completely fill the interstitial spaces of the developing testes at 3 months of gestation.

Two major hormones, testosterone and anti-Müllerian hormone, are synthesized in the testes and involved in the translation of gonadal sex to phenotypic sex. Anti-Müllerian hormone (also called Müllerian-inhibiting substance or Müllerian-inhibiting factor), a glycoprotein and a member of the transforming growth factor- β family, secreted from the Sertoli cells of the testes, promotes regression of the Müllerian ducts, resulting in lack of development of female internal structures (uterus, fallopian tubes, and upper vagina). The Müllerian ducts, which appear at 40–48 days of gestation, regress at approximately 8½ weeks of gestation in the male fetus.

Testosterone secreted by the Leydig cells of the testes beginning at 8 weeks of gestation mediates the differentiation of the Wolffian ducts to the epididymides, vasa deferentia, and seminal vesicles, or the internal masculinization. The process of Wolffian duct differentiation is mediated by testosterone, probably via a paracrine action, and completed by 12 weeks of gestation.

Male external genital differentiation begins soon after Wolffian ductal differentiation. The development of the prostate is dependent on the local conversion of testosterone to the more potent androgen dihydrotestosterone (DHT) by the 5α -reductase-2 isozyme present in these tissues. The urogenital tubercle becomes the glans penis, the urogenital folds become the shaft of the penis, and the urogenital swellings become the scrotum. The urogenital sinus forms the prostate, bulbourethral glands, and the prostatic and membranous portion of the urethra. The entire process of male external sexual differentiation is completed by 14–16 weeks of gestation. Descent of the testes and growth of genitalia occur during the last two trimesters of pregnancy.

The actions of both testosterone and DHT on internal and external genital masculinization are mediated via androgen receptor (AR). Thus, a functional AR is required for normal sexual differentiation. Any defect in the production or action of androgens during these critical periods can result in disorders in male sexual differentiation.

COMPLETE ANDROGEN INSENSITIVITY SYNDROME

Clinical Syndrome

Androgen unresponsiveness *in utero* causes a 46,XY fetus with testes and normal androgen secretion to be born with female genitalia and an absent or severely hypoplastic Wolffian ductal system. The labia, especially the labia minora, may be underdeveloped. The clitoris is normal or small. The vagina ends blindly. Due to normal secretion of anti-Müllerian hormone by the testes *in utero*, Müllerian-derived structures are absent or rudimentary, and thus the uterus and cervix are absent or rudimentary.

During puberty, there is normal or augmented breast development due to the unopposed estrogenic action by androgens. Pubic and axillary hair is scant or absent.

The testes of patients with complete androgen insensitivity syndrome (CAIS) are usually located in the abdomen or inguinal canal. They cannot be distinguished histologically from those of normal males before puberty. However, postpubertal histologic studies reveal immature tubular development with Sertoli cells, spermatogonia, and no spermatogenesis. There is frequent clumping of tubules with formation of tubular adenomas. Leydig cells are hyperplastic and electron microscopy reveals ample smooth endoplasmic reticulum and mitochondria with tubular cristae.

This correlates well with the usually elevated plasma testosterone levels, although in some respects Leydig cells have been reported to resemble fetal Leydig cells with absent crystals of Reinke.

Biochemical Characteristics

In postpubertal individuals with CAIS, plasma luteinizing hormone (LH) is frequently increased with high-normal or elevated testosterone and correlates well with the histological findings of Leydig cell hyperplasia. The elevation of LH apparently results from androgen unresponsiveness in the hypothalamus and/or pituitary. However, LH levels are not in the castrate range due to the negative feedback effect of estrogen on the hypothalamus and/or pituitary. Follicle-stimulating hormone is normal or elevated.

Although the plasma testosterone level is in high-normal or elevated, plasma DHT levels may be low-normal, resulting in an elevated testosterone:DHT ratio. This may be due to a secondary deficiency of 5α -reductase activity since DHT exhibits positive feedforward control of 5α -reductase activity.

Plasma and urinary estrogens range from high male to low female levels. The estrogens originate mainly from the testes and, to a lesser extent, peripheral aromatization of androstenedione and testosterone by aromatase. An unopposed estrogen effect, due to increased estrogen and androgen unresponsiveness, is the likely explanation for breast development during puberty.

The sex hormone binding globulin (SHBG) levels in individuals with CAIS are higher than those of normal males and similar to those of normal females. Castrated CAIS patients not receiving estrogen have SHBG levels similar to those found in normal males.

Molecular Biology of the Androgen Receptor and Genetic Basis of Androgen Insensitivity Syndrome

The AR, a member of the nuclear steroid receptor superfamily and a ligand-dependent nuclear transcription factor, was cloned in 1988. It has approximately 910–919 amino acids encoded by the AR gene located on Xq11–12 (Fig. 1). The AR gene is a single-copy X-chromosomal gene that spans approximately 90 kilobases of genomic DNA. The encoding region of the AR gene comprises eight exons separated by seven introns. Like other steroid receptors, the AR is a single polypeptide composed of relatively distinct domains: an amino-terminal domain, a DNA-binding

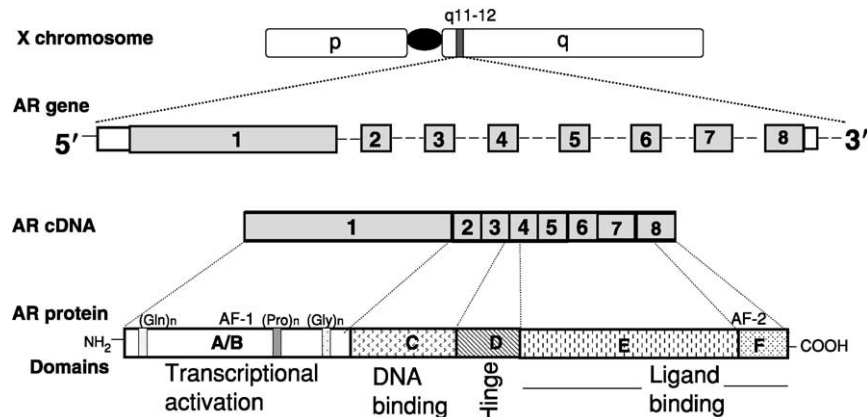

Figure 1 AR gene location, gene structure, and protein domains. (Top) The location of the AR gene at the q11–12 of the X chromosome. (Middle) The AR gene consists of eight exons (boxes) and seven introns (dashed line). (Bottom) The AR complementary DNA and AR protein, for which the AR domains and the exons encoding each domain are illustrated. Relative positions of glutamine (Gln), proline (Pro), and glycine (Gly) repeats within the N-terminal domain are shown. The transactivation functions AF-1 and AF-2 are located within the N-terminal domain and ligand-binding domain, respectively.

domain, a hinge region, and a steroid-binding domain in the carboxyl terminal.

The large amino-terminal domain that comprises approximately half of the AR molecule is encoded by exon 1. It is involved in the transcriptional activation of target genes and contains a transactivation domain, activation function 1 (AF-1). This domain plays a role in AR functions by intramolecular and/or intermolecular interaction with other factors. There are three highly polymorphic direct repeats of amino acid residues: one each containing glutamine, proline, and glycine residues. The increase in size of the glutamine homopolymeric segment is related to the pathogenesis of the spinal and bulbar muscular atrophy (Kennedy's disease).

The DNA-binding domain encoded by exons 2 and 3 contains two “zinc finger” motifs that are hallmarks of all nuclear steroid receptors, and it is the most highly conserved region among steroid receptors. The formation of the two zinc fingers involves eight cysteine residues. These two zinc-coordinated stem-loop structures are responsible for the specific interaction with the cognate DNA of target genes by interacting with the major groove of the DNA duplex. The first zinc finger (proximal to the N-terminal domain) is associated with the determination of the sequence specificity of DNA binding, whereas the second finger helps stabilize the DNA–receptor complex. Despite their exquisite functional specificity in the physiological context, receptors for androgens, glucocorticoids, progesterone, and mineralocorticoids can recognize the same DNA response element both in an *in vitro* binding assay and in functional analysis

using transiently transfection analysis. This paradox remains to be solved.

The carboxyl terminal of the AR is the ligand-binding domain, encoded by the 3' portion of exon 4 and exons 5–8, and is responsible for the specific high-affinity ligand binding. Studies indicate that androgens interact with the ligand-binding domain mostly through hydrophobic interaction as well as some hydrogen bonding. The carboxyl terminal also contains subdomains involved in dimerization and transcriptional activation. The second transactivation function (AF-2) domain of AR resides within the ligand-binding domain. Upon ligand binding, the AF-2 domain can interact with coregulators, such as coactivators, to affect AR function. Between the DNA-binding domain and the steroid-binding domain is the hinge region, which contains the nuclear translocation signal.

Both testosterone and dihydrotestosterone, potent natural androgens, bind to the same AR at the ligand-binding domain to regulate androgen target gene expression. The binding of androgen on the AR results in an AR conformational change that promotes the dissociation of chaperone proteins and facilitates receptor dimerization, nuclear transportation, phosphorylation, and DNA binding. Upon the recruitment of coregulators and general transcription factors, the transcription of a target gene is either induced or inhibited and ultimately leads to a change in androgen target proteins and cellular or biological structures and functions (Fig. 2). A number of coregulators have been identified that can interact with AR to either enhance or reduce androgen–AR action on target

Figure 2 The molecular events of androgen-AR action in a target cell. When testosterone enters the cell, it can be converted to DHT by the action of 5 α -reductase. Both testosterone (T) and DHT bind to the same AR. The androgen-AR complex translocates to the nucleus, interacting with other factors and target genes to regulate gene transcription. The changes in androgen-target proteins in the cell eventually affect cellular structure and function related to male sexual differentiation, physiology, and pathophysiology. ARE, androgen response element; GTFs, general transcription factors; ARA, androgen receptor-associated proteins; CoR, coregulator; TFs, transcription factors; hsp, heat shock protein.

gene transcription. Although significant progress has been made in the past decade in understanding androgen-AR action, the detailed process from androgen binding on AR to the alteration of target gene transcription remains to be elucidated.

The mutations of the AR that cause loss of function result in androgen insensitivity, which is inherited as an X-linked recessive condition, with genetic males expressing the condition (Fig. 3). To date, more than 490 different mutations in all eight exons in the AR gene have been reported, including the mutation for the largest pedigree of CAIS (see the AR gene mutation database at www.mcgill.ca/androgendb). These mutations range from a single point mutation to an entire gene deletion and can result in various AR dysfunction, including impaired androgen binding, impaired DNA binding, impaired cofactor interaction, blocked formation of a functional receptor (deletions, nonsense mutations, splice-junction alterations), decreased AR expression, and an unstable androgen-receptor complex. Depending on the type of dysfunction, various degrees of functional impairment of the AR occur, resulting in a wide spectrum of symptoms, ranging from a total female phenotype to

normal male phenotype with decreased secondary sexual hair, infertility, or gynecomastia. Although various individual mutations have been characterized, no correlation between the severity of the syndrome and a particular gene defect has been observed.

A variety of genetic defects impair the normal functioning of the AR. Generally, mutations that delete the entire AR gene or interrupt the AR open reading frame, blocking the formation of a functional receptor resulting from premature termination, aberrant splicing, or deletion of partial or complete exon segments, are associated with a phenotype of complete androgen insensitivity. This is due to the fact that AR DNA- and hormone-binding domains, critical for AR function, are located at the carboxyl terminus of the AR protein. As a consequence, defects that truncate the receptor protein at any point during its synthesis result in the removal of a portion of one or both of these important functional domains and will lead to a complete loss of AR function.

Mutations in the ligand-binding domain represent approximately 67% of AR mutations related to androgen insensitivity. The majority of these mutations are single nucleotide substitutions and cause defects in

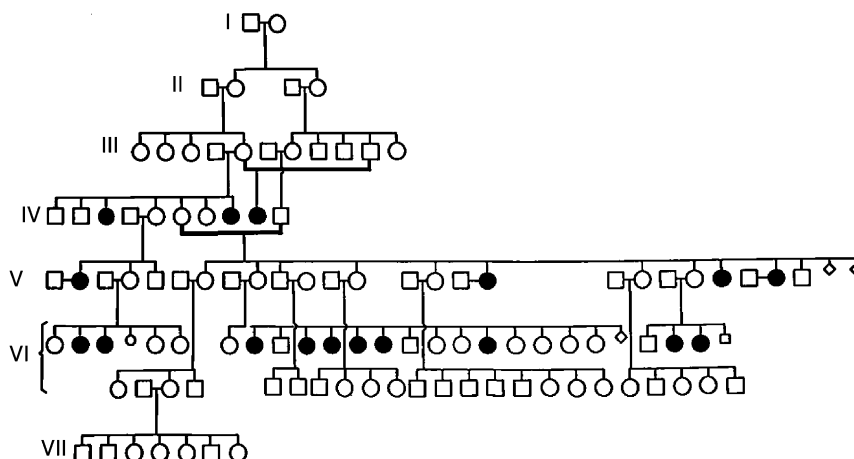

Figure 3 Pedigree of a kindred with complete androgen insensitivity indicates the maternal transmission of this disease. ○, normal females; □, normal males; ●, androgen insensitive subjects.

androgen binding that have been categorized as receptor-negative (the absence of detectable ligand binding), receptor-positive (quantitatively normal but qualitatively abnormal ligand binding), and receptor-reduced or receptor-deficient (reduced capacity or reduced affinity of ligand binding) defects, as demonstrated in patient genital skin fibroblasts. Substitution mutations in the AR ligand-binding domain have been identified in patients with the entire spectrum of androgen-insensitive phenotypes.

Approximately 15% of AR mutations are located in the DNA-binding domain, resulting in either complete or partial androgen insensitivity. Studies of these mutations have shown that the mutant receptors bind androgens with normal or near-normal affinity but fail to bind normally to the target DNA sequences by *in vitro* DNA-binding assays, resulting in a defect in androgen-AR function as demonstrated by *in vitro* transfection analyses.

It has been reported that some AR mutations result in decreased AR protein levels and decreased androgen-binding capacity in the genital skin fibroblasts of affected individuals. These mutant ARs may have subtle differences in function on selected target genes when analyzed by *in vitro* transfection. However, the levels of AR in these individuals are significantly decreased due to the mutations that alter AR gene transcription, translation, or posttranslational processes.

AR mutations that alter the stability of the androgen-receptor complex can also cause androgen insensitivity. It has been shown that replacement of arginine 774 of AR with cysteine residue leads to androgen resistance and undetectable androgen binding in genital skin fibroblasts. However, substitution of

the same residue by histidine leads to normal levels of androgen binding in fibroblasts that display a marked thermal lability in *in vitro* assays, suggesting that the stability of the androgen-receptor complex is important for normal AR activity.

A new type of defect has been reported at the postreceptor level in an individual with CAIS as diagnosed based on clinical and biochemical features. The AR gene in this patient is normal. However, the transmission of the activation signal from the AF-1 domain of the AR is disrupted, probably due to a defect in an AR coregulator or coactivator, indicating that defects in AR signal transmission to target gene expression can also result in androgen insensitivity despite the absence of AR mutation.

Diagnosis and Management

Since the phenotypic appearance of CAIS is totally feminine, the condition is usually diagnosed following breast development at puberty when patients seek medical advice for primary amenorrhea. Complete androgen insensitivity is the most likely diagnosis in a phenotypic female who presents with primary amenorrhea, breast development, scanty or absent pubic and axillary hair, a short vagina, and absent cervix and uterus. These subjects also have a clear, smooth, and acne-free complexion.

Occasionally, individuals with CAIS are diagnosed before or soon after birth. This diagnostic evaluation results from the discrepancy between the findings of a 46,XY karyotype on amniocentesis and the presence of a female phenotype on prenatal ultrasound examination or at birth. Some individuals with CAIS are

diagnosed during infancy when they develop inguinal herniae, often bilaterally. Occasionally, a 46,XY individual with 17 α -hydroxylase deficiency can also have the same phenotypic presentation at puberty.

5 α -Reductase-deficient individuals are most frequently born with severe ambiguity of the external genitalia (pseudovaginal and perineoscrotal hypospadias) and can occasionally present with female genitalia. However, puberty is significantly different from that in androgen-insensitive patients because distinct virilization without gynecomastia occurs. Urinary 5 β /5 α C21 steroid metabolite ratios are markedly elevated in 5 α -reductase-2-deficient patients, whereas these are only slightly changed or normal in patients with complete androgen insensitivity.

In summary, the diagnosis of CAIS can usually be made based on the clinical presentation and the biochemical features. Genetic analysis with identification of an AR mutation and functional demonstration of the mutation can assist and confirm the diagnosis.

Once diagnosed, the management of patients with CAIS depends on whether the individuals are prepubertal or postpubertal. CAIS subjects are phenotypic and psychosexual females. It has been reported that up to 25% of patients with CAIS develop testicular neoplasms, although seldom before 25 years of age. If a diagnosis is made before puberty, the patient is usually followed until puberty is completed and breasts have developed naturally before being referred to a surgeon for gonadectomy. However, the optimal time for gonadectomy with regard to psychological adjustment is still a matter of debate. It should be realized that waiting for the postpubertal period to perform the gonadectomy means that it will often be done during the tumultuous years of adolescence or soon thereafter. Gonadectomy performed at this time, however, has the advantage of involving adolescents or young adults in decision making.

It can be argued that gonadectomy should be performed in childhood, thus avoiding the difficulties of yet another psychologic adjustment during adolescence. However, some adult patients with this condition, who were gonadectomized in childhood, believe that gonadectomy should have been delayed until early adulthood, when they could have been more actively involved in decision making; thus making the psychologic adjustment easier. If a child has an inguinal hernia and is brought to a physician for this reason and the diagnosis is made, consideration should be given to perform gonadectomy at the time of hernia repair, thereby avoiding a second operation.

It is important that the patient learn about the condition from his or her doctor in a careful and

sensitive way. This will avoid severe psychologic problems. Therefore, it is critical that the doctor develop a good relationship with the patient and the parents. The timing of the information from initiation of the topic to a detailed discussion must be individualized. Psychologic counseling is needed for the patient and the family.

The postpubescent patient should be gonadectomized due to the probability of testicular neoplasms. Cyclic estrogen replacement therapy should be prescribed at the appropriate time to prevent osteoporosis and to maintain breast development, and patients should be followed regularly. For most patients, the vagina is of sufficient size to allow normal coital function. In a patient whose vagina is too small, vaginal dilation is the usual corrective measure, and vaginal surgery is rarely required.

PARTIAL (INCOMPLETE) ANDROGEN INSENSITIVITY SYNDROME

In partial or incomplete forms of androgen insensitivity, a spectrum of clinical phenotypes is present and includes gynecomastia and severely ambiguous genitalia, mild hypospadias, gynecomastia only, normal male genitalia with infertility, and decreased body hair in adulthood. A range of phenotypic abnormalities have been reported in 11 members of one family, indicating that a single mutant gene, variably expressed, may be a factor in the variant phenotypic forms of partial androgen insensitivity syndrome (PAIS).

The endocrine profile, analogous to that in patients with CAIS, shows elevated LH and testosterone levels. Total 17 β -estradiol produced and secreted by the testes has been reported to be greater than in patients with CAIS. However, the degree of feminization during puberty is not as prominent. This may indicate a less severe androgen and estrogen imbalance at the cellular level due to some androgen responsiveness.

Genetic analysis has revealed a variety of AR mutations responsible for PAIS. These mutations occur throughout the entire encoding region and result in various AR dysfunctions. There is no correlation between a specific AR gene mutation and phenotypic expression, although numerous mutations have been identified and characterized.

Treatment of patients with PAIS is dependent on the degree of virilization. In most cases, patients with profound genital ambiguity should be raised as females since deficient masculinization and gynecomastia will undoubtedly occur at puberty. Surgical correction of external genitalia and gonadectomy are indicated and female sex hormone therapy should be prescribed at

puberty. Surgical correction of mild hypospadias is necessary in patients raised as males, and surgical correction of gynecomastia may be necessary.

Supplemental high-dose androgen therapy to increase virilization is controversial due to its possible deleterious effect on the cardiovascular system. However, due to the fact that some AR mutations display conditional androgen-binding defects, the use or development of specific androgen analogs that can overcome the androgen-binding defects manifest in natural androgens is a therapeutic strategy in the management of PAIS that remains to be investigated.

SUMMARY

Androgen insensitivity syndrome due to AR mutations is a natural model for elucidating androgen actions in male sexual development, physiology, and pathophysiology. The identification and characterization of various AR mutations provide important information for understanding AR structure and function. The elucidation of AR–coregulator interaction in androgen action and the identification of an AR–coregulator defect in androgen insensitivity further indicate the complexity of androgen–AR action and open the door to a new therapeutic strategy.

Androgens, Gender and Brain Differentiation

Julianne Imperato-McGinley and Yuan-Shan Zhu

Weill Medical College of Cornell University, New York, New York, United States

Glossary

androgen receptor An intracellular protein that binds to androgens and mediates androgen action.

dihydrotestosterone A derivative of testosterone formed by the action of 5 α -reductase isozymes that is involved in male sexual differentiation and development.

5 α -reductase isozymes Microsomal nicotinamide adenine dinucleotide phosphate (NADPH)-dependent proteins that reduce the double bond at the 4–5 position of a variety of C₁₉ and C₂₁ steroids such as testosterone.

gender identity The sense of being male or female; the self-awareness of knowing one's sex.

gender role The expression of one's gender identity to the public; manifested by one's behavior or actions.

male pseudohemaphrodite A 46,XY individual who has the testicular tissue but whose external genitalia and other sexual characteristics are so ambiguously developed that the sex of the individual is uncertain.

testosterone A male hormone that is produced by the testes and that induces and maintains male secondary sexual characteristics.

Genetic and hormonal influences on phenotypic sex determination in humans have been shown to be similar to those in other mammals. Many animal studies have also demonstrated that hormones are essential for sexual differentiation of the brain during development and for the maintenance of sexually dimorphic behavior throughout life. However, the effect of hormonal influences on sexual dimorphic differences in the human nervous system and on gender identity and sex differences in human behavior is still an emerging field. This article discusses the importance of androgens in (1) determination of male gender identity and (2) cognitive function by reviewing specific inherited genetic defects in androgen biosynthesis and action. The complex interaction of nature versus nurture is also addressed.

ROLE OF ANDROGENS IN BRAIN MORPHOLOGY

Studies of brain morphology of various animals demonstrate the presence of sexual dimorphism. Androgens administered perinatally to female rats result in structural changes in the sexually dimorphic nucleus of the preoptic area of the brain, making its similar to that of male rats. In canaries (*Serinus canarius*) and zebra finches (*Poephila guttata*), areas in the brain that control the vocal cords are noticeably larger in males than in females. The area X of the lobus parolfactorius is well developed in males of both species but is hardly identifiable in females. These size differences correlate with differences in singing ability; males produce a complex song, whereas females do not normally sing at all (zebra finches) or sing an infrequent simple song (canaries). The influence of testosterone at a critical period in development induces enhancement of these song areas of the brain in female canaries and zebra finches. The action of testosterone on the song areas of the brain may be mediated by conversion to estradiol given that it has been shown that masculine patterns of song area development in genetic females can be induced with estrogen. However, feminine patterns cannot be reproduced in males with antiestrogens or inhibitors of estrogen synthesis. An unresolved issue involves studies of genetic females that have functional testicular tissue and virtually no ovarian tissue but that still have feminine song circuitry.

Morphological sex differences that can be induced by androgens are also present in the auditory system of the tree frog (*Eleuthero dactylus coqui*), the spinal cord of the cat, the brain of the juvenile macaque monkey, and the neurons innervating the bulbocavernosus and levator ani muscles as well as the neurons innervating the ischiocavernosus and levator ani muscles (dorsolateral motor nucleus [DLN]) of the rat.

Studies of the human brain have found that the volume of the nuclei in the preoptic area is 2.5 ± 0.6

times larger in men, containing approximately twice as many cells. One area (INH-3) is larger by a factor of three in the male compared with the female. Another cell group is twice as large in the male brain, varies in women according to hormone levels, and is 3.7-fold larger in women of childbearing age. However, it is still not clear whether these nuclei are subdivisions of the paraventricular nucleus or are separate anatomical entities.

Sex differences in areas such as the left cortical language regions, as well as in the shape and surface area of the human callosum, have been reported in some studies but not in others. Because the callosum consists of myelinated connecting fibers, larger callosal volumes in women are interpreted as providing better interhemispheric communication, resulting in less functional specialization of the two hemispheres.

ROLE OF ANDROGENS IN MALE BEHAVIOR

In animal studies, androgens administered early in females have been shown to organize neural systems in such a way as to stimulate or induce male sexual response during adulthood and to inhibit female sexual response. The critical period for this central nervous system effect of androgens might not coincide with the critical period for external genital differentiation. In some animals, pre- or perinatal androgen stimulation also affects nonsexual masculine patterns of behavior that are independent of hormonal exposure during adulthood. Comparable effects have been seen in animal models such as the guinea pig, rabbit, hamster, rat, dog, and rhesus monkey. The critical period of exposure (pre- and/or perinatal) differs among the various species. In offspring of pregnant rhesus monkeys, treatment with androgens during a specific period of gestation increases mounting and "rough and tumble" play in females. Thus, sexually dimorphic behavior in animals is secondary to sex steroid-induced differentiation and activation of the brain at critical periods.

GENDER IDENTITY DEVELOPMENT

The relative influence of hormonal versus environmental factors in the determination of gender identity has been an ongoing debate for many years.

Environmental Influence

In 1955, Money proposed that human sexuality was undifferentiated at birth and becomes differentiated as

a consequence of various experiences. This theory was revised later to acknowledge that male sexually dimorphic behavior is expressed at birth but that it can be incorporated into either a male or female gender identity pattern. This theory was tested by matching individuals with ambiguous genitalia that were "chromosomally, gonadally, and otherwise diagnostically the same." The "matched pairs" were reported as differing only in their sex assignment and sex of rearing. The results demonstrated that gender identity correlated with sex of rearing, and not with chromosomal or gonadal sex, leading to the conclusion that sex of rearing was predominant in establishing gender identity. However, at the time of the studies, adequate hormone evaluation was unavailable and individuals were not assessed for their hormonal environment. Therefore, the degree of androgen exposure was assumed to be similar for the phenotypically matched pairs but was not objectively known to be so. Consequently, the issue of nature (androgen imprinting) versus nurture (sex of rearing) was not resolved due to incomplete hormonal characterization of the individuals.

Individuals with inadequate testosterone production or action are not suitable models to assess the relative importance of environment (sex of rearing) versus nature (androgen imprinting) in determining male gender identity because deficient androgen exposure would result in a decrease in the androgen effect on the brain. In addition, when castration and sex hormone therapy are initiated in an individual born with ambiguous genitalia to coincide with the determined sex of rearing, the natural hormonal sequence of events in the evolution of gender is interrupted. As a consequence, no valid conclusions can be drawn about the relative importance of these factors.

Hormonal Influence

Gender Identity in Research Subjects with 5 α -Reductase-2 Deficiency

In research subjects with 5 α -reductase-2 deficiency, the unique biochemical defect affects male external genital development without altering testosterone response. In these individuals, the biosynthesis of testosterone and its peripheral action are normal; thus, prenatal and neonatal testosterone exposure of the brain proceeds as in the normal male. However, deficient 5 α -reductase-2 enzyme activity impairs conversion of testosterone to dihydrotestosterone (DHT), and the deficiency *in utero* results in genital ambiguity. As a result, many affected individuals with

this condition are believed to be female at birth and are raised as girls. However, at puberty, significant virilization occurs under the influence of normal to elevated plasma testosterone levels and a gender change occurs. Thus, 5 α -reductase-2-deficient individuals provide a unique opportunity to evaluate the relative influences of nature (testosterone) versus environment (sex of rearing) in the determination of gender identity in humans.

In the affected subjects from the Dominican kindred, those who were raised as females began to realize that they were different from other girls in the village because they did not develop breasts and/or they felt masses in either the inguinal canal or the "labia." They passed through a number of stages that included no longer feeling like girls, feeling like men, and finally identifying as men. When they became convinced of their maleness, a change in gender role occurred either during puberty or during the postpubertal period. In some individuals, the gender role change to male was delayed until they were confident of their ability to defend themselves. The average age of the gender role change was 16 years.

With one exception, those who were raised as girls changed to a male gender role and perform male work in a society where there is a definite division of labor; women perform household activities, whereas men work as farmers, miners, or woodsmen. Females are the affected males' choice for sexual intimacy. The adequacy of sexual intercourse depends on the severity of the chordee and the size of the phallus. With one exception, all of the subjects who changed to a male gender role either live or have lived with women in common law marriages. Some chose women with children from previous unions. One man lives alone in the hills working as a farmer since adopting a male gender role at 20 years of age.

The social and psychosexual development of New Guinean research subjects of the Sambian tribe with 5 α -reductase-2 deficiency has been recorded in field studies of Carlton Gajdusek over decades with similar observations. The Sambian tribal culture of the eastern highlands is rigidly gender segregated. Women are caretakers, whereas men are hunters and warriors. Male initiation rites during puberty include ritualized fellatio and other rituals for men of premarital age. Gender segregation during pubertal initiation was allegedly strictly enforced and included killing any female who accidentally witnessed these events. In the past, New Guinean 5 α -reductase-2-deficient individuals who were raised as girls until puberty, when they made the transition to boys, were reported. But today, as in the Dominican kindred, the condition is usually

recognized at birth by experienced midwives or is recognized during childhood. The female-to-male gender change produced the term "turnim man" from the Melanesian pidgin and was incorporated into the Sambian lexicon, connoting that these individuals are innately and biologically driven to change gender.

Some believe that New Guinean research subjects with 5 α -reductase-2 deficiency, as well as others with this condition, are regarded as a "third sex" and change to a male gender role to adapt to their "male-admiring" society. It has been our experience, as well as Gajdusek's experience, that these individuals clearly regard themselves as male. Three affected New Guinean 5 α -reductase-2 patients specifically requested and obtained genital correction during adulthood so that they could be, in their words, "complete men." In addition, gender change in 5 α -reductase-2 deficiency has been noted in affected individuals from many other countries such as Brazil, Turkey, Mexico, Cyprus, Algeria, Italy, Lebanon, Pakistan, Saudi Arabia, and Sweden as well as in Dominican individuals not part of the large kindred described previously. When puberty is allowed to occur without medical intervention, the majority of individuals identify as male.

It can be theorized that in normal males, the sex of rearing and androgen imprinting of the brain act in concert to determine male gender expression. Studies of 5 α -reductase-2-deficient individuals have shown that when the sex of rearing (female) is discordant with the testosterone-mediated biological sex, the biological sex will prevail when puberty occurs in a non-intervening environment. Thus, under the influence of testosterone-mediated puberty, "masculinization" of the brain theoretically occurs and a male gender identity develops, overriding the female sex of rearing. Therefore, androgens appear to act as inducers and activators in the evolution of male gender identity in humans. It is unclear whether it is testosterone or DHT that directly mediates this process given that both type 1 and type 2 5 α -reductase isozymes are present in the brain, and that the type 1 isozyme is normal in individuals with 5 α -reductase-2 deficiency.

Gender identity has been postulated to become fixed at around the time of language development, between 18 months and 4 years of age. Studies of individuals with 5 α -reductase-2 deficiency appear to demonstrate that the development of gender identity is not fixed during early life but rather evolves throughout childhood and becomes fixed during or after puberty.

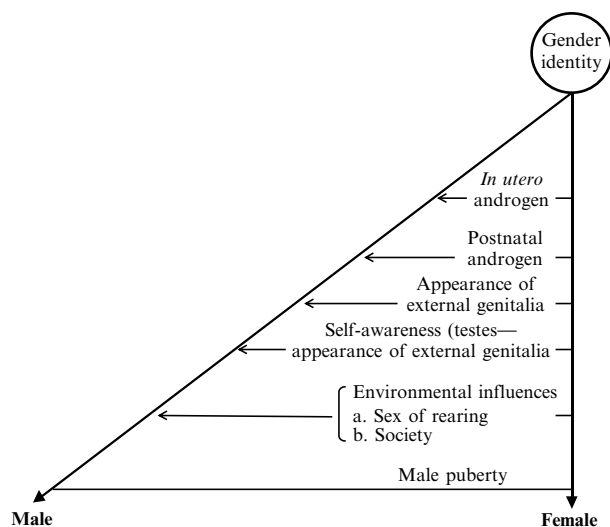

Figure 1 Schematic illustration of the critical factors involved in the evolution of a male gender identity in humans.

In summary, environmental and/or sociocultural factors are not the sole factors responsible for the formation of male gender identity; androgens make a strong and definite contribution (Fig. 1). Analogous to the induction of a male phenotype from an inherent female phenotype, the formation of male gender identity in humans appears to be at least partially induced by androgens from an undifferentiated and/or inherently female nervous system.

Gender Identity in Research Subjects with 17β -Hydroxysteroid Dehydrogenase-3 Deficiency

Genetic male research subjects with 17β -hydroxysteroid dehydrogenase-3 (17β -HSD-3) deficiency are born with severe ambiguity of the genitalia due to deficiency in conversion of androstenedione to testosterone. At puberty, they develop male secondary sexual characteristics (phallic enlargement and abundant body and facial hair), consequent to the peripheral conversion of androstenedione to testosterone by other 17β -HSD isozymes. Gender change from female to male has been reported in subjects with this condition, including those from a large Arab kindred in the Gaza Strip extending over eight generations. From published cases with 17β -HSD-3 deficiency, at least half of the research subjects raised as female change their gender from female to male spontaneously or in consultation with a physician and/or psychiatrist at various ages.

In the Arab kindred, some individuals raised as girls exhibited aggressive behavior, leading to their dismissal from school. Those who changed gender

did so on their own initiative, and some did so without parental consent or psychiatric help. The affected individuals are capable of having erections with ejaculations. Three individuals were castrated after diagnosis at the decision of the physicians, and they were raised as women. It is interesting that no individuals from this kindred living as females are known to have married. Some have stated that they would rather have been raised as males, revealing a questionable female identity. One elderly individual was found to have a female gender role but apparently identifies as male. This individual was a farm laborer and was proud to be stronger and more productive than male colleagues.

Conversion of androstenedione to testosterone is possible in the human brain. Except for the 17β -HSD-3 isozyme that is deficient in these research subjects, other 17β -HSD isozymes are normally expressed in the brains of both humans and animals. Thus, alternate pathways for testosterone and/or DHT formation via other 17β -HSD isozymes are in the brain as well as in extragonadal tissues of patients with 17β -HSD-3 deficiency and can theoretically cause androgen imprinting of the brain.

These studies suggest that hormones play a significant role in gender identity formation and that both environmental and hormonal factors influence male gender identity formation in humans.

SEX DIMORPHISM IN COGNITIVE FUNCTION AND LATERALITY

Meta-analyses of sex differences in spatial abilities have shown that spatial abilities of males are consistently greater than those of females on certain tasks. A number of tests showed significant male advantages that were stable across age and have not decreased during recent years. Tests included mental rotation tasks, the primary mental abilities (PMA) spatial relations subtest, and the rod and frame test. Male superiority in mathematics performance on the SAT has remained constant, and on a computerized version of a task of spatial ability, males outperform females across a variety of measures. On functional magnetic resonance imaging (fMRI) using a three-dimensional maze, sexually dimorphic differences in areas of brain activation have also been noted.

Women, on average, have slightly better verbal skills than do men. When all language measures are combined, women excel in tests of speech production and verbal fluency. Using echo-planer fMRI, a sex difference in brain organization was found during letter recognition, rhyme, and lexical-semantic tasks.

There is a trend toward greater right ear superiority in men. Auditory testing of laterality produces the most robust effect, with dichotic consonant–vowel (CV) syllable pairs tasks being the most reliable approach to testing of this type. From the past emerging data, it seems reasonable to suggest that the sex differences described previously are linked to differences in functional organization of the brain.

COGNITIVE ABILITIES IN ANDROGEN-INSENSITIVE INDIVIDUALS

Individuals with complete androgen insensitivity are phenotypic and psychosexual females due to the lack of androgen response consequent to androgen receptor gene mutations. Individuals with complete androgen insensitivity were studied using the Spanish version of the Wechsler Intelligence Scale (EIWA) to evaluate the relationship between androgen unresponsiveness and cognitive abilities, with particular attention to subtests of visual–spatial ability. In this study, affected individuals, as well as control males and females, all are members of a large kindred with this condition. Subjects with androgen insensitivity demonstrated significantly lower scores on subtests of spatial ability than did either control males or females from the kindred.

Because androgen-insensitive subjects are raised as females having a totally female psychosexual orientation, it should be considered that their cognitive performance may reflect the influence of their sex roles as a factor of socialization. However, this consideration does not explain their significantly lower overall performance on the perceptual organization factor and subtests of spatial ability when compared with control females from the same kindred. This exaggerated female pattern of performance suggests an effect of androgen unresponsiveness.

Studies of individuals with complete androgen insensitivity by other investigators demonstrate a modest but consistent and significant tendency toward superiority of verbal abilities over space–form abilities using the Wechsler Adult Intelligence Scale. Performance–perceptual scores are poorer in affected individuals than in both male and female controls.

CONCLUSION

Over the past two decades, studies of natural human genetic models with deficiency in androgen production or action have demonstrated the importance of

androgens in male sexual differentiation, development of male gender identity/role, and male-patterned behavior and cognitive function. These studies have also revealed that androgen, mainly testosterone, plays a vital “imprinting” role during a critical period of development. These actions appear to be mediated via androgen interacting with the androgen receptor, not via conversion of androgen to estrogen interacting with estrogen receptors as demonstrated in animal studies. This is further supported by the fact that 46,XY individuals with an estrogen receptor mutation or aromatase mutation, resulting in deficiency in estrogen production and action, develop a male gender identity and role. The fact that the majority of research subjects with 5 α -reductase-2 deficiency or 17 β -HSD-3 deficiency, who were raised as females, changed their gender identity and role to male during or after puberty suggests that the development of gender identity evolves throughout childhood and is fluid until the events of puberty.

It is important to bear in mind that androgen acts together with social or environmental factors within the endocrine milieu in the development of the male gender identity/role (Fig. 1). The critical period of androgen exposure of the brain for this development remains uncertain.

Angiogenesis

Andreas Bikfalvi

University of Bordeaux I, Bordeaux, France

Glossary

angiogenesis In a strict sense, the formation of vessels from preexisting vessels. Generally, the development of new vessels.

angiopoietins Factors implicated in the recruitment of accessory cells to the vasculature and vessel remodeling.

arteriogenesis Formation of larger blood vessels including arterioles.

endothelial cells Major cell type that is targeted by angiogenesis factors or inhibitors. Endothelial cells are in close contact with the blood and organize into tubular structures.

fibroblast growth factors Pleiotropic growth factors that also induce angiogenesis.

hypoxia-inducible transcription factors (HIFs) There are two HIFs, HIF-1 α and HIF-2 α , that regulate genes involved in angiogenesis.

integrins Heterodimeric cell surface receptors for matrix molecules.

lymphangiogenesis Formation of lymphatic vessels.

mural cells Cells lining the vessel wall in close contact with the subendothelial matrix and endothelial basement membranes. Pericytes are among the principal mural cells and are found in capillaries.

platelet-derived growth factors Growth factors implicated in the recruitment of accessory cells (mainly pericytes) to the vasculature.

proteolytic enzymes Enzymes that degrade proteins such as extracellular matrix molecules. The major proteolytic systems for the degradation of matrix molecules are the plasmin/plasminogen activator–inhibitor system and matrix metalloproteinases.

pruning Process that yields a mature remodeled vascular network.

RIP-Tag mouse model Transgenic mouse model with targeted expression of large T antigen in pancreatic β cells. A model for multistage carcinogenesis.

vascular endothelial growth factors (VEGFs) The major regulators of angiogenesis.

vasculogenesis Formation of blood vessels from progenitor cells.

The formation of vascular channels, angiogenesis, is a fundamental process that takes place during the embryonic life and also plays a crucial role in the adult organism.

INTRODUCTION

Generally, angiogenesis refers to two different mechanisms of vasof ormation and types of vessels. Angiogenesis, in a strict sense, describes the formation of new vessels from preexisting functional vessels. On the other hand, vasculogenesis involves the differentiation of endothelial progenitor cells that are incorporated subsequently into vessels. Until recently, it was believed that angiogenesis occurs in the embryo and the adult organism, whereas vasculogenesis occurs

only during embryonic development. This view has been challenged by the identification of circulating endothelial progenitor cells in the adult that are thought to arise in the bone marrow. These circulating progenitors are able to actively participate in angiogenesis processes, such as tissue ischemia, tumor angiogenesis, or ocular neoangiogenesis.

In the past, angiogenesis researchers mainly studied the mechanisms of formation of blood vessels. However, lymphatic vessels have become a focus of intense research. The study of arteriogenesis has also broadened the angiogenesis field. Arteriogenesis describes the formation of larger functional blood vessels—a process that is particularly important in the formation of collaterals that limit tissue ischemia.

This article provides a brief overview of the mechanisms of angiogenesis and the impact of angiogenesis research on the pathophysiology and therapy of disease.

BASIC MECHANISMS OF VASOFORMATION

Vasoformation is dependent on molecular regulations in both healthy and pathological tissue. This process is dependent on paracrine angiogenesis signals that induce proliferation and migration of vascular cells and their assembly into functional vessels. Vessel stabilization and remodeling are very important events that occur at a later stage. In microvessels, two major cell types, endothelial cells and pericytes, participate in these processes. In larger vessels, smooth muscle cells are involved instead of pericytes. A number of soluble factors, receptors, and extracellular matrix molecules play a role in vascular morphogenesis. Expression of these factors is under the control of a molecular switch inside the cells.

Hypoxia is a driving force for angiogenesis in tumors or ischemic tissue (Fig. 1). Hypoxia regulates angiogenesis via an increase in hypoxia-inducible transcription factor-1 α (HIF-1 α) that initiates a program of survival and adaptive gene expression. In angiogenesis, the major factor regulated through the HIF-1 α system is vascular endothelial growth factor (VEGF). In the presence of oxygen, the enzyme prolyl 4-hydroxylase (PHD) binds molecular oxygen and hydroxylates proline residues in HIF-1 α . Hydroxylated HIF-1 α associates with the von Hippel-Lindau (VHL) gene product, passes to the proteasome,

and is rapidly degraded. Under hypoxic conditions, hydroxylation is inhibited and HIF-1 α levels are stabilized. There are three sequence-related PHDs. Probably only one of these forms, PHD2, which resides in the cytoplasm, is involved in HIF-1 α regulation during angiogenesis. PHD2 is also transcriptionally induced by HIF-1 α in a low-oxygen environment. This provides an autoregulatory feedback loop.

In vascular cells, another form of HIF, HIF-2 α , is responsible for regulating gene expression. For example, an important receptor that binds VEGF, VEGFR2, is up-regulated through a HIF-2 α -dependent mechanism.

The molecular angiogenesis switch is dependent on hypoxia, oncogenic transformation, which occurs in tumor cells, or on autocrine growth factor loops. For example, activation of the ras gene product induces the expression of VEGF, a stimulator of angiogenesis, and down-regulates inhibitors such as thrombospondins in tumor cells. Similar effects are also observed when autocrine growth factor loops are present in tumor cells.

KEY FACTORS REGULATING VASCULAR DEVELOPMENT

Among the most important regulators of angiogenesis are the VEGFs. This family is composed of VEGF-A, -B, -C, and -D and the related placental growth factors (PLGFs). VEGFs are essential in embryonic and postnatal vascular development. They also play an important role in ischemia-driven or tumor angiogenesis. In fact, one of the VEGF prototypes, VEGF-A, is a permissive factor for multistage carcinogenesis, as evidenced in the RIP-Tag mouse model.

VEGFs bind three types of tyrosine-kinase receptors: VEGFR1 (flt1), VEGFR2 (flk1 or KDR), and VEGFR3 (flt3). VEGF-A binds VEGFR2 and VEGFR1. In contrast, VEGF-B binds only VEGFR1. VEGF-C and VEGF-D both preferentially bind VEGFR3 but also interact with VEGFR2. Finally, PLGFs bind only VEGFR1.

VEGFR2 is the critical receptor for angiogenesis in blood vessels and for vascular permeability. VEGFR1 may synergize with VEGFR2 in postnatal and pathological angiogenesis. VEGFR1 is also found on hematopoietic cells that accumulate at angiogenic sites. However, only VEGFR2 seems to be necessary for embryonic vascular development. Nevertheless, both receptors are needed for repair-associated, tumor, or retinal neovascularization in the adult.

Figure 1 The oxygen-sensing pathway. HIF1 α , hypoxia-inducible factor-1 α ; HIF1 β , hypoxia-inducible factor-1 β ; HRE, hypoxia response element; VHL, von Hippel-Lindau.

VEGFR3/*flt4* is required for the growth and the maintenance of the lymphatic vessels and is also mutated in primary human lymphedema (Milroy's disease), which illustrates the importance of this receptor in the lymphatic tissue. Targeted inactivation of VEGFR3 in mice results in abnormal lymphatic vessel growth. VEGF prototypes also use coreceptors for binding to target cells. Among the coreceptors, neuropillins seem to be the most important. For instance, neuropillin-1 is a coreceptor of VEGFR2. This interaction is critical for VEGF-A binding to VEGFR2.

VEGF-A is the main VEGF form that regulates angiogenesis in blood vessels, whereas lymphangiogenesis is primarily dependent on VEGF-C. Several splice variants of VEGF-A (VEGF-165, VEGF-121, and VEGF-189) have been identified that exhibit variable affinities for heparan sulfates. This interaction is important for VEGF's bioavailability. VEGF expression is regulated by a number of factors, including hypoxia, oxidative stress, reactive oxygen species, tumor suppressor genes or growth factors, or cytokines that activate the MAP kinase pathway.

VEGF alone appears to be unable to direct blood vessel organization or maturation. A number of other factors act not only on vascular endothelial cells but also on other vascular cells, such as pericytes. They may also contribute to vessel stabilization or pruning. Among these factors are fibroblast growth factors (FGFs), platelet-derived growth factors (PDGFs), angiopoietins, developmental gene products such as Notch/Delta, or molecules classically involved in axonal guidance. Particularly noteworthy among the latter are ephrins and neuropillins.

The major system involved in vessel stabilization is the angiopoietin system. Angiopoietin-1 (Ang-1) is thought to stabilize vessels by rendering them less sensitive to VEGF. The stabilizing effect of Ang-1 is disrupted by angiopoietin-2 (Ang-2) binding to the Ang-1 receptor Tie-2. Ang-1 stimulates endothelial cell migration by activating tie-2 and inducing the recruitment of Dok-R, Nck, and Pak. Ang-1, but not Ang-2, has been shown to be in the extracellular matrix. Ang-1 induces platelet-derived factors (PDGF), which is released and stimulates migration of pericytes, smooth muscle cells, and other accessory cells and, thus, favors mural cell coverage. Ang-1 is able to trigger vessel remodeling, as demonstrated in the retina.

Angiogenesis is also under the control of proteolytic enzymes and inhibitors, including the plasminogen activator system and matrix metalloproteinase and their inhibitors. The basic principle of the activity of

these enzymes is that they must be present at a critical concentration at the cell surface to promote invasion of vascular tubes. Furthermore, inhibitors such as tissue inhibitor of metalloproteinase-2 for matrix metalloproteinase (MMPs) may be required to localize the proteolytic activity at the cell surface, thus promoting activation of MMPs. This may account for the paradoxical stimulatory effects observed for these inhibitors in some circumstances.

Cell adhesion molecule receptors such as integrin $\alpha_v\beta_3$ (and, to a lesser extent, $\alpha_v\beta_5$) also play a critical role in angiogenesis. For example, the integrin $\alpha_v\beta_3$ is highly expressed in proliferating endothelial cells, and both a monoclonal antibody to $\alpha_v\beta_3$ and a low-molecular-weight antagonist have been shown to inhibit angiogenesis in *in vivo* models. This indicates that integrin $\alpha_v\beta_3$ has a promoting role in angiogenesis and may constitute a potential interesting therapeutic target. However, recent observations of $\alpha_v\beta_3$ knockout mice have challenged this view. In particular, it has been reported that mice lacking β_3 integrin show enhanced pathological angiogenesis. The reason for these apparent differences is not clear. Cheresh and collaborators attempted to explain the differences using the concept of ligated and unligated integrins.

Unligated integrins provide dead signals to endothelial cells that are blocked by ligation. Knocking out integrins affects both ligated and unligated integrins and may artificially increase the invasiveness of endothelial cells by increasing endothelial cell survival, assuming that more unligated than ligated integrins are present.

ANGIOGENESIS AND PATHOLOGY

Angiogenesis is a driving force for a number of pathologies, such as cancer, ocular neovascular disease, ischemic disease, and chronic inflammatory diseases. Cancer cells express a complex molecular repertoire that critically impacts the surrounding vascular stroma (Fig. 2). It is clearly recognized that tumor cells produce both negative and positive regulators of vasof ormation, and that the net effect on the vasculature is the outcome of the balance between these two types of regulators. That the growth of tumors is dependent on the vasculature was recognized by Algire in 1945 and later formulated as a paradigm by Judah Folkman. In general, tumors less than 2 or 3 mm are avascular and grow slowly. Tumor cells are then activated intracellularly by a mechanism called angiogenic switch and then start to favor the positive

Figure 2 Regulation of tumor angiogenesis. Tumors produce both positive (activators) and negative (inhibitors) regulators and regulate both angiogenesis and lymphangiogenesis. Inhibitors of lymphangiogenesis have not been identified. VEGF, vascular endothelial growth factor; FGFs, fibroblast growth factors; TSP, thrombospondins.

regulators over the negative regulators. First insight into the molecular mechanisms of the angiogenic switch was gained through the analysis of tumor progression in the RIP-Tag mouse model. Overexpression of the T antigen under the control of the insulin promoter induces an insulinoma that progresses to highly malignant and vascularized lesions. Tumor nodules from the early stage do not induce angiogenesis when cocultured with endothelial cells *in vitro*. At the later stage, however, angiogenesis is potently induced. A number of molecules are involved in the angiogenic switch. VEGF is required since mice with conditional inactivation of VEGF do not undergo the angiogenic switch. MMP3 and MMP9 are also required. These proteases allow the translocation of VEGF from the tumor matrix to the blood vessels. FGF prototypes also seem to be needed in this model.

Tumors are not identical and may be more or less dependent on one or the other angiogenesis factor or inhibitor. For example, prostate carcinoma and melanoma are more dependent on FGF and VEGF, whereas other tumors, such as ovarian carcinoma, are primarily dependent on VEGF. Furthermore, tumors may modify their angiogenesis repertoire during their lifetime and switch from one to the other growth factor/growth factor receptor system. This may constitute an escape mechanism for tumors due to environmental constraints.

Tumors may also express angiogenesis inhibitors, such as thrombospondin-1 (TSP-1) and TSP-2. Involvement of TSPs in tumor angiogenesis has been particularly well studied in mouse models of skin carcinogenesis. TSP-1 and TSP-2 both seem to inhibit tumor angiogenesis and tumor growth in models of skin carcinoma in mice. On the other hand, TSP-2, but not TSP-1, increases with tumor progression, indicating that TSP-2, but probably not TSP-1, is part of a host antitumor defense mechanism.

In addition to blood vessels, lymphatic vessels are also required for dissemination of tumor cells. Factors critically involved in the development of lymphatics, such as VEGF-C and FGFs, may also play a role in lymphangiogenesis in tumors. Blocking lymphangiogenesis in a highly metastatic human lung cancer cell line by inhibiting VEGF-C suppresses lymph node metastasis. Furthermore, crossing RIP-Tag mice with mice expressing VEGF-C under the control of the insulin promoter yields bigenic mice that develop pancreatic tumors with metastatic spread through the lymphatic system. Most important, Dadrás *et al.* reported that intratumoral lymphangiogenesis in melanoma patients is associated with poor survival.

Ocular neovascular disease is another pathological condition in which abnormal angiogenesis plays a leading role. Diseases include diabetic retinopathy and age-related macular dystrophy (ARMD). VEGF seems to be one of the principal factors in the pathophysiology of these diseases. In the case of ARMD, the fas/fas ligand system may also have a critical role. Indeed, fas/fas ligands are expressed in the retinal pigmented epithelium and the choroid vessels. Knockout mice for fas/fas ligand exhibit aberrant ocular neovascularization resembling ARMD.

Angiogenesis is also implicated in ischemic disease in two ways. First, capillary growth within the walls of large arteries may contribute to the establishment of a proliferative lesion and invasion into the intima. It has been reported that inhibition of plaque neovascularization reduces the accumulation of macrophages and progression to advanced atherosclerotic lesions. Second, the growth of the collateral circulation that limits the extent of the ischemic lesion is also controlled by angiogenesis factors such as VEGF or FGFs. This has offered novel therapeutic opportunities to salvage the ischemic area and to improve morbidity and mortality in patients with coronary or peripheral artery disease.

Finally, chronic inflammatory disorders such as chronic polyarthritis are also angiogenesis dependent. In the early phase, this disease is characterized by a

proliferative lesion of synoviocytes in the synovia. Within the inflamed synovia, the number and quality of microvessels are also altered. VEGF and integrin $\alpha_v\beta_3$ seem to play an essential role since blocking their activity in animal models results in disease improvement.

ANGIOGENESIS AND THERAPY

A number of molecules are under preclinical or clinical evaluation for angiogenic or antiangiogenic therapy. Clinical trials using VEGF or FGFs to stimulate the collateral circulation in patients with coronary disease or peripheral arterial ischemic disease are under way. On the other hand, inhibition of angiogenesis is therapeutically relevant in cancer, retinal neovascular disease, or chronic inflammatory disease. The major disease for which antiangiogenesis strategies have been investigated is cancer. Targeting the vasculature for angiogenesis inhibition may be achieved through extracellular or intracellular mechanisms (Fig. 3). Extracellularly, inhibitors may block binding of angiogenesis factors to receptors, interfere with coreceptor/ligand/receptor interactions, activate inhibitor receptors, or modulate integrin–extracellular matrix interactions or protease activity.

Intracellularly, inhibitors may directly inhibit tyrosine kinase receptors or signaling modules. Among inhibitors, molecules interfering with VEGF activity are a major focus of research. VEGF activity may be

blocked with anti-VEGF or VEGF receptor antibodies or specific VEGF receptor kinase inhibitors. Ferrara and collaborators were the first to show that antibodies to VEGF slowed tumor growth. Human forms of the antibody (Avastin) are now in phase 3 clinical trial for the treatment of solid tumors. Recently, remarkable results were announced in a phase 3 clinical trial with Avastin in combination with chemotherapy in colon carcinoma. Low-molecular-weight inhibitors of the tyrosine kinase activity of the VEGF receptor (VEGFR-KIs) are another venue for antiangiogenesis tumor therapies. Encouraging results have been obtained with VEGF-KIs in kidney and colon carcinoma. Another target for development of angiogenesis inhibitors is molecules encrypted within larger regulatory proteins, including endostatin, angiostatin, thrombospondin, platelet factor-4 (PF-4), and endorepellin. For example, a peptidomimetic of thrombospondin has been synthesized that exhibits high antiangiogenesis activity and is currently in clinical trials. A C-terminal fragment of PF-4 has also been developed that exhibits increased antiangiogenic and antitumor activity in glioblastoma.

Furthermore, antiangiogenesis properties of molecules already known to exhibit inhibitory activities on other cell types have recently been discovered. Particularly noteworthy is the fact that chemotherapy, when given at low dose and metronomically, has mainly antiangiogenic effects and greatly inhibits tumor development in mice.

Figure 3 Angiogenesis inhibition versus vascular targeting. For angiogenesis inhibition, inhibitors may block the interaction of angiogenesis factors with their receptor by disrupting specific binding to receptors or coreceptors. Furthermore, inhibitors may activate inhibitor receptors such as CD36 for thrombospondin-1. Inhibitors may also disrupt the interaction between integrins and matrix molecules. Targeting agents bind surface molecules that are specifically present on the surface of angiogenic endothelial cells or in the extracellular matrix around blood vessels.

Combinatory approaches involving several molecules or treatment regimens have been developed to increase therapeutic efficacy. Antiangiogenic molecules may be combined with chemotherapy or radiotherapy. These approaches have been validated in the mouse, and phase 3 clinical trials are under way involving, for example, the association of chemotherapy with Avastin in colon or kidney carcinoma. Another approach is to combine several antiangiogenesis drugs. For example, the combination of endostatin, angiostatin, and TNP470 has been shown to be more effective than any single agent alone. Bergers and colleagues associated a VEGFR-KIs with Gleevec, a drug used for the treatment of chronic myelogenous leukemia. In addition to inhibiting the BCR-abl tyrosine kinase activity, Gleevec also inhibits c-kit and PDGFR tyrosine kinase. Since PDGFs are critically involved in pericyte recruitment and vessel stabilization, inhibition of this receptor tyrosine kinase may be important to resensitize vessels to VEGF inhibition. This is indeed the case, as demonstrated by Bergers and colleagues using the RIP-Tag mouse model. Treatment of established tumors leads to regression when the two inhibitors are combined.

Vascular targeting is different from the approaches described previously (Fig. 3). It involves selective targeting of tumor blood vessels and their subsequent destruction. This approach is based on the assumption that the tumor vasculature is different from that in normal tissues. Much evidence supports this claim. Tumor endothelial cells are often hypoxic, lack nutrients, and exposed to a number of cytokines and stress factors. This modifies the gene expression profile, making them angiogenic. The proof of concept that targeting is a valuable approach for cancer treatment was provided in 1993 when Burrows and Thorpe used an anti-MHC class II antibody coupled to ricin toxin to destroy tumor vasculature in experimental animal models. Other compounds that target the vasculature include the combretastatins, which are currently in phase 1 trials. They are selectively toxic to tumor vasculature by disrupting the tubulin cytoskeleton.

Recently, impressive results were reported by Halin and collaborators using a vascular-specific antibody (L19) that was isolated from an antibody phage library and that recognized the ED-B domain of fibronectin. This antibody is selectively targeted to the tumor endothelium. Chimeras of the antibody with interleukin-12 or tissue factor caused regression of established tumors when injected in experimental mouse tumor models.

This oxygen-sensing pathway also offers opportunities for therapeutic intervention. PHD inhibitors should be proangiogenic, whereas molecules that

abrogate HIF-1 α binding to coactivators and/or the hypoxia response element reduce angiogenesis and tumor growth. Modulation of the iron content of the cell may also affect the activity of the PHDs because these enzymes are sensitive to the local Fe²⁺ concentration.

CONCLUSION

Angiogenesis is a fundamental mechanism in embryonic and postnatal development that also plays a major role in pathologies such as cancer, ocular neovascular disease, ischemic disease, and chronic inflammatory disease. Many molecules, receptors, and intracellular signaling modules have been implicated in vascular morphogenesis. These discoveries have offered novel opportunities for therapeutic intervention. There is an increasing repertoire of drugs with which to manipulate angiogenesis and new endothelial-specific genes with which to target the vasculature. Thus, angiogenesis research is currently at an exciting stage.

Angiotensin, Evolution of

Werner Kloas

Leibniz Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany

Glossary

angiotensin receptors All angiotensin receptors identified in several classes of vertebrates share a high degree of homology and belong to a superfamily of seven-transmembrane G protein-coupled receptors.

angiotensins Bioactive peptide hormones of varying length between 6 and 10 amino acids. The main functions of angiotensins are associated with osmomineral and water balance as well as maintenance of blood pressure in vertebrates.

evolution of the renin–angiotensin system (RAS) The functioning systems to produce angiotensin are present in all classes of vertebrates and some invertebrate groups, indicating an early appearance of endocrine function of angiotensin during evolution.

Angiotensin (Ang) is a classical peptide hormone important in osmomineral regulation and blood pressure maintenance of vertebrates. The Ang-producing renin–angiotensin system (RAS) and corresponding receptors for Ang are present in all classes of vertebrates. Comparative studies indicate that homologous Ang and RAS are present in several groups of invertebrates, implicating an important biological role of Ang during early evolution.

INTRODUCTION

The presence of the peptide hormone Ang produced by the renin–angiotensin system (RAS) and its corresponding receptors is reported in all classes of vertebrates. Ang plays an important role in the control of blood pressure and osmomineral regulation directly by vasoconstrictory actions in the circulatory system or indirectly by regulating osmominerals, affecting hormones such as corticosteroids, catecholamines, or nonapeptides, and by influencing drinking behavior as a dipsogenic agent. However, studies indicate that the evolution of Ang occurred at an earlier evolutionary period in several groups of invertebrates.

COMPONENTS OF THE RENIN–ANGIOTENSIN SYSTEM

In vertebrates, the major pathway of systemic Ang is the generation of the decapeptide Ang I (angiotensins 1–10) by the enzyme renin from liver-produced angiotensinogen. Ang I is subsequently converted to the octapeptide Ang II (angiotensins 1–8) by Ang-converting enzyme (ACE) and then metabolized to smaller peptides exhibiting biological activities, such as Ang III (angiotensins 2–8), Ang IV (angiotensins 3–8), and Ang V (1–7). In addition, the tissue-specific existence of Ang-producing RAS has been demonstrated within the brain, pituitary, gonads, and adrenal, where Ang is processed not only via renin and ACE but also by various other enzymes.

Angiotensins

Amino acid sequences of Angs are highly preserved throughout evolution and differ only in positions 1, 3, 5, and 9, where exchanges of amino acids may occur (Table I). However, species-specific differences in the structure of Angs can markedly modify their biological activities depending on the corresponding Ang receptors of the respective species. It is noteworthy that the structure of Ang I in humans and leeches is identical.

Renins and Angiotensin-Converting Enzymes

Renins and renin-like enzymes cleaving Ang I by proteolytic cleavage from angiotensinogen are present in all classes of vertebrates and also found in leeches and insects. The presence of ACEs generating the biologically active octapeptide Ang II from Angs I is established for all vertebrates, and functioning ACEs have been demonstrated in invertebrates such as insects, leeches, and mollusks.

Table I Angiotensin I Amino Acid Sequences from Vertebrates and Annelids^a

^aNative angiotensin I from all vertebrate classes and annelids. Among vertebrate classes additional species-specific differences in amino acid sequences in positions 1, 3, 5, or 9 are present or may be found.

ANGIOTENSIN RECEPTORS AND CELL SIGNALING PATHWAYS

All Ang receptors identified and cloned in vertebrates belong to the superfamily of seven-transmembrane G protein-coupled receptors, which have several second messenger systems, including phosphatidylinositol-4,5-bisphosphate, intracellular Ca²⁺, endothelium-derived relaxing factor, nitric oxide, and cGMP. In invertebrates, evidence of functioning Ang receptors in leeches was obtained by binding studies and physiological experiments.

BIOLOGICAL ACTIONS

The classical functions of Ang in vertebrates are the maintenance of water and osmomineral contents and blood pressure. In higher vertebrates, Ang decreases the glomerular filtration rate in the kidney and stimulates the adrenal to secrete mineralocorticoid aldosterone by the cortex and to release the catecholamines adrenaline and noradrenaline by the medulla. The effects on the central nervous system include dipsogenic behavior and increased hypophyseal secretion of nonapeptides (vasopressin or vasotocin), which act positively on water conservation and blood pressure. In addition, Ang acts on memory processes, reproduction, and immune response modulation of mammals.

The endocrine counterpart on nearly all target organs for Ang and its biological actions is the family of natriuretic peptides, which counteract the

maintenance of water and osmomineral homeostasis in all classes of vertebrates.

However, main target organs for Ang may differ in vertebrates during early evolution. In amphibians and fish, stimulatory effects of Ang on the adrenal homologues producing catecholamines or corticosteroids are found in some species but absent in others. Additional Ang targets in fish are osmoregulatory organs, such as gill, intestine, and chondrichthyan rectal gland, all of which are very important for osmoregulation. Angiotensin-induced effects on dipsogenic behavior and renal functions also vary widely among lower vertebrates, whereas vasopressor activities are always prominent.

In invertebrates, biological actions of Ang are reported for leeches, in which Ang has a diuretic effect by influencing Cl transport, demonstrating its physiological significance for maintenance of osmoregulation after a blood meal in these annelids.

Angiotensin is one of the classical vertebrate hormones involved in osmomineral and blood pressure regulation. The development of more complex endocrine effects of Ang on several target organs during vertebrate evolution is associated with changes from aquatic to semiterrestrial and terrestrial lifestyles, for which salt and water conservation as well as maintenance of blood pressure are essential. However, comparative studies indicate that Ang originated much earlier during evolution in annelids, in which it is also associated with water and osmomineral regulation.

Anorexia Nervosa

Jesús Argente

University Autónoma and Hospital Universitario Infantil Niño Jesús, Madrid, Spain

María Teresa Muñoz

Hospital Infantil Universitario Niño Jesús, Madrid, Spain

Glossary

amenorrhea The absence of menstruation during a minimum period of 3–6 months in women who have previously experienced menstruation (secondary amenorrhea) or the lack of menarche at 16 years of age (primary amenorrhea).

bone mass Total quantity of bone tissue, including the total volume of bone tissue and the total quantity of mineralized extracellular matrix.

malnutrition A pathological condition occurring when energy and nutrient requirements are not met by dietary intake. There is a wide spectrum of clinical forms, depending on the severity and duration of the deficit, the age of the subject, and the cause of the condition.

osteopenia Significant diminution of bone mass per unit volume in relation to what is considered normal for the age, pubertal stage, and sex of the subject.

osteoporosis A disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in fracture risk.

Anorexia nervosa (AN) is a childhood psychiatric disorder characterized by patient-induced and maintained weight loss that leads to progressive malnutrition and specific pathophysiological signs (disturbance of body image and fear of obesity). Diagnostic criteria were proposed for the first time in 1972 by Feighner *et al.* and were later modified by the American Academy of Psychiatry in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders*. These criteria allowed uniform classification of patients with these characteristics and also suggested the existence of less severe forms, called nonspecified eating disorders. These forms can also have a dangerous evolution and therefore require therapy equal to that of the clinical forms. The diagnostic criteria for AN were updated in 1994 in the fourth edition of the *DSM*.

PREVALENCE

The prevalence of anorexia nervosa (AN) among adolescents and young adults is approximately 0.5–1%, with a bimodal age distribution including peak ages of 14 and 18 years. However, a significant number of cases in girls during the initial stages of puberty, as well as before the onset of puberty, have been observed. The female/male ratio ranges from 5:1 to 20:1. A study of a Spanish female population between 12 and 21 years of age showed a prevalence of 0.3% for AN, 0.8% for bulimia, and 3.1% for nonspecified eating disorders; thus, a total of 4.1% of the population suffers from some type of eating disorder. However, 50–67% of adolescent females are dissatisfied with their weight and body shape, and most adolescents have been on a diet. Many of these teens use unhealthy weight control methods, including fasting, diet pills, and vomiting.

Adolescents with chronic diseases, especially females, have a higher incidence of eating disorders and special attention should be given to these patients to ensure that they do not develop clinically significant cases of anorexia or bulimia. Indeed, a cross-sectional study indicates that the prevalence is approximately twice that seen in age-matched controls.

ETIOPATHOGENESIS

The etiology of AN is multifactorial, including genetic, biological, psychological, and cultural factors. The coexistence of various risk factors increases the possibility of developing this disease (Table I).

Individual Factors

Patients with AN frequently have personality disorders, including low self-esteem and high anxiety. They are introverted, obsessive, and perfectionists, and feel as if they are little effective, although the

Table 1 Diagnostic Criteria for Anorexia Nervosa^a

| |
|---|
| Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected) |
| An intense fear of gaining weight or becoming fat, even though underweight |
| A disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight |
| In postmenarcheal females, amenorrhea (the absence of at least three consecutive menstrual cycles) |
| Two subtypes are described: restricting subtype and bingeing/purging subtype |

^aFrom the American Psychiatric Association (1994).

reverse is usually the case. In addition, those patients that use purgative methods have a tendency to steal and often have problems with alcohol and drugs.

It is significant that in these patients the loss of self-esteem and autocontrol culminates in them going on a diet. To this culturally accepted activity, they often add other useful activities, such as studying many hours and intense physical exercise, which often result in a brief improvement in their condition. The malnutrition provokes a series of alterations, both physical and mental, and the capacity to relate socially is altered, producing a new decrease in self-esteem and autocontrol. The response is a more strict diet, which can then perpetuate a dangerous spiral of events.

Some high-level athletes develop AN, but others present incomplete or subclinical forms with a more difficult diagnosis. A form called athletic anorexia has been described that includes high-level female athletes who have an intense fear of gaining weight or becoming fat, even though they are below their ideal weight, with low-caloric intake and often excessive exercise.

Genetic Factors

No specific marker has been identified that suggests an increased possibility of AN. Investigation has concentrated on analysis of polymorphisms of genes related to weight control and the serotonergic and dopaminergic pathways. One of the most frequently studied genes is that of the serotonin receptor. Serotonin [5-hydroxytryptamine (5-HT)] is involved in a broad range of biological, physiological, and behavioral functions and has been implicated in the development of eating disorders. Polymorphisms within different 5-HT receptor genes and the tryptophan hydroxylase gene have also been analyzed. Some studies have described an association between the-1438 A allele of the -1438 G/A polymorphism within the promoter region of the 5-HT_{2A} receptor

gene and AN. These studies indicate that patients with AN have enhanced 5-HT_{2A} receptor binding and provide further evidence for a serotonergic dysfunction in eating disorders, although further studies are needed.

The hypothalamus is also an important organ in the control of energy metabolism because it is responsible for the sensation of hunger and satiety and hence energy intake. In addition, via modulation of the sympathetic nervous system, it is involved in thermogenesis and, as a result, energy expenditure. Various neuropeptides control these functions. Regulation of acute eating behavior incorporates a system of satiety signals originating in the food. Cholecystokinin, bombesin, gastrin-releasing peptide, and others are involved in this signaling system and reach the brain via peripheral innervation or the circulation to activate their receptors.

Long-term energy balance is regulated via a system composed of different hormones secreted in proportion to corporal adiposity, such as leptin and insulin, that act at the level of the central nervous system. These respond to changes in body fat by activating anabolic or catabolic pathways, the first through production of neuropeptide Y (NPY), which stimulates food intake, and the second via the hypothalamic melanocortin system, which reduces food intake and stimulates weight loss (Fig. 1).

Leptin, a hormone synthesized by adipose tissue, plays an important role in the regulation of food intake and energy expenditure. Its mechanisms of action are unknown, although its primary target seems to be the hypothalamus. Leptin acts at the level of the hypothalamus to decrease appetite, resulting in weight loss. Plasma leptin levels and secretory pattern vary during the night and day and are influenced by food intake. Molecular analysis of the coding region and part of the promoter region of the leptin gene in patients with AN has yielded negative results. Hence, involvement of the leptin gene in the etiology of AN seems unlikely.

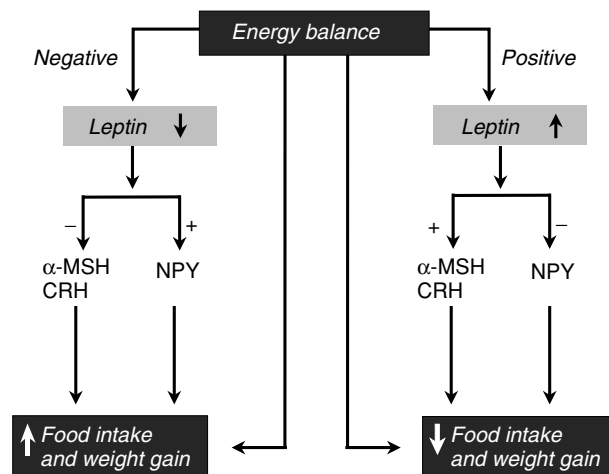

Figure 1 Hormonal response to malnutrition.

It has been demonstrated that a gastrointestinal peptide hormone, ghrelin, stimulates growth hormone secretion in rats and humans. Ghrelin also plays an important role in the regulation of energy balance. Plasma ghrelin levels are regulated by acute and chronic changes in energy balance (e.g., fasting increases, whereas feeding decreases, circulating ghrelin concentrations).

The actions of NPY, incrementing ingestion and decreasing thermogenesis, are opposite those of leptin. Neuropeptide YY5 and YY1 receptors in rats and humans are assumed to play a major role in NPY-induced food intake. The neuropeptide YY5 receptor gene (NPYY5R) is expressed in brain regions involved in the central regulation of feeding behavior, including the lateral hypothalamus, the paraventricular nucleus, and the arcuate nucleus. Systematic mutation screening within the coding region of the NPYY5R revealed a rare Glu-4-Ala variant in a single patient with AN. This allele was transmitted from the mother, who had no antecedents of any eating disorder. Association and transmission disequilibrium studies pertaining to variations and polymorphisms within NPYY1R and NPYY5R and AN were negative.

Glucocorticoids are also implicated in energy regulation. Via their effects on NPY, they act as endogenous antagonists of leptin and insulin. Other neuropeptides that stimulate food intake and energy storage are melatonin-concentrating hormone and orexin A and B, which increase in response to fasting and stimulate appetite. The melanocortins (MCs) are peptides derived from the precursor proopiomelanocortin (POMC) and act on specific receptors. The endogenous MC most implicated in food intake and body weight is α -melanocyte-stimulating hormone

(α -MSH), which has a high affinity for the MC receptors, especially MC3 and MC4. Mutation screening of the coding region of MC4-R in patients with AN and bulimia nervosa revealed two common polymorphisms in both groups. Allele and genotype frequencies did not differ between these groups and probands of different weight extremes.

Familial Factors

The families of patients with AN have certain characteristics in common. They are often overprotective, strict, and have a relative incapacity to solve their own conflicts. The mother figure is described as the boss of the family and the father figure as distant. In many families, the patient is often recognized as an individual only after the onset of the illness; consequently, the patient continues with the illness in order to remain the center of the family's attention.

Sociocultural Factors

These adolescents are often very vulnerable, receiving a large quantity of information that they cannot assimilate, which creates tension regarding problems normal for their age, including sexuality, competitiveness, individuality, and independence within the family.

It is well-known that every historic period determines the prototypes for fashion and beauty. During the past two decades, thinness for women and strong physic for men have been fashionable. These stereotypes have been perpetuated mainly via publicity. The adolescent is constantly bombarded with information regarding the ideal weight and figure, how to have the perfect body, what type of exercise one must practice to achieve this perfect body, and miracle diets.

EVALUATION

Multiple organ system complications are seen, including those involving the cardiovascular and peripheral vascular systems and gastrointestinal, hematological, renal, skeletal, endocrine, and metabolic disorders. These alterations are related not only to the state of malnutrition but also to the conduct of these patients to control their weight. A number of endocrine and metabolic disturbances described in patients with AN indicate hypothalamic dysfunction, including amenorrhea-oligomenorrhea, delayed puberty, hypothyroidism, hypercortisolism, interferon growth

factor-1 (IGF-1) deficiency, electrolyte abnormalities, hypoglycemia, and hypophosphatemia.

Medical Complications

The clinical manifestations of AN are broad, affecting all systems of the organism, and depend largely on whether the form is restrictive or purgative. Some anorexic patients (10–20%) have bulimic tendencies, which mainly include provocation of vomiting, the use of laxatives, and a compulsive increase in physical activity.

Cardiovascular problems occur in up to 80% of patients, including bradycardia and hypotension, due to autonomic nervous system imbalances. Electrocardiographic abnormalities may include atrial and ventricular arrhythmias and QTc abnormalities. In addition, changes in myocardial function have been reported with decreases in myocardial tissue mass, mitral valve prolapse, and pericardial effusions.

Gastrointestinal complications are also common. AN can cause a decrease in gastrointestinal motility, resulting in chronic constipation. Laxative abuse can lead to cathartic colon syndrome and chronic constipation that is sometimes refractory to treatment. Cases of acute gastric dilatation have been described during the phase of realimentation of extremely affected anorexia patients since gastric emptying of solids is retarded, and that of liquids is retarded in some patients. Esophageal problems include severe esophagitis and even ruptures of the esophagus associated with induced vomiting.

Neurological consequences result from severe malnutrition (Fig. 2). Computed tomography and magnetic resonance imaging have demonstrated cortical atrophy and ventricular dilatation. Malnourished patients have greater cerebrospinal fluid volumes and reduced white and gray matter volumes. Abnormalities on computed tomography scans are reversible with refeeding and nutritional recovery.

Biochemical Abnormalities

Hematological findings include anemia, leucopenia (relative neutropenia and lymphocytosis), thrombocytopenia, low erythrocyte sedimentation rate, and decreased fibrinogen levels in plasma. The anemia and occasional pancytopenia appear to be due to hypoplasia of the bone marrow, which is filled with a gelatinous mucopolysaccharide.

Vomiting results in the loss of sodium, hydrogen, and potassium, causing metabolic alkalosis. The use of

Figure 2 Patient with anorexia nervosa and severe malnutrition.

laxatives provokes the loss of potassium and bicarbonate, which can result in metabolic acidosis. Finally, the use of diuretics can cause increased loss of sodium, potassium, and calcium in the urine, depending on the dose and drug used.

Renal complications are present in 7% of these patients and can include a decrease in glomerular filtration, an increase in plasma urea and creatinine levels, electrolyte alterations, edema, and hypokalemic nephropathy. Renal concentration ability is impaired and polyuria may occur. An abnormal response of arginine vasopressin to an osmotic stimulus may be seen.

Cellular immune functions are also altered as a consequence of poor nutrition. These include modifications in some immunoglobulin fractions (IgG and IgA and complement factors C3 and C4), low response in the cutaneous delayed hypersensitivity test, and alterations in the lymphocyte subpopulations CD3, CD4, and CD57. However, infections are infrequent in these patients.

Plasma protein levels are usually normal, although in some cases hypoalbuminemia is present. Elevated amylase has been observed in the absence of clinical signals of pancreatitis. Predisposition factors are duodenal and jejunal dilation, and these are more frequent in patients with bulimia. There is an increase in

β -carotenes and vitamin A, although the reason for this is unclear. In contrast, blood levels of copper and zinc are reduced and iron and ceruloplasmin levels are normal.

Mild hypercholesterolemia is frequent in AN, with the elevation occurring in the low-density lipoprotein fraction, whereas both high-density lipoprotein and very low-density lipoprotein levels are normal. Plasma triglyceride levels are normal despite low values for hepatic lipase and lipoprotein lipase activities. The cause of the hypercholesterolemia is not known.

DIFFERENTIAL DIAGNOSIS

A differential diagnosis must be made in situations characterized by loss of weight in young persons, such as brain tumors and lymphomas, and in cases with gastrointestinal symptoms, such as chronic inflammatory disease. In addition, different endocrine pathologies, such as Addison's disease, hyperthyroidism, and diabetes mellitus, must be taken into consideration. Depending on the predominant psychopathological symptoms, depression and obsessive-compulsive alterations, social phobia, and schizophrenia must be ruled out.

COMPLICATIONS

Endocrine and Neurotransmitter Disturbances

Hypothalamic–Pituitary–Ovarian Axis

Patients with AN exhibit isolated hypogonadotropic–hypogonadism of hypothalamic origin. The etiology is uncertain, although multiple factors may play a role, including hypothalamic dysfunction, reduction of weight, sex steroids and neurotransmitters alterations, as well as physical exercise (Table II).

Adolescents with AN exhibit low basal levels of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) as well as low estradiol levels, indicating the abnormal function of the hypothalamic–pituitary–gonadal axis. In addition, spontaneous secretion of LH during a 24-h period is decreased in both frequency and amplitude of the secretory bursts. With weight gain, serum levels of both LH and FSH are increased, suggesting that malnutrition may play a role in the regulation of gonadotropin secretion. Disturbances in neurotransmitters have been described, including the dopaminergic system and endogenous opioids, both peptides related to GnRH regulation. Whether these alterations in

neurotransmitters are primary or secondary to malnutrition remains to be elucidated.

Malnutrition may be responsible for the delayed puberty and reduction in growth seen in these patients. This phenomenon has been interpreted as a mechanism of adaptation to the reduction in nutrients. Delayed puberty is present when symptoms appear in prepubertal patients; in contrast, if the disease begins after development has begun, puberty is detained and the growth spurt delayed and smaller. Finally, if symptoms appear after puberty, secondary amenorrhea is present. One of the indications that the process of adaptation to malnutrition has begun is hypoinsulinemia, present as a consequence of low glucose and amino acid levels. Furthermore, growth hormone (GH) abnormalities and low IGF-1 levels contribute to poor growth in prepubertal patients,

leading to a reduction in their final height. Reliable data are not available to establish the percentage of growth lost in relation to the target height. However, one study estimated that some patients were 3 cm shorter than their target height.

Whether leptin is a permissive factor or plays a central role in the initiation of puberty is unknown. In subjects with reduced fat stores, problems with reproductive system functioning are frequent, including a reduction in serum sex steroid levels. A similar phenomenon, the shutdown of the hypothalamic–pituitary–gonadal axis, occurs in patients with anorexia nervosa after the loss of fat stores. In both cases, it is speculated that the problems with gonadal function could be related to the decreased serum leptin levels as a result of the loss of fat tissue. We have observed that in patients with AN during partial weight recovery, there is no significant increase in leptin levels or in the recovery of gonadal function. Of course, it is possible that a longer weight recovery period is necessary for this to occur, which would result in loss of the linear correlation with the body mass index (BMI). Studies suggest that BMI is the most important control factor for the secretion of leptin in situations of modified food intake and that there is a loss in circadian rhythm in patients with AN. Of great interest is whether leptin is necessary for the recovery of menstruation in these patients. However, more studies are necessary to answer this question.

There is evidence of an association between melatonin levels and gonadal function in humans, with woman with hypothalamic amenorrhea having elevated nocturnal levels of melatonin. Patients with AN are also reported to have elevated nocturnal levels of 6-sulfatoxymelatonin (the principal metabolite excreted in the urine) both at diagnosis and after weight recovery if amenorrhea exists.

The percentage of total body fat can be evaluated by using dual-energy X-ray absorptiometry. In patients with AN and moderate malnutrition, the percentage of total body fat is a better indicator of the nutritional state than BMI. There is a significant correlation between leptin levels and the percentage of total body fat that is not found between BMI and leptin.

It has been reported that if patients with AN recuperate weight to obtain at least 90% of the weight adequate for their height, their menstrual cycles will return within 6 months. It therefore follows that one of the decisive factors for the normalization of gonadal function is the recuperation of the nutritional state.

Hypothalamic–Pituitary–GH Axis

Most studies indicate that a large percentage of patients with AN have elevated basal and GH-releasing hormone (GHRH)-stimulated GH levels. There are alterations in the GH response to different stimuli (decreased response after hypoglycemia, clonidine, and hexarelin) as well as paradoxical hormone responses [elevated GH after thyrotropin-releasing hormone (TRH) thyrotropin or after intravenous glucose], although these responses are heterogeneous. Few studies have analyzed spontaneous GH secretion (SGHS) in AN patients. We studied SGHS in a group of anorexic patients at diagnosis and at two different times during weight recovery and found that at diagnosis SGHS is heterogeneous. In 40% of subjects, mean 24-h GH secretion was >3 ng/ml (lower limit of normality), and the remaining 60% had levels below the normal range. The difference between these groups and the controls was due to modification in the amplitude of the GH peaks and not to pulse frequency. In both groups, recovery of at least 10% of initial weight resulted in the normalization of the parameters of SGHS. These observations suggest that alterations in GH secretion in these patients are due to modifications in its neuroendocrine control, with an increase in GHRH release and decreased somatostatin tone.

The GH pattern in conjunction with the negative correlation between basal and pulsatile GH secretion and BMI suggests that the observed alterations in GH secretion are directly related to malnutrition. One possible mechanism may involve the reduced IGF-1 levels caused by malnutrition. This would effect a reduction in the negative feedback action that IGF-1 exerts on GH secretion at the level of the hypothalamus and pituitary. Another variable that may be involved is the hypoestrogenism that accompanies amenorrhea. It has been suggested that malnutrition underlies the increase in the amount of GH secreted in each pulse and that hypoestrogenism is responsible for the increased pulse frequency. Definite conclusions, however, can not be drawn from these studies.

In patients with AN, plasma ghrelin levels are significantly increased and rapidly normalize after partial weight recovery. Whereas decreased leptin levels in AN patients might simply reflect reduced body fat mass, increased gastric ghrelin secretion in AN might reflect a physiological effort to compensate for the lack of nutritional intake and stored energy.

Serum GH-binding protein (GHBP) levels in patients with AN are dramatically reduced and tend to normalize with weight recovery. The reduction in GH

receptors is most likely one of the principal causes of GH resistance.

In malnutrition, the low GHBP levels may be related to hypoinsulinemia, alterations in thyroid function, or hypoestrogenism. On the other hand, many studies have demonstrated a correlation between serum GHBP levels and BMI or the percentage of body fat or, more specifically, visceral fat. Given that it has not been demonstrated that circulating GHBP is uniquely or even preferentially derived from liver GH receptors, it is possible that other tissues, such as adipose tissue, may contribute to plasma GHBP levels. If this is the case, the extreme reduction in adipose tissue in patients with AN may cause the observed decrease in serum GHBP levels.

Patients with AN have extremely reduced serum IGF-1 levels that tend to normalize with weight recovery; however, as observed for other forms of malnutrition, the time necessary for this to occur may be prolonged. Circulating IGF-1 is largely dependent on GH, but it is also very sensitive to nutritional changes. In AN patients, serum IGF-1 levels do not correlate with GH secretion, which suggests that the decrease in IGF-1 is independent of GH and probably directly due to the state of malnutrition. The coexistence of reduced IGF-1 levels and normal or elevated GH secretion suggests that these patients exhibit resistance to GH action.

Data on serum levels of free IGF-1 are limited and contradictory. Some authors have found normal levels, whereas others report a decrease; in both cases, weight recovery tended to increase free IGF-1 levels. Likewise, some authors have found serum IGF-2 levels to be normal at the time of diagnosis and to increase with weight recovery. In contrast, others report IGF-2 levels to be decreased, although not significantly, and to normalize with weight recovery. Serum levels of free IGF-2 are reported to be decreased in patients with AN and to increase with weight recuperation.

Patients with AN have elevated serum IGFBP-1 and IGFBP-2 levels that tend to normalize with weight recovery. Both are reported to be GH independent and very sensitive to nutritional regulation. The increase in IGFBP-1 in these patients is most likely related to hypoinsulinism, although other metabolic or hormonal factors, such as increased glucagon and glucocorticoids levels, as well as decreased intracellular glucose or other specific substrates may be involved. In AN, as in other forms of malnutrition, the increase in IGFBP-2 most likely depends on the combined influence of caloric-protein restriction, hypoinsulinism, and GH resistance.

Serum IGFBP-3 levels are decreased in AN patients as a consequence of GH resistance and tend to normalize after weight recovery. Indeed, all components of the trimolecular complex formed by the union between IGFBP-3, IGF, and the acid-labile subunit (ALS) are decreased. Given that these proteins are all GH dependent and regulated by the nutritional state, this is not unexpected. IGFBP-3 decreases significantly with caloric restriction, but in adults it decreases only with protein restriction. In contrast to other catabolic situations, in AN increased proteolysis of IGFBP-3 has not been observed.

Although present in serum in low concentrations, IGFBP-4 and IGFBP-5 are very important in bone formation: At the cellular level, they regulate the actions of the IGFs. In AN, serum levels of both of these IGFBPs are dramatically reduced and do not normalize with partial weight recovery.

The biological significance of the changes in IGFBPs that occur in AN or that are due to malnutrition is difficult to explain, in part because the physiological roles of the binding proteins are not totally understood. The decrease in serum IGFBP-3, and therefore the trimolecular complex IGFBP-3-IGF-ALS, impedes the retention of IGF in the vascular space, favoring the decrease in plasma levels. On the other hand, the increase in IGFBP-1 and IGFBP-2, two proteins with low molecular weights that can cross the vascular barrier, favors even more the movement of the IGFs to the tissues on which they can act. Therefore, modification of the serum and tissue levels of the IGFBPs could be one of the mechanisms by which malnutrition regulates the concentration and actions of the IGFs and the somatotrope axis.

Hypothalamic-Pituitary-Thyroid Axis

Thyroid function is affected by malnutrition in AN. Clinically, patients appear to be in a relative hypothyroid state, sometimes called euthyroid sick syndrome. Clinical manifestations include hair loss, dry skin, hypothermia, and bradycardia. All these findings are reversible with appropriate refeeding and successful treatment.

Laboratory findings include low-normal levels of thyroxine (T_4) and thyroid-stimulating hormone (TSH), below normal levels of triiodothyronine (T_3), and elevated levels of reverse T_3 . All these findings are the result of malnutrition and weight loss. In fact, the low T_3 level correlates with the amount of weight loss. The extremely reduced T_3 levels in these patients are due to altered peripheral deiodination that preferentially transforms T_4 into the inactive metabolite, reverse T_3 . Finally, blunting of the TSH response to

TRH is indicative of hypothalamic–pituitary dysfunction. Ultrasonographic methods in patients with AN demonstrate that the thyroid is markedly reduced in comparison to that of age- and sex-matched controls. This glandular atrophy is not due to low TSH levels because TSH levels are usually normal in AN. However, thyroid size is influenced by IGF-1, and the low IGF-1 levels in these patients may contribute to thyroid atrophy. These alterations normalize with weight recovery and thyroid hormone replacement is usually not indicated.

Hypothalamic–Pituitary–Adrenal Axis

Adrenocorticotropin (ACTH) and the endogenous opioids are derived from the same precursor, POMC. Increased ACTH secretion is preceded by activation of the POMC system. The opioid system has both direct and indirect influences over food intake and the level of physical activity. In laboratory animals, opioid administration stimulates appetite via receptors in the paraventricular nucleus, and opioid antagonists such as naloxone reduce appetite. Corticotropin-releasing hormone (CRH), synthesized in neurons of the paraventricular nucleus, is regulated, at least in part, by leptin and insulin. Its administration intracerebroventricularly induces a reduction in food intake and weight loss.

In AN, plasma cortisol levels are often elevated while circadian rhythm is conserved. Dexamethasone can partially suppress this hypercortisolemia, which is similar to what is observed in patients with depression and Cushing's disease. In acute situations of AN, the dexamethasone test has no medical significance; however, in patients who are gaining weight, it may have prognostic value. Refeeding studies of anorexic patients have shown that, irrespective of the initial weight, weight gains as low as 10% are associated with the normalization of cortisol secretion. The mean plasma half-life of cortisol is prolonged and ACTH levels are within the normal range, but the ACTH response to CRH is inferior to that of control patients. This hypercortisolemia may reflect a defect at the level of the hypothalamus, or even higher, that results in hypersecretion of CRF. Taken together, these observations suggest CRH hypersecretion more than cortisol resistance.

Osteoporosis or Osteopenia

Bone Mineral Density

Osteopenia is a frequent and often persistent complication in patients with AN, leading to clinical

fractures and increased fracture risk through life. According to the international literature, more than 50% of patients with AN present osteopenia at diagnosis.

The pathogenesis of osteopenia and osteoporosis is not completely known; however, numerous studies have highlighted a number of factors, including severe malnutrition, poor calcium intake, excessive exercise patterns despite malnutrition, hypoestrogenism, increased serum cortisol levels, and hormonal imbalances, such as decreased progesterone levels and decreased IGF-1 levels.

During infancy and puberty, obtaining adequate bone mineralization requires normal nutrition and metabolic and endocrine functions and the absence of chronic pathologies. Hormones and growth factors that play a major role in regulating bone metabolism include T₃, sex steroids, vitamin D, parathormone, and GH, together with the IGF–IGFBP system and an intricate local system of growth and transcriptional factors.

The degree of osteopenia possibly depends on the age at which the amenorrhea began as well as its duration. Indeed, patients with primary amenorrhea have a more severe osteopenia than those that present with secondary amenorrhea. There are significant concerns about the lasting impact and irreversibility of osteoporosis. Evaluation of bone density is recommended in patients who have been amenorrheic for 6 months to 1 year.

Investigation of the changes in bone mineral density (BMD) showed that nonrecovered AN patients with the binge eating/purging type have a significantly reduced BMD compared to patients with the restricting type. These results suggest that patients with the binge eating/purging type are at high risk for osteoporosis and may need additional therapy to prevent bone loss.

Karllson *et al.* reported that a substantial proportion of bone mass deficit in anorexic patients was due to smaller bone size. Recovery from illness was associated with near normal bone size and volumetric BMD. However, incomplete recovery of lean and fat mass may account for part of the remaining deficit in bone size but not volumetric BMD.

Administration of estrogens and gestagens to adolescents with reduced bone mass and amenorrhea for at least 1 year indicated that osteopenia cannot be reversed. In contrast, in patients who recovered menstruation spontaneously, a 20% increase in bone mass compared to that at diagnosis was seen.

The effects of estrogens on bone metabolism have been described as inhibitory for the resorption

process, although direct effects on osteoblastic activity have been described. It has been reported that AN occurring during adolescence impairs both mineral accrual and bone size. Although reduced volumetric BMD may be related to estrogen deficiency, there was no reduced bone size after adjusting for fat and lean mass. Weight, but not estrogen use, is a significant predictor of BMD in anorexic women at all skeletal sites. The reason why estrogens are incapable of increasing bone mass in adolescents with AN and amenorrhea is unknown. It may be due to the failure to administer estrogen therapy at diagnosis, poor compliance, or perhaps the short duration of recovery. In addition, decreases in other nutritional and hormonal factors are also involved in the pathogenesis of bone mass loss; hence, estrogen replacement alone may not be sufficient for BMD recovery.

IGF-1 and Leptin

IGF-1 is one of the most important regulators of bone metabolism. Circulating serum levels of IGF-1 correlate with BMD in the normal population. IGF-1 exerts a double effect on bone metabolism by stimulating osteoblastic activity and the resorption process.

Deficiency in growth factors, especially IGF-1, most likely due to the state of malnutrition, as well as the slow recuperation of their plasma levels with weight gain, is known to occur in these patients. However, it is not known whether these patients would benefit from the administration of biosynthetic GH or recombinant IGF-1. Several trials have analyzed the effect of recombinant human IGF-1 (rhIGF-1) on bone formation in AN patients. The administration of rhIGF-1 at a dose of 100 $\mu\text{g}/\text{kg}$ subcutaneously (sc) twice a day for 6 days increased metabolic markers of bone formation as well as resorption, whereas the injection of rhIGF-1 at a dose of 30 $\mu\text{g}/\text{kg}$ sc per day stimulated only bone production formation marker.

Improvement in nutritional status in AN patients via intravenous hyperalimentation therapy results in a rapid increase in serum IGF-1 levels, followed by a progressive increase in osteocalcin. This indicates that bone formation begins immediately. Nevertheless, increased bone resorption appears to continue for at least 5 weeks.

The effect of leptin administration compared to estrogen therapy in ovariectomy-induced bone loss in rats has also been reported. Leptin was effective in reducing trabecular bone loss, trabecular architectural changes, and periosteal bone formation. These findings suggest that leptin may regulate bone remodeling, and this effect may be, at least in part, mediated

by the osteoprotegerin/RANK (receptor for activation of nuclear factor kappa B) ligand pathway. RANK and RANK ligand (RANKL) are members of the tumor necrosis factor (TNF) and TNF receptor superfamilies, which are essential for osteoclast differentiation. In the bone microenvironment, the stimulatory effects of RANKL are neutralized by the secreted decoy receptor, osteoprotegerin (OPG). It follows that the balance between OPG and RANKL secretion by stroma cells is critical for the regulation of osteoclast formation.

The dramatic decline in leptin levels observed in AN may be one of the major hormonal factors involved in the pathogenesis of the associated bone fragility through diminishing cortical bone formation rates and skeletal growth. Leptin may play an important protective role in bone metabolism by inhibitory bone resorption.

Bone Markers

The available data are few and contradictory regarding markers of bone formation. The bone isoenzyme of alkaline phosphatase (bAP) and the amino-terminal pro-peptide of procollagen I (PNIP) have the greatest diagnostic sensitivity in detecting anomalies in bone remodeling, at least in osteoporetic women. Among the markers of bone resorption, the telopeptide carboxy terminal of the 1 chain of type 1 collagen (CTX) has demonstrated great specificity and sensitivity in the investigation of bone metabolism.

Osteoporosis in adolescents with AN is related to decreased bone formation and actual bone resorption. It is clear that markers of bone formation are decreased and markers of bone mineral resorption are increased. Trabecular bone seems to be more vulnerable than cortical bone. A significant positive correlation of BMI, IGF-1, and IGFBP-3 with osteocalcin as a bone formation marker was demonstrated, whereas a negative correlation for the bone resorption marker CrossLaps was found only with BMI.

Patients with AN exhibit a high degree of osteopenia that correlates with their bAP levels. Furthermore, the urinary fragments of CTX in patients with AN are derived primarily from old bone (β -CTX), whereas in young adolescents they are primarily from new bone (α -CTX). Therefore, α -CTX is more adequate for measuring bone resorption in controls, whereas β -CTX is more adequate in anorexic patients.

One study demonstrated that during undernutrition and amenorrhea, with low IGF-1 and extremely low circulating estradiol, biochemical markers of bone metabolism indicated a shift toward

bone resorption because bone formation markers (osteocalcin, bAP, and PNIP) were normal and bone resorption markers (CTX) elevated. However, in fully recovered patients, bone metabolism markers indicate accelerated bone turnover with an increase in both formation and resorption. Bone formation markers correlated positively with IGF-1 and bone resorption markers negatively with estradiol, indicating that IGF-1 is a major bone formation stimulator, whereas estradiol action predominately inhibits bone resorption.

In patients with AN, the mechanism of bone loss does not appear to be due to an increase in absorption over formation. It is possible that the observed increase in bone remodeling is a mechanism developed in an attempt to restore bone mass. However, the large deficit of calcium in these patients (the loss of exogenous sources due to the deficit in alimentation produces the liberation of bone calcium to maintain the homeostasis of the extracellular fluid) and the deficit in amino acids as a result of fasting make it very difficult to restore bone mass. The best predictors for osteopenia are BMI and the duration of amenorrhea, followed by the duration of regular menses before amenorrhea.

Treatment protocols emphasize the importance of nutritional rehabilitation and recovery. The addition of 1500 mg/day of calcium with vitamin D is recommended and lifestyle counseling with an emphasis on smoking cessation is relevant. The issue of exercise is controversial; for most women, including teens, weight-bearing exercise is an important factor contributing to bone mineral accretion and is more important than calcium intake in adolescent bone health. Hormone replacement therapy with oral contraceptives has been studied as a treatment for osteopenia/osteoporosis; results have been mixed. Some preliminary studies have demonstrated a minor protective effect on bone density of the lumbar spine, whereas others have not.

TREATMENT

An integrated treatment program should be instituted and carried out by a multidisciplinary team, including a pediatrician, endocrinologist, psychiatrist, psychologist, nurse, and possibly others. It is very important that the correct diagnosis is made and that the patient and family are made aware of the importance of the disease and the various aspects of treatment. They should be aware that treatment will necessarily last for a period not less than 5 years.

The role of the physician in the control of this process and the establishment of an adequate relationship with the patient and family is fundamental for successful treatment. Treatment should be on an outpatient basis if the diagnosis was made early, the degree of undernutrition is not too severe, and the mental disturbance is not incapacitating. If this is not the case, the patient must be hospitalized.

Treatment objectives should have a strict priority: prevent the death of the patient, prevent the disease from becoming chronic, and start physical and mental recuperation.

Nutritional Treatment

Refeeding

To successfully begin refeeding, it is fundamental that a therapeutic alliance with the patient be established in which the patient understands and accepts that he or she has a disease. This can be accomplished by asking the patient if he or she has the various signs and symptoms of AN so that, little by little, the patient can identify with this condition.

The physician should use height and weight graphs to explain what percentile the patient is currently in and what the patient's weight should be for his or her age and height. A target weight, acceptable to both the patient and the physician, should be agreed upon. The patient's understanding of caloric requirements to maintain a normal weight should be explored because very few possess knowledge of the appropriate requirements for their height, age, and sex. Patients must understand that their growth and physical activity depend on the adequate intake of calories, including proteins, fats, carbohydrates, and vitamins and minerals.

Obtaining and Maintaining an Adequate Weight

After the target weight has been achieved, a maintenance diet must be prescribed, and intake of foods not on the diet and eating between scheduled meals must be prohibited. This helps the patient overcome the fear of losing control or gaining weight.

Psychological Treatment

Psychotherapeutic help can consist of individual, familial, or group treatment. In AN, the initial phases of psychotherapy consist of helping the patient begin refeeding by alleviating the feelings of guilt of the patient or family. The next step is to treat the overall

psychological well-being of the patient such that eventually the medical problems become secondary. It is fundamental to work with the family using familial therapy or counseling.

Pharmacological Treatment

Psychotropic medication should not be used as the only or principal treatment but, rather, as a prevention of relapse in patients who have gained weight or for treatment of symptoms associated with AN, such as depression or obsessive-compulsive behavior. A variety of substances have been used to treat AN because it is basically unresponsive to pharmacological treatment.

PROGNOSIS AND EVOLUTION

The normal evolution of AN consists of cycles of recuperation and relapse even in the best controlled cases, and the evolution rarely lasts less than 2 or 3 years. Approximately 50% of AN patients achieve total recuperation, whereas 20% have residual problems and 30% become chronic. The mortality rate is between 0.5 and 1% per year of observation. The most frequent causes of death are severe undernutrition, gastrointestinal complications, infections, and suicide. With prolonged follow-up, the mortality rate increases slightly (up to 20% for patients older than 20 years of age).

CONCLUSION

The Academy Pediatric Association recommends a multidisciplinary treatment. The team should include a medical physician, dietician, and psychiatrist/psychologist. Evidence suggests that there is a hypothalamic dysfunction in patients with AN, and in general this normalizes with weight recovery. Disturbances in neurotransmitter, neuropeptide, and neuroendocrine systems have been reported in acutely ill patients and in patients during follow-up.

Due to scarce macro- and micronutrients, intact nonvital processes that increase energy output and are not necessary for survival, such as growth, pubertal development, and reproduction, are shut down until the nutritional situation improves. Early implementation of appropriate psychological and nutritional therapy and the best treatment for osteopenia/osteoporosis in these patients is necessary. The subtypes of AN and BMI at follow-up are the best

predictors of bone mineral density, and leptin may play an important protective role in bone metabolism.

Analysis of the genetic mechanisms underlying weight regulation is progressing rapidly. The genetic analysis of AN may help to define new drug targets and therefore lead to new treatment strategies.

The prognosis for adolescents with eating disorders is favorable. With early and aggressive treatment, most adolescents with AN recover, as demonstrated by a number of long-term follow-up studies at adolescent medicine centers.

Anti-Müllerian Hormone

Nathalie Josso and Nathalie di Clemente
Unite INSERM 693, Clamart, France

Glossary

activin receptor-like kinases (ALKs) ALKs act as signaling (type I) receptors for the transforming growth factor- β (TGF- β) family. They may be involved in the signaling pathway of several ligands [e.g., bone morphogenetic proteins (BMPs) and anti-Müllerian hormone (AMH)].

bone morphogenetic proteins (BMPs) Members of the TGF- β family; they are involved in many morphogenetic processes, namely cartilage and gonadal differentiation.

GATA-4 Members of the GATA family of proteins (GATA-1–6) recognize a consensus sequence on DNA due to conserved zinc fingers in their DNA-binding domain. They play important roles in erythroid cell differentiation. GATA-4 is abundantly expressed in the Sertoli cells of the differentiating testis and binds to the AMH promoter through a conserved proximal element.

high-mobility group (HMG) A 79-amino acid DNA-binding domain shared by SOX proteins and SRY.

Müllerian ducts Precursors of the uterus, Fallopian tubes, and upper part of the vagina; the main target organ of AMH.

Smad proteins Smad proteins are a family of intracellular signal mediators for members of the TGF- β family. They are classified into three broad categories. Receptor-specific Smads bind specifically either to type I receptors of TGF- β or activin (Smads 2 and 3) or to members of the BMP family (Smads 1, 5, and 8). After activation by their specific type I receptor, they bind to a co-Smad (Smad-4) and enter the nucleus to modulate gene transcription. Inhibitory Smads, Smads 6 and 7, prevent the activation of receptor-specific Smads.

SOX-9 Members of the SOX gene family are critical transcription factors for many developmental processes. SOX-9 is a key regulator of cartilage and testis development; mutations in humans lead to a malformative syndrome known as campomelic dysplasia and to gonadal aplasia in XY subjects. SOX-9 is a powerful activator of AMH transcription.

steroidogenic factor-1 (SF-1) Also known as Ad4BP, SF-1 is an orphan nuclear receptor that activates AMH transcription. It also activates P450 steroid hydroxylases and aromatase. In its absence, gonads, adrenals, the pituitary, and the hypothalamus do not develop normally.

Anti-Müllerian hormone, also called Müllerian inhibiting substance, is a member of the transforming growth factor- β family, whose main effect is the initiation of regression of the Müllerian ducts in the male fetus.

INTRODUCTION

Anti-Müllerian hormone (AMH), also known as Müllerian inhibiting substance, is a “sexually specialized” member of the transforming growth factor- β (TGF- β) family in the sense that it is expressed exclusively by gonadal somatic cells and that its effects are targeted to the gonads and reproductive tract. Its main biological effect, the inhibition of Müllerian duct development in male fetuses, represents the first

step of phenotypic male sex differentiation. Müllerian ducts are sensitive to AMH only during a short developmental window, before 8 weeks in the human fetus.

The existence of a specific factor dedicated to Müllerian regression was predicted in 1953 by Alfred Jost, who proposed that the fetal testis has a dual hormonal secretion: testosterone, responsible for the virilization of Wolffian ducts and external genitalia, and a second hormone, responsible for Müllerian regression (Fig. 1), that was identified and purified only many years later. AMH inhibits meiotic prophase maturation and the growth of the fetal ovary, in which it sometimes induces the differentiation of structures resembling seminiferous tubules. AMH also has effects postnatally. In the male, it inhibits the differentiation and function of Leydig cells; in

Figure 1 (Right) The role of AMH in fetal sex differentiation. AMH, secreted by fetal Sertoli cells, binds to an AMH receptor located on the membrane of target organs and induces the regression of Müllerian ducts, which would otherwise give rise to the uterus. (Left) The effect of testosterone secreted by Leydig cells. After binding to the androgen receptor, testosterone induces the differentiation of male excretory ducts and masculinizes the penis and urogenital sinus after reduction to DHT.

the female, it inhibits follicular maturation and breast cancer cell growth. However, the postnatal effects of AMH are not crucial because testicular or ovarian functions are not disrupted by mutations of AMH or its receptors.

BIOCHEMISTRY AND MOLECULAR BIOLOGY OF AMH AND ITS RECEPTORS

AMH is a 560-amino acid glycoprotein formed by two 70-kDa monomers linked by disulfide bonds. The hormone is cleaved at a proteolytic site 109 amino acids upstream of the C terminus, yielding a short bioactive C-terminal domain with homology to other members of the TGF- β family and a long N-terminal prodomain with no bioactivity of its own but which enhances the bioactivity of the C terminus.

The human AMH gene was cloned in 1986. It is located on the tip of the short arm of chromosome 19, band p13.3. Only 2.75 kilobase pairs (kbp) in length, it contains five exons; the 3'-end of the fifth one is particularly GC rich and codes for the bioactive C-terminal domain. The 200-bp minimal promoter is flanked by a housekeeping gene, *SAP-62*, coding for a spliceosome, and contains binding sites for various transcription factors (Fig. 2).

In keeping with its status as a TGF- β family member, AMH signals through two membrane bound receptors, both with serine/threonine kinase activity. Paradoxically, receptor type II is the primary

receptor; it binds to AMH and then recruits the signaling, so-called type I, receptor. The gene for the type II receptor, AMHR-II, cloned in 1994, is AMH specific; it is divided into 11 exons, has a molecular mass of 82 kDa, and maps to chromosome 12q13. Based on evidence obtained from different tissues and cell lines, it is believed that three type I receptors—ALK2,-3, and-6—involved in the signaling pathway of the bone morphogenetic protein (BMP) family also function as AMH type I receptors. As expected, all three signal through the BMP receptor-specific Smad molecules 1, 5, and 8 (Fig. 3).

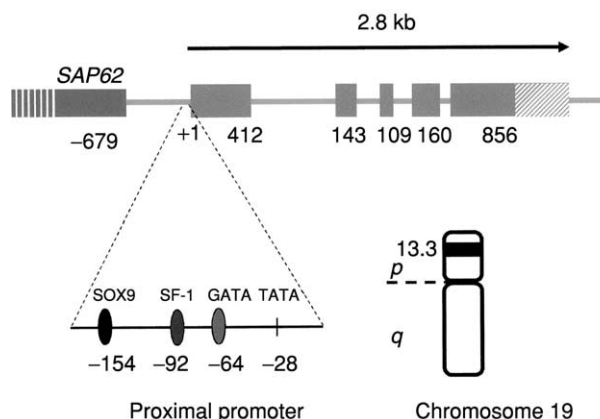

Figure 2 The AMH gene. The 3'-end of exon 5 (hatched) codes the 109-amino acid biologically active C terminus. The 200-bp promoter contains binding sites for transcription factors and is adjacent to a housekeeping gene, *SAP62*. AMH maps to chromosome 19 p13.3.

Figure 3 AMH signal transduction. AMH binds to autophosphorylating receptor type II (AMHR-II), which then recruits a type I receptor, ALK 2, 3, or 6. The complex transiently binds and phosphorylates a receptor-specific Smad (1, 5, or 8), which then binds to a common Smad (co-Smad), Smad 4. The receptor-specific and co-Smad then enter the nucleus and bind to the promoter of target genes with the help of cofactors and transcription factors.

EXPRESSION AND REGULATION

In the male, AMH is produced in large amounts by Sertoli cells just prior to the differentiation of fetal seminiferous tubules until puberty (Fig. 4). In sexually mature individuals, Sertoli cells continue to synthesize small amounts of AMH; after puberty, however, the hormone is preferentially secreted toward the lumen of the seminiferous tubule. Because of the formation of the blood–testis barrier, AMH concentration is higher in the seminal plasma than in serum. AMHR-II is expressed in the mesenchymal cells surrounding the fetal Müllerian duct, in Sertoli cells, and, to a lesser degree, in Leydig cells.

In the female, low amounts of AMH and AMHR-II are coexpressed by granulosa cells of preantral and small antral follicles. Expression decreases slightly as follicle maturation progresses. When follicles disappear from the ovary at the end of reproductive life, AMH is no longer detectable in serum.

The chronological expression of AMH is tightly regulated. In the male, it is essential that the hormone be produced during the short window of Müllerian responsiveness. Several transcription factors—*SOX-9* (a member of the high-mobility group gene family), steroidogenic factor-1, and *GATA-4*, all of which are expressed in the developing testis but not the ovary—bind to response elements on the AMH promoter (Fig. 2) and cooperate to trigger the early initiation of AMH transcription in the testis. After birth, AMH is regulated positively by follicle-stimulating hormone (FSH) and negatively by androgens. During puberty, when Leydig cells begin to produce testosterone, the

expression of AMH by Sertoli cells is repressed, provided normal androgen receptors are present. In their absence, the stimulatory influence of FSH becomes apparent.

In the female, initiation of AMH expression begins as soon as follicle maturation reaches the preantral stage, either after birth or in the last weeks of pregnancy. Little is known, however, about the mechanism of regulation.

Figure 4 Serum AMH in postnatal life measured by ELISA. Serum AMH can be measured by ELISA in both sexes. In the human male, serum AMH is high until puberty, except in the first month of life. It decreases slowly until puberty, when its serum concentration is inversely correlated to pubertal maturation. In the adult male, serum AMH is very low or undetectable. In the female, serum AMH is very low and becomes undetectable after menopause.

AMH IS A MARKER OF GONADAL FUNCTION

AMH is produced postnatally by the gonad of both sexes; ascertainment of its serum level is useful to assess gonadal function.

Testicular Function

Seminiferous Tubule Function in Prepubertal Subjects

AMH is expressed constitutively by prepubertal Sertoli cells. It follows that its circulating level reflects the presence and function of seminiferous tubules, with no need for prior stimulation by chorionic gonadotropin (Fig. 4). Pediatric endocrinologists assay serum AMH in children with impalpable testes to discriminate between anorchia and bilateral cryptorchidism and in patients with ambiguous genitalia to distinguish testicular dysgenesis from disorders affecting testosterone synthesis or sensitivity.

Androgen Action

Normally, AMH is down-regulated by testosterone produced by Leydig cells during puberty. A significant reduction of serum AMH is observed when testosterone concentration reaches 7 nmol/ng/liter. If testosterone is not synthesized or if the androgen receptor is abnormal, not only does serum AMH fail to decrease but also it increases higher than normal childhood levels because FSH is now produced and stimulates AMH transcription in Sertoli cells. Serum AMH may also be used as a sensitive marker for the effectiveness of medication inactivating the androgen receptor, such as cyproterone acetate.

Azoospermia

In oligospermic adult males, the level of AMH in seminal fluid is correlated with sperm concentration. In patients with nonobstructive azoospermia, it is higher if spermatozoa are detectable in a testicular biopsy. Thus, it may aid in predicting the success of an intracytoplasmic sperm injection procedure.

Adult Ovarian Function

In women, serum AMH reflects the function and number of granulosa cells. Between birth and menopause, serum AMH levels are less than 75 pmol/liter or may be undetectable. This is always the case after natural menopause or ovariectomy (Fig. 5).

Figure 5 Serum AMH in women with or without granulosa cell tumors. In normal women, serum AMH is low (<75 pmol/liter) or undetectable. It is always undetectable after menopause. In women with an active recurrence of a granulosa cell tumor, serum AMH is very high except during remission. Serum AMH is a sensitive marker of granulosa cell tumor recurrence, preceding the emergence of clinical symptoms.

Granulosa Cell Tumors

Granulosa cell tumors are relatively rare, but they tend to recur after treatment. Serum AMH is a sensitive and early marker of evolutive granulosa cell tumors (Fig. 5) and allows the detection of recurrence before clinical signs become evident.

Assessment of Ovarian Reserve: Application to *In Vitro* Fertilization

Studies of the human ovary suggest a correlation between the stock of resting primordial follicles (ovarian reserve) and the number of small growing follicles. No markers of the former exist, but because AMH is produced exclusively by small preantral follicles, it has been used as a marker of the depletion in follicle stock associated with ovarian aging. Serum AMH has also been shown to be a predictive factor for the number of oocytes retrieved during an *in vitro* fertilization procedure. In contrast, serum AMH is elevated in women with polycystic ovary syndrome.

Persistent Müllerian Duct Syndrome: Mutations of AMH and the AMH Receptor Gene

Persistent Müllerian duct syndrome is a rare intersex condition that is transmitted in an autosomal recessive mode and characterized by the persistence of uterus and Fallopian tubes in otherwise normally virilized genetic males. The condition is discovered at surgery performed for cryptorchidism and/or inguinal hernia. Genetic analysis (Fig. 6) usually reveals mutations of either the AMH gene, associated with a very low or

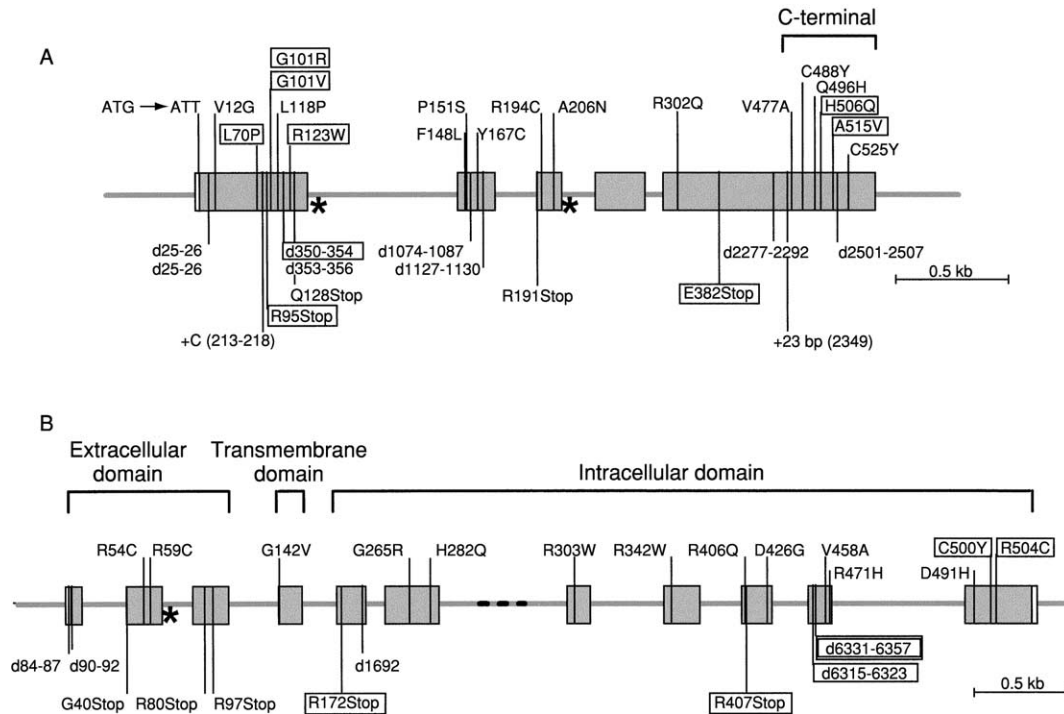

Figure 6 AMH and AMHR-II mutations in the persistent Müllerian duct syndrome. Missense mutations are shown above the gene; insertions or deletions, usually leading to a stop codon, are shown below. Splice mutations are indicated by an asterisk. Boxed mutations are those found in more than one family. (A) AMH gene mutations. Mutations affect all exons, especially the 3'-end of exon 5, which codes the bioactive C-terminal fragment, and the 3' half of exon 1. Most mutations are restricted to a given family. (B) AMHR-II mutations. Again, the mutations are spread more or less evenly along the gene. Many mutations are specific for a given family; with the exception of the deletion between bases d6331 and d6357, which is found in the homozygous or heterozygous state in approximately half of patients with an AMHR-II mutation.

undetectable serum AMH concentration, informative only before puberty, or the type II AMH receptor (AMHR-II), associated with normal serum AMH levels. The proportion of AMH and AMHR-II mutations is approximately equal. The goal of treatment should be the preservation of fertility. This involves replacement of the testes in the scrotum and requires careful partial resection of the Müllerian ducts. The uterus should never be removed *in toto* because the male excretory ducts are usually contained in the uterine wall. Women with homozygous mutations of either the AMH or the AMHR-II gene are normal and fertile.

CONCLUSION

Initially associated exclusively with male sex differentiation, AMH has gained recognition as a sensitive marker of gonadal function, useful in pediatric endocrinology, gynecology, and andrology. The availability of a commercial enzyme-linked immunosorbent

assay kit places AMH assay within the reach of the average clinician.

Antiadrenergic Agents

P. A. van Zwieten

University of Amsterdam, Amsterdam, The Netherlands

Glossary

adrenergic nervous system The sympathetic part of the autonomous nervous system, where the neurotransmitters (norepinephrine and epinephrine) are adrenergic.

cholinergic nervous system The parasympathetic part of the autonomic nervous system, where the neurotransmitter (acetylcholine) is cholinergic.

pre/postganglionic Anatomical position of the sympathetic neuron with respect to the ganglion.

pre/postsynaptic Anatomical position of receptors with respect to the synapse/nerve ending.

synapse Anatomic/functional structure allowing the transition of nerve activity from the nerve ending (postganglionic) through the synaptic cleft and toward the target organ (blood vessel, heart, etc.).

Antiadrenergic agents are drugs that suppress the activity of the sympathetic (adrenergic) nervous system, targeting the cardiovascular system and other organs.

INTRODUCTION

The autonomic nervous system is responsible for the homeostasis/regulation of several internal organs, tissues, and metabolic systems. Well-known examples of such targets of the autonomic nerves are the cardiovascular system (heart and blood vessels), the gastrointestinal system (stomach, intestine, biliary duct, etc.), the respiratory tract (lungs and airways), and glucose/lipid metabolism.

The autonomic nervous system is subdivided into the sympathetic and parasympathetic systems. The sympathetic or adrenergic system is activated with the purpose of adapting the individual organism for “flight, fright, or fight”—that is, the short-term availability and release of energy and alertness. In contrast, the parasympathetic nervous system facilitates the

storage of energy and metabolic components to allow the release of energy in a situation of flight, fright, or fight. As such, the sympathetic and parasympathetic systems counteract each other’s activities in a sort of “yin-yang” balance. Activation of the sympathetic nervous system implies the stimulation of the cardiovascular system, thus increasing heart rate, cardiac output, cardiac contractility, and blood pressure. During sympathetic stimulation, the activity of the gastrointestinal system is attenuated. Stimulation of the parasympathetic system implies the activation of the digestive system, particularly the gastrointestinal tract, with the aim of facilitating the storage of energy. During parasympathetic activation, the cardiovascular system’s activity is reduced.

Both the sympathetic and parasympathetic systems are subject to modulation by the central nervous system, particularly the brainstem. However, higher (cortical) brain centers can also modulate both subgroups of the peripheral autonomic nervous system.

Several diseases are associated with dysregulation of either subgroup of the autonomic nervous system. Relevant examples of this pathophysiological involvement particularly concern the sympathetic nervous system, which is known to be overactive in important cardiovascular derangements or diseases, such as hypertension, congestive heart failure, or cardiac tachyarrhythmia. For this reason, a vast body of research has accumulated with the aim of finding drugs that can attenuate the hyperactivity of the sympathetic nervous system. Drugs with such activity are called antiadrenergic agents.

SYMPATHETIC (ADRENERGIC) NERVOUS SYSTEM AND ITS RECEPTORS

The brainstem, consisting predominantly of the pons/medullary region, controls the peripheral sympathetic nervous system (Fig. 1). The peripheral sympathetic nervous system contains a kind of relay station called

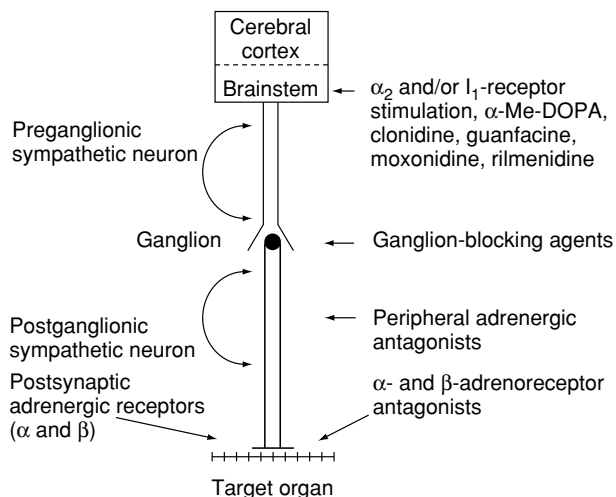

Figure 1 Schematic representation of the sympathetic (adrenergic) nervous system. Adrenergic structures and receptors in the brainstem modulate the activity of the peripheral sympathetic nervous system. The targets of all relevant antiadrenergic drugs are shown. Virtually every structure/receptor of the system can be manipulated selectively by drugs.

the sympathetic ganglion. Transmission in the ganglion is performed by the neurotransmitter acetylcholine (ACh), which targets the nicotine-like ACh_x

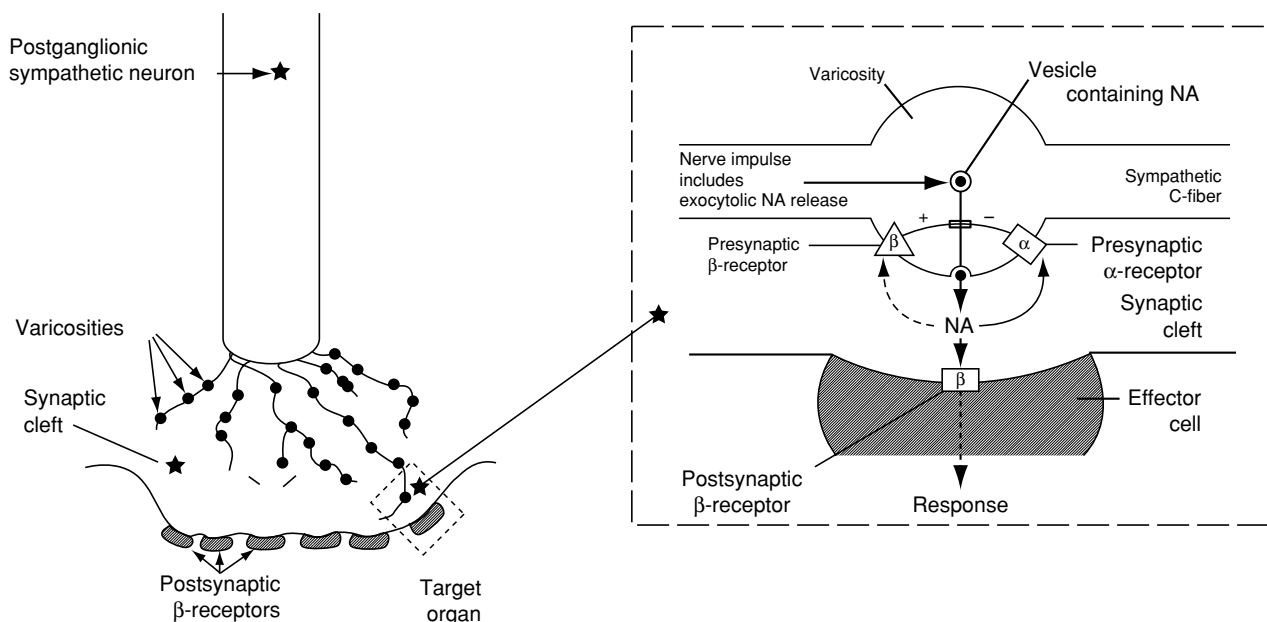

Figure 2 Schematic representation of a sympathetic (adrenergic) synapse. Nerve activity releases the endogenous neurotransmitter from the varicosities at the nerve endings. Stimulation of postsynaptic α -adrenoceptors causes a physiological/pharmacological effect (e.g., vasoconstriction). Blockade of the α -adrenoceptor (postsynaptic) counteracts the effect of norepinephrine. Stimulation of presynaptic α -adrenoceptors inhibits the release of the neurotransmitter. Conversely, presynaptic α -receptor blockade stimulates the release of the neurotransmitter.

receptors. Peripheral sympathetic neurons are subdivided into pre- and postganglionic types according to their anatomical position with respect to the ganglion.

The sympathetic activity is transferred from the postganglionic neuron to the target organ (e.g., the heart or a blood vessel). The anatomical transition structure required for this process is called the synapse (Fig. 2). The process of humoral neurotransmission within the synapse occurs as follows: The neurotransmitter norepinephrine (NE; also called noradrenaline) is released from the postsynaptic nerve ending, diffuses through the synaptic cleft, and then binds to the receptors in the target organ. The receptor thus activated mediates a physiological/functional process (e.g., constriction of a blood vessel) or an increase in cardiac frequency or contractility.

The receptor in the target organ is activated by the endogenous neurotransmitter NE but also by synthetic drugs, such as methoxamine, phenylephrine, and isoprenaline, that imitate the effects of NE. These activator drugs are called sympathomimetic agents. They are agonists with respect to the receptor.

Antagonists are chemical compounds that block the stimulating effect of NE (the neurotransmitter) and that of sympathomimetic agents. The antagonist or blocker binds to the receptor, thus preventing the stimulating effect of the endogenous neurotransmitter

Table I Functional Effects of the Stimulation/Blockade of α -Adrenoceptors by an Agonist and an Antagonist

| Receptor | Stimulation by an agonist causes | Blockade by an antagonist (blocker) causes |
|---------------------------------------|---------------------------------------|--|
| α_{1A} | Vasoconstriction | Vasodilation |
| α_{1A} (prostate) | Contraction | Smooth muscle relaxation |
| α_2 (postsynaptic) vascular | Vasoconstriction | Vasodilatation |
| α_2 (presynaptic) | NE release↓ | NE release↑ |
| α_2 (brainstem) | Sympathoinhibition Blood pressure↓ | |

NE. In the sympathetic nervous system, the receptor antagonists are also called antiadrenergic agents.

The sympathetic or adrenergic receptors are subdivided into a variety of subtypes. α -Adrenoceptors are predominantly located in blood vessels but also in the brainstem. β -Adrenoceptors are mainly present in various structures of the heart but also in the bronchi. In a later stage, there is a further subdivision into α_1/α_2 and $\beta_1/\beta_2/\beta_3$. The functional roles of the most important α - and β -adrenoceptors are summarized in Tables I and II. The tables also note the effects of stimulation by an agonist and the effects of blockade by an antagonist.

The α -adrenoceptors in the brainstem deserve special attention. These receptors in the pons/medulla region are involved in the central nervous regulation of the cardiovascular system, particularly that of blood pressure. The receptors belong to the α_2 subpopulation. Their stimulation by an agonist causes sympathoinhibition in the periphery, resulting in a reduced release of NE from the nerve endings and a decrease in blood pressure. These central α_2 -adrenoceptors are also the target of centrally acting antihypertensives, such as clonidine and α -methyl-DOPA (through its active metabolite α -methylnorepinephrine).

ANTIADRENERGIC AGENTS

As illustrated in Fig. 1, virtually any structure or receptor of the sympathetic nervous system can be

modulated more or less selectively by antiadrenergic drugs. Several of these drugs play a role (or have played a role) as therapeutic agents in the treatment of cardiovascular or respiratory diseases.

α -Adrenoceptor Antagonists (α -Blockers)

Competitive inhibition of α -adrenoceptors by appropriate antagonists predominantly causes vasodilatation and a reduction of blood pressure, particularly in hypertensive patients. Doxazosin and prazosin are the prototypes of α -blockers. They are selective for the postsynaptic α_1 -adrenoceptor subtype: This means that presynaptic α_2 -adrenoceptors are not blocked, thus preventing the enhanced release of NE from the sympathetic nerve endings (Fig. 2). Nonselective, older α -blockers, such as phentolamine or phenoxybenzamine, are no longer used because they are poorly tolerated.

Doxazosin and prazosin are moderately effective antihypertensive drugs. Orthostatic hypotension, headache, and reflex tachycardia are well-known adverse reactions, which are caused by vasodilation (also in the venous blood vessels).

A few newer α -adrenoceptor antagonists display a certain degree of selectivity for the α_{1A} -receptor in the smooth muscle of the prostate. These agents cause relaxation of this smooth muscle tissue and hence facilitate urinary flow in patients with benign prostate

Table II Functional Effects of the Stimulation/Blockade of β -Adrenoceptors by an Agonist and an Antagonist

| Receptor | Stimulation by an agonist causes | Blockade by an antagonist causes |
|-----------------------|--|--|
| β_1 (cardiac) | Heart rate↑ Contractility↑ A-V conduction↑ | Heart rate↓ Contractility↓ A-V conduction↓ |
| β_2 (vascular) | Vasodilatation | Vasoconstriction |
| β_2 (bronchi) | Bronchodilatation | Bronchoconstriction |
| β_2 (metabolic) | Blood glucose↑ | Blood glucose↓ |

hyperplasia (BPH). Alfuzosine, terazosin, and tamsulosin are examples of such agents.

β -Adrenoceptor Antagonists (β -Blockers)

β -Adrenoceptor antagonists are competitive inhibitors of the effects of endogenous catecholamines (norepinephrine and epinephrine) at the level of β -adrenoceptors in various tissues. In clinical medicine, they are widely used in the treatment of hypertension, angina pectoris, supraventricular tachyarrhythmias, congestive heart failure, and as secondary prevention following myocardial infarction. Their main therapeutic activity is to counteract the detrimental effects of catecholamines released by the hyperactive sympathetic nervous system.

Well-known adverse reactions are bronchoconstriction, cold hands and feet (caused by peripheral vasoconstriction), and sleep disturbances. The therapeutic actions are all mediated by the blockade of β_1 -adrenoceptors, whereas blockade of β_2 -adrenoceptors is the cause of most of the side effects. For this reason, β_1 -selective blockers are preferable. Atenolol, bisoprolol, and metoprolol are examples of β_1 -selective blockers. Newer β -blockers, such as carvedilol, celiprolol, and nebivolol, contain an additional vasodilator component that may offer a hemodynamic advantage.

Postganglionic Neuron Blockers

The electrical membrane activity in postganglionic neurons can be blocked (via the inhibitory influx of Na^+ ions) by drugs such as guanethidine, cyclazene, and bretylium. Although they are effective blood pressure-lowering drugs, these agents have been abandoned because of their poor tolerability.

Ganglion Blocking Drugs (Ganglioplegic Agents)

These agents are competitive blockers of the ACh_n receptors in the sympathetic and also the parasympathetic ganglia. Ganglionic blockade in the sympathetic ganglia accounts for their effective lowering of blood pressure, particularly in hypertensive patients. Pentamethonium, hexamethonium, and trimetaphan are examples of ganglioplegic agents. These agents have been abandoned as therapeutics because of their low tolerability, which is partly due to the blockade of the parasympathetic ganglia.

Rauwolfia Alkaloids

For the sake of completeness, I briefly mention these older drugs, which have lost their importance as therapeutics because of their poor tolerability. Reserpine and related alkaloids (from *Rauwolfia serpentina*) destroy the storage sites (granules) of norepinephrine in the sympathetic nerve endings and hence impair the function of the sympathetic system. Although reasonably effective blood pressure-lowering agents, their adverse reactions preclude their use in the treatment of hypertension.

Centrally Acting Antihypertensives

α -Adrenoceptors present in the pontomedullary region of the brainstem (e.g., the nucleus tractus solitarius and the vasomotor center) will cause peripheral sympathoinhibition when stimulated with endogenous norepinephrine and also centrally acting antihypertensives.

Clonidine, guanfacine, and α -methyl-DOPA (through its active metabolite α -methylnoradrenaline) are α_2 -adrenoceptor agonists and, accordingly, cause peripheral sympathoinhibition and the reduction of elevated blood pressure in hypertensive patients. The centrally acting drugs are effective antihypertensives, and their mode of action appears to be attractive on hemodynamic grounds. Their adverse reactions are unpleasant (sedation, dry mouth, and male sexual impotence). These side effects are also mediated by α_2 -adrenoceptors (although not located in the brainstem) and thus it is virtually impossible to develop drugs with the same mode of action as clonidine, etc., but with a better profile of adverse reactions.

Imidazoline (I_1) receptors in the brain (in the ventrolateral medulla) have been identified as targets for centrally acting drugs. Stimulation of central I_1 receptors also causes peripheral sympathoinhibition and lowering of blood pressure. Newer drugs causing this effect are moxonidine and rilmenidine, which display lower affinity for α_2 -adrenoceptors than clonidine or α -methyl-DOPA. It is hoped that these newer agents display a better tolerability.

THERAPEUTIC USE OF ANTIADRENERGIC DRUGS

Essential Hypertension

A subtle association between essential hypertension and hyperactivity of the sympathetic nervous system has been repeatedly demonstrated. On the other hand,

the treatment of hypertension was initially based on the use of various antiadrenergic drugs, which seems a rational approach. Other types of drugs have been introduced, such as diuretics, calcium antagonists, and suppressants of the renin–angiotensin system (ACE inhibitors and AT₁ blockers).

β-Blockers continue to be widely used in antihypertensive treatment, and this approach is supported by numerous clinical trials and a meta-analysis. α-Blockers, particularly doxazosin, have obtained a moderate position in antihypertensive treatment, which is not clearly supported by evidence on an epidemiological scale.

Centrally acting agents such as clonidine and α-methyl-DOPA have been largely abandoned because of their poor tolerability. This approach may be somewhat improved by the introduction of the imidazoline agonists (moxonidine and rilmenidine), but the clinical follow-up for the use of these agents is insufficient. Rauwolfia alkaloids, postganglionic neuron blockers, and ganglioplegic agents have been abandoned because of their poor tolerability.

Angina Pectoris

Stable angina pectoris is routinely treated with a variety of anti-ischemic drugs in addition to invasive interventions for revascularization, such as balloon dilatation of a stenosis, or cardiac surgery. Nitroglycerin and other nitrates are used for the treatment of acute symptoms. β-Blockers are first choice for long-term treatment, unless contraindications preclude the use of these drugs. The reduction in heart rate is the major basis of the anti-ischemic action of β-blockers, thus reducing myocardial oxygen consumption. Calcium antagonists, long-acting nitrates, low-dose aspirin, and a statin are usually included in the treatment schedule.

Secondary Prevention after Myocardial Infarction

Recurrent infarction and/or sudden death after myocardial infarction (MI) are major risks in post-MI patients. β-Blockers have been demonstrated to be significantly protective against these risks, probably as a result of their antiarrhythmic activity, which protects against the toxic effects of endogenous catecholamines released by the sympathetic system.

Supraventricular Tachyarrhythmia

The antisymphathetic effects of β-blockers explain their antiarrhythmic potency in the treatment of supraventricular tachyarrhythmia. Sotalol, frequently used as an antiarrhythmic agent, is a β-blocker with additional antiarrhythmic potency because of its class III (Vaughan–Williams' classification) activity.

Congestive Heart Failure

β-Blockers are recognized as beneficial therapeutics in the management of congestive heart failure (CHF). CHF is usually accompanied by sympathetic overactivity, which is detrimental for the decompensated heart. β-Blockers counteract this process. Inotropic activity of the β-blocker that is too negative can be avoided by uptitrating the dose over a period of 3 weeks. Beneficial activity in CHF has been demonstrated for carvedilol, bisoprolol, and metoprolol. β-Blockers are applied when treatment with ACE inhibitors and diuretics is not successful.

Glaucoma Simplex

In patients with glaucoma simplex (open-angle glaucoma), intraocular pressure can be lowered by the topical application of β-blockers such as timolol. The therapeutic activity is based on reduction of the production of aqueous humor.

Benign Prostate Hyperplasia

The moderately beneficial effect of α_{1A}-blockers in the symptomatic treatment of BPH was mentioned previously. Drugs used for this purpose are alfuzosine, terazosin, and tamsulosin. Hypotension is a side effect of these agents.

Antithyroid Drugs

Anthony D. Toft

Royal Infirmary, Edinburgh, United Kingdom

Glossary

Graves' disease The most common cause of hyperthyroidism, accounting for approximately 75% of cases and resulting from the inappropriate production of thyrotropin-receptor antibodies, which stimulate the thyroid gland to secrete excessive quantities of thyroxine and triiodothyronine.

hyperthyroidism (thyrotoxicosis) The clinical condition arising from sustained raised concentrations of thyroxine and/or triiodothyronine in the circulation. With rare exceptions (e.g., thyrotropin-secreting pituitary tumor), serum thyrotropin concentrations are low.

thionamides A group of antithyroid drugs comprising carbimazole, its active metabolite, methimazole, and propylthiouracil. Their main action is to inhibit the iodination of tyrosyl residues in thyroglobulin, one of the early stages of thyroid hormone synthesis.

The antithyroid drugs are principally used in the management of hyperthyroidism of Graves' disease. The antithyroid drugs carbimazole, methimazole, and propylthiouracil are heterocyclic compounds known as thionamides that contain a thiourylene group.

INTRODUCTION

Carbimazole (CBZ) is immediately metabolized in serum to methimazole (MMI), and it has been calculated that 10 mg of CBZ yields 6 mg of MMI. All the antithyroid drugs are rapidly and almost completely absorbed from the gastrointestinal tract, with peak serum concentrations at 1 or 2 h. Antithyroid drugs are actively transported into the thyroid, where they inhibit the synthesis of triiodothyronine (T_3) and thyroxine (T_4), principally by interfering with the iodination of tyrosine by serving as preferential substrate for the iodinating intermediate of thyroid peroxidase. Oxidized iodine is thus diverted from the tyrosyl iodination sites in thyroglobulin. The iodinated antithyroid

drugs are desulfurated and further oxidized to inactive metabolites. In addition, propylthiouracil (PTU) inhibits T_4 to T_3 conversion, but this is of little clinical significance other than perhaps in the management of thyrotoxic crisis, when it is important to lower the raised serum T_3 concentration as quickly as possible. There is also evidence that the thionamides have an immunosuppressive action, but any effect is short-lived because patients with Graves' hyperthyroidism frequently relapse after drug withdrawal.

Historically, CBZ has been the drug of choice in the United Kingdom, but MMI has been the drug of choice in all other areas of the world. PTU is also widely employed in the Americas but elsewhere tends to be restricted to use during pregnancy and breastfeeding and in patients who have reacted adversely to CBZ or MMI.

PHILOSOPHY OF TREATMENT OF GRAVES' DISEASE

Each of the treatments for Graves' disease is effective but none is perfect, and the conclusions of Hershman and colleagues in the 1960s remain valid today, namely that the experience with antithyroid drugs, thyroidectomy, and radioiodine have not provided clear-cut criteria that can be used to select the best treatment for individual patients. A course of antithyroid drugs is appropriate for the minority of patients in whom a single episode of hyperthyroidism is followed by prolonged remission (30%). The majority, however, have a relapsing and remitting course over many years, and efforts to predict the natural history of the hyperthyroidism in most patients at diagnosis, using biochemical and immunological markers, have proved disappointing. On a group basis, a small goiter, a low serum concentration of thyrotropin-receptor antibodies (TRAbs), and older age favor remission after a course of antithyroid drugs, whereas the risk of relapse in a young male with severe hyperthyroidism and a large vascular goiter is so high that most would advocate surgery as the primary treatment. Similarly, a

patient with a high concentration of TRAbs, significant ophthalmopathy, and pretibial myxoedema at the end of a course of antithyroid drugs is unlikely to remain in remission for very long.

Because of the difficulty in determining the future pattern of the hyperthyroidism, treatment remains empirical and is inevitably influenced by the prejudices of the physician and the patient and by the expertise locally available, such as provided by nuclear medicine facilities and an experienced thyroid surgeon.

Management varies from center to center and between countries such that the preferred treatment of a 43-year-old female presenting with hyperthyroidism of moderate severity who did not plan further pregnancy was antithyroid drugs (77%) by European physicians but iodine-131 (69%) by their North American counterparts. There was an even greater contrast in choice of therapy when the index case was that of a 19-year-old female. One-third of physicians in the United States regarded iodine-131 as most appropriate, whereas only 4% of physicians in Europe thought it was most appropriate.

Frustration caused by the failure to target antithyroid therapy more specifically and by the gradual acceptance that iodine-131 is neither carcinogenic nor teratogenic has led to a move during the 10 years since the previously discussed survey was performed to advocate the more liberal use of radioactive iodine, irrespective of age. However, there remain anxieties among the public about irradiation in general.

Antithyroid drugs are not normally indicated in the treatment of toxic nodular goiter, unless they are used to render the patient euthyroid prior to surgery since recurrence of hyperthyroidism is invariable after drug withdrawal. There is no role for antithyroid drugs in subacute or postpartum thyroiditis, in which the thyrotoxicosis is due to the release of preformed thyroid hormones.

DURATION OF TREATMENT

The conventional period of antithyroid drug therapy is best viewed as a method by which those destined to have a single short-lived episode of hyperthyroidism are identified and destructive therapy with iodine-131 or surgery avoided. Remission rates vary slightly, depending on the iodine status of the population, but approximately 50% remain in remission after 2 years of follow-up. The percentage is significantly less after only 6 months of treatment and is not improved by prolonging therapy for up to 3 years. Relapse can occur at any stage but is most common in the first 2 years.

Long-term treatment with antithyroid drugs is appropriate, however, in patients with underlying autonomous thyroid function (Graves' disease or nodular goiter) in whom hyperthyroidism has been precipitated by amiodarone and in whom chronic treatment with the antidysrhythmic drug is planned because iodine-131 is likely to be ineffective.

DOSAGE

Methimazole is available as 5- and 10-mg tablets and CBZ as 5- and 20-mg tablets. The initial dose is 20–30 and 30–40 mg daily, respectively, depending on the severity of the hyperthyroidism (Fig. 1). Once-daily dosage is appropriate in all but the most severely thyrotoxic patients, who benefit from a twice-daily regimen. After 3 or 4 weeks, the dose of MMI can be reduced to 10–20 mg daily and that of CBZ to 20–30 mg daily. Further adjustment should be made on the basis of measurements of serum concentrations of T_3 , T_4 , and thyroid-stimulating hormone (TSH) until a maintenance dose of 5 and 5–15 mg of MMI or CBZ, respectively, is achieved. Some patients can be maintained on as little as 5 mg CBZ on alternate days and, although this may a homeopathic dose, will promptly relapse if the drug is stopped. Patients begin to feel an improvement after 10–14 days. Initial changes in drug

Figure 1 Mean \pm SE serum-free T_4 concentrations during the first 10 weeks of treatment of hyperthyroidism of Graves' disease with either 20 mg (open circles) or 40 mg (closed circles) of CBZ daily. Although patients in both groups were clinically euthyroid by week 10, there seems little point in delaying the reversal of thyrotoxicosis by using the lower dose in the absence of evidence that adverse effects of the thionamides are dose related. Adapted from Page *et al.* (1996).

dosage should be based on thyroid hormone concentrations because delayed recovery of thyrotropes, previously exposed to high levels of T_3 and T_4 in the serum, may result in an inappropriately low serum TSH concentration. After 10–12 weeks of treatment, serum TSH is the best guide for adjustment of the dose, with high and low concentrations indicating excessive and inadequate therapy, respectively.

PTU is available as 50-mg tablets and the starting dose is 100–150 mg three times daily, reflecting its shorter half-life. The maintenance dose is 50–150 mg daily.

Block-and-Replace Therapy

In this regime, the antithyroid drug is continued at the high initial dose after the patient is euthyroid, and hypothyroidism is avoided in the long-term by adding thyroxine at a dose of 100–150 μg daily. The dose of thyroxine, but not that of the antithyroid drug, is adjusted to maintain serum TSH at the lower reference range. This combination has long been thought to be beneficial for patients with significant ophthalmopathy, presumably by avoiding hypothyroidism and possibly also due to the immunosuppressive action of the high-dose thionamide. It is also of value for those with so-called “brittle thyrotoxicosis,” often attributed to poor compliance but now known in some patients to be due to fluctuating concentrations and activities of TRAbs. Remission rates are not improved by standard block-and-replace therapy.

Claims that a negligible relapse rate can be achieved by following block-and-replace therapy for 18 months with thyroxine alone for up to an additional 3 years, thereby “putting the thyroid to rest,” reducing antigen release and TRAb concentrations, have not been substantiated.

ADVERSE REACTIONS

The adverse effects of antithyroid drugs can occur at any time but almost always do so within 3–6 weeks of starting treatment. There is some cross-sensitivity between CBZ or MMI and PTU. Although it is common practice to change to the alternative antithyroid drug in the event of a minor adverse reaction, such as a skin rash, opinion is divided over whether the development of agranulocytosis is an absolute contraindication to further drug therapy.

Life-Threatening Reaction

The most serious adverse reaction is agranulocytosis, which develops in 0.2–0.5% of patients.

Agranulocytosis is characterized by fever, systemic upset, oropharyngeal bacterial infection, and a granulocyte count of less than $0.25 \times 10^9/\text{liter}$. The onset is sudden, and the consensus is that routine monitoring of the white blood cell count serves no purpose. Patients should simply be instructed to contact their medical practitioner immediately in the event of developing a sore throat or mouth ulceration. After stopping antithyroid drug therapy, the white blood cell count returns to normal within 1–3 weeks, during which time the affected patient should be isolated and treated with broad-spectrum antibiotics. Recovery of the white blood cell count may be hastened by the use of granulocyte colony-stimulating factor, but its value in patients with the most profound reduction in granulocyte count ($< 0.1 \times 10^9/\text{liter}$) is unclear. Mild leukopenia with a relative lymphocytosis is common in Graves' disease and is not a contraindication to the use of antithyroid drugs.

Other Reactions

The most common reactions are nausea, loss of taste, headache, and hair loss, which may be self-limiting and do not necessarily require drug withdrawal. The most troublesome is a skin rash, which is usually urticarial and affects 1 to 2% of patients. A migratory polyarthritis may occur alone or in association with the rash and resolves within 4 weeks of stopping treatment. Much rarer adverse effects include cholestatic jaundice, vasculitis (almost exclusively in patients taking PTU, which may be associated with anti-neutrophil cytoplasmic antibody), a lupus-like syndrome, and the nephrotic syndrome.

ADJUNCT TO TREATMENT WITH IODINE-131

Iodine-131 requires approximately 6–8 weeks to be effective, and during this latent period hyperthyroidism may be exacerbated, with an increase in morbidity and even mortality in those with severe thyrotoxicosis and associated cardiovascular disease. For this reason, it is not uncommon not only to render the patient euthyroid before radioiodine treatment but also to continue the antithyroid drug for 6 weeks. The thionamides confer on the thyroid a degree of radioresistance. Unless PTU or MMI (CBZ) is stopped for at least 15 and 2 days, respectively, before and for a similar period after iodine-131 therapy, the cure rate, defined as abolishing hyperthyroidism, is reduced. If it is not clinically possible to discontinue PTU for such a prolonged period in relation to iodine-131 therapy, the dose of isotope should be increased by at least 25%.

ANTITHYROID DRUGS IN PREGNANCY

Maternal hyperthyroidism in pregnancy is usually due to Graves' disease. TRAb crosses the placenta and if the mother is thyrotoxic, it must be assumed that the fetus is similarly affected. Before effective treatment was available, the fetal death rate was as high as 50%. Fortunately, antithyroid drugs also cross the placenta and by careful monitoring of maternal thyroid function, normal fetal development can be achieved, even though cord blood may show evidence of overtreatment. Like other organ-specific autoimmune diseases, Graves' hyperthyroidism tends to improve or even remit during pregnancy. A small dose of antithyroid drug, such as 5 mg MMI daily, will maintain free T₄ and TSH concentrations in the reference ranges. It is good clinical practice to examine the mother every 4 weeks during pregnancy and to stop the antithyroid drug 4 weeks before the expected date of delivery to avoid any possibility of fetal hypothyroidism when brain development is at a maximum. There is evidence that maternal hypothyroidism may cause subtly impaired neuropsychological development in the subsequent offspring. Apart from meticulous control of maternal thyroid function during pregnancy, it is wise for thyrotoxic patients not to become pregnant until stable normal thyroid function has been achieved.

Measurement of the thyrotropin-receptor antibody concentration in maternal serum during the last examination before delivery may be helpful because a high level is a predictor of neonatal thyrotoxicosis. Since thyroid hormones cross the placenta relatively poorly, the block-and-replace regime is not recommended during pregnancy.

Methimazole (CBZ) or Propylthiouracil?

Aplasia cutis congenita (ACC) is a rare disorder of the skin, usually affecting the scalp and less than 3 cm in diameter, that has been reported in a small number of

neonates whose mothers received MMI during pregnancy. ACC has not been reported in association with PTU, which is widely used in North America, and some believe that PTU is the drug of choice during pregnancy or for those planning pregnancy. The consensus, however, is that there is insufficient evidence to establish a direct causal relationship between ACC and MMI. Because MMI (CBZ) and PTU are equally effective in controlling Graves' hyperthyroidism during pregnancy, it makes sense to use the preparation with which one has most experience.

If hyperthyroidism recurs after delivery, is due to Graves' disease and not postpartum thyroiditis, and the mother wishes to breast-feed, PTU is the drug of choice because it is transferred to the milk one-tenth as much as the other thionamides.

Asherman's Syndrome

Theodore A. Baramki and Carolyn J. Alexander
Johns Hopkins University School of Medicine, Baltimore, Maryland, United States

Glossary

amenorrhea The complete absence of menses.

curettage Scraping of the lining of the uterus.

hypomenorrhea Uterine bleeding less than normal in amount.

hysteroqram Radiologic image of the uterine cavity using radio-opaque medium.

hysteroscopy A procedure using an endoscope to visualize the uterine cavity.

missed abortion Nonviable pregnancy that has not been expelled.

placenta accreta Abnormal adherence of part or all of the placenta to the uterine wall.

sonography Imaging using ultrasonic waves.

synechiae Adhesions.

Asherman's syndrome denotes the presence of adhesions or synechiae in the endometrial cavity resulting in infertility or recurrent spontaneous abortions with or without amenorrhea.

INTRODUCTION

In 1948, Asherman described a clinical condition presenting with amenorrhea due to endometrial adhesions that he termed amenorrhea traumatica (atretica). The adhesions may partially or completely obliterate the endometrial cavity, the internal os, or a combination of these areas. The patient may present with amenorrhea, hypomenorrhea, or recurrent spontaneous abortion. The adhesions may be filmy or dense, arising in the center of the endometrial cavity or arising from a side wall and encroaching on the cavity. Histologically, these adhesions are formed of endometrial, myofibrous, or connective tissue.

ETIOLOGY

The most frequent cause of Asherman's syndrome is endometrial curettage for retained products of conception. In addition to curettage, mechanical evacuation methods for elective, incomplete, or missed abortion may lead to synechiae formation. Postpartum instrumentation of an infected uterus represents a significant risk factor for the development of endometrial scarring. Also, endometritis caused by intrauterine devices or pelvic inflammatory disease may lead to synechiae. Endometrial tuberculosis can destroy the endometrium. This can be confirmed by culture of the menstrual discharge or tissue obtained by endometrial biopsy.

Uterine synechiae may also result from myomectomy, cesarean section, or metroplasty. Synechiae are rare after diagnostic curettage.

DIAGNOSIS

The possibility of intrauterine synechiae (Asherman's syndrome) must be considered in individuals who develop amenorrhea following pregnancy-related curettage or endometritis. Despite the amenorrhea, patients will continue to have cyclic changes in the breasts and have a biphasic basal body temperature chart if they are ovulatory.

Hysteroqram with the aid of fluoroscopy can diagnose the extent and location of the synechiae (Fig. 1). The filling defects do not change appearance with extra distension of the uterine cavity or with changes of position of the patient. In case of severe Asherman's syndrome, intravasation of the dye into the venous system is not unusual (Fig. 2). However, careful placement of the tip of the cannula or catheter and avoidance of excessive force when injecting the contrast medium will give a clear picture of the uterine cavity (Fig. 3). With complete obliteration of the uterine cavity, only the cervical canal is visualized (Fig. 4).

Figure 1 Hysterosalpingogram showing partial obliteration of the uterine cavity due to synechiae.

Sonography, especially three-dimensional ultrasound, improves recognition of the uterine anatomy. Sonohysterography may also be helpful in the diagnosis of synechiae. Hysteroscopy gives direct visualization of the texture and extent of the synechiae (Fig. 5) and is a valuable therapeutic tool.

TREATMENT

In the past, uterine adhesions were treated with dilatation and curettage, and postoperative management included an intrauterine device to separate the walls of the uterus while estrogen and antibiotics were being given. Occasionally, a post-treatment hysterosalpingogram was performed to ensure normalization of the cavity. Hysteroscopy now plays a major role in the approach to the diagnosis and treatment of uterine synechiae. The fibrous nature of the lesion and its precise location can be determined. Filmy adhesions

Figure 2 Hysterosalpingogram showing intravasation of dye into the venous system of a uterus involved with marked synechiae. The tip of the cannula does not seem to be free in the uterine cavity.

Figure 3 Hysterosalpingogram of the same patient in Fig. 2 performed at a later date, with proper placement of the cannula, showing the extensive adhesions. Only the left tube is visualized.

Figure 4 Hysterosalpingogram of a patient who developed amenorrhea following postpartum infection. The tenaculum is applied to the cervix at the level of the external os. The cervical canal is visualized with total uterine cavity occlusion (Asherman's syndrome).

Figure 5 Hysteroscopic view of central synechiae showing the lateral recesses.

frequently rupture under the pressure of the distending medium or may be dislodged by the uterine sound, cervical dilator, or the tip of the hysteroscope.

In cases of severe Asherman's syndrome, one can use fluoroscopy to improve the hysteroscopic resection of adhesions. Radio-opaque medium is injected through a 16-Touhy needle through bands of adhesions into pockets of endometrium previously identified by sonography. This technique provides an intraoperative fluoroscopic view of pockets of endometrium behind an otherwise blind-ending endocervical canal in women with severe Asherman's syndrome, allowing guided hysteroscopic division of adhesions and reducing the likelihood of perforation and formation of a false passage. Hysteroscopy with simultaneous laparoscopy can also help prevent, or help make a prompt diagnosis of, uterine perforation. In severe cases, repeated hysteroscopic attempts at adhesiolysis may be needed.

In order to prevent recurrence of adhesions, a silastic triangular balloon, a No. 14 pediatric Foley catheter, or an intrauterine device may be used to separate the walls of the uterine cavity. The balloon or catheter may be kept in place for 7 days, during which time the patient is given broad-spectrum antibiotics. Estrogen in the form of conjugated estrogens given in a dose of 2.5 mg daily for 1 or 2 months will help the regeneration of the endometrium. During the final 10 days of this course of estrogen, 10 mg daily of medroxyprogesterone acetate is given to slough the endometrium. If an intrauterine device is

used, it can be removed at the time of withdrawal bleeding.

In patients with intrauterine adhesions severe enough to produce amenorrhea, biologically active endometrium can undergo malignant change. One case of endometrial carcinoma arising within intrauterine synechiae has been reported.

IMPLICATIONS FOR PREGNANCY

Hysteroscopic treatment of Asherman's syndrome can be effective in reconstructing a functional uterine cavity. In a series of 187 patients who were treated with hysteroscopic lysis of adhesions during a 10-year period, Valle and Sciarra found 43 patients with mild or filmy adhesions, 97 with moderate or fibromuscular adhesions, and 47 with severe or connective tissue adhesions. Normal menstruation was restored in 88% of patients who had menstrual abnormalities. Among the 187 patients, 143 (76%) became pregnant; of these, 114 (80%) achieved a term pregnancy, 26 (18%) had a spontaneous abortion, and 3 (2%) had ectopic pregnancies. The reproductive outcome parallels the severity of the disease. In patients with mild disease, the term pregnancy rate was 81%, in those with moderate disease it was 60%, and in patients with severe disease it was 32%.

There is a distinct risk of placenta accreta after lysis of intrauterine adhesions. Of three such women, two required treatment by cesarean hysterectomy. Deaton *et al.* reported uterine rupture after aggressive treatment of Asherman's syndrome that seemed to occur not from uterine contractions but rather from the uterine expansion of pregnancy. Their patient underwent two hysteroscopic resections of adhesions, both complicated by uterine perforation. She subsequently conceived and required hospitalization at 25 weeks of gestation for vaginal bleeding without labor. After 40 days in the hospital, still without evidence of contractions, she had an acute uterine rupture that required an emergency cesarean hysterectomy. The fundus was described as "paper-thin from cornu to cornu."

Uterine synechiae may be diagnosed during pregnancy using ultrasonography. A retrospective case-control study was performed by Buchmeier and Longnecker between March 1988 and March 1995. Cases and controls were part of a population of 29,543 pregnant patients who underwent ultrasonographic examination during the second trimester. Synechiae were diagnosed by the sonographic finding of a shelf-like protrusion into the amniotic cavity. The overall prevalence of uterine synechiae was 0.47% (140 of

29,543) in the scanned population. No significant difference was found between cases and controls with respect to maternal age, reproductive losses, and medical problems. The mean gestational age at the time of diagnosis was 18.3 ± 4.2 weeks. No differences in outcome existed between cases and controls except for mean birth weight. The researchers concluded that the presence of uterine synechiae does not appear to confer an increased risk for poor pregnancy outcome.

Rambam Medical Center, Haifa, Israel

Glossary

anovulation Absence of ovulation even though menstruation may continue.

AID Artificial insemination with donor's sperm.

AIH Artificial insemination with husband's sperm.

assisted hatching The process of helping the blastocyst hatch from its shell (zona pellucida) by making a hole in the zona pellucida; may increase the chance of embryo implantation in some patients.

asthenospermia Poor motility of sperm in the seminal fluid.

azoospermia An absence of sperm in the seminal fluid.

blastocyst The stage at which the embryo has reached 5 to 6 days after fertilization, a fluid-filled cyst has formed, and the cells have begun to differentiate into the inner cell mass (which will form the fetus) and the trophoctoderm (which will form the placenta and fetal membranes).

chromosome/chromosomal abnormalities Thread-like structures within the nucleus that contain the hereditary material DNA, where mistakes can occur either in chromosome numbers (46 in humans) or in structure.

cleavage The mitotic division of the fertilized egg (zygote) into two or more cells; usually starts at about 26 h after fertilization.

corpus luteum A small endocrine organ that develops within the ruptured follicle after the oocyte has been released from the ovary; mainly produces the hormone progesterone.

cryobiology The use of low-temperature techniques on cells, tissues, and organs, usually by freezing and storage.

cryopreservation Freezing tissues and storing them in liquid nitrogen at -196°C (e.g., sperm, oocytes, ovarian and testicular tissue, embryos).

egg donation When a woman who has no fertility problems donates her eggs (oocytes) to another woman to enable her to carry pregnancy and have a child.

egg recovery (collection, pickup) When eggs are aspirated from the ovary; performed by vaginal ultrasound-directed method or by laparoscopy.

embryo The product of fertilization; at early stage of development, usually in the uterus, but also *in vitro* in the laboratory.

embryo biopsy Taking one or more cells (blastomeres) from an embryo (often at the 8-cell stage but can be at the blastocyst stage) for genetic or other analysis.

embryo transfer/replacement Stage in *in vitro* fertilization when the embryo is transferred to the uterus.

endometrium The lining of the uterus that develops at the beginning of each cycle so that it is ready to receive an embryo; endometrium breaks down, leading to menstruation, if there is no embryo.

endometriosis The presence of endometrium outside the uterus.

fallopian tubes A pair of small, fine, delicate tubes where fertilization usually takes place; transport ova and sperm to the fertilization site and transport the developing embryo to the uterus.

fertilization The penetration of the oocyte by the sperm, a process that results in the formation of an embryo.

follicle-stimulating hormone (FSH) A hormone produced by the pituitary gland in the brain; in women, stimulates ovulation and the production of estrogen; in men, stimulates the production of sperm.

gamete intra-fallopian transfer (GIFT) When eggs retrieved (usually under laparoscopy) are mixed with a prepared semen sample and introduced into the fallopian tube.

gametes Male and female reproductive cells (sperm and oocyte).

gonadotropin-releasing hormone (GnRH) Responsible for initiating the production of FSH and luteinizing hormone from the pituitary.

GnRH agonist Drugs that have a similar effect to GnRH and that activate the receptor sites in the gonadotropin secretory cells of the pituitary (e.g., buserelin, triptorelin, leuprolide) and finally suppress (down-regulate) the pituitary.

GnRH antagonist Drugs that compete with natural GnRH on its receptor but do not activate it, thereby blocking its effect (e.g., ganirelix, cetrorelix).

human chorionic gonadotropin (hCG) The hormone produced by placental cells in pregnancy; detection of this hormone in blood or urine is the basis of pregnancy testing; this hormone mimics the activity of luteinizing hormone and so is used for triggering ovulation.

hysterosalpingogram (HSG) An X-ray study in which a radio-opaque fluid is injected into the uterus so that the uterus and the fallopian tubes are visualized.

hysteroscopy The use of a fine optical instrument to view the inside of the uterus via the cervix.

implantation The embedding of an embryo in the endometrium of the uterus.

infertility Arbitrarily defined as the inability of a couple to produce a pregnancy after 1 year of intercourse with no contraception; one in six couples affected; can be described as primary or secondary infertility.

intrauterine insemination (IUI) Insemination of a prepared sperm sample into the uterus through the cervix.

intra-cytoplasmic sperm injection (ICSI) Injecting the sperm directly into the egg; major advance in male factor infertility.

in vitro fertilization (IVF) Fertilizing the egg in the laboratory for subsequent embryo transfer; requires egg retrieval/pickup; can be done in a natural or simulated cycle (when the ovaries are made to produce more eggs); after recovery, eggs placed in a plastic dish with a specially prepared semen sample, where fertilization may take place; pre-embryo then transferred to the uterus, where it may implant and develop further into a fetus and eventually a baby.

laparoscopy Procedure allowing visualization of abdominal organs using an optical instrument introduced through the abdominal wall.

luteinizing hormone (LH) A pituitary gonadotropic hormone that stimulates maturation and rupture of the follicle in women.

micromanipulation Procedures used (as an extension of IVF) to manipulate the embryo by blastomere biopsy, zona drilling, and the like.

microsurgical epididymal sperm aspiration (MESA) When sperm cells are aspirated from the epididymis and used in the IVF procedure.

ovarian hyperstimulation syndrome (OHSS) A complication of gonadotropin therapy in which there is excessive stimulation of the ovaries; women having treatment undergo frequent scans and hormone testing to prevent OHSS.

oligospermia A condition in which there are fewer sperm cells in the ejaculate than are considered "normal."

oocyte Female gamete or egg.

polycystic ovarian disease (PCOD) A condition where multiple small follicles appear in the ovary; abnormal imbalance can arise, causing problems in ovulation and infertility.

progesterone A hormone produced by the corpus luteum after ovulation has occurred; also produced by the placenta in pregnancy.

teratospermia A condition in which less than 50% of the sperm are morphologically normal.

testicular sperm aspiration (TESA) Obtaining sperm directly from the testis.

ultrasound scanning A procedure in which high-frequency sound waves are emitted into the pelvis and, as they bounce back, are used to build up a picture; used in many areas of medicine; can be performed abdominally or via the vagina in reproductive medicine; many organs (e.g., kidneys, liver, heart, uterus, ovaries) can be visualized.

Y chromosome One of the chromosomes (X or Y) that determine the sex of an individual; XX determines that the embryo will be female; presence of the Y chromosome determines that it will be male.

zygote intra-fallopian transfer (ZIFT) Similar to GIFT except that the embryo is transferred into the fallopian tube rather than sperm and eggs, where the advantage is that fertilization is established before transfer.

zona drilling The process of making a hole (by acid tyrode solution or laser) in the zona pellucida (the egg shell) to assist in the hatching process.

On July 25, 1978, Louise Joy Brown (Fig. 1), the world's first *in vitro* fertilization baby, was born in Great Britain. Infertility affects millions of couple worldwide. Before the birth of Louise Brown, those women who were found to have blocked or ruined fallopian tubes had no hope of becoming pregnant if surgical procedures failed to correct the situation.

INTRODUCTION

Patrick Steptoe and Robert Edwards (Fig. 2), two physicians from the United Kingdom, had been actively working on finding an alternative solution for conception since 1966. Although Steptoe and

Figure 1 Louise Joy Brown, the world's first *in vitro* fertilization baby.

Edwards had successfully found a way in which to fertilize an oocyte outside a woman's body, they were still troubled by problems after replacing the fertilized egg back into the woman's uterus. By 1977, all of the pregnancies resulting from their procedure (approximately 80) had lasted only a few short weeks.

Lesley Brown, Louise Brown's mother, changed that when she successfully passed the first few weeks of pregnancy. This amazing achievement opened a new era in reproductive medicine, an era of rapid developments and achievements.

INDICATIONS

Pregnancy is always a matter of chance. A normal couple attempting pregnancy in their 20s has about a 20% chance of getting pregnant in any one month,

Figure 2 (A) Dr. Patrick Steptoe and (B) Dr. Robert Edwards.

and couples in their 30s have about a 10% chance in any one month. Sooner or later, a couple will achieve pregnancy if the partners have (1) a reasonably high monthly chance of fertility (more than 5% per month) and (2) a reasonable time in which to keep trying (say, 2 years). If pregnancy has not happened within 1 or 2 years, then it is likely that the monthly chance of pregnancy will be less than 5%. Tests are then done.

For normal fertility, sperm in the vagina must swim up through the cervix, uterus, and fallopian tubes to meet an ovulated egg that has been carried from the surface of the ovary to the middle part of the fallopian tube. The embryo that results (strictly speaking, it is still a "pre-embryo") develops for 3 days in the fallopian tube. It then travels to the uterus, where it floats and develops for another 3 or 4 days before attaching to and implanting within the endometrium (lining of the uterus), thereby establishing pregnancy. A few days before the period is missed, a blood pregnancy test will be positive. It is at about this time of implantation, a week after fertilization, that the first few cells in the center of the "embryo" actually differentiate into what will be the fetus. All other cells (the majority of cells at this stage) go to form the placenta (Fig. 3).

In general, a couple may be relatively infertile (with a reduced monthly chance of conception) or completely infertile (with no chance of conception, sometimes called sterility). The following are the leading causes:

Figure 3 Embryo at the blastocyst stage. Inner cell mass (ICM) will produce the fetus itself. Trophoblast (TR) will produce the placenta and membranes.

- Problems with ovulation (the release of the egg from the ovary). There will be complete infertility if ovulation does not take place and periods are absent (amenorrhoea), although many such patients are treatable with hormones or drugs (patients with polycystic ovary syndrome). If there are no responsive eggs in the ovaries (ovarian failure), egg donation is required.
- Problems with sperm production (often not treatable except by assisted conception). There will be complete infertility if there are no sperm cells in the ejaculate (azoospermia).
- A blockage between the uterus and the ovary, preventing fertilization (Fig. 4). The most common site of blockage is the fallopian tubes, sometimes treatable with microsurgery or assisted conception.
- Endometriosis, a common condition in which the endometrium grows outside the uterus, disturbing a number of events essential to conception and implantation of the embryo in the uterus. Treatment can be medical, surgical, or with assisted conception. Infertility is usually relative rather than complete.

Fertility tests involve the following:

- Progesterone level in the second half of the menstrual cycle (luteal phase) to establish ovulation. Other hormonal tests (e.g., prolactin, luteinizing hormone [LH], follicle-stimulating hormone [FSH], thyroid-stimulating hormone [TSH], testosterone, estradiol) are also often done to assess endocrine integrity and ovarian reserve.
- Sperm count (or a postcoital test looking for sperm in the mucus of the cervix).
- X ray of the uterus and fallopian tubes (a hysterosalpingogram) or a laparoscopy to look at the pelvic organs.

Figure 4 Mechanical infertility. Both fallopian tubes are greatly dilated and blocked.

These tests may show the following:

- Complete infertility (“sterility”): (a) ovarian failure, with no chance of inducing ovulation; (b) complete absence of sperm (“azoospermia”); or (c) complete obstruction of the fallopian tubes.
- Relative infertility: (a) infrequent ovulation or absent ovulation, resolved partly by treatment; (b) a decrease in the sperm count; (c) partial blockage of the tubes or the presence of scar tissue around the tubes or ovary; (d) endometriosis of any degree; (e) an abnormality of the uterus such as fibroids, polyps, or scarring of the lining; (f) an abnormality of the cervix such as a previous cone biopsy or inflammation (“cervicitis”); and/or (g) an immune reaction against sperm cells (“anti-sperm antibodies”) in either partner.
- Unexplained infertility: sometimes no abnormality is obvious.

Some causes of infertility can be overcome with drugs or surgical intervention. Otherwise, assisted reproductive technology (ART) is needed, with *in vitro* fertilization (IVF) being the cornerstone of this treatment.

SUPEROVULATION FOR IVF

The first step of the IVF procedure involves stimulation of egg growth. Spontaneously, a cycling woman will ovulate only one egg each month. This single egg (Fig. 5) may be used for IVF. In fact, the first IVF baby was produced in this way. However, the procedure is

Figure 5 Mature oocyte surrounded by cumulus cells.

cumbersome and laborious because the natural cycle must be followed very carefully to time egg retrieval. To increase the chance of obtaining pregnancy, an effort is made to recruit 10 to 12 eggs, with an eye on patient safety to prevent ovarian hyperstimulation syndrome. This goal is achieved by stimulating the ovaries with drugs (e.g., Pergonal, Puregon, Humegon, Metrodin, Gonal-F, Menogon). These drugs contain gonadotropins produced from urine of postmenopausal women (e.g., Pergonal, Humegon, Menogon, Metrodin) or recombinant human FSH (e.g., Puregon, Gonal-F). Because spontaneous ovulation might occur, leading to cycle cancellation, other drugs are used to prevent the endogenous production of LH, which triggers ovulation.

Gonadotropin-releasing hormone (GnRH) agonists are a group of drugs (e.g., Decapaptyl, Leuprolide, Buserelin, Nafarelin) that activate the pituitary GnRH receptors. Following an initial burst of gonadotropins, prolonged exposure of these receptors to the GnRH agonist leads to pituitary down-regulation, with prevention of endogenous LH surge. Newer compounds act as GnRH antagonists (e.g., Orgalutran, Antagon, Cetrotide). They bind to the receptors but do not activate them (competitive inhibition).

The growth and development of the ovarian follicles are closely monitored by repeated ultrasound studies and blood tests for hormone levels (estradiol and progesterone). Based on the information obtained from these tests, the optimal timing for ovulation is determined. Ovulation itself is triggered by an injection of human chorionic gonadotropin (hCG) (e.g., Chorigon, Profasi, Pregnyl), after which the egg retrieval is scheduled (usually after 34–36 h).

THE LABORATORY

Egg Retrieval

The procedure itself is performed under general anesthesia or sedation at the hospital by a transvaginal route. A needle, guided by ultrasound imaging, is inserted through the vaginal wall into the ovaries, where the follicles containing the eggs are punctured and aspirated. The released eggs are transferred to the lab, where their developmental stage is assessed under the microscope.

Sperm Preparation

Sperm is obtained by masturbation. It then undergoes a series of lab procedures to prepare it for interaction

with the egg. During these procedures, the sperm is washed and resuspended in special medium.

Fertilization

Eggs are kept in dishes, to which sperm is added at the proper concentration. The dishes are kept in an incubator where the environment (temperature, humidity, and gas composition) is carefully monitored. In given time intervals, the eggs are assessed for fertilization and subsequent cleavage (divisions). This assessment is based on morphology; hence, the detailed chromosomal composition of the embryos cannot be addressed without further tests. Approximately 18 h after fertilization, the eggs are examined for the appearance of 2 pronuclei (maternal and paternal) (Fig. 6A). If the number of pronuclei is greater than 2, the eggs are discarded (Fig. 6B). On day 2 postfertilization, the eggs are examined for cleavage. The number

Figure 6 (A) Fertilized oocyte with 2 pronuclei clearly visible, indicating normal fertilization. (B) Fertilized oocyte with 3 pronuclei visible, indicating abnormal fertilization.

of cells and their morphological appearance are recorded, and based on these parameters, each embryo is graded for quality.

Embryo Transfer

Embryos that have satisfactorily divided are transferred to the uterus 2 to 3 days after fertilization (Fig. 7). This simple and painless procedure does not

Figure 7 (A) A 2-cell embryo, day 2 postfertilization. (B) A 4-cell embryo, day 2 postfertilization. (C) An 8-cell embryo, day 3 postfertilization.

require sedation or anesthesia. The embryos are laden on a small plastic catheter, which is gently introduced through the cervix into the uterus. Once in the uterine cavity, the embryos are gently released and the catheter is withdrawn. Given the nature of cycle stimulation, medications are prescribed to support the young embryos hormonally. With an eye to preventing multiple pregnancy, the number of embryos transferred to the uterus should be considered very carefully. In good prognosis cases (young patients in first IVF treatment), 1 or 2 high-quality embryos are usually transferred. Patients with a history of repeated failures, or who are more than 40 years of age, may receive more embryos.

Other Technologies

Cryopreservation

The average number of retrieved oocytes is 10 to 12, of which about 8 are expected to fertilize and cleave. Because only 1 or 2 “fresh” embryos are transferred, the rest are cryopreserved to be used later. Frozen embryos that are kept in -196°C (liquid nitrogen) can be used successfully many years after they were created.

Intracytoplasmic Sperm Injection

The intracytoplasmic sperm injection (ICSI) technique (Fig. 8), first introduced in 1993, revolutionized the treatment of male infertility: each mature oocyte is injected with a single sperm cell. ICSI is a very successful solution in cases of extreme oligospermia, even when only a few viable sperm cells can be found in the ejaculate.

Figure 8 ICSI: A mature oocyte is injected with a single sperm.

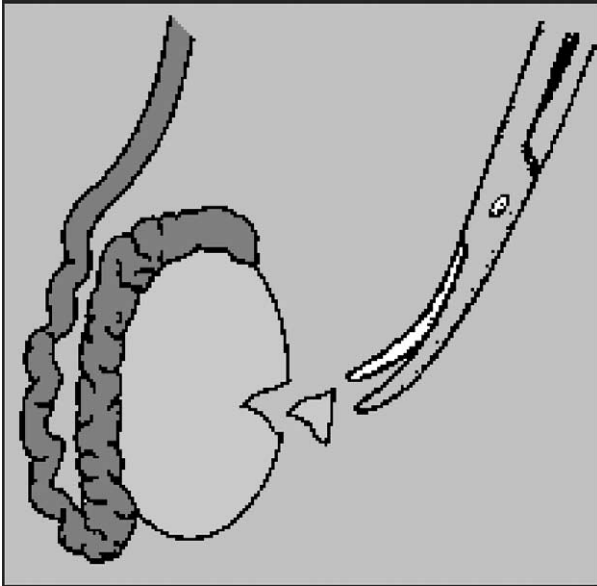

Figure 9 Testicular sperm extraction: A piece of testicular tissue is surgically removed, and sperm cells will be obtained from this tissue to be used in ICSI.

Microsurgical Epididymal Sperm Aspiration

Microsurgical epididymal sperm aspiration (MESA) involves obtaining immature sperm cells from the epididymis (which joins the testicle to the vas) in cases where obstruction in the genital tract leads to absence of sperm in the ejaculate. The recovered sperm can be used for ICSI, either immediately or after cryostorage.

Testicular Sperm Aspiration

Testicular sperm aspiration (TESA or TESE) (Fig. 9) is a surgical procedure to obtain sperm from within the testicular tissue in azoospermic patients.

Preimplantation Genetic Diagnosis

In preimplantation genetic diagnosis (PGD), a single blastomere is obtained by embryos biopsy (Fig. 10) at the 6- to 8-cell stage (3 days postfertilization). The chromosomal composition of this cell is assessed by DNA hybridization technology, or a potential abnormal gene is targeted by polymerase chain reaction (PCR). If found to be normal, the embryo is transferred to the uterus. Abnormal embryos are discarded.

Blastocyst Culture

The first stage, when embryo differentiation is observed, is the blastocyst stage. Embryos reach that stage 5 to 6 days after egg retrieval (Fig. 11). In “natural pregnancy,” the embryo reaches the uterus at this stage. In some cases (e.g., patients after repeated IVF failure),

Figure 10 (A) Embryo biopsy: An 8-cell embryo is held, while a biopsy capillary is introduced through a hole in the zona pellucida. (B) Embryo biopsy: A single cell is gently removed from the embryo.

embryo culture up to the blastocyst stage should be considered. In addition, this technology may help to minimize the multiple pregnancy rate because the implantation potential of embryos at the blastocyst stage is higher than that of embryos at the cleavage stage (days 2–3); therefore, 1 or 2 transferred blastocysts have a good chance of achieving pregnancy.

OUTCOME

In general, it is recommended that the patient should refrain from physical exertion following embryo

Figure 11 An embryo at the blastocyst stage.

transfer; however, complete bed rest does not seem to be necessary. The presence of pregnancy is established by using a sensitive test for hCG, which is the hormone secreted by the placenta. The test is done 14 days after egg retrieval. If pregnancy is established, monitoring is continued until ultrasound imaging allows a direct visualization of the developing fetus. Success depends on many variables. The most important predictor of success is the age of the female patient. Current IVF technology can deliver approximately a 20% implantation rate (the number of gestational sacs that develop in the uterus divided by the number of transferred embryos). This is close to the natural implantation rate.

Complications

Multiple Pregnancy

Usually, 1 to 3 embryos are transferred to the uterus in a given cycle, with the hope that 1 or at most 2 will implant and develop. However, occasionally the procedure “over-succeeds” and it is found that a patient has a triplet pregnancy. The outcome of these pregnancies is not optimal given that premature delivery is the rule, with potential severe impact on the newborns. In these cases, selective fetal reduction should be considered.

Ovarian Hyperstimulation Syndrome

Fertility drugs override the natural process of egg development for the purpose of obtaining many eggs. Occasionally, a patient may develop a large number of eggs, a process that can give rise to a clinical syndrome known as ovarian hyperstimulation syndrome (OHSS). The syndrome is characterized by lower abdominal pain, ovarian cysts, and (in its severe form) accumulation of fluid within the abdomen. Occasionally, hospitalization is required, and in extreme cases, termination of pregnancy is necessary.

Increased Risk of Cancer?

About 1 in 10 women will develop cancer of the breast at some stage of their lives. About 1 in 90 women who live to their 70s will develop cancer of the ovary. Because IVF has become a common procedure, it is understandable that quite a number of cancers will develop among women once they are treated in this way. However, like pregnancy itself, stimulating the ovaries during IVF causes the ovarian hormones to reach high levels, and this may accelerate the development of a breast cancer (or an ovarian cancer) that is already present but that has not been detected. It is not known whether the long-term risk of breast

cancer is increased after repeated IVF treatments, although studies are currently under way. There is a strong presumption that repeated IVF cycles, especially if there has been no pregnancy, are likely to increase the risk of cancer of the ovary during later life. There are two reasons for this. First, some studies have implied that the use of fertility drugs is associated with an increase in risk. Second, it is known that anything that stops ovulation and menstruation, such as having been on birth control pills for a number of years or having been pregnant and having breast-fed, is rather protective against later cancer of the ovary. Ovulating 10 eggs in 1 month in an IVF program may have the same effect as 10 months of normal ovulation in terms of risk.

THE FUTURE

Current efforts focus on technologies that will let us know which embryo in the lab has the potential to implant and become a healthy baby. Routine use of techniques such as PGD and assessing biochemical markers will improve implantation rates.

Figure 12 Dolly, the cloned sheep.

The ability to produce embryos *in vitro* has introduced us to cloning and stem cell technology. In short, cloning is based on enucleation of a mature unfertilized oocyte and injection of a nucleus taken from an adult diploid cell. The oocyte cytoplasm has the capacity to reprogram and de-differentiate the donor nucleus to be followed by cleavage and embryo development. Healthy newborns have been produced in domestic animals (with Dolly the cloned sheep being the first [Fig. 12]), although with low efficiency and high rates of abortion, congenital malformations, and neonatal deaths.

The inner cell mass detected at the blastocyst stage is composed of cells that have the potential to differentiate to any tissue. These cells can be kept undifferentiated in culture for a long time, and can serve as a source for any needed tissue, once the signal for differentiation is known. Theoretically, it will be possible to produce any type of tissue or organ to suit the individual patient's needs. A major advantage of "therapeutic cloning" is that immunity-based rejection will be avoided because the genetic material of the implanted cells/organs will be identical to that of the patient.

Atherogenesis

Lina Badimon and Vicenta Llorente-Cortés

Cardiovascular Research Center, ICCV/CSIC-Hospital Santa Creu i Sant Pau, Barcelona, Spain

Glossary

atherogenesis Early changes within the artery wall that are associated with atherosclerosis.

atherosclerotic plaque Thickening of the arterial wall through the accumulation of lipids, macrophages, T lymphocytes, smooth muscle cells, extracellular matrix, calcium, and necrotic debris.

endothelium Continuous monolayer composed of endothelial cells that covers the inner surface of the entire vascular system.

inflammation Response of the arterial wall to endothelial injury that leads to elevated microbial antigens and elevated circulating levels of immune cytokines.

lipid accumulation One of the main events that leads to atherosclerotic plaque progression and that is caused by extracellular and intracellular abnormal lipid clearance.

Atherosclerosis has been defined as a thickening of the arterial wall through the accumulation of lipids, macrophages, T lymphocytes, smooth muscle cells, extracellular matrix, calcium, and necrotic debris. Atherosclerosis is the main cause of cardiovascular disease, affecting large and medium-size arteries and coronary arteries. Atherosclerotic plaques may remain silent, without any clinical symptoms, but when plaques suffer fissuring, rupture, or disruption, the ensuing thrombotic complication produces the clinical manifestation of the disease. The pathogenesis of atherosclerosis is complex and multifactorial. Among the identified risk factors are age, insulin resistance syndrome and diabetes, obesity, lack of exercise, smoking, hypertension, and hypercholesterolemia. Various epidemiological studies suggest a crucial role of hyperlipidemia in early atherogenesis. However, high cholesterol levels are not the only causative factor.

INTRODUCTION

The American Heart Association classified the various stages of lesion progression into six phases and lesion

types (Fig. 1). The first stage has been called arterial intimal thickening (AIT) (type I) and starts with the migration of vascular smooth muscle cells (VSMCs) to the intima and the small accumulation of low-density lipoprotein (LDL) and macrophages in the subendothelial-intimal space. Modified LDL is a chemottractant for monocytes and VSMCs; these cells, by taking up modified LDL in a noncholesterol down-regulated manner, become foam cells initiating the fatty streak formation (type II). The extracellular lipid accumulation coming from death cells besides the foam cells is characteristic of lesion type III and lesion type IV typical of the third decade of life. In more advanced lesions (types V, VI, and VII), pathological changes occur in VSMCs of the media layer that contain a significant number of foam cells. In type V lesions, several collagen layers cover the lipid core. These lesions may have a cap of VSMCs and extracellular matrix (ECM) covering the lipid core that modulates their susceptibility to rupture and thrombus formation. The successive accumulation of collagen fibers leads to a progressive lumen narrowing. During the fourth decade of life, lesions can rupture and trigger thrombotic depositions (type VI lesions). During this stage, the formation of an occlusive thrombus can have dramatic effects. During the fifth decade of life, most of the lesions show an advanced stage and are composed mainly of calcifications (type VII lesions) or fibrous tissue (type VIII lesions).

Still not much is known about the disease initiation and progression, and the major risk factors can explain only approximately 50% of the coronary events found in humans. A major mystery in human atherogenesis is the well-known variation in lesion progression among individuals with similar plasma lipid profiles or risk factors. Furthermore, other factors affecting the molecular and cellular mechanisms in the arterial wall may be critical for the pathogenesis of the disease. Various findings suggest a diversity of agents that can induce endothelial injury, leading to a vascular response in a harmful chronic state. Besides LDL,

Figure 1 Classification of the atherosclerotic lesions according to the American Heart Association. AIT, arterial intimal thickening; type I-II; type III-IV; type V; type VI; type VII. (Original preparations.)

cytokines and growth factors are important regulators of the inflammatory response, cellular growth, and lipid deposition. All of these processes are responsible for atherosclerotic plaque progression. During the final stages of the disease, arterial plaques become complex aggregations of lipids, ECM, and necrotic and apoptotic cells covered by a fibrous cap consisting primarily of smooth muscle cells surrounded by collagens and proteoglycans (PGs). The vulnerable plaques contain a lipid-rich core and a soft fibrous cap.

ROLE OF INFLAMMATION

It has been postulated that inflammation is involved in atherogenesis due to the observation that elevated levels of cytokines can be measured during acute coronary syndrome (ACS) presentation. In fact, one of the hypotheses for the initiation of atherosclerosis is the so-called “response to injury hypothesis” involving the response of the innate immune system to the accumulation and modifications of lipoproteins in the arterial intima. Various constituents of the modified lipoproteins trigger the production of mediators of innate immunity. There are also nonlipid mediators involved in inflammation such as homocysteine, angiotensin II, and microbial products that can induce the elaboration of cytokines from atheroma-associated cells.

In normal circumstances, the endothelial monolayer in contact with flowing blood is inert to the adhesion of leukocytes. The situation changes in dysfunctional endothelium. One of the endothelial-leukocyte adhesion molecules involved mainly in the early adhesion of mononuclear leukocytes to arterial endothelium is the vascular cell adhesion molecule-1 (VCAM-1), which binds particularly

those classes of leukocytes found in nascent atheroma: the monocyte and the T lymphocyte. In addition to VCAM-1, P- and E-selectin and intercellular adhesion molecule-1 (ICAM-1) also seem to contribute to leukocyte recruitment. As shown in Fig. 2, once the leukocyte adheres to the endothelium, it enters into the intima by diapedesis, a process that is facilitated by various chemokines such as monocyte chemoattractant protein-1 (MCP-1), interleukin-8 (IL-8), and a trio of CXC chemokines induced by interferon- γ . Once they are in the intima, monocytes acquire characteristics of macrophage by expressing certain scavenger receptors (SRs), such as scavenger receptor A (SRA-I and SRA-II) and CD36, that internalize modified lipoproteins, leading to foam cell formation.

One of the most important clinical markers of inflammation is the C-reactive protein (CRP), a marker of inflammation that has been shown in multiple epidemiological studies to predict incidence of myocardial infarction, stroke, peripheral arterial disease, and sudden cardiac death. In terms of clinical application, some data indicate that CRP seems to be a strong predictor of cardiovascular events and adds prognostic information at all levels of calculated Framingham risk and at all levels of metabolic syndrome. The feature that distinguishes CRP from LDL cholesterol is the fact that inflammation (but not elevated cholesterol LDL) plays a major role in nearly all processes associated with metabolic syndrome.

ROLE OF LIPOPROTEINS

Cholesterol is transported into the vessel wall as a component of the lipoproteins. LDLs are considered the most atherogenic lipoproteins because they accumulate in the intima and carry large amounts of plasmatic cholesterol (up to 70%). The coronary risk lipid profile that uses the total cholesterol/high-density lipoprotein (HDL) ratio (or the LDL/HDL ratio) predicts risk of vascular disease and is used as a tool for therapeutic management of patients at risk for vascular disease. Although these methods are predictive of coronary artery disease (CAD) in general, it is also well known that the extent of occlusive disease and CAD varies greatly among individuals with similar cholesterol and HDL lipid profiles. For this reason, the National Cholesterol Education Program Expert Panel revised these guidelines and recommends monitoring LDL and HDL in the context of coronary heart disease (CHD) risk factors and “risk equivalents.”

High levels of circulating LDL have shown to be predictive markers of high risk of cardiovascular disease (CVD) in individual persons. It appears that

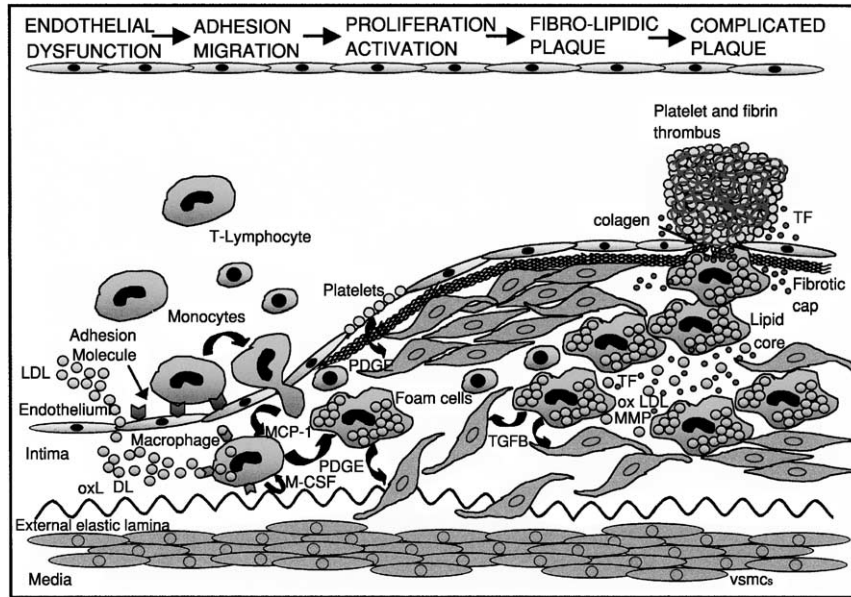

Figure 2 Illustration showing the molecular mechanisms that lead to initiation and progression of the atherosclerotic lesions. PDGF, platelet-derived growth factor; M-CSF, macrophage colony-stimulating factor; MCP-1, monocyte chemoattractant protein-1; oxLDL, oxidized LDL; TF, tissue factor.

discrete LDL subclasses carry various levels of atherogenicity. The “atherogenic lipoprotein phenotype” describes a combination of moderate hypertriglyceridemia, low HDL cholesterol, and a predominance of small dense LDL particles. This dyslipemia is prevalent in patients with metabolic syndrome, in those with type 2 diabetes, and in postmenopausal women.

Oils, Lipoproteins, and Coronary Risk

Dietary fats and oils differ in the chain lengths of their constituent fatty acids and the number and geometry of their double bands. These differences markedly affect concentrations of lipids in plasma, and differences in the amount and type of fat in the diet can induce differences of 30 to 40% in serum LDL concentrations. [Table I](#) shows the main saturated fatty acids (SFAs), monounsaturated fatty acids (MUFAs), and polyunsaturated fatty acids (PUFAs). When SFAs are replaced by unsaturated fats, total plasma cholesterol is lowered. A review of metabolic studies, prospective cohort studies, and clinical trials indicates that there are multiple mechanisms by which diet potentially influences risk of CHD, and there are dietary strategies that are effective in preventing CHD ([Table II](#)). As such, the substitution of nonhydrogenated unsaturated fats for saturated and *trans* fats; the increase in the consumption of omega-3 fatty acids from fish, fish oil supplements, and plant sources; and the consumption

of a diet high in fruits, vegetables, nuts, and whole grains and low in refined grain products are good strategies to prevent CHD.

Modified Forms of LDL

Extracellular accumulation of lipids in the arterial intima occurs very early in response to increased plasma lipoprotein levels in animals. PGs and protein-bound lipoprotein particles, perhaps in a micro-environment shielded from plasma antioxidants, can undergo modifications. As shown in [Table III](#), such modifications include oxidation, aggregation, and enzymatic and nonenzymatic modifications of LDL. Modified forms of LDL are associated with increased atherogenicity because the physicochemical

Table I Main Dietary Fatty Acids

| Saturated fatty acids | Monounsaturated fatty acids | Polyunsaturated fatty acids |
|-----------------------|-----------------------------|------------------------------------|
| Lauric acid (12:0) | Oleic acid (18:1n-9) | Linoleic acid (18:2n-6) |
| Myristic acid (14:0) | <i>Trans</i> (16:1 + 18:1) | α -Linolenic acid (18:3n-3) |
| Palmitic acid (16:0) | | Eicosapentenoic acid (20:5n-3) |
| Stearic acid (18:0) | | Docosahexenoic acid (22:6n-3) |

properties of the lipoprotein become altered. This results in changes in the biological properties of the LDL and also in an increase in the susceptibility of the LDL to other types of modifications.

Cellular Effects of Modified LDL

Endothelial Dysfunction

Hypercholesterolemia induces an increase of leukocyte recruitment by an increased expression of adhesion molecules per se and those induced by cytokines, a decrease in endothelium-dependent vasodilatation,

and alterations in the thrombosis/fibrinolysis balance. Our group has demonstrated that systemic hypercholesterolemia can induce endothelial dysfunction by altering the expression of genes that are regulated through the down-regulation of sterol regulatory element-binding proteins (SREBPs) in endothelial cells.

Synthesis and Degradation of Extracellular Matrix

Modified LDL can modulate the synthesis of PGs in various cell types. The increase of PG synthesis induced by LDL might have important consequences for the intimal LDL retention. In addition, the exposure of endothelial cells to apolipoprotein E (apoE)-containing HDL has been shown to stimulate the production of heparan sulfate proteoglycans (HS-PGs) that have increased sulfation.

Lipoproteins also modulate the expression of metalloproteinases (MMPs), that is, enzymes that are able to digest various connective tissue components. An increase in metalloproteinase expression and activity is associated with the disruption of the fibrous cap of lesions and plaque rupture. In addition, the breakdown products of the ECM may be biologically active and might increase processes that are fundamental for the pathogenesis of the atherosclerosis.

Foam Cell Formation

Modified lipoproteins are taken up through mechanisms not regulated by cholesterol, leading to high intracellular cholesteryl ester accumulation and foam cell formation. The accumulation of lipid-laden foam cells is one of the earliest steps in the progression of the atherosclerotic plaque. In macrophages, the SRs are mainly responsible for modified LDL uptake. Our group has described a main role for LDL receptor-related protein (LRP) in the uptake of aggregated LDL (agLDL) by VSMCs. SRs and the LRP have been detected in human atherosclerotic lesions and, therefore, could play an important role in foam cell formation in the arterial intima. Several modified lipoproteins have demonstrated to up-regulate their own receptors; for example, oxidized LDL (oxLDL) increases the expression of several SRs such as CD36, SR-A, and lysil oxidase-1 (LOX-1) in various cell types. In addition, agLDL up-regulates the expression of their receptor LRP in VSMCs. Most of the modified lipoproteins could lead to a progressive cholesteryl ester accumulation, not only by being taken up through non-down-regulated receptors but also by up-regulating their own receptors.

Lipoproteins and Metabolic Syndrome

Metabolic syndrome was defined by the National Institutes of Health in 2001 as a cluster of disorders that include abdominal obesity, insulin resistance, diabetes, endothelial dysfunction, elevated blood pressure, and impaired fibrinolysis. The risk factors that constitute metabolic syndrome consist of atherogenic dyslipidemia, elevated blood pressure, elevated plasma glucose, and a prothrombotic state. Metabolic syndrome is closely linked to the metabolic derangement called insulin resistance. This condition is characterized by a generalized defect in the insulin-signaling pathway. Because insulin induces a myriad of metabolic responses, a defect in insulin signaling results in several metabolic changes. The presence of insulin resistance predisposes to the development of type 2 diabetes. There are four major causes of insulin resistance: genetics, obesity, lack of exercise, and diet composition. Insulin resistance and metabolic syndrome are related to the atherogenic dyslipidemia also called “atherogenic lipoprotein phenotype,” which is characterized by increased triglyceride-rich lipoproteins, increased small LDL particles, and reduced HDL levels. These changes in lipoprotein and fatty acid profile observed in insulin resistance may influence various proatherosclerotic mechanisms such as membrane lipid composition, metabolism, and signal–transduction pathways.

ROLE OF THE VARIOUS COMPONENTS OF THE VASCULAR WALL

Extracellular Matrix

The ECM of the arterial intima is a relatively large compartment made of collagen, elastin, complex PGs, hyaluronate, and multidomain proteins such as fibronectin, laminin, and tenascin (Fig. 3). The ECM occupies 60% of the arterial intima and regulates numerous cellular functions. The main PGs structuring the ECM are chondroitin sulfate (CS)-PGs, such as versican and biglycan, which have the longest negatively charged glycosaminoglycan (GAG) chains and are synthesized mainly by VSMCs. HS-PGs, such as perlecan, are constituents of the basement membrane and are synthesized mainly by endothelial cells and VSMCs. In addition, other HS-PGs, such as syndecan and glypican, are found in the cell membranes of the vascular cells. Whereas CS-PGs play a major role in LDL retention in the arterial intima, cell surface HS-PGs are dynamic molecules that mediate

Figure 3 Extracellular matrix ultrastructure of VSMCs. Cells were washed, fixed, and processed for freeze-drying and replication in electron microscopy. (A) Nonenzymatically treated human VSMCs. ligand catabolism. Collagens play a central role not only in maintaining the integrity and stability of the wall but also in many cellular functions.

Heparan Sulfate Proteoglycans

HS-PGs consist of a protein core and at least one heparan sulfate side chain. HS-PGs can be secreted (perlecan) or shed from the cell surface (perlecan, syndecan, and glypican). Syndecan and perlecan can function as receptors for several growth factors and

lipoproteins. HS-PGs act as a receptors for basic fibroblast growth factor (bFGF), which stimulates VSMC proliferation. They may act as potential receptors for atherogenic lipoproteins, such as apoE-triglyceride-rich lipoprotein particles and lipoprotein lipase, or may facilitate the uptake of ligands by a process called ligand transfer to lipoprotein receptors, such as the LRP.

Chondroitin Sulfate Proteoglycans

CS-PGs are considered to be atherogenic due to their ability to trap and aggregate cholesterol-rich lipoproteins. Because one of the key initiation events in early atherogenesis is the subendothelial retention of atherogenic lipoproteins, CS-PGs play a main role in the initiation of atherogenesis (“response to retention” hypothesis). Apoproteins have been found to colocalize with specific PGs in human atherosclerotic plaques, providing support to the “response to retention” hypothesis. Several studies demonstrate that CS-PGs act as sites for apoB-100 lipoprotein retention by the interaction between positively charged heparin-binding domains on apoB-100 or apoE and negatively charged GAG chains of the PGs. The GAGs of versican induce alterations in the LDL particles that facilitate oxidative enzymatic modification, fusion, and aggregation of LDL particles. **Figure 4** shows an electron microscopy image of versican-modified LDL in comparison with nLDL and agLDL. Versican clearly induces the aggregation of LDL particles. Aggregation substantially increases its binding to arterial PGs due to the creation of a multimeric ligand with better exposure of key positive residues on apolipoprotein B. Modified LDL is avidly taken up by macrophages and VSMCs, leading to foam cell formation. In addition, some CS-PGs such as decorin, a small DS/CS PG, regulate cell growth and growth factor activity.

Collagen

Collagen is the major component of the ECM of the vessel wall and has a critical impact in atherogenesis. Collagen is essential for the maintenance of vessel wall integrity and elasticity. Collagen is involved in the process of cell differentiation, adhesion, migration, proliferation, and apoptosis. It has been reported that the bulk of vascular collagen is produced by smooth muscle cells. However, collagens can also be produced by endothelial cells, adventitial fibroblasts, and macrophages. Among the 19 collagens described, 13 are found in the vessel wall or are expressed by cells of the vessel wall *in vitro*. The most abundant are type I and type III collagen, which form an interconnected

network of cross-banded fibers along with smaller amounts of type VI and type VIII collagen, associated with the fibers and the elastic lamellae in the blood vessel wall. Type I and type III collagen seems to play an important role in arterial wall remodeling in response to hypertension. It has also been reported that type I collagen expression was localized mainly in the adventitia, outer media, and intima and that type III collagen expression was uniformly localized across the arterial wall in response to an elevation of blood pressure. Type III collagen accumulates in atherosclerotic lesions, and in various *in vitro* studies in cultured endothelial cells. The involvement of type

VIII collagen in processes of endothelial differentiation and organization and *in vitro* angiogenesis has been demonstrated.

Cellular Components

Endothelium

In health, the vascular endothelium forms a multifunctional interface between circulating blood and the various tissues and organs in the body. It constitutes a selectively permeable barrier for macromolecules as well as a nonthrombogenic surface that actively maintains the fluidity of blood. The endothelium is a complex and dynamic organ that responds to environmental stimuli and activates vasoactive substances, including vasoconstrictors such as angiotensin II and vasodilators such as nitric oxide (Table IV). These vasoactive substances mediate vascular tone, structure, and function influencing VSMC growth, apoptosis, platelet aggregation, monocyte and leukocyte adhesion, and thrombosis. The homeostasis of vasoactive substances is disrupted by endothelial dysfunction, leading to changes in vascular structure and function. Hypertension and other risk factors for CVD are associated with endothelial dysfunction and vascular remodeling. Elevated angiotensin II activity,

which is strongly correlated with hypertension, is a major trigger of endothelial dysfunction in hypertensive patients. Angiotensin II stimulates nicotinamide adenine dinucleotide phosphate (NADPH)/nicotinamide adenine dinucleotide (NADH) oxidase in the endothelium, VSMCs, and adventitia of blood vessels to generate reactive oxygen species, leading to endothelial dysfunction, cell growth, and inflammation. These changes result in up-regulation of endothelin-1, adhesion molecules, nuclear factor- κ B (NF- κ B), and other inflammatory mediators as well as increased breakdown of nitric oxide and uncoupling of nitric oxide synthase. Thus, the balance of vasoconstriction and vasodilation is disrupted, with resultant vascular remodeling and injury. Through these processes, endothelial dysfunction aggravates existing hypertension, accelerating the progression of atherosclerosis. Endothelial dysfunction is now recognized as a key early risk factor for cardiovascular morbidity and mortality. Certain consequences of endothelial dysfunction are directly related to the pathogenesis of atherosclerosis and its complications. Pathophysiological stimuli of arterial endothelial dysfunction that are especially relevant to atherogenesis include activation by cytokines and bacterial endotoxin, infection by viruses, advanced glycosylation end products that are generated in diabetes and with aging, hyperhomocysteinemia, and hypercholesterolemia and oxidized LDL. In addition to these humoral stimuli, it is clear that biochemical forces generated by flowing blood can also influence endothelial cell structure and function, modulating the expression of pathophysiologically relevant genes. The possibility that hemodynamic forces can act as pathophysiological stimuli for endothelial dysfunction provides a conceptual rationale for the long-standing observation that the earliest lesions of atherosclerosis characteristically develop in a nonrandom pattern, the geometry of which correlates with branch points and other regions of altered blood flow. There have been documented a variety of changes in the metabolic and synthetic activities of endothelial cells in response to defined biomechanical forces. These include the production of arachidonate metabolites, growth factors, coagulation and fibrinolytic components, ECM components, and vasoactive mediators. Certain of these more acute shear-induced changes appear to involve regulation at the level of rate-limiting enzymes and/or substrate availability. However, especially in the case of delayed responses in which *de novo* synthesis occurs, up-regulation of gene expression appears to occur as a direct consequence of exposure to fluid mechanical forces. There are genes, such as platelet-derived

Table IV Factors Synthesized by the Endothelium

| Factors | Process | Contribution |
|--|----------------|--------------|
| PDGF | Growth | Stimulator |
| TGF- β | | Inhibitor |
| Heparin-like GAG | | Inhibitor |
| NO | Vasodilatation | Stimulator |
| Endothelin | | Inhibitor |
| Angiotensin II | | Inhibitor |
| TF | Thrombosis | Stimulator |
| Trombomodulin | | Stimulator |
| vWF | | Inhibitor |
| t-PA | Fibrinolysis | Stimulator |
| PAI-1 | | Inhibitor |
| Prostacyclin | Others | |
| E-selectin, P-selectin, ICAM-1, VCAM-1. | | |
| IL-1, IL-6, IL-8, MCP-1, GM-CSF | | |

Note. PDGF, platelet-derived growth factor; TGF- β -transforming growth factor; NO, nitric oxide; TF, tissue factor; vWF, von Willebrand factor; tPA, tissue plasminogen activator; PAI-1, tissue plasminogen activator inhibitor; ICAM-1, intercellular cell adhesion molecule; VCAM-1, vascular cell adhesion molecule; IL, interleukin; MCP-1, monocyte chemoattractant protein; GM-CSF, granulocyte macrophage colony-stimulating factor.

Table V Cell Surface Receptors That Mediate the Uptake of Modified LDL

| Receptors | Ligands | Cellular type | Atherosclerotic plaque | References |
|----------------|--------------------------|-------------------|------------------------|-------------------------------|

| | ApoE-lipid complexes | | | |

Note. Expression levels: ±, low or absent; +, moderate; ++, high; + + +, very high. EC, endothelial cells; VSMCs, vascular smooth muscle cells, MØ, macrophages; SRs-AI, SR-AII, scavenger receptors class A; SRs-BI, scavenger receptors class B; CD68, scavenger receptors class D; FcR2II-B2, receptor for the Fc domain of immunoglobulins; LOX-1, scavenger receptors class E; SRs-PSOX, scavenger receptors for phosphatidylserine and oxidized lipoproteins; LRP, low-density lipoprotein receptor-related protein.

growth factor-B (PDGF-B), MCP-1, VCAM-1, and endothelin-1, that have a “shear stress response element” in the promoter.

Monocytes/Macrophages

The state and function of the macrophages in the atherosclerotic lesions may be critical for the development of atherosclerosis. Macrophages play an important role in innate immune responses, cellular adhesion, phagocytosis of apoptotic cells, and lipid uptake. Most of these macrophage functions are mediated by SRs. Since the cloning of the first two macrophage SRs (now called SRA-I and SRA-II), the broad SR family has

grown considerably (Table V). On the basis of functional studies and expression in the arterial intima, only some of the SRs are good candidates to contribute to atherosclerotic foam cell formation.

Besides their role in lipid accumulation, macrophages may contribute to atherosclerosis through secretory inflammatory products. In fact, atherosclerosis can be considered a chronic inflammatory process. Activated lymphocytes and macrophages with a wide expression of class II histocompatibility antigen have been found at every stage of atherosclerotic lesions, indicating that macrophages may participate in local immune responses.

Vascular Smooth Muscle Cells

VSMCs represent an average of 50% of the cellular component in advanced atherosclerotic plaque and may reach 90 to 95% in early lesions. In response to multiple stimuli, VSMCs from the arterial tunica media are activated and migrate to the intima, where

they proliferate. These seem to be early steps in the onset of the atherosclerotic process. The proliferation and migration of VSMCs from the media to the intima is one of the key events in early atherosclerosis. The understanding of the molecular mechanisms involved in VSMC activation and differentiation requires an accurate mapping of the cascade of transcription factors induced by atherogenic stimuli. Recently, various nuclear receptors, including peroxisome proliferator-activated receptors (PPARs), retinoid receptors, both retinoid X receptors (RXRs) and retinoic acid receptors (RARs), and retinoid-related orphan receptors (RORs), have been identified in VSMC activation/proliferation and, consequently, have been implicated in atherogenic processes. Our group has identified neuron-derived organ receptor-1 (NOR-1) as a new early-response gene in VSMCs. NOR-1 is strongly increased by growth factors and thrombin. NOR-1 is overexpressed in atherosclerotic lesions from patients with CAD (Fig. 5), and balloon angioplasty transiently induces NOR-1 in porcine coronary arteries. These results suggest that NOR-1 may play a role in the molecular mechanisms underlying both spontaneous and accelerated atherosclerosis.

VSMCs also contribute to the lesion by synthesizing ECM. In fact, proliferative VSMCs have a high capacity to synthesize sulfated PGs, and it is well established that PGs in the arterial wall are involved in the focal deposition of cholesterol-rich particles during the early phases of atherogenesis.

Finally, VSMCs also have great importance in foam cell formation. Our group demonstrated that agLDL can cause high intracellular cholesteryl ester accumulation in VSMCs. We demonstrated, for the first time, that in VSMCs, LRP mediates the binding and internalization of agLDL. We also demonstrated that in the absence of LRP function, VSMCs are unable to accumulate cholesterol. In addition, this receptor is up-regulated by agLDL uptake, leading to intracellular lipid accumulation. Figure 6 shows LRP up-regulation in VSMCs of hypercholesterolemic animals.

Atherosclerosis

Jesus A. Araujo and Aldons J. Lusis
University of California, Los Angeles, California, United States

Glossary

atherosclerotic plaque Deposit of lipids and cellular and fibrous elements in the artery wall.

foam cells Lipid-engorged cells, mostly macrophages.

infarction Tissue necrosis caused by hypoxia or anoxia resulting from insufficient or absent blood perfusion.

ischemia Insufficient blood flow to satisfy the tissue metabolic needs.

vascular thrombosis Thrombus formation frequently occurring at the level of an unstable atherosclerotic plaque.

Atherosclerosis is a chronic inflammatory disease characterized by the progressive accumulation of lipids and cellular and fibrous elements in large and medium-sized elastic and muscular arteries.

INTRODUCTION

Atherosclerosis is a vascular syndrome that is the primary cause of ischemic heart disease and stroke. In Western societies, it is the underlying cause of approximately 50% of total mortality. For many decades, it was considered a degenerative disease with no major potential for intervention, but it is better understood as a very dynamic, chronic inflammatory condition that is converted to an acute clinical event by the induction of plaque rupture leading to thrombosis, with a great potential for intervention. Epidemiological studies have revealed several important environmental and genetic risk factors. Work with genetically modified mice has made it feasible to experimentally examine mechanistic hypotheses, resulting in a clearer understanding of the cellular and molecular processes involved. Important tools for the management of the various clinical entities have been developed for diagnosis, risk stratification, and

therapeutics. Risk factors can be classified as those with a strong genetic component and those that are mostly environmental (Table I). However, approximately 50% of the casualties related to ischemic vascular disease are not explained by known pathogenic factors, posing a challenge to achieve a more complete understanding.

PATHOGENESIS

Progression of the Atherosclerotic Lesions

Stary described the microscopical evolution of atherosclerosis. The earliest stage (Stary I lesion), which is not apparent macroscopically, consists of subendothelial accumulations of lipid-loaded macrophages, called foam cells, and is found in 45% of infants up to 8 months of age. By puberty, it is common to see the classical “fatty streak” (Stary II lesions), visualized macroscopically with Sudan IV stain as a flat or slightly raised streak, consisting of lipid-loaded macrophages and smooth muscle cells containing lipid droplets and minimal, scattered, extracellular lipid. More advanced lesions include those with multiple extracellular lipid cores (Stary III lesion) that appear as a raised fatty streak or an atheroma (Stary IV lesion), characterized by a single confluent extracellular lipid core. By the third decade of life, fibrous lesions (Stary V lesions) appear when Stary III or Stary IV lesions are surrounded and/or capped by smooth muscle cells and collagen. These plaques can harbor calcification and areas of microthrombi in different stages of fibrotic organization. Different components of an advanced atherosclerotic lesion are shown in Fig. 1. The majority of acute coronary ischemic events occur as a result of plaque fissuring/rupture, with exposure of the subendothelial matrix and the subsequent development of an occluding thrombus on the surface of the plaque.

Table 1 Genetic and Environmental Factors Associated with Atherosclerosis and CAD^a

| Factor | Evidence |
|--|---|
| Strong genetic component | |
| Elevated levels of LDL/VLDL | Epidemiologic studies, studies of genetic disorders, and animal models; Small, dense LDL particles are particularly strongly associated with CAD. Clinical trials have shown benefits of cholesterol reduction. |
| Reduced levels of HDL | Epidemiological studies, studies of genetic diseases, and studies of animal models |
| Elevated levels of Lp(a) | Epidemiological studies: Animal studies have yielded both positive and negative results. |
| Elevated blood pressure | Epidemiological studies: Clinical trials have demonstrated benefits of blood pressure reduction, with a particularly strong effect on stroke. |
| Elevated levels of homocysteine | Epidemiological studies: Animal studies have been inconclusive. |
| Family history | Independent factor in nearly all studies. |
| Diabetes and obesity | Epidemiological and animal studies |
| Elevated levels of hemostatic factors | Associations have been observed with elevated levels of fibrinogen, plasminogen activator inhibitor type 1, and platelet reactivity. |
| Depression and other behavioral traits | Associations have been observed in several studies. The results are complicated by associated traits. |
| Gender (male) | Men younger than 60 years of age develop CAD at more than twice the rate as women. Recent trials has raised concerns about the benefits of postmenopausal estrogen replacement. |
| Systemic inflammation | Elevated levels of inflammatory molecules, such as sPLA ₂ , or inflammation markers, such as CRP, are associated with CAD. |
| The metabolic syndrome | This cluster of metabolic disturbances, with insulin resistance as a central feature, is strongly linked to CAD. |
| Environmental factors | |
| High-fat diet | Population migration studies have revealed very strong associations with lifestyle, and diet appears to be the most significant factor. High-fat, high-cholesterol diets are usually required for development of atherosclerosis in experimental animals. |
| Smoking | Epidemiological studies: It has been estimated that approximately 30% of CAD deaths are due to smoking. Clinical trials have demonstrated benefits of cessation of smoking. |
| Low antioxidant levels | Antioxidants protect against atherosclerosis in experimental animals. However, clinical trials with antioxidants are mixed and are not conclusive. |
| Lack of exercise | A significant independent relationship has been observed. |
| Infectious agents | Animal studies: Epidemiological studies have shown associations with various agents, such as <i>Chlamydia pneumoniae</i> . Clinical trials have been inconclusive. |

^aAbbreviations used: CAD, coronary artery disease; HDL, high-density lipoprotein; LDL, low-density lipoprotein; VLDL, very low-density lipoprotein.

Initial Events: Foam Cell Formation and Generation of the Fatty Streak

The events of atherosclerosis have been greatly clarified by studies in animal models, including rabbits, pigs, nonhuman primates, and rodents. Mice deficient in apolipoprotein E or the low-density lipoprotein (LDL) receptor develop advanced lesions and are the models most used in genetic and physiological studies. [Figure 2](#) depicts a model of the main events that occur in atherosclerotic plaque formation. The first observable change in the artery wall following the feeding of a high-fat, high-cholesterol diet is the accumulation of lipoprotein particles and their aggregates in the intima at sites of lesion predilection. LDL diffuses passively through endothelial cell (EC) junctions, and it is

retained in the vessel wall, which seems to involve interactions between the LDL constituent apolipoprotein B (apoB) and matrix proteoglycans. In addition to LDL, other apoB-containing lipoproteins, namely lipoprotein(a) and remnants, can accumulate in the intima and promote atherosclerosis.

The buildup of LDL in the subendothelial space is determined by the rate of retention as well as the rate of influx. Trapped LDL is modified by oxidation, lipolysis, proteolysis, and aggregation. Lipid oxidation as a result of exposure to oxidative waste of vascular cells is the most significant modification. Such modifications initially give rise to “minimally oxidized” LDL species, which can stimulate the overlying ECs to produce a number of proinflammatory molecules, including adhesion molecules and growth

Figure 1 Human coronary artery lesion. (A) All three main layers of the arterial wall are seen: intima (I), media (M), and adventitia (A). The internal elastica lamina (IEL) clearly separates the intima from the media. The fibrous plaque core is rich in extracellular lipids and foam cells. Staining with mAb to macrophages (HAM-56) allows visualization as dark infiltrates in the atherosclerotic plaque, prominent at the shoulder of the lesion. Notice the remarkable difference in the intima thickness between the neighbor normal arterial wall and the affected wall by the atherosclerotic plaque. (B) Staining with mAb to muscle actin (HHF35) allows visualization of the smooth muscle cells on top of the lesion core.

factors such as macrophage colony-stimulating factor (M-CSF). The retention of LDL and the biological effects of the trapped LDL depend on the extent that they are oxidatively modified, which is related to the balance of pro-oxidant and antioxidant elements. Two important factors in the antioxidant repertoire are heme oxygenase-1 (HO-1) expression and high-density lipoprotein (HDL). HO-1 seems to be both an anti-inflammatory and an antioxidant gene. HDL is strongly protective against atherosclerosis, presumably because of its capacity to remove cholesterol from the vascular tissue and also to inhibit lipoprotein

oxidation. The antioxidant properties of HDL derive in part from serum paraoxonase, an esterase carried on HDL that can degrade certain biologically active oxidized phospholipids.

Within days or weeks of diet initiation, monocytes can be observed adhering to the surface of the endothelium. The first step in adhesion, the “rolling” of leukocytes along the endothelial surface, is mediated by selectins that bind to carbohydrate ligands on leukocytes. The firm adhesion of monocytes to endothelium can be mediated by the integrin VLA-4 on these cells, which interacts with both VCAM-1 on the endothelium and the CS-1 splice variant of fibronectin. Monocyte chemoattractant protein-1 and its receptor, CCR2, are also important in monocyte recruitment. Once present in the subendothelial space, monocytes are stimulated to proliferate and differentiate into macrophages, a process partly mediated by M-CSF.

LDL is extensively modified to generate the highly oxidized LDL by the action of reactive oxygen species and by several enzymes, such as lipoxygenases, myeloperoxidase, sphingomyelinase, and secretory phospholipase produced by the vascular cells. Oxidized LDL is then rapidly taken up by macrophages through their scavenger receptors, especially SR-A and CD36, to form foam cells. Macrophage scavenger receptor expression is regulated by peroxisome proliferator-activated receptor- γ , an important transcription factor whose ligands include oxidized fatty acids, and by cytokines such as tumor necrosis factor- α , interferon- γ (IFN- γ), and M-CSF. Oxidized LDL can also inhibit the production of nitric oxide, a chemical mediator with multiple antiatherogenic properties, including vasorelaxation. When sufficient foam cells accumulate in addition to extracellular lipid, a fatty streak lesion can be seen macroscopically by staining with Sudan IV.

Advanced Lesions: Progression to Fibrous Plaques and Complicated Plaques

The increasing number of macrophages and T lymphocytes secrete cytokines and growth factors (e.g., platelet-derived growth factor) that are responsible for smooth muscle cell (SMC) migration, proliferation, and extracellular matrix production. In addition to the growing mass of extracellular lipid, this leads to the formation of fibrous plaques.

Various factors contribute to the development of advanced lesions. The engagement of CD40-CD40L between all major vascular cell types results in the production of inflammatory cytokines, matrix-degrading

Figure 2 Atherosclerosis model. The artery wall architecture has three main segments: the intima, from the endothelial cell (EC) monolayer to internal elastic lamina membrane (IEL); the media, consisting of smooth muscle cells (SMC); and the adventitia, which is the outer layer. Low-density lipoproteins (LDL) or other atherogenic lipoproteins enter and accumulate in the subendothelial space. Trapped LDL particles become oxidized probably as a result of interactions with reactive oxygen species (ROS) produced by vascular cells. Such minimally modified LDLs (MM-LDL) induce endothelial cells to express adhesion molecules for monocytes (X-LAM), monocyte chemotactic protein (MCP-1), and macrophage colony-stimulating factor (M-CSF), resulting in more recruitment of blood monocytes and subsequent differentiation into macrophages. With time, LDL particles become highly oxidized (Ox-LDL) and are then recognized by scavenger receptors on macrophages that endocytose them, giving rise to cholesterol-engorged foam cells. Such foam cells, the hallmark of fatty streaks, contribute to the development of advanced lesions by the production of various cytokines and growth factors that stimulate smooth muscle proliferation and fibrous cap formation. Calcification, hemorrhage, and thrombosis complicate plaques at advanced stages.

proteases, and adhesion molecules. Elevated homocysteine levels appear to injure ECs and to stimulate proliferation of vascular SMCs. Activation of the renin-angiotensin system also stimulates SMC growth and the production of extracellular matrix. A vicious cycle of inflammation ensues as inflammatory conditions promote the retention and modification of LDL and increasingly more modified LDL stimulates inflammation.

As the atherosclerotic plaque grows, active intimal calcification, development of new vessels from the media, and rupture of vessels with resulting intramural hemorrhage or thrombosis may occur. The progressive and insidious growth of plaque burden into the lumen of the vessel leads to narrowing of the arterial lumen. When this reaches a critical level, ischemia occurs, causing various symptoms depending on the affected tissue.

However, it is the unstable plaque that ruptures and exposes its subendothelial components with subsequent thrombus formation that has the most significance, at least in the coronary arteries, and is

responsible for the majority of myocardial infarctions. Plaque vulnerability is related to the fibrous cap thickness, which reflects the dynamics of matrix production and degradation. Vulnerable plaques generally have thin fibrous caps, increased numbers of inflammatory cells, and frequently rupture at the lesion edges where macrophages produce proteases that degrade extracellular matrix, including collagenases, gelatinases, and stromelysin. At the same time, matrix production by SMCs may be inhibited by IFN- γ produced by T lymphocytes.

CLINICAL MANIFESTATIONS

Atherosclerotic plaques may compromise the lumen of the vessels and obstruct blood flow to the respective tissue. Ischemia and/or infarction occur depending on the magnitude of the obstruction (partial, subtotal, or total), the duration of the obstruction, the time course (acute vs chronic), the collateral circulation, the degree of reversibility, and/or spontaneous reperfusion of

Table II Clinical Manifestations due to Atherosclerosis

| Organ/system | Clinical entity |
|------------------------|--|
| Heart | Coronary artery disease (stable and unstable angina and myocardial infarction) Congestive heart failure |
| Central nervous system | Cerebrovascular disease (transient ischemic attacks and strokes) |
| Peripheral vasculature | Peripheral vascular disease (intermittent claudication, vascular insufficiency, and gangrene) |

the affected vascular territory. The most common clinical entities are shown in [Table II](#).

Atherosclerosis is a long and silent disease. By the time the patient presents with chest pain due to coronary artery disease or intermittent claudication due to arterial insufficiency, years and decades of lipid deposition and plaque progression have occurred. Atherosclerosis is a debilitating disease. Stroke and congestive heart failure due to ischemic cardiomyopathy incapacitate a large number of individuals, imposing an incredible burden on the patients, their families, and society in general. It is of extreme concern that the first manifestation is frequently sudden death, eliminating opportunities for intervention. Symptomatic patients may be fortunate in the sense that there is an opportunity for diagnosis, risk factor modification, and therapeutic intervention. It is clear that we cannot rely on the clinical manifestations for the diagnosis of these entities since it may be too late by then.

ASSESSMENT

In animals, assessment has been performed mostly by postmortem evaluation of atherosclerotic lesions that originate at different levels in the arterial vasculature (aorta, carotid, coronary or femoral arteries, etc.) under the defined experimental variables employed. The evaluation can be quantitative or qualitative and either at the macroscopic or at the microscopic level.

In humans, the situation is much more complex given the necessity of achieving a phenotypic characterization *in vivo*. Postmortem correlations can also be established and are useful, but they provide only a narrow view of the very dynamic and multifactorial process in question. When present, the specific clinical manifestations in the corresponding clinical scenario help in deciding which diagnostic modality to use. It is even more difficult to approach the asymptomatic individual. The same strategies used with clinical atherosclerosis have been used here, but often these miss the earlier stages of the disease, when preventive actions are desirable. Diagnostic modalities can be classified as invasive and noninvasive

techniques. Invasive techniques, such as angiography (the gold standard) and intravascular ultrasound, offer the greatest degree of accuracy available, limited by cost and potential complications. Angioscopy allows direct visualization of the arterial wall, revealing plaque surface traits that are not representative of the internal heterogeneity of the plaque.

Noninvasive techniques can be classified as anatomic methods aimed at detecting the atherosclerotic plaque per se and physiologic methods aimed at detecting a physiologic abnormality created by impairment of blood flow in an arterial bed or impairment of vasodilation. Among the former, transesophageal echocardiography, electron-beam computed tomography, magnetic resonance angiography, and magnetic resonance imaging stand out. Among the latter, stress testing, coronary positron emission tomography, ultrasonic brachial vasodilatation, and the ankle–arm systolic blood pressure index techniques are commonly used. There is no one single and optimal method for phenotypic assessment, and the choice must be based on the specific indication.

THERAPEUTICS

[Table III](#) lists various treatment strategies for atherosclerosis-related disorders, mainly coronary artery disease. These include drugs that improve symptoms or modify risk factors, invasive medical procedures, and surgical procedures. Some agents improve both symptoms and survival; for example, beta-blockers decrease cardiac work and myocardial oxygen demand by decreasing heart rate and cardiac contractility. Some agents improve symptoms without affecting mortality; thus, nitrates decrease cardiac work and oxygen demand by increasing venous capacitance, decreasing venous return, and decreasing cardiac volume preload. Also, some agents improve symptoms but may have harmful effects (e.g., short-acting calcium channel blockers).

The development of interventional cardiology in recent years has revolutionized the treatment of coronary disease. Angioplasty with or without stent

Table III Strategies for Treatment of Symptoms or Improvement of Life Expectancy for Atherosclerosis-Related Disorders

| Therapy | Intervention | Mechanism |
|---------------------------|--|--|
| Lipid-modifying drugs | Statins | Decrease LDL cholesterol, and/or increase HDL cholesterol, and/or decrease triglycerides (varies with the specific drug) |
| | Gemfibrozil | |
| | Niacin | |
| Antiplatelet drugs | ASA | Decrease platelet reactivity |
| | Clopidogrel, ticlopidine | Decrease thrombus formation |
| | Glycoprotein IIB–IIIa inhibitors | |
| Antithrombotic drugs | Thrombolytic agents | Lysis of thrombus |
| | Unfractionated heparin | Decrease thrombus formation |
| | Low-molecular-weight heparin | |
| Antiangina drugs | Beta blockers | Improvement of myocardial oxygen offer–demand balance |
| | Nitrates | |
| | Calcium channel blockers | |
| Antihypertensive drugs | Diuretics | Blood pressure control |
| | ACE inhibitors | |
| | Beta blockers | |
| | Calcium channel blockers | |
| | Alpha blockers | |
| | Direct vasodilators | |
| Antioxidant drugs | Vitamin E | Increase antioxidant reserve |
| Interventional techniques | Angioplasty | Mechanical resolution of coronary and peripheral artery blockages |
| | Stents | |
| | Catheter-based endarterectomy | |
| Surgical techniques | Coronary artery bypass graft surgery | Surgical bypass or repair of coronary, carotid, or peripheral artery blockages |
| | Peripheral artery bypass surgery | |
| | Endarterectomy for carotid and peripheral arteries | |
| | Aortic aneurysm repair | |
| | | |

placement is the customary choice of one- and two-vessel coronary disease. It is particularly useful after medical therapy has been optimized without resolution of symptoms. With the better understanding of this disease and the development of better agents, surgical cases are decreasing in frequency.

However, cardiovascular disease is still the most common cause of death in the Western world. The known risk factors explain only about 50% of susceptibility to the disease. A better understanding of how to optimize therapy for the individual patient is required.

GENETIC DISSECTION

Atherosclerosis is a multifactorial and complex disease. Risk factors can be classified as those with an important genetic component and those that are largely environmental (Table I). Common forms

of coronary artery disease result from the combination of genetic susceptibility and an unhealthy environment.

Rare mendelian forms, such as familial hypercholesterolemia and Tangier disease, have provided important insights into the disease. Studies of candidate genes associated with predisposing conditions, such as hyperlipidemia, low HDL levels, diabetes, hypertension, and pro-coagulant disorders, have revealed a number of genes with significant or suggestive association or linkage with traits relevant to atherosclerosis.

As a result of the genome project and large-scale sequencing, thousands of single-nucleotide polymorphisms are being identified and a catalogue of all common variations in humans will be generated during the next few years. It can be anticipated that profiles of genetic factors, perhaps in the form of risk haplotypes, can be generated and that individuals in the future may be screened for these and therapies

may be tailored based on the particular risks for each individual.

NEW VENUES

Active and intense research is being conducted at all levels, from the basic aspects of genetics and molecular and cellular biology to the development of better diagnostic resources and risk-stratifying tools and the formulation of better therapeutic strategies. In the middle of the great genomic revolution, as our understanding of the genetics of the disease grows, genetic diagnosis will become increasingly important. It is hoped that this will allow genetic screening for diagnostic and risk-stratification purposes, which will enable better assignment of management resources and adequate and tailored pharmacological therapy.

CONCLUSION

Atherosclerosis is a chronic inflammatory disease characterized by progressive accumulation of lipids and cellular and fibrous elements in large and medium-sized elastic and muscular arteries. Elevated cholesterol levels, especially in the LDL fraction, are a principal risk factor. Lipoprotein retention and oxidation in the vascular wall leads to endothelium activation, monocyte infiltration, foam cell formation, inflammation, and proliferation of smooth muscle cells. Subsequently, a necrotic core of lipid and cell debris develops and vulnerable plaques rupture, leading to thrombosis. Clinical manifestations result from ischemia and vascular thrombosis in the respective vessels, leading to myocardial infarction, stroke, vascular insufficiency, and gangrene of the extremities.

Various resources are available for diagnosis and risk stratification, but all are limited and far from ideal. Despite an array of therapeutic options tailored for the different clinical manifestations, better strategies are needed to stop or reverse the disease and to be able to adjust pharmacological agents to each individual. It is hoped that the genetic dissection of this syndrome will allow genetic diagnosis to support screening and tailored therapy.

Atrial Natriuretic Factor and Family of Natriuretic Peptides

Kenneth K.-Y. Ma and Adolfo J. de Bold
University of Ottawa, Ottawa, Ontario, Canada

Glossary

cis-acting elements Short DNA consensus sequences located upstream (5'-flanking region) of the transcription start point. They can be either enhancers, which increase transcription, or silencers, which decrease transcription.

diuresis The increased excretion of urine, especially in greater than normal amounts.

exon Segment of a gene that corresponds to a sequence in the final processed RNA transcript of that gene.

heart failure Defective cardiac filling and/or impaired contraction and emptying, resulting in a heart's inability to pump a sufficient amount of blood to meet the needs of the body tissues or to be able to do so only with an elevated filling pressure.

hypertrophy An increase in the size of a tissue or an organ due to an increase in the size of its component cells. Contrast with hyperplasia.

immediate-early gene (IEG) Class of genes whose expression is low in quiescent cells, but whose transcription is activated within minutes of stimulation. Many IEGs encode *trans*-acting factors.

intron A noncoding sequence of DNA within a gene that is transcribed into nuclear RNA, but is subsequently removed by RNA splicing in the nucleus and rapidly degraded.

natriuresis The excretion of sodium in the urine, especially in greater than normal amounts.

TATA-box A consensus segment, 5'-TATAAA-3', that is 19–27 bp upstream from the start point of eukaryotic structural genes to which RNA polymerase II binds. Also known as a Goldberg-Hogness box.

trans-acting factors DNA-binding proteins that recognize *cis*-acting elements on the 5'-flanking region of the regulated gene.

(BNP), and C-type natriuretic peptide (CNP). These polypeptide hormones play central roles in maintaining fluid and electrolyte balance and circulatory homeostasis. In mammals, the bulk of ANF and BNP is produced and secreted by the cardiac muscle cell (cardiocyte), whereas CNP is produced mainly by the vascular endothelium and brain.

PHYSIOLOGY, STRUCTURE, BIOSYNTHESIS, AND REGULATION OF ANF

Physiology, Structure, and Biosynthesis of ANF

Physiological Actions of ANF

In 1981 it was demonstrated that injections of heart atrial extracts into rats gave rise to pronounced diuresis, natriuresis, and lowered blood pressure. Within a short time, a peptide with the same biological properties as the crude atrial extracts was isolated and its amino acid sequence was identified. This peptide, now known as atrial natriuretic factor (also known as atrial natriuretic peptide), firmly established the heart as an endocrine organ and heralded a new era of research on the control and maintenance of blood pressure, blood volume, and vascular tone.

ANF is a potent natriuretic and diuretic agent, owing these properties to both its renal hemodynamic actions and its direct tubular actions. By simultaneous dilation of afferent arterioles and constriction of efferent arterioles, ANF increases the glomerular filtration rate and filtration fraction. ANF will directly inhibit water reabsorption by the renal cortical collecting duct and contributes to inhibition of Na⁺ reabsorption by the renal inner medullary collecting duct.

ANF also has profound effects on the cardiovascular system. Acute administration of ANF causes a fall in arterial pressure due to a reduction in cardiac output mediated by a decreased preload and vascular resistance. The decreased preload is believed to be a consequence of venodilation and reduction of the intravascular volume. Furthermore, ANF also reduces

The atrial natriuretic factor family of natriuretic peptides (NPs) consists of three members: atrial natriuretic factor (ANF), brain natriuretic peptide or B-type natriuretic peptide

sympathetic tone by inhibiting arterial baroreceptor response and suppression of catecholamine release from autonomic nerve endings.

The renin–angiotensin–aldosterone system (RAAS) is also a target for ANF. ANF will directly reduce renin secretion, which has the cascade effect of lowering circulating levels of angiotensin II (Ang II), a potent vasoconstrictor and stimulator of aldosterone. ANF can also directly inhibit aldosterone synthesis and secretion from the glomerulosa cells of the adrenal cortex.

The central actions of ANF include inhibition of secretion of vasopressin and of salt and water intake. ANF also possesses important anti-mitotic actions on vascular endothelial cells, smooth muscle cells, and cardiac fibroblasts.

Structure and Biosynthesis of ANF

The sequencing of ANF permitted the generation of oligonucleotide probes that were used to isolate cDNA clones for ANF-coding sequences. The mRNA is approximately 1 kb long and encodes a preproANF that contains between 149 and 153 amino acids depending on the species (Fig. 1). The human amino acid sequence shares strong homology with peptides from other species including rat, mouse, and pig. In the human atria, ANF is stored mainly within organelles referred to as specific atrial granules as a prohormone called proANF_{1–126}. Subsequent processing releases into the bloodstream the biologically active hormone, ANF_{99–126}. Normal human plasma concentrations of ANF are approximately

6 fmol/ml. The biological half-life of ANF_{99–126} is very short (0.5–2 min).

All members of the ANF family of natriuretic peptides [ANF, B-type natriuretic peptide (BNP), and C-type natriuretic peptide (CNP)] share a common central ring structure formed by a disulfide bridge (positions 105 and 121 for ANF). Disruption of this 17-member ring leads to a loss of biological activity (Fig. 2).

ANF Gene Regulation

The ANF gene is mapped to chromosome 1 in humans, chromosome 4 in mouse, and chromosome 5 in rats. Structurally, the ANF gene is similar in all mammals and consists of three exons and two introns (Fig. 1).

Tissue-Specific and Developmental Regulation of ANF Gene Expression

Atrial expression of ANF rises continuously during fetal and postnatal development to comparatively high levels (1–3% of total atrial mRNA), whereas ventricular expression of ANF, although quite high during fetal development, falls quickly after birth (1% of atrial levels). Extracardiac (aortic arch, hypothalamus, pituitary, and kidney) sites of synthesis have also been documented, but the major site of ANF production remains the atria. In adulthood, ANF expression by the heart can be markedly increased by mechanical stretch of the cardiocyte and/or by neuroendocrine hormones.

Cis-acting elements responsible for tissue- or stage-specific expression of ANF have been identified on the 5'-flanking promoter of the ANF gene. The characteristic TATAA-box motif for binding the ubiquitous transcription initiation factor IID (TFIID) transcription factor is 30 bp upstream of the transcription initiation site (CAP site). Within the –700 bp ANF promoter, certain regions that confer chamber and temporal-specific activity have been identified. A CARG motif at –405 bp plays a critical role in the ventricular and stage-specific activity of ANF expression. Furthermore, located between –380 and –300 is cardiac regulatory element (CARE). CARE and the *trans*-acting factor Catf-1 are active in the embryonic atria and ventricle but not in the postnatal ventricular cardiocyte. Finally, there are a few elements that are important in maintaining basal expression of ANF. These are located in the proximal promoter from –135 to –1 and include GATA-, Nkx2.5 response element (NKE), and T-box 5 (Tbx5)-binding elements.

Figure 1 Structure of the gene and biosynthetic pathway of human ANF. Solid black sections are those that code for the mature ANF_{99–126}. Gray sections code for NH₂-terminal fragments and the striped section codes for the signal peptide. Numbers indicate the amino acid position relative to the sequence encoded in proANF. T indicates the location of the TATAA-box. UTR, untranslated region.

Figure 2 The biologically active forms of the natriuretic peptides. Amino acids that are shared by all members of the natriuretic peptide family are identified by filled circles. A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine.

Mechanical and Neuroendocrine Regulation of ANF Gene Expression

Acute Mechanical Myocardial Stretch

ANF is continuously released from the atria of the heart, but appropriate mechanical stretch can increase the rate of ANF secretion. In acute experiments with isolated atrial preparations, increases in atrial wall stretch are met with corresponding increases in ANF secretion with no change in ANF gene expression. Despite continued mechanical stimulation, the acute increase in ANF release eventually decays to baseline values within minutes. The precise mechanism underlying mechanotransduction of stretch-induced ANF release remains to be elucidated.

Neuroendocrine Hormones or Agents

Numerous neuroendocrine agents can also increase ANF gene expression and release. α_1 -Adrenergic agonists (e.g., phenylephrine) and vasoactive peptides, such as endothelin-1 (ET-1) and Ang II, are potent stimulators of ANF gene expression and release. The vasoconstrictor ET-1 is synthesized and released by the endothelial and mesothelial cells. It is believed that ET-1 can act in a paracrine fashion *in vivo* to modulate ANF gene expression and release. Ang II, an effector molecule of RAAS, is a potent vasoconstrictor as well as a growth factor for cardiocytes.

Ang II, ET-1, and catecholamines bind to the heterotrimeric G protein heptahelical transmembrane family of receptors. In general, activation of the receptor leads to the recruitment of secondary effector molecules that activate cytosolic and/or nuclear substrates. In particular, Ang II, ET-1, and phenylephrine will rapidly stimulate protein kinase C and the mitogen-activated protein kinase, p44/42 (ERK), which in

turn will activate *trans*-acting factors responsible for the increase in ANF expression. These include the immediate-early genes (IEGs), such as the *c-fos* and *c-jun* heterodimer, that can bind to activator protein-1 (AP-1) consensus elements on the 5'-flanking region of the ANF promoter.

Hormonal ligands for nuclear receptors, such as glucocorticoids, have also been shown to up-regulate ANF gene expression and release. A cytokine produced by the cardiocyte, called cardiotrophin I, has been shown to up-regulate ANF gene expression.

Chronic Hemodynamic Overload and Changes in ANF Expression

Under chronic hemodynamic overload, mature terminally differentiated cardiocytes will respond with cellular hypertrophy to normalize wall stress. Importantly, ANF gene expression and release are markedly increased not only from the atrial cardiocytes, but also from the ventricular cardiocytes by the hypertrophic stimuli. This can translate into a 100-fold increase in ANF plasma concentrations in certain pathophysiological conditions such as chronic congestive heart failure. Hypertrophic stimuli, such as prolonged myocardial stretch or humoral growth factors, will activate the IEGs, such as *c-myc*, *c-fos*, and/or *c-jun*. This is followed by activation of the characteristic embryonic gene program seen during cardiac development. Molecularly, this gene program accounts for the re-expression of ANF, BNP, β -myosin heavy chain, and skeletal α -actin in the hypertrophic adult ventricle.

The precise mechanisms responsible for the chronically increased ventricular ANF gene expression and secretion have not been fully elucidated. *In vivo*

experiments have demonstrated that there may be two components responsible for these changes in natriuretic peptide expression: one that is dependent on hemodynamic load (i.e., mechanical stretch) and one that is load independent (i.e., direct effects of humoral growth factors, such as ET-1 and Ang II, on cardiocytes).

OTHER MEMBERS OF THE ANF FAMILY OF NATRIURETIC PEPTIDES

Physiology, Structure, Biosynthesis, and Regulation of BNP

Physiological Actions of BNP

Brain natriuretic peptide was originally isolated from porcine brain. However, it was later discovered that the highest concentrations were found in the heart. BNP, like ANF, is a potent natriuretic, diuretic, vasorelaxant, anti-mitotic factor as well as an antagonist of the renin-angiotensin-aldosterone axis. Of interest, however, BNP may have functions not associated with ANF. BNP has been shown to have anti-fibrotic properties. This effect may be particularly important in cardiovascular diseases in which cardiac fibrosis contributes to the progression to heart failure.

Structure and Biosynthesis of BNP

BNP is synthesized as a 121- to 134-amino-acid preprohormone (Fig. 3). In humans, subsequent processing releases a mature biologically active 32-amino-acid carboxy-terminal fragment. Unlike ANF or CNP, the amino acid sequence of BNP is not as highly conserved and may differ by as much as 50% between species. The plasma half-life of BNP is approximately 22 min, which is approximately six times longer than that of ANF. The normal circulating BNP level in humans is approximately 0.9 fmol/ml.

Regulation of BNP Gene Expression

The BNP gene is mapped to chromosome 1 in human and to chromosome 4 in mouse. Structurally the BNP gene is similar to the ANF gene in that it is composed of three exons and two introns. However, there are important differences between the regulation of BNP and ANF at the transcriptional and posttranscriptional levels. Hemodynamic overload increases both atrial and ventricular expression of BNP (and ANF) dramatically. In pathological states such as chronic congestive heart failure, the plasma BNP level can increase 1000-fold.

Figure 3 Structure of the gene and biosynthetic pathway of human BNP. Solid black sections are those that code for the mature BNP₇₇₋₁₀₈. Gray section codes for the NH₂-terminal fragment and the striped section codes for the signal peptide. Numbers describe the amino acid position relative to the sequence encoded in proBNP. G's indicate the location of the GATAAA sequences (TATAAA-box). UTR, untranslated region.

The 5'-flanking region of the BNP gene resembles more of an erythroid- than of a muscle-specific promoter. *Cis*-acting elements within 114 bp upstream of the CAP site appear to be responsible for conferring not only tissue-specific expression but also hemodynamic stress responsiveness. This region of the promoter contains conserved AP-1 and GATA recognition sites. GATA transcription factors are believed to be important in both basal and stimulated expression of BNP.

In response to certain hypertrophic stimuli, BNP mRNA is rapidly up-regulated in a protein synthesis-independent manner with quick turnover. These features are characteristic of an IEG. In support of this, the BNP 3'-untranslated region contains many AU-rich elements that may confer instability to the BNP transcript (mRNA $t_{1/2}$ ~60 min) not found in ANF mRNA, which is quite stable. Interestingly, BNP mRNA stability can be enhanced after treatment with phenylephrine or ET-1. In addition to neurohumors such as ET-1 and phenylephrine, BNP gene expression and secretion can also be up-regulated by pro-inflammatory cytokines, such as interleukin-1 β and tumor necrosis factor α (TNF α).

In summary, the significant increase in BNP expression during overload may be due a combination of specific transcriptional and posttranscriptional mechanisms.

Physiology, Structure, Biosynthesis, and Regulation of CNP

Physiological Actions of CNP

CNP is found in the cerebellum, hypothalamus, anterior pituitary, kidney, and the vascular endothelial cells but not in the heart. The central actions of CNP include antagonizing angiotensin II-mediated increases in vasopressin, which in turn decreases salt and water intake.

The natriuretic activity of CNP is only approximately 1% of that of ANF. CNP has potent anti-growth properties on vascular smooth muscle cells, suggesting that CNP may be an important regulator of blood vessels.

Structure and Biosynthesis of CNP

CNP is the most conserved of all natriuretic peptides, with 90% homology observed among human, mouse, pig, and rat. Produced from a 126-amino-acid preprohormone, the bioactive hormone, unlike ANF or BNP, is only 22 amino acids long, because CNP has no carboxy-terminal tail (Fig. 2).

Regulation of CNP Gene Expression

The gene for CNP is located on chromosome 2 in humans, in contrast to the ANF and BNP genes, which are located on chromosome 1 in humans. The

mouse CNP gene consists of least two exons and one intron. The 5'-flanking region of CNP contains numerous *cis*-acting regulatory elements including dinucleotide CA repeats, cyclic AMP-response element-like, nuclear factor κ B, and shear stress recognition sites. Cytokines, such as transforming growth factor- β and TNF α , can up-regulate CNP.

NATRIURETIC PEPTIDE RECEPTORS

Many of the biological actions of the natriuretic peptides are mediated through association with specific high-affinity receptors on the surface of target cells and the generation of cyclic guanosine monophosphate (cGMP) (Fig. 4). There are three natriuretic peptide receptors (NPR-A, NPR-B, and NPR-C). NPR-A and NPR-B are linked to guanylate cyclase and, on activation of the receptor, cGMP is formed. cGMP targets may include cGMP-dependent protein kinases and cGMP-gated ion channels. NPR-A binds both ANF and BNP, with preference for ANF. NPR-B binds CNP with far less preference for either ANF or BNP. NPR-C is the clearance receptor and binds CNP with slightly greater affinity than ANF or BNP. Circulating natriuretic peptides are also inactivated by neutral endopeptidases present within renal tubular and vascular cells.

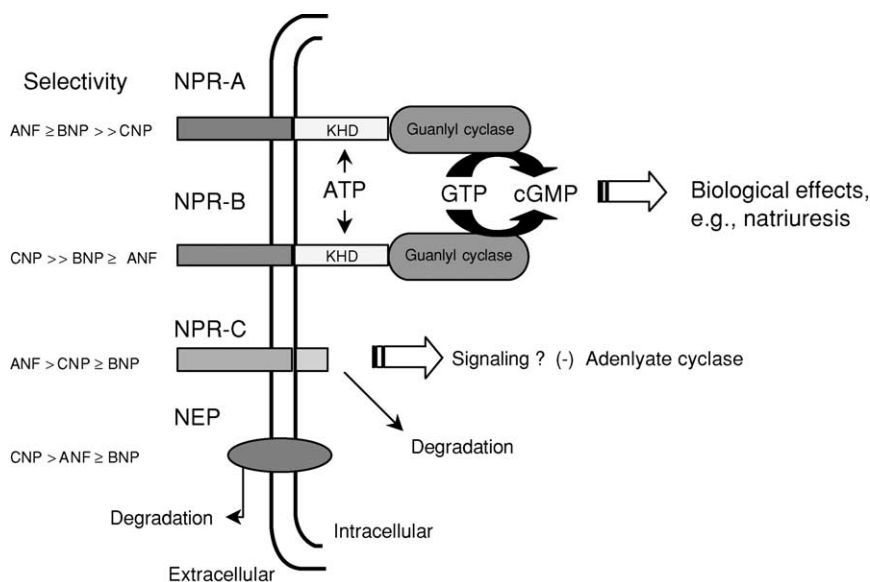

Figure 4 The natriuretic peptide receptors. Binding of ANF and BNP to NPR-A and CNP to NPR-B stimulates intrinsic guanylyl cyclase activity of the receptor. The transduction of ligand binding to cGMP generation is ATP dependent and requires participation from the KHD portion of the receptor. NPR-A, natriuretic peptide receptor-A; NPR-B, natriuretic peptide receptor-B; NPR-C, natriuretic peptide receptor-C; KHD, kinase-like homology domain; NEP, neutral endopeptidase 24.11.

NATRIURETIC PEPTIDES AND PATHOPHYSIOLOGY

A hallmark of chronic congestive heart failure (CHF) is enhanced atrial and ventricular synthesis and release of ANF and BNP secondary to increased hemodynamic load and humoral stimulation. The severity of heart failure correlates well with plasma levels of ANF and BNP such that these peptides are reliable diagnostic and prognostic markers. In severe cases, the plasma level of BNP may surpass that of ANF. It is very likely that the increases in ANF and BNP serve to limit or delay the progression of CHF, in part by its renal, vascular, and endocrine actions.

SUMMARY

The atrial natriuretic factor family of natriuretic peptides plays an important role in regulating blood pressure, extracellular fluid homeostasis, and cardiovascular growth under normal physiological conditions and in diseased states. Natriuretic peptides defend against excess salt and water retention, promote vascular relaxation, inhibit RAAS, inhibit sympathetic outflow, and have potent anti-mitotic properties. For many pathophysiological cardiovascular conditions, ANF and particularly BNP have become important diagnostic and prognostic tools. At present, many clinical treatment strategies for

heart failure are based on the application of the knowledge base developed about the natriuretic peptides. These include systemic administration of natriuretic peptides and pharmacological approaches, such as the dual angiotensin-converting enzyme and neutral endopeptidase inhibitors. The beneficial outcomes of these agents only highlight the importance of further study of the endocrine heart and the ANF family of natriuretic peptides.

Autoimmune Polyglandular Syndrome

Andrew Muir

Medical College of Georgia, Augusta, Georgia, United States

Glossary

adrenocortical failure Insufficient production of steroid hormones from the cortex of the adrenal gland, including clinically important deficiencies of cortisol and aldosterone.

autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) A commonly used alternate name for type 1 autoimmune polyglandular syndrome.

autoimmune thyroiditis Inflammation of the thyroid gland caused by abnormal self-reactive immune responses that can cause either low thyroid function (Hashimoto's thyroiditis) or high thyroid function (Graves' disease).

autoimmunity Abnormal responsiveness of cells of the immune system against the body's own (self) organs.

hypoparathyroidism Insufficient parathyroid hormone production, resulting in serum calcium levels below normal.

mucocutaneous candidiasis Infection of mucosal surfaces or skin by the yeast *Candida albicans*.

nonobese diabetic (NOD) mouse An inbred strain of mice that spontaneously develop immune-mediated destruction of pancreatic beta cells, causing diabetes.

Type 1 and type 2 autoimmune polyglandular syndromes (APS-1 and APS-2) include clusters of immune-mediated diseases that overlap in their clinical presentations but appear to have distinct underlying pathogeneses. The components of APS-1 are mucocutaneous candidiasis, hypoparathyroidism, and adrenocortical failure; the diagnosis requires that two of these three conditions be present. APS-2 is defined by the presence of adrenocortical failure and either autoimmune thyroiditis or type 1 diabetes mellitus. Individuals with either form of APS frequently develop autoimmune disease in target organs that are not included in the syndrome definitions (e.g., gonadal failure, atrophic gastritis, vitiligo, alopecia), and some individuals with autoimmune polyglandular failure do not fulfill the strict criteria for either form of APS but have close relatives who do.

INTRODUCTION

The explanation for the immune system's faulty targeting of specific groups of organs in patients with either type 1 or type 2 autoimmune polyglandular syndrome (APS-1 or APS-2, respectively) has been elusive, but genetic, immunological, and environmental influences are believed to be important. A normal immune system eliminates foreign antigens from its host while remaining tolerant to self-antigens. Multiple mechanisms exist to establish and maintain tolerance in lymphocytes. Through an interaction with stromal bone marrow cells, self-reactive B-lymphocyte precursors usually die. Immature B lymphocytes that have not completed B-cell receptor (BCR) gene rearrangement may "edit" their light chain gene in an attempt to produce a specificity that will not be subject to negative selection. B lymphocytes do not survive more than a few days in the circulation unless their BCR is bound in a manner that activates the cell.

Intrathymic tolerance is the process whereby T-lymphocyte precursors from the bone marrow are first positively selected if their antigen-specific T-cell receptor (TCR) is likely to be recognized by the host's immune system and, therefore, useful for fending off foreign antigen. Cells that are not positively selected will die. Interaction between young T lymphocytes and epithelial cells in the thymic cortex mediate this process. The T lymphocytes that survive positive selection are then subjected to negative selection, a process whereby bone marrow-derived antigen-presenting cells (and, to a lesser extent, epithelial cells) trigger apoptosis (programmed death) of cells whose TCR specificities bind self-antigens too avidly. Once they are released from the thymus, naive T lymphocytes must receive ongoing "survival signals" as they circulate through blood, lymphoid organs, and lymphatics. Those cells that bind antigen to their TCR may either be activated, become anergic (unresponsive), or die (activation-induced cell death). Control of this fate is dependent on multiple factors, including the avidity of the TCR for the human

leukocyte antigen (HLA) molecular complex containing the antigen on the surface of antigen-presenting cells, accompanying signals generated by accessory molecule interactions, the preexisting activation state of the lymphocyte, and the presence of soluble mediators of immunity (e.g., cytokines).

Immune function experiments and genome mapping have delineated both similarities and differences between people with isolated target organ destruction and those with polyglandular autoimmune disease. In addition, important distinctions between APS-1 and APS-2 have been demonstrated. Therefore, the two syndromes are addressed as separate entities in this article.

TYPE I AUTOIMMUNE POLYGLANDULAR SYNDROME

Epidemiology

APS-1 is a rare condition, even among the three ethnic groups in which it is seen most frequently. Prevalence estimates place the rate among Iranian Jews at 1 in 9000, among Sardinians at 1 in 14,400, and among Finns at 1 in 25,000. Even a Norwegian prevalence estimate of 1 in 80,000 is still probably below the rate seen in most of North America and Western Europe. A slight female predominance among APS-1 patients has been reported by some groups, but this bias was not obvious in a group of 68 Finnish patients or in 23 affected Iranian Jews. Immune system dysfunction typically becomes clinically apparent at an early age, often during the first 5 years of life. However, initial signs may be delayed until adulthood.

Mucocutaneous candidiasis is uncommon among Iranian Jews, but in most populations, infections of the nails, skin, and gastrointestinal tract affect 73 to 100% of patients. Indeed, it is the most frequent first sign of APS-1. Hypoparathyroidism, diagnosed in 76 to 96% of patients, usually appears during the first decade of life, and the diagnosis of adrenocortical insufficiency, seen in 72 to 100% of patients, is made an average of approximately 5 years later. About one-third of patients worldwide develop all three of the defining diseases, although variations of the degrees of severity exist among different ethnic groups.

Etiology

Genetics

Single-gene, autosomal recessive inheritance with complete penetrance marks APS-1 as unusual among autoimmune diseases. Its relatively simple genetics

provides hope that an understanding of the molecular basis for deranged immune tolerance in APS-1 may be achieved more easily than that for more common autoimmune conditions that are polygenic. The gene conferring the condition, designated the autoimmune regulator (*AIRE*) gene, was first mapped to chromosome 21q22.3 and then positionally cloned. The gene consists of 14 exons that transcribe a 2445-bp mRNA transcript. The translation product contains 545 amino acids with a predicted molecular weight of 57.5 kDa.

A proposed molecular model for *AIRE* is presented in Fig. 1. The protein contains at least three DNA-binding domains (two PHD or zinc finger domains and one SAND domain). The presence of these domains and the localization of *AIRE* to the nucleus suggested that the protein was a transcription factor. This postulate has received strong support from subsequent functional studies. Inclusion of an *AIRE* construct in a eukaryotic transactivation system, in which the protein was fused to a heterologous DNA-binding domain, increased expression of reporter genes by one to two orders of magnitude. Cotransfection of an *AIRE* construct and an interferon- β (IFN- β) minimal promoter upstream of luciferase into monkey kidney cells resulted in a 5.5-fold

Figure 1 A model for the *AIRE* protein. Reprinted with permission from Kumar, P. G., Laloraya, M., Wang, C-Y., Ruan, Q-G., Davoodi-Semiromi, A., Kao, K-J., and She, J-X. (2001). The autoimmune regulator (*AIRE*) is a DNA-binding protein. *J. Biol. Chem.* 276, 41357-41364.

increase in reporter activity compared with the activation induced when only vector sequence was cotransfected with the promoter.

Gel shift assays that distinguish whether a protein is free or bound into a complex showed that the PHD domains of AIRE homodimers and tetramers bound T-box (TTATTA) or G-box (ATTGGTTA) sequences, whereas AIRE monomers bound no DNA sequences. The formation of oligomers is likely to be essential for AIRE activation. The process may be stimulated by phosphorylation of AIRE by cyclic AMP (cAMP)-dependent protein kinase A and/or protein kinase C. Finally, interaction between AIRE and cAMP response element-binding (CREB) protein suggests a link to the control of cAMP-mediated signaling within cells by AIRE.

AIRE is expressed in a subset of epithelial cells in the thymic medulla and corticomedullary junction, in medullary thymocytes derived from monocytes, and within lymphocytes and neutrophilic granulocytes of the lymph nodes and spleen. Among circulating cells, it is expressed most prominently in CD14-positive monocytes and dendritic cells.

Mouse studies suggest that thymic expression of *Aire* (the mouse homologue of human *AIRE*) is dependent on signals from surrounding thymocytes. Prenatal expression of *Aire* in thymic medullary epithelium is normally recognized by day E14, a time after lymphocytes have started committing to the $\alpha\beta$ subset of TCR lineage. This expression is not observed in Tg ϵ 26 mice, a transgenic line characterized by early thymocyte developmental arrest and consequent disruption of thymic architecture. In contrast, RAG^{null} mice experience late thymocyte developmental arrest. Their thymic architecture is normal, and they exhibit normal *Aire* expression. Furthermore, *Aire* expression is dependent on the expression of the RelB transcription factor. RelB is a member of the NF- κ B family and is required for the normal development of the thymic dendritic cells and the medullary-activated stromal cells that express a surface molecule that binds antibody 29. It is these 29-positive cells that predominantly produce *Aire*. RelB-deficient transgenic mice are deficient of 29-positive stromal cells, do not express *Aire*, and have abnormal thymic architecture and negative selection. However, absent *Aire* expression is not merely the result of 29-positive epithelial cell hypoplasia. The thymi of the Tg ϵ 26 mice contain 29-positive epithelial cells but do not express *Aire*.

Elegant studies in congenic mice with specific deficiencies of negative or positive selection provide functional evidence of a link between *Aire* production

and intrathymic negative selection of T lymphocytes. Therefore, our understanding of normal *AIRE* function suggests that it is a transcription factor whose expression is activated at a relatively late stage of thymic ontogeny by signals from developing thymocytes. The absence of AIRE is associated with abnormal negative selection. However, a causal relationship with this functional defect has not been proven.

Nearly 50 mutations of AIRE have been reported worldwide in patients with APS-1. Founder effects are apparent. Of 67 mutant alleles in Finnish patients, 55 (82%) had the most common error, R257X, in which a substitution of thymidine for cytosine resulted in an arginine being changed to a stop codon in exon 6. The resulting 256-amino acid translation product had no function. This mutation was also common among Russian patients, but among studies of other continental European populations, only 15 of 47 alleles (32%) had the R257X mutation. In the United Kingdom, a 13-bp deletion in exon 8 that encoded a functionless truncated protein accounted for 20 of 25 cases (80%), and only 1 allele contained the R257X sequence. The exon 8 mutation was also the one reported most frequently in North America, where it was found in 21 of 42 cases (50%). In Norway, the 13-bp deletion was the most common mutation found in a series of 20 patients, but interestingly, it was detected in at least four different haplotypic backgrounds. Founder effects were very apparent in Italian and Iranian populations. Among Sardinians, 10 of 11 mutant alleles demonstrated a mutant R139X allele in exon 3, and a missense mutation in exon 2 (W78R) was reported to be frequent among APS-1 patients living in a restricted area of southern Italy. All affected Iranian Jews who have been studied expressed a homozygous Y85C missense mutation in exon 2.

The total number of patients with APS-1 who have been genotyped is small; therefore, it has been impossible to perform adequately powered analyses of the relationship between genotype and phenotype. Such endeavors are made very complex by the intrafamilial heterogeneity of phenotypes and the inability to determine the eventual phenotype in young patients who, in time, may develop other features. Nonetheless, it is of interest that the missense mutation among Iranian Jews that allows production of a full-length protein is associated with a clinical spectrum that includes lower rates of mucocutaneous candidiasis and adrenocortical failure than is the case with other populations.

Functional assays with mutant *AIRE* constructs have shed some light on normal molecular function.

The nuclear pattern of AIRE labeling in wild-type monkey kidney cells became predominantly cytoplasmic, rather than nuclear, when the cells were transiently transfected with the common Finnish mutant gene. Two other missense mutations that interfered with PHD domain formation similarly disrupted nuclear staining, but the introduction of the Y85C mutation of Iranian Jews did not change the nuclear AIRE labeling pattern from that seen in the wild type.

A peptide comprising AIRE amino acids 101 to 141 contains a consensus nuclear localization signal. Its transient transfection into monkey kidney cells permitted transport of endogenously produced green fluorescent protein into the nucleus. C-terminal peptides that did not contain this 41-amino acid sequence were also normally transported to the nucleus, suggesting the possibility of another undefined transport sequence.

Disruption of the PHD domains is reported to reduce transcription activation, and mutant homogeneously staining region (HSR) sequences (Fig. 1) may prohibit dimer formation and, therefore, preclude promoter activation.

Perhaps the most important aid for delineating the role of AIRE in the pathogenesis of APS-1 will be strains of Aire knockout mice. The phenotype of an Aire-deficient mouse strain was reported to include many features of APS-1, including atrophy of the adrenal cortex, ovaries, and thymus. Hepatitis was common, and autoantibodies were detected against multiple organs. A second group also demonstrated organ-selective mononuclear cell infiltrates in multiple organs and circulating autoantibodies in another Aire knockout mouse model. The group further proposed that low expression of selected self-antigens by thymic medullary epithelial cells was associated with the autoimmune phenotype.

It is not clear whether genetic influences apart from AIRE influence the progress of APS-1. Various genes in the class I and class II HLA complex have been implicated, but none has been observed consistently. One observation of interest is the increased frequency of DQB1*0602 in patients with APS-1 compared with that in control populations. This same allele is associated with protection from type 1 diabetes.

Immunology

APS-1 includes an unusual mixture of conditions suggesting that multiple defects exist in the control of immune responses. Whereas a high incidence of mucocutaneous candida suggests immune deficiency, most of the other component diseases arise from unbridled responses against self-targets. However, the

apparent paradox may be resolved when one considers that antigen-specific tolerance is established by an active process that requires interaction between T lymphocytes and self-antigen.

The best experimental evidence for disrupted tolerance in APS-1 is the presence of autoantibodies against multiple organs. These immunoglobulins arise before organ failure is clinically apparent and frequently become undetectable after diagnosis, presumably indicating that the autoimmune response has completely eliminated its target. In most autoimmune diseases, the autoantibodies are not the primary effectors of target organ damage, but they do serve as markers of immune autoreactivity. Based on this premise, the requirement of B lymphocytes in immune-mediated pancreatic beta cell destruction was questioned. Nonobese diabetic (NOD) mice that normally develop diabetes spontaneously did not, however, become hyperglycemic if their B-lymphocyte compartment was genetically eliminated. Diabetes was restored in these knockout mice after their bone marrow was reconstituted with wild-type B-lymphocyte precursors. Studies suggest that the antigen-presenting function of the grafted B lymphocytes helps to establish organ destruction that is caused by T lymphocytes and macrophages.

Originally, organ-specific autoantibodies were detected by overlaying patient sera on normal frozen tissue sections and then identifying specific immunoglobulin binding to the tissue with fluorescently labeled anti-immunoglobulin second antibodies. The method is labor intensive, highly complex, and somewhat inconsistent between runs. It also lacks the sensitivity of more modern techniques.

Adrenocortical failure in patients with APS-1 features autoantibodies that bind selectively to normal adrenal cortex. The presence of a distinct population of circulating autoantibodies in patients with adrenocortical failure that also bind steroid-producing cells of gonads and placenta is associated with gonadal failure. The antigens recognized by these autoantibodies have been identified, and as a result, improved immunoassays are now available, albeit on a limited basis. Targets include the cytochromes P450c21 (21-hydroxylase), P450c17 (17-hydroxylase), and P450scc (side chain cleavage) as well as the neurotransmitter synthetic enzyme aromatic L-amino acid decarboxylase (AADC). In some but not all laboratories, adrenocortical failure is more closely associated with autoantibodies against P450c21 and AADC, whereas gonadal failure is more strongly linked with responses to P450scc and P450c17. Apart from their association with APS-1-related adrenal gland failure,

autoantibodies against AADC are seen in approximately 90% of APS-1 patients who have either hepatitis or vitiligo.

When interpreting autoantibody results (or tests of other immune phenomena), it is important to consider the particular patient under study. Positive results in patients with isolated autoimmune endocrinopathy do not necessarily carry the same importance as does similar positivity in patients with polyorgan disease. The poor predictive value of GAD₆₅ autoantibodies for diabetes in patients with APS-1 is a good example. Another involves the autoimmune hepatitis that arises in some 15% of patients with APS-1. It is clinically and histologically indistinguishable from other forms of chronic active hepatitis. Hepatic autoantigens in APS-1 patients with chronic hepatitis include four P450 cytochromes: 1A1, 1A2, 2A6, and 2B6. Autoantibodies against P450 1A2 are specific for APS-1-related hepatitis, and antibodies recognizing P450 2A6 are uncommon outside of the APS-1 setting but do not necessarily correlate with clinically detectable hepatitis. Furthermore, no immunity against autoantigens typically observed in other forms of autoimmune hepatitis has been reported in patients with APS-1. Female gender and genes in the HLA complex, including DRB1*0301 (or a gene close to it), are other determinants of isolated forms of hepatitis that are not important in APS-1.

The calcium sensor in the parathyroid gland was reported to be a target of autoantibodies in the sera from 6 of 17 patients (35%) with APS-1 and hypoparathyroidism and in 8 of 8 patients with isolated adult-onset idiopathic hypoparathyroidism. No parathyroid autoantigens were immunoprecipitated from the sera of 72 euparathyroid controls who either were healthy or had an autoimmune disease affecting just one organ. The limited reports of autoantibodies against parathyroid antigens in patients with APS-1 have been difficult to reproduce. Furthermore, tissue samples are rarely available for direct microscopic or biochemical scrutiny because chronically affected glands become atrophic and cannot be found at postmortem examination.

The susceptibility to candida infection in APS-1 has not been explained satisfactorily. Patients are able to generate spontaneous humoral responses against candida antigens. Standard immunological techniques have not convincingly defined an abnormality in the maturation or function of T lymphocytes of patients with APS-1. A disturbing association with oropharyngeal squamous cell carcinoma is becoming apparent, further suggesting the possible existence of a subtle but functionally important defect in immune

surveillance. Local effects of chronic mucocutaneous candida could also be important in this susceptibility. The significance of defective immunoglobulin production, including immunoglobulin A (IgA) deficiency in patients with APS-1, is unclear.

Environment

Infectious agents harbor antigens that are similar enough to human self-components that they can induce cross-reactive autoimmunity that persists long after the germ has been eliminated from the host. This process of antigen mimicry is important in causing rheumatic heart disease and some HLA-B27-positive forms of connective tissue disease. Microbes could also induce autoimmunity by infecting immune cells directly, disrupting target tissues that then release sequestered antigens to the extracellular space, or altering the soluble immune milieu.

Alternatively, the "hygiene hypothesis" suggests that infections may prevent autoimmunity. In general, autoimmune diseases are becoming more frequent among affluent populations worldwide. It has been proposed that improved infection control has reduced rates of cyclic immune stimulation and regulation. It is further reasoned that this reduced immune activity provides a permissive environment for autoimmunity among genetically predisposed individuals.

A modifying role of environmental agents in APS-1 may account for members of the same kindred experiencing remarkably different disease courses; however, specific data to support the hypothesis are lacking. A female bias for APS-1 has been reported, and the definite female predisposition for gonadal failure could reflect hormonal effects on immune function. Anatomical and genetic effects could also account for these phenomena. The *Aire*^{-/-} mouse should provide a good experimental model for assessing the effects of environment on APS-1.

Clinical Aspects of APS-1

Patients with undiagnosed APS-1 are frequently assessed many times before the diagnosis is established. Recurrent hypocalcemic, hypoglycemic, or hyponatremic seizures might be misdiagnosed as epilepsy, or the primary cause of altered metabolism might not be sought once the metabolic derangement is corrected. Patients with undiagnosed adrenocortical failure may receive extensive and uninformative assessments of the gastrointestinal tract because of anorexia, weight loss, malaise, and/or abdominal discomfort. In a Norwegian report, 7 of 17 patients

who were diagnosed with APS-1 in the midst of a metabolic crisis were misdiagnosed at earlier medical visits for a manifestation of the condition. The author's North American experience suggests that this problem is not limited to Norway.

The diagnosis of APS-1 should be fairly straightforward in children once the first clinical manifestation is recognized. Among 43 children who had at least a 2-year history of mucocutaneous candidiasis and who did not have a demonstrable defect in T-lymphocyte function, 19 (44%) had an associated autoimmune endocrinopathy, with adrenal cortex and thyroid diseases being most frequent. Thus, candida infections that are prolonged, severe, or unresponsive to routine treatment merit an evaluation of immune function. If that proves to be normal, serum calcium and phosphorus concentrations and autoantibodies against adrenal, gonadal, gastric parietal cell, thyroid, and pancreatic islet autoantigens should be examined. If signs or symptoms suggesting the presence of specific organ failure arise, functional tests of that organ should also be performed. Annual monitoring of calcium concentrations and adrenal, steroidal cell, and gastric parietal cell autoantibodies should be considered in children who initially have no evidence of autoimmunity. It is hoped that these recommendations will be revised when assays for autoantibodies against defined autoantigens become widely available.

Hypoparathyroidism is uncommon in children outside of the neonatal period and should prompt routine monitoring for polyglandular autoimmunity unless another cause for parathyroid dysfunction is diagnosed. Children who present with isolated autoimmune adrenocortical failure are more likely to have isolated disease (or perhaps APS-2) than to have APS-1. A number of historical features (outlined later in the article) will help to identify those with the more common forms of disease. Recall that APS-1 is autosomal recessive; therefore, family history should carefully seek consanguinity as a clue to its diagnosis.

Patients with component diseases of APS-1 will benefit from genetic testing of *AIRE* when it becomes commercially available. A negative result will not exclude APS-1, but a positive result will confirm the need to monitor gland function.

Despite appropriate hormone and vitamin replacement therapy, patients with APS-1 often fare poorly. Pernicious anemia is often misdiagnosed for many months due to its nonspecific presentation. Acquired hyposplenism and cholethiasis were reported in one American series. Issues of self-esteem arise when hypogonadism, alopecia, and/or vitiligo become

important. Of even more concern are severe, poorly understood complications that interfere with quality of life, can be life threatening, and respond poorly to treatment. These include malabsorption, hepatitis, oropharyngeal carcinoma, progressive idiopathic myopathy, Sjögren syndrome, and red cell hypoplasia.

TYPE 2 AUTOIMMUNE POLYGLANDULAR SYNDROME

APS-2 is defined by the presence of autoimmune adrenocortical failure and either type 1 diabetes or any type of autoimmune thyroiditis. As outlined in [Table 1](#), other organs are frequently targeted by the immune system in patients with this condition.

Epidemiology

The prevalence of APS-2, from studies in the United Kingdom and Western Europe, is estimated to be 1.4 to 5.0 per 100,000 population. Type 1 diabetes is most often the first disease to be identified. Whereas adrenocortical failure is typically the last feature of APS-1 to be diagnosed, it is more frequently the first component disease diagnosed in patients with APS-2. The peak age of patients at the time of their diagnosis of APS-2 is between 20 and 40 years. Females are affected about twice as often as are males, with the bias being more obvious among patients who are affected by thyroiditis. Component diseases that frequently coexist with thyroiditis in the absence of adrenal gland disease (e.g., vitiligo, atrophic gastritis/pernicious anemia) also show a female bias. It is not established whether these associated conditions are independently influenced by gender or whether the bias is related to their association with thyroiditis. Gonadal insufficiency occurs predominantly in females with APS-2, but at a lower rate than that seen in patients with APS-1.

Etiology

Genetics

Higher concordance for APS-2 among monozygotic twins than among dizygotic twins attests to the genetic influences on the condition. Polygenic inheritance with genetic heterogeneity (a similar phenotype resulting from distinct genotypes), gene interactions, variable penetrance, and environmental influences all complicate the APS-2 phenotype.

The HLA-DRB1*0301/DQB1*0201 haplotype is associated with a high risk of APS-2. This is expected because isolated autoimmune adrenocortical failure,

Table 1 Characteristics of APS-1 and APS-2

| | APS-1 | APS-2 |
|---------------------------|---|--|
| Definition | Two of three diseases: Mucocutaneous candidiasis Hypoparathyroidism Adrenocortical failure | Adrenocortical failure plus at least one of the following: Type 1 diabetes mellitus Autoimmune thyroiditis |
| Associated conditions | Hypogonadism (~45%) Alopecia (~40%) Ectodermal dysplasia (e.g., teeth, nails, cornea) Atrophic gastritis/Pernicious anemia (~15%, young onset) Vitiligo (~15%) Hepatitis (~15%) Malabsorption (~15%) Thyroiditis (~15%) Type 1 diabetes (~5%) Hyposplenism Cholelithiasis | Hypogonadism (<5%) Alopecia (rare) Atrophic gastritis/Pernicious anemia (rare, adult onset) Vitiligo (~5%) Myasthenia gravis Sjögren syndrome |
| Usual first manifestation | Mucocutaneous candidiasis | Type 1 diabetes |
| Prevalence | 1 in 9000 to 1 in 80,000 | 1.4 to 5.0 per 100,000 |
| High-risk populations | Iranian Jews Finns Sardinians | Females |
| Genetics | Autosomal recessive AIRE gene | Polygenic HLA DR3 |
| Age of onset | First decade | Third or fourth decade |

type 1 diabetes, and thyroiditis share this association. Early reports suggested that APS-2, like diabetes, was associated with the DRB1*04/DQB1*0302 haplotype. It was subsequently determined that this effect partitioned with the presence or absence of diabetes. The high-risk haplotype was not seen at a higher frequency in APS-2 patients with disease restricted to the adrenal and thyroid glands.

Although much more information is available about the genetics of the individual component diseases of APS-2, little else is known in the strict context of polyglandular autoimmunity. A number of inferences can be drawn from what is known. Recall first that APS-2 was originally defined by a clinical phenotype that had to include adrenocortical failure. Other combinations of autoimmune gland failures that were similar to APS-2 but did not include adrenocortical failure either were relegated to a heterogeneous group of disease clusters, called APS-3, or were left unclassified. Most evidence developed since the original description in 1980 suggests that the genetic predisposition to APS-2 and its component diseases arises from a convergence of autoimmune susceptibility genes. Therefore, from a genetic perspective,

the mandatory inclusion of adrenal insufficiency to distinguish APS-2 may be somewhat arbitrary.

Our group has proposed that polyglandular autoimmunity is genetically influenced by three major categories of genes: (1) antigen/organ nonspecific, (2) antigen/organ specific, and (3) protective (Fig. 2). The first category of genes encodes proteins that provide an internal immunological milieu that permits autoimmune processes in general to initiate or persist. One or more genes associated with the DR3 haplotypes listed previously represents an example. In addition to APS-2, associations with DR3 have been reported for myasthenia gravis, autoimmune hepatitis, rheumatoid arthritis, and systemic lupus erythematosus.

The second category of genes encodes proteins that provide absolute or relative organ specificity to the autoimmune responses. The HLA-DRB1*04 association with type 1 diabetes in APS-2, but not adrenocortical failure or thyroiditis, is an example of this phenomenon. To date, variations in the number of tandem repeat sequences in the upstream untranslated region of the insulin gene are associated with diabetes but no other autoimmune disease. The third category of autoimmune genes confers protective effects.

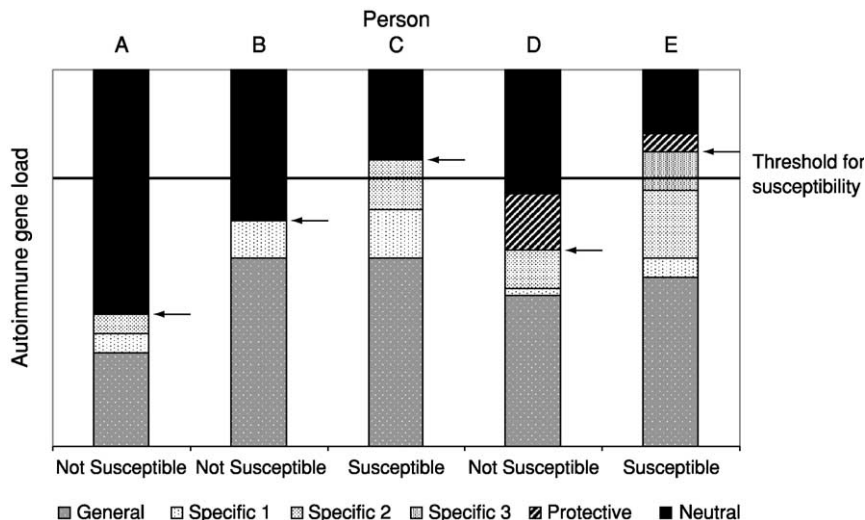

Figure 2 A model for polygenic inheritance of susceptibility to autoimmune disease. Each bar represents a portion of one individual's genome. The combined genetic load of general and specific autoimmune genes (arrow) in person A is below the threshold where disease susceptibility occurs. Person B has more general susceptibility genes than does person A. Genetic interactions cause some augmentation of the influence of the specific autoimmune gene, but the combined effects are still inadequate to confer susceptibility to clinical disease. Person C has an additional specific autoimmune gene (specific gene 2) that interacts with specific autoimmune gene 1. The combined effects now exceed the threshold of susceptible, and this person may develop autoimmune disease if required environmental influences also act. Person D has a protective gene that reduces the activity of specific gene 1 and some general autoimmunity genes. Gene interactions cause a slight reduction in the action of specific gene 2. This person's genetic load is below the threshold, and there is no susceptibility to autoimmunity. Person E has three specific genes. In addition to promoting autoimmunity directly, the third gene modulates the effects of other susceptibility and protective genes. The total genetic load is above the susceptibility threshold.

Protection from type 1 diabetes conferred by DQB1*0602 is an example.

This model oversimplifies the true pathological processes causing APS-2. For example, the CTLA-4 locus may encode a protein that provides general pro-autoimmune effects, but only in certain circumstances. The locus encodes a T-lymphocyte protein that binds most avidly to CD80 (B7-1) on antigen-presenting cells, and this cell-to-cell signal contributes prominently to immunoregulatory responses. Polymorphisms of CTLA-4 are reported to be associated with susceptibility to type 1 diabetes, Graves' disease, Hashimoto's thyroiditis, Wegener's granulomatosis, systemic lupus erythematosus, and celiac disease but not multiple sclerosis. In addition, the DQB1*0602 gene powerfully exerts protection from type 1 diabetes unless the patient has APS-1 or APS-2. Furthermore, DQB1*0602 is a susceptibility gene for the autoimmune attack of the central nervous system in multiple sclerosis. This difference may reflect different avidities of binding between the HLA-antigen complexes and the TCRs of pathogenic clones. It is also possible that the molecular and biochemical processes that promote one self-reactive response in one disease may inhibit or have no effect on another disease.

It is also important to recall that genes may exert control on portions of the autoimmune response but not on the entire process. Experiments with congenic mouse strains have identified genetic intervals that control (1) insulinitis but not progression to diabetes and (2) autoantibody production but not progression to overt lupus nephritis. In humans, inheritance of a propensity to make autoantibodies against thyroid gland components appears to be inherited in a dominant fashion from affected mothers. However, progression to overt thyroiditis is not transmitted as completely.

The genetic data further support the hypothesis that polyorgan failure in APS-2 is not the result of a single process that generalizes to multiple organs, as may be the case with APS-1. More likely, multiple autoimmune processes with both distinctive and overlapping components are coexpressed. The NOD mouse model of diabetes and sialoadenitis provides an example of diverse mechanisms causing autoimmunity simultaneously in the same animals. When the interleukin-4 (IL-4) gene was disrupted in NOD mice, the rate of spontaneous diabetes and islet infiltration by immune cells was unchanged compared with the wild type. In contrast, salivary gland infiltration by

leukocytes persisted in the IL-4 knockout mice but was not associated with xerostomia.

Immunology

The epidemiology and genetics of APS-2 and its component diseases are similar (with the exception of gonadal failure). Therefore, the immunological processes underlying the diseases may overlap significantly. The immunology of APS-2 specifically has not been studied as well as it has for the individual component diseases. Autoantibodies appear to bind the same target antigens, irrespective of whether the autoimmune response occurs in isolation or as part of APS-2 (Table II). Immune cell infiltrates have been reported in virtually all target organs, including adrenal cortex, islets, thyroid, and developing ovarian follicles. In patients with vitiligo, small clusters of immune cells are seen around melanocytes of skin biopsied along the edges of the lesions. Alopecia is associated with mononuclear immune cell infiltrates in and around the hair bulbs.

Premature ovarian failure associated with either APS-2, autoimmune adrenocortical failure, or asymptomatic adrenal autoantibody positivity has been distinguished from that occurring in the presence of

autoimmune conditions that do not affect the adrenal gland. Autoantibodies against the P450c17 and P450scc cytochrome enzymes are rarely observed in patients with idiopathic premature gonadal failure who also have disease involving thyroid, islet, and/or gastric parietal cells. Microscopically, lymphocytic oophoritis appears almost exclusively in conjunction with adrenal gland autoimmunity. The association of autoimmune oophoritis and adrenocortical failure may prove to be invaluable in understanding the organ specificity of autoimmune disease.

Changes of cellular immune function in thyroiditis and type 1 diabetes have been investigated intensively. Altered function of antigen-presenting cells, regulatory and responder lymphocyte populations, cytokine environment, and production of mediators of cell destruction all have been reported. Whereas experimental animal models have been explored in great detail, causal phenomena from studies of humans have not been demonstrated.

Environment

Associations of the component diseases of APS-2, particularly diabetes and thyroiditis, have been investigated intensively, yet few agents have been associated

Table II Defined Autoantigens in APS-1, APS-2, and Component Diseases

| Organ | APS-1 | APS-2 | Isolated component diseases |
|------------------------|---------------------------------------|---------------------------------------|---------------------------------------|
| Adrenal cortex | P450c21 | P450c21 | P450c21 |
| | AADC | ?P450c17 | ?P450c17 |
| | ?P450c17 | ?P450scc | ?P450scc |
| | ?P450scc | | |
| Gonads | P450c17 | P450c17 | None to steroid-producing cells |
| | P450scc | P450scc | |
| Islet | GAD ₆₅ | GAD ₆₅ | GAD ₆₅ |
| | GAD ₆₇ | IA-2 | IA-2 |
| Vitiligo | Tyrosinase | | Insulin |
| | AADC | | Tyrosinase ^a |
| | | | TRP-2 |
| Thyroid | Thyroid peroxidase | Thyroid peroxidase | Thyroid peroxidase |
| | Thyroglobulin | Thyroglobulin | Thyroglobulin |
| | TSH receptor | TSH receptor | TSH receptor |
| Gastric parietal cells | H ⁺ ,K ⁺ ATPase | H ⁺ ,K ⁺ ATPase | H ⁺ ,K ⁺ ATPase |
| | Intrinsic factor | Intrinsic factor | Intrinsic factor |
| Liver | P450 1A2 | | P450 2D6 |
| | P450 2A6 | | Asialoglycoprotein receptor |
| | AADC | | |
| Parathyroid | Calcium sensor | | Calcium sensor |

Note. GAD, glutamic acid decarboxylase; AADC, aromatic-L-amino acid decarboxylase; TSH, thyroid-stimulating hormone; TRP-2, tyrosinase-related protein-2.

^aMany vitiligo patients had other autoimmune endocrinopathy but did not have APS-1 or APS-2.

with disease unequivocally. A proven causal association exists between congenital rubella infection and diabetes. Hypothetical precipitants of type 1 diabetes have included other viruses (e.g., Coxsackie B4 or other enteroviruses), diet components (e.g., cow milk proteins), routine childhood immunizations, and chemicals (e.g., nitrosamines in smoked meat). Of these, the relationship between enterovirus infection and type 1 diabetes is most compelling. Although proof that enteroviruses can initiate in human islet autoimmunity is lacking, convincing data suggest that enteroviral infections at least accelerate the process. Patients with newly diagnosed type 1 diabetes carry enteroviral RNA in their serum more frequently than would be expected. In addition, seroconversion for islet autoantibodies among young children has been temporally associated with recent enterovirus infections.

Thyroiditis has been associated with environmental agents such as dietary iodine, *Yersinia enterocolitica*, and Epstein–Barr virus. Autoimmune adrenocortical failure has no reported associations with environmental triggers. Thus, there are no known environmental exposures that completely account for the spectrum of polyglandular autoimmunity. However, most of the proposed environmental agents for organ-specific autoimmune diseases are commonly encountered. It remains plausible that various autoimmune diseases coexist given that multiple disease-specific environmental exposures have occurred.

Clinical Aspects of APS-2

It can be difficult to distinguish patients with APS-2 from those with a single autoimmune condition when they present with their first organ failure. About half of patients with autoimmune adrenocortical failure either have or will develop a second autoimmune condition. Therefore, it is obvious that autoantibodies against thyroid, islets, steroid-producing organs, and gastric parietal cells should be monitored. The presence of organ-specific autoantibodies should prompt close clinical and laboratory testing for failure of the targeted organ.

Type 1 diabetes is frequently the first sign of APS-2, and occasionally thyroiditis can precede other components. Autoantibodies against other organs are far less prevalent in patients with either of these two conditions than in those with adrenocortical failure. Therefore, laboratory investigations are not cost-effective, and close attention must be paid to the medical history and physical examination. A family history of polyglandular autoimmunity should prompt periodic antibody screening, as should the

appearance of vitiligo or alopecia (areata, totalis, or universalis). The onset of idiopathic premature ovarian failure in patients with thyroiditis or diabetes is cause for concern about the risk of future adrenocortical failure, especially if the P450 cytochrome autoantibodies are present.

Patients with type 1 diabetes, especially females, have at least a 20% risk of developing thyroid autoantibodies. Monitoring for thyroid disease among patients with type 1 diabetes is usually considered as standard care. This may be accomplished with either sensitive thyrotropin (TSH) or thyroid peroxidase autoantibody assays. Patients who have clinical or laboratory evidence of both islet and thyroid autoimmunity should be monitored clinically and serologically for other autoimmune conditions. Parietal cell autoantibodies will be positive in these individuals more frequently than will adrenal or steroidal cell autoantibodies.

Important clinical clues to the presence of adrenocortical failure in patients with other autoimmune conditions include chronic fatigue despite adequate thyroid hormone replacement, skin crease pigmentation that does not have the texture of acanthosis nigricans in patients with insulin resistance, and improved blood glucose control in patients with diabetes who have not changed their treatment or daily routines. Finally, it is also worth recalling that the institution of thyroid hormone replacement in hypothyroid patients who have undiagnosed adrenocortical failure can precipitate an adrenal crisis.

CONCLUSION

The two forms of APS include groups of autoimmune diseases that coexist at rates beyond those expected by chance. Despite the endocrinological emphasis in the syndrome names, disease is not restricted to endocrine organs. APS-1 and APS-2 have distinct epidemiologies and genetics, but investigators have been less successful at identifying specific abnormalities of immune function or environmental precipitants of autoimmunity. To minimize morbidity and mortality, it is important for clinicians to anticipate which patients with an autoimmune disease are likely to develop a second organ failure. Patients with APS-1 often become ill during their second or third decade of life and may develop any of a number of severe illnesses that can prove to be fatal. The prognosis of APS-2 is somewhat better, but patients with diabetes are at risk for its chronic complications. Further research into the nature of the autoantigens, immune tolerance, immune surveillance, the AIRE transcription factor, and genes

controlling susceptibility and resistance to autoimmunity is of great importance in improving the lives of these patients.

Autonomic Nervous System, Aging and

K. E. Hall and John W. Wiley

University of Michigan Healthcare System, Ann Arbor, Michigan, United States

Glossary

age-associated Describing a condition that is more prevalent in a specific age segment of the population, specifically advanced age.

apoptosis Programmed cell death or “cell suicide”; a genetically mediated series of events by means of which cells actively trigger their own destruction.

homeostasis In an organism, the fact or process of maintaining the internal environment in a balanced state that promotes health and survival, by means of various sensory, adaptive, and control mechanisms that react to internal and external conditions to produce this balance.

oxidative stress Excessive production of, and/or impaired removal of, oxidants (chemicals that withdraw electrons from other chemicals) with a concomitant decrease in the reducing capacity of cells; associated with various age-related diseases and degenerative conditions.

As humans age, many body functions begin to deteriorate, including the function of various neuronal systems. The peripheral nervous system in the body is divided into those nerves that affect voluntary movement (the voluntary system) and those that regulate the function of internal organs such as the heart and gastrointestinal tract (the autonomic system). Significant alterations in the function of the autonomic nervous system appear to occur with aging.

INTRODUCTION

Deciphering the mechanisms of physiological aging versus the consequences of disease is an ongoing challenge for gerontologists. In general, autonomic nervous system (ANS) function is well preserved in otherwise healthy individuals through the seventh decade of life. However, there are some notable changes in neuromuscular function of the cardiovascular and gastrointestinal (GI) ANS that accompany advanced age. These changes have been reported in

human and animal models. Age-dependent autonomic dysfunction could involve loss of neurons and/or altered neuronal or smooth muscle function. This article explores age-associated changes in the sympathetic and parasympathetic innervation of the cardiovascular system and the intrinsic innervation in the GI tract (enteric nervous system [ENS]). Studies performed on human subjects are emphasized, and animal research is discussed where the results provide insights regarding potential mechanisms and future directions in this field.

AGE-ASSOCIATED CHANGES IN CARDIOVASCULAR FUNCTION

The ANS is an important factor implicated in cardiovascular pathophysiology such as hypertension, myocardial ischemia, and cardiac arrhythmias.

AGING AND THE SYMPATHO-ADRENAL SYSTEM

The sympathetic nervous system (SNS) plays an essential role in the maintenance of physiological homeostasis in general and arterial blood pressure in particular. This appears to be the case both under basal (resting) conditions and in response to acute stress. Postganglionic sympathetic neurons innervating the heart and resistance vessels help to control cardiac output, arterial blood pressure, and regional vascular conductance, thereby ensuring the proper perfusion of vital organs. SNS stimulation of adrenalin (epinephrine) release from the adrenal medulla contributes significantly to the regulation of cardiovascular function and regulates energy metabolism. The SNS also has a key role in the regulation of internal body temperature. Impairment of SNS function has been implicated in the development of a variety of common medical conditions, including hypertension, congestive heart failure, sudden cardiac death, insulin resistance (metabolic) syndrome, and obesity. Thus, understanding the mechanisms of

SNS dysfunction in these conditions is of major clinical significance.

The current literature supports the view that basal SNS activity increases with advancing age in healthy adult humans. Elevation in SNS activity appears to be region specific, targeting skeletal muscle and the gut rather than other organs innervated by the SNS such as the kidney. The SNS tone of the heart is increased, due primarily to reduced neuronal noradrenalin reuptake. In contrast, basal and stress-associated adrenalin secretion from the adrenal medulla is reduced markedly in human aging. Despite decreased secretion, plasma adrenalin concentrations are relatively unchanged due to a concomitant reduction in plasma clearance of adrenalin. The mechanisms underlying these age-associated changes in sympatho-adrenal function have not been established. Evolving research suggests that the increase in basal peripheral SNS activity with age is associated with elevated forebrain noradrenergic activity. These studies support the hypothesis that increased central nervous system sympathetic activity may underlie peripheral increases in SNS tone noted in studies of aged humans. The situation in other animal models appears to be rather different. In particular, whereas reduced peripheral baroreflex inhibition appears to be an important primary change with aging in animal studies, baroreceptor function in aged humans appears to be relatively preserved.

Reduced arterial compliance is a well-described feature of aging. It is less clear whether neuromuscular function of the venous system is altered by aging. Age-associated changes in venous compliance have been difficult to document, although some studies in humans have shown that aging reduces venous compliance and capacity. The constrictor response of the human dorsal hand vein to the α -adrenoceptor agonists noradrenalin and phenylephrine is unchanged. However, aging is associated with a reduced dilator response to the β -adrenoceptor agonist isoprenalin, and this may have clinical implications in patients who require these agents for blood pressure support. In summary, adult human aging is associated with significant changes in SNS physiological function and regulation that likely have clinical implications.

AGING AND PARASYMPATHETIC REGULATION OF THE CARDIOVASCULAR SYSTEM

In contrast to the lack of effect of aging on human sympathetic baroreceptor function, significant

decreases in cardiovagal baroreflex sensitivity (BRS) have been described. Diminution in cardiovagal BRS is associated with impaired regulation of arterial blood pressure and, in the presence of myocardial ischemia, with enhanced risk of ventricular tachyarrhythmias and sudden death. A sedentary lifestyle is associated with a reduction in cardiovagal BRS, even in healthy individuals. This effect can be documented as a decreased R-R interval variability in the electrocardiogram (ECG). It has been hypothesized that these changes in the cardiovagal BRS are related to diminished compliance of the large elastic arteries (aorta and carotid) in which the arterial baroreceptors are located. Decreased cardiovagal baroreceptor sensitivity in aged individuals can be ameliorated by exercise, with improvement noted in aged individuals who exercise regularly as compared with sedentary age-matched adults.

AGING, GENDER, AND ANS REGULATION OF CARDIOVASCULAR FUNCTION

Gender differences in the incidence and clinical course of a range of cardiovascular states are also well recognized. Both short- and long-term prognoses after myocardial infarction are worse for women than for men. However, women with nonischemic cardiomyopathy have improved survival as compared with age-matched men. In addition to the well-known difference in age of presentation of coronary heart disease (CHD), women with CHD are more likely to suffer from autoimmune phenomena such as Raynaud's disease and to experience dysautonomic symptoms such as presyncopal or syncopal episodes. Therefore, an appreciation of gender differences in the structure and function of the ANS is important to a full understanding of a number of common and important clinical presentations.

Cardiac responses to the sympathetic agonist isoprenalin were similar in older males and females but greater in younger males than in younger females. This implies that women may undergo a relatively greater age-dependent decline in autonomic function. A similar observation was made for muscle contractile response to SNS activity. Under 50 years of age, muscle response to sympathetic nerve activity was significantly greater in men than in women, but no differences between the genders were noted for older individuals.

AGE-ASSOCIATED CHANGES IN GASTROINTESTINAL FUNCTION

Much of the clinical literature suggests that as healthy humans age, the GI tract functions adequately. Problems with swallowing (dysphagia) and gastroesophageal reflux disease (GERD) are relatively common complaints in the elderly, and some studies have shown an age-related loss of enteric neurons in the human esophagus. However, when objective criteria are assessed, actual age-related changes in esophageal physiology appear to be minimal. In fact, quantitative manometry reveals that esophageal contractile wave amplitudes and velocity and duration of lower esophageal sphincter relaxation in healthy individuals over 70 years of age are not different from those in younger individuals. Nevertheless, there is evidence of reduced amplitude of peristaltic contractions in the lower esophagus of the elderly, consistent with the observation that esophageal clearance after gastroesophageal reflux is impaired in older individuals. In general, the rates of gastric emptying and small intestinal transit are unchanged with age in humans. However, there may be subtle alterations in control of gastric and small bowel neuromuscular function that render aged individuals more susceptible to the effects of superimposed disease (e.g., diabetes) or anticholinergic side effects of medications. Medications, in particular, are a potent source of GI problems in older patients and should be reviewed in patients presenting with impaired GI function.

Evidence that colonic transit is reduced in the elderly is mixed. Some reports document increased colonic transit time in aged healthy adults, whereas others show no difference when compared with younger controls. Some of these discrepancies may be attributed to the presence of chronic illness with systemic effects and concomitant use of multiple medical therapies with GI side effects.

AGING EFFECTS ON GASTROINTESTINAL AUTONOMIC INNERVATION AND FUNCTION

Morphological data from human tissues suggest that the total number of colonic neurons in the myenteric plexus may decrease by as much as one-third with aging. Age-related changes in the human colonic submucosal plexus in advanced age have not been reported. Unfortunately, there is a lack of morphological data concerning the aging human ENS compared with that obtained in animal studies.

Therefore, many conclusions concerning the effect of aging on neuromuscular function in the GI tract are based on nonprimate animal studies that correlate age-related impairment in colonic neuromuscular function with decreased neuronal number and function. The number of cholinergic neurons, acetylcholine release, and smooth muscle response all are decreased in colon preparations from aged rats as compared with youthful controls. Decreased numbers of neurons immunoreactive for nitric oxide have been demonstrated in the colon of rat models of aging, and limited data indicate that this may also be the case in humans. Nitric oxide-containing neurons are essential for normal coordination of motility and inhibit spasmodic nonpropagating contractions. Thus, a significant decrease in this myenteric neuronal population with age could explain the increase in colonic spasticity and constipation in geriatric-aged patients. A separate, but equally important, issue is the effect of aging on extrinsic sympathetic and parasympathetic innervation to the GI tract. Neuroanatomical tracing studies have failed to show neurodegenerative changes in motor or sensory vagal fibers that project to the proximal gut (stomach and small intestine) in rats. Some animal studies suggest that vagal motor innervation of the distal GI tract declines with advanced age and may correlate with reports of region-specific loss of enteric neurons.

Advanced age may be associated with selective impairment of neuronal function without significant loss of neurons. In the peripheral, prevertebral, and paravertebral sympathetic ganglia of aged humans and rodents, terminal axonal dystrophy and remodeling of synapses occur rather than neuronal cell loss. Because these neurodegenerative changes are documented to affect only some neurons, this suggests that a subset of adult postganglionic sympathetic neurons is more sensitive to neurodegenerative effects of aging. One of the characteristics of the aging-resistant postganglionic sympathetic neurons is that they appear to have an increased capacity to take up neurotrophic factors (e.g., nerve growth factor [NGF]). This may be a compensatory response to decreased release of neurotrophins at the nerve terminal and cell body (soma) documented in aged animal models. There are little data on the effect of aging on the differential responsiveness of neuronal subpopulations to distinct neurotrophins such as glial-derived neurotrophic factor (GDNF) and brain-derived neurotrophic factor (BDNF). Data in younger animals indicate that this kind of differential sensitivity to neurotrophins may be important in neuronal survival because BDNF pretreatment enhances the survival-promoting effects of

NGF. The role of advanced age in the expression and function of these neurotropic factors in the ANS is an active area of investigation. In summary, the observations outlined here suggest that the effects of advanced age on the ENS are likely to be region specific and more pronounced in the distal GI tract.

POSSIBLE MECHANISMS UNDERLYING PHYSIOLOGICAL AGING IN THE NERVOUS SYSTEM

As the preceding discussion indicates, two fundamental questions have emerged as critical issues surrounding aging of the nervous system. Does loss of neurons occur naturally with aging (i.e., senescent loss)? If so, is physiological neuronal senescence a process that begins with neurodegeneration and culminates with neuronal death? Neuronal death appears to occur via at least two distinct pathways. Neurons are capable of undergoing programmed death (apoptosis) when the apoptotic enzyme cascade is activated by appropriate conditions. These include infection, injury, or as a normal feature of nervous system development *in utero*. A second distinct self-destruct program involving the long processes (axons) that precedes the death of the soma has also been described. This second mechanism of “die-off” is more prevalent than apoptosis in many neurodegenerative diseases associated with aging; thus, it is more relevant to a patient’s clinical course. The relative contributions of these two pathways in normal aging is unclear and is a focus of current research. There is considerable interest in identifying genes that may be directly linked to physiological aging and assessing how environmental factors influence the function of these genes and their products. A number of laboratories are examining the potential contribution of oxidative stress as a contributing factor to the diminution in neuronal function observed with advanced age.

Glossary

anthropometry The science and technology of measurement of the human body.

centile (or percentile) An arbitrary division of a range of variability. For example, the 25th centile for height at age 6 years would define the height at which 25% of the healthy 6-year-old population would be at or below.

consonance The ordered progression of events in a predetermined order, e.g., the events of puberty.

cross-sectional Growth data collected on a single occasion from children of many different ages.

longitudinal Growth data collected on at least two occasions from each child of a study group.

Auxology is the science and study of physical growth and development. It derives from a Greek root, *αυξεν* (*auxein*), a term that was first used in France in 1919 and subsequently entered English usage in the 1970s. It encompasses many aspects of physical anthropology, genetics, and physiology.

GROWTH IN HEIGHT

The Human Growth Curve

Most human dimensions follow a similar pattern of growth throughout childhood and height may be used as a typical example. The height curve of an individual boy is shown in Fig. 1: Fig. 1a shows the height attained or distance curve and Fig. 1b shows the height velocity curve. The distance curve represents all the height accumulated over time until the latest measurement and is therefore relatively insensitive to recent changes in the child's circumstances. In contrast, the velocity curve represents growth over a clearly defined and relatively short period of time, conventionally 1 year.

The height velocity curve shows a trend for a decelerating growth rate from birth to maturity, but with

two interruptions to this trend. The first is the smaller of the two and is not seen in all individuals; it occurs between the ages of 6 and 8 years and is called the midgrowth or midchildhood spurt. There is little difference between sexes except that it may occur approximately 6 months earlier in girls. The mechanism of this spurt is unknown although its timing approximates the initial rise in the secretion of adrenal androgens.

A second and much greater interruption of the downward velocity trend is the adolescent growth spurt, which is illustrated for the average British girl and boy in Fig. 2. Before the onset of the adolescent growth spurt, there is a negligible difference in velocity between the sexes, but the girls' growth spurt starts approximately 2 years before the boys and for approximately 4 years girls are, on average, taller than boys. However, by the time they reach maturity, males are 14 cm taller than females and this difference is almost entirely due to events at puberty. Males grow for 2 years longer before puberty at an average rate of 5–6 cm/year, with the remainder accruing from the rather more intense male growth spurt.

National Growth Reference

The preceding descriptions concern only the average child, in terms of both size and the timing of events such as the adolescent growth spurt. There is, however, considerable variation in both. The magnitude of variation in size at a given age is illustrated in Fig. 3, which shows the growth reference for height of boys in the United Kingdom. Although the variation in size seems very straightforward, this figure obscures the variation in timing (or tempo, as this aspect is usually termed). This problem is of sufficient clinical importance to justify detailed consideration.

Tempo of Growth

Consider a boy who will ultimately reach a mature height that is exactly average for the population. If he

Figure 1 (A) The growth curve for height of a single boy from birth to maturity. (B) The same data as for (A), but expressed as height gain or velocity. Reprinted from Preece, M., Ch. 7.1.1 of “The Oxford Textbook of Endocrinology and Diabetes” (2002) (Wass and Shalet, eds.), by permission of Oxford University Press.

is also exactly average in tempo, then he will follow the mean growth curve, start the adolescent growth spurt at 12 years, reach the peak at 14 years, and reach mature height at approximately 18 years. However, if he is an early developer with fast tempo, then he will always be rather further along his personal growth curve at any given age than average children. He will therefore seem tall at each stage until maturity, which he reaches early, say 16 years. In exact contrast, the late developing boy, also destined for average mature height, will seem short until maturity. These patterns for early and late development are illustrated in Fig. 4. A similar

Figure 2 Median growth velocity curves of British girls and boys whose peak growth spurt is reached at an average age (12 and 14 years, respectively). Reprinted from Preece, M., Ch. 7.1.1 of “The Oxford Textbook of Endocrinology and Diabetes” (2002) (Wass and Shalet, eds.), by permission of Oxford University Press.

process occurs for children with potential for all levels of mature height so that variation in height at any age before maturity may be a combination of varying adult height potential and variation in tempo.

Population Height Standards

The construction and role of growth standards have previously been reviewed in many texts. Much controversy exists concerning the relative merits of cross-sectional and longitudinal growth references. The former uses data from a large number of children, each of which is measured on one occasion. In contrast, pure longitudinal standards are based on a smaller number of children measured on multiple occasions over many years. It has been argued that the latter are more appropriate for clinical use because they reflect the correct shape of an individual growth curve. In contrast, cross-sectional curves will tend to distort the pattern of individual growth at approximately the age of puberty because of the variability of

Figure 3 Growth reference charts for boys in the United Kingdom. Obtained from Harlow Printing Co., Tyne and Wear, UK.

timing of the adolescent growth spurt among individuals. However, the analysis of longitudinal data to provide individual-type growth standards requires a number of assumptions that are not really tenable: a typical assumption is that the growth spurt has essentially the same shape in all children of the same sex, varying only in timing and intensity. A further disadvantage is that the length of time needed to collect longitudinal data makes regular revision difficult. In actual practice, it makes little difference which type of standard is used as long as it is remembered that individuals will probably cross centile lines upward or downward at the time of puberty, needing careful interpretation by the clinician. Figure 3 shows the latest British height chart for boys, which is derived from cross-sectional data from a nationally representative sample of British children. The centile lines shown are the 0.4th, 2nd, 9th, 25th, 50th, 75th, 91st, 98th, and 99.6th, which are selected to allow a regular distance between adjacent centiles of 0.67 standard deviations. Children whose height falls below the 0.4th centile represent the shortest 4 per 1000 of the population and require immediate investigation. Those between the 0.4th and 2nd centile need careful follow-up and those above the 2nd centile a less intense evaluation.

Height Velocity Standards

Figure 5 shows an example of standards for height velocity for boys. The data are based on pure longitudinal

Figure 4 Schematic representation of the height growth curves of three boys who all have the same mature height, but who are, respectively, 2 years early, average, and 2 years delayed in tempo. Reprinted from Preece, M., Ch. 61 of "Clinical Endocrinology" (1998) (A. Grossman, ed.), 2nd ed. Blackwell Science, Oxford, UK, with permission.

observations and the extremes of normality are indicated by centiles. It is important to make three qualifications. In the first place, these standards are based on data collected before 1966 and might not represent modern children. However, in the nationally representative sample of modern-day children, the *shape* of the average growth curve has changed very little except in the first 2 years of life. This indicates that height velocity at any age over 2 years is also unchanged and in the absence of any more modern data these standards remain approximately valid.

The second qualification is that it must be remembered that these normal values and the position of the various centiles are based on velocity measurements taken over a whole year. This is because if shorter intervals are used, measurement errors assume greater importance and because there are substantial variations in growth velocity during any single year. It is important to interpret cautiously growth velocities in patients when they are based on periods of measurements of less than 1 year.

A final point is that centiles for height velocity do have a slightly different meaning than do height centiles. On average, over a year or more any individual child who is growing normally should have a height velocity somewhere near the 50th centile for the

Figure 5 Height velocity growth reference for boys in the United Kingdom; see text for explanation. Reprinted from Preece, M., Ch. 61 of "Clinical Endocrinology" (1998) (A. Grossman, ed.), 2nd ed. Blackwell Science, Oxford, UK, with permission.

population. If a child is to maintain his position on, say, the 25th centile for height, he should grow somewhere near the 40th centile for velocity. The child persistently growing at a 10th centile velocity will steadily fall further and further behind his peer group and soon become distinctly short.

In Fig. 5, there are two large gray areas flanking the adolescent growth spurt. The centiles for the latter are those for a child whose growth spurt peaks at an average age, i.e., 14 years for a boy. There is substantial variation in this age, which may be 2 years earlier or later in healthy children; the gray-shaded areas take this into account. In an individual case, the growth spurt should occur within the gray area with a shape similar to the centile centered at 14 years. Note that earlier growth spurts tend to be more intense and later growth spurts less so.

PUBERTY

The Events of Puberty

There are many skeletal and soft tissue events that occur during puberty that are important in the development in differences in shape between the adult male

and female. Delineation of these events requires a standardized method of describing progress through puberty and almost universally the systems in use depend on the criteria formalized by Tanner. These depend on rating breast and pubic hair development on a 5-point scale for girls and external genitalia and pubic hair on similar scales for boys. Axillary hair is rated on a 3-point scale for both sexes. Details of the stages are available in many standard texts and will not be repeated here.

In much the same way as variation in height for age was discussed, variation in the age of attainment of different pubertal stages should also be considered. Standards for attainment of puberty stages are usually included on the stature charts, as illustrated in Fig. 3. The designations PH2, PH3, etc., represent the time when attainment of these stages first becomes apparent, though the instant at which this occurs is never observable; the doctor can only see that a child has attained PH2 but not yet PH3. Therefore, the subject is described as being in PH2+ and the standards give the centiles for age of *being in* that stage. Quite arbitrarily, the centiles are ordered such that lower centiles relate to delayed pubertal progress and higher centiles to advanced progress.

Tempo and the Consonance of Puberty

In general, the events of puberty, involving skeletal, soft-tissue, and secondary sexual characteristics, unfold in an orderly and highly integrated manner. The whole process may be advanced or delayed by several years, but still maintains an internal order that closely follows that of the typical child. Whenever this consonance is disturbed, for example, with an absent growth spurt but normal pubertal progression, then pathology must be suspected. In an otherwise healthy child, this pathology will usually be endocrinological.

PRINCIPLES OF AUXOLOGICAL ANTHROPOMETRY

Introduction

In clinical endocrinology, the most useful auxological measurements are height (or supine length in those who cannot stand), sitting height (or crown-rump length), weight, and skinfolds (especially triceps and subscapular). Sitting height is a preferable measurement for the assessment of trunk-to-limb proportions as opposed to the use of measurement of span or upper and lower segments. The first of these is vulnerable to positional problems as the measurement is

significantly affected by rotation of the shoulder girdle and the second depends on accurate placement of the pubic symphysis, which can be difficult, especially in the obese.

The basic rules for making auxological measurements should be the same as for any other endocrine parameters such as hormone measurements. There must be adequately trained technicians using appropriate equipment in a reserved area. Quality assurance is every bit as important although this usually takes the form of repeat measurements on a series of children at appropriate intervals and analysis by appropriate statistical methods.

Body Composition

Convenient assessment of body composition would be of great clinical value. Direct measurements are difficult or even impossible to obtain in young children and thus indirect methods must be used. In general, these fall into one of three categories: isotope dilution methods, electrophysiological measurements, and anthropometry. Details of these methods and their application are beyond the scope of this article, but they are covered in a number of other sources. The anthropometric methods are among the least accurate, but have the advantage of low cost and simplicity. Generally, they depend on the use of various combinations of height, weight, skinfold thickness, and upper-arm circumference. The techniques for these additional measurements are described briefly.

Weight

Weight is an often neglected measurement because of its complex make-up and vulnerability to short-term fluctuations. However, it has the great advantage of being measurable to a high degree of precision and reproducibility if a few basic precautions are taken. The patient should be weighed either nude or in the minimum of standard clothing, which can be corrected for, if necessary. A modern electronic scale should be used.

Skinfold Measurements

These measurements are prone to many errors and, of the techniques described here, are the most difficult. However, they are the most convenient method for assessment of subcutaneous fat; extrapolations to total body fat and other measures of body composition are less certain and require care. The two most useful sites for measurement are the triceps and subscapular

areas and a suitable instrument is the Harpenden skinfold caliper

Upper-Arm Circumference

This is one of the most straightforward measurements to make and is used widely in nutritional anthropometry. It reflects both subcutaneous fat and muscle bulk, which can be relevant in anthropometric nutritional assessment. The measurement is taken midway between the acromion and the olecranon, while the child is positioned with the arm completely relaxed and extended at the side. The tape must be inextensible and in a plane perpendicular to the long axis of the limb; the tissues must not be compressed.

Body Mass Index

Although not strictly a body composition measurement, body mass index (BMI) is increasingly being used as a proxy measurement for obesity or underweight states. It is calculated as $BMI = [\text{weight (kg)}] / [\text{height (meters)}^2]$. A number of different national reference charts exist to aid in interpretation.

INTERPRETATION OF GROWTH DATA

Reproducibility

Sources of Error

The basic requirement of any measuring instrument is that it gives precise and reproducible readings. However, the simple provision of an adequately mounted and well-designed instrument, though essential, does not necessarily solve all the problems associated with taking measurements. The technique of measurement is vital and many errors are introduced by bad practices at this stage. Attention to detail is probably the most important method of limiting error to an irreducible minimum. The errors that are left are intrinsic in the measurement of children, particularly in the younger age groups.

Reliability

Good anthropometrists have standard errors of measurement (s_{meas}) ranging from 1.5 to 2.5 mm. This means that a technician with an s_{meas} of 2.0 mm (determined, say, over subjects of an age range from 3.0 to 18.0 years) obtains a value for height that 95% of the time is within 4 mm above and 4 mm below the true value. s_{meas} can be determined by taking a series of duplicate measurements and calculating the difference d for each of the subjects. Provided there is no consistent change from first to second occasion (and

there should not be), the $s_{\text{meas}} = SD_d/\sqrt{2}$, where SD_d is the standard deviation of d .

When the precision of measurements of growth velocity is considered, the problems are much greater. The errors of each of the component measurements are as described above, but the absolute change between them may be quite small and the total error assumes a far greater proportion of the actual measurement.

Interpretation of Growth and Its Changes

A frequent problem arises as to the best methods of expressing growth variables (height will be taken as a typical example) and of analyzing the changes. While children are within the normal range, transformation of the height to its centile is perfectly acceptable and is often the easiest way to explain the situation to the child and family. However, centile values do not lend themselves to easy statistical analysis and are clearly useless when the subjects are below the lowest recorded centile.

In analyzing growth data, especially in children outside the normal range, the use of standard deviation scores (SDS) is more appropriate. In principle, any variable can be so transformed, provided the mean value and the standard deviation for each age and sex are known and the variable assumes a Gaussian distribution. The width of the age band used for calculating SDS should be quite narrow, ideally 6 months for children between the ages of 2 and 10 years and 3 months for children under 2 years and for those between the ages of 10 and 16 years. The SDS is calculated from the relationship $SDS = (X - X_i)/SD_i$, where X is the actual measurement, and X_i and SD_i are the mean and standard deviation for the i th age band of the appropriate sex. The SDS can be treated as a variable independent of age and sex. In a normal population, the mean SDS will have a value of 0 and a standard deviation of 1; the 95% confidence limits will be -2 and $+2$ SDS. This transformation is made more powerful by extension to data with a non-Gaussian distribution, such as weight.

When SDS are applied to a population of subjects with delayed growth at approximately the time of normal puberty, a problem can arise. As subjects in the normal population of adolescents commence their growth spurt (e.g., males at 12 years), the mean height increases rapidly. This is an inappropriate mean to use for calculating a patient's SDS, if he is prepubertal, and if SDS are calculated, they will be artificially more negative than they should be. Some researchers advocate using the appropriate mean for skeletal age. In

simple pubertal delay, this is probably acceptable, although it should be remembered that the link between skeletal age and the timing of puberty is not exact. In many chronic diseases, especially when corticosteroids are used, this relationship is even weaker and skeletal age seldom resolves the problem. The best approach would be to create values for the mean heights of children with various degrees of growth delay. Using Swedish data, Johan Karlberg has attempted a formal development of this approach and created charts that go some way toward providing this type of curve, but only within the variation seen in healthy children.

There is a further caution to be exercised with velocity measurements, whether expressed as centimeters per year or as SDS. All the reference data are based on velocities measured over a whole year; strictly, this should apply in the case of test subjects, as shorter time periods will be associated with larger relative errors and therefore larger SD at any particular age. In many situations, whole-year velocities are not practical, particularly for children with complex diseases where the course of the illness is unstable. In this case, shorter time intervals may be required, but interpretation of results requires caution. Periods of less than 6 months are probably valueless.

Bardet-Biedl Syndrome

Philip L. Beales

University College London, London, United Kingdom

Glossary

brachydactyly Short broad fingers or toes.

hydrometrocolpos An enlarged fluid-filled uterine cavity, often secondary to a nonpatent hymen.

nyctalopia Night blindness.

orthologue One of a set of homologous genes in different species.

postaxial Lateral to the mid-axis of the limb.

proband The affected index case in a pedigree.

syndactyly Pronounced webbing between digits.

Bardet-Biedl syndrome is an inherited disorder that includes the following cardinal features: retinal dystrophy, obesity, polydactyly, cognitive impairment, hypogonadism, and renal anomalies.

INTRODUCTION

Eponyms

During recent times, a good deal of confusion has arisen over the naming of what has come to be called Bardet-Biedl syndrome (BBS). Laurence-Moon-Biedl syndrome, Laurence-Moon-Bardet-Biedl syndrome, and (more recently) Bardet-Biedl syndrome all have been applied. In 1866, Laurence and Moon described members of an English family with retinitis pigmentosa (RP), mental retardation, obesity, and male hypogonadism. More than 55 years later, Bardet and Biedl reported cases with the triad of retinal dystrophy, polydactyly, and obesity. Since the 1980s, it has been suggested that the condition described by Laurence and Moon is distinct from BBS in that they did not report the presence of polydactyly in their family and that affected members of this family later went on to develop spastic lower limb signs, thereby giving birth to a separate entity, the Laurence-Moon

syndrome (LMS). The label “Bardet-Biedl syndrome” is the current preference despite very little evidence to support this division. Mutational analyses will resolve this issue in time.

Prevalence

BBS has been described in most populations, although with differing frequencies. In populations of North European descent, rates range from 1 in 100,000 to 1 in 160,000. Among certain Arab populations, the syndrome is twice as common (1 in 65,000), and it is at least 10-fold more frequent in the Newfoundland population (1 in 17,500) owing to a founder effect.

NATURAL HISTORY AND DIAGNOSIS

Despite recent advances in the genetics of BBS, diagnosis remains clinical for the most part. The phenotype is emerging in that often the only discernible feature at birth may be postaxial polydactyly (up to 30% do not have polydactyly). Most affected infants are of normal birthweight and have normal vision until 7 or 8 years of age, when nyctalopia may ensue. A steady decline in visual acuity progresses over the subsequent two decades of life, with most patients being registered as fully blind by the time they reach their 20s. The cardinal features of BBS are a rod-cone dystrophy, central obesity, dystrophic extremities (including postaxial polydactyly), varying degrees of cognitive impairment, male hypogonadism (and female genital tract anomalies), and structural and functional renal abnormalities. Four of six features have been considered enough for a positive diagnosis. However, in recognition of many secondary features and to facilitate early diagnosis, modified criteria have been proposed; either four primary features (of the six cardinal signs) or three primary and two secondary features should be present (Table I). Among the secondary features are diabetes mellitus (type 2), hypertension, speech and behavioral abnormalities,

Table 1 Diagnostic Criteria for Bardet–Biedl Syndrome**Primary features**

Retinal dystrophy
 Polydactyly
 Obesity
 Learning disabilities/Mental retardation
 Male hypogonadism
 Renal anomalies

Secondary features

Speech disorder/delay
 Strabismus/cataracts/astigmatism
 Brachydactyly/Syndactyly
 Developmental delay
 Nephrogenic diabetes insipidus
 Ataxia/Poor coordination/Imbalance
 Diabetes mellitus
 Dental anomalies
 Heart disease (congenital)/Hypertension
 Hepatic fibrosis

Note. Four primary features or three primary plus two secondary features should be present.

endocrinopathies, atresia ani, Hirschsprung disease, and gait anomalies. There appears to be as much intrafamilial variation as there is interfamilial variation in the expression of the clinical features, and no fastidious phenotype–genotype correlations can be claimed.

MAJOR CLINICAL FEATURES

Ophthalmologic Findings

For the majority of patients, visual acuity is normal at birth and throughout infancy. Most children will attend school with near-perfect vision, only to experience a gradual decline over the ensuing two to three decades. Despite the presence of early visual disturbance such as nyctalopia, fundoscopic changes remain minimal with some vessel attenuation. The classical “bony corpuscular” distribution characteristic of RP is usually a late manifestation; therefore, normal fundoscopy should not be regarded as synonymous with normal function. Electroretinogram (ERG) remains the cornerstone of investigation but is often difficult to perform in very young children and may be normal in children under 7 years of age. Extraretinal features, such as horizontal nystagmus, high myopia,

**Figure 1** Postaxial polydactyly in the foot.

strabismus, diabetic retinopathy, cataracts, and glaucoma, should not be overlooked.

Dystrophic Extremities

Polydactyly is almost always postaxial in distribution, ranging from a fully formed and functional extra digit to a vestigial nubbin (Fig. 1). Likewise, the number of limbs involved is variable. Probably even more common is the presence of brachydactyly (more often in the feet than in the hands) in the majority of patients, and syndactyly frequently presents between the second and third toes.

Obesity

Weight gain is significant in BBS, usually beginning within the first 2 years of life, following weaning. There is little evidence to support an abnormality in basal metabolic rate, and a combination of excess intake with potentially reduced activity levels may contribute to this aspect of the phenotype. Body mass index (BMI) in BBS adults usually lies between 30 and 39, with a minority constantly above 40. Adiposity is generalized.

Cognitive Impairment

There is a range of conflicting reports regarding the degree of intellectual impairment prevailing in BBS. It is clear that there is a great deal of variation, with a minority displaying severe mental retardation and the majority showing some form of learning difficulty to the extent that special educational arrangements are required. There are anecdotal reports of autistic tendencies in some BBS children, and behavioral traits

(e.g., obsessiveness, disinhibition) abound but have not been objectively corroborated. A study assessing behavior and IQ in 21 BBS children reported that only 3 children (17%) had full-scale IQs in the average range (>79) and that 11 (52%) fell within the mental retardation range (<70); nonetheless, the majority were mildly intellectually impaired.

Genital and Reproductive Anomalies

Hypogonadism among males has been well described and may also be accompanied by infertility. The case among female patients is less clear, although there are many examples of pregnancy leading to viable birth. A number of reports of genital malformations suggest that these are a common manifestation of BBS and include hypoplastic fallopian tubes, uterus, and ovaries; partial and complete vaginal atresia; septate vagina; duplex uterus; hematocolpos; persistent urogenital sinus; vesico-vaginal fistula; absent vaginal orifice; and absent urethral orifice. Hydrometrocolpos is one of the three features of McKusick-Kaufman syndrome (MKS) in which the underlying gene (*MKKS/BBS6*) has been shown to harbor mutations common to both MKS and BBS.

Renal Dysfunction

Until the 1980s, the renal component of BBS had been reported only infrequently, although a high frequency of structural abnormalities was observed at postmortem.

Structural Changes

Renal dysplasia can be present without clinical evidence of renal disease; thus, careful imaging of the urinary tract is warranted. Among the renal structural anomalies encountered are cystic spaces communicating with the collecting system, parenchymal cysts (Fig. 2), persistence of fetal lobulation, small kidneys with parenchymal scarring, prolonged nephrogram, and blunting and clubbing of the calyces. Persistent fetal lobulation has been described in isolation, and it has been suggested that this may reflect a defect in maturation.

Ultrasound scanning and intravenous pyelography are the primary investigations of choice.

Functional Renal Impairment

Chronic renal failure has been reported in several studies and ranges from 30 to 100% of the cohort described. Many end-stage patients have undergone

Figure 2 Abdominal computed tomography (CT) scan depicting polycystic kidneys (arrow) in a young male with BBS.

renal transplantation successfully, although no studies of long-term follow-up have been reported.

Minor Diagnostic Features

The recent recognition of several less well-characterized features has helped to secure a diagnosis particularly in young patients, where retinal degeneration might not have emerged at the time of examination.

Endocrine Disturbance

One study of 38 patients reported that 2 were insulin dependent, 4 were maintained on oral hypoglycemic agents, and 6 were managed with diet alone. The researchers concluded that 25% of BBS patients were diabetic by 35 years of age and that 50% were diabetic by 55 years of age. The underlying cause is unknown, and there have been no reports of abnormal pancreas at postmortem. It is likely that diabetes mellitus is secondary to insulin resistance.

Other reported endocrinopathies include hypothyroidism, hypopituitarism, and gonadotropin and testosterone deficiency. Diabetes insipidus is common and is mainly nephrogenic in origin.

GENETICS

BBS has emerged as one of the most heterogeneous monogenic conditions known, with evidence for at least eight loci: *BBS1* on 11q13, *BBS2* on 16q21, *BBS3* on 3p12, *BBS4* on 15q22.2–q23, *BBS5* on 2q31, *BBS6* on 20p12, *BBS7* on 4q27, and *BBS8* on 14q32 (all mapped loci, with the exception of *BBS3* and *BBS5*, have been cloned as of September 2003). However, the cloning of the first BBS locus, *BBS6*,

followed by mutational analyses on a large multiethnic cohort implied that some mutations do not conform to a traditional model of autosomal recessive disease transmission.

Multiallelic Inheritance in BBS

Following the identification of two BBS loci, *BBS2* and *BBS6*, sequence analyses showed that, in some families, a total of three mutations in two genes are necessary for pathogenesis, thereby establishing a digenic triallelic model of disease transmission and suggesting that BBS might be a useful model to study oligogenic traits.

BBS Proteins

The search for conceptual homologues using corresponding nucleotide and amino acid sequence from each of the BBS genes has yielded only modest similarities. The closest orthologue to *BBS6/MKKS* is that of the archaeobacterial thermosome or chaperonin-containing T-complex polypeptide (CCT), members of the group of type II chaperonins. These are thought to have a role in facilitating the correct folding of nascent peptides into their functional configuration, and perhaps the BBS phenotype results from misfolding of *BBS6* peptides.

BBS1, -2, -4, and -7 all are representative of novel peptides without any chaperonin homology, but many have domains with multiple tetratricopeptide (TPR) repeats that are probably important as for protein-protein interactions. *BBS4* has similarity to O-linked N-acetyl glucosamine transferase (OglcNac).

Clinical Genetics

Recurrence Risks

For the majority of families with BBS probands, the recurrence risk for another affected child will be that for an autosomal recessive disorder, that is, 1 in 4. The risk that any sibling may be a carrier is 2 in 3. Less than 10% of all cases exhibit multiallelic inheritance. If such a case is proven, then the recurrence risk must be modified accordingly; that is, in a triallelic pedigree, the risk of further affected offspring will theoretically fall to 1 in 8, although such risks have yet to be substantiated.

Prenatal Diagnosis

Until recently, prenatal diagnosis was inaccurate and limited to ultrasound scanning for potential anomalies such as postaxial polydactyly and renal anomalies in those families at risk. With the advent of screening, *in utero* mutation detection can be offered at amniocentesis or by chorionic villus sampling provided that the responsible mutation(s) has been identified in the parents. Nevertheless, given the large number of genes that require screening (not to mention those that have not yet been cloned), it is not surprising that most diagnostic laboratories do not offer this service.

Baroreceptor Responses

Edward M. Stricker and Alan F. Sved
University of Pittsburgh, Pittsburgh, Pennsylvania, United States

Glossary

- bradycardia** Decreased heart rate.
hypotension Reduced arterial blood pressure.
hypovolemia Reduced blood volume.
tachycardia Increased heart rate.

Given the importance of the cardiovascular system, it is not surprising that elaborate mechanisms have evolved to promote the stability of blood volume and arterial blood pressure. These mechanisms include well-known physiological responses that restore blood volume and blood pressure after blood loss with or without accompanying decreases in arterial blood pressure. Those responses include adaptive cardiovascular responses, autonomic reflexes, endocrine secretions, and ingestive behaviors motivated by thirst and salt appetite.

INTRODUCTION

Animals must be able to detect changes in blood volume and blood pressure for any compensatory responses to occur. Insight into the location of the receptors and their properties comes from a consideration of how changes in blood volume and blood pressure affect the cardiovascular system. For example, after a moderate hemorrhage, the blood loss is not distributed uniformly throughout the cardiovascular system but instead is borne nearly entirely on the venous side of the circulation. Thus, the veins, which are very distensible, collapse around the remaining blood and thereby help to reduce the impact of the blood loss on venous blood pressure. Together with an appropriate increase in heart rate, arterial blood volume and blood pressure undergo little change. Thus, it makes sense that receptors are situated to monitor blood volume on the venous side of the circulation. In contrast, after severe hemorrhage, the effects of blood loss may extend to the arterial side of the circulation and reduce arterial blood volume and blood pressure. Thus, it also makes sense that

additional receptors are situated to monitor blood pressure on the arterial side of the circulation. In fact, the receptors that monitor the stretch of venous and arterial blood vessels are known to be located at key sites in the cardiovascular system. One such site is at the junction of the inferior vena cava and the right atrium. Another site is the aortic arch through which arterial blood leaving the heart is carried. A third site is the carotid artery through which blood flows to the brain.

The receptor cells in question are called “baroreceptors,” which literally means that they are responsive to changes in pressure. However, the sensory endings actually are stretch receptors, located on the outside walls of the blood vessels and cardiac atria, that respond to changes in the conformation of the vessel walls much like other stretch receptors on the outside walls of the stomach and bladder detect the fullness of those organs. Thus, following moderate hemorrhage, the stretch receptors on the low-pressure side of the circulation decrease their firing rate as the loss in blood volume decreases the distension of the right atrium and adjacent vena cava. Following a more severe hemorrhage, the stretch receptors on the high-pressure side of the circulation also detect the loss in arterial blood pressure as a decrease in the distension of the proximal aorta and the carotid sinus.

RESPONSES

Neural afferents from these low- and high-pressure baroreceptors project as part of the cranial nerves IX and X to the nucleus of the solitary tract (NST) in the caudal brainstem. From there, complex neural circuitry enables the variety of responses that occur in response to decreases in blood volume or arterial blood pressure (Fig. 1). The most prominent responses are discussed in the following subsections.

Cardiac Reflexes

Changes in heart rate help to compensate for changes in blood volume and blood pressure. For example, an

Figure 1 Baroreceptor-evoked responses to hypovolemia and hypotension. The activity of veno-atrial baroreceptors and the activity of arterial baroreceptors are related to changes in blood volume and blood pressure, respectively. Neural and endocrine baroreceptor reflex responses to decreases in blood volume or blood pressure produce increases in heart rate and cardiac output, increases in vasoconstriction, and decreases in fluid excretion by the kidneys. In addition, baroreceptor input to the brain elicits ingestive behaviors to increase body fluid volume. In general, increases in blood volume and blood pressure elicit baroreceptor-evoked responses that are the converse of those seen with decreases in these parameters.

increase in heart rate occurs during hypovolemia or hypotension and is one of the well-known “baroreceptor reflexes.” This response appears to reflect the three autonomic effects that result from baroreceptor input to the NST. The first effect involves the control of sympathetic neural activity; this accelerates heart rate and increases cardiac contractility when stimulated during volume contraction or decreases in arterial pressure. The second is the converse effect on parasympathetic neural activity; this also causes tachycardia. The third involves stimulation of the adrenal medulla and the release into the systemic circulation of epinephrine; this has a prominent effect on beta-adrenergic receptors on the heart and thereby further stimulates increased heart rate. The multiple controls of heart rate ensure that these responses are rapid and precise.

Vasoconstriction

Another baroreceptor response to hemorrhage involves the release of norepinephrine from sympathetic postganglionic fibers that innervate vascular smooth muscle, resulting in activation of the alpha-adrenergic receptors on the arterioles that carry blood to various tissues, most prominently abdominal viscera and

muscle, and constriction of those vessels. Vasoconstriction at these sites causes arterial blood to be pooled in the central circulation, thereby enabling perfusion of the major organs to be maintained while compromising blood flow to less critical tissue. Activation of sympathetic neural input to veins causes venoconstriction, thereby increasing venous return of blood to the heart and cardiac output.

Renin–Angiotensin System

Sympatho-adrenal activity stimulates renin secretion from the kidneys, beginning a cascade of biochemical events that result in the generation of the peptide hormone angiotensin II, the most potent pressor agent available to animals in response to blood loss. Briefly, renin is a proteolytic enzyme that is synthesized in renal juxtaglomerular cells and is released in response to increased activation, either by sympathetic nerves or by circulating epinephrine, of beta-adrenergic receptors that are located on the cell walls. Renin acts by cleaving four amino acids from a 14-amino acid protein (angiotensinogen) that is synthesized in the liver and is always present in the circulation. The resultant 10-amino acid protein (angiotensin I) then quickly loses 2 more amino acids through the action of an enzyme that converts angiotensin I to angiotensin II. This enzyme is heavily concentrated in the lungs, an arrangement that allows the hormone to be delivered into the arterial blood that leaves the heart (as opposed to renin, which enters the general circulation through the renal veins and has no direct vasomotor effects).

Circulating angiotensin II acts directly on angiotensin II receptors in vascular smooth muscle to support blood pressure. In addition, it acts in the adrenal cortex to stimulate secretion of the mineralocorticoid aldosterone, which promotes urinary sodium (Na^+) retention (and, secondarily, fluid retention) as well as urinary potassium (K^+) excretion; this is especially useful when blood loss is associated with tissue damage. Angiotensin II also acts on angiotensin receptors in the brain, specifically in the subfornical organ (SFO). The SFO, which is situated dorsal to the third cerebral ventricle, lacks a blood–brain barrier and, therefore, can detect variations in blood levels of the hormone. Neural circuits from the SFO then appear to stimulate central systems that increase sympatho-adrenal activity. They also stimulate secretion of vasopressin, another hormone with pressor properties, from the posterior lobe of the pituitary gland.

Vasopressin

The release of pituitary vasopressin is stimulated by neural projections from the NTS to the supraoptic and paraventricular nuclei of the hypothalamus in response to decreased baroreceptor input during hemorrhage. Vasopressin levels in blood of only 6 to 8 pmol (i.e., 6–8 pg/ml) are required for maximum antidiuresis. Effective pressor levels of vasopressin are substantially higher (50–60 pg/ml), and those elevated levels are obtained following hemorrhage or arterial hypotension. Pituitary secretion of the other neurohypophyseal hormone, oxytocin, parallels the secretion of vasopressin in response to these stimuli. The contribution of oxytocin to the regulation of blood volume and arterial blood pressure in rats was revealed recently by observations that it constituted yet another significant stimulus of renin secretion.

Pituitary–Adrenal Axis

Neural projections from the NST to the paraventricular nuclei of the hypothalamus also stimulate release of corticotropin-releasing factor (CRF), and this elicits secretion of adrenocorticotrophic hormone (ACTH) from the anterior lobe of the pituitary gland. ACTH, in turn, stimulates the adrenal cortex to increase its synthesis and release of two steroid hormones: aldosterone and the glucocorticoid cortisol. Cortisol improves vascular reactivity to the catecholamines and other general responses to stress.

Ingestive Behavior

In addition to these physiological responses, hypovolemia is known to stimulate thirst and (in rats but not humans) salt appetite. Remarkably, the resultant ingestion of water and sodium chloride (NaCl) solution occurs in amounts equivalent to a fluid mixture that is isotonic to plasma. Baroreceptor input to the brainstem is presumed to provide the main signal of thirst under hypovolemic conditions, although angiotensin II is a known dipsogen and presumably contributes stimulation as well. The signal of salt appetite is less clear and is controversial, although an important role of angiotensin II seems to be apparent. Thirst (but not salt appetite) also is stimulated by arterial hypotension in rats, but the induced water intake is mediated exclusively by angiotensin II, and baroreceptors do not appear to provide a direct neural signal.

In addition to these various responses stimulated by cardiac and arterial baroreceptors, it may be noted that renin secretion is stimulated by “renal baroreceptors.”

Despite its name, this latter mechanism does not resemble the other baroreceptors in that neural input to and from the central nervous system is not involved. Instead, a decrease in renal perfusion, associated with systemic hypovolemia or arterial hypotension, reduces the fullness of the distensible renal arterioles. The cells that synthesize and secrete renin line the walls of those blood vessels; therefore, decreased renal perfusion produces conformational changes in the cells, and this stimulates renin secretion. Finally, it has been proposed that decreased renal perfusion also provides a neural signal of hypovolemia and arterial hypotension, mediated by renal afferents projecting to the spinal cord; this might contribute additional stimulation of the compensatory physiological and behavioral responses.

CONCLUSION

Many adaptive responses occur during hypovolemia and arterial hypotension that appear to involve signals originating in the activity of cardiovascular baroreceptors. These responses include several chemical agents that independently provide vasoconstriction and support of arterial blood pressure, hormone secretions that promote urinary conservation of water and Na⁺, and the sensations of thirst and salt appetite that lead to water and NaCl consumption. The precise stimulus of each response is not always certain, but it may involve neural signals, bloodborne signals, or both. This redundancy of stimuli is a common feature of homeostatic regulatory systems; it is adaptive because it allows compensation for damage- or disease-induced impairments of individual components of the system. On the other hand, this redundancy makes it very difficult to identify all of the contributing signals and effector systems that participate in homeostasis as well as their importance relative to one another.

Although this article has focused on the baroreceptor responses seen after reductions in blood volume and blood pressure, it is important to recognize that many, but not all, of these same variables are influenced by increases in blood volume and blood pressure. For example, a reflexive bradycardia is signaled by low-pressure baroreceptors during hypervolemia and by high-pressure baroreceptors during hypertension. These effects result when sympathetic fibers to the heart are inhibited while parasympathetic fibers are stimulated. Other baroreceptor responses to hypervolemia and hypertension are generally analogous, although some inconsistencies are evident. Thus, vasopressin secretion is decreased when blood volume is expanded but not when blood pressure is elevated.

Conversely, thirst is decreased when arterial blood pressure is elevated acutely but not when blood volume is expanded. In short, baroreceptors mediate a variety of adaptive autonomic, endocrine, and behavioral responses to both decreases and increases in blood volume and blood pressure.

Bartter's Syndrome

I. Lenga and K. S. Kamel
 University of Toronto, Toronto, Ontario, Canada

Glossary

hypocalciuria A low rate of calcium excretion in the urine, usually defined as the excretion of less than 0.1 mmol of calcium per millimole of creatinine in the urine.

hypokalemia A serum potassium level that is lower than 3.5 mmol/L.

hypomagnesemia A serum magnesium level that is lower than 0.7 mmol/L.

metabolic alkalosis An arterial blood pH that is higher than 7.40 due to an elevated plasma bicarbonate concentration.

Bartter's syndrome and Gitelman's syndrome are autosomal recessive tubulopathies characterized by hypokalemia with renal potassium wasting, metabolic alkalosis, and normal or low blood pressure despite hyperreninemia and secondary hyperaldosteronism.

INTRODUCTION

More than 40 years ago, Bartter's syndrome and Gitelman's syndrome of inherited hypokalemic metabolic alkalosis were described. Yet despite numerous studies and hundreds of publications, their pathophysiology remained enigmatic. Recently, the recognition of distinct phenotypes within this heterogeneous group of patients has permitted the application of powerful molecular genetic methods to define the primary basis of these disorders. Although these findings have significantly improved our understanding of renal physiology and may have implications for the development of novel therapeutic agents, a number of questions remain to be answered. This article presents a concise overview of the topic, highlighting areas where progress has been made and also pointing out issues that remain to be explored.

EPIDEMIOLOGY

Bartter's and Gitelman's syndromes are rare diseases that exhibit autosomal recessive inheritance. There is no known racial predilection, and both genders seem to be affected equally. Gitelman's syndrome is more common, although its true prevalence is unknown.

MOLECULAR LESIONS

Bartter's Syndrome

The fundamental defect in Bartter's syndrome is tubular dysfunction in the thick ascending loop of Henle (TAL) (Fig. 1). Na^+ reabsorption in this nephron segment occurs via the electroneutral furosemide-sensitive $\text{Na}^+/\text{K}^+/2 \text{Cl}^-$ cotransporter (NKCC2). Recycling of K^+ through an apical membrane K^+ channel (ROMK) provides the K^+ for continued operation of the transporter and also generates the positive luminal voltage that drives the paracellular reabsorption of Na^+ and of the divalent cations, Ca^{2+} and Mg^{2+} . Cl^- exits the cells via a basolateral Cl^- channel, ClC-Kb .

Loss of function mutations have been described in these three ion channels. Another variant, type IV

Figure 1 Molecular lesions causing Bartter's syndrome. Schematic presentation shows transport mechanisms in the thick ascending limb of the loop of Henle. Defects at five sites that can lead to diminished reabsorption of Na^+ and Cl^- , and thereby Bartter's syndrome, are illustrated.

Bartter's syndrome, has also been described. It is caused by mutation in BSND, the gene that encodes for a protein called barttin, an essential β -subunit of the ClC-Kb channel. It is associated with sensorineural deafness because barttin is also expressed in the K^+ -secreting dark cells of the inner ear.

Ca^{2+} binds to the calcium-sensing receptor (CaSR) expressed in the basolateral membrane on the cells of the TAL. This leads to the generation of an arachidonic acid metabolite that inhibits ROMK and hence causes a loop diuretic-like effect. A Bartter's-like syndrome has also been described in severe cases of autosomal dominant hypocalcemia. The genetic defect in this case is an activating mutation (gain of function) in the gene encoding for CaSR.

Gitelman's Syndrome

Gitelman's syndrome is usually caused by a loss of function mutation in the thiazide-sensitive sodium chloride cotransporter (NCC) in the distal convoluted tubule (DCT) (Fig. 2). In addition, mutations in other transporters in the DCT can indirectly cause functional impairment of the NCC, leading to similar phenotypes. Mutations have been documented in the ClC-Kb of the DCT. Mutations in the γ -subunit of the basolateral Na-K-ATPase have been found in isolated patients with hypomagnesemia and hypocalciuria.

CLINICAL FEATURES

The phenotypic expression of Bartter's syndrome is highly variable. Types I and II tend to present during the neonatal period, whereas type III typically

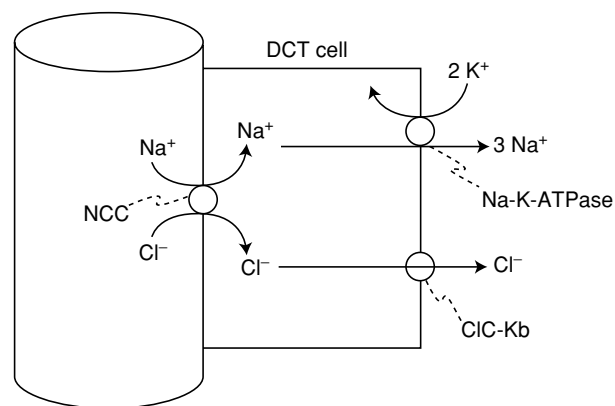

Figure 2 Molecular disorders causing Gitelman's syndrome. The most common defect causing Gitelman's syndrome is a mutation involving NCC, but others include a lesion in the γ -subunit of the Na-K-ATPase or in Cl⁻ channels on basolateral membranes in this nephron segment (ClC-Kb).

presents during infancy or childhood. Polyuria and polydipsia with clinical extracellular fluid (ECF) volume contraction are very common. Muscle weakness and cramping are nearly universal. Other complaints may include constipation, vomiting, and salt craving. There may be growth retardation and neurocognitive impairment to a variable degree. Nephrocalcinosis occurs in some patients but is notably absent in type III Bartter's syndrome. Sensorineural hearing loss is a unique feature of type IV Bartter's syndrome.

Neonatal Bartter's syndrome is the most severe form of the condition. Maternal polyhydramnios and premature labor are common due to excessive urine production *in utero*. Infants have characteristic triangular facies, with a drooping mouth, large eyes, and large pinnae. Polyuria, polydipsia, failure to thrive, and growth retardation are common findings.

Gitelman's syndrome presents during late childhood or even during adulthood, and at times it is discovered incidentally during routine blood work. Patients often complain of muscle cramps and may also present with tetany. Chondrocalcinosis (calcium pyrophosphate deposition disease) is a recognized association.

BIOCHEMICAL FEATURES AND PATHOPHYSIOLOGY

Fluid and Electrolytes

The TAL is responsible for 30% of NaCl reabsorption in the nephron. Failure of this cotransporter leads to the ECF volume depletion that typifies Bartter's syndrome. The reabsorption of NaCl in this segment also serves to generate the high tonicity of the renal interstitium, providing the osmotic force for water reabsorption in the medullary-collecting duct. Patients with Bartter's syndrome fail to concentrate their urine maximally in response to exogenous vasopressin. The salt wasting and urine-concentrating defect manifest symptomatically with polyuria and polydipsia.

The NCC accounts for only 5% of NaCl reabsorption and has no role in establishing the osmolality of the renal interstitium. Consequently, patients with Gitelman's syndrome have only a mild degree of ECF volume contraction and no urine-concentrating defect. Nevertheless, chronic hypokalemia may impair urine-concentrating ability.

Hypokalemia in these syndromes results from increased urinary potassium excretion. Excretion of potassium depends on its rate of secretion in the cortical collecting duct (CCD) and on the flow rate in this nephron segment.

$$K^+ \text{ Excretion} = [K^+]_{\text{CCD}} \times \text{Flow Rate}_{\text{CCD}}$$

In the presence of vasopressin actions, flow in the terminal CCD is determined by the rate of delivery of osmoles to the CCD. Inhibition of NaCl reabsorption in the TAL or DCT increases the delivery of osmoles to the CCD, leading to a higher rate of flow in the terminal CCD. Secretion of K^+ by principal cells in the CCD requires a lumen-negative voltage and open K^+ channels (Fig. 3). The lumen-negative voltage is generated by electrogenic reabsorption of Na^+ . In Bartter's and Gitelman's syndromes, there is increased delivery of Na^+ and Cl^- to the CCD. The high levels of serum aldosterone due to ECF volume contraction open luminal epithelial sodium channels (ENaC) in the CCD. If the capacity for reabsorption of Na^+ exceeds that for Cl^- , a negative luminal voltage is generated and drives the secretion of K^+ via luminal K^+ channels (Fig. 3).

Metabolic alkalosis is a feature of both syndromes. Hypokalemia stimulates ammoniogenesis and generation of bicarbonate by the cells of the proximal convoluted tubule. Most of the filtered HCO_3^- is reclaimed in the proximal tubule by secretion of H^+ via the Na^+/H^+ exchanger (NHE-3). The activity of NHE-3 is stimulated by angiotensin II and intracellular acidosis. In patients with Bartter's and Gitelman's syndromes, ECF volume contraction stimulates the release of

Figure 3 K^+ secretion in the distal nephron. Secretion of K^+ by principal cells in the CCD requires (1) an open ROMK channel and (2) a lumen-negative voltage (NEG). The latter is generated when Na^+ is reabsorbed via ENaC at a rate faster than the accompanying anion, Cl^- . In patients with Bartter's and Gitelman's syndromes, there is increased delivery of Na^+ and Cl^- to the CCD. A lumen-negative voltage is generated if the capacity for Na^+ reabsorption via ENaC (stimulated by aldosterone) exceeds that for Cl^- .

angiotensin II. Furthermore, during hypokalemia, a shift of K^+ from the intracellular fluid to the ECF in exchange for H^+ results in intracellular acidosis.

Divalent Cations

The perturbations in divalent cation metabolism in these disorders are less well understood. In the TAL, recycling of K^+ through ROMK channels generates a positive luminal charge that drives paracellular Mg^{2+} and Ca^{2+} reabsorption. Ca^{2+} and Mg^{2+} are reabsorbed in the DCT, although the mechanisms involved are not fully understood. Hypercalciuria is expected in patients with Bartter's syndrome. Surprisingly, and despite the fact that a large proportion of filtered Mg^{2+} is normally reabsorbed in the TAL, hypomagnesemia is not a common finding in these patients. On the other hand, patients with Gitelman's syndrome are usually hypomagnesemic. Hypocalciuria is also a characteristic finding in patients with Gitelman's syndrome.

A unifying hypothesis to explain these findings focuses on the DCT being the final critical nephron site for reabsorption of Mg^{2+} but not of Ca^{2+} . Although calcium reabsorption does occur in the DCT, the final critical nephron site for its reabsorption is the connecting segment (CS). In Bartter's syndrome, the DCT function is up-regulated to compensate for less reabsorption of NaCl in the LOH. The enhanced function of the DCT increases Mg^{2+} reabsorption and maintains magnesium homeostasis. On the other hand, enhanced Ca^{2+} reabsorption in both the DCT and the CS is still insufficient to overcome the increased delivery of Ca^{2+} from the LOH, and hypercalciuria results. Alternatively, patients with Gitelman's syndrome are likely to have decreased DCT cell mass due to chronic low activity of the transporters in this nephron segment. Thus, magnesium wasting with hypomagnesemia occurs, underscoring the DCT in the final nephron site for magnesium reabsorption. DCT dysfunction leads to enhanced delivery of NaCl to the CS, with up-regulation of its function. Because calcium reabsorption in the TAL in Gitelman's syndrome is intact, the enhanced Ca^{2+} reabsorption at the CS renders the urine hypocalciuric.

Prostaglandin E_2

Prostaglandin E_2 is hypersecreted in patients with Bartter's syndrome. In fact, neonatal Bartter's syndrome, in which PGE_2 levels are particularly elevated,

has been called the hyperprostaglandin E₂ syndrome. However, this term is inappropriate because the prostaglandin synthesis in this condition is a secondary phenomenon resulting from the persistent ECF volume contraction. In Gitelman's syndrome, where ECF volume is less contracted, PGE₂ synthesis is normal. The effects of high PGE₂ levels are thought to be fever, secretory diarrhea, and osteopenia.

DIAGNOSIS

Bartter's and Gitelman's syndromes must be differentiated from other causes of hypokalemic metabolic alkalosis. Primary hyperaldosteronism and Liddle's syndrome can be distinguished from these syndromes by the presence of hypertension, absence of ECF volume contraction, and suppressed plasma renin activity. Surreptitious vomiting can often be identified through a careful history or, more objectively, by the presence of a low urine chloride concentration (≤ 20 mEq/L). Diuretic abuse may present a distinct challenge. As mentioned earlier, the NKCC2 is directly inhibited by loop diuretics such as furosemide, and its chronic use will present a clinical and biochemical profile indistinguishable from Bartter's syndrome. Similarly, thiazide diuretics inhibit the NCC and will generate a clinical picture identical to Gitelman's syndrome. This diagnosis can often be made if a spot urine sample reveals low sodium and chloride concentrations (≤ 20 mEq/L), reflecting physiological salt avidity during periods when the diuretic effects have worn off. Urine samples with abundant Na and Cl should be assayed for diuretics prior to making a diagnosis of Bartter's or Gitelman's syndrome.

TREATMENT

Because the ion channel defects in these patients cannot be corrected, treatment must be directed as the secondary hormonal and electrolyte derangements in these syndromes. Correction of hypokalemia in these patients is rather difficult even with large K⁺ supplements. Hypomagnesemia may be an important factor in the enhanced kaliuresis in some patients with Gitelman's syndrome. Again, correction of hypomagnesemia with oral magnesium is usually difficult and also limited by gastrointestinal side effects. K⁺-sparing diuretics (e.g., amiloride, spironolactone) may help to conserve K⁺. A common clinical observation is that

even high doses of amiloride fail to curtail the excessive kaliuresis in patients with Bartter's and Gitelman's syndromes. Part of the explanation of this diminished effect could be related to the higher flow in the CCD due to inhibition of NaCl reabsorption in upstream nephron segments. This higher volume delivery to the CCD lowers the concentration of ENaC blockers, diminishing their effectiveness. A potential concern using these agents in patients with Bartter's and Gitelman's syndromes is that they may aggravate the salt wasting in these patients. This may become evident, for example, if dietary salt intake is decreased or if there is a nonrenal loss of NaCl.

ACE inhibitors have been used with variable success to reduce levels of angiotensin II and aldosterone, with hypotension being a major concern. In Bartter's syndrome, prostaglandin synthesis can be reduced with cyclo-oxygenase inhibitors such as indomethacin. Inhibition of PGE₂ attenuates salt wasting and hypokalemia and minimizes the systemic symptoms of prostaglandin excess. Caution is advised in using these agents during the neonatal period because acute renal failure and patent ductus arteriosus are documented complications. The prolonged use of these drugs also is discouraged due to the potential for chronic renal dysfunction.

Glossary

cryptorchidism A developmental abnormality in which the testes fail to descend normally into the scrotum and remain in the abdomen.

hyperplasia An increase in the size of a tissue or an organ due to an increase in the number of its constituent cells.

hypoglycemia A condition in which the concentration of glucose in the blood is abnormally low; can cause symptoms such as a cold sweat, piloerection, tremulousness, hypothermia, headache, irritability, confusion, hallucinations, bizarre behavior, convulsions, and coma.

macroglossia An abnormally large tongue.

Beckwith-Wiedemann syndrome was initially described independently by J. B. Beckwith in 1963 and H. R. Wiedemann in 1964. It is associated with prenatal and postnatal overgrowth, with the most characteristic features occurring at birth: omphalocele or umbilical defects, macroglossia, and gigantism (Table I and Fig. 1).

INTRODUCTION

Up to half (30–50%) of children with Beckwith-Wiedemann syndrome (BWS) may have severe persistent hypoglycemia, beginning during the first days of life, from hyperinsulinism as a result of pancreatic islet cell hyperplasia. The hypoglycemia usually subsides by 4 months of age. Other features include neonatal polycythemia, prominent eyes with relative infraorbital hypoplasia, prognathism, large fontanelles, capillary nevus in the central forehead and eyelids, unusual creases in the lobule of the external ear, and indentations or marks in the posterior rim of the helix. The head is relatively small and may have a protruding occiput. There is visceromegaly with

enlargement of the liver, kidneys, pancreas, and (at times) cardiomegaly; renal medullary dysplasia; fetal adrenal cortical cytomegaly; and interstitial cell hypoplasia of the gonads. Gastrointestinal malrotation and cryptorchidism are also seen. In 1983, Wiedemann reported hemihypertrophy in 12.5% of cases.

There is an increased incidence of malignant tumors in children with BWS. In 1983, Wiedemann reported that of 388 children, 29 (7.4%) developed 32 neoplasms, with the most frequent being Wilms' tumors and adrenal cortical carcinoma. Other tumors could be nephroblastoma, hepatoblastoma, and rhabdomyosarcoma. Nearly half (49%) of the children with neoplasms had partial or complete hemihypertrophy. Tumors usually occur during the first 5 years and rarely occur after 7 years of age.

Table I Beckwith-Wiedemann Syndrome Characteristics

| |
|---|
| Overgrowth |
| Prenatally and postnatally ^a |
| Advanced bone age |
| Craniofacial |
| Macroglossia ^a |
| Prominent eyes |
| Capillary nevus, forehead |
| Earlobe creases |
| Malformations |
| Omphalocele ^a |
| Renal medullary dysplasia |
| Hemihypertrophy (12.5%) |
| Other |
| Hypoglycemia—severe ^a (nesidioblastosis) |
| Adrenocortical cytomegaly ^a (consistently) |
| Interstitial cell hypoplasia of the gonads |
| Risk of malignant tumors^a (7–10%) |

^aMost characteristic.

Figure 1 (A, B) A 4 1/2-month infant with Beckwith–Wiedemann syndrome showing macroglossia, umbilical hernia, prominent calf muscles, and overgrowth. The length is 67.3 cm (26 1/2 inches), and the weight is 7.7 kg (both >75 percentile). (C) At 15 months, the height is 87.5 cm (34 1/2 inches), and the weight is 14.6 kg (both >95 percentile). Macroglossia is still evident. The infant did not have hypoglycemia.

GROWTH

Children with BWS are large at birth, with increased muscle mass, thick subcutaneous tissue, and advanced bone maturation. Birthweights average 4 kg (8 pounds 13 ounces). The mean birthlength for males is greater than the 95 percentile and for females is on the 75 percentile, increasing to above the 95 percentile by 2 years. Growth velocity is usually above the 90 percentile until 4 to 6 years of age and is normal thereafter. Affected children reach an average height of 2.5 standard deviation score (SDS) at or after puberty, with weights between the 75 and 95 percentiles. In 1989,

W. G. Sippell and associates reported adult heights exceeding parental heights by 13.2 cm (5.2 inches) on the average. One girl with a predicted adult height of 190 cm (6 feet 3 inches) was treated with a high dose of estrogens.

FREQUENCY

BWS is not rare. Several hundred cases have been reported. The prevalence is not known but is estimated to be approximately 1 in 14,000 persons. Approximately 85% of the cases are sporadic and 15% are inherited. There have been many families reported to have members affected in two or three generations, transmitted vertically, suggesting autosomal-dominant inheritance with incomplete penetrance.

ETIOLOGY

BWS is a complex and heterogeneous genetic disorder resulting from alterations of the expression of imprinted genes, involved in growth and cell cycle control, in the 11p15 chromosomal region. In the epigenetic phenomenon of imprinting, the DNA of the two alleles of a gene is differentially modified in such a manner that only one parental allele, parent specific for each gene, is normally expressed.

The 11p15 region harbors a cluster of imprinted genes (Fig. 2). IGF-2, insulin, and LIT1 normally show paternal expression, whereas H19, p57^{KIP2}, and KvLQT1, except for some tissue variation, are predominantly maternally expressed. H19 is closely linked to IGF-2, and p57^{KIP2} is separated by 700 kb from the IGF-2. The KvLQT1 gene spans much of the interval between p57^{KIP2} and IGF-2.

Based on many studies, it would appear that the phenotype of BWS and tumor predisposition are caused by the balance between increased expression of paternally expressed growth-promoting genes and loss of maternally expressed growth-inhibiting genes. Despite the overwhelming number of studies, the etiology remains elusive.

The loss of imprinting of the maternal IGF-2 gene, with resulting biallelic expression, is one of the most common molecular defects found in patients with BWS without chromosomal abnormalities (Table II). In a proportion of these patients, loss of maternal IGF-2 imprinting is associated with complete suppression of maternal H19 expression. However, in a significant number of cases, IGF-2 shows biallelic expression, even though H19 expression and methylation are normal. This indicates that there

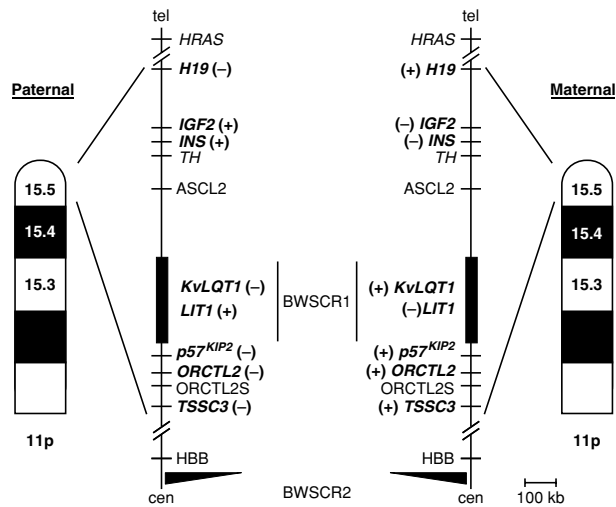

Figure 2 Map of the chromosome 11p15.5 region showing a cluster of imprinted genes, indicated in bold. (+) indicates genes that are expressed, and (–) indicates genes that are imprinted. BWSCR1 and BWSCR2 indicate Beckwith–Wiedemann syndrome critical translocation regions. See text for explanation. Modified from R. Weksberg and C. Shuman (2001).

must be an alternative H19-independent pathway by which allele-specific IGF-2 expression is established or maintained. Overexpression of IGF-2 can also result from paternal uniparental disomy (UPD) of chromosome 11 or from duplications of the paternal 11p15 region associated with trisomy of 11p. In each case, UPD appears to result from a postzygotic event resulting in mosaicism for segmental paternal isodisomy containing the 11p15 region.

IGF-2 is an important growth factor for fetal growth. Transgenic experiments in mice have shown

that loss of the functional paternal IGF-2 allele results in 40% prenatal growth retardation, overexpression of IGF-2 can result in most of the symptoms of BWS, and targeted disruption of IGF-2 receptor (which is involved in degradation of IGF-2) results in overgrowth. It is of interest that overgrowth in BWS is in organs rich in IGF-2. In addition, IGF-2 imprinting is lost in sporadic Wilms' tumors, suggesting that IGF-2 overexpression is responsible for overgrowth and development of tumors. Biallelic expression of IGF-2, however, would not appear to be sufficient for tumor development because many patients with BWS do not develop embryonal tumors.

The contribution or role of the loss of function of maternally expressed genes that act as growth or tumor suppressors (e.g., H19, $p57^{KIP2}$, KvLQT1) by methylation defects, mutations, translocations, or inversions is difficult to assess. Alterations in any of these suppressors could cause BWS, and the phenotypic spectrum might depend on which maternally expressed gene is mutated.

In a 2002 study of 92 patients, there was a significantly higher frequency of altered DNA methylation of H19 in patients with cancer and of LIT1 in patients with midline abdominal wall defects and macrosomia. Paternal UPD of 11p15 was associated with hemihypertrophy, cancer, and hypoglycemia.

H19 is closely linked to IGF-2 and encodes for a biologically active, nontranscribed mRNA that may function as a tumor suppressor. Biallelic expression of IGF-2, by disruption of maternal IGF-2 imprinting, has been shown in mice as a result of a maternally inherited targeted deletion of the H19 gene. Also, biallelic expression of IGF-2 associated with methylation

Table II Chromosome 11p15.5 Region: Genetic Abnormalities Observed in Beckwith–Wiedemann Syndrome—Allelic Expression of IGF-2 Gene

| | Father | Mother | Frequency (percentage) | Inheritance/Sporadic |
|--|---------------|----------------------|------------------------|-----------------------|
| Normally | Active | Inactive (imprinted) | | |
| Beckwith–Wiedemann syndrome | | | | |
| Paternal disomy (UPD) | Active-Active | — | 10–20 | Sporadic |
| Paternal 11p15 duplications (trisomy of 11p) | Active-Active | Inactive | <1 | Sporadic or inherited |
| Normal karyotype IGF-2 loss of imprinting | Active | Active | ~50 | Unknown |
| Maternal H19 methylation | Active | Active | 5–10 | Unknown |
| Maternal 11p15 translocations, inversions, and KvLQT1 disruption | Active | Active | <1 | Inherited or sporadic |
| Maternal $p57^{KIP2}$ mutations | Active | ? | 5–20 | Usually inherited |
| Maternal LIT1 loss of imprinting | Active | Usually inactive | ~50 | Unknown |

Note. See text for explanation.

and silencing of the maternal, normally expressed H19 gene has been found in BWS and Wilms' tumors, suggesting that H19 might directly regulate IGF-2 expression. Some studies, however, have demonstrated uncoupled expression of IGF-2 and H19 in patients with BWS and some tumors, suggesting that biallelic expression of IGF-2 can be independent of H19 control.

p57^{KIP2} (CDKN1C) is a member of a family of cyclin-dependent kinase (cdk) inhibitors that negatively regulates cell proliferation and is potentially a negative regulator of fetal growth and a tumor suppressor. Only the maternal allele is expressed in both mice and humans. Mice with targeted disruption of the p57^{KIP2} have a number of abnormalities (omphalocele, renal medullary dysplasia, and adrenal cortical hyperplasia and cytomegaly) that overlap with, but do not completely resemble, BWS.

In a study of 9 patients with BWS, two were heterozygous for mutations in the p57^{KIP2} gene. In one of the cases, the missense mutation was transmitted from the proband's carrier mother. The expression of the maternal allele was mutant, and the repressed paternal allele was normal. In an analysis of 40 unrelated BWS patients, only 5% showed mutations of p57^{KIP2}. In 1 case, the mutation was transmitted to the proband's mother, who was also affected, from the maternal grandfather. A 1997 study found a maternally transmitted coding mutation in the cdk inhibitor domain of the KIP2 gene in one of five cases of BWS. No somatic mutations in KIP2 were found in 12 primary Wilms' tumors, suggesting that KIP2 is a BWS gene but is not a Wilms' tumor suppressor. The manner by which loss of p57^{KIP2} function results in the BWS phenotype is not yet clearly understood.

The KvLQT1 (KCNQ1) gene spans much of the interval between P57 and IGF-2 and is paternally imprinted and maternally expressed in most tissues, with the exception of the heart. Each of the break points in chromosomal rearrangements (inversions or translocations) in BWS disrupts this gene. The KvLQT1 gene product forms part of a potassium channel, and mutations in the gene are known to cause at least two cardiac arrhythmia syndromes. Patients with BWS with disruption of this gene have biallelic IGF-2 expression. It has been proposed that this gene may serve as an imprinting center for the 11p15 region and that disruption may affect transcription and DNA replication of distant genes such as IGF-2.

LIT1 (KCNQ1-AS) is an antisense transcript that is normally expressed from the paternal allele and that lies within the KvLQT1 (KCNQ1) gene. Loss of

imprinting of the maternal LIT1 gene with biallelic expression of LIT1 is the most frequent abnormality in BWS, accounting for 40 to 50% of patients, and is not linked to loss of imprinting of IGF-2.

TSSC3 and ORCTL2 were recently identified imprinted genes that show preferential maternal expression. Neither of them has yet been implicated with BWS.

Despite the overwhelming number of observations, the etiology of BWS remains elusive.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The BWS diagnosis is based on the clinical manifestations that have been described. Some of the phenotypic changes are somewhat similar to those of infants of diabetic mothers. Other disorders to consider would be hypothyroidism (because the enlarged tongue) and glycogen storage disease type I (because of the hepatomegaly and hypoglycemia), but they should be easy to distinguish.

Reports have indicated that, in many cases, BWS may be milder than one would expect from other published reports, and some cases may have only one or a few signs of BWS. The hemihypertrophy could be a good diagnostic clue in detecting the syndrome in relatives of affected patients.

Hemihypertrophy is associated with an increased tumor rate of 3% and a spectrum of tumors similar to those seen in BWS. Hemihypertrophy may represent BWS with minimal clinical findings, but it is seen with other syndromes such as Proteus syndrome and neurofibromatosis.

Patients with BWS may be difficult to distinguish from patients with Simpson–Golabi–Behmel syndrome (SGBS). Patients with SGBS have some features similar to those with BWS such as omphalocele, macrosomia at birth, visceromegaly, ear lobe creases, renal dysplasia, neonatal hypoglycemia, and a risk of embryonal tumor, including Wilms' tumor. Distinguished characteristics of SGBS are a cleft lip and palate, cardiac defects, polydactyly, vertebral and rib anomalies, hypoplastic or absent index fingernails, and X-linked recessive transmission.

Perlman syndrome is characterized by macrosomia, nephromegaly, neonatal hypoglycemia, mental retardation, and a high incidence of bilateral Wilms' tumor, usually occurring during the first year of life. It is not known whether this syndrome represents a separate entity or is actually a subtype of BWS with autosomal recessive inheritance.

NATURAL HISTORY AND PROGNOSIS

The main problems with BWS are those encountered during the neonatal period with apnea, cyanosis, respiratory and feeding difficulties, polycythemia, and (particularly) hypoglycemia. The clinical findings tend to become less distinctive with age. The visceromegaly regresses, and there is a tendency to attain normal facial features. The other risk is the development of malignant neoplasms in 7 to 10% of patients.

A number of patients die during the neonatal period. Affected individuals who survive infancy generally are healthy and usually mentally normal. Some may have mild to moderate mental deficiency that may be related to severe hypoglycemia during the first few months.

Nephromegaly during infancy and early childhood is a risk factor for the development of Wilms' tumor in BWS. Infants with nephromegaly should be considered at greatest risk for Wilms' tumor, and screening may be best targeted at this group.

Fully 85% of the cases are sporadic and 15% could be inherited. Patients with mutations in the maternal 11p15 region are at risk for inheritance. Patients with maternal p57^{KIP2} mutations and 11p15 translocations and inversions have a risk as high as 50%. Patients with paternal UPD have a low risk because the UPD is believed to arrive from a postzygotic somatic recombination event.

TREATMENT

Detection and treatment of hypoglycemia are most important for surviving and for preventing neurological damage. The excessive rate of growth for the first few years and the tall stature during childhood and adolescence require no treatment unless an excessive adult height is predicted, particularly in females.

Muscle hypertrophy characteristic of macroglossia results in malocclusion, and surgical reduction of the tongue during early life should be considered.

Regular follow-up for possible tumor development is needed, and routine ultrasonography of the kidneys is mandatory, because Wilms' tumor and adrenocortical carcinoma are the most frequent neoplasms.

Abdominal ultrasound every 3 months to the age of 6 years is recommended. A baseline abdominal magnetic resonance imaging study during the first year of life is also advisable. For early detection of hepatoblastoma, alpha-feto protein testing should be done periodically up to 6 years of age.

Benign Prostatic Hyperplasia (BPH)

Jaspreet S. Sandhu and Alexis E. Te

Weill Medical College of Cornell University, Cornell, New York, United States

Glossary

cystoscopy An endoscopic procedure used to evaluate the urethra, prostate (in males), and bladder. It is often used to rule out bladder cancer or other bladder/urethral pathology as a cause of hematuria or irritative voiding symptoms.

lower urinary tract symptoms A symptom complex caused by lower urinary tract dysfunction consisting of obstructive and irritative symptoms. It is associated with, but not pathognomonic of, benign prostatic hyperplasia.

prostate-specific antigen A normal product of the prostate that is secreted via prostatic ducts during semen emission. Under pathologic conditions, such as prostate cancer, infection, or benign prostatic hyperplasia, it may be elevated in serum.

transition zone The part of the prostate most likely to be pathologically enlarged due to benign prostatic hyperplasia. It includes the periurethral part of the prostate and is therefore involved in outflow resistance to the bladder.

transrectal ultrasound An imaging modality used to evaluate the size and structure of the prostate. It is usually used to help guide prostate biopsies.

urodynamics A test that measures pressure within the bladder at different volumes and flow rates during voiding. It is useful in complex voiding dysfunction cases to determine the etiology of dysfunction.

Benign prostatic hyperplasia (BPH) is a pathologic process that consists of androgen-dependent increases in the number of epithelial and stromal cells in the periurethral area of the prostate. BPH contributes to, but is not the sole cause of, lower urinary tract symptoms in aging men.

INTRODUCTION

BPH is a pathologic process characterized by an increase in the number of cells in the periurethral area

of the prostate. This process contributes to the development of lower urinary tract symptoms (LUTS) in aging men that were classically described as “prostatism.” LUTS are symptoms arising from lower urinary tract dysfunction that are further subdivided into obstructive (urinary hesitancy, straining, weak stream, terminal dribbling, prolonged voiding, incomplete emptying) and irritative (urinary frequency, urgency, nocturia, urge incontinence, small voided volumes) symptoms. BPH is a histologic diagnosis that is but one cause of LUTS. Autopsy series have shown that no men less than 30 years of age have the disease, whereas more than 50% of men greater than 60 years of age have histologic evidence of the disease. This prevalence reaches almost 100% in the ninth decade. BPH is, as its name implies, a benign process, with symptoms being the most common cause for treatment. However, untreated BPH can lead to severe complications including urinary retention, obstructive uropathy, azotemia, intractable hematuria, and urinary tract infections.

PATHOPHYSIOLOGY

Etiology

The etiology of BPH is multifactorial and not definitively established. BPH is an overgrowth of the periurethral area (transition zone) of the prostate that is dependent mainly on androgens, particularly dihydrotestosterone (DHT). 5 α -Reductase is responsible for the conversion of testosterone to DHT, which has five times more potency for its receptor than testosterone. DHT binds to androgen receptor and the complex is primarily responsible for the stimulation of growth factors that influence prostate cell division and growth. DHT is responsible for maintaining the balance between cell proliferation and cell death and therefore prostate growth. Elevated levels of DHT, along with hypothesized hormonal imbalances, result in BPH. A lack of DHT results in a lack of prostate growth and resultant BPH or prostate cancer as

demonstrated in a cohort of patients with type 2 5 α -reductase deficiency reported by Imperato-McGinley.

Natural History

The natural history of BPH is progression in the majority of patients. Progression results in increased prostate size, worsening of symptoms, deterioration in urinary flow rate, increased risk of acute urinary retention, and increased risk of surgery for BPH. Some patients do not progress, although in longitudinal studies the risk of BPH-related surgery and of acute urinary retention increases as patients age. Determining which patients will progress continues to be an area of intense study.

DIAGNOSIS

BPH is a difficult diagnosis because of the many causes of LUTS, including bladder dysfunction, bladder cancer, urethral stricture disease, and prostatitis. A strategy for the management of BPH is to follow objective signs after an initial evaluation and intervene when symptoms become moderate to severe or when other clinical indications apply.

Initial Evaluation

Initial evaluation for men presenting with LUTS consists of a detailed history and physical exam, including a digital rectal exam and a neurological exam. Oral intake history, including intake amounts of caffeine and alcohol, should be obtained. Medications affecting urinary volume, such as diuretics and stool-bulking agents, and those affecting voiding, such as antihistamines and decongestants, should be noted. Systemic diseases, such as diabetes, congestive heart failure, and neurological or neoplastic diseases, should also be noted.

Objective Signs

Symptoms

LUTS symptoms are well known. The American Urological Association (AUA) has created a validated, reproducible index that is designed to determine disease severity and determine response to therapy. This 35-point scale has questions about both obstructive and irritative symptoms. An AUA symptom score of 0–7 is considered mild, 8–19 is moderate, and 20–35 is severe.

Urodynamic Parameters

Formal urodynamic testing, including bladder volume, detrusor pressure, and urinary flow, is the gold standard for the diagnosis of LUTS associated with obstruction. However, there is no clear consensus on the role of urodynamics in the routine evaluation of men with BPH. There is a clear role for urodynamics in complex cases. Maximum flow rate using a simple uroflowmeter is an easy parameter to use for following men with BPH for progression. Postvoid residual urine (PVR) is also an easy parameter to document; however, there are no guidelines for its use and there is no proven correlation between PVR and BPH.

Transrectal Ultrasound

Transrectal ultrasound (TRUS) is an important imaging modality, particularly as a guide for directed biopsies in suspected prostate cancer cases. TRUS gives an accurate evaluation of prostate size and might be useful in determining transition zone size; however, prostate volume is not diagnostic of BPH. This imaging modality is most useful in BPH treatment selection, particularly for minimally invasive therapy.

Prostate-Specific Antigen

Prostate-specific antigen (PSA) is an important serum marker for prostate cancer. It is also elevated, albeit less so, in men with BPH. Although some evidence exists for the use of PSA in following men with BPH, PSA should be obtained in these men for the purpose of prostate cancer screening. This is because the population at risk for BPH is the same one at risk for prostate cancer.

Cystoscopy

Although a large prostate is evident on cystoscopy, it is not routinely indicated in the diagnosis and management of BPH. Cystoscopy has a role in the evaluation of hematuria and prior to invasive therapy.

Indications for Treatment

Symptom relief is the most common reason for treatment of BPH. The most common form of therapy for mild to moderate symptoms is medical therapy. Surgical therapy is usually reserved for medical failures. There are, however, some clear indications for surgical therapy including frequent urinary tract infections, bladder stones, azotemia, urinary retention, and intractable hematuria.

TREATMENT

Medical Therapy

The initial management for BPH includes watchful waiting or medical therapy, especially in those patients with mild or moderate symptoms and no indications for surgical intervention. Medical therapy consists of phytotherapy, alpha-blocking agents, and 5 α -reductase inhibitors.

Phytotherapy consists of common plant extracts and herbs, such as *Serenoa repens* (saw palmetto) and *Pygeum africanum* (African plum). Although phytotherapy is touted as being effective, the active ingredients and therapeutic dosages are unknown for most extracts, the mechanism of action is poorly understood, and the safety profile has not been adequately studied with clinical trials. Therefore, phytotherapy is not often prescribed by urologists or other medical professionals.

Alpha-blocking agents are the first line of prescribed medical therapy. Their efficacy has been documented by multiple clinical trials and they have a low risk of morbidity. These agents reduce symptoms equally well in obstructed and nonobstructed patients and they generally increase flow rate by approximately 2–3 ml/s compared to placebo. Nonselective alpha-blocking agents are particularly useful in hypertensive patients because of their effect on lowering blood pressure. Common alpha-blockers include phenoxybenzamine, prazosin, terazosin, doxazosin, and alfuzosin. The alpha-blocker tamsulosin has the advantage of being prostate-selective and not needing titration.

5 α -Reductase inhibitors, such as finasteride and dutasteride, have been shown to prevent the progression of BPH over time. They decrease the prostate volume by approximately 20% through reduction of DHT stimulation. These agents have a slower onset of action and should be used only in patients with large prostates (>40 g). Finasteride has been studied extensively and has shown mild decreases in symptoms and mild increases in flow rate, along with a reduction in prostate volume. The risk of BPH-related surgery and the risk of acute urinary retention were reduced by 55 and 57%, respectively, in those patients on this drug. Studies with dutasteride produced similar results. Combination therapy with alpha-blocking agents and 5 α -reductase inhibitors has shown greater efficacy than either agent alone in patients with large prostates.

Minimally Invasive Surgical Therapy

Minimally invasive surgical therapy consists of office-based therapies, such as transurethral needle ablation of the prostate, transurethral microwave therapy, or

interstitial laser coagulation. Each of these therapies can be performed with minimal anesthesia and has shown significant improvement in symptom scores and flow rates. However, the durability of these therapies is still being assessed and each has a significant retreatment rate (approximately 15–20% in most series). Minimally invasive surgical therapies are a good option for those patients who are poor surgical candidates or who are concerned about surgical morbidities.

Transurethral Surgery

Transurethral resection of the prostate (TURP) has traditionally been the gold standard for comparison of treatments for BPH. TURP is associated with durable significant relief of symptoms and increase in flow rates with excellent 10-year results including low reoperation rates. TURP is associated with a low morbidity rate, but the morbidities that do occur are significant and include dilutional hyponatremia and excessive blood loss requiring transfusions or reoperation. Variations of TURP have gained prominence due to the decreased amount of anesthesia required and the decreased rates of complications.

Transurethral vaporization of the prostate is associated with less blood loss than TURP with similar efficacy. Transurethral incision of the prostate, useful for select patients with small-volume prostates, is associated with decreased anesthesia requirements and less operative time. Transurethral laser prostatectomy, performed by using the neodymium, holmium, or potassium-titanyl-phosphate lasers, has an efficacy similar to that of TURP with decreased morbidity and decreased anesthesia requirements. Long-term efficacy data on these newer transurethral techniques have not yet been reported.

Open Surgery

Open prostatectomy remains an option for those patients with large-volume prostates (>80 g) or those with concomitant bladder pathology, such as bladder stones or diverticula. Open prostatectomy has had excellent durable results with approximately 98% of patients experiencing relief of symptoms and increases in flow rate. However, it is associated with the morbidities and complications expected for pelvic surgery, such as pulmonary embolus, bleeding, and infection, as well as incontinence and impotence.

SUMMARY

BPH, an overgrowth of the periurethral transition zone of the prostate, is very prevalent in elderly men.

It is associated with significant symptoms and morbidity. Although the definitive diagnosis of BPH is not easy to make, there exist validated tools to help clinicians with the diagnosis. Most cases of BPH are progressive and dependent on androgens. Effective therapies for the management of BPH-related symptoms and complications, including medical and surgical options, exist and continue to evolve.

Lance J. Kriegsfeld

Columbia University, New York, New York, United States

Glossary

biological rhythm Any recurrent endogenous cycle (behavioral or physiological) that persists in constant conditions in the absence of geophysical or environmental temporal cues.

circadian rhythm Endogenous rhythm that is approximately 1 day in length.

circannual rhythm Endogenous rhythm that is approximately 1 year in length.

entrainment Synchronization of an internal endogenous rhythm by a recurring external time cue such as the day–night cycle.

free running Expression of a biological rhythm in the absence of any environmental temporal cues.

photoperiod Amount of daylight in a given day; day length.

seasonal rhythm Yearly rhythm that is exogenously regulated by geophysical cues.

suprachiasmatic nucleus The primary “biological clock” located in the anterior hypothalamus of the brain that coordinates rhythmic and photoperiodic information via inputs and outputs of the nervous and endocrine systems.

A biological rhythm is any recurrent endogenous cycle (behavioral or physiological) that persists in the absence of geophysical or environmental temporal cues but is normally synchronized (entrained) with a period that approximates that of the geophysical cycle.

INTRODUCTION

As most people have experienced throughout their lifetimes, timing is everything. The ability to modify one’s behavior or physiology on a regular basis, be it daily, monthly, or yearly, is arguably one of the most

adaptive responses of life and occurs in virtually all organisms, ranging from single-celled algae to complex vertebrates, including humans. But why have biological rhythms evolved, and what functions do they serve? All physiological systems require proper coordination and synchronization with one another to ensure that a wide variety of rhythmic events occur during an optimal time of the day or year. For example, for the body to prepare appropriately to digest a meal, numerous physiological processes must occur in anticipation of eating. Many species must also predict the time of year to coordinate breeding activities. These daily and yearly changes require critical coordination among numerous internal processes necessary to maintain homeostasis. Furthermore, for biological rhythms in behavior and physiology to be coordinated with the appropriate time, these rhythms need to be synchronized to external time cues within the environment. The means by which intrinsic rhythms are generated by a clock in the brain, and how these rhythms are synchronized to local time, is the primary focus of this article.

HISTORICAL OVERVIEW

The importance of coordinated timing of biological events has been known since the dawn of civilization. For example, written records dating back to Alexander the Great in the 4th century B.C. noted the daily movements of flower petals. However, the study of biological timing as an empirical science is in its relative infancy. Chronobiology, the scientific study of biological rhythms, formally began in 1729 with a brief communication by Jean Jacques d’Ortous de Mairan, who noted that the daily leaf movements of a heliotropic plant persisted in complete darkness and in the absence of any other geophysical cues. However, it was not until the 1950s, based on the pioneering work of noted “clock watchers” Colin

Pittendrigh, Serge Daan, and Jergen Aschoff, that a firm scientific understanding of the characteristics and formal properties of biological rhythms began to take shape.

TYPES OF RHYTHMS

Since these early discoveries, a wide variety of biological rhythms have been identified in both vertebrate and invertebrate species, and these rhythms are typically categorized by the length of a single cycle. For example, circadian rhythms are daily rhythms that are approximately 24 h and mimic the geophysical cycles of day and night. The alternating pattern of activity followed by periods of rest (sleep) that are observed in most vertebrate species is the most salient example of a circadian rhythm. However, biological rhythms need not be 24 h in length. Ultradian rhythms are rhythms that occur more frequently than 24 h. For example, many hormones (e.g., cortisol) and enzymatic reactions display rhythms only a few hours in length. In contrast, infradian rhythms are rhythms longer than 24 h but shorter than 1 year. Cycles of reproductive endocrine activity, such as menstrual cycles in humans and estrous cycles in nonhuman animals, are examples of this kind of rhythm. Finally, some species display circannual rhythms, with cycle lengths of approximately 1 year that persist in the absence of environmental influences. Circannual rhythms commonly involve yearly cycles in breeding activity and reproductive endocrinology. For example, some species of birds and rodents display yearly fluctuations in gonadal mass and changes in reproductive hormones (e.g., testosterone, estrogen), and these fluctuations persist when the animals are maintained within constant conditions of the laboratory. Closely related to circannual rhythms are seasonal rhythms, which also approximate 1 year. However, unlike true circannual rhythms, seasonal rhythms are generated in response to environmental cues and do not persist in the absence of these cues.

Although many kinds of biological rhythms have been identified, the majority of research within the field of chronobiology has focused on circadian and circannual/seasonal rhythms. As will be seen later, the neuroendocrine mechanisms responsible for generating circadian rhythms are also intimately involved in generating seasonal rhythms. Because the circadian clock is necessary for seasonal rhythms, the discussion that follows outlines the means by which circadian rhythms are generated and maintained and then the mechanisms by which seasonal rhythms are generated. The

article concludes with a discussion of various endocrine disorders that have been tied to abnormalities in circadian and circannual/seasonal rhythms.

CIRCADIAN RHYTHMS

Circadian comes from the Latin *circa* (meaning “around”) and *diem* (meaning “a day”). Virtually all measurable physiological and behavioral responses display circadian rhythms. There are circadian rhythms in everything from heart rate and liver metabolism to attention and speed of decision making and reaction time. It is now known that all of these rhythms are controlled by a bilateral nucleus at the base of the brain. This brain region was identified in 1972 as an area of the hypothalamus called the suprachiasmatic nucleus (SCN). Lesions that destroy the SCN result in an abolition of all rhythmic processes from daily rhythms in hormone secretion to the sleep–wake cycle. As will be seen later, SCN lesions can also abolish seasonal rhythms.

Further evidence that the SCN is the circadian clock comes from studies showing that rhythmicity can be restored in SCN-lesioned animals by transplanting SCN tissue from a donor animal into the brains of animals with their own SCN destroyed. This procedure restores circadian rhythms in these formerly arrhythmic animals, demonstrating that one can literally remove the circadian clock from one animal and provide it to another animal whose own clock is not functioning. Importantly, the rhythm is restored with the period of the donor, demonstrating that the restoration of circadian behavior is a property of the transplant rather than restoring function in the host animal’s brain. Finally, the SCN can be removed from an animal and maintained in a culture dish, and it will continue to show circadian rhythms in neural firing rate. These studies are important because they show that circadian rhythms are contained within the SCN and are not simply being driven by temporal input to this brain region.

Knowledge of where the primary biological clock is located within the brain set the stage for investigations of the SCN at the cellular level to determine what makes the clock “tick.” To draw an analogy between the SCN and a watch, if one opened the back of a watch, a large number of gears could be seen. One might know that the gears are all working together to allow the watch to function properly. However, to fully understand the watch’s internal mechanism, one would have to carefully remove one gear at a time to see how it is connected to the next gear, and so on,

Figure 1 Basic molecular model of the intracellular circadian feedback loop. The process begins in the cell nucleus when the CLOCK and BMAL proteins dimerize to drive the transcription of the *per* and *cry* genes. In turn, *per* and *cry* are translocated to the cytoplasm and translated into their respective proteins. Throughout the day, the PER and CRY proteins build within the cell cytoplasm. When levels of PER and CRY reach a threshold, they form a heterodimer, feed back to the cell nucleus, and negatively regulate CLOCK:BMAL-mediated transcription of their own genes. This feedback loop takes approximately 24 h, thereby leading to an intracellular circadian rhythm.

until all of the gears were taken out. In much the same way, one can study individual cells within the SCN to see how all of the cells (approximately 10,000) in a unilateral SCN work together to keep time. Unlike the gears of a watch, individual cells within the SCN are capable of showing their own independent circadian rhythms. When one begins to look at other cells, one can see that they too show rhythms, but each cell has its own intrinsic period. So, like the question of how all of the gears of a watch work together to keep accurate time, one question of interest to circadian biologists is how all the cells of the SCN work together to produce a rhythm of 24 h.

The knowledge that individual cells of the SCN can produce a rhythm on their own suggested that the complete machinery for producing a rhythm is contained within each cell of the SCN. This information allowed researchers to begin investigating the cellular mechanisms responsible for rhythm generation. Over the past 10 years or so, enormous progress has been made uncovering the cellular and molecular

Figure 2 Neural pathway by which environmental light reaches the suprachiasmatic nucleus (SCN) and pineal gland to regulate circadian entrainment and regulation of melatonin secretion. Light enters the retina and is transmitted to the SCN located directly above the optic chiasm (OC). The SCN then reaches the pineal through a multisynaptic pathway, first synapsing in the paraventricular nucleus of the hypothalamus (PVN). From here, fibers proceed through the medial forebrain bundle to the spinal cord. At this point, fibers actually exit the central nervous system and synapse onto the superior cervical ganglion (SCG) of the sympathetic nervous system. From here, sympathetic nerve fibers terminate in the pineal, where they regulate melatonin secretion.

mechanisms responsible for the generation of circadian rhythms within a cell. It is now known that these rhythms are produced by a feedback loop within the cell that takes approximately 24 h to complete. The process begins in the cell's nucleus when two proteins called CLOCK and BMAL bind to one another and drive the transcription of messenger RNA (mRNA) of the *period* (*per*) and *cryptochrome* (*cry*) genes. The mRNA for these genes then migrates to the cytoplasm of the cell and is translated into PER and CRY proteins. Over the course of the day, these proteins build up within the cytoplasm, and when they reach high enough levels, they bind to one another (PER:CRY). These newly formed PER:CRY dimers then feed back to the nucleus, where they bind to the CLOCK:BMAL protein complex to turn off their own production. Although numerous other clock genes and their protein products have been identified, this regulatory loop provides the core molecular clock mechanism in mammals (Fig. 1).

Interestingly, over the past several years, the same clock genes (e.g., *clock*, *bmal*, *per*, *cry*) that are found in cells of the SCN have been identified in other brain areas as well as in many other peripheral tissues in the body. However, these “clocks” in other parts of the body are different from those found in the SCN. If these clocks are removed from the body, their endogenous rhythms will cycle for only a few days before dampening, whereas those present in the SCN will continue to cycle indefinitely. These findings suggest that the SCN is the master clock that is required to communicate with other subordinate

Figure 3 Typical pattern of seasonal/photoperiodic changes in reproductive physiology in a long-day breeding rodent. Reproductive activity is maximal during the long days of summer, but reproductive regression occurs as the days get shorter during the autumn. The reproductive system maintains a period of quiescence (inactivity) during the short days of winter. As the day length increases during the spring, reproductive activation (recrudescence) occurs anew.

clocks so that they can continue to keep time. There are many reasons why these subordinate clocks might be needed in tissues other than the SCN. These clocks may be necessary for tissues to anticipate upstream signals stimulating production of specific factors. For example, the cellular machinery necessary to produce a hormone in response to stimulation could require hours of preparation within the cell. However, if the tissue has its own clock, it can turn on this machinery in advance of stimulation and be prepared to produce the hormone much faster.

The preceding findings summarize what is known about the physiological functioning of the SCN. However, for a clock to be adaptive for an organism, the clock needs to coordinate all of these rhythms with local time in the environment. In mammals, this synchronization is accomplished via a direct projection, the retinohypothalamic tract (RHT), from the eye to the SCN (Fig. 2). Unlike rod and cone photoreceptors in the retina that are responsible for black/white and color vision, respectively, the photoreceptors that communicate with the SCN are ganglion cells that are directly responsive to light because they contain a photopigment called melanopsin. Essentially, these melanopsin-containing ganglion cells project to the SCN to inform the SCN of the time in the environment. Because the SCN is synchronized (entrained) to local time, it can prepare the brain and body well in advance of the time that rhythmic processes need to occur. For example,

the SCN can stimulate the pancreas to produce insulin before one eats lunch. In this way, one's body can be prepared to digest the food before one even eats.

Now that the intrinsic rhythm within the SCN is synchronized to local time, this “time-stamped” rhythmic information needs to be communicated all over the brain and body to coordinate the timing of thousands of physiological and biochemical processes. For example, the SCN needs to communicate with brain areas involved in sleep to coordinate sleep with nighttime. The SCN accomplishes this communication using both neural and humoral signals. Researchers can determine neural communication from the SCN relatively easily by using chemicals to trace the “wiring” from the SCN to its targets. Through the use of tracing techniques, it is now known that the SCN communicates neurally to a vast array of brain targets as well as to targets in the periphery such as the liver and heart. It is also known that the SCN regulates some rhythmic functions through humoral signals. For example, if the fibers exiting the SCN in an animal are surgically cut, some circadian rhythms persist. However, because diffusible signals can essentially travel anywhere in the brain and body, the means by which these neurochemicals communicate is much more difficult to investigate experimentally. To date, two neurochemicals found in neurons of the SCN, transforming growth factor- α (TGF- α) and prokineticin-2, have been implicated

as diffusible factors that may be used by the SCN to control locomotor behavior in rodents. However, determining where specifically in the brain these chemicals act to regulate locomotor behavior requires further investigation.

CIRCANNUAL/SEASONAL RHYTHMS

Just as animals experience large fluctuations in physiology and behavior throughout a single day, many organisms experience pronounced changes across the seasons of the year. Recall that circannual rhythms are endogenously driven rhythms that approximate 1 year. Such rhythms have been demonstrated in several birds and a few mammalian species (e.g., ground squirrels, sheep). In contrast to true circannual rhythms, the majority of species display seasonal rhythms in behavior and physiology in response to predictable changes in the environment such as day length. Although seasonal rhythms are not endogenously regulated, they still produce pronounced changes in physiology and behavior throughout the year. Much of the research conducted in the area of seasonality has focused on seasonal changes in breeding and reproductive endocrinology.

Many animals are faced with potentially large seasonal fluctuations in environmental conditions, including changes in day length, ambient temperature, rainfall, humidity, food availability, and social interactions. These potentially large fluctuations can dramatically affect the world in which an animal lives. For many animals, the energy required for thermoregulation is high during the winter, a time when energy availability is typically low. Because of this “energetic bottleneck,” many animals have evolved specific physiological and behavioral adaptations to cope with winter conditions. For example, some animals may migrate or reduce activity (e.g., hibernate, enter torpor) when food availability is low and energetic demands are high. Other animals restrict breeding to specific periods of the year (e.g., April–August) (Fig. 3) because breeding at inappropriate times can potentially compromise the survival of both the parents and their offspring. But how does an animal determine the optimal time of year?

As discussed previously, a wide variety of proximate environmental factors can be used in the timing of seasonal breeding, and all of these factors fluctuate seasonally. However, the majority of scientific studies suggest that animals rely mainly on day length as a primary cue with which to estimate the time of year. Most environmental cues other than day length vary

in relatively unpredictable ways throughout the year. For example, although winter is usually associated with lower ambient temperatures compared with summer in the Northern Hemisphere, an unseasonably warm “Indian summer” may occur during the autumn/winter or a cold wave may roll through during the summer. Furthermore, food and water may be available to animals only sporadically throughout the year. In contrast to these seasonal factors, day length information is relatively “noise free” and can be used to coordinate energetically expensive activities (e.g., breeding) to coincide with adequate energy availability. By relying on just two pieces of information, the absolute period of daylight and the direction of change across time, animals can determine the precise time of year. For many species, breeding occurs during the long days of summer, whereas short “winter-like” days result in complete regression of the reproductive system as well as in changes in body weight and fur thickness. Interestingly, some species (e.g., sheep) actually breed during the winter. As would be predicted, the effects of day length on reproductive physiology and behavior are generally reversed in these species because their lengthy gestation time allows for birth during summer. The ability of an animal to use seasonal changes in day length to coordinate physiological and behavioral adaptations is commonly referred to as photoperiodic time measurement (PTM).

How is day length information interpreted physiologically in mammals? As with circadian rhythms, seasonal changes in day length are detected by the photosensitive retinal ganglion cells within the eye that send projections to the SCN (Fig. 2), suggesting that seasonal rhythms are regulated to some extent by the circadian system. In fact, abnormalities within the circadian system that “speed up” the circadian clock also appear to accelerate the rates of seasonal responses. The SCN projects multisynaptically to the pineal gland, where the photoperiodic signal is transduced into an endocrine message. Specifically, neural activation of the pineal gland results in the production of the indolamine hormone melatonin. During prolonged periods of darkness (e.g., night), melatonin is synthesized and secreted in abundance, whereas exposure to daylight will immediately suppress the nocturnal synthesis of melatonin. The resulting rhythmic secretion of melatonin, which is intimately tuned to the presence or absence of environmental light, provides the biochemical “signal” for photoperiod in mammals. In other words, the long nights and short days characteristic of winter enable the pineal gland to synthesize melatonin for a longer duration than that which occurs during the short nights and long

days of summer. The increased duration of melatonin release during short days, as compared with long days (i.e., winter vs summer), is responsible for inducing many seasonal changes, including gonadal regression and the cessation of breeding activities. Interestingly, surgical removal of the pineal gland (which removes the endogenous source of melatonin) prevents photoperiodic responses in nearly all mammalian species studied to date. Furthermore, it is the duration of nocturnal melatonin secretion, and not the total amount of melatonin, that appears to provide important photoperiodic information, with longer durations (e.g., > 12 h) associated with short days (i.e., winter) and shorter durations (e.g., < 8 h) associated with long days (i.e., summer).

Following secretion by the pineal during nighttime, melatonin travels to target tissues via the bloodstream, where it can bind to specific receptors located in either the brain or the periphery. Three types of melatonin receptors have been identified: Mel_{1a}, Mel_{1b}, and Mel_{1c}. Mel_{1a} and Mel_{1b} receptors have been identified in a wide range of species, whereas the Mel_{1c} receptor occurs exclusively in invertebrates. Furthermore, melatonin receptors have been identified in a wide variety of brain sites, including the SCN of the hypothalamus, the thalamus, and the pars tuberalis (a structure within the pituitary gland that is involved in regulating endocrine responses), suggesting that these brain sites may be important targets for the actions of melatonin. In addition, melatonin receptors have been isolated in several peripheral tissues, including the spleen, gonads, and adipose tissue.

The modulation of seasonal responses involves the effect of melatonin on brain mechanisms regulating peripheral responses as well as more direct actions of the hormone on organs and glands in the periphery. For example, in the context of seasonal breeding in rodents, melatonin can act on the hypothalamus to regulate the release of gonadotropin-releasing hormone (GnRH), a critical hormone in the endocrine axis regulating reproductive physiology and behavior. Thus, during short winter-like days, prolonged melatonin secretion can exert a negative influence on GnRH, resulting in reduced secretion of the reproductive hormones luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary. Decreases in LH and FSH, in turn, act at the level of the gonads (e.g., testes, ovaries) to decrease sex steroid hormones (e.g., testosterone, estrogen). Reductions in these hormones lead to regression of the reproductive system and cessation of reproductive behavior, typical of winter. As

the days grow longer as spring approaches, the brain becomes insensitive to long durations of melatonin. The inhibitory influence of this hormone on the reproductive endocrine axis and reproductive physiology and behavior is restored the following winter.

CLINICAL SIGNIFICANCE OF BIOLOGICAL RHYTHMS

As mentioned previously, circadian and seasonal rhythms are critical for organisms to survive in a changing environment. To maintain homeostasis, hundreds of physiological and biochemical processes need to be coordinated temporally with both the environment and relative to one another within the body. As a result, normal behavioral, physiological, and psychological functioning is dependent on the body's timing systems.

For example, one particular type of clinical depressive disorder, seasonal affective disorder (SAD), is of particular interest to chronobiologists. SAD is a cyclic illness characterized by recurrent episodes of winter depression alternating with periods of normal affect during the summer. Because of the seasonal component of SAD, it has been suggested that the shortened day lengths of winter may be part of the etiology of this disorder. In fact, exposure to bright lights during early morning or early evening results in marked improvements in clinical symptoms of SAD; therefore, bright light phototherapy has become the treatment of choice for SAD. Although the precise causes of SAD are still not known, abnormal phase shifts in one's circadian rhythms and abnormal patterns of melatonin secretion both have been suggested. Phototherapy may act to shorten the duration of melatonin secretion by suppressing its production early in the morning. Alternatively, phototherapy may act to change the phase of circadian rhythms in numerous physiological factors that may contribute to this seasonal depression.

In addition to seasonal changes in mood, many organisms, including humans, display pronounced seasonal fluctuations in disease and death. Although some of these are due to seasonal changes in the pathogen (e.g., viruses, bacteria), there are also potentially large fluctuations in one's immune system. These changes in immunity likely contribute to the seasonal fluctuations in disease, although researchers are just beginning to understand the physiological mechanisms underlying these changes. As with other seasonal adjustments, seasonal changes in immunity

are regulated by changes in day length. As animals use photoperiod to time changes in reproduction, this same signal can be used to organize the timing of immune alterations throughout the seasons. Because most human societies use artificial lighting yet still experience seasonal changes in disease and death, the mechanisms regulating seasonal changes in human immune function are likely different and require further study.

Bisphosphonates

H. Fleisch

University of Bern, Bern, Switzerland

Glossary

bisphosphonates Synthetic compounds characterized by a P–C–P group that are used in various industrial applications and more recently in clinical medicine to decrease bone resorption. The main indications are osteoporosis, tumor bone disease, and Paget's disease.

osteolytic tumor bone disease Condition in which tumors of various origins induce bone destruction, which can lead to fractures, pain, and hypercalcemia.

osteoporosis Disease characterized by a decrease in bone mass and a deterioration in its architecture and quality, resulting in a greater risk of fracture.

Paget's disease A localized and progressive disorder of bone, characterized by increased bone remodeling, bone hypertrophy, and abnormal bone structure.

Bisphosphonates, formerly called diphosphonates, are compounds characterized by two C–P bonds. If the two bonds are located on the same carbon atom, resulting in a P–C–P structure, the compounds are called geminal bisphosphonates; in clinical practice, these are referred to simply as bisphosphonates.

PRECLINICAL

Chemistry

Bisphosphonates are analogues of pyrophosphate that contain a carbon instead of an oxygen atom. The P–C–P structure allows a great number of possible variations, especially by changing the two lateral chains on the carbon atom. Many bisphosphonates have been investigated in animals and humans with respect to their effect on bone. Alendronate, clodronate, etidronate, ibandronate, pamidronate, risedronate, tiludronate, and zoledronate are commercially available in various countries for use in human bone disease (see Fig. 1).

Each bisphosphonate has its own physicochemical and biological characteristics. Thus, each compound

must be considered on its own, with respect to both its use and its toxicology. The P–C–P bonds of the bisphosphonates are stable to heat and most chemical reagents and are completely resistant to enzymatic hydrolysis. The bisphosphonates have a strong affinity for metal ions, including calcium.

Actions

Physicochemical Effects

The physicochemical effects of bisphosphonates are very similar to those of pyrophosphate. Thus, they inhibit the formation and aggregation and slow the dissolution of calcium phosphate crystals. These effects are related to the marked affinity of these compounds for solid-phase calcium phosphate, to the surface of which they bind strongly. This property is the basis for the use of these compounds as skeletal markers in nuclear medicine and the basis for their selective pharmacological effect on bone.

Inhibition of Bone Resorption

The main effect of the pharmacologically active bisphosphonates is to inhibit bone resorption.

In Vitro

Bisphosphonates block bone resorption induced by various means in cell and organ culture. In the former, they inhibit the formation of pits by isolated osteoclasts cultured on mineralized substrata. In organ culture, they decrease the destruction of bone in embryonic long bones and in neonatal calvaria. This inhibition is present whether or not resorption is stimulated. At present, results indicate that the effect of all the stimulators of bone resorption, such as parathyroid hormone, 1,25(OH)₂ vitamin D, and prostaglandins, as well as the products of tumor cells, has been inhibited by bisphosphonates.

In Intact Animals

In growing rats, bisphosphonates can block the degradation of both primary and secondary trabeculae,

thus arresting the modeling and remodeling of the metaphysis. The latter therefore becomes club-shaped and radiologically denser than normal. This effect is often used as an experimental assay to estimate the potency of new compounds (Schenk test). The inhibition of bone resorption by bisphosphonates has also been documented using ^{45}Ca kinetic studies and hydroxyproline excretion, as well as by other means. The effect occurs within 24–48 h and is therefore slower than that of calcitonin. The decrease in resorption is accompanied, at least in the growing animal, by a positive calcium balance and an increase in the mineral content of bone and in bone mass. This is possible because of an increase in intestinal calcium absorption. The increase is, however, smaller than expected because after a certain time, bone formation also decreases, so that the main effect of bisphosphonates is a reduction in bone turnover.

In Animals with Experimentally Induced Bone Resorption

Bisphosphonates can also prevent an experimentally induced increase in bone resorption. Thus, they impair resorption induced by many bone resorbing agents, such as parathyroid hormone, 1,25(OH) $_2$ vitamin D, and retinoids, the effect of the last agent having been used to develop a powerful and rapid screening assay for new compounds.

Bisphosphonates also inhibit bone loss induced by different procedures to induce experimental osteoporosis, such as immobilization, ovariectomy, administration of corticosteroids, or lactation combined with a low-calcium diet. When not given in excess, bisphosphonates also have a positive effect on mechanical characteristics both in normal animals and in various experimental osteoporosis models. This effect seems to be due to alterations in bone mass, architecture, and quality.

Finally, bisphosphonates also inhibit bone resorption induced experimentally by implantation of various tumor cells. *In vivo*, three types of models have been investigated, namely, the subcutaneous implantation of tumor cells leading to tumoral hypercalcemia, their intracardiac injection inducing osseous metastases, and their implantation next to bone-inducing local erosion. In all three models, the tumoral effect is diminished by bisphosphonates. This effect is the basis for their use in tumor-related bone disease. It used to be thought that bisphosphonates had no direct effect on tumor cells. However, recent results show that *in vitro* they inhibit the adhesion and spreading of tumor cells and induce the apoptosis of tumor cells. They may also act indirectly by decreasing, as a result of the lower bone resorption, the release from bone of

cytokines that stimulate tumor cell multiplication, decreasing the tumor burden in the skeleton.

Relative Activity of Bisphosphonates in Inhibiting Bone Resorption

The activity of bisphosphonates on bone resorption varies greatly from compound to compound. For etidronate, the dose required to inhibit resorption is relatively high; in the rat, the dose is greater than 1 mg/kg parenterally per day. This dose is very near that which impairs normal mineralization. One of the aims of bisphosphonate research has therefore been to develop compounds with a more powerful anti-resorptive activity, without a stronger inhibition of mineralization. This has proven to be possible. Compounds have been developed that are up to 10,000 times more powerful than etidronate in the inhibition of bone resorption in experimental animals without being more active at inhibiting mineralization.

At present, the structural requirements for activity are only partially defined. The length of the aliphatic carbon chain is important. The presence of a hydroxyl group bound to the carbon atom at position 1, the presence of a nitrogen atom, or the presence of cyclic substituents increases activity.

Mechanisms of Action

There is no doubt that the action *in vivo* is mediated through mechanisms other than the physicochemical inhibition of crystal dissolution, as was initially postulated, namely, by acting on the osteoclast. Indeed, both the number and the morphology of the latter are altered with signs of apoptosis and alterations in the cytoskeleton and the ruffled border. Four mechanisms are likely to be involved: (1) inhibition of osteoclast recruitment; (2) possible inhibition of osteoclastic adhesion; (3) shortening of the life span of osteoclasts due to earlier apoptosis; and (4) inhibition of osteoclast activity. The first three will lead to a decrease in the number of osteoclasts, which is usually seen after treatment. The fourth will lead to inactive osteoclasts. These effects are made possible by the uptake of these compounds by the osteoclasts during the resorption process, a process favored by the fact that the bisphosphonates also deposit preferentially under the osteoclasts, where they can attain very high concentrations, in the range of 10^{-4} M or higher.

Very recently, the cellular mechanism was partially unraveled. It was found that nitrogen-containing bisphosphonates can inhibit the mevalonate pathway, by inhibiting farnesyl pyrophosphate synthase and possibly some other enzymes in this pathway. This leads to a decrease in the formation of isoprenoid

lipids, such as farnesyl- and geranylgeranylpyrophosphates. These are required for the posttranslational prenylation (transfer of fatty acid chains) of proteins, including the GTP-binding proteins Ras, Rho, Rac, and Rab, which are important for many cell functions, including cytoskeletal assembly and intracellular signaling. Therefore, N-containing bisphosphonates will induce a series of changes leading to decreased activity, probably the main effect, and to earlier apoptosis in several cell types, including osteoclasts. In osteoclasts, the lack of geranylgeranylpyrophosphate appears to be responsible for the effects.

In contrast, some non-nitrogen-containing bisphosphonates that closely resemble pyrophosphate, such as clodronate, etidronate, and tiludronate, can be incorporated into the phosphate chain of ATP-containing compounds so that they become nonhydrolyzable. The new P–C–P-containing ATP (AppCCl₂p) analogues impair cell function by decreasing mitochondrial function through an inhibition of ADP/ATP translocase. This may lead to apoptosis and cell death. Thus, the bisphosphonates can be classified into two major groups with different modes of action.

Bisphosphonates also have some effects on osteoblasts, such as decreasing their apoptosis and stimulating them to secrete an inhibitor(s) of osteoclast recruitment. The role *in vivo* of these effects is not yet clear.

Inhibition of Mineralization

Bisphosphonates inhibit calcification *in vivo* very efficiently. Thus, they prevent experimentally induced calcification of many soft tissues, both when given parenterally and when given orally. However, they also inhibit, at similar doses, the mineralization of normal calcified tissues. The amount required to have this effect is similar for the various bisphosphonates, in contrast to bone resorption, where the different compounds vary greatly in their activity. The inhibition of calcification can lead to fractures and to an impairment of fracture healing. The propensity to inhibit mineralization of normal bone has hampered the therapeutic use of bisphosphonates in ectopic calcification. It is probable that the effect on mineralization is due to a physicochemical mechanism of crystal growth inhibition following the tight binding of the compound to the mineral surface.

Pharmacokinetics

The bisphosphonates on which data have been published appear to be absorbed, stored, and excreted

unaltered in the body. Therefore, these bisphosphonates seem to be nonbiodegradable, at least with respect to their P–C–P bond.

Intestinal Absorption

The bioavailability of an oral dose of a bisphosphonate in animals as well as in humans ranges between less than 1 and 10%, probably because of their low lipophilicity, which prevents transcellular transport, and their high negative charge, which prevents paracellular transport. Bioavailability shows great inter- and intraspecies variation. Absorption is substantially diminished when the drug is given with meals, especially in the presence of calcium and iron. Therefore, bisphosphonates should never be given at mealtimes and never together with milk or dairy products or with calcium or iron supplements.

Distribution

The half-life of circulating bisphosphonates is short, on the order of minutes to hours. Some 20–80% of the absorbed bisphosphonate is taken up very rapidly by bone and the remainder is rapidly excreted in the urine. This rapid uptake by bone means that the soft tissues are exposed to bisphosphonates for only short periods, explaining why practically only bone is affected *in vivo*. The areas of deposition were generally thought to be mostly those of bone formation. This property is used to measure areas of high bone turnover in nuclear medicine by means of ^{99m}Tc-linked bisphosphonates. However, bisphosphonates have also recently been found to accumulate under the osteoclasts.

Once deposited in the skeleton and covered under new layers of bone, the bisphosphonates will be released to a large extent only when the bone in which they were deposited is resorbed. The half-life in bone bisphosphonates is therefore very long; for humans, it can be over 10 years. However, there is no indication that the bisphosphonates in the skeleton usually have any pharmacological activity as long as they are buried. But this may not be true at the sites of high turnover, where large amounts of the drug are deposited focally, for example, in patients with bone metastases or with Paget's disease. This would explain why a single administration of a bisphosphonate can be active for long periods of time in these conditions.

Renal Clearance

The rate of renal clearance of bisphosphonates is high. When it is taken into account that they have only partial ultrafilterability, the rate of renal clearance

can be, at least in animals, higher than that of inulin, indicating active secretion.

CLINICAL

Paget's Disease

Clinical Features

Paget's disease is a localized and progressive disorder of bone, with a genetic predisposition, presenting itself usually after the age of 40, and characterized by increased bone remodeling, bone hypertrophy, and abnormal bone structure. It is in some countries the second most common metabolic bone disease after osteoporosis.

For as yet unknown reasons, bone turnover becomes abnormally increased at certain sites in the skeleton; the cause is probably a slow paramyxovirus infection. The first event is a marked elevation of bone resorption, followed by a compensatory increase in formation. This leads to a mosaic of lytic and sclerotic lesions and local deformations of the skeleton.

The condition is most commonly asymptomatic. The most common complaint is pain, which may be very severe, and bone deformity. Laboratory findings reflect increased bone turnover. Thus, the indices of both bone formation, reflected by increased total and bone-specific serum alkaline phosphatase activity, and resorption, as assessed today by urinary pyridinium cross-links, especially the C-terminal and N-terminal cross-linked telopeptides of type I collagen, are elevated. Scintigraphy with 99m technetium-labeled compounds, in which the lesions show up as hot spots, is of great diagnostic value.

Treatment

Treatment should be offered to all symptomatic patients as well as to asymptomatic patients with involvement of skeletal areas that have the potential to give rise to complications, such as the skull, vertebral bodies, long bones, and areas near major joints. Practically the only treatment, apart from bisphosphonates, is calcitonin. Calcitonin has, however, some drawbacks, so that the bisphosphonates are now the therapy of choice in Paget's disease.

Effects of Bisphosphonate Therapy

All bisphosphonates that have been tested thus far have proven to be active in decreasing bone turnover. The difference between the compounds lies in their potency and in their adverse event profile. Most clinical studies in Paget's disease deal with alendronate, clodronate, etidronate, pamidronate, risedronate, and tiludronate. Other bisphosphonates

showing clinical efficacy include ibandronate, neridronate, olpadronate, and zoledronate. The effects observed are qualitatively very similar, but differ with respect to the rapidity with which they develop, the absolute reduction of turnover, and the duration of effect.

Both bone resorption and formation are decreased. The effect on resorption precedes the effect on formation, suggesting that, as in animals, the decrease in formation is secondary, due to the coupling between the two processes. This time differential has a practical consequence in that markers of bone resorption are a better way to assess the acute effect of treatment than alkaline phosphatase. The latter will give useful information only after approximately 4 weeks and sometimes even longer. The decrease in bone turnover can be accompanied by a small decrease in serum ionized calcium and an elevation of serum parathyroid hormone (PTH). The last two results are often seen when patients with very active osteolysis are treated with a powerful inhibitor of bone resorption. In order to avoid the secondary increase in PTH, it is strongly advised that the bisphosphonates be administered, especially in patients with severe disease or elderly people, together with 0.5–1.0 g calcium and 400–800 units of vitamin D per day.

Morphological studies confirm the reduction in turnover. The number of osteoclasts is diminished, but the virus-like cellular inclusions in the nuclei and the measles-type viral antigens in the osteoclasts persist unmodified. The bone formed during treatment with bisphosphonates often returns to a lamellar organization, in contrast to the woven bone formation typical of this disease.

Bone pain usually decreases and can disappear completely, except when it is due to arthritic changes. Neurological spinal syndromes can be improved and elevated cardiac output can be normalized. The pathological uptake of radioactive technetium is markedly decreased and some of the radiological alterations may be improved.

The effect of treatment is monitored by one of the biochemical markers of bone turnover. Serum alkaline phosphatase is currently the simplest and least expensive marker for bone formation. Collagen I pyridinium cross-linked telopeptides are becoming increasingly used for bone resorption. The aim of the treatment is to decrease bone turnover to the normal range. Indeed, a relationship appears to exist between the decrease in turnover obtained during treatment and the duration of the effect. If a normalization of turnover is not possible with a specific bisphosphonate, even after longer therapy, a more potent compound

should be used if available. Patients with more active forms of the disease require larger total amounts of bisphosphonates. The plateau is usually reached within 3–6 months for alkaline phosphatase in the case of oral administration and is faster for the parameters of bone resorption. Treatment is then discontinued until the indices of bone turnover start to increase again or symptoms recur. An increase above the normal range, or if the latter was not attained, an increase of at least 25%, seems to be a reasonable guideline for resuming treatment. However, the decrease in bone turnover, as well as the other improvements, can also last for a long time, often many years, after the discontinuation of treatment. In some patients, resistance to the bisphosphonate may develop with time. The cause of this resistance is unknown. Sometimes it can be overcome by increasing the dose; in other cases, it can be overcome by switching to another bisphosphonate, a more potent one, if possible.

Treatment Regimens for Widely Available

Commercial Compounds

- *Alendronate*: Oral administration of 40 mg daily for 6 months is the dose recommended by the manufacturer.

- *Clodronate*: A daily oral dose of 1600 mg *per os* for 6 months is used in some countries.

- *Etidronate*: This compound was the first to be used in this disease but is practically not administered any longer, because the required doses to normalize bone turnover also induce an inhibition of mineralization.

- *Pamidronate*: Intravenous infusions of 60–90 mg given once are usually used. Treatment can be repeated after 6 months if the result is not satisfactory.

- *Risedronate*: A dose of 30 mg daily for 2 months, followed by another course 6 months later, if necessary, is recommended by the manufacturer.

- *Tiludronate*: Daily oral administration of 400 mg for 3–6 months is used in some countries, but this treatment is less efficient than some of the above-mentioned regimens.

Conclusion

Bisphosphonates can normalize bone turnover in most patients and improve the clinical signs and symptoms. The improvements can last for many years after discontinuation of therapy. They are today the drug of choice for treatment of Paget's disease.

Osteolytic Tumor-Induced Bone Disease

Clinical Features

Osteolytic tumor-induced bone disease is a condition in which tumors of various origins, mostly breast, lung, prostate, and multiple myeloma, induce bone destruction, which can lead to fractures, pain, and hypercalcemia with its symptomatology. The osteolysis occurs either through local invasion or at distance by secreting into the bloodstream bone-resorbing products, mostly PTH-related protein (PTHrP). Often they work through both mechanisms. The mechanism of local resorption of bone involves the secretion of an array of bone resorbing cytokines, including PTH-related protein, by the tumor cells or by other cells that are stimulated by said tumor cells. If generalized bone destruction is accompanied by hypercalcemia, the term humoral hypercalcemia of malignancy is used. The hypercalcemia is then due to both increased bone destruction and increased renal tubular reabsorption, both being stimulated by PTHrP. The fact that hypercalcemia is produced by various mechanisms has therapeutic consequences. Because only bone resorption is influenced by bisphosphonates, plasma calcium will be less influenced by these compounds in patients in which nonosteolytic mechanisms, that is renal reabsorption, are prominent. This is the case, for example, in humoral hypercalcemia of malignancy.

The parameters usually followed for diagnosis and during the treatment of tumor-induced bone disease are primarily pain, fractures, and osteolytic foci, as well as plasma calcium, urinary calcium, and pyridinium cross-links or their peptides. The radiophysical techniques used include X-rays, scintigraphy, computed tomography, and magnetic resonance imaging.

Treatment

Treatment of tumor-induced bone disease is of course primarily the usual cancer therapy, such as excision of the primary tumor, chemotherapy, hormonal therapy, or radiotherapy. Hypercalcemia in the acute stage is first treated with fluid repletion. Thus, the bisphosphonates should by no means replace the latter treatments, but should be used only as a supportive treatment to improve the quality of life. They are effective in most tumors, including breast, lung, myeloma, and prostate, at decreasing hypercalcemia as well as decreasing the occurrence of skeletal complications, such as fractures, pain, and new osteolytic lesions.

Effects of Bisphosphonate Therapy

Bisphosphonates are currently the drugs of choice for the treatment of tumoral hypercalcemia in patients in whom cancer therapy and fluid repletion are not effective. They effectively reduce and often normalize hypercalcemia. With intravenous administration, the effect starts to be clinically significant after 2–3 days; normocalcemia is obtained after 3–5 days and the full effect is obtained after approximately 1 week. The effect is more pronounced in patients in whom hypercalcemia is completely or largely a result of bone resorption only, as is the case, for example, in myeloma. Hypercalciuria is greatly decreased by treatment in all types of tumor. The markers of bone resorption, urinary pyridinium cross-links and their C- and N-terminal telopeptides, are markedly decreased. The most practical procedure for treating tumoral hypercalcemia is to monitor plasma calcium and to resume treatment when hypercalcemia resumes. The duration of the effect after discontinuation of treatment is variable, usually less than 1 month. It seems to depend on the potency of the bisphosphonate, the total dose administered, and the type of bone disease. In patients with focal involvement, resorption appears to be inhibited for a longer time than in those with humoral hypercalcemia.

Bisphosphonates also decrease the occurrence of skeletal-related events, such as bone pain, pathological fractures, vertebral collapse, spinal cord compression, the requirement of radiation and bone surgery, as well as the development of new osteolytic foci, leading sometimes to a marked improvement in the quality of life. The onset of these effects is relatively slow. The efficacy is lost after discontinuation of the drug. Recent results with clodronate suggest that bisphosphonates may possibly also diminish in some cases the formation of bone metastases in patients who have not developed them yet. This effect, if confirmed, would open the possibility of using these compounds in patients who have not yet developed skeletal metastases.

Treatment Regimens for Widely Available Commercial Compounds

From the available data, there is no indication that there are any fundamental differences in the qualitative effect of the various bisphosphonates in tumor-induced bone disease. There is, however, a great difference in their quantitative effect. If resistance to the treatment develops, either increasing the dose or switching to another, preferably more potent, bisphosphonate may solve the problem.

- *Alendronate*: This compound is commercially available only in Japan for hypercalcemia of malignancy at a dose of 10 mg, or if necessary 20 mg, administered in intravenous infusions.

- *Clodronate*: For hypercalcemia, one infusion of 1500 mg in no less than 500 ml is usually used. Sometimes oral treatment of 1600 mg is administered daily as maintenance therapy. The latter is especially used as long-term therapy for skeletal complications of tumor bone disease.

- *Etidronate*: Among the various bisphosphonates used, the effect of etidronate, which is the least potent, is the least satisfactory and the compound is used very little today.

- *Ibandronate*: This compound, administered as a single intravenous (iv) infusion of 2–4 mg, is used for hypercalcemia.

- *Pamidronate*: One infusion of pamidronate is usually sufficient to normalize plasma calcium in hypercalcemia. The dose can be adapted to the degree of hypercalcemia and is usually between 60 and 90 mg. Treatment is repeated when plasma calcium rises again. In order to reduce or prevent skeletal morbidity, infusions of 90 mg monthly are usually recommended.

- *Zoledronate*: Infusion of 4 mg iv of this compound has a more powerful effect on hypercalcemia than 90 mg iv of pamidronate. Zoledronate is commercially available for tumor-induced bone disease at this dose, infused intravenously every 3–4 weeks.

Conclusion

In addition to classic anti-neoplastic treatments, bisphosphonates are today the drugs of choice for treating tumor-induced bone disease. By inhibiting bone resorption, bisphosphonates correct hypercalcemia, reduce pain, prevent the development of new osteolytic lesions, and reduce the occurrence of fractures, and as a consequence improve the quality of life.

Non-Tumor-Induced Hypercalcemia

Only a few data are available concerning the use of bisphosphonates in hypercalcemias due to causes other than malignant bone disease. Most of the reports are on hyperparathyroidism. The effects seem to be limited and of short duration, also because part of the elevation in plasma calcium is due to increased reabsorption in the kidney. The compounds that are most frequently used are pamidronate and clodronate.

Osteoporosis

Clinical Features

Osteoporosis is a disease characterized by a decrease in bone mass and a deterioration in the architecture of the bones, which leads to an enhanced fragility of the skeleton and, therefore, to a greater risk of fracture. It is defined as being present in women when the bone mineral density is more than 2.5 standard deviations below that of the young female adult (*T*-score). It is a very common disorder that will become even more common with increased life expectancy. It is also frequent in men, although less so than in women. Its main cause is the continuous loss during life of both cancellous and cortical bone, which is exacerbated in women after menopause. The second contributory factor is failure to achieve adequate peak bone mass during adolescence. The causes of these changes are not yet clear, although genetic factors are involved, at least for the latter factor.

The clinical manifestations of osteoporosis are fractures, often occurring spontaneously or after minimal trauma, and their consequences. Osteoporosis is diagnosed and assessed quantitatively by techniques that measure bone mineral density (BMD), most commonly dual X-ray absorptiometry. Chemical analyses cannot be used to diagnose osteoporosis. Markers of bone turnover, however, are useful to determine bone turnover and consequently to identify those patients who are likely to be losing bone rapidly and to follow the effect of treatment.

Treatment

Many remedies are used to prevent and treat osteoporosis. Practically all of them aim to decrease bone resorption. Probably the treatment that was the most often used and the most effective for osteoporosis, apart from the bisphosphonates, was estrogen replacement after menopause. However, it was shown recently that estrogen replacement can increase the risk of breast cancer and of vascular insults when given over a longer time. Calcitonin is sometimes used, but parenteral administration sometimes has unpleasant side effects and the nasal form has a relatively weak effect on BMD and fracture incidence. Calcium can also decrease bone turnover and diminish bone loss in certain conditions. A daily intake of 1–1.5 g is recommended in the adult, especially during lactation and in the elderly. Vitamin D should be present in sufficient amounts and is generally recommended as a supplement for elderly people. Today only very few compounds are able to increase bone formation, namely, fluoride and PTH. Fluoride has not been shown to

decrease the occurrence of fractures. However, PTH appears very promising, since it increases BMD and decreases the occurrence of fractures.

Effects of Bisphosphonate Therapy

Most of the studies on the effects of bisphosphonate therapy have been performed with alendronate, etidronate, and risedronate. Many well-controlled studies proved the efficacy of bisphosphonates in preventing skeletal loss, actually increasing skeletal calcium as assessed by BMD, and in decreasing bone turnover. However, BMD is not necessarily a true reflection of actual bone mass, since it is influenced not only by the amount of bone, but also by the degree of mineralization of the bone present, which increases when bone turnover is decreased. Bisphosphonates are active in white, Asian, and black osteoporotic women. They are also effective in the elderly and healthy women, as well as in men. They prevent and even partially reverse the bone loss in glucocorticoid-treated patients and are therefore a standard therapy in patients receiving this drug over a longer time. When given together with hormone replacement therapy or raloxifene, they have a greater effect on bone mineral density than either treatment given alone. All the bisphosphonates induce a marked decrease in bone turnover when given in doses effective on bone mineral density. Both bone formation and bone resorption are decreased. Both alendronate and risedronate decrease by approximately one-half the occurrence of vertebral and nonvertebral fractures in osteoporotic patients. This effect is due both to the increase in BMD and to the decrease in bone turnover.

After discontinuation of short-term treatment, bone turnover returns to pretreatment values within months and bone loss appears to resume, although at a later time. This reversal occurs more slowly and later if the bisphosphonates have been given over a longer period, such as years.

Treatment Regimens for Widely Available

Commercial Compounds

- *Alendronate*: The dose recommended by the manufacturers is 10 mg orally daily and 5 mg in Japan. Since this compound has a similar effect on BMD when given once weekly at 70 mg, the weekly regimen is used today in countries where this regimen is commercially available.
- *Etidronate*: The regimen recommended by the manufacturer is 400 mg daily orally for 2 weeks every 3 months.
- *Risedronate*: The recommended regimen is 5 mg daily orally or 35 mg once weekly.

Conclusion

Bisphosphonates stop bone loss, increase BMD, and decrease bone turnover in various types of osteoporosis in women and men. This leads to a decrease in vertebral and nonvertebral fractures. Bisphosphonates are an important addition to the therapeutic modalities available for the treatment and prevention of osteoporosis.

Heterotopic Calcification and Ossification

Etidronate is the only bisphosphonate investigated thus far for the prevention of ectopic calcification and ossification. Although it appears to be useful in some cases, this has not yet proven by double-blind studies. Furthermore, the effective dose is the same as that which inhibits normal mineralization, which makes its use difficult. Etidronate is commercially available in some countries at an oral dose of 20 mg/kg initially for 2–4 weeks before the intervention, followed by 10 mg/kg for 10–12 weeks to prevent heterotopic ossifications following a hip prosthesis implantation and after spinal lesions with immobilization.

Other Diseases

Bisphosphonates can be useful treatments in other diseases. Among these diseases, osteogenesis imperfecta, fibrous dysplasia of bone, and reflex sympathetic dystrophy syndrome are the best known.

Adverse Events

As was the case in animals, studies in humans have revealed only a few important adverse events. The most frequently seen are the following: Rapid injection led to renal failure, probably because of the formation of a solid phase of bisphosphonate in the blood, which is then held back in the kidney. No further events of that kind have been observed since bisphosphonates, when given intravenously, are administered by slow infusion in a large volume of fluid, usually 250–500 ml. Bisphosphonates may sometimes induce a certain degree of hypocalcemia, which is usually clinically irrelevant. An exception may be the association with aminoglycoside antibiotics with which very severe hypocalcemia can occur, so that the two drugs should not be administered together. Oral administration of bisphosphonates, especially those containing a nitrogen atom, can be accompanied by digestive tract disturbances. The latter can be substantially reduced by taking the drug with enough fluid and by not reclining after the intake.

They appear to be further reduced by administering the compounds at the same total dose weekly instead of daily. The intravenous administration of N-containing compounds can induce a transient pyrexia of usually 1–2°C, accompanied by flu-like symptoms. There is an increase in serum C-reactive protein, so that the events resemble an acute-phase response. As yet, no negative consequences of these episodes have been described. Finally, compounds with little efficiency and which must be administered in higher doses, such as etidronate, can inhibit normal skeletal mineralization. This can happen at doses of etidronate that are greater than 800 mg daily.

Contraindications

At present, only a few contraindications have been described for the bisphosphonates. The question is often raised as to whether these compounds can be administered for renal failure. Because they are cleared from the blood to a large extent by the skeleton, there is no theoretical reason to deny bisphosphonates in patients with moderate renal failure. However, plasma levels are likely to be higher, so that the dose should possibly be reduced. Fracture healing or new orthopedic implants are not contraindications to the use of bisphosphonates, provided they are not given in doses that inhibit mineralization. In view of the potential for gastrointestinal effects of bisphosphonates during oral administration, this mode of administration should be used with caution in patients with inflammatory gastrointestinal and esophageal conditions and with esophageal dysmotility. Finally, bisphosphonates should not be given during pregnancy and lactation.

Future Prospects

The bisphosphonates represent an important development in the treatment of bone diseases and it is possible that this is only the beginning of a new era of therapy. Many issues are still unresolved. For example, it is not yet known whether the optimal regimen for the various compounds available has been found. Will there be an advantage in the future to combine bisphosphonates with other inhibitors of resorption or with a stimulator of bone formation? In view of the persistence of bisphosphonates in the body, which is a concern for some, it might be considered to interrupt treatment for osteoporosis for a certain time. It may be possible in the future to devise drugs that have effects similar to those of the bisphosphonates, but are metabolically broken down.

Possibly bisphosphonates can be of use in diseases other than bone diseases, such as arthritis, dental disease, and tumors in general. Finally, bisphosphonates may be used as carriers for drugs to be brought to the bone or to other calcified tissues.

Body Composition During Growth

Kenneth J. Ellis

Baylor College of Medicine and Texas Children's Hospital, Houston, Texas, United States

Glossary

body cell mass The cellular mass of the body containing the oxygen-exchanging, potassium-rich, glucose-oxidizing, work-performing tissue.

body composition The mass of the human body can be described in terms of its chemical, molecular, cellular, physiological, and anatomical makeup.

bone mineral z-score calculator Normalizes the measured bone mineral content for an individual child with a pediatric reference population based on age, gender, ethnicity, and height.

reference model Multicomponent model of body composition used to describe changes in the relative proportions of bone, muscle, visceral tissues, and fat stores during normal growth.

Growth is not only a change in height but also a change in the relative proportions of bone, muscle, water, visceral tissues, and body fat that comprise body weight.

INTRODUCTION

Based on an extensive review of the scientific literature, a task group of the International Commission on Radiological Protection developed a comprehensive model of the chemical and compositional makeup of the young adult male body, called Reference Man. During growth, however, not only does the human body increase in size but also there are changes in the relative proportions of bone, muscle, visceral tissues, and fat stores. To describe these changes, Samuel Fomon and colleagues developed the concepts of the Reference Infant, Reference Child, and Reference Adolescent models of body composition. These models have proven to be very practical on a population basis for estimating the nutritional requirements needed in support of normal growth. There has been an increasing clinical interest in body composition, and

the Fomon models have often been used as the reference or standard for examining abnormal growth. Although these reference models have been of great value for establishing pediatric nutritional requirements, there were several limitations in the modeling process that the authors acknowledged could constrain their utilization for the assessment of the individual child. These included the paucity of reliable pediatric body composition data 30 years ago, which necessitated the pooling of data from different populations, and the extrapolation or interpolation of missing values at many ages. Also, there were insufficient data to adequately develop models suitable for minority or non-Caucasian children. This article provides a contemporary update to the basic Fomon models using body composition data as reported by Nancy Butte and colleagues for infants and by Kenneth Ellis and colleagues for older children and adolescents from a multiethnic population.

CONSTRUCTION OF A REFERENCE MODEL

The modeling scheme originally developed by Fomon and colleagues was used to describe the changes in body composition during growth for contemporary populations. This approach was chosen to allow for a direct comparison with Fomon's models. The basic components of this model are illustrated in Fig. 1. To construct this model, three separate *in vivo* measurements are needed: total body potassium (TBK), total body water (TBW), and total body bone mineral content (BMC). In order to obtain estimates for the subcategories of the fat-free mass (FFM), the following set of assumptions were used: (i) intracellular and extracellular potassium concentrations of 150 and 4 mEq/liter, respectively; (ii) intracellular and extracellular mineral concentrations of 9.0 and 9.4 g/liter, respectively; (iii) nitrogen content of protein is 160 g/kg; (iv) lean tissue accretion during growth contains 2.17 mEq potassium per gram of nitrogen; and (v) glycogen

Figure 1 Multicompartment model of body composition. Body weight = fat mass + fat-free mass (FFM), where total body water = extracellular water (ECW) + intracellular water (ICW).

makes up 0.6% of the FFM. Based on these assumptions and the measurements of TBK, TBW, and BMC, the size of the subcategories of FFM can be derived using the following set of equations:

$$\text{Extracellular water (ECW)} = 1.027 \times \text{TBW (liter)} - 0.00685 \times \text{TBK (mEq)}$$

$$\text{Intracellular water (ICW)} = \text{TBW (liter)} - \text{ECW (liter)}$$

$$\text{Protein (kg)} = 0.002881 \times \text{TBK (mEq)}$$

$$\text{Glycogen (kg)} = 0.006 \times \text{FFM (kg)}$$

$$\text{Nonosseous mineral} = [9.0 \times \text{ICW} + 9.4 \times \text{ECW}] \times 10^{-3}$$

$$\text{Osseous mineral (kg)} = \text{BMC}$$

Fat-free mass was defined as the sum of the TBW, protein, mineral, and glycogen compartments. Using the Fomon modeling approach, the body's fat mass (FM) was calculated as body weight minus FFM.

BODY COMPOSITION MEASUREMENTS

The review article by Kenneth Ellis provides a comprehensive description of the various body composition techniques that are used to assess the living human body. For the assay of TBW, the deuterium dilution method is most frequently used. For infants and toddlers, urine samples are collected at baseline and 3–5 h after administration of an oral dose of the nonradioactive tracer. For older children, plasma is the preferred fluid sample taken at the baseline and postdose time points. Measurement of the deuterium content of the fluid sample can be obtained using gas-isotope-ratio mass spectrometry. During the 3- to 5-h equilibration period, some of the deuterium will exchange with nonaqueous hydrogen in the body, such that the deuterium dilution space has to be corrected by approximately 4% to obtain an accurate measure of TBW. The body water assay technique has a reported precision of 1 or 2%.

The total body potassium (TBK) measurement is based on a unique nuclear property of natural potassium. A small percentage of natural potassium exists in a radioactive (^{40}K) state, such that approximately 200 gamma rays per minute are emitted per gram potassium. The energy of these gamma rays is sufficiently high (1.46 MeV) that most of this signal can be detected external to the body. This is accomplished using an instrument called a whole-body counter. Typical counting times are less than 15 min, with a reported precision of ± 1 –3% depending on the subject's body size and the design of the counter.

The measurement of BMC of the whole body can be obtained using dual-energy X-ray absorptiometry (DXA). This technology did not exist at the time the original Fomon models were developed. For the DXA measurement, a narrowly collimated X-ray beam is passed through the body, and the relative intensity of the transmitted beam is measured on the opposite side of the body using an array of detectors. Two different energies of X rays are used to separate the attenuation response due to the difference in density between bone and soft tissue. Newer DXA instruments can scan the total body in a few minutes. There is a small exposure to X rays resulting from the scan, but it is well within the variation in the natural background levels throughout the United States. The precision for whole-body BMC measurements is reported to be $\pm 1\%$ for older children and adolescents, increasing to approximately $\pm 3\%$ for infants. An important feature of the whole-body DXA measurement is that estimates of the body's FM and nonfat lean tissue mass can also be obtained. However, in this article, FM is estimated using only the model developed by Fomon (i.e., FM = body weight – FFM).

BODY COMPOSITION REFERENCE DATA

The tabulated and graphical results presented in this article are derived from the data of Butte and colleagues for infants and Ellis and colleagues for older children and adolescents. Stepwise multiple regression analysis (MINITAB, Version 12) was used to identify the best set of anthropometric parameters that could be used to predict body composition. The general linear model with the analysis of variance was used to test for possible ethnic differences in these relationships.

Butte *et al.* reported longitudinal body composition data for 72 healthy infants obtained at 0.5, 3, 6, 9, 12, 18, and 24 months of age. Both bottle-fed and

^aData from Butte *et al.* (2000). Data presented as mean (SD). TBW, total body water; TBK, total body potassium.

breast-fed infants were included in the study, and the infants were Caucasian, African American, or Mexican American. The mean values for body length and weight, TBW, and TBK are listed in [Table I](#) for each

gender. The corresponding values for FM, body fatness, and FFM and its subcategories are listed in [Table II](#). It is also interesting to note that these same researchers published body composition data for infants grouped by their primary feeding method during early life. As one would expect, the amount of protein, osseous mineral, and intracellular water increased with age, whereas the total hydration of FFM and its extracellular water content decreased. Butte *et al.* used these data to calculate the average daily incremental growth rates for FM, FFM, TBW, protein, and glycogen. The mean rates are illustrated in [Fig. 2](#). The deposition rates tended to be highest during the first 6–12 months of life, followed by a 12-month period of relatively constant accretion. For example, in boys, the average protein accretion was approximately 2.3 ± 0.8 g/day for the first year of life, followed by a slower rate of approximately 1.3 ± 0.6 g/day for the next 12 months. Overall, the accretion patterns for girls were very similar to those observed for boys, although the average rates were approximately 10% lower for each of the FFM subcategories.

Most of the studies in older children and adolescents that have included body composition data have been cross-sectional in design. In one study, Ellis and colleagues reported the mean body composition values for Caucasian, African American, and Mexican American children. The weight, height, TBW, TBK, and BMC for each ethnic group are shown in [Table III](#)

^aData from Butte *et al.* (2000). Data presented as mean (SD). FM, fat mass; FFM, fat-free mass; BMC, bone mineral content; ECW, extracellular water; ICW, intracellular water.

Figure 2 Average daily accretion rates for fat mass (FM), fat-free mass (FFM), total body water (TBW), and protein mass during the first 2 years of life for boys and girls. Adapted from Butte *et al.* (2000).

for girls and Table IV for boys. Using the Fomon model, the corresponding values for FM and each of the subcategories of the FFM were also reported and are given in Table V for girls and Table VI for boys.

The data presented in Tables I–VI provide a contemporary update of body composition for infants, children, and adolescents based on the reference models originally developed by Fomon more than 30 years ago. A major advantage of the current data is that the measurements of body potassium, body water, and bone mineral mass were obtained for each of the subjects. Furthermore, subjects at all ages were examined for the contemporary population, thus eliminating the need to extrapolate for missing ages.

Compared to Fomon's reference models, there are no significant differences in height for the Caucasian children, whereas body weights, on average, are substantially higher, especially for older children and adolescents. These differences can be attributed to a clear increase in body fatness relative to that of the

original Fomon population. There are also differences in the general growth patterns for the protein and bone mineral categories. However, bone mineral mass was directly measured using the DXA technology for the contemporary population, whereas it had to be extrapolated from a measurement of the radius for the Fomon models.

Some of the differences in the body composition categories between the Fomon and contemporary models have not been fully resolved as true physiological changes or as methodological-induced artifacts. The results of the contemporary models, however, provide an updated reference suitable for assessing the current status of today's children, especially if there are conditions such as disease that may have altered normal growth. This assessment can be accomplished by comparing the patient's values with those of healthy children of similar age from the reference population. Many childhood diseases, however, often contribute to stunted or delayed growth, which is also frequently accompanied by altered body composition. Therefore, if one performs only age-matched comparisons, the effects of the smaller physical size of the patient may not be adequately taken into consideration. A better assessment in these cases can be obtained when there is also an adjustment made for any height deficiency. Thus, several prediction equations, using multiparameter regression analysis, have been calculated using the data for the contemporary reference population. These equations are presented in Table VII for children in the 5- to 18-year age range. In all cases, height was the primary anthropometric-based predictive parameter, with adjustments for gender, age, and ethnicity. Inclusion of the Tanner stage was also tested, but it did not add substantially to the predictive power of the models, and it may not always be available for the patient. Body weight was not used since it consists of the sum of FFM and FM and therefore would introduce a bias into the prediction results for extremes of either category.

In summary, the tabulated data presented here provide a contemporary update of body composition reference values from infancy through adolescents, illustrating the changes that can be expected during normal growth for different ethnic populations. In the case of bone, these models have been further refined to construct a z-score calculator for the DXA measurement of bone mineral density. Calculators are readily available to the pediatric clinical and research community on the Internet at www.bcm.tmc.edu/bodycomplab. Future expansion of this Web site will include similar z-score calculators for the body's protein, water, and potassium composition.

Table III Body Weight, Height, TBW, TBK, and BMC for Girls^a

| Age (years) | Weight (kg) | Height (cm) | TBW (liters) | TBK (g) | BMC (g) |

Body Proportions

William J. M. Gerver

University of Maastricht, Maastricht, The Netherlands

Glossary

mastoid process Cone-shaped extremity of the temporal bone, extending forward and downward just posterior to the acoustic opening.

occiput The back part of the head.

The growth process that transforms a newborn into an adult implies that there is not only an increase in height but above all a constant change in body proportions due to differing rates and times of growth of different parts of the body.

INTRODUCTION

In 1943, Medawar gave a clear description of the transformation that occurs during growth, showing the head–trunk–legs gradient, which indicates that the development of the head is advanced over that of the trunk and the development of the trunk is advanced over that of the legs during the maturation process. This clearly shows that the growth of different parts of the body does not occur simultaneously or at the same speed.

In a child, this transformation can be defined by the interrelationship of a number of linear measurements, such as sitting height to full height, or head circumference to crown–rump length. The ease with which one can equate the human body's shape with an accurate estimate of human age—whether the compactness of a 5 year old, the coltishness of a young teenager, or the dimensions of a mature adult—tends to be taken for granted. Nevertheless, this feat is remarkable. Even more extraordinary is the precision with which the human eye registers any deviation from the norm.

The mathematical expression of these perceptions for scientific purposes is a highly complex task with imperfect results. Vital information is lost. It is possible, however, to use a reference population to

organize the complexity of what even the untrained eye perceives naturally.

Knowledge of the body proportions gives insight into the natural process of maturation and any disturbance will be visible in abnormal body proportions. A principal distinction can be made between a child with stunted growth affecting the whole body or affecting just some body parts. Such an observation leads to different conclusions about the origin of some growth deviation.

In this article, an overview is given of the different measurements: the techniques of taking the measurements, the normal values based on a Dutch study of 2001, and the methods of interpretation. Of the 20 measurements taken in the Dutch study, the most important are selected for discussion here.

THE MEASUREMENTS

Length and Height

In pediatrics, the curve representing a child's increase in height with age is used as one of the indicators of the child's health. The child's height is compared to that of a reference population in order to judge whether the child is atypical in terms of the height distribution of this population. Child and reference population must share the same geographical and socioeconomic background. Also, parental or familial height should be taken into consideration to assess the relative contribution of genetic and other factors to the child's height at any particular age.

Since growth is a dynamic process, one isolated measurement in time is meaningless for judging growth. Repeated measurements are needed to calculate the growth velocity. Knowledge of growth velocity is particularly relevant when dealing with a sick child. Depressed growth velocity may indicate the severity of an illness, whereas normalization of growth velocity or catch-up growth may signal recuperation.

Height is the distance between the top of the head and the sole of the foot. This distance is the sum of

the height of the skull, the length of the spine, and the length of the lower extremities. Each of these different parts of the body has its own age-dependent growth velocity. Therefore, height is the result of the sum of different values, which are not linearly related in time.

Method of Measurement

The distance between the top of the head and the sole of the foot is called length when an individual is measured lying down and height when the individual is measured standing upright.

Height is measured using a stadiometer. The stadiometer comprises a rigid vertical backboard and a horizontal headboard running free, perpendicular to the backboard and without cross-play. The top of the head must be in contact with the headboard. A 0.5 kg weight is placed on the headboard. This serves the purpose of flattening the child's hair and frees the physician's hands so as to enable him to keep the child in the correct upright position.

To measure standing height, the subject's shoes and socks are removed. The child is placed so that his heels, buttocks, and shoulders are in contact with the vertical plane of the stadiometer. The child's feet must be flat against the floor while either ankles or knees remain in contact. The child's head is held in the "Frankfurt plane": the lower borders of the orbits are in the same horizontal plane as the external auditory meati. The measurement is taken while a gentle upward pressure is exerted on the mastoid processes so that the child is fully extended. In older children, stretching is achieved by telling them to breath deeply.

To measure supine length, a measuring table resembling a stadiometer is used but on a horizontal plane. The headboard is fixed and the footboard is movable. Both the headboard and the footboard must be large enough to ensure that both the top of the head and the feet are in contact with them. To measure supine length, two people are necessary: one holds the infant's head in the vertical Frankfurt plane while at the same time another individual keeps the child's legs straight. The child's shoulders and buttocks must be in contact with the table. Supine length is measured in the first 2 years of age.

Crown Rump Length, Sitting Height, and Subischial Leg Length

As stated earlier, height defined as the distance between the top of the head and the sole of the foot is

the result of the sum of different values, which are not linearly related in time. Therefore, the first step is to split height into its different components.

Generally, sitting height is taken as one of the components and compared to height. The relationship between sitting height and height is often expressed as an age-dependent ratio. The use of ratios can be misleading for two reasons: first, two ratios may be equal, although their nominators and denominators are not; and second, when a change in the nominator automatically leads to a change in the denominator, the change in the ratio will be even more misleading. Therefore, a more straightforward approach is to simply plot height against sitting height and an even clearer one is to use sitting height and subischial leg length as variables for comparison, since a change in sitting height will automatically induce a change in height but not a change in subischial leg length.

Method of Measurement

The distance between the top of the head and the buttocks is called sitting height when the measurement is taken of a child sitting upright and is called crown rump length when an infant is measured lying down.

Sitting height is measured using a sitting height table. The table comprises a rigid vertical backboard and a horizontal headboard running free perpendicular to the backboard and without cross-play. The surface of the headboard must be in contact with the top of the head. A 0.5 kg weight is placed on the headboard. This weight flattens the child's hair and also frees the physician's hands so as to be able to keep the child in the correct position. The child must be in the sitting position with his feet on a footrest so that his full weight is on his buttocks. Insofar as is possible, arching of the back is avoided by gently applying upward pressure to the mastoid processes. In older children, stretching of the back is achieved by asking them to breathe deeply. The child's head is held in the Frankfurt plane: the lower borders of the orbits are in the same horizontal plane with the external auditory meati.

The recommended instrument for measuring crown rump length is similar to the stadiometer used for supine length. The headboard is fixed and the footboard is movable. Headboard and footboard must be large enough to ensure that the most protruding points of both head and buttocks are in contact with the boards. In order to measure this length, an assistant holds the infant's head in the vertical

Frankfurt plane while the physician holds the child's legs at a 90° angle with the table. When this is achieved, the footboard is pressed against the buttocks.

Subischial leg length is defined as the arithmetic difference between height and sitting height or between supine length and crown rump length.

Head Circumference

The head circumference is routinely measured in newborn infants since it correlates well with skull volume. Skull volume is highly correlated with gestational age, body weight, and body length. Since in intrauterine growth retardation, the brain is less affected than the weight and the length, the extent of the discrepancy between these measurements in the newborn will be an indicator of the severity of the retardation.

Because of the fast growth velocity of the head circumference, especially during the first year of life, its measurement provides important information about the general condition of the child. In full-term healthy newborns, the head circumference increases approximately 1 mm per day initially.

Method of Measurement

To measure head circumference, a fiberglass-reinforced tape of nonstretchable material is used. The tape is placed around the head at the most protruding points of occiput and forehead. In younger children, the tape is placed just above the brow ridges. The tape is placed gently so as to leave no marks after removal.

Arm Span

The measurement of the limbs so as to describe body proportions is an important tool when evaluating development. Arm span is the most common way to measure upper limb length. However, one must realize that by measuring the span of the outstretched arms from the tips of the longest fingers, the distorting information of the width of the trunk is added.

Method of Measurement

To measure arm span, a measuring rod can be used. The distance between the tips of the stretched middle fingers is measured while the subject stands with his arms fully extended.

APPLICATION

To judge the body proportions of an individual, the following steps must be taken.

First, for each measurement, the standard deviation score, $z(t)$, is calculated by

$$z(t) = \frac{x(t) - \mu(t)}{\sigma(t)}$$

where $x(t)$ denotes the individual's body measurement score at age t (e.g., height), $\mu(t)$ denotes the population mean at age t , and $\sigma(t)$ denotes the corresponding standard deviation.

The z -scores are given in the reference tables. Since the distribution of the reference population is skewed, two different SD values are calculated. In the reference tables, they are given as +1 SD and -1 SD, the SD value above and below the P_{50} (popular mean), respectively. Calculating a z -score or SD score, one needs to use the +1 SD if the individual's measurement is above the P_{50} of the reference group and -1 SD if the individual's measurement is below the P_{50} of the reference group.

Second, the typicality or atypicality of an individual can be calculated by means of the squared distance D^2 , which follows a χ^2 distribution if normal children are considered.

The squared distance is calculated as follows:

$$D^2 = [1 - r^2(b, b')]^{-1} [z_b^2 + z_{b'}^2 - 2z_b z_{b'} r(b, b')]$$

where r denotes the correlation coefficient of the two measurements b and b' according to Table I.

$D^2 \leq 5.991$ indicates that the considered individual is typical or normal, whereas $D^2 \geq 5.991$ suggests that something is wrong with size and/or shape.

Size and shape can be separated by $z_b + z_{b'}$ as characteristic for size and $z_b - z_{b'}$ as characteristic for shape. This leads to the statement that size is atypical if

$$|z_b + z_{b'}| / [2 + 2r_t(b, b')]^{1/2} \geq 1.960$$

and shape is atypical if

$$|z_b - z_{b'}| / [2 - 2r_t(b, b')]^{1/2} \geq 1.960$$

Table I Correlation Coefficient of Pairs of Measurements of Body Proportions According to Sex

| | Boys | Girls | Mean |
|---------------------------|------|-------|------|
| Height/arm span | 0.87 | 0.85 | 0.86 |
| Height/sitting height | 0.82 | 0.82 | 0.82 |
| Length/head circumference | 0.36 | 0.36 | 0.36 |

Note. These correlations are almost independent of age for children between the ages of 3 and 17 years.

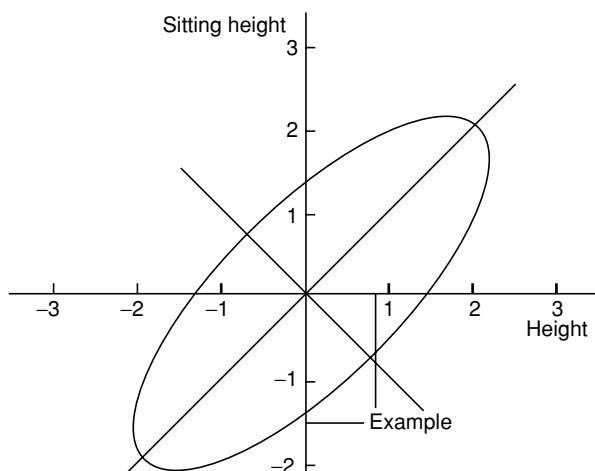

Figure 1 The 95% confidence limits of the pair of z -scores of height and sitting height. The example is the patient mentioned in the text.

Graphically, one can display the atypicality of a particular individual by constructing an ellipse, which comprises 95% of the pairs of scores (Fig. 1).

Example

If a boy of 6.5 years has a height of 134.6 cm and a sitting height 63.5 cm, the corresponding z -scores for height and sitting height are $z_b = 0.92$ and $z_{sb} = -1.5$.

These scores considered separately do not indicate that something is wrong with this child. The difference in sign, however, is somewhat alarming because the correlation between the measurements is positive.

Using the value 0.82 for the correlation coefficient between height and sitting height (Table I), one obtains

$$\begin{aligned} |z_b - z_{b'}|/[2 + 2r(b, b')]^{1/2} &\geq 1.960 = 16.05 \\ &\geq \chi_{2,05}^2 = 5.991 \end{aligned}$$

with the consequence that the two scores considered together indicate atypicality. This is interesting because, as discussed earlier, separate considerations did not indicate sufficient evidence of abnormality.

If one considers the size and shape characteristics based on the z -scores, then one obtains

$$|z_b + z_{b'}|/[2 + 2r_t(b, b')]^{1/2} = \frac{-0.58}{(2 + 1.64)^{1/2}} \approx -0.2$$

and

$$|z_b - z_{b'}|/[2 - 2r_t(b, b')]^{1/2} = \frac{2.42}{(2 - 1.64)^{1/2}} \approx 4$$

indicating that size is normal, whereas shape is abnormal, because the absolute value of the shape characteristic, 4, is larger than 1.960.

CONCLUSION

Pediatricians are often confronted with children of all ages who are referred for growth problems, such as growth retardation or dimorphism. Growth standards are therefore needed and one of the incentives of this article was to provide data that will give the possibility of discerning growth variation according to typical or atypical patterns. In other words, the child's growth deviation concerns only size or shape or both. It is customary to define shape by one or more ratios of measurements, such as height to sitting height. It should be realized that a simple ratio of two measurements is only one characteristic for shape. Moreover, when studying the typicality of particular individuals, it should be kept in mind that two ratios may be equal although there exist great differences between their nominators and denominators. Hence, one should not ignore size. This problem can be dealt with by defining typicality or atypicality by means of the squared distance D^2 .

If $D^2 > \chi^2$, the child is regarded as atypical but the cause of this atypicality can be discussed only by reconsidering the original scores b and b' or their standardized equivalents z_b and $z_{b'}$. If the size/shape representation based on $z_b + z_{b'}$ and $z_b - z_{b'}$ is used, then the interpretation of a significant result is immediate. In the example given here, a score of -0.2 was obtained for the standardized size characteristic and a score of approximately 4 was obtained for shape. Size is satisfactorily normal but shape is too large, which means that b is too large and/or b' is too small, when considered in relation to each other.

Body Weight, Body Composition, and Aging

Lyndon J. O. Joseph and Alice S. Ryan

University of Maryland School of Medicine and Baltimore VA Medical Health Care System, Baltimore, Maryland, United States

Glossary

body mass index (BMI) A practical measure of an individual's weight in relation to height. It is used to define overweight and obesity.

fat-free mass (FFM) Encompasses all of the body's nonfat tissues, including the skeleton, water, muscle, connective tissue, and organ tissues.

osteoporosis A condition characterized by low bone mass (density) and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture.

sarcopenia A condition characterized by an involuntary age-related decline in lean body mass, primarily due to the loss of skeletal muscle, that affects functional capacity and strength of older adults.

visceral fat (intra-abdominal fat) A portion of the internal fat in the abdominal cavity lining the intestinal tract.

One of the fastest growing segments of the population is individuals >65 years of age. This age group, which currently accounts for ~15% of the population, is expected to grow to between 19 and 25% by 2025. Increased body fat and loss of bone mineral density (BMD) and muscle mass are defining characteristics of the aging process. These changes in body composition occur as a result of normal aging, have a detrimental effect on health status, and have substantial economic consequences on the health care system. Obesity is associated with an increased prevalence of comorbidities, including cardiovascular disease, type 2 diabetes mellitus, hypertension, dyslipidemia, and other metabolic diseases. The decline in skeletal muscle mass is associated with weakness, functional disability, frailty, and morbidity, whereas the decrease in BMD increases the risk of bone fractures and ultimately results in high rates of disability, morbidity, and mortality in the elderly. This article discusses the classification and prevalence of overweight and obesity and the changes that occur during the aging process, with emphasis on body weight, fat mass, and fat-free mass and its constituents of skeletal muscle mass, total body water, and bone. These changes in body composition are also described in context with metabolic disease states.

CLASSIFICATION OF OVERWEIGHT AND OBESITY

Body mass index (BMI), a practical measure of an individual's weight in relation to height, is used to define overweight and obesity. A BMI between 25 and 29 kg/m² defines overweight in adults, whereas obesity is defined as a BMI ≥ 30 kg/m². These criteria are based on epidemiologic evidence that shows a strong association between a BMI >25 kg/m² and an increased incidence of cardiovascular disease, type 2 diabetes mellitus, hypertension, and dyslipidemia, which affect mortality and morbidity. Although BMI is simple to obtain, it does not differentiate between fat mass and lean muscle mass. Therefore, it can overestimate body fat in persons who are very muscular and underestimate body fat in persons who have excess fat and reduced muscle mass but normal body weight. Thus, other methods, such as hydrodensitometry, bioelectric impedance, and dual-energy X-ray absorptiometry, are used to determine body composition in research settings.

PREVALENCE OF OVERWEIGHT AND OBESITY

The National Center for Health Statistics examined the prevalence and trends of overweight U.S. adults from 1960 to 2000 via the National Health Examination Survey I and National Health and Nutrition Examination Surveys (I–III, continuous). The prevalence of overweight and obesity increased significantly during the 40-year period from 43% in 1960–1962 to 64.5% in 1999–2000. Most of this increase is attributable to a dramatic increase in the prevalence of obesity (BMI >30 kg/m²) that remained stable at ~15% for the first three survey periods (1960–1980) and then increased dramatically to 30.5% in 1999–2000. The increased prevalence of overweight and obesity in adults during this time period was evident in both genders, across all races and ethnicities, and across all age groups (Table I).

Table 1 Prevalence of Overweight and Obesity by Age, Sex, and Racial/Ethnic Group: United States, 1999–2000

| Sex | Age (years) ^a | Sample size | | | Prevalence of overweight (BMI ≥25) (%) | | | Prevalence of obesity (BMI ≥30) (%) | | | | | |

CHANGE IN BODY WEIGHT AND FAT MASS WITH AGING

In healthy people, body weight increases gradually from early adulthood until the fifth or sixth decade of life and then remains stable until age 65–70. During the period of weight gain, body weight increase occurs at a rate of 0.39–0.45 kg/year for women and 0.36–0.41 kg/year for men, irrespective of race. The slightly higher rate for women suggests that the transition from pre- to postmenopausal status affects the amount of weight gain. After age 60, body weight decreases slowly at a rate of 0.05–0.36 kg/year, depending on race and gender. The rate of decrease is usually higher in women than in men, regardless of ethnicity. Moreover, the rate of body weight decrease is highest in African American women and lowest in African American men. The variation in body weight regulation suggests that a nonlinear pattern of weight change occurs through the aging process.

The pattern of weight gain is generally consistent between cross-sectional and longitudinal studies and is characterized by a greater increase of fat than lean mass accounting for the increase in body weight. The relationship between age and body fat is curvilinear, with the greatest increase in body fat occurring in middle-aged persons and smaller increases occurring in both the young and the elderly. That is, there is a pattern of increasing fat mass with age until 50–69 years, followed by a slow decline in fat mass in older age groups (>70 years). Irrespective of the age group, 7–31% of the variation in the increase in fat mass (absolute or relative) in the adult population is accounted for by age.

The increase in weight with age is accompanied by an age-related redistribution of fat to the abdominal region. Sedentary women in their fifth decade of life have an average 1.5- to 3-fold higher visceral and subcutaneous abdominal fat area compared to their younger counterparts and athletes of similar age (Fig. 1). Similarly, older women athletes in the fifth and sixth decades of life have a 2- or 3-fold higher visceral fat area compared to younger athletes despite similar BMI and percentage body fat (Fig. 1). Therefore, there is an accumulation of fat in the abdominal region during the aging process irrespective of physical activity status. However, maintaining an active lifestyle partially negates the consequences of aging by dramatically reducing the amount of abdominal fat deposition. The ability to alter the accumulation of fat in the abdominal region is of clinical significance when one considers that intra-abdominal fat areas >100–110 cm² increase the risk

Figure 1 Intra-abdominal adipose tissue area determined by computed tomography in women athletes and sedentary women by age group. Significant differences ($p < 0.05$): *, 18- to 29-year-old women athletes vs 50- to 70-year-old women athletes; #, 18- to 29-year-old sedentary women vs 40- to 50-year-old sedentary women; ++, 40- to 49-year-old women athletes vs 40- to 50-year-old sedentary women; +, 18- to 29-year-old women athletes vs 18- to 29-year-old sedentary women. Adapted from Ryan *et al.* *Am. J. Physiol.* 271, E916–E921.

for developing cardiovascular disease and other metabolic diseases. The age-associated increase in visceral adiposity may contribute to the increase in triglyceride and total cholesterol concentrations and glucose intolerance with age.

An increase in the infiltration of fat around and within skeletal muscle occurs with aging and adversely affects glucose and lipoprotein metabolism. Computed tomography scans document a twofold increase in midhigh subcutaneous fat between pre- and postmenopausal sedentary women. There is also a twofold increase in low-density lean tissue, a marker of intramuscular fat. Approximately 27–33% of the variation in the increase in midhigh subcutaneous fat and low-density lean tissue areas in the midhigh region is accounted for by age. Aging studies on fat infiltration in leg muscles in men are lacking, but presumably a similar increase in intramuscular fat with age occurs. The contribution of intramuscular fat to the metabolic dysfunction associated with the insulin resistance syndrome may help explain racial differences in glucose metabolism.

CHANGE IN FAT-FREE MASS AND ITS CONSTITUENTS WITH AGING

As body weight and fat mass increase with aging, total fat-free mass (FFM) and its constituents (skeletal

muscle mass, body cell mass, total body water, and bone mineral mass) gradually decrease. Peak FFM is reached in the mid-thirties and then progressively declines. In females, FFM remains relatively stable until approximately age 50, after which the decline in FFM occurs at a slower rate than in males. The average loss of FFM is approximately 16% between ages 25 and 70 in both men and women at a rate of ~ 0.16 kg/year. Since skeletal muscle accounts for more than half ($\sim 55\%$) of total FFM, the decrease in skeletal muscle mass between ages 20 and 70 is slightly lower than the loss of FFM at 10–15%, with the rate of decline greater in men (0.8–1.9 kg/decade) than in women (~ 0.4 –1.1 kg/decade). Although FFM starts to decrease during the third decade, skeletal muscle mass is preserved until the fifth decade, with a noticeable decrease in absolute skeletal muscle mass occurring at ~ 45 years in both men and women (Fig. 2).

The involuntary age-related decline in FFM, primarily due to the loss of skeletal muscle, is called sarcopenia, and it affects functional capacity and strength of older adults. The prevalence of sarcopenia varies from 6 to 24% in persons younger than 70 years of age to $>50\%$ in persons older than 80 years of age, depending on the definition and measure of muscle mass. Sarcopenia is associated with a three- or four-fold increase in functional impairment, disabilities, and falls in the elderly.

The loss of skeletal muscle mass is strongly associated with a loss of body water because a large proportion of skeletal muscle (~ 75 – 80%) is water. Total body water (TBW) accounts for approximately 80% of FFM at birth. In young adults, TBW comprises approximately 72% of FFM. Thus, a loss of body water occurs until maturity but remains relatively constant throughout adulthood and middle age. On average, TBW is lower in females than in males. Losses of body water occur after age 70 in females and even more so in the very old. The decline in TBW suggests a change in the hydration of the fat-free compartment (increased with normal aging), although definitive conclusions are lacking.

In addition to the losses of FFM, skeletal muscle mass, and TBW with age, the loss of bone mass is consistently documented. Peak bone mineral mass is reached at age 20–30 years, followed by a progressive decline. By age 70, spinal and femoral neck bone mineral density (BMD) are diminished by

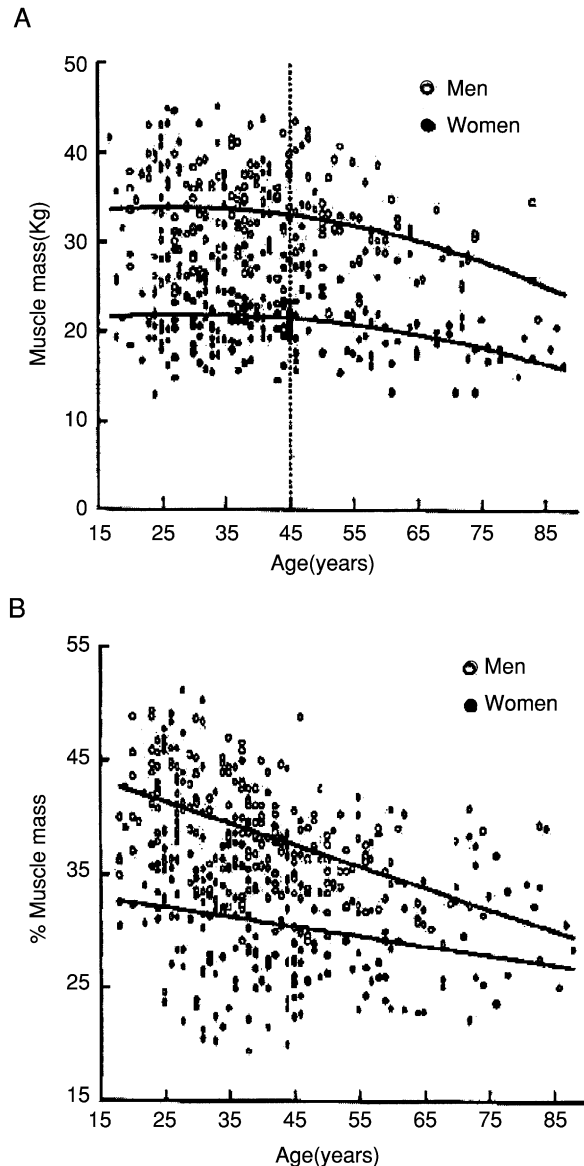

Figure 2 (A) Relationship between whole body skeletal muscle mass and age. (B) Relationship between relative skeletal muscle mass (body mass/skeletal muscle mass) and age. Adapted from Janssen *et al.*, *J. Appl. Physiol.* **89**, 81–88 (2000).

approximately 20 and 25%, respectively. Furthermore, the rate of bone loss varies with site and may be greater in areas with more trabecular bone than in those with predominantly compact bone. Total body mineral may decline at a slower rate than the decline observed in specific sites. In women, a more dramatic loss of bone mass occurs during menopause. The rate of BMD loss is greater among perimenopausal women compared to pre- and postmenopausal women and is site specific. Longitudinal studies estimate the rate of premenopausal BMD loss at 0.7–1.3% per year

at the lumbar spine and 0.2–0.3% per year at the femoral neck. In contrast, the rate of BMD loss for perimenopausal women is 2 or 3%/year at the lumbar spine and 0.6–1% per year at the femoral neck. The estimated BMD loss at the lumbar spine and the femoral neck is 1.3–1.5% and 1–1.4% per year, respectively, in postmenopausal women, with the fastest rate of bone loss occurring immediately after menopause.

The rate of osteoporotic fracture risk is higher in women than in men, such that the loss of BMD in the spine in men is two-thirds the rate in women and that at the femoral neck is one-half the rate in women. Despite these differences, an age-related increase in fractures associated with osteoporosis is evident in men as well. The slower rate of bone loss results in a lower prevalence of osteoporosis in men (~6%) compared to women (~20%), as well as an incidence of hip and vertebral fractures in men older than 65 years that is approximately half that of similar-aged women.

CONCLUSION

The changes in body weight and composition associated with aging have major public health implications. The increase in total and abdominal obesity usually observed during midlife is associated with increased risk for developing cardiovascular disease, type 2 diabetes, hypertension, dyslipidemia, and other metabolic diseases at an estimated cost of more than \$100 billion per year to the health care system. More important, approximately 300,000 deaths per year may be attributable to obesity. Osteoporotic fractures cost \$17 billion per year due to acute hospitalization and subsequent rehabilitation and, like obesity, increase morbidity and mortality (e.g., there is a 12% mortality rate during the first year after a hip fracture). However, structured programs that emphasize lifestyle behavior changes, such as proper nutrition, increased regular physical activity, and intentional weight loss, reduce the risk for developing metabolic and cardiovascular diseases. Moreover, caloric restriction to induce weight loss of 5–10%, aerobic exercise alone, and weight loss in combination with an aerobic exercise training program reduce the incidence of developing type 2 diabetes and improve the cardiovascular risk profiles of obese individuals. Aerobic and resistive exercise training programs >6 months

duration maintain or increase muscle and bone mass and may prevent the progression to sarcopenia and osteoporosis. Because epidemiologic studies document that the fastest growing segment of the population is individuals >65 years of age and an increase in the average life span, structured behavioral programs that include nutrition and exercise should be recommended to alter the adverse body composition changes observed with aging.

Bone Mass Measurement

Paul D. Miller

University of Colorado Health Sciences Center, Denver, Colorado, United States

Glossary

least significant change (LSC) The minimal change necessary between two measurements to be significant rather than a measurement error as defined by the precision error of the measurement. In bone densitometry, the LSC is defined by the *in vivo* precision error of repeated measurements multiplied by the confidence level desired to be certain that a change in bone mineral density (BMD) is real rather than due to a measurement error.

prevalence The percentage of the population being studied that is affected by a particular disease at a given time. In bone densitometry, prevalence is usually applied to the percentage of the population above or below a certain standard deviation cut-point from the mean BMD of the reference population.

risk The possibility of loss, injury, disadvantage, or destruction. In bone densitometry, risk is used to define either the relative or absolute risk of fracture at any given BMD value at a particular age.

The clinical application of bone densitometry is one of the advances in the field of osteoporosis that has led to increased patient awareness of this increasingly prevalent disease. Bone densitometry has made it possible for clinicians to diagnose osteoporosis before the first fracture has occurred and to predict risk for fracture in postmenopausal women, men, and patients receiving glucocorticoids. It can be used as a surrogate marker to follow the efficacy of therapies and to examine those patients that might be osteoporosis-specific therapeutic non-responders. Hence, there are three reasons clinicians perform bone mineral density (BMD) measurements: diagnosis using the World Health Organization criteria for osteoporosis, fracture risk prediction, and monitoring the natural progression of diseases that effect BMD or monitoring the therapeutic response to osteoporosis-specific treatments. This article examines each of these applications of bone mass measurements and provides principles of clinical application.

DIAGNOSIS

In 1994, the World Health Organization (WHO) selected a bone mineral density (BMD) cut-point for defining the prevalence of osteoporosis in the Caucasian postmenopausal female population. The main intent of the WHO committee was to assess the prevalence of low bone mass in the population and relate bone mass to the anticipated lifetime fracture risk in order to advise health policymakers of the potential medical and economic burden of osteoporotic fractures in this population. The use of standard deviation (SD) scores (*t* score) rather than absolute BMD in grams per centimeter squared was decided upon because of the known different absolute BMD calibrations that exist between the BMD measuring devices. A SD score mitigates some of the variance in absolute BMD measured by different manufacturer devices.

The WHO cut-point of $t = -2.5$ or lower used for the diagnosis of osteoporosis is based on a close association between prevalence at this cut-point and lifetime fracture risk of hip fractures or all fractures (hip, vertebrae, forearm, humerus, and pelvis). At the femoral neck, as assessed by the young, normal reference population database, 16% of postmenopausal women 50 years of age or older have a score of -2.5 SD or less, and the lifetime fracture risk after age 50 in postmenopausal Caucasian women is 16%. In addition, approximately 30% of this population has a score of -2.5 SD or less as measured at the hip, spine, and wrist, which approximates the lifetime fracture risk of all or global fractures after age 50. However, the relationship between low BMD and increased fracture risk is a gradient and not a threshold. Thus, the WHO created a separate classification, osteopenia, to recognize this gradient of risk and to help clinicians assess additional risk factors besides the level of BMD that may lead to increased fracture risk. In this regard, in the National Osteoporosis and Risk Assessment (NORA) dataset, although the 1-year fracture rates and relative risk for fracture/SD

reduction in BMD were highest at t scores of -2.5 SD or lower, the largest number of fractures in NORA, partially related to the larger sample size of the population with t scores between -1.0 and -2.5 SD, was seen in this osteopenic category.

Low BMD in the postmenopausal population assessed by any BMD device and by any database is predictive of an increased fracture risk if the value is low; this relationship is also seen in the multiethnic U.S. population. However, for various reasons, t scores obtained by peripheral devices may not always be as low as t scores determined from central DXA devices. The major reason for underdetection of osteopenia or osteoporosis is inconsistent young, normal reference population databases: Peripheral devices seem to underestimate the prevalence so that less people may be detected than would be by central DXA. The prevalence of WHO osteoporosis (<-2.5 SD) in the NORA dataset of postmenopausal women 50 years of age or older averaged 7% for all four peripheral devices combined; half of the prevalence was determined by measuring only the femoral neck. Thus, although a low peripheral BMD predicts an increase in fracture risk, any t score can only be predictive if the value is low. Thus, a normal peripheral BMD should be followed up with a central BMD measurement if the patient has additional risk factors that would lead the clinician to believe that there could be a low central DXA BMD.

Discrepancies between t scores from various BMD devices are well recognized, and they also exist between different skeletal sites using central DXA technology. Different peripheral devices yield different prevalences of WHO-defined osteoporosis or osteopenia. The development of a standardized young, normal reference population database would do much to mitigate t score discrepancies and unify the WHO diagnosis between central and peripheral devices. In addition, it has been shown that using a consistent young, normal database mitigates the t score discrepancies that exist between different devices (heel ultrasound, heel DXA, and hip DXA).

When a clinician must interpret different t scores obtained by different machines for a single patient, it is difficult to determine whether the patient has osteoporosis. Until the t score discrepancies can be resolved, the clinician must base his or her opinion on the evidence that the probability of a t score lower than -2.5 SD at the hip when the heel ultrasound measurement is higher than -1.0 SD is low ($<10\%$), and the probability of a hip t score being <-1.0 SD if a heel t score is 0 is also low. On the other hand, if the heel ultrasound is <-1.0 SD, the likelihood that a hip

score is <-2.5 SD is high (70%). In the absence of central DXA access, clinical decisions about risk assessment and interventions may be considered for patients 50 years of age or older if a peripheral t score is <-1.0 SD. Alternatively, if the physician is uncertain about a particular t score value and needs confirmation, central DXA should be performed, if available. Although there are approximately 15,000 central DXA devices in the United States, many urban elderly people or rural people of all age ranges have limited access to these "gold standard" devices.

The National Osteoporosis Foundation and the International Society for Clinical Densitometry (ISCD) have undertaken a joint project, called the t -score equivalence, to try to equate different t scores from different BMD devices. The fundamental concept behind this project is to select a device-specific t score cutoff that predicts the same 5-year hip fracture risk as that predicted from the femoral neck t score at -2.5 SD as determined by the National Health and Nutrition Examination Survey III (NHANES III) reference population database. NHANES III is the only consistent database in existence. It exists only for hip DXA measurements and is the default database for all central DXA manufacturers. Most of the data for t score equivalence are derived from the Study of Osteoporotic Fractures (SOF), one of the largest prospective epidemiological fracture studies in postmenopausal women in the United States. In SOF, at the age of 70 years, the 5-year hip fracture risk as determined at a t score of -2.5 SD at the femoral neck is 5%. Using the heel ultrasound device manufactured by Hologic, a manufacturer-specific database derived a t score at the same age of -2.0 SD. Hence, if a physician had only the Sahara heel ultrasound available and the patient (age specific) had a t score as determined on the Sahara that predicted the same hip fracture risk as if the patient had a hip DXA performed at a t score of -2.5 SD, this specific heel t score would be the value for the diagnosis of osteoporosis (i.e., for the 70 year-old example, -2.0 SD by ultrasound and -2.5 SD by femoral neck). In this way, the physician with a specific peripheral device can use a different t score cutoff point for the diagnosis of osteoporosis because it predicts an equal risk as a -2.5 SD by the femoral neck, as assessed by the NHANES III database. This short-term solution to the t score discrepancy problem is supported by the scientific community and the Food and Drug Administration (FDA) regulatory device division.

Despite some limitations, the t score equivalency project offers the best short-term answer to the clinical

application of the t score discrepancy problem. Abandonment of the t score has been suggested for all BMD devices and skeletal sites with the exception of the hip t score; all other skeletal sites and BMD/ultrasound technologies should be used only for fracture risk assessment. If we abandon the t score, what will replace it? Absolute BMD measurements in grams per centimeter squared also differ between BMD devices even for the same skeletal site and the same region of interest. This is true for both peripheral devices and central DXA devices. For example, the average BMD of the axial skeleton (L2–L4) in a healthy 20-year-old Caucasian women is 1.25 g/cm² by Lunar-GE and 1.00 g/cm² using a different device. These different BMD values are related to the different calibrations of the two manufacturers. Since there are so many devices that yield inconsistent absolute BMD values, there is no standardized BMD for all devices related either to prevalence or to fracture risk. However, there is a standardized BMD for the three central DXA devices for the spine and hip. This was developed by performing duplicate BMD measurements on 100 postmenopausal women and by the use of a linear regression to derive a mathematical equation that reduces much of the absolute BMD between the central DXA manufacturers. In the central DXA computer printout reports, the BMDs should automatically be calculated at the bottom of the page so the clinician can compare absolute BMDs between manufacturers. Although a standardized BMD helps in the serial monitoring of patients, there are no data relating BMD to fracture risk prediction. Furthermore, there are no BMDs for the wrist by central DXA or any of the multiple peripheral devices. After the universal, standardized database is completed for both the young, normal reference population database and the older population with and without spine and hip fractures on all FDA-approved devices, it will be possible to calculate a common standardized BMD value for different devices, with this standardized BMD number linked to fracture risk prediction.

PREDICTION

Both central and peripheral BMD devices can predict an increased risk for fracture. Risk approximately doubles for each standard deviation reduction in BMD in the postmenopausal population. However, the risk associated with low BMD is very dependent on the age of the patient. Risk is far greater as age increases. In fact, the risk for hip fracture is

approximately 45-fold greater at age 80 than at age 50, even at the same BMD or t score. Although some of the increased risk seen with advancing age may be related to an increase in falls, there are bone quality changes with aging that render a bone more susceptible to fracture at equivalent BMDs. Clinicians cannot capture these qualitative features with BMD devices.

The best documented application of peripheral technologies is fracture risk prediction. The first prospective observation documenting the ability of BMD technology to predict fracture risk was made in 1988 when forearm BMD was shown to predict an increased risk for nonspinal fractures in postmenopausal women. This study was followed by a large meta-analysis that documented the ability of multiple technologies, both peripheral and central, to predict an increased risk for vertebral, nonvertebral, and hip fracture risk. It has been suggested that the femoral neck is a more robust skeletal site for predicting the risk of hip fracture (RR/SD = 2.4). Although this suggestion is based on the SOF head-to-head hip/heel ultrasound device study, the hip fracture risk that was predicted in NORA using wrist or heel DXA was also 2.4, and the receiver operating characteristic (ROC) curves of the two peripheral devices used in NORA match the ROC curves seen with femoral neck DXA obtained from SOF. NORA was not a head-to-head comparison with hip DXA. Nevertheless, it appears that low peripheral device values in the postmenopausal population are powerful predictors of hip fracture risk in untreated postmenopausal women.

What about risk prediction in men and women of other ethnic groups? Data from head-to-head trials comparing fracture rates in Caucasian men and women indicate that both genders have the same absolute hip fracture risk at the same absolute BMD at the femoral neck and that both have the same 10-year absolute hip fracture risk at the same t score when the t score is derived from the female NHANES III reference hip database. These head-to-head comparisons, whether based on absolute BMD or SD scores, suggest that there may be no Caucasian gender differences in fracture rates, although there are clear differences in prevalence rates when calculating t score from a male vs female reference population database, as expected from the basic analysis of the t score equation. Small differences in the SD of the reference population database profoundly affect the subsequent t score calculation. Thus, when t scores are calculated from two different young, healthy reference population databases, they

invariably differ for the same patient. As mentioned previously, the only consistent young, normal reference population database for different BMD measurement devices is the NHANES III database for the central DXA hip.

The percentage of men with t scores < -2.5 SD at the femoral neck when the t scores are calculated from a male database is 6% and that from the female database is 4%. There are few differences between the two databases with regard to hip prevalence. Thus, when considering only the hip, the small differences in prevalence between the two genders using NHANES III databases will not miss many men at risk. On the other hand, when the prevalence of osteoporosis by WHO criteria is determined in men from a male or a female database by using the spine, wrist, and hip measurements, it is 19% when the t score is calculated from a male database and 6% when calculated from a female database. Thus, when t scores are calculated from a female database, men are underdiagnosed if the clinician examines multiple skeletal sites. Therefore, the number of men determined to be at risk for fracture is underestimated when all three central DXA-measured skeletal sites are combined if a female reference population database is used. It is for this reason that the ISCD Position Development Conference recommended that gender-specific reference databases be used to calculate t scores. Head-to-head trials examining volumetric BMD (that takes bone size into account) and areal BMD assessed by DXA (that does not take bone size into account) with fracture outcomes are required to determine if there are differences in fracture risk between the genders as a function of bone size. Preliminary data, however, suggest that men may fracture at the same volumetric BMD as women.

In contrast to the equal prevalence of vertebral fractures between men and women, a longitudinal study of incident vertebral fractures in Caucasian men vs women suggested that incident fractures are twice as frequent in women as men. The reason for this difference is unknown since there are only three known risk factors: age, BMD, and the prevalence of vertebral fracture.

The NHANES III reference database provides the only head-to-head ethnic comparison in which both t and z scores are calculated from both gender- and ethnic-specific databases for prevalence comparisons. Ethnic-specific databases were calculated from Caucasian, Hispanic, and African American male and female populations ranging in age from 20 to 80 years. There are no Asian populations in the NHANES III database. In this robust study,

there are clear prevalence differences when t or z scores from different ethnic groups are calculated from a non-ethnic-specific database. However, no fracture data correlate with the t or z scores from the NHANES III database. Hence, there are no data regarding whether there are differences in fracture rates as a function of the ethnicity-derived t scores from this valuable dataset.

The only multiethnic head-to-head prevalence and fracture data derive from NORA, in which all SD scores were calculated from the Caucasian female reference population database. The RR/SDs for global fractures are similar between Caucasians, American Hispanics, and Native Americans and lower for the American Asian and African American populations. On the other hand, the fracture rates across all ethnicities at t scores < -2.5 SD are very similar. In the WHO-defined osteopenic category in NORA, American Asians had an unexpectedly low rate of fracture events. The reasons for this are unclear. However, because all of the risk calculations in NORA were done using a Caucasian female reference population database and fracture rates were not too dissimilar across ethnicities, at least for the U.S. multiethnic female postmenopausal population, it might be acceptable to calculate risk from a Caucasian female database, regardless of ethnicity. Native Chinese have a lower hip fracture risk (but similar vertebral fracture risk) despite having a much lower absolute BMD, even after adjusting for body mass index. It is possible that in the United States, lifestyle, nutrition, or even some elements of gene pool mix may result in non-Caucasian ethnic groups having the same fracture risk as Caucasians. Until there are ethnic-specific databases for all BMD manufacturers and prevalence data are linked to risk assessment, the ISCD suggests using ethnic-specific databases for t score calculation. However, if a physician uses a BMD device without any ethnic-specific database, the Caucasian database can be used for risk assessment.

MONITORING

The surrogate endpoint markers for monitoring the efficacy of osteoporosis-specific agents are changes in BMD and changes in biochemical markers of bone turnover. Both of these surrogate markers have their proper place in clinical management, although neither is a perfect indicator of pharmacological response or nonresponse to therapeutic interventions to anti-resorptive agents. The prevention or reduction of

fractures is the ultimate goal of treatment. However, none of the osteoporosis-specific agents eliminate fracture risk. Hence, the occurrence of another (i.e., vertebral) fracture while on antiresorptive agents does not necessarily mean that the patient has not had a pharmacological effect of antiresorptive treatment. On the other hand, clinicians are uncomfortable about waiting for another fracture event in order to define treatment effectiveness; thus, the use of surrogate markers to assist therapeutic strategies is analogous to lowering blood pressure or cholesterol to measure treatment effect of antihypertensive or cholesterol-lowering agents.

The surrogate markers for osteoporosis-specific therapies are BMD and biomarkers of bone turnover (BCM); there is increasing evidence for the latter's clinical application. Since most data exist for changes in BMD and BCM with antiresorptive agents, this section emphasizes these two surrogate markers.

Although the FDA requires proof of a significant 3-year vertebral fracture reduction for registration of PMO osteoporosis-specific therapies, the FDA has approved both the once-a-week alendronate and the once-a-week risedronate formulations not based on any prospective-derived fracture data but on evidence that these weekly formulations increase BMD and reduce BCM to equivalent degrees as daily dosing. Hence, the FDA acknowledges that these surrogate markers for bisphosphonates cause improvement in bone strength and a reduction in fracture incidence. Since the once per week bisphosphonate registration has been done with no adequately powered fracture benefit, trust in these surrogate markers is the underpinning for confidence in drug effect. Thus, these FDA registrations are based on the assumption that daily dosing of bisphosphonates must be equivalent to weekly dosing. However, to the extent that the bone half-life may not reflect the bone biological, functional, bisphosphonate half-life, and because the bone binding and alteration in activation frequency of bisphosphonates differ between amino bisphosphonates, these assumptions may or may not be entirely valid.

In addition, there is evidence that bisphosphonates alter bone microarchitecture and, in part, their improvement in bone strength might be unrelated to their capacity to improve BMD or reduce BCM and bone turnover. In this regard, several studies have examined the relationship between the changes in BMD and/or BCM and the magnitude of reduction in either vertebral or nonvertebral incident fractures by robust meta-analysis of randomized, controlled clinical trials. In general, the meta-analyses are

in agreement that a portion (24–54%) of the risk reduction of antiresorptive agents can be attributed to the increase in BMD. Also, these meta-analyses are in agreement that there is an approximately 24% reduction in vertebral fracture risk at the intercept (no change in BMD), indicating that other non-BMD mechanisms play a role in the improvement in bone strength. The meta-analysis of the relationships between the changes in BMD and BCM due to antiresorptive agents and the reduction in nonvertebral fractures shows that all of the effects of antiresorptive agents that reduce the incident of nonvertebral fractures can be attributed to either the magnitude of increase in BMD or the magnitude of reduction in BCM of bone turnover. In this meta-analysis, risk reduction related to either the increase in BMD or the reduction in BCM could not be distinguished because the adjusted variances that the components contribute to risk reduction are so similar. Since the bisphosphonates are the only antiresorptive agents that show reductions in vertebral, nonvertebral, and hip fracture rates, and because they are the only agents that produce large increases in BMD in nonspine sites or a reduction in BCM that might be necessary to cause a reduction in the risk of nonvertebral fractures, the meta-analyses provide evidence to support their therapeutic effect at nonvertebral sites. By reducing bone turnover, there may be microarchitectural changes in bone that might not be reflected in BMD measurements that lead to increased bone strength. Alternatively, the areal BMD measurements that are routinely used in bone densitometry may underestimate the real magnitude of BMD increases. Areal BMD by DXA is a derived equation: $BMD = BMC/area$. The bone area may increase without any change or a small change in BMC; thus, the calculated BMD would decline, not necessarily due to any reduction in BMC but due to an increase in bone area. Evidence for this effect of bone area on calculated BMD derives from studies measuring changes in areal BMD by DXA vs quantitative computerized tomography (QCT), which measures the true bone mass and volumetric changes in bone mineral content. QCT changes were larger than DXA changes in this intermittent PTH study, even though BMC increased in both, suggesting that areal BMD measurements may underestimate the change in BMD. Nevertheless, areal BMD at both baseline and longitudinal over time reflects both the basal bone strength as it relates to fracture prediction and the improvement in bone strength as it relates to changes in BMD that are induced by antiresorptives.

CONCLUSION

Serial BMD has come under scrutiny as a means of monitoring therapy in patients receiving antiresorptive agents. Skepticism is more a function of the performance of the DXA measurement as well as the clinical interpretation. For a clinician to know with certainty that a change in BMD between two measurements in an individual patient is real as opposed to an inherent measurement error of the DXA device or an error of the researcher performing the test, the *in vivo* precision error for the DXA site must be known. Performing daily phantom (*in vitro*) scanning is important in order to detect a “drift” in serial BMD values that may indicate the need to obtain manufacturer assistance to search for problems that affect machine performance, such as X-ray tube viability and software deterioration. However, phantoms do not move, whereas patients do. For a DXA facility to determine whether differences are due to the machine or biological, *in vivo* precision studies must be performed. The basic principle is to determine the *in vivo* coefficient of variation % (CV%) between multiple measurements, which allows the physician to determine whether the difference between two measurements is within or beyond the least significant change (LSC). If the independent precision error is not known for a DXA site, changes in BMD may be assumed to be significant (or nonsignificant) when in fact they may not be. For example, when the spine BMD increases slightly (~2%) and the total hip BMD decreases (~4%), DXA reports often indicate that the patient is nonresponding when in fact the precision error at the total hip is ~2%, requiring at least a 5.6% change in BMD to be significant. Unfortunately, when the BMD change is within the LSC but misinterpreted to be significant, many patients are often taken off therapy or their therapy is changed. The densitometry community has set a standard requiring a 95% confidence limit for determining whether a difference between two BMD measurements in an individual patient is significant. Using this standard, the change in BMD must be 2.77 times the CV% (precision error). Hence, *in vivo* precision studies must be performed to competently interpret BMD differences between two measurements.

None of the peripheral devices show changes in BMD between measurements in patients on antiresorptive therapy. This is not due to precision error differences between central and peripheral devices because these devices have similar errors. For reasons that are unclear, none of the peripheral technologies have shown BMD changes in any antiresorptive

clinical trials. In fact, there was a loss of forearm BMD in patients in an anabolic trial using teriparatide, which might be an artifact of the areal DXA measurement in which the bone area is increased by subperiosteal bone apposition. As measured by peripheral QCT in the teriparatide dataset, bone size increased, as did bone strength. Hence, with regard to monitoring BMD with teriparatide, areal (especially spine) DXA and QCT may be complimentary. However, one of the frustrating aspects of bone densitometry is the inability to monitor pharmacological therapy with peripheral devices, whereas they can be used quite appropriately to assess risk. Until improved methodology allows peripheral devices to be used for monitoring therapy, the physician has three choices when starting osteoporosis-specific therapy:

1. Do not monitor.
2. Use axial (central) DXA to obtain a baseline for monitoring since this is the preferred methodology for monitoring osteoporosis-specific therapies.
3. Use BCM of bone turnover to assess the bone biological response to the antiresorptive agent. Data suggest that if there is at least a 40% decline in urinary collagen cross-link markers 1–3 months after initiating a bisphosphonate, there is a greater likelihood that the 2-year follow-up repeat DXA will increase or at least not decline. In addition, data on the relationship between the magnitude of increase in BMD and the magnitude of decrease in BCM with the various antiresorptive agents suggest that the greater the decrease in BCM, the greater the risk reduction in vertebral as well as nonvertebral fractures. The strength of this relationship was as powerful as the strength of the relationship between the changes in BMD and the risk reduction. Hence, if a BCM declines adequately, a fracture-reduction benefit can be anticipated.

No professional scientific organization recommends substitution of BCM for DXA as a means of monitoring therapy. The two should be complimentary. The advantage of the 1- to 3-month BCM assessment is that it provides earlier feedback to the patient and the clinician: If it does decline below the LSC for BCM, then the following clinical assumptions are fair: The patient is taking the drug, the fastidiously absorbed oral bisphosphonates are being absorbed, and there is evidence for a bone biological effect.

Last, it is important to address the issues of “nonresponders” as measured by BMD and the principle of regression to the mean as it has been applied to clinical osteoporosis management. From clinical trials, it is assumed that the response rate

to bisphosphonates exceeds 90%. Clinic patients differ from clinical trial patients. Clinical trial patients are carefully selected. They have no secondary diseases affecting bone, nor are they taking other drugs that might alter bone metabolism. Clinical trial patients are highly motivated and have frequent compliance (i.e., pill-count) checks. The real-world response rate to osteoporosis-specific therapies is unknown.

Regression to the mean is an old statistical observation. It has been used in BMD testing to examine the change from pretreatment baseline in two pharmacological clinical trials of postmenopausal osteoporosis. This study stated that those patients treated for the first 2 years of these trials who either lost or gained bone during the first year subsequently either gained or lost bone during the second year, such that when the two data points were regressed to mean values, there were no differences. The study suggested that measuring BMD over time may not have meaning for those patients who gain BMD during the first year and lose it during the second year and those who lose it during the first year and gain it during the second year. One scientific flaw of these data is that it is a statistical fact that regression to the mean occurs in all biological measurements, especially at the extremes of a distribution, such that values that are high subsequently decline and those that are low subsequently increase due to regression to the mean in both treated and control groups. In addition, the control group data were not shown; in order to determine whether regression to the mean has any real meaning, the differences between the treated and nontreated groups at the regression point must be shown. Regression to the mean can never be applied to individual patients since it is always a group phenomenon seen at the extremes of distribution.

Serial BMD and increases in BMD while on osteoporosis-specific therapy are a valid surrogate marker of assessing improvement in bone strength. BMD increases account for a significant proportion but not all of the fracture risk reduction seen with antiresorptive agents.

BMD testing has allowed clinical application in diagnosis, risk prediction, and monitoring of disease or therapy. Without BMD availability, the field of osteoporosis would be relegated to guesswork. However, like all biological measurements, BMD testing at baseline and/or longitudinally is imperfect. Only competent clinical judgment and subsequent interpretation of bone mass measurement performance and data will allow this important quantitative technology to remain an important clinical tool.

Bone Remodeling, Dynamics of

Susan M. Ott

University of Washington, Seattle, Washington, United States

Glossary

activation frequency The frequency at which a particular point on the bone surface will be reached by a basic multicellular unit.

basic multicellular unit (BMU) A group of osteoblasts and osteoclasts that resorb a volume of bone and replace it with new bone.

bone mineral density The weight of mineral per volume of bone tissue.

bone tissue The total material found within a bone, including the bone marrow, fat, mineralized bone, and unmineralized osteoid.

bone turnover An ambiguous term that is either the bone formation rate or the bone resorption rate and is meaningful only when these rates are equal.

bone volume The bone material, including mineralized bone and unmineralized osteoid.

mineral apposition rate The rate at which mineral is deposited at a discrete point on the bone surface; expressed in micrometers per day.

mineralization density The weight of mineral per bone volume.

osteoid Newly formed bone, composed primarily of lamellar collagen with small amounts of other bone proteins and glycoproteins, that forms a matrix that can accept deposition of hydroxyapatite crystals and that will become mineralized bone.

wall thickness The thickness (in three dimensions) of a completed volume of new bone, measured perpendicularly from the interface with the bone marrow.

Bone remodeling is a physiological process in which bone is resorbed and replaced with new bone. It occurs in millions of discrete locations within the bone, with an overall effect of continuous bone renewal.

INTRODUCTION

Bone is such a solid substance that an orthopedic operating room resembles a carpenter's workshop, with its saws, drills, screws, and hammers used to repair broken and damaged furniture. This reinforces the concept that bones are mechanical structures; indeed, one of the major functions of the skeleton is to support the rest of the body. The dynamic properties of the bone, however, are seldom considered, except to acknowledge that living bone, unlike the leg of a table, can repair a fracture. Actually, the bone is continually remodeling, responding to external stresses and internal signals. When bone remodeling is not in balance, osteoporosis results. Most pharmaceutical agents that improve bone strength act by altering the bone remodeling sequence.

BASIC MULTICELLULAR UNIT

A fundamental property of bone remodeling is that it occurs in discrete locations and involves a group of different kinds of cells. This secondary level of organization, analogous to the nephron, was named the basic multicellular unit (BMU) by Harold Frost. Unlike a nephron, a BMU is not a permanent structure. In cancellous bone, the BMUs travel along the bone surface, spreading over an area. In the cortical bone, they tunnel through the bone, with the osteoclasts at the cutting edge and newly formed bone in the wake.

At any moment, ~20% of the cancellous bone surface is undergoing remodeling, and at any point on the surface remodeling will occur on average every 2–4 years. This rate is the activation frequency.

The cells in a BMU are osteoclasts and osteoblasts. The individual cells in a BMU have shorter active life spans than that of the BMU; osteoclasts and osteoblasts are formed from precursor cells and undergo

apoptosis, with replacement by new cells. Some of the osteoblasts differentiate into osteocytes or lining cells that remain in the newly formed bone. Other cells, including bone marrow stromal cells, bone marrow adipocytes, nerve cells, and vascular endothelial cells, can influence the BMU but are not actively resorbing or forming bone.

Each BMU performs its functions in the same sequence: origination and organization of the BMU, activation of osteoclasts, resorption of old bone, recruitment of osteoblasts, formation of new bone matrix, and mineralization (Fig. 1). Many of the details of this sequence have been elucidated by Michael Parfitt, and measurements of the timing of each phase were done by Erik Eriksen.

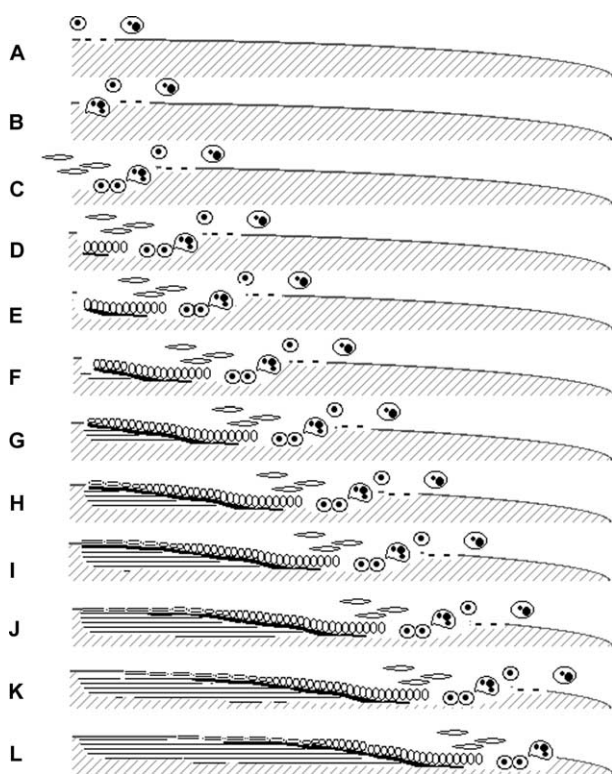

Figure 1 The basic multicellular unit (BMU), moving along a cancellous surface. Each step represents approximately 10 days, and the BMU moves approximately $10\ \mu\text{m}$ each day. (A) Origination of BMU: lining cells contract to expose collagen and secrete RANK ligand. (B) Osteoclasts fuse into multinucleated cells that resorb cavity. (C) Mononuclear cells continue resorption, and preosteoblasts are stimulated to proliferate. (D) Osteoblast team forms at the bottom of the cavity and starts forming osteoid. (E) Osteoblasts continue forming osteoid (●) and previous osteoid starts to mineralize (horizontal line). (F–H) Osteoblasts continue formation and mineralization. (I and J) Osteoblasts begin to flatten. (K and L) Osteoblasts turn into lining cells; bone remodeling at initial surface (left of drawing) is now complete, but BMU is still advancing (to the right).

SEQUENCE OF BONE REMODELING

Origination

There is debate about which factors are the most important for initiation of new BMUs. Small cracks caused by microdamage will initiate a BMU. Signals from osteocytes or lining cells that have detected mechanical stress, local cytokines from marrow cells, or systemic hormones that regulate mineral metabolism may also initiate a BMU. Possibly, the BMUs commence at random.

Mori and Burr demonstrated an association between fatigue damage and intracortical remodeling. They anesthetized mature dogs and applied a cyclic load to the radius, which caused asymptomatic microscopic cracks. Eight days later, an identical load was applied to the opposite radius. Histologic sections showed an equal number of cracks on each side. However, at the site with the earlier load, there was a significant increase in resorption cavities that were adjacent to the cracks. The temporal design of the study demonstrated that the resorption occurred after the fatigue damage.

Origination occurs only once for each BMU at a quiescent surface of the cancellous bone or on a surface nearest a crack in the cortical bone. Lining cells change their shape from that of flat, epithelial-like cells to rounded cells, thereby exposing some of the collagen matrix. They also secrete collagenase to expose the bone mineral. These activated cells then produce RANK ligand, which binds to receptors on preosteoclasts and causes them to fuse and become mature multinucleated osteoclasts. In the cancellous bone, some of the lining cells appear to form a layer or canopy that separates the bone marrow from the resorbing bone.

Activation

Activation is a continuing process that occurs at the cutting edge of the BMU, and as the BMU spreads, new surfaces undergo activation. The BMU “front” travels at a rate of approximately $10\ \mu\text{m}/\text{day}$ and is followed by osteoblasts and, in the cortex, a new blood vessel. The original osteoclasts undergo apoptosis while the BMU is still progressing; thus, new cells must replenish the dying ones. Where do the replacement osteoclasts come from? Systemic hormones, growth factors, and interleukins may enlarge the precursor pool, but systemic factors cannot localize the preosteoclasts to the cutting edge. The new vascular cells may determine when circulating osteoclasts

should enter the tissue. It is not clear how the replacement osteoclasts are formed from preosteoclasts, but this probably involves RANK ligand from either adjacent lining cells or osteoblasts within the BMU.

Resorption

There are two phases of resorption. The first is the most rapid, carried out by multinucleated osteoclasts, and lasts ~8 days. Then a slower phase occurs that involves mononuclear cells and lasts ~34 days. Multinucleated osteoclasts are active for ~12 days and then undergo apoptosis. This process may be promoted by transforming growth factor- β (TGF- β). The suicidal cells have been located at the junction between the resorbing surface and the reversal surface, which suggests that the process might also be involved in signaling new osteoblasts. Osteoclasts have been shown to excrete interleukin-6 (IL-6) and annexin-II, both of which may signal new osteoblasts. The depth of the eroded cavity is also linked to the life span of the active osteoclasts so that early apoptosis will result in a shallower eroded cavity.

During resorption, bone-derived growth factors are released, including TGF- β , insulin-like growth factor (IGF), and fibroblast growth factor (FGF), which were deposited into the matrix by the previous generation of osteoblasts. Some, such as TGF- β , may be activated by the acid environment caused by osteoclastic proton secretion. These growth factors (delayed autocrine factors) might account for the coupling between resorption and formation that is seen in normal situations, but direct evidence for this theory is lacking. High correlations between total skeletal resorption and formation may also be seen if the biochemical stimuli (e.g., IL-6) for origination of BMUs also participated in the recruitment of osteoblasts.

Formation

After the maximum eroded depth has been achieved, there is a reversal phase that lasts ~9 days. During this phase, the osteoblasts converge at the bottom of the cavity. The osteoblasts derive from precursors in the marrow stromal cells, which can differentiate into either osteoblasts or adipocytes, depending on the transcription factor *Cbfa1*. The team of osteoblasts then begins to form osteoid. After 15 days, the osteoid begins to mineralize. The osteoblasts continue to form and to mineralize osteoid until the cavity is filled or nearly filled, which takes 124–168 days at any point on the surface.

At the bottom of the cavity, the new osteoblasts are plump and vigorous, have tall nuclei, and make a thick layer of osteoid. The cells then gradually flatten as they slow production, and finally they become quiescent lining cells. Some of the osteoblasts differentiate into osteocytes and remain in the matrix. The osteocytes may secrete inhibitory factors that slow the rate of bone formation as the resorbed cavity is nearly filled. As the BMU progresses, new osteoblasts are added, but only at the edge behind the osteoclasts.

The density of the osteoblasts at the formation site may vary. When the cells are more crowded, they are taller and narrower, and they collectively can make more osteoid than when there are fewer cells. Osteoporotic patients have the same rate of osteoid production per cell, but overall the wall thickness is decreased and the amount of newly formed bone is inadequate to fill the resorbed cavity. Some investigators think that bone formation is discontinuous (on and off), but studies with tetracycline labeling suggest that the osteoblast team does not take vacations.

Mineralization

Mineralization begins ~15 days after osteoid has been formed. In most situations (except in the case of osteomalacia), the average rate of osteoid formation and the rate of mineralization are the same and are measured by tetracycline labels.

After the BMU has completely restored the bone volume, the mineralization density continues to increase as the crystals become more densely packed (Fig. 2). It is not known how long it takes to reach the maximum mineralization density, but indirect evidence suggests this takes approximately 3 years.

The mineralization density is related to the bone formation rate. When the bone formation rate is high, mineralization density is low. When the bone formation rate is low, more of the bone is older and more highly mineralized.

CONTROL OF BONE REMODELING

Mechanical Stress

The osteocytes and lining cells form a network that allows direct cellular communication. They are ideally located to detect mechanical stress. The osteocytes secrete factors such as IGF that probably lead to origination of a BMU.

Figure 2 Electron backscattered image of iliac cortical bone showing two new osteons, with plot profiles taken along the white lines. The line A profile shows that density is low in the newly formed osteoid (dark gray) and gradually increases as the bone becomes older (toward the left). The line B profile shows an abrupt change from the Haversian canal space to the bone; this line crosses a surface of bone resorption. The downward spikes in the plot profiles represent the osteocyte lacunae. Near the end of line B (right), there is higher mineralization after line B crosses the cement line into an area of older bone, which appears whiter on the image.

Growth Factors and Cytokines

Locally produced cytokines, such as IL-1,-6, and-11, can stimulate the lining cells and osteoblasts. Growth factors such as TGF- β , FGF, bone morphogenic proteins, platelet-derived growth factors, and colony-stimulating factors can increase proliferation of osteoblasts or preosteoblasts. Osteoprotegerin, which is a decoy receptor for RANK ligand, is produced locally by osteoblasts and can inhibit the fusion of preosteoclasts.

Hormones That Regulate Mineral Metabolism

Parathyroid hormone (PTH) and PTH-related protein can activate lining cells to secrete RANK ligand and originate a BMU. PTH may also affect osteoblast proliferation. When given as intermittent injections, it can bypass the bone remodeling system and stimulate bone formation directly on quiescent surfaces. PTH-related protein causes increased bone resorption and loss of bone during lactation.

Vitamin D can also activate lining cells to secrete RANK ligand. It increases the proliferation of preosteoclasts and may play a role in osteoblast recruitment. Indirectly, it is important in the maintenance of serum mineral levels.

Calcitonin receptors are present on osteoclasts, and when activated, the cells stop resorbing bone. The calcitonin gene-related protein appears to increase bone formation, but the mechanism is not clear.

Estrogen exerts a major effect on bone remodeling, possibly through different mechanisms. Estrogen can inhibit IL-6 production, which reduces bone resorption. The sensitivity of lining cells to mechanical stress depends on the estrogen levels. Estrogen also controls the timing of osteoclast apoptosis so that estrogen deficiency results in a longer life span of the osteoclasts.

Vasculature

Each BMU is associated with a capillary. In cortical bone, the capillary grows along the excavated tunnel. On trabecular surfaces, small capillary-like structures are frequently seen adjacent to the osteoblasts. The cells that form these structures have characteristics that are unlike endothelial cells and resemble lining cells. In addition to supplying nutrients and a source of precursor cells, the vasculature may help direct the localization of the BMU.

Nerves

Anatomic studies have documented a dense and intimate innervation of bone tissue. The fibers contain markers for neural tissue, both sensory fibers and sympathetic fibers. Nerve endings are seen in contact with bone cells. Glutamate is expressed in the fibers that are in proximity to bone cells, suggesting a potential role of glutamatergic innervation in the bone remodeling process.

Recent evidence has demonstrated a role for the central nervous system in the control of bone formation rates. Leptin injected into brains of mice causes a substantial decrease in bone formation rates at doses that do not affect body weight. These effects appear to be transmitted by the sympathetic nerves.

Adipocytes

Adipocytes and osteoblasts derive from the same precursors, and factors such as lipid levels can favor differentiation into adipocytes, which will reduce the number of available osteoblasts. The adipocytes

also secrete leptin, but the ability of leptin to either stimulate or inhibit bone formation is still debated.

BONE REMODELING IN OSTEOPOROSIS

When the bone resorption rate is higher than the bone formation rate, the bone volume will decrease, resulting in osteoporosis. The balance between formation and resorption is more important than the rate of either one alone. Thus, postmenopausal osteoporosis is a heterogeneous disorder, with either high or low bone formation rates. Menopause is associated with an increase in the origination of BMUs, possibly because estrogen deficiency results in increases in IL-6 and other cytokines. Also, longer osteoclast life span results in more bone resorption. This alone does not necessarily cause loss of bone mass, but each BMU does not completely replace as much bone as was resorbed.

With aging, the osteoblasts lose their ability to fill the resorbed spaces. This is shown by age-related decreases in the wall thickness. When bone porosity increases, the remaining bone accumulates microdamage at an exponential rate. A vicious cycle is begun: Bone mass decreases, so the remaining bone is subject to more fatigue damage that increases bone resorption, which may further weaken the bone and disrupt the osteocyte network.

Understanding bone remodeling is important for predicting the response to therapeutic agents used for osteoporosis. Antiresorptive agents (estrogen, bisphosphonates, risedronate, and calcitonin) all decrease bone resorption, but they also decrease bone formation. The more potent amino bisphosphonates decrease the tetracycline-labeled bone formation rate by ~95%. Small increases in bone volume occur while the BMUs that were forming bone continue to fill in the eroded cavities. Eventually, a new steady-state bone volume is reached, after which there is no further gain in bone volume because bone remodeling has been inhibited. Bone density will increase even after bone volume has reached a steady state because the mineralization density continues to increase. Women taking bisphosphonates have increasing bone density at the hip for ~3 years; thereafter, the bone density does not increase further. The long-term (>7 years) consequences of prolonged suppression of bone formation rates are not known, but potentially fatigue damage and microcracks could accumulate.

Intermittent PTH is an anabolic agent that increases both bone formation and resorption, but the balance is positive, with large increases of bone

density. Mineralization density decreases because a larger proportion of the bone is newly formed. Therefore, intermittent PTH has a completely different mechanism of action from that of antiresorbing agents. It is hoped that research on combinations or the sequential use of anabolic and antiresorbing agents will yield new treatment regimens that will prevent more fractures than the current treatments.

OTHER MECHANISMS OF ALTERING BONE STRUCTURE

Microcallus Formation

When trabeculae fracture, a microcallus can form that resembles the familiar "macrocallus" of a fractured bone. These microcallus formations in the spine increase after age 50, mostly in the lower thoracic and lumbar spine near the endplates. There are more in females than in males and even more in osteoporotic persons. These formations can account for up to 10% of the trabecular bone volume. Microcallus formations can allow creation of new trabeculae by forming bridges between existing trabeculae. They undergo resorption and modeling, eventually becoming mineralized and indistinguishable from trabecular bone. This mechanism of altering trabecular structure could be relatively important in patients with osteoporosis.

Direct Activation

In some situations, bone formation can also occur along surfaces in the absence of previous resorption. With fluoride therapy, bone formation surfaces increase markedly, but the bone is woven and not normal lamellar bone. Beagles treated with aluminum show new bone formation in some, but not all, experimental conditions, but this phenomenon is not seen in humans, who develop osteomalacia when exposed to parenteral aluminum. Intermittent PTH causes increases in the bone formation rate that occur too soon to be explained by the bone remodeling cycle. Measurements of the distance from new bone edges to cement lines also suggest that previously quiescent surfaces start to form bone.

Bone Arising from the Marrow Space

Patients with metastatic prostate cancer can develop osteoblastic lesions within the marrow spaces. First, spindle-shaped cells with characteristics of osteoblasts appear in the marrow spaces adjacent to the cancer

cells, and then these calcify and become woven bone. The bone eventually becomes osteosclerotic.

Periosteal Bone Formation

The periosteal surfaces of cortical bone gradually expand throughout adult life. This compensates for loss of bone tissue because bone with a larger diameter has greater bending strength. Periosteal expansion occurs without prior bone resorption. In some cases, when there have been repetitive stresses on the bone, woven bone will form at the periosteal surface. This has been noted, for example, in young military recruits during basic training. The woven bone can be formed more rapidly than the lamellar bone formed during usual bone remodeling.

Bone Structure

Paul R. Odgren, Alison Gartland, April Mason-Savas, and Sandy C. Marks, Jr.[†]
University of Massachusetts Medical School, Worcester, Massachusetts, United States

Glossary

compact bone Solid, dense bone, such as that found in the shafts of the limb bones or the vertebral bodies (see trabecular bone), also called cortical bone when it occurs in the bone shaft, or lamellar bone due to its highly organized layers of collagen fibrils.

diaphysis The cylindrical shaft of a long bone composed of cortical bone and enclosing a marrow cavity.

epiphysis The region at the end of a long bone, often enlarged in a knob that is covered with articular cartilage and that transmits mechanical load from the joint to the rest of the bone.

Haversian system In large mammals, including humans, microscopic, concentric rings of bone organized around central canals containing small blood vessels.

metaphysis The region where a long bone flares between the cylindrical shaft to the broadened epiphysis that contains trabecular bone and is a site of metabolic activity; also called the primary spongiosa.

osteoblast Bone-synthesizing cell residing on the surface of bone and secreting type I collagen-rich protein matrix and vesicles that contain the mineral components of bone.

osteoclast Large, multinucleated bone-resorbing cell that forms by the fusion of mononuclear precursors of the monocyte lineage and attaches to bone, releasing degradative enzymes and absorbing the digested bone.

osteocyte Mature bone-forming cell that is completely surrounded by bone matrix, remaining in contact with the circulation and other bone cells via a dense network of cytoplasmic processes that permeate the surrounding bone.

trabecular bone Bone comprising an open network of fine spicules; also called spongy bone; occurring internally within skeletal elements, e.g., near the ends of the long bones and in the pelvis and vertebrae.

Contrary to common perception, bone is a complex and dynamic tissue throughout life. It plays critical roles in both mechanical support and mineral homeostasis, and its macroscopic and microscopic structure vary widely at different sites to reflect these functions. Specialized cell types cover all bone surfaces and fully inhabit the bone matrix. Principal cell types are osteoblasts, which secrete bone matrix, osteoclasts, which resorb bone, and osteocytes, which inhabit the matrix. Bone is a composite of protein and mineral. It derives tensile strength from a highly ordered protein matrix rich in type I collagen and compressive and shear strength from crystals of the hydroxyapatite form of calcium phosphate. Blood vessels permeate bone through a system of Haversian canals. Bone provides a microenvironment rich in growth factors and other molecules that participate in its complex metabolism and its interactions with other cells and tissues.

INTRODUCTION

The structure of bone can be usefully considered in several different ways that reflect its variety of functions and constituents. Its precise form and composition vary with location, nature having selected optimal designs for different roles. First and most obviously, bone provides mechanical support and protection. It is a composite material, with tough, resilient protein fibers embedded in a hard and rigid mineral matrix (Fig. 1). Its great advantage over sophisticated human-designed composite materials is its ability to repair itself. Within a single skeletal element, there usually are dramatically different forms of bone, some, such as the cortical shaft, designed for load bearing and some, such as trabecular bone in the metaphysis, providing both a supporting network and a fractally large surface area for metabolic responses to the requirements of mineral homeostasis. Both of these types of bone are evident in the longitudinal section of the human tibia depicted in Fig. 2.

Given its obvious structural role, bone is not always appreciated as one of the more complex and dynamic

[†]Deceased.

Figure 1 Composition of bone. Human fibula before (left) and after (right) extraction with (ethylenedinitrilo)tetraacetic acid (EDTA). EDTA removes the mineral by chelation and what remains is the tough, fibrous protein matrix, 90% of which is type I collagen. This demineralized bone matrix has very high tensile strength, greater than that of steel on a per weight basis. It has, however, little resistance to compressive or bending forces, enabling it to be tied in a knot. The calcium phosphate crystalline form (hydroxyapatite) that constitutes the mineral component has high compressive strength, but alone is brittle and has little resistance to tensile forces. Together they make the hard, somewhat flexible, composite material known as bone.

tissues in the body. Its cellular constituents include not only the bone-forming osteoblasts and the bone-resorbing, phagocytic osteoclasts, but also the matrix-embedded osteocytes, which maintain communication with one another and with the bone surface from deep within the solid bone matrix through a dense, interconnected network of submicrometer-sized canaliculi. Interactions between bone cells and those of cartilage, blood vessels, teeth, and cells that degrade and/or remodel the extracellular matrix during growth are regulated in part locally, in part systemically, and in part by mechanisms that are still under intensive investigation.

Figure 2 Structure of a typical long bone (longitudinal section of an adult human tibia with all cellular material removed). Typically, a long bone can be divided into three regions. The epiphysis (E) of the tibia is the widened “knob” that articulates at the knee joint (the joint cartilage is removed in this specimen). The central shaft, or diaphysis (D), is formed by a cylinder of dense, high-strength cortical bone (C) that surrounds a marrow cavity (Ma). Between these two regions, the metaphysis (Me) is filled with a highly anastomosing network of bony trabeculae, or spicules, that both distributes mechanical load between the joint and the bone shaft and provides an extraordinarily large surface area for metabolic activity. Between the epiphysis and the metaphysis, one can see a boundary that is the remnant of the cartilage growth plate, all turned to bone in this adult specimen, indicated by the arrow. The arrowheads indicate the area shown at higher magnification in the bottom panel. The bottom panel shows in greater detail the meshwork of metaphyseal trabeculae. Note that as more trabeculae join the cortical bone shaft, thereby transferring greater mechanical load from the joint, there is a corresponding thickening of the cortex (C) to bear the extra weight.

Bone also contains pools of stem cells, one type of which is the bone-lining cell that covers all bone surfaces and responds to osteogenic signals by proliferating and maturing into matrix-secreting osteoblasts. In addition to the obvious protection bones provide

for the brain, spinal column, and thoracic organs, they enclose the soft and vulnerable hematopoietic marrow, providing homing signals for colonization by hematopoietic and stromal stem cells. Also, bone plays host to arteries, veins, and venous sinuses.

Bones also interface seamlessly with the tendons, ligaments, and cartilage of the joints to transduce muscular contractions into movement. Bones of the skull must join directly with one another, forming highly interdigitated sutures that in effect constitute a continuous, planar surface. Finally, the unique relationship between the jaws and the teeth results in a special form of joint, the tooth socket, with the jaw and tooth interlocked through the cementum and the periodontal ligament. The structure of bone, both macro- and microscopically, reflects all these functions and interactions.

MACROSCOPIC STRUCTURAL FEATURES

There are three major subdivisions of the skeletal elements. The axial skeleton consists mainly of the vertebral column and ribs. The appendicular skeleton comprises the limbs and digits and their associated structures. The cranial skeleton consists of the skull, face, and jaws. Bones of the former two skeletal subdivisions are formed by a developmental process called “endochondral ossification,” in which a cartilage model, or anlage, is replaced by bone during development and growth, in a sense recapitulating the evolutionary path from a nonmineralized to a mineralized endoskeleton that characterizes all the vertebrates. In contrast, the flat bones of the skull, the mandible, and the clavicles are formed by a different developmental process in which bone-forming cells differentiate directly from the surrounding mesenchyme, a process called “intramembranous ossification.”

The overall structure of a typical long bone is shown in Fig. 2, a longitudinal section of an adult human tibia. The shaft of the bone, called the diaphysis, consists of a hollow cylinder of dense, or cortical, bone (C) surrounding a marrow space (Ma). The external surface of bone is covered by the periosteum and the internal surface (i.e., facing the marrow space) is covered by the endosteum. These are fibro-cellular layers not shown on the dried bone specimen in Fig. 2. At the end of the bone, one sees the widened region called the epiphysis (E), which supports the articular cartilage that forms the cushioned interface of the joint. The region where the bone narrows, or flares, from the epiphysis to the diaphysis is called the

Figure 3 Dynamic balance of bone formation and resorption (light micrograph of 2-week-old rat tibia). This microscopic section shows a large, multinucleated osteoclast (Oc) actively resorbing trabecular bone spicules (b). Immediately adjacent to this resorptive activity, there are many plump, active osteoblasts secreting bone matrix, several of which are marked with asterisks. Although the overall activity level in this young, growing animal is extremely high, this simultaneous resorption and formation of bone continue throughout life.

metaphysis (Me). The metaphysis is a key structural and metabolic region that plays a crucial role in endochondral ossification and in mineral homeostasis. The metaphysis is occupied by cancellous, or spongy, bone, organized in a highly anastomosing, trabecular network of bone spicules that transmits forces between the joint and the shaft of the bone. This region of the bone is called the primary spongiosa. As each delicate trabecular arch joins the bone shaft, the cortical bone thickens to bear the additional load being transferred (see inset in Fig. 2). The crossing arches of bone trabeculae are reminiscent of human architectural solutions to the problem of transmitting the weight of a heavy roof to a building’s walls while leaving open interior spaces.

Of equal importance, the metaphysis provides signals and cell types required for the replacement of cartilage by bone during endochondral ossification in growing bones. When bones reach their adult size in humans and other large mammals, the layer of growth cartilage, called the physis or the epiphyseal growth plate, ceases its growth activity and becomes fully mineralized. The ossified remnant of the growth plate is visible as a boundary between the epiphysis and metaphysis in Fig. 2 (arrow).

Figure 4 Life cycle of bone-forming cells (transmission electron micrographs of rat tibia). (A) Quiescent bone-lining cells (arrows) cover the surface of bone. At the top is the marrow space with marrow cells at the right and left edges. Bone-lining cells can differentiate into active osteoblasts when stimulated. (B) Osteoblasts (asterisks) actively secreting bone matrix. They are roughly cuboidal and contain well-developed organelles needed to synthesize and secrete bone matrix. They lie upon the layer of osteoid (Os) they have just secreted. Part of one osteoblast at the right-hand edge of the image can be seen in the process of being entrapped within the bone matrix, thus becoming an osteocyte. (C) An osteogenic osteocyte is newly entrapped in bone and is still actively synthesizing matrix components: note the well-developed rough endoplasmic reticulum that fills the cytoplasm. Young osteocytes completely fill the lacuna that they inhabit. The lower margins of osteoblasts on the bone surface can be seen at the top of the image. (D) An osteolytic osteocyte. Late in their life cycle, osteocytes contract and also begin to degrade the surrounding bone matrix, creating unoccupied space within the lacuna. Some of the cytoplasmic projections that permeate the bone matrix can be seen around the cell's margin. Bar equals 3.2 μm in A, 4.1 μm in B, 1.5 μm in C, and 1.7 μm in D.

The high-magnification inset in Fig. 2 shows in detail the enormous surface area achieved by the metaphyseal bone spicules. As bone is the body's chief reservoir of calcium and phosphorus, the metaphysis is a site of constant metabolic activity. On microscopic examination, it is common to find both bone formation (by osteoblasts) and bone resorption (by osteoclasts) occurring side by side on the same trabecular surface (Fig. 3). This achieves an active dynamic balance that is poised to respond to environmental demands, maintaining mineral homeostasis over the long term without compromising mechanical needs.

BONE CELLS

There are four principal bone cell types. Bone-lining cells are a pool of quiescent, fibroblastoid cells that cover all bone surfaces (Figs. 4A and 5). When called upon, they differentiate into osteoblasts (Fig. 4B) that secrete the proteinaceous bone matrix called osteoid

Figure 5 Bone is completely clad in living cells (scanning electron micrograph of the endosteal surface of a rat tibia). For this image, the marrow was removed from the tibial marrow cavity, leaving the endosteum, i.e., a layer of potentially osteogenic bone-lining cells, intact. Note that 100% of the bone surface is covered by cells. The pits in the surface are points of entry for the blood vessels via the Volkmann's canals of the Haversian system. Individual cells are scale-like in appearance and are clearly bounded by dark margins.

and subsequently matrix vesicles that deliver the mineral component and initiate the precipitation of hydroxyapatite crystals in the matrix. Note that unlike the nomenclature used for some other cell systems, osteoblasts are fully differentiated and functioning cells. As the layer of bone matrix deposited by osteoblasts thickens, a subset of the osteoblasts becomes fully surrounded by the matrix. Once encased in bone, the cell is called an osteocyte (Figs. 4C and 4D). Osteocytes inhabit a lacuna within the matrix and maintain contact with other cells and with the bone surface via cytoplasmic processes throughout the bone matrix (Figs. 6 and 7). The fourth cell type is the osteoclast (Fig. 8), which differentiates via fusion of mononuclear cells of the monocyte/macrophage lineage. This process occurs on the bone surface and results in very large, multinucleated cells. Osteoclasts form a tight seal against the bone surface, acidify the subcellular compartment to dissolve the mineral, and secrete degradative enzymes. The solubilized bone is phagocytosed, broken down further, transported through the cell, and released from the free surface.

INTRAMEMBRANOUS, OR "MEMBRANE," BONES

The intramembranous bones are defined by their non-endochondral developmental origin, forming directly

Figure 6 Haversian systems in human cortical bone (transverse section of human cortical bone, polished and stained with India ink). Three Haversian canals (H) and their associated structures are visible in the micrograph at left (H). A transverse Volkmann's canal (V) is also evident. The concentric ring-shaped patterns are produced by the osteocytes surrounding the canals. Each Haversian canal, along with its accompanying concentric rings (Haversian system), is called an osteon. (Inset) The dense meshwork of canaliculi that interconnect the osteocytes to permit the transport of nutrients and signaling molecules from the blood vessels that occupy the canals throughout the entire bone volume.

from condensing mesenchyme without an intermediary cartilaginous stage. They also participate in two unique types of joints not found in the appendicular or articular skeleton. At their edges, the flat bones of the skull and face form nonmotile joints called sutures (Fig. 9), in which they interdigitate with adjoining bones to form a tightly interlocked, continuous layer of bone that protects the brain and forms the facial structures. The mandible and maxilla contribute the bony half of the tooth socket, which is composed of a unique type of bone called alveolar bone (Fig. 10). Interactions between tooth and alveolar bone are required to develop and maintain the tooth sockets of the jaws. Without the tooth, all the alveolar bone is resorbed down to the end of the root space.

BONE MATRIX

The extracellular matrix of bone consists of crystalline precipitates of mineral (the hydroxyapatite form of calcium phosphate) that permeate a dense protein substrate. Type I collagen fibrils constitute 90–95% of the proteinaceous material in bone and provide very high tensile strength, which, gram for gram, is greater than that of steel. Also present are dozens of other glycoproteins, proteoglycans, integrin-binding proteins, other low-abundance collagens, and growth factors. Bone is first laid down as immature, “woven” bone, in which collagen fibrils are oriented randomly (Fig. 11). This bone is later resorbed by osteoclasts

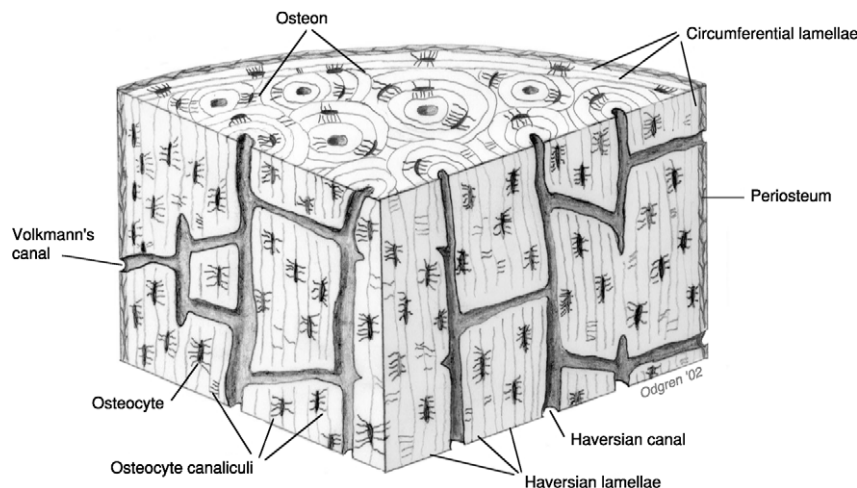

Figure 7 Illustration showing Haversian bone (also called compact, or cortical, bone). Haversian and Volkmann's canals penetrate the bone, providing contact with the osteocytes that inhabit the bone. Cytoplasmic processes of the osteocytes occupy the canaliculi and permit responses to environmental stimuli, such as mechanical loading and circulating levels of hormones, minerals, and other factors. At the inner (not shown) and outer surfaces, bone forms circumferential lamellae, in which the cells are sufficiently near the surface so as not to require Haversian organization to retain metabolic contact.

Figure 8 The osteoclast (transmission electron micrographs of rat tibia). (Top) Three nuclei are visible in this bone-resorbing osteoclast. It is firmly attached to the bone (B) by the so-called clear zone (asterisks), a dense ring of actin filaments that seals off the compartment under the cell where bone resorption occurs. The ruffled border (RB) is a specialized region of highly invaginated plasma membrane where active secretion and resorption take place. Proton pumps in the ruffled border membrane acidify the extracellular compartment to dissolve the mineral, and proteolytic enzymes degrade the proteinaceous matrix. The degraded bone is engulfed and transported through the osteoclast and released from another specialized domain on the free surface. Several marrow cells are visible along the top of the image. (Bottom) Higher magnification of a ruffled border reveals details of the elaborate ruffling that occurs over the area of bone (B) being resorbed. Several cytoplasmic processes of osteocytes can be seen in the process of being broken down (arrows), with one (open arrow) still inside its surrounding canaliculus.

and replaced by osteoblasts as mature, lamellar bone, in which the collagen fibrils are ordered. Lamellar bone contains highly oriented type I collagen fibrils that are layered in alternating directions, much like the grain in layers constituting plywood, supplying maximal strength with minimal mass (Fig. 12).

The posttranslational processing of the collagen needed to assemble this ordered extracellular matrix is complex, beginning within the osteoblast and

continuing after secretion. Collagen molecules are assembled in the endoplasmic reticulum of osteoblasts into trimers of highly posttranslationally modified monomers, designated α chains. Type I collagen consists of two $\alpha 1(I)$ chains and one $\alpha 2(I)$ chain, each 1050 amino acids long and encoded by different genes, with a middle region rich in glycine, lysine, and proline. At both the amino and carboxy termini, there are registration peptides that are not a part of

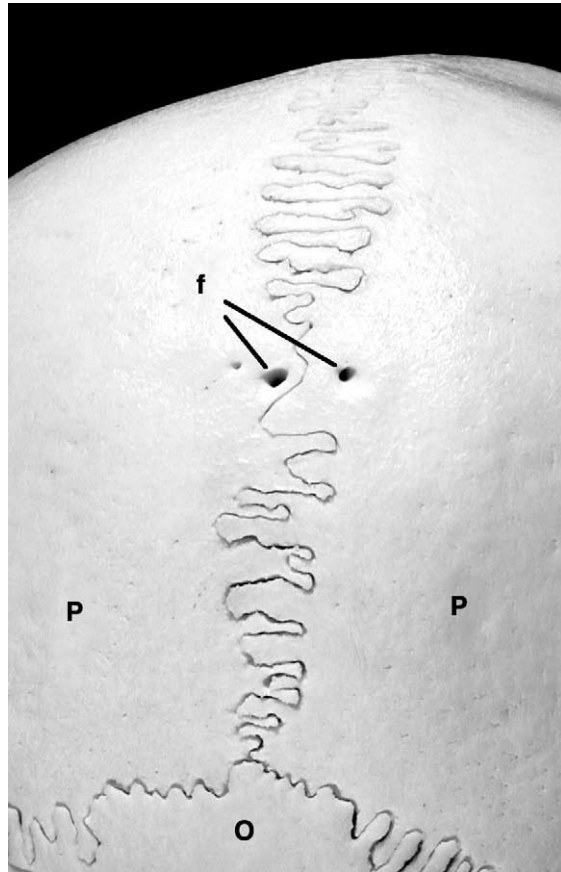

Figure 9 Sutures of the skull, as seen in a human skull with all cellular material removed. Where they interface with one another, the flat bones of the skull and face form immobile joints called sutures. Lacking a cartilage growth stage, these intramembranous bones can grow only along their edges and on their surfaces. The deep interdigitations provide a rigid, flat joint with high resistance to compressive injury. The figure shows the three-way suture formed at the rear of the skull by the occipital (O) and parietal bones (P), with the cranial ridge at the top. Two foramina, passages for nerves and blood vessels, are also shown (f).

the triple-helix, but are required to align the monomers in proper registration. Within the endoplasmic reticulum, signal peptides are cleaved off and hydroxyl groups are added to the side chains of proline and lysine residues in hydroxyltransferase-mediated reactions that are vitamin C-dependent. The failure of this pathway in the absence of vitamin C is a major contributor to the pathogenesis of scurvy. Disulfide bonds form between the carboxy-terminal registration peptides of adjacent chains, aligning the monomers. Thus modified and registered, three monomers readily form right-handed, triple-helical bundles 300 nm long and 1.5 nm in diameter wound in a C-to-N direction. O-linked sugars are added to some hydroxylysines and N-linked sugars are added to

Figure 10 Bone/tooth interface in the jaw (cutaway section of human mandible with all cellular material removed). The dense bone of the mandibular cortex (Mc) gives way to the spongy alveolar bone of the interior, in which trabeculae are present in proportion to the mechanical support required by the teeth. First and second molars are labeled m1 and m2. Note the very close apposition (open arrows) of dense alveolar bone (A) to the tooth roots. In the absence of teeth, the entire supporting structure of alveolar bone is resorbed by osteoclasts down to the point where the roots end. Note that the trabeculae also form a bony passage that protects the blood vessels and nerve that supply the tooth through each root (arrows).

the terminal regions. The assembled trimers, or “procollagen” molecules, move to the Golgi apparatus, where they are packaged into secretory vesicles and secreted.

Once outside the cell, the terminal peptides are cleaved off and the resulting triple-helical molecules are called “tropocollagen.” Tropocollagen then polymerizes in aligned bundles, with covalent bonds forming between the C and N termini of adjacent trimers to assemble highly ordered collagen fibrils. The periodicity of the overlapping collagen molecules within the fibrils is seen at very high magnification as a banding pattern 67 nm in length (Fig. 13). The alternating orientation of the fibrils in successive layers of bone collagen fibrils that is crucial to the mechanical resilience and strength of bone can be seen in electron micrographs (Fig. 12). The surface of bone is generally covered by a “capsule” of collagen fibers, called the circumferential lamellae, arranged parallel to the surface. The exception to this occurs at the points of attachment of tendons and ligaments, whose collagen

Figure 11 Woven bone in polarized light (dog mandible). Collagen fibril orientation is visible in light micrographs with polarized illumination. Double-headed arrows indicate the orientations of several domains. This “first-generation” bone matrix is brittle and weak and needs to be resorbed by osteoclasts and replaced by osteoblasts as mature, lamellar bone to attain full strength and resilience. Bar, 75 μm .

Figure 12 Collagen fibrils in lamellar bone (transmission electron micrograph of rat tibia). Mature lamellar bone is so named because of the layered, highly oriented collagen fibrils that constitute it, as seen in this electron micrograph of newly synthesized bone matrix. A portion of an osteoblast can be seen at the top (asterisk). In the upper layer of matrix (A), the cartilage fibrils are seen end-on, i.e., projecting out of the plane of the page. In the lower layer (B), they are cut longitudinally and run along the surface of the page. As a result of this alternating orientation of the collagen fibrils, lamellar bone has much greater strength and resilience than woven bone.

Figure 13 Type I collagen fibrils. The ends of adjacent tropocollagen trimers are staggered by 67 nm, as diagrammed in the top illustration. The N-terminal region of one trimer forms covalent bonds (represented as ball-and-stick figures) with the C-terminal region of adjoining trimers. The spacing between the overlapped ends is seen as a banding pattern in high-magnification electron micrographs, as in the bottom panel. The cross-linked trimers form collagen fibrils that constitute 90–95% of the proteinaceous component of bone matrix.

fibers penetrate the bone surface at an angle and become continuous with the bone collagen fibers. These are called Sharpey's fibers.

In addition to its high collagen content, the proteinaceous bone matrix secreted by osteoblasts (called “osteoid”) contains many noncollagenous proteins, approximately 5–10% of protein weight. Osteoid provides the microenvironment where mineral precipitates in a controlled way and it is thought to mediate a wide range of other biological processes. Although no definitive *in vivo* functions for the dozens of noncollagenous proteins are known, there are among them many growth factors, cytokines, and integrin-binding proteins as well as a host of other bone-specific proteins. With such an array of cell regulatory molecules thus embedded within the bone matrix, it is clear that bone provides an information-rich environment that helps direct and integrate diverse cellular activities, such as cell attachment, bone synthesis, collagen assembly, and bone resorption, as well as responses to environmental cues, such as mechanical loading or dietary status. Presumably some of these noncollagenous bone matrix proteins are also essential for the remarkable ability of osteocytes to survive while inhabiting lacunae deep within the matrix, interconnected via cytoplasmic processes that inhabit the profuse networks of canaliculi, and for the formation and maintenance of the capillary network that thoroughly permeates the entire Haversian system. Identifying specific biological functions for

the many noncollagenous bone matrix proteins is an important area of ongoing research.

Bone mineral is composed mainly of calcium and phosphate in the form of hydroxyapatite, $\text{Ca}_4(\text{PO}_4)_6(\text{OH})_3$, which is secreted in matrix vesicles by osteoblasts. Thus, even though mineral deposition takes place outside the cells, it is a cell-regulated process. Matrix vesicles are seen near osteoblasts that supply mineral to the matrix and are approximately 100 nm in diameter. They contain alkaline phosphatase and other enzymes needed to produce high concentrations of calcium and phosphorus. The vesicles rupture, releasing their contents and permitting the precipitation of hydroxyapatite crystals that eventually permeate the osteoid completely to form the composite material called bone. The mineral adds great rigidity and resistance to compressive and bending forces to the skeletal elements (Fig. 1).

THE HAVERSIAN SYSTEM: METABOLIC LIFELINE

In large mammals such as humans, compact bone, such as that found in the shafts of the limb bones, is generally too thick to permit adequate nutrient, signal, and waste exchange with the embedded osteocytes. The evolutionary solution to this problem is the Haversian system, in which concentric cylinders of bone surround a nutrient artery and vein located within a central Haversian canal oriented parallel to the long axis of the bone (Figs. 6 and 7). These concentric rings are arranged much like growth rings in trees. One Haversian canal plus its accompanying concentric lamellae is called an “osteon.” Adjacent Haversian systems are interconnected at frequent intervals by blood vessels that travel in transverse

Figure 14 Remodeling of osteons over time. This diagram depicts the chronology of remodeling of a region of bone over time. The osteons are numbered in order of their formation. As newer osteons form, they invade and erode the preexisting osteons.

passages called Volkmann’s canals. Together, the Haversian and Volkmann’s canals penetrate the entire bone substance and maintain communication among all the osteocytes embedded within the cortex. Note that small mammals, such as rats and mice, do not possess Haversian systems, because their bones are small enough to permit survival of osteocytes without intra-osseous circulatory elements.

Osteons, like other bony structures, are subject to remodeling. Successive waves of resorption by osteoclasts and formation by osteoblasts leave telltale structural evidence. The osteons most recently formed are generally the least densely mineralized and, more noticeably, have the most complete sets of rings. As new osteons form, they invade the territory of older osteons and erode their outer edges. This phenomenon is shown diagrammatically in Fig. 14. This remodeling is essential to maintain the bones and to repair microdamage that accumulates over time. Metabolic studies have revealed that in the adult human, approximately 10% of the skeleton is remodeled per year. This indicates that a complete skeletal replacement occurs approximately once a decade.

Glossary

bone formation marker Enzyme or secretory molecule of the osteoblastic cells released during the process of bone synthesis.

bone resorption marker Enzyme of the osteoclastic cells or component of the bone matrix released during the process of bone degradation.

osteoporosis A systemic skeletal disease characterized by a low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture risk.

Paget's disease A localized disorder characterized by a marked increase in bone turnover, leading to overproduction of bone of poor quality, responsible for hypertrophy, osteosclerosis, and bone fragility.

Bone turnover is characterized by two opposite activities, the formation of new bone by osteoblasts and the degradation (resorption) of old bone by osteoclasts. Both are tightly coupled in time and space in a sequence of events that define the same remodeling unit.

INTRODUCTION

Bone mass depends on the balance between resorption and formation within a remodeling unit and on the number of remodeling units that are activated within a given period of time in a defined area of bone. Bone loss characterizing metabolic bone diseases including osteoporosis depends on both an imbalance between resorption and formation within the remodeling unit and an increased activation frequency (i.e., bone turnover) that can be assessed noninvasively

by systemic biochemical markers of bone formation and bone resorption.

The rate of formation or degradation of bone matrix can be assessed either by measuring the enzymatic activity of the bone-forming or -resorbing cells, such as alkaline and acid phosphatase, or by measuring bone matrix components released into the circulation during formation or resorption (Table I). These have been classified as markers of formation and resorption, but it should be kept in mind that in disease states in which both events are coupled and change in the same way, such as in osteoporosis, any marker will reflect the overall rate of bone turnover. Current bone markers cannot discriminate between turnover changes in a specific skeletal envelope (i.e., trabecular vs cortical) but reflect whole body net changes. Circulating levels of these markers can be influenced by factors other than bone turnover, such as the metabolic clearance (liver uptake, renal excretion, and/or trapping on bone hydroxyapatite), and by the pattern of immunoreactive moieties recognized by a given antibody. Thus, each marker needs to be validated carefully in a specific clinical situation before conclusions about its clinical utility can be drawn.

Although bone markers may be useful in the management of a variety of metabolic bone diseases, most studies have focused on their potential use in postmenopausal osteoporosis. Bone turnover markers have been suggested to predict the occurrence of osteoporotic fractures in combination with other risk factors, including bone mineral density (BMD), and to monitor the efficacy of treatment, especially anti-resorptive therapies (hormone replacement therapy, bisphosphonates, and calcitonin) and also, recently, anabolic treatment such as parathyroid hormone. In this article, we review bone marker technology and discuss the use of these markers for the management of osteoporosis and Paget's disease.

Table 1 Biochemical Markers for Bone Remodeling^a

| |
|---|
| Formation |

BIOCHEMICAL MARKERS OF BONE FORMATION

Serum Alkaline Phosphatase

The skeletal alkaline phosphatase (ALP) is an enzyme localized in the membrane of the osteoblasts that is released into the circulation by an unknown mechanism. Among the several tissues containing ALP, the liver and bone isoenzymes are the major contributors. Until recently, serum total ALP activity was the most commonly used marker of bone formation, but for the previously mentioned reasons it lacks sensitivity and specificity. In an attempt to improve the specificity and sensitivity of serum ALP measurement, techniques have been developed to differentiate the bone and the liver isoenzymes, which differ only by post-translational modifications because they are coded by a single gene. In general, these assays have slightly enhanced the sensitivity of this marker, but most are indirect and/or technically cumbersome. A real improvement was achieved by using monoclonal antibodies that preferentially recognize the bone isoenzyme. These direct immunoassays have been shown to exhibit a low cross-reactivity with the circulating liver isoenzyme (15–20%) and to be more sensitive than total ALP activity to detect the increase in bone

turnover following menopause. Also, an automated immunoassay for serum bone ALP with improved precision compared to manual immunoassay and high throughput has been developed.

Serum Osteocalcin

Osteocalcin (OC) is a small, noncollagenous protein that is specific for bone tissue and dentin, but its precise function is unknown. OC is predominantly synthesized by osteoblasts and is incorporated into the extracellular bone matrix, but a fraction of newly synthesized osteocalcin is released into the circulation, where it can be measured by radioimmunoassay. Circulating OC has a short half-life and is rapidly cleared by the kidney. Serum OC concentrations correlate with skeletal growth at the time of puberty and are increased in a variety of conditions characterized by increased bone turnover, such as primary and secondary hyperparathyroidism, hyperthyroidism, Paget's disease, and acromegaly. Conversely, they are decreased in hypothyroidism, hypoparathyroidism, glucocorticoid-treated patients, and in some patients with multiple myeloma and malignant hypercalcemia. Comparisons of serum OC levels with iliac crest histomorphometry and calcium kinetic data have shown that under most conditions, serum OC is a valid marker of bone turnover when resorption and formation are coupled and is a specific marker of bone formation when formation and resorption are uncoupled.

Circulating OC consists of different molecular entities. We found that the intact molecule represents approximately one-third of the immunoreactivity in the adult serum (or plasma), one-third is represented by several small fragments, and another third by a large N-terminal, midmolecule fragment (N-mid fragment). Some *in vitro* studies using purified rat osteoclasts cultured on bovine bone slices suggest that both intact and fragmented OC may be released from bone matrix during bone resorption. Thus, some specific urinary OC fragments may actually reflect bone resorption. However, the relative contribution of osteoclast-versus osteoblast-generated OC to the total circulating level is unknown, and we showed that short-term treatment with a potent bisphosphonate did not decrease either intact or the major circulating N-mid fragment despite a dramatic decrease in bone resorption, suggesting that *in vivo*, serum OC mainly reflects bone formation. After a few hours of incubation of serum samples at room temperature, a significant amount of plasma intact OC is rapidly converted

into the large N-mid fragment, resulting in a significant loss of immunoreactivity with intact OC assay and with most polyclonal antibodies because they recognize the C-terminal end of the molecule. From a practical standpoint, it is recommended to use assays that measure both the intact molecule and the N-mid fragment, providing a more robust and sensitive assay.

Procollagen Type I Propeptides

During the extracellular processing of type I collagen, there is cleavage of the amino-terminal (PINP) and carboxy-terminal (PICP) extension peptides prior to fibril formation. These peptides circulate in blood, in which they may represent useful markers of bone formation since collagen is by far the most abundant organic component of bone matrix.

In contrast to serum PICP, which is a single glomerular protein the same size as the authentic propeptide, immunoreactive PINP circulates in different forms, including the intact PINP corresponding to the authentic trimeric *in vivo* cleaved propeptide, intact monomeric α chains, and smaller fragments. The trimeric structure is unstable at 37°C and can be transformed into the stable monomeric forms. The first developed assays for serum PINP, which use immunogen synthetic peptides from the α_1 chain of type I collagen propeptide, recognize both trimeric and monomeric forms and PINP fragments but, as has serum PICP, have been disappointing with regard to osteoporosis. In contrast, assays recognizing the intact trimeric form of PINP have been shown to be more sensitive than PICP and to be as valuable as OC and bone ALP for detecting the increase in bone turnover following menopause and for monitoring the response to antiresorptive therapy. Serum PINP appears to be particularly sensitive for assessing the anabolic effects of PTH in postmenopausal women with osteoporosis.

BIOCHEMICAL MARKERS OF BONE RESORPTION

Fasting Urinary Calcium, Hydroxyproline, and Hydroxylysine Glycosides

Fasting urinary calcium measured in a morning sample and corrected for creatinine excretion is the cheapest assay of bone resorption. It is useful in detecting a marked increase in bone resorption but lacks sensitivity. Fasting urinary calcium reflects the amount of calcium released during resorption and also

the renal handling of calcium that is influenced by calcium-regulating hormones and by estrogens. Hydroxyproline (Hyp) is found mainly in collagen and represents approximately 13% of the amino acid content of the molecule. Ninety percent of the Hyp liberated during the degradation of bone collagen is primarily metabolized in the liver. Approximately 10% of the Hyp released by the breakdown of collagen circulates in a peptide-bound form, and these peptides are filtered and excreted in urine without any further metabolism. Urinary Hyp is usually considered an index of bone resorption. However, it should be noted that significant amounts of urinary Hyp are derived from the degradation of newly synthesized collagens, Hyp can be found in other tissues such as the skin, and Hyp can also be liberated from the metabolism of elastin and C1q. Urinary Hyp is therefore considered an unspecific index of collagen turnover and, consequently, has been largely replaced by more specific markers.

Hydroxylysine is another amino acid unique to collagen and proteins containing collagen-like sequences. Like hydroxyproline, hydroxylysine is not reused for collagen biosynthesis, and although it is much less abundant than hydroxyproline, it is a potential marker of collagen degradation. Hydroxylysine is present in part as galactosyl hydroxylysine and in part as glucosyl-galactosyl hydroxylysine. The relative proportion and total content of galactosyl hydroxylysine and glucosyl-galactosyl hydroxylysine vary in bone and soft tissues, with a higher content of galactosyl hydroxylysine in bone, suggesting that its urinary excretion might be a more sensitive marker of bone resorption than urinary hydroxyproline.

Plasma Tartrate-Resistant Acid Phosphatase

Acid phosphatase is a lysosomal enzyme present primarily in bone, prostate, platelets, erythrocytes, and spleen. Bone acid phosphatase is resistant to L-(+)-tartrate, whereas the prostatic isoenzyme is inhibited.

Acid phosphatase circulates in blood and shows higher activity in serum than in plasma because of the release of platelet phosphatase activity during the clotting process. In normal plasma, tartrate-resistant acid phosphatase (TRACP) corresponds to plasma isoenzyme 5, which originates partly from bone because osteoclasts contain TRACP that is released into the circulation. Isoenzyme 5 is represented by two subforms, 5a and 5b, with TRACP 5b being more specific for osteoclasts. Total plasma TRACP activity

can be measured by colorimetric assays. However, the lack of specificity of plasma TRACP activity for the osteoclast, its instability in frozen samples, and the presence of enzyme inhibitors in serum are potential drawbacks that limit the development of clinically useful enzymatic TRACP assays for osteoporosis. To overcome these limitations, antibodies have been developed against TRACP isolated from different sources, including recombinant human TRACP and purified bone TRAP, to develop immunoassays for TRACP 5b.

Plasma TRACP activity measured by conventional colorimetric assays is increased in a variety of metabolic bone disorders with increased bone turnover, including osteoporosis, but it is not clear whether this marker is more sensitive than urinary hydroxyproline. When measured using specific immunoassays, serum TRACP 5b isoenzyme has been shown to be more sensitive than total TRACP for detecting increased bone turnover after menopause and decreased turnover induced by hormone replacement therapy in postmenopausal women, suggesting that this marker may be a useful indicator of the effect of antiresorptive therapy on bone resorption.

Collagen Pyridinium Cross-Links and Associated Type I Collagen Peptides

Pyridinoline (PYD) and deoxypyridinoline (DPD), also called hydroxylslypyridinoline and lysylpyridinoline, respectively, are nonreducible pyridinium cross-links present in the mature form of collagen. The posttranslational covalent cross-linking generated from lysine and hydroxylysine residues is unique to collagen and elastin molecules. It creates interchain bonds that stabilize the molecule within the extracellular matrix. The highest concentration of PYD (expressed in mol/mol of collagen) is found in articular cartilage, whereas DPD is present in minute amounts in this tissue. PYD and DPD are present in tendon and aorta but absent from the skin, an abundant source of type I collagen. PYD and DPD are released into the circulation after resorption of bone matrix and then excreted in urine, in which they are found as free and peptide bound forms (Fig. 1). Peptide-bound but not free cross-links can be generated directly at the bone resorption site. The total amount of pyridinoline cross-links can be measured by fluorimetry after reversed-phase high-performance liquid

Figure 1 Type I collagen breakdown products as markers of bone resorption. Type I collagen molecules consist of two α_1 chains and one α_2 chain associated in triple helix except at the ends (telopeptides). In the extracellular matrix, type I collagen molecules are cross-linked by pyridinoline (PYD) and deoxypyridinoline (DPD) in the region of N and C telopeptides. PYD differs from DPD by the presence of a hydroxyl residue shown in *italic*. During osteoclastic bone resorption, fragments originating from the telopeptides and the triple helix region (e.g., helicoidal peptide 620–633) are released into the circulation and excreted in the urine. PYD and DPD are released into the circulation mainly as peptide-bound cross-links [i.e., attached to fragments of C-terminal (CTX) or N-terminal (NTX) telopeptides]. Some of the peptide-bound cross-links are further degraded in the kidney in free cross-links. Immunoassays for detecting free PYD, free DPD, CTX and NTX, and helicoidal peptide 620–633 in serum or urine are available.

chromatography (HPLC) of a cellulose-bound extract of hydrolyzed urine.

Immunoassays for the PYD cross-links and related telopeptide fragments that advantageously substitute for the HPLC measurement of the total excretion are now available and represent the best indices of bone resorption. These comprise measurements of urinary free PYD (free PYD) and DPD (free DPD) and related peptides in urine and, recently, in serum. These peptides include the C-terminal cross-linking telopeptide of type I collagen generated by matrix metalloproteases (MMPs) (S-CTX MMP; also called ICTP), the C-terminal cross-linking telopeptide of type I collagen in serum (S-CTX) and in urine (U-CTX), and the N-terminal cross-linking telopeptide of type I collagen in serum (S-NTX) and in urine (U-NTX). Most of these type I collagen-related resorption markers can be measured either manually or by an automated system with improved precision and high throughput. In contrast to its poor sensitivity in osteoporosis, CTX MMP appears to be a useful bone resorption marker in patients with malignant bone disease. The different sensitivity of this marker in these two clinical situations may be related to differences in the pattern of type I collagen degradation. The epitope of CTX MMP is destroyed by cathepsin K activity, an osteoclastic-specific cysteine protease that is the key enzyme responsible for bone collagen degradation in normal physiological conditions, whereas it is generated by MMPs, whose activity has been suggested to play an important role in collagen degradation associated with cancer. In contrast, CTX and NTX epitopes are highly efficiently generated by cathepsin K and not by MMPS (Fig. 2). Available markers of type I collagen degradation are based on the measurement of either pyridinoline cross-links or associated cross-linked C or N telopeptides, both originating from the telopeptide region. Recently, a type I collagen-specific peptide corresponding to residues 620–633 of the helical region of the α_1 chain was isolated from urine of patients with Paget's disease. We found that the urinary excretion of this helical peptide increased markedly after menopause and was as sensitive as urinary CTX for assessing the antiresorptive effects of bisphosphonate and estrogens, suggesting that it may be useful for the investigation of patients with osteoporosis. However, additional studies are required to fully evaluate its clinical utility.

Urinary and serum markers of bone resorption have significant circadian rhythms. Urinary excretion of PYD and DPD peaks between 2:00 and 8:00 AM and reaches a nadir between 2:00 and 11:00 PM. In healthy premenopausal women, the magnitude of the

Figure 2 The type I collagen fragments CTX and ICTP (also called CTX-MMP) are released from human bone collagen by distinct enzymatic pathways. Demineralized insoluble human bone collagen was incubated with active human recombinant cathepsin K, matrix metalloprotease (MMP)-2, MMP-9, MMP-13, and MMP-14 for 24 h at 37°C. CTX and ICTP fragments were measured in the supernatant. The bars represent the mean and SEM of nine (cathepsin K) or three (MMPs) different incubations per experimental condition. As shown in the figure, CTX is released by cathepsin K but not MMPs, whereas ICTP is released by MMPs but not cathepsin K. Reproduced from Garnero, P., Ferreras, M., Karsdal, M. A., NicAmhlaoibh, R., Risteli, J., Borel, O., Qvist, P., Delmas, P. D., Foged, N. T., and Delaissé, J. M. (2003). The type I collagen fragments ICTP and CTX reveal distinct enzymatic pathways of bone collagen degradation. *J. Bone Miner. Res.* **18**, 859–867. Reproduced with permission of the American Society for Bone and Mineral Research.

rhythm may be as much as 100% of the 24-h mean, with a decrease of 25–35% between 8:00 and 11:00 AM. Urinary cross-linked telopeptides have similar rhythms as total cross-link excretion. Serum CTX peaks between 1:30 and 4:30 AM at levels that are more than twice those at the nadir between 11:00 AM and 3:00 PM. The amplitude of the rhythm of CTX MMP is only 15–20% of the 24-h mean, suggesting that the different type I collagen peptides may have different bone specificity and/or reflect different aspects of bone resorption. Fasting results in a diminution in the amplitude of the circadian rhythm of urinary and, more markedly, serum CTX (Fig. 3). Among the factors that may influence the circadian pattern of serum CTX, food intake appears to be the most important determinant; its effect can be mediated by gastrointestinal hormones. In summary, although the amplitude of the circadian rhythm differs according to the markers, its effect is substantial for most of them and indicates the importance of standardizing the time of sampling and the fasting condition of the patient.

Posttranslational Modifications of Collagen Molecules

Type I collagen molecules in bone tissue undergo enzymatic and nonenzymatic posttranslational modifications,

and some may be of clinical relevance for the investigation of metabolic bone diseases, including osteoporosis. Among the enzymatic transformations, biochemical studies performed on bone specimens have shown that the extent of hydroxylation of lysine residues and glycosylation of hydroxylysine, the content of nonreducible cross-links, and the PYD:DPD ratio may be associated with bone strength. Nonenzymatic modifications of collagen such as pentosidine, an index of nonenzymatic advanced glycation end products, may also play a role as a determinant of bone strength. Racemization and β -isomerization of the Asp–Gly sequence within the $^{1209}\text{AHDGGR}^{1214}$ sequence (CTX) of the C telopeptide of type I collagen are other nonenzymatic posttranslational modifications (Fig. 4). Histological studies have shown a decreased degree of isomerization/racemization within the woven pagetic bone (characterized by increased fragility) that can be detected *in vivo* by the differential measurement of native (αL) CTX and isomerized (βL) CTX in urine. In a prospective study of postmenopausal women, we found that an increased urinary ratio between native and age-related forms of type I collagen CTX was associated with increased fracture risk, independent of the level of BMD of the hip and the bone turnover rate (Table II). This suggests that a decreased degree of type I collagen isomerization/racemization may be associated with alterations of

Figure 3 Circadian variation of serum CTX levels: effect of fasting status. Eleven premenopausal women were sampled every 3 h over two consecutive 24-h periods in a crossover design. In one period, women fasted throughout the study (○); in the other period, they were allowed to eat and drink (●). For fasting subjects, the average variation was 13.6%, whereas the variability under nonfasting conditions was 34%. Reproduced with permission from Qvist, P., Christgau, S., Pedersen, B. J., Schlemmer, A., and Christiansen, C. (2002). Circadian variation in the serum C-terminal telopeptide of type I collagen (serum CTx): Effects of gender, age, menopausal status, posture, daylight, serum cortisol and fasting. *Bone* 31, 57–61.

Figure 4 Racemization and isomerization of type I collagen C-telopeptides. An attack by a peptide backbone nitrogen on the side chain carbonyl group of an adjacent aspartyl residue can result in the formation of a succinimide ring (I → II). The succinimide ring is prone to hydrolysis and racemization producing peptides and β-aspartyl peptides in both the D and L configurations. Racemization is thought to proceed primarily through the succinimide pathway (II → V), but other pathways, such as direct proton abstraction (I ↔ IV and III ↔ VI), may also contribute to the formation of D-aspartyl. The peptide backbone is shown as a bold line. The four types of C telopeptides are present in bone matrix; the native form (αL) and three age-related forms—an isomerized form (βL), a racemized form (αD), and an isomerized/racemized form (βD). With increasing age of type I collagen molecules, the proportion of β isomerized and D racemized forms within bone matrix increases. Degradation products of these four CTX forms of type I collagen can be measured in urine independently by immunoassays using specific conformational monoclonal antibodies.

bone strength properties, a hypothesis that requires confirmation by studies correlating the degree of type I collagen racemization/isomerization with mechanical properties of bone specimens. Clearly, these findings open new perspectives for the clinical use of bone markers, not only to measure quantitative changes of bone turnover but also to assess changes of bone quality.

CLINICAL USES OF BONE TURNOVER MARKERS IN OSTEOPOROSIS

Bone Markers and Fracture Risk Assessment

With the emergence of effective-but expensive treatments, it is essential to detect those women at higher risk of fracture. Several prospective studies have shown that a standard deviation decrease of BMD measured by dual X-ray absorptiometry (DXA) or

heel ultrasound is associated with a two- to fourfold increase in the relative fracture risk, including the hip, spine, and forearm. In this context, the question arises as to what extent bone markers could add to bone mass measurement to improve the assessment of fracture risk.

Prospective studies relating levels of bone formation markers to the risk of fracture have yielded conflicting results. Indeed, a decrease, no difference, or an increase in bone formation markers have been reported to be associated with increased fracture risk. The different results among studies may be related to the type of fracture, the population studied, and the duration of follow-up. Thus, whether bone formation marker levels are related to fracture risk remains unclear. In contrast to bone formation markers, data on the relationship between bone resorption markers and fracture risk are more consistent. Results obtained from three large prospective studies (EPIDOS, Rotterdam, and OFELY) indicate

Table II Degree of Isomerization and Racemization of Type I Collagen and Risk of Fracture in Postmenopausal Women^a

| Urinary CTX ratio | Relative risk (95% CI) of fracture for values in the upper quartile | |
|--|---|-----------------------------|
| | All fractures | Nonvertebral fractures only |
| α L/ β L | | |
| Unadjusted | 2.0 (1.2–3.5) | 2.5 (1.3–4.6) |
| Adjusted for bone ALP | 1.8 (1.1–3.2) | 2.2 (1.1–4.2) |
| Adjusted for femoral neck BMD | 1.8 (1.03–3.1) | 2.2 (1.2–4.0) |
| Adjusted for bone ALP + femoral neck BMD | 1.7 (0.95–2.9) | 2.0 (1.04–3.8) |
| α L/ α D | | |
| Unadjusted | 1.8 (1.02–3.2) | 1.9 (1.01–3.7) |
| Adjusted for bone ALP | 1.6 (0.92–2.9) | 1.7 (0.87–3.3) |
| Adjusted for femoral neck BMD | 1.7 (0.97–2.9) | 1.8 (0.95–3.5) |
| Adjusted for bone ALP + femoral neck BMD | 1.6 (0.89–2.8) | 1.7 (0.86–3.2) |

^aIn this study, 408 healthy untreated postmenopausal women aged 50–89 (mean; 64 years) who were part of the OFELY cohort were followed for a median of 6.8 years. During follow-up, 16 incident vertebral fractures and 55 peripheral fractures were recorded in 65 women. The baseline levels of the four CTX isoforms (α L CTX, β L CTX, α D CTX, and β D CTX; see Fig. 4) in women who subsequently had a fracture were compared to those of the 343 women who did not have a fracture. As shown in the table, women with baseline levels of the ratio α L/ β L CTX in the highest quartile had a twofold higher risk of fracture than the other women, independent of bone turnover rate assessed by serum levels of bone alkaline phosphates (bone ALP) and/or femoral neck bone mineral density (BMD). From Garnero, P., Cloos, P., Sornay-Rendu, E., Qvist, P., and Delmas, P. D. (2002). Type I collagen racemization and isomerization and the risk of fracture in postmenopausal women: The OFELY prospective study. *J. Bone Miner. Res.* **17**, 826–833. Reproduced with permission of the American Society for Bone and Mineral Research.

that increased levels of bone resorption markers are associated with increased risk of hip, vertebral, non-hip, and nonvertebral fractures over follow-up periods ranging from 1.8 to 5 years. This predictive value is consistently on the order of a twofold increase in the risk of fracture for levels above the upper limit of the premenopausal range. Both increased levels of serum CTX and urinary CTX and of free DPD have been shown to be associated with a higher risk of hip, vertebral, and nonvertebral fractures. Increased bone resorption is associated with increased risk of fracture

only for values that exceed a threshold, suggesting that bone resorption becomes deleterious for bone strength only when it exceeds the normal physiological range. Because bone resorption rate predicts fracture independently of BMD, these data suggest that increased bone resorption can lead to increased skeletal fragility due to two factors. First, because high levels of bone turnover markers have been shown to be associated with increased bone loss in subsequent years, a prolonged increase in bone turnover will lead to a lower BMD, which is a major determinant of reduced bone strength. Second, increased bone resorption above the upper limit of the normal range may induce microarchitectural deterioration of bone tissue such as perforation of trabeculae, a major component of bone strength.

OC contains three residues of γ -carboxyglutamic acid, a vitamin K-dependent amino acid. It was postulated that impaired γ -carboxylation of osteocalcin could be an index of both vitamin D and vitamin K deficiency in elderly populations. In two prospective studies performed in a cohort of elderly institutionalized women and in a population of healthy elderly women (the EPIDOS study), levels of undercarboxylated osteocalcin (ucOC) over the premenopausal range were associated with a two- or threefold increase in the risk of hip fracture, although total osteocalcin was not predictive. Like markers of bone resorption, the prediction remained significant after adjusting for hip BMD.

Because increased levels of bone resorption markers and of ucOC have been shown to predict the risk of fracture independently of the level of BMD and of clinical risk factors including history of previous fragility fractures, the combination of different risk factors could be useful to improve the identification of women at high risk for fracture. Using the database of the EPIDOS study, we showed that the combination of a bone resorption marker (or ucOC) and hip BMD measurement can detect elderly women at very high risk of hip fracture. Indeed, women with both low hip BMD (according to the World Health Organization definition of osteoporosis) and high bone resorption (or high ucOC) had a four- or fivefold higher risk compared to the general population. However, the use of an odds ratio is not ideal for clinical decision making since the risk may decrease or remain stable with age, whereas absolute risk increases. Thus, calculating absolute risk such as 10-year probabilities, which depend on knowledge of the fracture and death hazards, is probably more appropriate. Based on the probability of hip fracture in the Swedish population and on the marker data of the

EPIDOS study, Johell *et al.* found that combining urinary CTX with BMD or history of previous fracture resulted in a 10-year probability of hip fracture that was approximately 70–100% higher than that associated with low BMD alone (Table III). Thus, clearly the use of multiple risk factors, such as BMD, biochemical markers, and personal history of previous fracture, likely results in better performance than the use of BMD alone.

Bone Markers for Monitoring Treatment of Osteoporosis with Antiresorptive Therapy

As for most chronic diseases, monitoring the efficacy of treatment of osteoporosis is a challenge. The goal of treatment is to reduce the occurrence of fragility fractures, but their incidence is low and the absence of events during the first year(s) of therapy does not necessarily indicate that treatment was effective. Thus, the use of surrogate markers with a more rapid response is clearly needed for an efficient monitoring of treatment of osteoporosis. A surrogate marker is a laboratory measurement or a physical sign used as a substitute for a clinical meaningful endpoint that directly measures how a patient feels, functions, or survives. Changes induced by a therapy on a surrogate endpoint are expected to reflect changes in a clinical meaningful endpoint.

Measurement of BMD by DXA is a surrogate marker of treatment efficacy that has been widely used in clinical trials. Its use in the monitoring of treatment efficacy in the individual patient, however, has not been validated. Given a short-term precision error of 1–1.5% of BMD measurement at the spine

and hip, the individual change must be >3–5% to be considered significant. With bisphosphonates such as alendronate, repeating BMD 2 years after the initial therapy will allow the determination of whether a patient is responding to therapy (i.e., shows a significant increase in BMD, at least at the lumbar spine, which is the most responsive site). With treatments such as raloxifene or nasal calcitonin that induce much smaller increases in BMD, DXA is not appropriate for monitoring therapy. With any treatment, DXA does not allow the identification of all responders within the first year of therapy. Failure to respond may be due to noncompliance (probably the most important factor), poor intestinal absorption (i.e., oral bisphosphonates), other factors contributing to bone loss, or other unidentified factors. Monitoring may improve compliance, although this needs to be proven for osteoporosis treatment.

Several randomized, placebo-controlled studies found that resorption-inhibiting therapy was associated with a prompt decrease in bone resorption markers that was seen as early as 1 month, with a plateau reached within 3–6 months (Fig. 5). The decrease in bone formation markers is delayed, reflecting the physiological coupling of formation to resorption, and a plateau is usually achieved within 6–12 months (Fig. 5). Several placebo-controlled studies have demonstrated that the magnitude of the decrease in bone turnover markers under antiresorptive therapy including HRT and bisphosphonates, usually expressed as a percentage of the initial value, is strongly correlated with the increase in BMD after 2 or 3 years.

For the clinician, the primary concern is the identification of nonresponders (i.e., patients who fail to demonstrate a significant increase in BMD after

Table III Effect of Risk Factors Alone or in Combination on the Relative Risk of Hip Fracture in Women Age 80^a

| Risk factor | Threshold value | Prevalence (%) | Odds ratio | Relative risk ^b | Ten-year probability (%) ^c |
|---------------------------|----------------------------|----------------|------------|----------------------------|---------------------------------------|
| Average | — | 100 | | 1.0 | 18.0 |
| Low BMD | <i>t</i> score < -2.5 | 56 | 2.8 | 1.40 | 23.6 |
| Prior fracture | Yes | 39 | 3.5 | 1.77 | 28.8 |
| High CTX | Above premenopausal values | 23 | 2.4 | 1.82 | 29.5 |
| Low BMD + prior fracture | Above premenopausal values | 23 | 4.1 | 2.39 | 36.3 |
| Low BMD + high CTX | Above premenopausal values | 16 | 4.1 | 2.74 | 40.1 |
| Prior fracture + high CTX | Above premenopausal values | 12 | 5.3 | 3.50 | 47.3 |
| All of the above | Above premenopausal values | 7 | 5.8 | 4.43 | 54.5 |

Figure 5 Effect of different doses of transdermal estradiol on markers of bone turnover. In this study, 201 postmenopausal women aged 40–60 years who had a time since menopause of less than 6 years were given either a placebo or a new matrix delivery transdermal 17β -estradiol in a dosage of 25, 50, or 75 μg twice a week for 28 days. The decrease of bone formation markers (osteocalcin and bALP) is delayed compared to that of bone resorption (urinary CTX), reflecting the coupling mechanism. This delayed decreased bone formation is amplified by the transdermal route of administration of estradiol. Reproduced with permission from Cooper, C., Stakkestad, J. A., Radowicki, S., Hardy, P., Pilate, C., Dain, M. P., and Delmas, P. D. (1999). Matrix delivery transdermal 17β estradiol for the prevention of bone loss in postmenopausal women. *Osteoporos. Int.* 9, 358–366.

2 years of treatment). Although bone markers do not allow an accurate prediction of bone gain in individual patients, recent studies indicate that the measurement of a marker for resorption and/or formation can provide the same information on therapeutic efficacy as the measurement of BMD. Retrospective analyses of several clinical trials using HRT or alendronate suggest that, for a given marker of resorption or formation, a cutoff value of change from baseline after 3–6 months of treatment, which is dependent on the type of therapy (HRT vs bisphosphonate) and the marker, can be defined that provides adequate predictive value of the subsequent 2- or 3-year BMD response in a single patient. The value of BMD changes to predict the risk of fracture with treatment is debated, especially because treatments such as raloxifene can induce a 30–50% reduction in vertebral fracture rate despite a 2 or 3% increase in BMD at all skeletal sites. Recent reanalyses of placebo-controlled studies suggest that BMD changes under treatment account for only a small part of the efficacy of antiresorptive therapy on fracture risk. Thus, BMD changes may not be an adequate surrogate endpoint to analyze the ability of bone markers to predict fracture risk. There have been few attempts to correlate bone marker changes with fracture risk. In the MORE study, it was found that the short-term changes of serum OC and bone ALP with raloxifene treatment were associated with

the subsequent risk of vertebral fractures in a large subgroup of osteoporotic women, whereas changes in hip BMD were not predictive (Fig. 6). In postmenopausal women with osteoporosis treated with oral risedronate, it was shown that changes in urinary CTX and NTX after 3–6 months predicted the risk of subsequent incident vertebral fractures after both 1 and 3 years (Fig. 7). These changes accounted for 50–70% of the effect of risedronate on fracture risk. Interestingly, in the MORE study, it was shown that the relationship between vertebral fracture risk and changes from baseline in CTX and NTX during 3–6 months of treatment was not linear (Fig. 7) and that there may be a level of bone resorption reduction below which there is no further fracture benefit. A significant association between changes of bone ALP and vertebral, hip, and nonspine fracture was also found in women treated with alendronate who participated in the FIT trial. Ultimately, recommended cutoff values of bone marker changes with treatment should be based on prospective studies with incident fractures as an endpoint.

BONE MARKERS IN PAGET'S DISEASE

Paget's disease is a localized disorder characterized by a marked increase in bone turnover, leading to

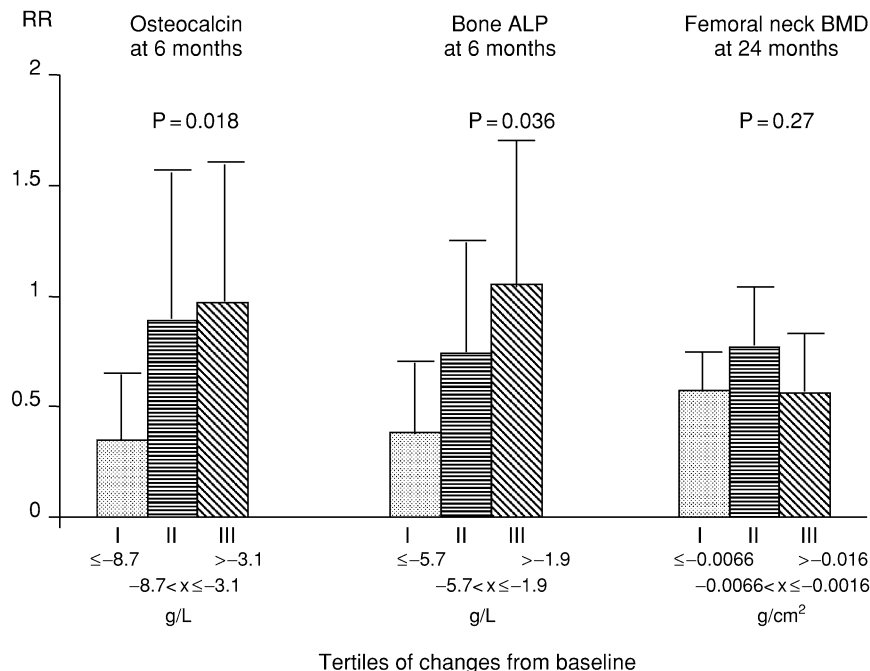

Figure 6 The relative risk of new vertebral fracture at 3 years (raloxifene vs placebo) by tertile of change in serum osteocalcin, serum bone alkaline phosphatase (bone ALP) after 6 months, and femoral neck BMD after 24 months. Postmenopausal women with osteoporosis participating in the MORE study were treated with raloxifene (60 or 120 mg/day) or placebo for 3 years. Note that there was a significant relationship between the magnitude of changes in bone markers at 6 months and the relative risk of new vertebral fracture at 3 years, whereas changes in femoral neck BMD at 24 months were not predictive. The *p* values are for interaction and indicate the presence of a differential antifracture efficacy across tertile of changes for a model including tertile of change, therapy, and tertile therapy. *n* = 2413, 2403, and 6745 for osteocalcin, bone ALP, and femoral neck BMD, respectively. Reproduced with permission from Bjarnason, N. H., Christiansen, C., Sarkar, S., Mitlak, B., Knickerbocker, R., Delmas, P., Cummings, S., for the MORE Study Group (2001). 6 months changes in biochemical markers predict 3-year response in vertebral fracture rate in postmenopausal, osteoporotic women: Results from the MORE study. *Osteoporos. Int.* **12**, 922–930.

overproduction of bone of poor quality, responsible for hypertrophy, osteosclerosis, and bone fragility. The architecture of the lamellar texture of the pagetic bone matrix is disorganized, with a predominance of woven bone that is characterized by an irregular and patchy arrangement of collagen fibers. Biochemical markers of bone turnover are routinely used for assessing the disease activity and for monitoring the efficacy of bisphosphonate therapy. Because of a marked increase in bone turnover, serum total ALP activity is the most commonly used bone marker for Paget's disease for both applications. Although serum total ALP is adequate to monitor most patients with active disease, this marker may lack sensitivity in patients with monostotic disease affecting a small bone and in patients with purely osteolytic lesions.

To overcome these limitations, the new markers described previously and validated for osteoporosis have been suggested to be useful for patients with Paget's disease. However, because a given marker may not perform equally in different metabolic bone diseases, they must be tested independently in pagetic

patients. Among formation markers, bone ALP and PINP appear to be the most sensitive markers for assessing disease activity. These markers may be particularly interesting for patients with monostotic disease. Although osteocalcin is one of the most sensitive markers in osteoporosis, it lacks sensitivity in Paget's disease probably because the fraction of newly synthesized osteocalcin that is incorporated into bone matrix may be increased because of the high mineral content of the woven bone. For bone resorption, the type I collagen-related markers have advantageously replaced urinary hydroxyproline. Among these, urinary NTX and urinary nonisomerized α CTX appear to be the most sensitive bone resorption markers both for assessing disease activity and for monitoring efficacy of bisphosphonate therapy. As discussed previously, the pagetic bone matrix is characterized by an impaired degree of β -isomerization of type I collagen molecules. We found that in patients with active Paget's disease, the urinary excretion of nonisomerized α CTX was markedly increased (13.5-fold vs controls) compared to β CTX (3.5-fold vs controls),

Figure 7 Relationship between percentage change in bone resorption markers (urinary NTX and CTX) and the incidence of new vertebral fractures. A total of 693 women with at least one vertebral deformity (mean age, 69 years; SD, 7 years) who received placebo or 5 mg oral risedronate daily for 3 years were studied. The relationships between vertebral fracture risk after 1 and 3 years of treatment and changes from baseline in NTX and CTX were not linear ($p < 0.05$). There was little improvement in fracture benefit after a decrease of 35–40% for NTX and 55–60% for CTX. The placebo group is represented by the dashed line and the risedronate group by the solid line. All patients received calcium supplementation (1000 mg/day) and vitamin D (if levels were low). From Eastell, T., Barton, I., Hannon, R. A., Chines, A., Garnero, P., and Delmas, P. D. (2003). Relationship of early changes in bone resorption to the reduction in fracture risk with risedronate. *J. Bone Miner.* **18**, 1051–1056. Reproduced with permission of the American Society of Bone and Mineral Research.

resulting in a urinary α CTX: β CTX ratio that was 3-fold higher than that in controls. Bisphosphonates induce a marked decrease in bone turnover rate in pagetic patients, and histological studies have shown

Figure 8 Effect of bisphosphonate treatment on the urinary ratio of nonisomerized to α -isomerized C-telopeptide breakdown products (α CTX/ β CTX) in Paget's disease. Twenty-eight patients with active Paget's disease were studied before and 2 months after a single injection of the bisphosphonate zoledronate (200 or 400 μ g) or placebo. Before treatment, most patients (93%) were characterized by an elevated urinary α CTX: β CTX ratio with a mean 2.7-fold increase compared to controls (2.1 vs 0.8). Two months after treatment, the α CTX: β CTX ratio was decreased by 50% in zoledronate-treated patients and returned to the normal range (gray area: mean \pm 2 SD) in 65% of patients. No significant change was observed in the placebo group. Reproduced from Garnero, P., Gineyts, E., Shaffer, A. V., Seaman, S., and Delmas, P. D. (1998). Measurement of urinary excretion of nonisomerized and α -isomerized forms of type I collagen breakdown products to monitor the effects of the bisphosphonate zoledronate in Paget's disease. *Arthritis Rheum.* **41**, 354–360., with permission of the American College of Rheumatology.

that a few months of treatment induce the formation of normal lamellar bone, suggesting that treatment restores bone quality. In patients with active Paget's disease, we found that a single injection of 200–400 μ g of zoledronate induced a significant decrease in the urinary α CTX: β CTX ratio, which was 3-fold higher than in controls before treatment, and that it returned to the reference range in most patients after 2 months of treatment (Fig. 8). This observation suggests that bisphosphonate treatment induced progressive replacement of woven bone by lamellar bone with a higher degree of β -isomerization of type I collagen, although this remains to be confirmed by direct histological evidence. Thus, the urinary α CTX: β CTX ratio may be a novel index of bone quality that might be useful for monitoring pagetic patients.

Brain, Effects of Steroid Hormones

Russell D. Romeo and Bruce S. McEwen
Rockefeller University, New York, New York, United States

Glossary

dendrite Branching neurites that emanate from the neuronal cell body.

dendritic spine A small protrusion of the cell membrane of the dendrite that receives excitatory input.

glucocorticoids Steroid hormones released from the cortex of the adrenal gland such as cortisol and corticosterone.

neurogenesis The production of new neurons.

sex steroids Steroid hormones released from the gonads such as androgens, estrogens, and progestins.

steroid hormones A family of hormones derived from cholesterol and characterized by their three six-carbon rings and one five-carbon ring.

Steroid hormones have profound effects on the structure and function of the nervous system. Steroids are responsible for organizing neural circuits early in development and for activating the appropriate physiology and behavior during adulthood. Steroids also continue to shape the structure and function of the brain throughout the life span of the organism. This article focuses on these developmental, structural, and functional influences of steroids on the brain and their behavioral and physiological consequences.

INTRODUCTION

The brain receives a rich supply of blood and is constantly in contact with circulating hormones in the bloodstream. Thus, it is not surprising that the brain is influenced and modulated by hormones. One major class of hormones is the steroid hormones, which gain access to the brain because of their hydrophobic chemical structure that allows them to pass across the blood–brain barrier. Steroid hormones have a wide range of effects on the brain. For instance, steroids help to shape the brain during perinatal development and continue to modulate the structure and

function of the central nervous system (CNS) into adulthood and throughout the life span. Specifically, steroids can influence factors such as neuronal survival, neurogenesis, neurite outgrowth, synaptogenesis, receptor expression, RNA synthesis, and neuronal excitability. The effects of the steroid hormones on the development, structure, and function of the brain are the focus of this article.

THE MECHANISMS OF STEROID HORMONE ACTION IN THE BRAIN

In mammals, the precursor to all steroid hormones is cholesterol. The sex steroids (e.g., androgens, estrogens, progestins) and glucocorticoids (e.g., corticosterone) are synthesized from cholesterol via enzymatic cleavage. For example, testosterone is produced by a series of enzymatic reactions that convert cholesterol to progesterone, then to testosterone acetate, and finally to testosterone. Testosterone is converted to estrogen by the aromatase enzyme in a reaction called aromatization. Although testosterone is considered the “male sex steroid” and estrogen is considered the “female sex steroid,” it is important to note that testosterone and estrogen are found in both males and females. In fact, estrogen formed locally in the brain of males by the aromatization of testosterone is responsible for masculinization of the male brain and plays a major role in activating male sexual behavior during adulthood. Corticosterone (or cortisol in primates) is produced from a series of enzymatic reactions that convert progesterone to 11-deoxycorticosterone and then to corticosterone. Corticosterone is involved in carbohydrate metabolism and is released in response to stressful stimuli. These steroids bind to specific receptors located throughout the brain. However, the spatial distribution and concentration of these receptors are different for each hormone.

There are three mechanisms through which steroid hormones exert their actions on neurons: genomic, indirect genomic, and nongenomic. The genomic

mechanism of steroid hormone action begins by the hormone diffusing through the plasma membrane of the neuron and binding to its intracellular receptor located in either the cytoplasm or the nucleus. This hormone–receptor complex then undergoes a conformational change allowing the hormone–receptor complex to migrate, dimerize, and bind to particular hormone response elements (HREs) on the DNA. Once the hormone–receptor complex binds to its HRE, transcription or repression of a particular gene is initiated, ultimately allowing the production of proteins that may alter the functioning of the neuron.

Recent advances in our understanding of steroid hormone action in neurons have uncovered several indirect genomic and nongenomic actions of steroids. For instance, steroids have been shown to bind to receptors located in the plasma membrane of neurons, which activate second messenger cascades that initiate gene transcription. These indirect genomic effects of steroids are not mediated through HREs but instead are mediated by other DNA regulatory sites such as the cyclic AMP (cAMP) response element (CRE) and activator protein-1 (AP-1). In addition to these indirect genomic effects, steroids can act through nongenomic mechanisms such as directly modulating the permeability of ion channels and acting as antioxidants in neurons. Steroids may also act at specific local sites in the neurons that do not involve interactions with the DNA. Extranuclear estrogen receptors were found in axon terminals and spines of hippocampal CA1 pyramidal cells of the female rat. Various mRNAs for synaptic proteins and translation machinery have been localized in spines, suggesting that translation of such proteins can occur locally in the dendrite. Thus, estrogens may act directly on the synaptic apparatus and mRNAs to affect synaptic function and synaptogenesis. These various mechanisms of steroid hormone action are presented in Fig. 1.

ORGANIZATION VERSUS ACTIVATION

Steroid hormones not only allow for the activation of certain behavioral and physiological events during adulthood but also shape the nervous system during development. During perinatal development, the brains of males and females are exposed to different hormonal milieus that ultimately lead to many of the sex differences observed in the brain and behavior of males and females during adulthood. For instance,

males experience increases in testosterone production and secretion during both prenatal and early neonatal development. This, on conversion in the brain to estradiol via the aromatase enzyme, organizes the brain in a masculine fashion. This early masculinization of the brain then allows the hormonal stimulation received during adulthood to act on these organized neural pathways to activate the appropriate male behaviors. In the perinatal female, the estrogen produced by the mother and the prenatal ovary does not masculinize her brain because this estrogen is bound by alpha fetoprotein and is unable to cross the blood–brain barrier. Indeed, the feminized brain appears to be the default pattern of development in that a brain that does not receive androgenic and estrogenic stimulation during development results in a feminized brain.

The organizing influences of steroid hormones on the perinatal brain and the resulting morphological and functional differences between the sexes can be profound. Indeed, the organizing effects of steroids result in certain sexually dimorphic nuclei in the nervous system that may be as much as five times larger in one sex than in the other. The effects of steroids on the adult brain are much more subtle than these organizing effects during perinatal development. However, steroids are still capable of shaping the adult brain in important ways.

STEROID-INDUCED NEURONAL PLASTICITY DURING ADULTHOOD

Sex steroids have been shown to affect the density and morphology of dendritic spines. Spines are membranous protrusions emanating from dendrites and are sites of synaptic contact between neurons. Neurons receive excitatory input via these dendritic spines, which contain various types of glutamate receptors, scaffolding proteins, and signaling molecules. Spines come in various sizes and shapes that may be indicative of their maturity. Different steroids can affect the growth and development of spines, thereby modulating excitatory neuronal signaling.

The hypothalamus was the first brain area in which sex steroids were shown to influence synapse formation and spine maturation. Ovariectomized females have significantly fewer synaptic contacts in their ventromedial nucleus (VMN) than do ovariectomized females treated with estrogen. Furthermore, females in the proestrous stage of their estrous cycle (i.e., when estrogen levels are high) have a greater spine density than do females in diestrus (i.e., when

Figure 1 The genomic, indirect genomic, and nongenomic mechanisms of steroid hormone action on neurons. Indirect genomic mechanisms include the activation of steroid receptors linked to second messenger cascades that activate gene transcription through DNA-binding domains such as cAMP response element (CRE) and activator protein-1 (AP-1), ultimately altering neuronal function. In the genomic mechanism, the steroid binds to the intracellular form of the receptor, permitting the steroid–receptor complex to translocate to the nucleus. This steroid–receptor complex then binds to the hormone response element (HRE), activating transcription of the genome and altering neuronal function. Nongenomic mechanisms of steroid action include the ability of steroids to influence ion permeability and possibly to affect local protein synthesis in the spine head. This later mechanism presumably would allow for the rapid regulation of spine-specific mRNAs and proteins. Akt, protein kinase B; CaMK, Ca²⁺/calmodulin-dependent protein kinase; CREB, cAMP response element-binding protein; Gαs and Gαq, guanosine triphosphate (GTP)-binding proteins; MAPK, mitogen-activated protein kinase; PKA, protein kinase A; PKC, protein kinase C.

estrogen levels are relatively low). The VMN is a fundamental component of the neural circuit that mediates the expression of female reproductive behavior. Thus, it is not surprising that estrogenic stimulation that activates female mating behavior would also promote spine density and, hence, increase excitatory input to the VMN. In males, VMH spine density increases after castration, whereas estrogen-treated males exhibit a relatively low number of spines, similar to the density observed in intact males. Thus, the effect of estrogen on VMN spine density in males is

opposite that in females. Interestingly, when males are treated with an aromatase inhibitor on the first day of life to block the normal masculine organization of the brain, estrogen treatment during adulthood results in an increase in spine density similar to that observed in females.

The arcuate nucleus (ARC) of the hypothalamus plays an important role in mediating the release of the gonadotropins from the anterior pituitary. The dendrites of these neurons exhibit a sex difference such that females have twice as many spines as do males.

Similar to the VMN, androgenic and estrogenic stimulation received early in development appears to organize these neurons. Specifically, females that receive testosterone neonatally have fewer spines than do untreated females during adulthood. Conversely, adult males that are castrated neonatally show a greater number of spines than do control males. The greater number of spines, and presumably the greater excitatory input to the female ARC, may help to modulate the luteinizing hormone surge that causes ovulation in females.

The effects of sex steroids on brain areas outside of the hypothalamus and their role in biological events other than reproductive physiology and behavior have been explored recently. The sex steroid receptors are located in many extrahypothalamic regions of the brain, such as the hippocampus and the cortex, and steroids have been implicated in mediating diverse phenomena from immunity to cognition. An accumulating body of evidence shows that estrogen can improve an organism's ability to learn and remember. How estrogen mediates these effects on learning and memory is unclear. However, a very interesting and emerging story points to the ability of estrogen to affect the structure and function of the hippocampus, an area of the brain implicated in learning and memory.

Female rats that have been ovariectomized have significantly fewer dendritic spines on the dendrites of the CA1 pyramidal cells of the hippocampus than do estrogen-treated females. Moreover, female rats experiencing the normal fluctuations of estrogen during their 4- to 5-day estrous cycle show changes in spine density. Specifically, females in proestrus, when estrogen levels are at their highest, had a significantly greater number of dendritic spines on their CA1 cells than did females that were sacrificed on the day of estrus, when estrogen levels are relatively low. Additional studies have shown that this increase in spine density is also accompanied by an increase in synaptic input to the apical dendrites of the CA1 pyramidal cells. These structural alterations are paralleled by physiological and behavioral changes as well. Specifically, adult female rats experiencing high levels of estrogen show enhanced hippocampal long-term potentiation (LTP), a putative electrophysiological correlate of learning and memory, and improved memory retention on a hippocampal-dependent spatial memory task.

A study that examined estrogen-treated female nonhuman primates revealed that estrogen increases hippocampal spine density in higher order mammals as well. Whether estrogen increases hippocampal

spine formation in humans is unknown, but estrogen replacement therapy has been shown to promote cognition in postmenopausal women and possibly to aid in the prevention or amelioration of neurodegenerative diseases such as Alzheimer's disease.

Males do not show the same increase in spine density in response to estrogen. However, testosterone has been shown to increase the number of spines on the CA1 pyramidal cells of males. It is unknown whether testosterone enhances LTP or improves memory retention in males, although one study conducted on elderly men suggests that testosterone can increase performance on certain memory tasks.

In addition to synaptogenic effects of estrogen and testosterone on the hippocampus, one study has shown that estrogen can induce greater spine density in the prefrontal cortex of nonhuman primates. Given that the prefrontal cortex of primates is involved in many aspects of cognitive function, it is possible that the memory-enhancing effects of estrogen are mediated, at least in part, by its actions on both the hippocampus and the cortex.

Not all steroid hormones increase spine density and synaptogenesis. Studies investigating the effects of progesterone on synaptogenesis have shown that progesterone in the presence of estrogen actually decreases spine density in the female CA1 hippocampal region. The effects of progesterone alone on hippocampal spine density have not been fully explored. However, recent experiments suggest that progesterone in the absence of estrogen may actually promote spine growth and synaptogenesis.

In contrast to the spine-promoting effects of estrogen and testosterone on the male and female hippocampus, high levels of corticosterone induced by repeated stressors have been shown to decrease the branching of hippocampal CA3 pyramidal cells and to cause dendritic atrophy. In severe cases, extensive exposure to high levels of stress and the resulting chronic elevation of corticosterone can actually kill hippocampal neurons. Animals experiencing chronic stress also tend to perform more poorly on learning and memory tasks than do nonstressed animals. It is important to note that low to intermediate levels of "stress hormones" enhance performance on learning and memory tasks. Studies investigating the effects of corticosterone on hippocampal LTP parallel these behavioral results such that high levels of corticosterone suppress LTP, whereas intermediate levels enhance plasticity. It is interesting to speculate that individuals experiencing severe and prolonged chronic stress will have compromised hippocampal

and cognitive function. Although some human research points to this possibility (e.g., in the case of depressive illness), more research is needed to establish a causal link.

NEURONAL PROTECTION AND NEUROGENESIS

As discussed previously, steroids can have profound influences on the structure and function of neurons early in development and into adulthood. In addition to these influences, steroids can alter the survival and production of new neurons, even in the adult brain. For instance, at high concentrations, estrogen can protect neurons by working as an antioxidant. Estrogen has also been shown to diminish the neural damage induced by stroke and reduced blood flow to the cortex. These neurotropic effects after stroke may be through the antioxidant properties and/or through the influence of estrogen on growth factor synthesis and receptor expression.

Steroid hormones have also been shown to affect neurogenesis. Estrogen has been demonstrated to increase the production of new neurons in the dentate gyrus of the female hippocampus. Specifically, ovariectomized females treated acutely with estrogen have a greater number of proliferating cells than do untreated ovariectomized females. Moreover, normally cycling females experiencing the relatively high levels of estrogen during proestrus have more cellular proliferation in the dentate gyrus than do females experiencing the relatively low levels of estrogen associated with estrus and diestrus.

Conversely, animals experiencing high levels of corticosterone show less cellular proliferation in the dentate gyrus than do animals experiencing low levels of corticosterone. This corticosterone-induced decrease in neurogenesis suggests that high levels of corticosterone not only promote atrophy (and even loss) of neurons in the hippocampus but also slow the production of new neurons that may be needed to replace the lost cells.

CONCLUSION

Steroid hormones secreted from the gonads and adrenals act on the brain and are known to influence diverse functions such as reproduction and learning and memory. These hormones can act on neurons through a genomic, an indirect genomic, or a nongenomic mechanism of action. The sex steroids have been shown to organize the male and female perinatal brain so that the proper physiology and behavior can be activated by these hormones during adulthood. Furthermore, steroids continue to shape the adult brain by affecting factors such as synaptogenesis, spine maturation and growth, neuronal branching, neuroprotection, and neurogenesis. Therefore, steroids not only contribute to the development of the nervous system but also continue to influence neuronal structure and function throughout the life span.

Breast Disease: Impact of Sex Steroid Replacement

Michael E. Carney

University of Hawaii, Honolulu, Hawaii, United States

Glossary

hormone replacement therapy (HRT) Steroidal hormones containing an estrogen with or without a progesterone taken for various indications, including (most commonly) estrogen withdrawal symptoms that occur on cessation of endogenous ovarian sex steroid production; these medications are usually delivered as either oral or transdermal preparations.

oral contraceptive pill (OCP) Steroidal hormones usually containing both an estrogen and a progesterone that act in several ways, including ovulation inhibition and implantation hindrance, to effectively and reversibly prevent pregnancy.

sex steroid hormones Substances generally derived from a carbon backbone that affect sexual growth and development; in the body, these are secreted by the adrenal gland, ovary, and testis.

An understanding of the relationship between sex steroidal hormones and breast disease begins with an understanding of the connection between the sex steroids and the breast itself.

INTRODUCTION

Growth and development of the normal healthy breast is dependent on the sex steroid hormones, specifically estrogen and progesterone. This relationship is initially most evident in a woman's life during puberty, when undeveloped and quiescent breast tissue is exposed to increasing amounts of estrogen and progesterone, ultimately resulting in the development of the adult breast. Simply put, exposure to these hormones causes growth and development of the breast tissue. Throughout premenopausal life, during a normal menstrual cycling, physiological changes occur within the breast tissue in response to varying levels of the steroid hormones. Perhaps the most dramatic evidence for this change is during pregnancy, when

the breast responds remarkably to the changing hormone milieu with breast enlargement, engorgement, lactation, and involution after breast-feeding has stopped. Finally, withdrawal of estrogen at menopause, either naturally or surgically, results in breast changes that are clinically measurable.

As medicine has progressed over the past several decades, so has the development of hormonal medications. Tremendous advancements have been achieved using these medications in the areas of pregnancy prevention and relief of vasomotor symptoms related to estrogen withdrawal. Hormonal contraception and hormone replacement are the two most common medications prescribed today in the United States.

Unfortunately, the most common cancer in U.S. women, affecting 1 in 8 women, is breast cancer. The incidence of breast cancer has risen over the past two decades, and there is mounting concern over the connection between exogenous hormone exposure and the development of breast cancer. This concern is not unfounded given that it stands to reason that the exposure of breast tissue to exogenous steroid hormones might affect breast physiology, including growth and development. This article initially examines breast anatomy, growth, and development and the relationship of the breast to sex steroid hormones. Later, it reviews the interaction between exogenous steroid hormones and breast tissue. Finally, it reviews the current literature examining hormone replacement therapy (HRT), including testosterone, oral contraceptives, and the development of breast disease, specifically breast cancer.

THE BREAST, GROWTH AND DEVELOPMENT, AND SEX STEROIDS

Mammals are defined by the presence of breast tissue. In humans, the development of the breasts begins *in utero* at about the 6th week of fetal life along the "milk ridge" running from the groin to the axilla, similar to other mammals. However, unlike many other mammals, all but the chest portion of the human milk

ridge regresses by the 9th week of fetal life. At approximately the 12th to 16th weeks, mesenchymal cells develop into the smooth muscle of the nipple and areola. Epithelial buds form at 16 weeks and become 8 to 20 strips of epithelium, representing the future breast ducts and secreting alveoli.

In the male fetus, androgens interact with the early epithelial buds to induce suppression and even destruction. In the female at this time, early sweat glands begin to form the breast parenchyma. This early development is genetically determined and appears to be relatively independent of hormonal direction. Later, fetal breast development occurs in the rich hormonal environment of the mother, where estrogen and progesterone are at very high levels being produced by the placenta and maternal ovary. At the 20th week, the branched epithelial tissue is canalized and coalesces with sebaceous glands near the epidermis. Parenchymal differentiation occurs near term with the formation of a lobular–alveolar unit containing colostrom.

The breasts of both the male and female fetus respond to the continuous progesterone and estrogen hormonal milieu. Breast tissue is often palpable in the breasts of both genders at birth, and 85% of newborns will have nipple discharge on the second or third day of life. With the sudden drop of hormones at parturition in the newborn, the discharge and breast swelling quickly resolve. The response of breast tissue to estrogen and progesterone is undeniable, even at this early age. Several investigators, including Nicholas Petrakis, have speculated that the fetal hormonal environment and variable exposure to the estrogen and progesterone might contribute to an individual's risk for the future development of breast cancer.

The time between birth and puberty is relatively quiet in terms of breast tissue growth. Between 10 and 12 years of age in most girls, the hypothalamus begins releasing gonadotropin-releasing hormone (GnRH). When GnRH is released appropriately and rhythmically, it stimulates the pituitary to release luteinizing hormone (LH) and follicle-stimulating hormone (FSH), thereby promoting the primordial follicles in the ovary to produce estrogen. Ovulation does not occur for the first 1 or 2 years; thus, the predominant hormone released at this time is estrogen. The pubertal breast is exposed to estrogen, causing longitudinal ductal epithelial growth and the formation of more terminal ductile epithelial buds. Growth of the surrounding connective tissue, including fat, elastin, and vascularity, is similarly stimulated to grow. Interestingly, progesterone alone cannot cause this breast ductile epithelial growth.

With the onset of ovulation and, hence, exposure to circulating progesterone, full ductular–lobular–alveolar growth is achieved. At maturity, the functional breast is composed of 5 to 10 major nipple ducts that branch into several smaller collecting ducts to form a particular lobe. Each lobe has up to 40 lobules, with each lobule containing up to 100 alveoli that connect to a terminal duct. It is important to understand the role that hormones play in the development and growth of the breast given that virtually all breast cancers arise from the ductular–lobular–alveolar unit, with more than 90% arising from the ductile epithelium itself.

HORMONAL MICROENVIRONMENT OF THE BREAST

The immature breast ducts and alveoli are lined by two epithelial layers. On exposure to estrogen, this epithelium grows and becomes multilayered with continuous terminal branching and alveolar development. The growth occurs during the proliferative phase of the menstrual cycle, when the ductile cells demonstrate increased mitosis, RNA synthesis, and ribosomal and Golgi apparatus activity. With the surge of progesterone during the mid-luteal phase, the ducts dilate and terminal alveolar cells differentiate into secretory cells, where lipid droplets form and are secreted into the lumen. Premenstrual breast fullness is directly attributable to the growth and secretion that occur as a result of estrogen and progesterone. Breast volume is at its minimum 5 days following menstruation due to the drop in hormone levels.

The hormonal effect on breast growth is even more dramatic during pregnancy. Estrogen causes marked ductile growth, branching, and lobule formation. Progesterone causes significant lobular growth and further formation during the second half of pregnancy. At parturition, the ductular–lobular–alveolar unit stops growing. The breast enlargement that occurs is related more to the secretion and storage of milk and fluid. An interesting cellular event occurs with the termination of lactation at weaning. On withdrawal of the hormones and growth factors of lactation, the terminally differentiated epithelial cells of the lactating gland enter into apoptosis. At menopause, with the decline of circulating estrogen and progesterone, the epithelial structures and stroma regress, leaving an intact ductile system but shrunken and collapsed lobules.

Breast duct growth occurs in response to hormonal exposure due to the presence of estrogen and progesterone receptors within the duct epithelial cells. A

complex symphony of molecular interactions involving the hormone–receptor complex occurs, ultimately resulting in cellular growth and differentiation. This mechanism is not completely understood but does involve many different transmembrane and intracellular growth factor receptors that respond not only to the growth message from the steroid hormone but also to the messages from other hormones, including prolactin, oxytocin, and growth hormone. Certainly, several of the cellular growth factors involved in normal breast growth and development have been implicated in the development of cancer. HER-2/neu, an epidermal growth factor, is just one of those factors known to be overexpressed in some aggressive breast cancers. It is unknown whether over- or underexposure to estrogen or progesterone, either endogenous or exogenous, directly contributes to malfunctions of the growth regulatory system; however, epidemiological and experimental evidence suggests that there may be a connection.

Breast disease, specifically breast cancer, is the most common form of cancer among women. The incidence of this cancer has been increasing recently and simultaneously with the increase in the general use of common hormonal medications, including estrogen and progesterone as either hormone replacement or contraception. Given the clear association between breast growth and the steroid hormones as well as the stimulatory molecular changes that occur at the cellular level, concern has arisen over the likelihood of malignant transformation in the breast as a result of exogenous hormone exposure. Several epidemiological studies have been conducted examining the relationship between hormone use and the development of breast cancer, often with conflicting results. Despite the numerous studies and basic science investigations, there still is no clear direct relationship between exogenous hormone exposure and the development of breast cancer.

HRT AND BREAST CANCER

By far the largest, most expensive, and most important study ever conducted examining the relationship between hormone replacement and breast cancer is an ongoing study by the National Institutes of Health called the Women's Health Initiative (WHI). This study enrolled 161,809 healthy postmenopausal women (50–79 years of age) and examined the health benefits/risks of a number of interventions, including hormone replacement, in a randomized, blinded prospective fashion. After 5.2 years of follow-up, the portion of that trial following 16,608 enrolled women

with uteri was prematurely stopped and the results were reported. In that subtrial, half of the women were given daily conjugated equine estrogens (0.625 mg) plus medroxyprogesterone (2.5 mg), and half were given placebo. The trial was stopped prematurely as a direct result of the observed increased incidence of breast cancer seen in the women taking the hormone replacement. The risk for invasive breast cancer was 26% higher for the group taking the estrogen and progesterone. In other words, 38 of 10,000 women were observed to develop breast cancer rather than an expected 30 of 10,000. This increase was seen after 4 years of use and appeared to increase further with longer use of hormone replacement.

However, even with the increase in breast cancer, there was no observed difference in mortality between the two groups. Also interesting, the portion of the WHI trial that included women who had undergone hysterectomies and who were randomized to either estrogen without progesterone or placebo was not stopped, suggesting no increased risk of breast cancer in that group. This has led many to speculate that the contribution made to the increased incidence of breast cancer seen in this trial may be a consequence of the progesterone and not of the estrogen. There is epidemiological evidence that estrogen and progesterone affect the breast differently than does estrogen alone.

We can see the effect of progesterone on mammography. In one study, the Postmenopausal Estrogen Progestin Intervention (PEPI) trial evaluating cardiovascular effects of various HRT regimens, the researchers found that the three study groups of women taking different estrogen and progesterone preparations had significantly denser breasts on mammography than did the estrogen only and placebo groups. Several studies have reported that dense breasts on mammography are an independent risk factor for the future development of breast cancer. More abnormalities are found on mammography in patients on hormone replacement.

The WHI represents the only randomized controlled trial to examine and confirm that combined estrogen and progesterone increases the risk of invasive breast cancer in healthy postmenopausal women. However, the study is not the first to suggest a relationship between breast cancer and hormone replacement.

A 1997 study published by the Collaborative Group on Hormonal Factors in Breast Cancer analyzed 51 epidemiological studies reviewing hormone replacement information on 160,000 women, one-third of whom had breast cancer. In that meta-analysis, the research group found a 15% increased risk for breast cancer in women using estrogen plus progesterone for

shorter than 5 years and a 53% increase in those using the combination for longer than 5 years.

The Heart and Estrogen/Progestin Replacement Study (HERS) was conducted to rigorously examine the potential cardiovascular benefits seen in previous studies of women on hormone replacement. In a 2002 publication in *Lancet*, that group reported a 26% (not statistically significant) increase in the risk of breast cancer in women taking hormone replacement at 6.8 years follow-up.

Two separate Southern California studies, a University of California, Los Angeles/Los Angeles County case-control study and a retrospective breast cancer detection project, identified progesterone use as part of hormone replacement to be an independent risk factor for the development of breast cancer. In both studies, the relative risk for the development of breast cancer was 1.4 when progesterone was used with estrogen in HRT. Estrogen alone was found to contribute only a minimal increase in breast cancer risk. These findings seem to be consistent with the WHI's findings that progesterone, when used with estrogen, increases the risk of subsequent development of breast cancer.

More recently, androgen replacement in conjunction with estrogen has become increasingly popular for libido enhancement in postmenopausal women. The impact of exogenous testosterone use on the risk of breast cancer has not been critically evaluated. However, a few articles have reviewed serum sex steroid levels and risk of breast cancer. In a 2002 British study reviewing all of the previous studies examining serum sex steroid hormones and breast cancer risk, the researchers found that elevated levels of all the endogenous sex steroid hormones, including estrogens and androgens, were strongly associated with risk of breast cancer in postmenopausal women. This is in contrast to clinical evidence that androgens inhibit breast growth and proliferation. The physiological interplay among serum sex steroid hormone levels, binding globulins, and receptor status at the cellular level is complex and is the subject of tremendous investigation. A 2002 National Institutes of Health study suggested that the risk of breast cancer in postmenopausal women on hormone replacement might be explained by the suppression of androgens as a result of exogenous estrogen.

HORMONAL CONTRACEPTION AND BREAST CANCER

Tens of millions of premenopausal women in the United States use hormonal contraception, most

commonly oral contraceptive pills (OCPs) that usually contain both estrogen and progesterone, to prevent unwanted pregnancy. "The pill" represents the most common form of birth control and the most effective for women since its introduction some 40 years ago. Since that time, given the known hormonal responsiveness of breast tissue, there have been concerns about the possible association between OCPs and risk of breast cancer. Over the years, the pill has undergone a progressive and continual modification of its formula. In general, the doses of estrogen and progesterone contained within the pill have been continually lowered so that women are now able to have the lowest effective dose. In addition, new formulations of estrogens and progestones have been introduced such that several different ones are available to be used in the modern OCP.

Unlike the WHI study, no prospective, randomized, placebo-controlled study has ever been conducted to answer the question of association between OCP use and risk of breast cancer. However, many studies have analyzed OCP use and breast cancer in other ways and found varying results. Because OCP formulations and strengths have changed over the years, a study published just 5 or 10 years ago analyzing patients who took the OCP 15 to 20 years ago possibly does not appropriately reflect current risk. The risk of an immediately measurable event, such as stroke or deep vein thrombosis (DVT), related to OCP use has dropped precipitously since the early years of the pill, so it is possible that a more long-term measurable event, such as risk of breast cancer, has also changed.

One of the more recent reports evaluating OCP use and risk of breast cancer was a population-based, case-control study published by the Centers for Disease Control and Prevention (CDC) enrolling more than 9000 women. In that study, the researchers found no increase in the risk of breast cancer in women who were current or former OCP users regardless of duration of use, doses of estrogen, duration of use, or age at initiation of use.

Another CDC study, published in 1983, also found no evidence of a connection between OCP use and risk of breast cancer in the Surveillance, Epidemiology, and End Results (SEER) case-control investigation of 2000 breast cancer cases. In that study, duration of use, age at initial use, family history, and personal history of benign breast disease did not increase the risk of breast cancer. A follow-up CDC study in 1986 found that the relative risk of breast cancer remained similar to that in women not taking OCPs despite different progesterone formulations.

However, not all studies dismiss the risk of breast cancer in OCP users. A Harvard University study examined the relationship between OCP use and breast cancer in 1799 women who developed breast cancer in a prospective cohort of 118,273 nurses. In that study, past users of OCPs (defined as more than 2 years of use prior to a breast cancer diagnosis) realized no increased risk for the development of breast cancer as a result of their OCP use. However, current users realized a relative risk of 1.5.

A 2000 study from the Netherlands following 12,000 women over 7.5 years found 309 cancer cases. When risks were analyzed for the women who developed breast cancer, those women who were over 55 years of age at the time of their cancer diagnosis and who had used OCPs for more than 10 years were twice as likely to have developed breast cancer.

Hormonal contraception can also be achieved by progesterone injection (depot-medroxyprogesterone acetate [DMPA]) or by subcutaneous implantation of progesterone pellets. In several reported studies examining thousands of women, no connection between this type of hormonal contraception and breast cancer could be established.

CONCLUSION

Sex steroid hormones play a critical role in breast growth and development early in life as well as in breast physiology throughout the remainder of reproductive life. At the cellular level, sex steroid hormones directly affect the function of ductular–alveolar system of the breast. Multiple factors not reviewed in this article, including serum hormone levels, hormone-binding proteins, interaction between hormones, hormone receptor type, hormone receptor expression, and affected intracellular growth mechanisms, all act independently to influence the risk of breast cancer.

The concern regarding the impact of exogenous steroid hormones on breast disease is valid and is the subject of hundreds of studies, some of which were presented in this article. Mounting evidence suggests that hormone replacement increases the risk of breast cancer in women and that the increased risk may be due to the progesterone component of the replacement regimen. One significant limitation of these studies is that relatively few preparations of estrogen or progesterone have actually been examined. Mortality and type of breast cancer may also influence interpretations of these studies. There are also questions about serum levels, other hormone interactions, and specific cellular events that may contribute to that risk, further

clouding the interpretation of large epidemiological studies. It is difficult to draw conclusions about all hormone replacement given these limitations. Even so, given the current studies, there does appear to be an elevated risk for the development of breast cancer in the general population of women taking progesterone and estrogen as hormone replacement.

Similar to hormone replacement, hundreds of studies have been published examining the risk of breast cancer given exposure to oral contraceptives, and a definite risk has not been firmly established. Although most studies find no increased risk, there are some that do in fact point to an increased risk of breast cancer. However, on balance, and given our current understanding, OCPs appear to be safe.

Our understanding of the impact of sex steroid hormones and the risk of breast disease continues to evolve. It is critical to weigh all of the studies, risks, and benefits and to be aware of the limitations of our current understanding of the complex interactions between these hormones and breast tissue.

Glossary

calcitonin receptor-like receptor (CL receptor)

G protein-coupled receptor (GPCR); pharmacology of this receptor is defined by its interaction with a group of accessory proteins called receptor activity-modifying proteins (RAMPs). CL receptor functions as a CGRP1 receptor when dimerized with RAMP1 and as an adrenomedullin (AM) receptor when dimerized with RAMP2 or RAMP3.

CGRP receptor component protein (RCP) Intracellular protein that facilitates signal transduction through the CGRP1 receptor.

migraine Complex neurological disorder characterized by severe head pain, nausea, and exacerbated sensitivity to external stimuli such as light and sound. It presents in one of two forms, migraine without aura or migraine with aura, with the latter characterized by visual disturbances such as zigzag lines and blind spots.

receptor activity-modifying proteins (RAMPs)

A family of three single type I transmembrane proteins, RAMP1, RAMP2, and RAMP3, required for the transport, glycosylation, and pharmacological classification of the calcitonin receptor-like receptor (CL) as CGRP1 or adrenomedullin (AM) receptor.

Calcitonin gene-related peptide (CGRP) is a neuropeptide expressed in a variety of cells in the central and peripheral nervous systems. It exerts a broad range of biological effects such as vasodilation, increasing rate and force of cardiac contraction, regulation of calcium and glucose metabolism, reduction of gastrointestinal motility, and inflammation.

INTRODUCTION

Calcitonin gene-related peptide (CGRP) is a product of alternative splicing of the calcitonin (CT) gene. Its dual occurrence in nerves and endocrine cells suggests

potential functions as a neuromodulator and an endocrine/paracrine hormone. CGRP biological activity is mediated by type II G protein-coupled receptors (GPCRs). Although pharmacological studies suggest the existence of multiple CGRP receptors, only one receptor has been cloned and named CL receptor. In the past few years, the classical concept of GPCRs has been challenged by the discovery of a group of accessory proteins, receptor activity-modifying proteins (RAMPs) and receptor component protein (RCP), that interact with CL receptor and modulate both its ligand-binding selectivity and its signal transduction. Structural and functional analysis of these multiple associations will provide new insights into molecular determinants of multiple CGRP functions and will help to design new drugs to regulate CGRP activity under pathological conditions.

CT/CGRP GENE, ALTERNATIVE SPLICING, AND TRANSCRIPTIONAL REGULATION

CGRP is a 37-amino acid neuropeptide discovered by Rosenfeld and co-workers in 1983. After Rosenfeld's group observed that serially transplanted rat medullary thyroid carcinoma cells generated tumors in which CT biosynthesis was decreased more than 10-fold, attempted cloning of the CT gene in these tumors revealed a new, longer cytoplasmic mRNA, later identified as α -CGRP mRNA.

The human genome contains at least three CT/CGRP genes, all of which localize to chromosome 11p. Alternative splicing of the gene and posterior processing of the prepro-peptides generate two different mature peptides: CT and CGRP.

The CT/ α -CGRP gene contains six exons and is processed in two different ways, depending on the tissue (Fig. 1). In parafollicular cells of the thyroid, 95% of the CT/CGRP pre-RNA is processed to include exon 4 followed by polyadenylation, which

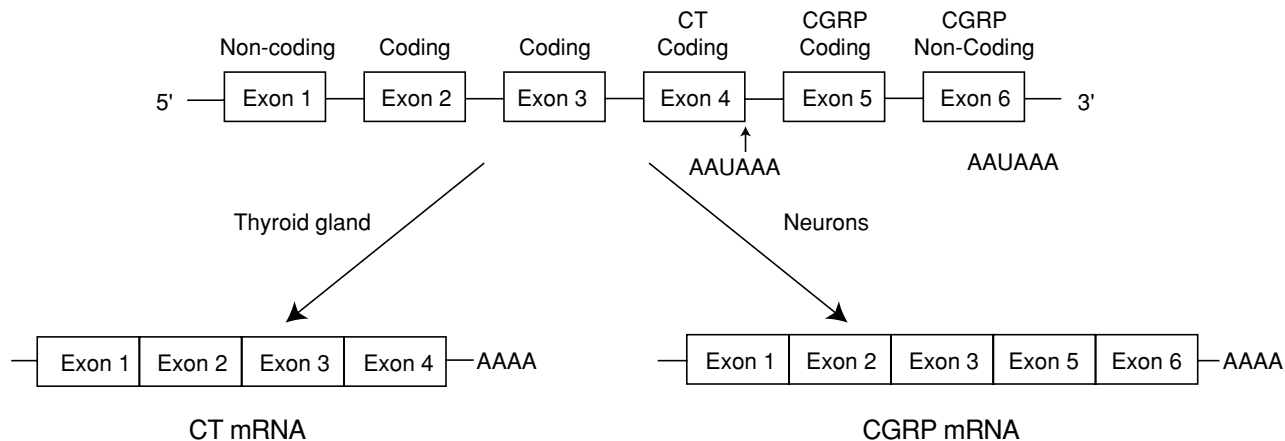

Figure 1 Alternative mRNA splicing of the CT/α-CGRP gene yielding both CT and α-CGRP in a tissue-specific manner. Boxes are exons; lines in between are introns.

leads to the production of the calcium-regulating hormone CT. In neurons, 99% of the pre-CT/CGRP includes exons, 1, 2, 3, 5, and 6 with a poly(A) tail at exon 6. This is translated into the neuropeptide α-CGRP. The key regulatory event in the processing choice is the tissue-specific inclusion or exclusion of the alternative 3'-terminal exon 4. This is modulated by factors that bind to an intronic enhancer element that contains both 3' and 5' splice site consensus sequence elements. Although factors involved in the tissue-specific alternative splicing of the CT/CGRP pre-RNA have not been identified, members of the serine- and arginine-rich RNA-binding protein family seem to participate in multiple interactions that coordinate individual recognition events during the early steps of RNA processing.

A second CGRP gene (β-CGRP) was predicted from analysis of cDNA in rat and human. The β-CGRP gene encodes a molecule closely related to α-CGRP. β-CGRP differs from α-CGRP in one amino acid in rat and in three amino acids in human. The lack of a poly A signal within exon 4 of the β-CGRP prevents alternative splicing; consequently, transcripts from this gene produce only β-CGRP and not CT.

The third CT/CGRP-like gene has also been identified on chromosome 11 and contains nucleotide sequences corresponding to exons 2 and 3 of CT/α-CGRP and β-CGRP genes. However, this gene does not transcribe and has been considered as a pseudogene.

Specific stimuli that modulate the expression of CT/CGRP genes in various cell types and some sequences in the gene promoter responsible for transcriptional regulation have been identified. For instance, thyroid C cells treated with either glucocorticoid hormone or retinoic acid show reduced

expression of the CT/CGRP gene, an effect associated with decreased activity of an enhancer element that normally increases promoter activity in thyroid C cells. In neurons, the CT/CGRP gene is activated by cyclic AMP (cAMP) and nerve growth factor (NGF). Both stimuli induce the phosphorylation of the cAMP response element (CRE)-binding protein (CREB) transcription factor on Ser-133. In the trigeminal ganglia, the regulation of CGRP gene expression has also been associated with MAPK signal transduction cascades. This signaling pathway may be of particular relevance to migraine because many inflammatory mediators implicated in this pathology are known activators of MAPK pathways.

Both α-CGRP and β-CGRP are synthesized as precursor prepro-peptides, consisting of 128 and 127 amino acids, respectively. The mature, C-terminally amidated α-CGRP and β-CGRP are produced by further cleavage of the leader sequence. Although α- and β-CGRP coexist in a large number of neurons, β-CGRP is predominant in the enteric nervous system and in the human pituitary gland, whereas α-CGRP is preferentially found in the trigeminal ganglia, the main source of cerebrovascular CGRP. Moreover, these two peptides activate different CGRP receptor subtypes and mediate distinct biological activities. For example, β-CGRP causes a selective suppression of gastric acid secretion, whereas α-CGRP stimulates renin and aldosterone secretion.

CGRP RECEPTORS

Pharmacology of CGRP Receptors

CGRP is a member of a peptide family that also includes CT, amylin (AMY), and adrenomedullin

(AM). Although these peptides have only limited sequence identity, they share a number of structural features, including a six- or seven-amino acid ring formed by a disulphide bond at the N termini (implicated in triggering signal transduction), an amphipathic α -helix, and a C-terminal amide (responsible for the interaction of the molecule with the receptor). The structural convergence among these peptides results in a significant degree of cross-reactivity between receptors. This, in combination with the lack of fully selective agonists/antagonists, has hindered the accurate classification of CGRP receptors.

CGRP acts via type II GPCRs that primarily stimulate adenylate cyclase through the G_s subunit. The involvement of other G subunits in the activation of alternative pathways has also been described. Pharmacologically, the existence of at least two classes of CGRP receptors, named CGRP1 and CGRP2, has been proposed based on the differential potencies of CGRP peptide analogues in a variety of *in vitro* and *in vivo* bioassays.

CGRP Receptor Antagonists

Structure-activity characterization of various fragments of human α -CGRP ($h\alpha$ -CGRP) demonstrated the potent antagonist properties of C-terminal fragments such as CGRP₈₋₃₇, CGRP₉₋₃₇, and CGRP₁₂₋₃₇. Shorter C-terminal fragments, including CGRP₁₉₋₃₇ and CGRP₂₃₋₃₇, also displayed competitive antagonist properties but with much lower potency when compared with CGRP₈₋₃₇. The ability of the peptide fragment CGRP₈₋₃₇ to antagonize α -CGRP effects with higher ($pA_2 \geq 6.9$) or lower ($pA_2 \leq 6.6$) potency has been used as the main criterion for classifying CGRP receptors in CGRP1 or CGRP2 type, respectively. However, characterization of CGRP receptors based on the antagonist properties of CGRP₈₋₃₇ as the only parameter has proven to be limited. Indeed, CGRP₈₋₃₇ affinity at CGRP1 receptors varies considerably (pA_2 values 6.9–9.3) depending on species, tissues, and regions within the same organ. CGRP₈₋₃₇ also shows higher affinity in radioligand-binding studies than in functional bioassays. It has been difficult to reconcile such a wide range of pA_2 values accounting for a single CGRP receptor subtype. The differences in CGRP affinities have been attributed to various factors such as temperature modulation of the CGRP₈₋₃₇ affinity, differences in the distribution of proteolytic enzyme(s) that may affect CGRP₈₋₃₇ metabolism, and (most recently) the potential interaction of CGRP with different CGRP/non-CGRP receptor subtypes.

During the past few years, a significant effort has been invested in the identification of the CGRP primary structure and the significance of each single amino acid and its side chain in receptor interaction. These studies have led to a better understanding of the agonist and antagonist properties of multiple truncated CGRP analogues and to the development of smaller molecules with potent antagonist effect such as [Asp31, Pro34, Phe35]CGRP₂₇₋₃₇ and [Pro35, Phe35]CGRP₂₇₋₃₇. One of the most relevant contributions in this field has been the recent development of the first highly potent and selective nonpeptide CGRP receptor antagonist, BIBN4096BS. This compound is more potent than CGRP₈₋₃₇, exhibits more than 200-fold higher affinity at human CGRP receptors (neuroblastoma SK-N-MC cell line $K_i = 14.4 \pm 6.3$ pM) than at rat CGRP receptors (spleen $K_i = 3.4 \pm 0.5$ nM) and does not have significant affinity for other related receptors, including those for CT, AMY, and AM. BIBN4096BS has also become a useful pharmacological tool in identifying other potential CGRP receptors in various animal species such as rat, pig, and human.

CGRP Receptor Agonists

The use of agonists alone to define CGRP receptor subtypes has been of limited value unless they are combined with CGRP receptor antagonists. Three main CGRP forms, the natural peptide β -CGRP and the linear synthetic α -CGRP analogues Cys [(acetaminomethyl)^{2,7}]human- α CGRP ([Cys(ACM)^{2,7}]h α CGRP) and Cys [(ethylamide)^{2,7}]human- α CGRP ([Cys(Et)^{2,7}]h α CGRP), have been identified as putative CGRP2 receptor agonists. Although α -CGRP and β -CGRP induce responses with about equal potency in most tissues, the dilation induced by β -CGRP in guinea pig basilar artery, rat aorta, and pig coronary artery is less potently antagonized by h- α CGRP₈₋₃₇ than that induced by α -CGRP. This observation suggests the presence of two CGRP receptors, an α -CGRP-sensitive receptor and a β -CGRP-sensitive receptor, with the former being more potently blocked by CGRP₈₋₃₇. On the other hand, [Cys(ACM)^{2,7}]h α CGRP and [Cys(Et)^{2,7}]h α CGRP have also been identified as selective CGRP2 receptor agonists based on their potent agonist effect (EC_{50} values ~ 76.0 and ~ 3.4 nM, respectively) in the rat vas deferens as compared with the weak inotropic effect (EC_{50} values > 700 nM and 1 μ M, respectively) in the guinea pig atria. However, the CGRP2 receptor selectivity of [Cys(ACM)^{2,7}]h α CGRP and [Cys(Et)^{2,7}]h α CGRP has been challenged by more recent studies indicating

that both peptides are partial agonists with higher or lower activity largely dependent on the experimental conditions. Interestingly, [Cys (Et)^{2,7}]hαCGRP seems to stimulate another unidentified class of receptors in rat vas deferens, human fetal astrocytes, and pial vessels.

The molecular identity of CGRP2 receptors has not been revealed to this point. Because of the disparity of responses and affinity values obtained in various cell types and experimental conditions, it is still not clear whether CGRP2 receptors are a homogenous group or whether they represent more than one pharmacologically/molecularly distinct receptor population.

Molecular Identity of CGRP1 Receptors

RDC-1 versus CRLR

The complexity of the CGRP receptor pharmacology appeared even more obscure after the cloning of two genes, RDC-1 and CRLR, reportedly encoding the same pharmacologically defined CGRP₁-type receptor. Interestingly, RDC-1 and CRLR share only 10% of sequence identity. With the use of a polymerase chain reaction (PCR)-based approach, several members of the GPCR family were cloned from the thyroid gland. Among them, the canine orphan receptor gene RDC-1 was shown to encode a protein with specific responsiveness to rat α-CGRP in transfected COS-7 cells. However, the failure to reconstitute CGRP receptors by transfecting RDC-1 in other cell lines, as well as the mismatch in distribution between specific RDC-1 *in situ* hybridization signals and CGRP receptor-binding sites in the brain, have raised doubts concerning the real nature of this receptor. RDC-1 seems to be up-regulated during hypoxic conditions, in parallel with an increase in AM mRNA and protein levels. However, there is no conclusive evidence that RDC-1 represents an AM receptor. For this reason, RDC-1 is considered as an “orphan” receptor.

Only a few years after the cloning of RDC-1, another GPCR clone, the calcitonin receptor-like receptor (CRLR), was isolated from rat pulmonary blood vessels. In this article, CRLR is referred to as CL receptor, according to the International Union of Pharmacology (IUPHAR) guidelines. Although initial transfection of human or rat CL receptor into mammalian cells failed to elicit CGRP- or AM-induced responses, a stable expression of this gene in human embryonic kidney 239 (HEK 239) cells resulted in increased density of high-affinity ¹²⁵I-CGRP binding sites and stimulation of intracellular cAMP levels

by CGRP. However, the most conclusive proof that CL receptor can behave as a CGRP1 receptor was provided by MacLatchie and colleagues in 1998. The group discovered three accessory proteins called receptor activity-modifying proteins.

Receptor Activity-Modifying Proteins

RAMPs are a family of single transmembrane domain proteins that are required for the transport, glycosylation, and ligand specificity of the CL receptor (Fig. 2). They have a relatively long extracellular amino terminus, a single membrane-spanning domain, and a short intracellular C terminus. Three members, RAMP1, RAMP2, and RAMP3, have been identified in this family by homology searches. They are 148, 175, and 148 amino acids long, respectively, with about 30% of sequence identity. RAMP1, although unable to bind CGRP on its own, can combine with CL receptor to form a CGRP1 fully glycosylated receptor complex of 66 kDa. Interestingly, the combination of CL receptor with RAMP2 or RAMP3 seemingly yields an AM receptor of 58 kDa (core glycosylated) that can cross-react with CGRP only at high concentrations.

The capacity of CGRP family members to interact with various receptors has raised the question as to whether AM-induced responses are mediated by CGRP or by specific AM receptors. Many effects of AM are blocked by α-CGRP₈₋₃₇ and not by AM₂₂₋₅₂, a more selective AM receptor antagonist. In some cases, both α-CGRP₈₋₃₇ and AM₂₂₋₅₂ can partially inhibit CGRP- and AM-induced cAMP production. The first report documenting the interaction between CL receptor and RAMP1 in SK-N-MC cells showed that this complex selectively responds to CGRP but not to AM, suggesting that CL receptor/RAMP1 heterodimers define a very selective CGRP1 receptor. Later, it was shown that, although α-CGRP has far lower affinity than does AM for CL receptor/RAMP2 and CL receptor/RAMP3 complexes, the affinity of AM for CL receptor/RAMP1 is comparable to that of αCGRP in some biological systems. Furthermore, in cells expressing higher levels of CL receptor/RAMP1 than of CL receptor/RAMP2 or-RAMP3, the effects of AM were blocked by αCGRP₈₋₃₇ but not by AM₂₂₋₅₂. Combined, these observations suggest that CL receptor/RAMP1 heterodimer defines a functional AM-sensitive receptor potentially antagonized by αCGRP₈₋₃₇ and distinct from CL receptor/RAMP2, which is more sensitive to AM₂₂₋₅₂. This dual interaction of the CL receptor/RAMP1 complex with both αCGRP and AM may explain why many actions of AM are potentially antagonized by αCGRP₈₋₃₇.

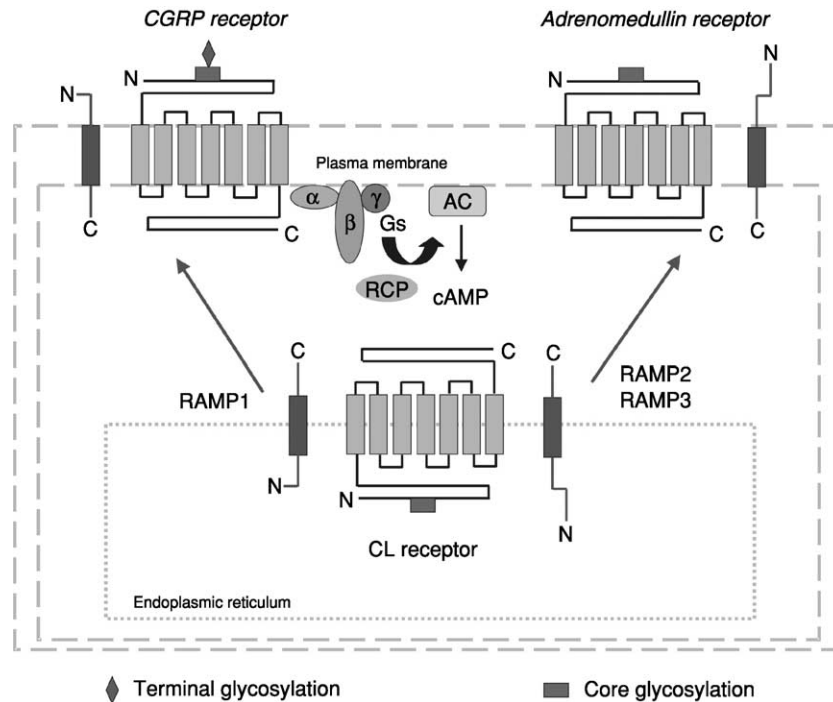

Figure 2 Schematic representation of the CGRP₁/AM receptor showing the interaction between a ligand-binding protein (CL receptor), accessory proteins (RAMP1, RAMP2, and RAMP3) for trafficking, glycosylation and pharmacology, and a receptor component protein (RCP) for coupling to cellular signal transduction pathways. AC, adenylyl cyclase. Figure modified from McLatchie *et al.* (1998) and Evans *et al.* (2000).

RAMPs act as a chaperon for CL receptor trafficking to the cell surface. When expressed individually, RAMPs and CL receptor are retained intracellularly, with CL receptor sequestered in the endoplasmic reticulum and RAMP1 sequestered in both the endoplasmic reticulum and the Golgi system, predominantly as a disulfide-linked homodimer. When coexpressed, both proteins can be detected on the cell surface, suggesting that the interaction between CL receptor and RAMP1 facilitates their trafficking to the plasma membrane.

RAMP1 is also required for the terminal glycosylation of the CL receptor. After cotransfection of HEK cells with RAMP1 and CL receptor, the molecular weight of CL receptor increases and it becomes resistant to endoglycosidase H. In contrast, RAMP2 does not change the molecular weight of the core glycosylated AM receptor. Differential glycosylation of CL receptor in the presence of RAMP1 or RAMP2 does not define receptor specificity for CGRP or AM. Moreover, core glycosylation is not sufficient for plasma membrane incorporation of CL receptor in the absence of RAMPs. Human CL receptor presents three asparagine (Asn) consensus glycosylation sites at positions 60, 112, and 117 of the amino acid sequence.

Selective mutations of these sites have demonstrated that Asn117 is important for direct interaction of CGRP or AM with CL receptor and RAMP1 or RAMP2 and, therefore, for the functionality of the receptor complex. However, Asn117 substitution does not affect N-glycosylation, association with RAMP1, and/or cell surface expression of receptor/RAMP1 heterodimers.

The extracellular N terminus of RAMP1 plays an important role in determining ligand specificity through association with the amino terminus of CL receptor that results in formation of a CGRP-binding pocket. The observation that CGRP receptor antagonist BIBN4096BS exhibits up to 100-fold higher affinity for the human CL receptor than for the rat CL receptor, despite more than 90% sequence homology of CL receptors between the two species, suggested that this selectivity is likely conferred by the interaction of BIBN4096BS with RAMP1 (homology ~ 71%). In support of this idea, Malle and colleagues subsequently demonstrated that tryptophan 74 in RAMP1 is responsible for the selective high-affinity binding of BIBN4096BS to the human CGRP receptor. Future structural analyses of CL receptor/RAMP complexes are needed to map residues important for

ligand recognition and to provide a basis for design of therapeutics with high affinity and selectivity for these receptors.

RAMPs can also compete in the regulation of CGRP/AM receptor function. For instance, coexpression of RAMP3 and RAMP1 results in reduced RAMP1-dependent CGRP receptor activity in a rabbit aortic endothelial cell line. On the other hand, the expression of RAMPs is also selectively regulated by different factors such as hypoxia and corticosterone. Therefore, balance of expression of various RAMPs, as well as their modulation by physiological or pathological conditions, may affect the affinity, function, and “molecular switch” between CGRP and AM receptors.

In summary, evidence gathered during recent years demonstrates the important contribution of RAMPs to various aspects of CGRP receptor biology: (1) trafficking of CL receptor to the cell surface, (2) glycosylation of CL receptor, (3) ligand specificity, and (4) receptor activity. Furthermore, the importance of RAMPs in receptor pharmacology also extends to other members of the CT/CGRP family. It has been shown that multiple AMY receptors arise from RAMP interaction with the CT receptor gene product. This indicates that the cellular profile of the CT/CGRP family of receptors, and potentially other class II GPCRs, can be dynamically regulated by the level and combination of these sets of proteins.

CGRP Receptor Component Protein

In addition to RAMPs, the CGRP receptor complex seems to require another protein for optimal function (Fig. 2). A protein cloned from the guinea pig organ of Corti and the cerebellum, known as the receptor component protein (RCP), has been found to confer CGRP responsiveness to oocytes. RCP is expressed in CGRP-responsive tissues, and its expression correlates with CGRP efficacy *in vivo*. RCP is a 146-amino acid protein that does not belong to any known class of proteins, including RAMPs. RCP does not contain any obvious protein motifs that may help to predict its function. RCP is a peripheral membrane protein attached to the membrane by ionic interactions. It seems to facilitate signal transduction by coupling the CGRP receptor to downstream effectors. CGRP binding and receptor density are not affected in RCP antisense-treated NIH3T3 cells, despite reduction in CGRP-mediated signal transduction, suggesting that RCP is not a chaperon protein for CL receptor. The nature of the interaction between RCP and CL receptor is unclear. It has been suggested that RCP may facilitate CL receptor activation, couple the receptor

to G proteins or other effector molecules, or coordinate the receptor–effector complex in the plasma membrane.

The requirement for the expression of at least three proteins (CL receptor, RCP, and RAMPs) to form a functional CGRP receptor may explain the difficulty in determining the molecular identity of CGRP receptors. Structural analysis and antisense studies will allow determination of sites of interaction and assignment of functions to the emerging subset of accessory proteins that bind to and regulate the activity of GPCRs.

SIGNAL TRANSDUCTION

The binding of CGRP to its receptors activates multiple signaling pathways. The main signaling event triggered by CGRP is stimulation of adenylyl cyclase. However, CGRP has also been reported to activate guanylate cyclase and phospholipase C (PLC) and to increase intracellular calcium concentrations (Fig. 3).

Activation of CGRP receptors stimulates adenylyl cyclase via G_{α_s} . This induces an increase in intracellular cAMP in a concentration-dependent and saturable manner that, in some tissues, can be more pronounced (two- to threefold) than that produced by forskolin. An increase in cAMP activates protein kinase-A (PKA), which then triggers multiple changes in the downstream signaling pathways. In some cases, the CGRP-induced increase in cAMP is followed by a membrane hyperpolarization associated with the activation of an adenosine triphosphate (ATP)-sensitive potassium channel. In blood vessels, CGRP can increase nitric oxide (NO) production via two different pathways: (1) stimulation of adenylyl cyclase followed by activation of PKA and subsequent phosphorylation of eNOS by PKB through a phosphatidylinositol 3-kinase (PI3K)-mediated mechanism or (2) induction of calcium influx through voltage-gated calcium channels, an effect mediated by a cAMP-dependent PKA. Increased intracellular calcium may stimulate eNOS and nNOS, leading to the generation of NO.

In bone cells, activation of CGRP receptors does not stimulate adenylyl cyclase but instead activates PLC- β_1 via pertussis toxin (PTX)-insensitive $G_{\alpha_q/11}$ protein. This induces the formation of diacylglycerol, a direct activator of PKC, and inositol 1,4,5-triphosphate (IP3), which binds to receptors on the endoplasmic reticulum and causes a transient release of calcium.

There is also solid evidence that CGRP, at high concentrations, can signal through G_i coupled to either calcium or potassium channels in various tissues.

nociceptive, and acoustic information during aversive conditioning. Moreover, CGRP evokes fear-like behavior in rats not trained with aversive stimuli.

A potential role for CGRP in neurological disorders, such as dementia and depression, has been supported by anatomical, biochemical, and clinical data. CGRP receptors are often localized in dopamine (DA)-containing neurons. When administered directly into the brain, CGRP markedly affects DA release and metabolism in selected brain regions as well as learning and memory. On the other hand, both psychomimetics and antipsychotic drugs influence regional brain concentrations and release of CGRP *in vivo*. Taken together, these findings support involvement of CGRP in DA-related disorders. In demented patients, cerebrospinal fluid (CSF) levels of both CGRP-LI and CT-LI are lower, but their concentration ratio is similar to that of age-matched healthy controls. This may be explained by a general neuronal loss or, alternatively, by a down-regulation of the CT/ α -CGRP gene expression. In depressed patients, only CT-LI appears to be diminished, resulting in an increase of the α -CGRP/CT ratio. This most likely reflects an altered splicing mechanism favoring the formation of α -CGRP mRNA. Although more studies are needed to draw definitive conclusions, combined measurements of CGRP-LI and CT-LI in CSF may be of diagnostic and perhaps prognostic value in dementia and affective CNS disorders, including depression.

CGRP in the Cardiovascular System

CGRP and its receptors are expressed in the cardiovascular system. CGRP participates in various functions, including modulation of vascular tone, microvascular permeability, inotropy, chronotropy, cell proliferation, and inflammation.

In healthy volunteers, CGRP plasma levels vary between 2 and 35 pmol/L in a gender-independent manner. Neuronal tissues, especially peripheral nerve terminals, and the thyroid gland contribute to the influx of CGRP into the circulation. CGRP is one of the most potent vasodilating substances known and also exhibits positive chronotropic and inotropic effects. However, the physiological significance of circulating CGRP remains uncertain. Various studies have supported the role of CGRP in the regulation of peripheral vascular tone and regional organ blood flow in physiological conditions through either endothelium-dependent or endothelium-independent mechanisms. Moreover, CGRP is likely involved in

blood pressure regulation given that CT/ α CGRP gene knockout mice display a significantly higher mean blood pressure than do wild-type mice.

Reduced levels of CGRP have been associated with various vascular pathologies, including hypertension and Reynaud's syndrome. CGRP agonists have shown efficacy in reversing vascular dysfunction in these diseases. Increased release of CGRP is also causally linked to other cardiovascular pathologies, including migraine, inflammation, and cardiogenic shock associated with sepsis. In some cases, increases in CGRP levels are a compensatory mechanism to counteract pathological vasoconstriction or increased plasma volume such as that observed in myocardial ischemia or pregnancy, respectively.

Role of CGRP in Vascular Disorders Associated with Aging

Wimalawansa and co-workers demonstrated age- and circadian rhythm-related changes of CGRP tissue content. With aging, CGRP levels decrease in neural cells and increase in both the thyroid gland and circulation. The relevance of these changes for deteriorating hemodynamics in the elderly is unclear. CGRP content also decreases in major arteries, including carotid, cerebral, and coronary arteries, a phenomenon likely linked to vasomotor dysfunction and higher risk of ischemic cerebrovascular and cardiovascular events in the elderly. The dorsal root ganglia contain cell bodies of primary afferent neurons that extend CGRP-containing nerves to peripheral blood vessels and the central spinal cord. An age-dependent reduction in CGRP nerve function, including decreases in CGRP mRNA expression in the dorsal root ganglia, neurogenic CGRP release, and CGRPergic nerve-mediated vasodilation, have been observed in spontaneously hypertensive rats. Although various circulating CGRP levels have been reported in essential hypertension in humans, the beneficial effect of calcium intake on lowering the high blood pressure in these patients seems to be associated with a calcium-induced CGRP release into the circulation and the resulting vasodilation induced by the peptide.

Role of CGRP in Migraine Headache

The implication of CGRP in migraine headache is supported by clinical and experimental evidence. Although the initial triggers of this painful and debilitating condition and the factors involved in susceptibility of migraine sufferers to certain stimuli are not well defined, activation of the trigeminovascular system has been shown to play an important role in

Figure 4 Schematic representation of the putative sites of action for triptans in the symptomatic treatment of migraine headache. (A) Constriction of distended intracranial blood vessels via activation of 5-HT_{1B} receptors in the smooth muscle layer. (B) Inhibition of CGRP release from perivascular trigeminal afferents through the activation of 5-HT_{1D} and possibly 5-HT_{1F} receptors. (C) Inhibition of nociceptive signaling in trigeminal nucleus caudalis (TNC) via 5-HT_{(1B),1D,1F}. TG, trigeminal ganglion. Reprinted, with permission, from Hamel, E. (2000). Serotonin receptors: Relevance to migraine pathogenesis and treatment. In "The Headaches" (J. Olesen, P. Tfelt-Hansen, and K. M. A. Welch, eds.), 2nd ed., pp. 133–139. Lippincott Williams & Wilkins, Philadelphia.

the genesis and maintenance of migraine pain. The trigeminal ganglion consists of bipolar neurons that send fibers to the meninges, to the meningeal (dural) and cerebral (pial) blood vessels involved in the manifestation of head pain, and (centrally) to the caudal brainstem and upper cervical spinal cord. Trigeminal ganglion neurons contain the neuropeptides CGRP, substance P, and neurokinin A. Moskowitz and colleagues documented that abnormally intense neuro-metabolic brain activity is an important activator of trigeminal nerve fibers and trigger of headache in migraine with aura. Activation of the trigeminovascular system causes peripheral release of neuropeptides that induce meningeal blood vessel dilation, blood flow increase, and plasma protein extravasation, in part by central reflex activation of the perivascular parasympathetic system via the superior salivatory nucleus. This inflammatory process is also thought to cause sensitization of nerve fibers and, consequently, lowering of the nociceptive threshold.

CGRP levels increase in the cranial circulation of migraine sufferers during an attack and return to normal values after administration of the antimigraine drug, sumatriptan, concomitant with relief of migraine pain. The efficacy of sumatriptan and other triptans to relieve migraine pain has been attributed to actions at three different levels of the trigeminovascular system (Fig. 4): (a) constriction of distended intracranial blood vessels via activation of 5-hydroxytryptamine (5-HT)_{1B} receptors in the smooth muscle layer, (b) inhibition of CGRP release from perivascular trigeminal nerves through the activation of 5-HT_{1B,1D} and possibly 5-HT_{1F} receptors, and (c) inhibition of nociceptive signaling in trigeminal nucleus caudalis via 5-HT_{1D,1F} receptors.

The use of CGRP receptor antagonists has emerged as a potential strategy to regulate CGRP activity during migraine attacks. The nonpeptide CGRP receptor antagonist BIBN4096BS was found to inhibit neurogenic vasodilation induced by

trigeminal nerve stimulation in marmoset monkeys without affecting basal blood pressure or heart rate. This represents an interesting advantage over the application of sumatriptan, which is contraindicated in patients with cardiovascular symptoms. BIBN4096BS has proven to be efficacious in clinical trials and is undergoing more advanced clinical evaluation as a putative therapeutic for treatment of acute migraine headache.

CGRP IN THE GASTROINTESTINAL SYSTEM

CGRP-containing neuronal afferents form a major component of the sensory innervation in the gastrointestinal tract, including the esophagus, stomach, hepatobiliary tract, pancreas, vasculature, and a portion of nonvascular fibers distributed to the intestinal wall. CGRP nerve fibers arise mainly from dorsal root ganglia, where both α -CGRP and β -CGRP mRNAs are coexpressed. However, capsaicin treatment was able to completely deplete the rat intestine of α -CGRP but not of β -CGRP. This observation suggested that distinct neuronal populations impinging on the enteric system express these two peptides in a preferential manner, α -CGRP by capsaicin-sensitive sensory fibers and β -CGRP by enteric autonomic neurons.

In various animal species, peripheral or central administration of CGRP inhibits gastric acid secretion and motility and increases gastric mucosal blood flow. The central inhibition of acid secretion is due primarily to suppression of the vagal efferent activity, whereas the antisecretory effect of peripherally administered CGRP involves release of gastric somatostatin and inhibition of cholinergic transmission. The central inhibitory effect of CGRP on gastric motor functions is due to increased sympathetic outflow given that adrenalectomy or celiac ganglionectomy abolishes this effect. Peripheral CGRP injections reduce gastric emptying and motility by increasing intracellular cAMP via smooth muscle receptors. CGRP also raises gastric blood flow, an effect that correlates with the capacity of CGRP to prevent ethanol-induced lesions of the gastric mucosa. Therefore, CGRP may have an important protective action against gastric ulcer.

CONCLUDING REMARKS

There is sufficient evidence to highlight the potential therapeutic benefit of drugs modulating abnormal

CGRP functions in pathological conditions. However, CGRP itself is not suitable for long-term clinical application because it is rapidly metabolized in plasma. Developing synthetic, nonpeptide CGRP receptor agonists and antagonists will open new perspectives for clinical manipulation of CGRP receptor functions. The novel compound BIBN4096BS exemplifies the feasibility of this approach; this highly potent and selective nonpeptide CGRP antagonist is in an advanced stage of clinical trials for the treatment of migraine. In the past few years, considerable progress has been made in understanding the complexity of CGRP receptor structure and pharmacology. The biggest challenge in the future will be to map interactions among different sets of constitutive proteins involved in the formation of functional CGRP receptors. This information will be of great value for a rational drug design aimed at producing specific and potent modulators of CGRP activity.

Calcitonin, Overview

Sunil J. Wimalawansa

Robert Wood Johnson Medical School, New Brunswick, New Jersey, United States

Glossary

bone mineral density (BMD) A reliable estimate for assessment of risk factor for future fractures; BMD is measured using dual-energy X-ray absorptiometry (DXA) and is expressed as the amount of mineralized tissue in the area scanned.

calcitonin (CT) A 32-amino acid polypeptide hormone produced in C cells of the thyroid gland; its main action is to inhibit osteoclast-induced bone resorption.

calcitonin gene-related peptide (CGRP) The most potent endogenous vasodilator.

osteoporosis A chronic progressive disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to bone fragility and increase in fracture risk.

Calcitonin (CT) is a 32-amino acid peptide hormone whose existence was postulated in 1962 by Copp and colleagues. CT is a hormone produced by the C cells in the thyroid gland. Together with parathyroid hormone, it helps to regulate serum calcium and calcium in bone. Synthetic preparations of CT are available for treatment of various metabolic bone disorders (e.g., osteoporosis) and localized bone diseases (e.g., Paget's disease of bone). CT may be administered via nasal spray or injection. Nasal administration is preferred due to ease of use and because the injections tend to be associated with more nausea and flushing. CT is a natural hormone, and there is no evidence of carcinogenesis in animals or humans.

INTRODUCTION

Calcitonin (CT) is synthesized by parafollicular cells (C cells) in the thyroid in mammals and by C cells associated with the ultimobranchial gland in lower vertebrate animals. C cells derive from the neural crest and migrate forward to become the ultimobranchial body in lower vertebrates and the parafollicular cells in humans. Therefore, during migration, C cells may concentrate in regions other than the thyroid and ultimobranchial body.

STRUCTURE OF CT AND ITS MEASUREMENTS

CT has been relatively conserved during evolution. CT from nine different species has been identified, generating 11 known sequences (Table I). Six of the invariant amino acid residues are clustered at the amino terminal, and two are at the carboxy-terminal end of the molecule. Furthermore, all CT has a 1–7 disulfide bridge and prolin amide at the C terminus. All 32 amino acids are required for its hypocalcemic activity and its inhibitory effects on osteoclasts. Substitution of some of these amino acids, as with some of the synthetic CT preparations (e.g., synthetic eel CT), enhance its half-life and thereby its biological activity but may enhance allergenicity.

CT is produced as a precursor molecule; a number of posttranslational modifications, including cleavage and C-terminal amidation, will occur prior to secretion of the mature form of biologically active CT_(1–32) into circulation. The release of CT from C cells is stimulated by cations Ca²⁺ and Mg²⁺ and also by glucagons, dibutyryl cyclic AMP (cAMP), theophyllin, gastrin, and cholecystokinin. CT causes a dose-dependent elevation of the cAMP level, and the effects of CT on osteoclasts can be mimicked by dibutyryl cAMP. Measurement of plasma immunoreactive calcitonin (i-CT) levels (for hypersecretion) has been used as a screening and diagnostic test for premalignant and malignant C-cell disease (i.e., families of patients with medullary thyroid carcinoma [MTC]). There are a number of diagnostic stimulation tests available for detecting MTC, including infusion of calcium and partagastrin. Table II illustrates some causes of elevated and suppressed serum i-CT levels.

COMMERCIALY AVAILABLE CT PREPARATIONS

Both parental and nasally administered forms of CT are available. Miacalcin nasal spray (Novartis Co.) is

a synthetic salmon CT that is 10- to 15-fold more potent than human CT. Its major action is the inhibition of bone resorption by a direct action on osteoclasts. In females more than 5 years postmenopause, 200 IU of miacalcin nasal spray once daily is the recommended dose for the treatment of osteoporosis. However, CT should be reserved for those patients who refuse or cannot tolerate other anti-osteoporosis agents or for patients with acute bone pain. Use of CT

nasal spray is recommended in conjunction with a total daily intake of at least 1200 mg of calcium and 400 IU of vitamin D to retard the progressive loss of bone mass.

In some countries, the only available form of CT still is the injectable preparation. Using injectable CT formulations, a dose of 40 to 50 IU three or four times per week is recommended for prevention or treatment of osteoporosis. Small doses of injectable CT such as

10–40 IU three times per week may have the same beneficial effect on bone, may delay onset of receptor-mediated resistance with far fewer side effects, and are more economical. Salmon CT has fewer side effects, but the main drawback with CT is its high cost and a decrease in efficacy secondary to antibody formation.

From a therapeutic point of view, CT can be administered by intravenous, intramuscular, subcutaneous, or an intranasal route. Side effects are greatest with intravenous administration, less with intramuscular and subcutaneous injections, and least with intranasal administration. The recommended dose of intranasal CT is 200 IU per day, and its biological effects are similar to those observed after 50 IU by subcutaneous injection. All forms of CT should be stored at 4°C and protected from light. Shelf life is approximately 2 years. Nonhuman CTs can be allergenic, with roughly 50% of patients developing antibodies over time. However, this leads to actual clinical resistance (e.g., neutralizing antibodies) only in less than a third of patients.

ADVERSE REACTIONS

Potentially Life-Threatening Effects

There are no reports of any deaths or long-term side effects attributable to CT use over 30 years of clinical experience. CT is a safe drug with few side effects. The main drawback of CT therapy is its cost, nasal irritation, and only a modest effect on the bone mineral density (BMD) and fracture reduction. In addition, the absorption of nasally administered CT is variable and poor, and a consequent, specific bioavailability is not guaranteed. Therefore, in some patients, the dose may need to be increased by two- to threefold the recommended dose to achieve the desired effects. Alternative routes of administration are under investigation (e.g., pulmonary, rectal, buccal [liposomes], depo-preparations, and oral), but no breakthrough has been yet reported.

Acute Overdose

Overdose has not been reported. Transient nausea and vomiting is the only potentially hazardous symptom.

Severe or Irreversible Adverse Effects

Anaphylactic reactions have been reported only rarely in association with CT (nonhuman CT) therapy.

Symptomatic Adverse Effects

CT is generally well tolerated. With the injectable CT, the most commonly encountered adverse effect is cutaneous flushing, particularly of the face. This is noticed by at least a third of patients and probably occurs to some extent in the majority. The onset may be within minutes of the injection and may last for up to 1 h. Nausea is common but is usually mild. If it is troublesome, the suitable timing of an injection (e.g., on retiring at night) or the prior administration of an antiemetic may often alleviate the problem. Increased urinary frequency occurs in up to 5 to 10% of patients, but diarrhea and vomiting are rare. Fewer than 1 in 10 patients discontinues therapy due to adverse effects even at higher doses. No significant side effects have been observed with long-term treatment with CT. The most common adverse effect of intranasal CT is nasal irritation and runny nose. Rarely it may associate with nasal bleeding and exacerbation of asthma.

Interference with Clinical Pathology Test

No technical interferences of CT with pathological tests have been reported.

Drug Interaction

There are no known specific interactions between CT and any other drugs.

PHYSIOLOGICAL ROLE OF CT

The physiological role of CT is to maintain skeletal mass during periods of calcium “stress” such as growth, pregnancy, and lactation (i.e., preserve the skeleton). During pregnancy and lactation, retention of calcium by the fetus and secretion into milk may occur at the expense of the maternal skeleton (i.e., stimulation via parathyroid hormone-related protein [PTHrP]). In these situations, increased secretion of CT may exert a protective effect to preserve skeletal mineral content and control excessive bone resorption. For example, pregnancy-associated osteoporosis is possibly due to a relative CT deficiency. Testosterone and estrogen both are stimulants for the synthesis of CT by C cells. Physiological concentrations of CT are likely to have a tonic effect to restrict osteoclastic bone resorption.

CLINICAL PHARMACOLOGY

The main target cells for CT are the osteoclasts. CT suppresses the bone resorption activity of osteoclasts and thereby decreases bone resorption. Therefore, CT is a useful agent in patients with conditions associated with high bone turnover. Inhibition of bone resorption due to CT follows a direct inhibitory effect of it on the osteoclasts. Osteoclasts are multinucleated giant cells (Fig. 1) and create resorption cavities on the bone surface (Fig. 2); CT suppresses this bone-resorbing

Figure 1 An osteoclast cell, one of the largest cells in the body. Using its pseudopodia, osteoclasts move over the surface of bone, making resorption pits en route.

Figure 2 Scanning electron micrograph of a bone slice illustrating an osteoclast and its path and showing the number of excavations it has made. These cells make a tight sealing over the bone surface using its cell membrane and secrete acid and proteases to digest the contents underneath. Once a pit is formed, it moves on to a different site. CT will control this bone resorbing activity.

activity. CT also causes a reduction in osteoclast numbers when given over several months. It is not clear whether this decrease in the number of osteoclasts is a consequence of an acute effect of CT on osteoclasts or is an independent effect on its precursor cells. A plasma calcium-lowering effect of CT is not seen in normal adults due to the slow rate of bone turnover. Therefore, the administration of CT has little or no effect on plasma calcium in normal adults. However, when bone turnover is high, as in children or in disease states (e.g., Paget’s disease), administration of CT may be followed by decreases in plasma calcium.

Several pharmacological actions of CT in the gastrointestinal system have been documented. CT enhances the intestinal secretion of sodium, potassium, chloride, and water, and it inhibits both gastric emptying and acid secretion. It also inhibits the secretion of several gastrointestinal regulatory peptides, including gastrin, insulin, pancreatic glucagons, motilin, pancreatic polypeptide, and (perhaps) gastric inhibitory peptide. Inhibitory effects on the secretion of pituitary hormones, including growth hormone, thyroid-stimulating hormone, and luteinizing hormone, have also been reported.

PHARMACOKINETICS

The most convenient analytical method for CT is radioimmunoassay or enzyme-linked immunosorbent assay (ELISA). The usefulness of the former is flawed

by the fact that it may also detect inactive fragments and precursors. Picogram quantities of CT can be detected by such assays, and the biological activity of similar amounts can now be detected using isolated osteoclast systems. CT is rapidly degraded by gastric contents and therefore needs to be given parenterally. Following subcutaneous injection, the peak plasma concentrations are seen between 15 and 45 min. The initial plasma half-life is short: approximately 4 min for porcine and human CT but approximately 15 min for salmon and eel CT. Animal studies have shown that tissue uptake is greatest in bone, liver, and kidney. The volume of distribution varies widely. Significant protein binding probably does not occur.

THERAPEUTIC USES

Osteoporosis

Osteoporosis is a result of an imbalance between bone formation and resorption, resulting in a net loss of bone (leading to a decrease in bone mass) and a loss of trabecular integrity (leading to fractures). CT has been in use for more than three decades to treat patients with various metabolic bone disorders, especially osteoporosis that is characterized by accelerated bone resorption. CT seems to be beneficial in prevention and treatment of osteoporosis, but its effect in fracture prevention is not convincing. The effect of CT in preventing bone loss and decreasing osteoporosis-associated fractures is much less than that of hormone replacement therapy (HRT) or bisphosphonates. Clinically, a reduction in the rate of bone loss, rather than a significant sustained increase in bone mass, should be considered as the therapeutic goal with any CT preparation.

The hormone CT may be used as an alternative treatment to HRT and bisphosphonate in the prevention and treatment of osteoporosis, especially when these agents either are not appropriate or cannot be tolerated due to adverse effects. It is also an alternative therapy for women who cannot tolerate estrogen therapy due to social or medical reasons and for patients who cannot tolerate oral bisphosphonate. However, the efficacy of CT is approximately 50% that of HRT and 25% that of bisphosphonates.

With reference to osteoporosis, other Food and Drug Administration (FDA)-approved drugs are usually recommended over CT because it is not clear whether CT increases bone density or strength and decreases the fracture rate outside the spine. However, because of its pain-relieving (analgesic) effects, CT may be used as a firstline therapy for those who have

an acute intense onset of back pain due to vertebral crush fractures. For pain relief, higher doses of CT (e.g., 600–800 IU) are required, but only for few days (i.e., total of 1–2 vials). The treatment regimen should typically change when the acute pain subsides or if the pain fails to subside within a week or so.

CT has been used successfully for the prevention and treatment of postmenopausal osteoporosis and for treatment of osteoporosis in men. After prolonged administration of CT, it may lose its beneficial effects on bone due to down-regulation of receptors and/or the development of neutralizing anti-CT antibodies (with nonhuman CT) or increased catabolism of the peptide. Administering small doses of CT less frequently, and switching salmon or eel CT to a synthetic or genetically engineered human CT, can minimize these two problems.

Doses of injectable CT as small as 60 IU per week have been shown to be effective in arresting the postmenopausal bone loss. CT is more widely used in Southern Europe and Japan than it is elsewhere in the world. In a small, controlled, 2-year dose-finding study of intranasal CT in postmenopausal women with osteoporosis, spine BMD increased by 2%. There was no effect on other skeletal sites, and slight decrease incidences of vertebral fracture were observed compared with placebo.

Although the ideal treatment for osteoporosis is with anabolic agents to increase bone mass, inhibitors of bone resorption can arrest further bone loss, increase BMD, and decrease fracture rates. CT has also been shown to stabilize or modestly increase indexes of cortical and trabecular bone mass and total body calcium, when it is administered to patients with established osteoporosis. The increments in bone density seen with CT are modest, appear to be transient, and are likely to be due to reduction in bone resorption with bone formation remaining unaffected until remodeling spaces are filled. However, the reason for the reduction of fracture rate in the light of little increase of BMD is not yet understood. Perhaps anti-resorptive therapies (e.g., CT, bisphosphonates), in addition to their well-known effects on decreasing bone turnover, may also have a positive effect on preservation of osteoblasts and osteocytes, enhancement of osteoclast apoptosis, and preservation of the microarchitecture of bone. This may result in disproportionate reduction of fracture rates in comparison with a slight increase of BMD observed.

The PROOF (Prevent Recurrence of Osteoporotic Fractures) study was a 5-year, multicenter, double-blind randomized study designed to test whether miacalcin nasal spray reduces the risk of new vertebral

fractures in postmenopausal women with established osteoporosis. A total of 1255 women with at least one but not more than five vertebral compression fractures were randomized to receive miacalcin nasal spray (100, 200, or 400 IU or placebo daily). Patients also received daily supplements of 1000 mg of calcium plus 400 IU of vitamin D.

The results demonstrated that miacalcin nasal spray, at the recommended dose of 200 IU daily, reduced the risk of new vertebral fractures as compared with placebo. At 5 years, there was a statistically significant reduction in the risk of new vertebral fractures with CT nasal spray (200 IU daily) as compared with placebo in patients with one to five vertebral compression fractures at baseline, but no such effects were seen with either 100 or 400 IU of the same agent. The study did not show hip fracture (or nonvertebral fracture) reduction. The study also showed somewhat of a reduction in the serum type I collagen cross-linked telopeptide (CTX), a biochemical marker for bone resorption. In the study, the frequency of adverse events in all treatment groups was comparable to placebo except for an increase in rhinitis. Other studies using CT have shown small increments in spinal BMD and marginal antifracture efficacy. Most of these studies have fewer fractures and are underpowered to detect a significant effect of CT on fracture reduction.

Synthetic salmon, human, and eel CTs have been developed as therapeutic agents for osteoporosis, but there are no extensive or multiple clinical trial data to show convincing reduction of fracture rates except for the PROOF study. Unfortunately, in many patients, circulating antibodies will be developed with nonhuman CTs (e.g., salmon CT, eel CT) within 2 to 3 years of therapy, and these antibodies may significantly impair the actions of this hormone.

Like other antiresorptive therapies, CT decreases the remodeling phase, thereby achieving a new lower rate of bone turnover. Consequently, increases in bone densities are generally seen only during the first 2 to 3 years of treatment. It may be possible to minimize this by administering CT (e.g., nasal CT 200 IU/day) in a cyclical fashion. There is some evidence to suggest that CT may prevent glucocorticoid-induced bone loss, but the efficacy is considerably less than that of bisphosphonates. It is unclear how CT and similar antiresorptive agents reduce bone loss given that glucocorticoids predominantly depress bone formation rather than stimulate bone resorption. Recent evidence suggests that this may be due to enhanced osteoclast apoptosis with both CT and amino-containing bisphosphonates.

Paget's Disease of Bone

CT has been used successfully as a treatment for Paget's disease of bone for several decades. Several types of CT have been used, but salmon CT is the most commonly used. CT is a useful treatment for Paget's disease (which is characterized by very high bone turnover) because it not only inhibits osteoclast activity but also prevents the recruitment of new osteoclasts. Inhibition of osteoclastic activity explains the short-term (acute) effects of CT, whereas long-term responses are presumably related to the decreased number of osteoclasts. CT is effective in alleviating bone pain and in improving clinical, biochemical, radiological, and histological features of the disease. The major indication for CT therapy in Paget's disease is bone pain of Pagetic origin. CT relieves bone pain rapidly and helps to decrease excessive blood flows over the affected bones. It can also alleviate some of the chronic neurological problems associated with the disease such as early spinal cord compression due to Paget's disease of vertebrae. CT can decrease biochemical markers of bone turnover, such as serum alkaline phosphatase and N-telopeptide levels, by approximately 40 to 50%. Use of CT will rarely normalize serum bone-specific alkaline phosphatase levels, which is the key marker for Pagetic activity. However, the effectiveness of CT is dependent on its continued use; discontinuation of the drug will reactivate the Paget's disease process within a short period. There are no serious side effects associated with this treatment, although minor side effects are common and include nausea, diarrhea, and pain and redness at the injection site.

Hypercalcemia

CT produces an acute reduction in plasma calcium in patients with hypercalcemia due to malignancy and hypercalcemic emergency. A fall in plasma calcium of 0.5 to 1.0 mmol per liter may be observed within 24 h of commencing CT therapy. However, in the absence of additional therapy, the effect might not be maintained beyond 48 to 72 h. CT is most likely to be effective in cases of hypercalcemia where a generalized increase in bone resorption is a prominent feature. The calciuric effect of CT may also play a small role in reducing the raised plasma calcium. In patients with hypercalcemia, CT can be used to obtain an immediate calcium-lowering effect. However, in most patients, it is necessary to start a bisphosphonate (e.g., pamidronate, zoledronate) concomitantly for further reduction and maintenance of serum calcium levels.

These agents also have the beneficial effects of controlling metastatic osteolysis.

ANALGESIC ACTION OF CT

Miacalcin nasal spray is not FDA approved for use as an analgesic. Most of the literature concerning the analgesic action of CT employed the use of the injectable form. The reduction in pain occurs significantly earlier than any demonstrated improvement in skeletal dynamics, and in some instances no objective improvement in the underlying skeletal condition can be observed.

Use of CT to Control Bone Pain

Although the efficacy of CT in fracture reduction is controversial, there is convincing evidence for efficacy of CT as an analgesic in patients with acute vertebral fractures. In contrast to HRT and bisphosphonate therapies, CT (at three- to fourfold higher doses than that recommended for osteoporosis) reduces pain in patients with recent osteoporotic fractures (e.g., crush fracture syndrome). Because of its analgesic effect, CT can be useful as an adjunct therapy in the management of osteoporotic patients following osteoporotic fractures (i.e., a high-dose short course such as 800 IU/day for 1 week).

CT can be used effectively in patients with osteoporotic fracture syndrome to relieve pain on a short-term basis. In addition to its use in patients with crush fracture syndrome and bone pain, to be cost-effective, CT could be useful in selected patients with high bone turnover and increased bone remodeling. Painful episodes of osteoporosis are not due to the osteoporotic process itself but rather are associated with fractures. The presentation of pain is usually acute, continuous, exacerbated with movement, and ameliorated by rest. The pain can be severe and will generally resolve with bed rest. However, it is essential to mobilize these patients at the earliest possible time to avoid immobilization-associated complications. High-dose, short-term use of CT could assist in this process.

Intranasal CT has been investigated for its analgesic effect in acute back pain due to osteoporosis. In one double-blind, placebo-controlled study, more than 50% of patients receiving 200 IU of CT nasal spray daily showed a "good" response in mobility and functional capacity, whereas patients receiving placebo nasal spray experienced only a moderate response with respect to the same parameters. In addition, intranasal CT appears to be more rapid in providing analgesia to postmenopausal osteoporotic women with acute pain

than does injectable salmon CT. A double-blind, double-placebo study by Pontiroli and colleagues examined the analgesic effect of intranasal CT (200 IU daily) versus intramuscular CT (100 IU daily) versus placebo in 28 women with painful postmenopausal osteoporosis for a period of 4 weeks. In the 24 patients who completed the trial, treatment with intranasal CT resulted in a statistically significant reduction in pain score, as measured by a visual analogue scale, by the second week of treatment. With intramuscular CT, as well as with placebo, the pain scores decreased significantly by the fourth week of treatment. At week 4, the final pain scores were not different among the three treatment groups.

The mechanism of the pain associated with acute fractures is different from that of the pain associated with fractures of long duration. CT nasal spray seems to demonstrate its greatest analgesic activity when administered shortly after a new fracture has occurred. The analgesic effect of various therapies for osteoporosis can diminish over time, and in some studies it is no different from placebo at 4 weeks. This may be due to either the tolerance or the spontaneous improvement that usually occurs over 4 weeks with most vertebral compression and wedge fractures.

Metastatic Bone Pain

CT has been used for the treatment of bone pain in patients with metastatic bone disease, where an analgesic effect has been observed in three-quarters of patients. CT has also been used successfully in the treatment of intractable pain from advanced malignancy, especially when injected into the subarachnoid space. It is likely that the main site of this analgesic action is in the central nervous system. Although the mechanism of CT's analgesic action is still not fully understood, it has been postulated to occur through both direct action at the hypothalamic level and indirect action through interference with neurotransmitters such as serotonin and prostaglandin, independent of endorphin, and a peripheral action mediated via the inhibition of the chemical factors involved in inflammation.

There have been no placebo-controlled studies conducted in patients with metastatic bone pain. However, Jelic and colleagues used CT to treat 16 patients with pain due to diffuse osteolytic or osteoblastic-osteolytic metastases who had not obtained satisfactory pain relief with opiate-type analgesics. Most of the patients on CT experienced a decrease in pain with an accompanying decreased intake of opiate-type analgesics. Of the 16 patients, 2 were

able to discontinue opiate intake completely, whereas 3 had no pain relief at all. The authors concluded that CT may be useful in relieving metastatic bone pain in some patients resistant to opiate-type analgesics.

Migraine

Migraine reportedly responds to CT, but the mechanism of action is unclear. Intramuscular doses of 100 IU per day were significantly more effective than placebo in reducing the frequency, intensity, and duration of migraine. However, administration of CT via injections can lead to nausea and thereby may aggravate some of the migraine-associated problems. Salmon CT has also been administered prophylactically via the nasal route and shown to be effective in preventing attacks of common migraine. However, disease-specific agents such as sumatriptan have now superseded these therapies.

Arthritis

There have been no placebo-controlled studies conducted using CT in patients with rheumatoid or osteoarthritis. There is corroborative evidence to suggest that pain and inflammation of inflammatory arthropathy may respond to CT at least partially. Dainotto and colleagues conducted an open-label study of 70 patients with osteoarthritis. They noted a decrease in spontaneous pain in patients using CT (100 IU intramuscular) for 40 days.

OTHER CLINICAL USE OF CT

CT has been used successfully in the treatment of Sudeck's atrophy. Clinical experience suggests that the administration of CT shortens the healing time of fractures, but this has not been confirmed. Another possibility is that CT could be administered intrathecally (to decrease the postoperative requirements of narcotics) in patients undergoing hip replacement under spinal anesthesia and in patients with metastatic bone disease.

CONCLUSION

The 32-amino acid polypeptide hormone CT is a potent inhibitor of the osteoclast cells. Therapy with CT is particularly effective in controlling osteoclastic

bone resorption in disorders characterized by high bone turnover, including Paget's disease of bone, osteoporosis, Sudeck's atrophy, and hypercalcemic states. However, the efficacy of CT in the treatment of osteoporosis is significantly less than that of bisphosphonates, HRT, and SERMs. Nevertheless, CT can be used effectively to control bone pain (e.g., crush fracture syndrome) in patients using higher doses (e.g., 800 IU intranasal daily for 5–7 days). This will allow for early mobilization of patients (and hence prevent immobilization-associated complications) and decrease the doses, or eliminate the necessity, of potent analgesia.

Caloric Restriction, Aging and Oxidative Stress

Holly Van Remmen and Arlan Richardson

University of Texas Health Science Center, San Antonio, Texas, United States

Glossary

oxidative stress theory of aging The oxidative stress theory of aging proposes that a chronic state of oxidative stress exists in cells of aerobic organisms even under normal physiological conditions because of an imbalance of pro-oxidants and antioxidants.

reactive oxygen species Reactive oxygen species include free radicals and other nonradical molecules such as peroxides that are continually formed endogenously as a consequence of metabolism and result in oxidative modifications to cellular components.

Caloric restriction (also called dietary restriction or food restriction) is a consistently proven method of extending the mean and maximum life span in rats and mice based on reducing the total caloric intake without altering the intake of other essential dietary components.

INTRODUCTION

In 1935, McCay and colleagues first demonstrated that the life span of rodents could be increased by caloric restriction. Since then, numerous laboratories have confirmed that reducing calorie intake (without malnutrition) significantly increases both the mean and the maximum survival in a variety of strains of mice and rats. Furthermore, caloric restriction has been shown to retard a variety of age-related deteriorations in physiologic systems and to delay or prevent the onset of a variety of diseases. Thus, caloric restriction is believed to increase life span by retarding aging; however, the mechanism whereby caloric restriction retards aging has not been elucidated. Increased resistance to oxidative stress and enhanced protection against oxidative damage appear to be important factors in the underlying mechanism of the life span-extending properties of caloric restriction.

IMPACT OF STUDIES USING CALORIC RESTRICTION

The classic study by McCay *et al.* in 1935 was the first to show that one could increase the life span of rodents by caloric restriction. In these studies, life extension was achieved by a very severe restriction in total food intake, which also stunted the growth and sexual development of the rats. Later studies demonstrated that the life span of rodents could be increased by caloric restriction less severe than the conditions used by McCay *et al.* In fact, many subsequent studies have confirmed that caloric restriction of 30–50% consistently increases both the mean and the maximum life span of both rats and mice. In addition, caloric restriction has been shown to be effective for both long-lived and short-lived strains of rats and mice.

Many studies have provided convincing evidence that caloric restriction increases life span by retarding the aging process. A number of studies show that caloric restriction can delay or reduce the onset of most age-related diseases and alter most physiological processes that change with age. This is an important point because changes in life span alone do not necessarily mean that the aging process per se has been altered.

POSSIBLE MECHANISMS FOR THE LIFE SPAN-EXTENDING PROPERTIES OF CALORIC RESTRICTION

Current studies are aimed at elucidating the mechanism(s) of caloric restriction—that is, the biochemical/molecular process(es) responsible for the antiaging action of caloric restriction. Several possible mechanisms have been proposed. Initially, caloric restriction was thought to increase survival by retarding growth and development. However, caloric restriction begun in adult life, well after development and maturation, can increase both the mean and the maximum survival

of mice and rats. Body fat content was also thought to play a role, and this was supported by the fact that rodents fed *ad libitum* have a greater body fat content than calorie-restricted rodents. However, no relationship was found between body fat content and survival in calorie-restricted genetically obese (*ob/ob*) and normal mice of the same inbred strain, suggesting that body fat content per se does not play a major role in the biological mechanism responsible for the increased life span of caloric restriction. Reduced metabolic rate was also thought to play a role. However, neither the metabolic rate per unit of lean body mass nor that per unit of "metabolic mass" are reduced significantly by caloric restriction in rats; therefore, caloric restriction cannot be due to a general reduction in the metabolic rate of rodents. Possible mechanisms for the action of caloric restriction are modulation of glycemia and hyperinsulinemia by caloric restriction, hormesis or increased tolerance to stress, and attenuation of oxidative damage.

RESISTANCE TO OXIDATIVE STRESS

Evidence indicates that caloric restriction may act at least in part by decreasing oxidative stress and increasing antioxidant defense and repair. The oxidative stress hypothesis of aging proposes that a chronic state of oxidative stress exists in cells of aerobic organisms even under normal physiological conditions because of an imbalance of pro-oxidants and antioxidants. Reactive oxygen species produced during the course of normal aerobic metabolism may cause random deleterious damage that accumulates over time and contributes to the process of aging and various age-associated diseases. Evidence indicates that the antiaging action of caloric restriction might occur through a mechanism that involves increased resistance to oxidative stress. For example, studies of invertebrates (nematodes and *Drosophila*) that show life extension suggest that enhanced resistance to stress plays a key biological role in the increased longevity of these organisms. In addition, the activities of one or more of the antioxidant enzymes either remain the same or increase with caloric restriction in rodent tissues. More important, caloric restriction has consistently been shown to reduce oxidative damage in rodent tissues. Caloric restriction can also enhance repair of oxidatively damaged molecules by retarding the age-related decrease in DNA repair proteins and increasing proteolytic removal of damaged proteins.

OXIDATIVE DAMAGE TO CELLULAR COMPONENTS

A number of studies have measured the levels of oxidative damage in macromolecules in various tissues from young and old *ad libitum*-fed and caloric-restricted animals. Early studies focused on measuring oxidative damage to lipid; recent studies, however, have also measured oxidative damage in protein and DNA. In 1992, the first data were published showing that the levels of oxo8dG in nuclear DNA from liver of 26-month-old male F344 rats were reduced significantly (36%) by caloric restriction. It has also been reported that caloric restriction reduced oxo8dG levels in nuclear DNA from the livers of 28-month-old male F344 rats by 25% compared to *ad libitum*-fed rats. However, this difference was not observed until the rats were 27 months of age. In mice, oxo8dG in the total DNA isolated from brain, skeletal muscle, heart, and liver of 26-month-old male C57BL/6 mice fed a calorie-restricted diet was reduced compared to that of their *ad libitum*-fed counterparts. Caloric restriction has also been shown to significantly reduce (21%) the level of oxo8dG in liver mitochondrial DNA from 24-month-old male F344 rats. The level of oxo8dG is significantly lower in nuclear DNA in tissues of old mice fed a calorie-restricted diet compared to old mice fed *ad libitum*. However, caloric restriction does not always reduce oxidative damage to nuclear DNA in rodent tissues. Even in those tissues in which oxidative damage to nuclear DNA is reduced, the decrease is often relatively mild. Caloric restriction completely prevented the age-related increase in oxo8dG levels in liver mitochondrial DNA in rats and mice, but it had no effect on the age-related increase in oxo8dG levels in rat liver nuclear DNA and reduced oxo8dG levels only 19% in mouse liver. Thus, data suggest that caloric restriction has a much greater effect on the age-related accumulation of oxidative damage to mitochondrial DNA than that to nuclear DNA.

Caloric restriction also alters oxidative damage to proteins and lipids with age. The age-related decline in protein degradation and the accumulation of oxidatively modified or abnormal proteins with age are both delayed by caloric restriction. For example, the level of oxidized proteins has been shown to increase with age in the brain, and this increase is ameliorated by caloric restriction. Age-related changes in lipid peroxidation and in membrane fatty acid composition are also altered by caloric restriction. Membrane fatty acid composition is affected by caloric restriction, resulting in decreased amounts of polyunsaturated fatty acids, reduced peroxidizability, and maintenance

of membrane fluidity. Thus, caloric restriction acts to protect membrane integrity and function.

MITOCHONDRIA

Since mitochondria continuously produce endogenous reactive oxygen species as a consequence of the action of the electron transport chain, it is possible that mitochondrial production of reactive oxygen species and oxidative damage to mitochondria could be altered by caloric restriction. In fact, caloric restriction has been shown to reduce mitochondrial reactive oxygen species generation and to reduce oxidative damage to mitochondrial DNA. In particular, caloric restriction decreases reactive oxygen species production at complex I of the respiratory chain. Decreased reactive oxygen species production has also been associated with reduced protein oxidation in rat heart mitochondria.

Glossary

angiotensin I Inactive decapeptide produced by the action of renin, elaborated by the juxtaglomerular cells of the kidney, on angiotensinogen (an α_2 globulin).

angiotensin II Octapeptide resulting by the splitting of two amino acids from angiotensin I as a result of angiotensin-converting enzyme (ACE) activity.

angiotensin-converting enzyme (ACE) inhibitors Blood pressure-lowering agents that reduce peripheral vascular resistance via blockage of the activity of the ACE, inhibiting the conversion of angiotensin I to angiotensin II.

mass spectrometry (MS) Analytical structural method based on the identification of the particular pattern of fragmentation of the organic molecules resulting in electrically charged species analyzed against their mass/charge ratio.

nuclear magnetic resonance (NMR) Analytical structural method based on the interaction of some specific nuclides characterized by an uneven quantum number of nuclear spins (^1H , ^{13}C , ^{14}N , ^{19}F , and ^{31}P) with intense external magnetic fields.

renin-angiotensin system (RAS) One of the most important regulatory systems, regulating blood volume, arterial pressure, and cardiac and vascular function.

type 2 diabetes mellitus More often known simply as type 2 diabetes, a metabolic disease in which the body cannot get its energy from glucose in the normal way because the body does not produce enough insulin or cannot use the insulin it has (known as insulin resistance).

Captopril, (2S)-1-[(2S)-3-mercapto-2-methylpropanoyl]pyrrolidine-2-carboxylic acid, is an inhibitor of angiotensin-converting enzyme (ACE), acting directly on the adrenal gland to stimulate the release of aldosterone. It prevents high blood

pressure by inhibiting the enzymatic conversion of angiotensin I to angiotensin II. Also, during the metabolic pathway, it converts to a disulfide compound.

HISTORY

The discovery of Captopril appeared as a result of two basic research directions. The first one emerged from the identification and description of the renin-angiotensin system (RAS); it started in 1934 and was concluded by scientific articles that identified angiotensin I and angiotensin II and were published during the late 1950s. The second direction is based on research in Brazil on the cause of death from snake venom; it identified a natural substance that acts on its victim by fatally lowering blood pressure. It was finalized in 1965 when it was shown that this natural substance blocks the conversion of angiotensin I to angiotensin II. Based on these data, the scientists from Squibb synthesized the first angiotensin-converting enzyme (ACE) inhibitor during the early 1970s. It was subsequently approved for marketing by the U.S. Food and Drug Administration in 1981.

SYNTHESIS

N-acylation of L-proline with (S)-3-acetylthio-2-methylpropionyl chloride, in the presence of sodium hydroxide, leads to the sodium salt of 3-acetylthio-2-D-methylpropionyl-L-proline, which is treated with hydrochloric acid and hydrolyzed in the presence of ammonia. The resulting captopril (Fig. 1) is then extracted with ethyl acetate and further purified.

PHYSICAL-CHEMICAL PROPERTIES

Captopril ($\text{C}_9\text{H}_{15}\text{NO}_3\text{S}$, $M_w = 217.29$) is a white crystalline powder having a characteristic sulfide-like odor

Figure 1 Captopril (A) and its disulfide derivative (B) chemical structures.

and a melting point between 105 and 108°C. It is freely soluble in water or diluted solutions of alkali hydroxides, in alcohols, in methylene chloride, or in chloroform. The elemental analysis leads to 49.75% carbon, 6.96% hydrogen, 6.45% nitrogen, 22.09% oxygen, and 14.73% sulfur. A solution of 2% captopril in water produces a pH value in the range of 2.0 to 2.6 with a dissociation constant of 3.7 ± 0.2 . It is recommended that captopril be stored in airtight containers, although it is known to be relatively stable up to 50°C.

In aqueous solutions, captopril is oxidized mainly to captopril disulfide (II), which can be favored by higher pH values. There are two chiral carbon atoms in the captopril molecule, so two pairs of diastereoisomers exist. The drug should be characterized by an optical rotation of $-84 \pm 2^\circ$. The UV spectrum in methanol shows only a single absorption band situated at 210 nm. The IR spectrum of captopril recorded as KBr dispersion exhibits three characteristic absorption bands: 3450 to 2500 cm^{-1} (assigned to carboxyl and thiol groups), 1750 cm^{-1} (specific to the CO group in carboxyl), and 1580 cm^{-1} (CO from amide group). The ^1H -nuclear magnetic resonance (NMR) spectrum recorded for a solution in deuterated chloroform exhibits the following signals (δ [ppm]): 9.38 (broad), 4.63 (m), 3.61 (m), 2.83 (m), 2.48 (m), 2.31 (m), 2.04 (m), 1.52 (t), and 1.21 (d). The main mass spectrometry (MS) spectral lines correspond to the following mass fragments: 114, 172, 184, and 192 amu.

METABOLIC FUNCTIONALITY

The thiol group from the captopril structure interacts with zinc ion from the catalytic moiety of ACE inhibitors. Because of this functional group, the tolerance toward nitrates is greatly potentiated. Thus, captopril can enhance the antianginal effect of isosorbide dinitrate.

In general, an excessive hypotension may occur when ACE inhibitors are used concurrently with diuretics, other antihypertensives, or other agents

such as alcohol. An additive hyperkalemic effect is possible in patients receiving ACE inhibitors with potassium-sparing diuretics, potassium supplements (including potassium-containing salt substitutes), or other drugs that can cause hyperkalemia (e.g., ciclosporin, indometacin), and serum potassium concentrations should be monitored. Therefore, potassium-sparing diuretics and potassium supplements should generally be stopped before initiating ACE inhibitors in patients with heart failure. The adverse effects of ACE inhibitors on the kidneys may be enhanced by other drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs), which can affect renal function.

ANTIDIABETIC ACTIVITY

Hypertension occurs with twice the frequency in the diabetic population compared with the nondiabetic population, and up to 50% of patients with type 2 diabetes mellitus become hypertensive. In addition to being a major risk factor for atherosclerosis in large blood vessels, hypertension in diabetes appears to contribute to small vessel disease and is a risk factor for diabetic nephropathy and possibly for diabetic retinopathy. Recent studies have shown that ACE inhibitors can slow the progression to diabetic nephropathy in patients with type 1 or type 2 diabetes with microalbuminuria or macroalbuminuria.

A major way in which to protect the kidney from the complications of diabetes is to treat high blood pressure aggressively, regardless of the antihypertensive drug types used. In early studies in patients with type 1 diabetes, antihypertensive drugs such as diuretics, beta blockers, and hydralazine were used, indicating that lowering blood pressure reduces proteinuria and slows the decline of renal function. A preponderance of evidence indicates that ACE inhibitors protect the kidney better than do other blood pressure-lowering medications, probably because ACE inhibitors specifically lower the intrarenal pressure.

Lewis and colleagues performed a landmark study in patients with type 1 diabetes, albuminuria, and mildly impaired creatinine clearance, that is, patients who were just beginning to develop renal failure. The ACE inhibitor captopril reduced the risk of a decline in renal function more effectively than did other antihypertensive regimens (not including calcium channel blockers).

Captopril and atenolol are equally effective in reducing blood pressure to means of 144/83 and 143/81 mm Hg, respectively, with similar proportions

of patients (27 and 31%, respectively) requiring three or more antihypertensive treatments. A value lower than 130/85 mm Hg is a reasonable target. It has not been firmly established whether lower blood pressures accrue further benefits.

Captopril and atenolol are also effective in reducing the risk of macrovascular end points. Similar proportions of patients in the two groups showed deterioration in retinopathy by two grades after 9 years (31% in the captopril group and 37% in the atenolol group) and developed clinical-grade albuminuria ≥ 300 mg/L (5% and 9%, respectively). The proportions of patients with hypoglycemic attacks were not different between the groups, but mean weight gain in the atenolol group was greater (3.4 vs 1.6 kg).

Blood pressure lowering with captopril and atenolol was similarly effective in reducing the incidence of diabetic complications. Neither drug has any specific beneficial or deleterious effect, suggesting that blood pressure reduction in itself may be more important than the treatment used.

In patients with non-insulin-dependent diabetes mellitus, treatment with captopril or enalapril does not normalize the exaggerated systemic norepinephrine responsiveness.

It was proved that captopril does not produce any significant changes in the blood levels of ionized calcium or phosphorous ions and that it does not alter the serum levels of parathyroid hormone (PTH) and metabolites of vitamin D.

After oral administration of captopril, maximum effect is reached in 1 to 2 h, although the full effect might not develop for several weeks during chronic dosing. The duration of action is dose dependent and may persist for 6 to 12 h.

PHARMACOKINETICS

After oral administration, 60 to 75% of a captopril dose is absorbed from the gastrointestinal tract and peak plasma concentrations are usually attained within 1 h. Absorption is reduced by 25 to 55% on administration with food, without a significant effect on the antihypertensive activity of captopril.

Pharmacokinetic studies have revealed that about 30% of the captopril amount in human plasma is bounded to proteins. It is eliminated in the urine as unchanged drug (40–50%), disulfide, and other metabolites. The elimination half-time has been reported to be 2 to 3 h, but this is increased in renal impairment (2.5 times for captopril and 4 times for the disulfide metabolite).

ANALYTICAL ASPECTS OF CAPTOPRIL DETERMINATION IN BIOLOGICAL FLUIDS

The first approaches to captopril determination in biological matrix were made by gas chromatography (GC) and gas chromatography/mass spectrometry (GC-MS).

High-performance liquid chromatography (HPLC) is a challenging method of captopril determination in blood, plasma, and urine. However, the low concentration levels and the relative sensitivity of captopril to oxidation determine that these methods follow three different directions: (1) the use of electrochemical detection, as a more sensitive alternative detection than UV, without any derivatization of the analyte of interest; (2) the UV or fluorescent detection of a derivatization product of captopril, with labeling done prior to or after the chromatographic separation; and (3) the use of preconcentration techniques such as liquid-liquid extraction and multicolumn switching setup.

Concerning the derivatization reagents frequently used for captopril labeling, the following list can be considered: (1) N-(4-benzoylphenyl)maleimide, (2) 1-benzyl-2-chloropyridinium bromide, (3) 2,4'-dibromoacetophenone, (4) N-(4-dimethylamino-3,5-dinitrophenyl)maleimide, (5) N-(4-dimethylaminophenyl) maleimide, (6) N-(1-pyrenyl)maleimide, (7) 7-fluorobenzofurozan-4-sulfonic acid, (8) N-(7-dimethylamino-4-methyl(coumarin 3-yl)maleimide, and (9) 5,5'-dithio-(bis-2-nitrobenzoic acid).

More interest was paid, during the last period, to finding highly specific fluorescent reagents for the thiol function. From this category, monobromobimane was the last one investigated. The derivatization of free captopril with monobromobimane and plasma matrix removal by precipitation with trichloroacetic acid (TCA) should be realized immediately after plasma collection. In such conditions, the plasma samples can be stored for at least 2 months at -40°C . Collection of blood samples can be achieved either on heparin or citrate. Disulfide can be reduced to captopril with pyrophosphoric acid, allowing total drug determination. The mean plasma concentration profile of this drug, assessed according to the monobromobimane fluorescent labeling method (after a single-dose crossover bioequivalence study), is in very good agreement with previously used methods and is illustrated in Fig. 2.

Some other separation techniques, such as electrophoresis, capillary zone electrophoresis, capillary

Figure 2 Plasma concentration profile of captopril.

izotachophoresis, and LC–chemiluminescence-based detection, were also used.

Carbenoxolone

Decio Armanini and Cristina Fiore
University of Padua, Padua, Italy

Glossary

aldosterone The main mineralocorticoid hormone produced by adrenals.

bioassay for mineralocorticoid effect Measurement of the biological effect of mineralocorticoids at the level of target tissues; for example, the potassium/sodium ratio in urine and the rectal potential difference.

carbenoxolone A derivative of glycyrrhetic acid; the active principle of licorice root.

11- β -hydroxysteroid dehydrogenase type 1 The enzyme that converts inert cortisone to active cortisol in fat and liver.

11- β -hydroxysteroid dehydrogenase type 2 The enzyme that inactivates cortisol to cortisone at the level of the kidney and other classical target tissues for aldosterone, allowing aldosterone to bind to its receptors.

glucocorticoid effect The effect of glucocorticoids at the level of target tissues; for example, the effect on fat deposition and on liver metabolism.

mineralocorticoid effect The classical effect of aldosterone in retaining sodium and water and in excreting potassium in urine.

plasma mineralocorticoid-receptor activity A method that measures the sum of all the plasma substances that bind to mineralocorticoid receptors in kidney cytosol in relation to their plasma concentration and affinity for the receptor itself.

pseudohyperaldosteronism A syndrome characterized by the clinical picture of primary hyperaldosteronism and suppression of renin and aldosterone due to volume expansion related to endogenous or exogenous substances that retain sodium and water.

Carbenoxolone sodium is a hydrogen succinate of glycyrrhetic acid, the active principal of licorice, and has been used for 40 years in the treatment of gastritis and peptic ulcer. Optimal therapeutic effect in gastric ulcer is achieved with a dose of 50 to 100 mg three times daily. The drug can produce endocrine side effects at the level of water and electrolyte

balance and on the metabolism of cortisol, but it also has some potential therapeutic applications in other endocrine clinical situations.

INTRODUCTION

Carbenoxolone sodium is a hydrogen succinate of glycyrrhetic acid, the active principle of licorice (Fig. 1), and has been used for 40 years in the treatment of gastritis and peptic ulcer. Prolonged treatment with carbenoxolone can lead to the appearance of a syndrome of pseudohyperaldosteronism, which is characterized by water and sodium retention, hypertension, hypokalemia, low plasma renin activity, low aldosterone, and impaired glucose tolerance. These side effects are more evident in conditions that predispose to hypokalemia, in old age, and in association with chronic diseases of the liver, kidney, and heart.

PATHOGENETIC MECHANISMS OF THE MINERALOCORTICOID ACTIVITY

After the introduction of carbenoxolone as a therapeutic agent in 1968, it was demonstrated that the drug shares some aldosterone-like effects in adrenalectomized patients and rats and that it can enhance the action of submaximal amounts of aldosterone, with both effects being abolished by therapy with the aldosterone receptor antagonist spironolactone. Spironolactone can also lessen the therapeutic effect of carbenoxolone. The mineralocorticoid effector mechanism of the drug was investigated by measuring the potassium/sodium ratio in urine or the rectal potential difference.

Direct Mineralocorticoid Effect and Enhancement of Mineralocorticoid Activity of Aldosterone and of Other Endogenous Steroids

In 1982, Armanini and colleagues found that carbenoxolone has (1) a low but measurable affinity for

Figure 1 Structure of glycyrrhetic acid (A) and its derivative carbenoxolone (B).

mineralocorticoid receptors in kidney cytosol (1/3000 that of aldosterone), (2) a direct mineralocorticoid effect *in vivo* in adrenalectomized rats at doses consistent with receptor affinity, and (3) a powerful action of amplifying the electrolyte effects of near maximal doses of aldosterone when administered to adrenalectomized rats. Plasma concentration of carbenoxolone after 1 week of oral administration is up to 10 mg/dl, a value consistent with a direct mineralocorticoid effect of the drug, even considering the low receptor affinity.

In another study, Armanini and colleagues evaluated the plasma mineralocorticoid receptor activity, which measures the levels of all plasma factors that bind to mineralocorticoid receptors of rat kidney cytosol, in six volunteers treated with carbenoxolone. The volunteers showed a clear syndrome of pseudohyperaldosteronism, and the plasma mineralocorticoid receptor activity decreased significantly at day 3 of treatment, suggesting a local effect of carbenoxolone in amplifying endogenous steroid action. At day 7, the values were still decreased but were significantly higher than at day 3, suggesting a direct mineralocorticoid effect of the drug as well.

In 1990, Morris and Souness demonstrated that carbenoxolone (1) amplifies the antinatriuretic activity of aldosterone and of desoxycorticosterone, which are not affected by 11-hydroxysteroid dehydrogenase, and (2) confers mineralocorticoid properties to steroids that are not mineralocorticoids such as 11-desoxycortisol and 2 α -methyl cortisone.

Inhibitory Effect of 11- β -Hydroxysteroid Dehydrogenase

In 1988, Stewart and colleagues emphasized the implication of 11- β -hydroxysteroid dehydrogenase in the effector mechanism of aldosterone. This enzyme has two isoforms: (1) 11-hydroxysteroid dehydrogenase type 1 (11HSD1), which is present in the liver and fat and which activates cortisone to cortisol, regulating the physiological functions of these tissues (Fig. 2), and (2) 11-hydroxysteroid dehydrogenase

type 2 (11HSD2), which is present in the kidney (Fig. 3) and other classical target tissues for aldosterone (e.g., colon, salivary and sweat glands), where it inactivates cortisol to cortisone, thereby allowing aldosterone to bind to its renal receptors (when the enzyme is not active, e.g., when cortisol becomes a potent mineralocorticoid and produces a severe pseudohyperaldosteronism syndrome due to an inactivating mutation of the 11HSD2 gene). The authors demonstrated that carbenoxolone (1) increases the urinary-free cortisol/free cortisone ratio due to the block of 11HSD2 in the kidney and (2) has no effect on the urinary ratio of tetrahydrocortisol + allo-tetrahydrocortisol/tetrahydrocortisone, which are produced by the liver from cortisol and cortisone and are excreted in urine (thus, their ratio is dependent on liver 11HSD2 and does not increase when this isoform is inactivated).

Central Effects of Carbenoxolone

In 1992 Gomez-Sanchez and Gomez-Sanchez reported that the infusion of carbenoxolone into the lateral ventricle of the brain produces hypertension without affecting saline appetite, meaning that hypertension was not linked to sodium and volume,

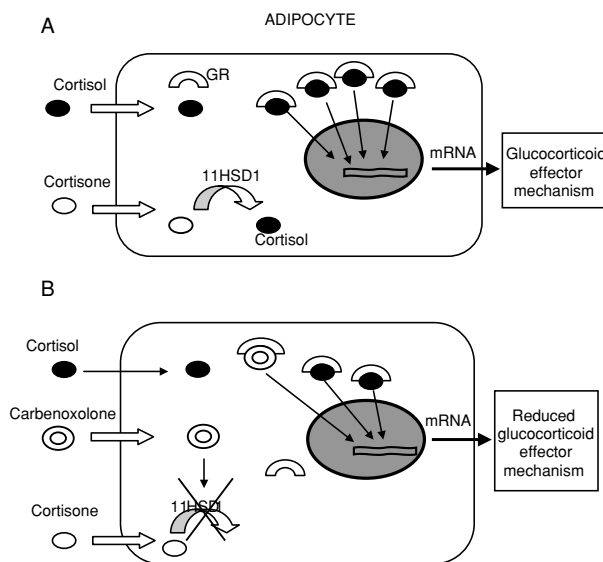

Figure 2 (A) Mechanism of action of cortisol in fat and liver. The availability of cortisol is increased by the activation of inert cortisone to active cortisol. (B) Mechanism of action of carbenoxolone. The availability of cortisol is decreased due to the inhibition of 11-hydroxysteroid dehydrogenase type 1. This effect reduces the depositing of triglycerides in adipocytes and the differentiation of preadipocytes into adipocytes. GR, glucocorticoid receptor.

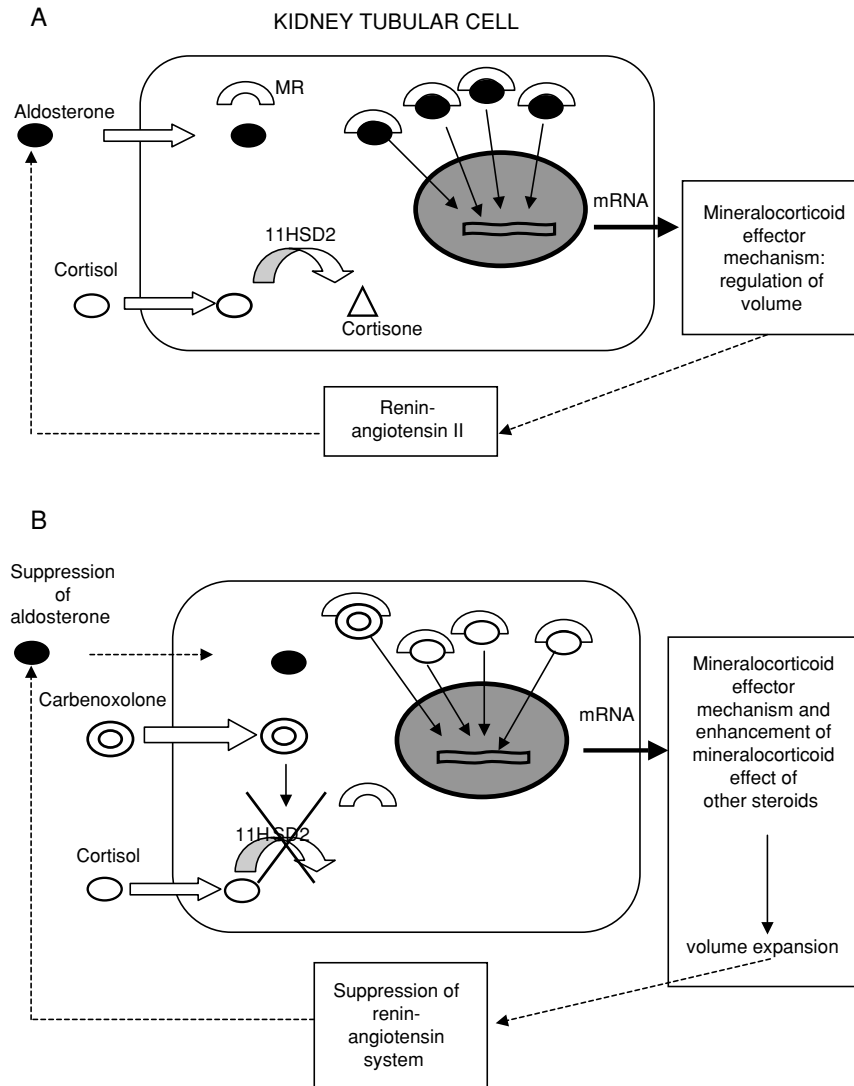

Figure 3 (A) Mechanism of action of aldosterone. Mineralocorticoid receptors are protected from cortisol by the enzyme 11-hydroxysteroid dehydrogenase type 2, which inactivates cortisol to inert cortisone. (B) Mechanisms of mineralocorticoid action of carbenoxolone. The drug can bind directly to mineralocorticoid receptors, can amplify or confer mineralocorticoid activity to other steroids, and can block 11-hydroxysteroid dehydrogenase type 2. All of these effects produce a volume expansion and the suppression of renin and aldosterone. MR, mineralocorticoid receptor.

consistently a central role of mineralocorticoids in blood pressure control.

Carbenoxolone and Heart Fibrosis

More recent studies have focused on the importance of aldosterone as a profibrotic agent, in particular at the heart level. In 2003, Young and colleagues demonstrated that carbenoxolone can produce a marked mineralocorticoid effect in coronary vascular inflammatory responses, probably mediated by binding of glucocorticoids to mineralocorticoid receptors

due to the block of inactivation of cortisol by 11HSD2. At high concentrations, carbenoxolone can also enhance vasoconstrictor action via selective toxicity to the endothelium and elimination of endothelium-dependent relaxation.

PATHOGENETIC MECHANISMS OF THE GLUCOCORTICOID ACTIVITY

Carbenoxolone binds to glucocorticoid receptors with low affinity and inhibits 11HSD1, thereby reducing the availability of cortisol at the level of the liver and

adipose tissue (Fig. 2B). The inhibition of 11HSD1 is involved in the physiological regulation of these tissues. An increased activity of the enzyme is probably involved in visceral obesity, which is related to a local action of cortisol.

CARBENOXOLONE AS A THERAPEUTIC AGENT

Pseudohypoaldosteronism

Carbenoxolone can suppress the renin–aldosterone system in some patients with pseudohypoaldosteronism type 1. The syndrome is characterized by salt wasting, hyperkalemia, hyperreninemic hyperaldosteronism, and unresponsiveness to mineralocorticoids. In some cases, an inactivating mutation of the mineralocorticoid receptor gene has been demonstrated. The response to carbenoxolone suggests that there is at least a partly functional mineralocorticoid receptor in some patients with renal pseudohypoaldosteronism.

Obesity

Carbenoxolone in effect has a dramatic inhibitory effect on preadipocyte differentiation into mature adipocytes and reverses the inhibition of insulin release by pancreatic islets, probably due to the block of 11HSD at this level.

Hypercholesterolemia

In 2003, Andrews and colleagues found that carbenoxolone reduces total cholesterol in healthy individuals, but not in diabetics, and reduces the release of free fatty acids, the glucose uptake, and the incorporation of glucose into triglycerides in rat epididymal fat pad. All of these studies have pointed out the importance of 11HSD1 in fat tissue distribution and the usefulness of inhibitors of the enzyme in reducing fat mass.

21-Hydroxylase Deficiency

This syndrome is characterized by reduced cortisol synthesis. The effect of carbenoxolone on 11HSD1 can explain the ability of the drug to augment the adrenal androgen-suppressing activity of hydrocortisone in patients with 21-hydroxylase deficiency. This combination could improve the treatment of congenital adrenal hyperplasia.

Gonadic Dysfunction

By blocking 11HSD1, carbenoxolone reduces the availability of cortisol and testosterone in Leydig cells in women with hyperandrogenism.

CONCLUSION

Carbenoxolone was first introduced as a therapeutic agent. Subsequently, its use was greatly limited by the fear of important side effects. Now, interest in this agent is once again growing due to the finding of a potential therapeutic application in some endocrine diseases.

Carbohydrate Metabolism and Hormone-Fuel Interrelationships

Keith Tornheim

Boston University School of Medicine, Boston, Massachusetts, United States

Glossary

carbohydrate Sugar; chemical compounds of empirical formula $(\text{CH}_2\text{O})_n$ that are carbon chains with an aldehyde or keto group and two or more hydroxyl groups.

gluconeogenesis Metabolic process in which glucose is synthesized from nonsugars.

glycogen A branched polymer of glucose; used for storage in mammalian cells.

glycolysis Metabolic process in which glucose is broken down to pyruvate or lactate.

kinase An enzyme that adds a phosphate to a substrate, usually from ATP.

Carbohydrates [named for their empirical formula, $(\text{CH}_2\text{O})_n$] include simple sugars (monosaccharides), disaccharides consisting of two linked sugars, and polysaccharides such as the glucose storage polymer glycogen.

INTRODUCTION

By definition, simple sugars are aldehydes or ketones with two or more hydroxyl groups; thus, the smallest sugars are the trioses (three-carbon sugars) glyceraldehyde and dihydroxyacetone. Sugars with three to seven carbons are commonly involved in cellular metabolism. Glucose is a hexose (six-carbon sugar) with an aldehyde group at one end; by convention, this is carbon-1. Fructose is also a hexose, but it has a keto group at carbon-2. Sucrose (common table sugar) is a disaccharide of glucose and fructose.

Glucose is the most important of the biological sugars. It is the essential fuel of the brain and thus control of its blood concentration is critical. It is also

important in powering intense muscular work. A major metabolic function of the liver is to maintain blood glucose through appropriate release of the sugar from the storage polymer glycogen and through resynthesis of glucose from nonsugar precursors (gluconeogenesis). The blood glucose concentration is under hormonal control, with insulin promoting glucose uptake and storage in muscle and liver and the counterregulatory hormones, such as glucagon and epinephrine, promoting glycogen breakdown as well as gluconeogenesis in liver. Lack of or insufficient insulin is the cause of diabetes, and the resulting chronic elevated glucose levels lead to vascular damage and much of the cases of blindness and kidney disease and increased risk of heart disease. This article discusses the metabolism of glucose in the glycolytic pathway and the production of energy; the storage of glucose in glycogen and its breakdown; the resynthesis of glucose through the pathway of gluconeogenesis; the branch to the pentose phosphate pathway that produces ribose 5-phosphate, which is necessary for DNA and RNA synthesis; and how the metabolism of glucose is linked to the secretion of insulin in the β cells of the pancreatic islets.

GLYCOLYSIS

The chemical logic of the glycolytic pathway is the generation of high-energy phosphate compounds that can be used to phosphorylate adenosine diphosphate (ADP) to adenosine triphosphate (ATP). ATP is the energy currency of the cell. The breakdown of ATP is used to power energy-consuming reactions of the cell, from biochemical syntheses to ion pumping to muscular contraction. The early steps in glycolysis actually involve the consumption of two ATPs, but in the later reactions four ATPs are produced, giving a net production of two ATPs per glucose molecule.

Reactions

The reactions of glycolysis are shown in Fig. 1. First, glucose is phosphorylated by the enzyme hexokinase (“kinase” means a phosphorylating enzyme) to yield glucose 6-phosphate. Glucose 6-phosphate is isomerized from the aldo sugar to the keto sugar fructose 6-phosphate, which is then phosphorylated at the other end by the key enzyme phosphofructokinase to generate fructose 1,6-bisphosphate. (By current convention, “bis” indicates that the phosphates are on separate carbons, not attached together as in adenosine diphosphate.) Fructose 1,6-bisphosphate is cleaved in the aldolase reaction to two triose phosphates, dihydroxyacetone phosphate and glyceraldehyde 3-phosphate. Since the rest of glycolysis proceeds from the latter, dihydroxyacetone phosphate is converted to glyceraldehyde 3-phosphate by triose phosphate isomerase so

Figure 1 The glycolytic (glucose breakdown) and gluconeogenic (glucose synthesis) pathways. The purely glycolytic enzymes are listed on the left. All tissues have hexokinase, but liver and pancreatic β cells have the high K_m isoform glucokinase that makes them sensitive to the glucose concentration. The purely gluconeogenic enzymes are listed on the right and their reactions are shown with dashed arrows. Liver and kidney have glucose 6-phosphatase, which allows them to produce glucose. All other enzyme reactions shown are used in both glycolysis and gluconeogenesis.

that both halves of the glucose molecule can be metabolized. In the glyceraldehyde 3-phosphate dehydrogenase reaction, the aldehyde of glyceraldehyde 3-phosphate is oxidized to a carboxylic acid, but the energy of oxidation is used in part for the uptake of inorganic phosphate (P_i) into a phosphate anhydride in the product 1,3-bisphosphoglycerate. In this reaction, the acceptor of the reducing equivalents is the cofactor nicotinamide adenine dinucleotide (NAD), which becomes NADH with the addition of the hydride (hydrogen with both electrons), whereas a second hydrogen is released simply as a proton in solution. The phosphate anhydride generated at carbon-1 is high energy and thus can be used to phosphorylate ADP to ATP in the phosphoglycerate kinase reaction (so named from the reverse reaction). 3-Phosphoglycerate is then converted to the second high-energy intermediate phosphoenolpyruvate in two steps: The phosphate is moved from the 3 to the 2 position by phosphoglycerate mutase and then water is removed in the enolase reaction. Phosphoenolpyruvate is then used to phosphorylate ADP to ATP by pyruvate kinase. It is the highly favored conversion of the initial product enolpyruvate to the normal keto form of pyruvate that pulls the reaction forward and causes phosphoenolpyruvate to be a high-energy phosphate donor.

Fate of Pyruvate

The fate of pyruvate depends on the oxidative state of the tissue. For glycolysis to proceed, the NADH produced in the glyceraldehyde 3-phosphate dehydrogenase reaction must be reoxidized back to NAD. Under aerobic conditions, the reducing equivalents from NADH may be transferred to the mitochondrial electron transport chain and ultimately to molecular oxygen. However, if there is insufficient oxygen or insufficient activity of the electron transport chain, then the pyruvate must be used to oxidize NADH and regenerate NAD in the lactate dehydrogenase reaction. This is the reason why strong muscular exercise produces lactate (lactic acid). Yeast lack lactate dehydrogenase and so instead under anaerobic conditions the pyruvate is first decarboxylated to acetaldehyde, which is then used in the alcohol dehydrogenase reaction, generating ethanol in the reoxidation of NADH to NAD. This is why fermentation to produce wine or other alcoholic beverages must be done anaerobically in sealed containers; otherwise, the acetaldehyde would be oxidized to acetic acid (vinegar), making a less palatable drink.

If pyruvate is not needed to be converted to lactate in order to reoxidize NADH, then the pyruvate can enter the mitochondria and be converted to acetyl-coenzyme A (CoA) in the pyruvate dehydrogenase reaction. Acetyl-CoA can be completely oxidized to CO₂ in the citric acid cycle. ATP production by oxidative phosphorylation from the two molecules of pyruvate, together with the reducing equivalents transferred from the two NADHs from the glyceraldehyde 3-phosphate dehydrogenase reaction, is on the order of 15 times greater than the two ATPs produced in glycolysis alone. The details of the citric acid cycle and oxidative phosphorylation are not considered here. If there is excess use of glucose beyond what would be necessary for energy production, then acetyl-CoA can also be used for synthesis of fatty acids.

Regulation of Glycolysis

Phosphofructokinase

The key regulatory enzyme of glycolysis is phosphofructokinase. It is inhibited by ATP and citrate and activated by AMP (and ADP), P_i, and fructose 2,6-bisphosphate. Although ATP is a substrate of the enzyme, it is also an important product of glycolysis, and the inhibition at a regulatory site is an example of classic feedback inhibition. Since ATP usage produces AMP, ADP, and P_i, these activators also signal a need for more ATP production, as would a decrease in ATP. Citrate may serve as an indicator of the sufficiency of alternative fuel, particularly fatty acids that are broken down to acetyl-CoA, which may then increase citrate so that glucose may be preserved for the brain. The importance of fructose 2,6-bisphosphate as an activator has principally been established in liver; it is discussed later in the context of reciprocal regulation of gluconeogenesis and glycolysis. (It is made by phosphorylation of fructose 6-phosphate on the 2 position by a phosphofructokinase-2, distinct from the glycolytic phosphofructokinase.)

Hexokinase and Glucose Transport

Hexokinase is nominally the first step in glycolysis, but it is not the major point of regulation because glucose 6-phosphate is a branch point leading to glycogen and to the pentose phosphate pathway. Importantly, glucose 6-phosphate is an inhibitor of hexokinase, so if the other pathways are slow and if phosphofructokinase is inhibited, then glucose 6-phosphate will increase and inhibit hexokinase. Conversely, if phosphofructokinase is activated, such

as by a decrease in ATP and increase in AMP, then fructose 6-phosphate and glucose 6-phosphate will decrease and hexokinase will be disinhibited. Glucose transport into the cell is also stimulated by insulin in muscle and fat cells, which are tissues that have the insulin-regulated transporter Glut4. In contrast, glucose transport in and out of liver is rapid, catalyzed by Glut2.

Regulation of Pyruvate Dehydrogenase

Regulation of the conversion of pyruvate to acetyl-CoA is of great importance because although pyruvate can be converted back to glucose in the process of gluconeogenesis, there cannot be a net production of glucose from acetyl moieties in animal cells. Pyruvate dehydrogenase is inhibited by its products acetyl-CoA and NADH, and this is countered by the corresponding substrates CoA and NAD; thus, it can be considered that the enzyme is inhibited by high acetyl-CoA/CoA and NADH/NAD ratios. In addition, the enzyme is inactivated by phosphorylation by a specific protein kinase, which is itself activated by high acetyl-CoA/CoA, NADH/NAD, and ATP/ADP ratios. The enzyme can be reactivated by removal of the phosphate by a specific protein phosphatase that is stimulated by high pyruvate levels and by insulin. The pyruvate dehydrogenase reaction is carried out by a multienzyme complex, to which the specific kinase and phosphatase are also bound.

GLYCOGEN METABOLISM

Reactions of Glycogen Breakdown

Liver and muscle can contain large amounts of glycogen, a polymer that is a storage form of glucose. It is a branched polymer, with glucose residues largely linked 1–4 but with branches approximately every 10 residues with a 1–6 linkage. The enzyme mainly responsible for breaking down glycogen is phosphorylase (which is short for glycogen phosphorylase because it was the first of its class discovered); it breaks 1–4 linkages by the addition of P_i, releasing a residue as glucose 1-phosphate. However, it can only come within 4 residues of a branch point. Then a “transferase” transfers the branch, except for the penultimate residue, to the end of the main chain; α-1,6-glycosidase cleaves off the final branched residue as free glucose. With the branch removed, phosphorylase can continue.

Interestingly, the phosphorylase reaction can go in both directions, $\text{glycogen}(n) + \text{P}_i \leftrightarrow \text{glucose}$

1-phosphate + glycogen($n - 1$), with the equilibrium at $[P_i]/[\text{glucose 1-phosphate}] = 3.7$. Carl Cori, the discoverer of phosphorylase, received the Nobel prize for finding the first enzyme that can synthesize a biological polymer since glycogen can be formed in the test tube in the presence of high glucose 1-phosphate. However, *in vivo* the $[P_i]/[\text{glucose 1-phosphate}]$ ratio is approximately 100, and the enzyme catalyzes glycogen breakdown. This was clearly demonstrated in individuals lacking phosphorylase who have a glycogen storage disease with excess glycogen, not low levels.

Since glucose 1-phosphate is in equilibrium with glucose 6-phosphate through the phosphoglucomutase reaction, the sugar residues released from glycogen can serve as fuel in the glycolytic pathway in muscle. In this context, the fact that glucose 6-phosphate is derived from glycogen phosphorolysis rather than hydrolysis means that there is a net three ATPs produced in glycolysis per glucose residue. In liver, the glucose 6-phosphate produced is generally dephosphorylated to provide blood glucose as needed, along with gluconeogenesis.

Reactions of Glycogen Synthesis

In the synthesis of glycogen by the enzyme glycogen synthase, the glucosyl residue donor is UDP-glucose. UDP-glucose in turn is synthesized from glucose 1-phosphate and UTP, with the release of pyrophosphate (which can be cleaved by pyrophosphatase to pull the reaction). Glycogen synthase resembles phosphorylase in that it makes only 1–4 linkages. The branches in glycogen are made by branching enzyme, which takes a chain of seven residues from the end of a growing chain and attaches it in 1–6 linkage to a glucosyl residue four positions further on.

Regulation of Glycogen Metabolism

The controlling enzymes of glycogen breakdown and synthesis are phosphorylase and glycogen synthase, respectively. Their regulation involves allosteric actions by activators and inhibitors as well as phosphorylation and dephosphorylation. The phosphorylation state affects the sensitivity to the allosteric effectors, and the effectors can modulate the phosphorylation state. Hormonal regulation is important to glycogen metabolism. Insulin, a 51-amino acid small protein secreted by the β cells of the pancreatic islets in response to high glucose, promotes glycogen storage. Glucagon, a 29-amino acid peptide secreted by the α cells of the pancreatic islets in response to

low glucose, promotes glycogen breakdown in liver as well as gluconeogenesis. Glycogen breakdown in both liver and muscle is promoted by epinephrine, a catecholamine secreted by the adrenal medulla in response to nerve impulses, such as when a rabbit sees a fox.

Phosphorylase was originally found to exist in two forms: a nonphosphorylated form (phosphorylase *b*) that required AMP for activity and a phosphorylated form (phosphorylase *a*, with a phosphate on a serine residue of each of its four subunits) that was active in the absence of AMP. Phosphorylase *b* is also inhibited by glucose 6-phosphate and ATP. Glucagon and epinephrine can activate phosphorylase by causing a sequence of reactions (the cascade; Fig. 2) that results in the conversion of phosphorylase *b* to *a*. First, these hormones bind to their specific receptors. (Glucagon is only effective on liver and not on muscle because muscle does not have glucagon receptors.) The binding of the hormone causes activation of adenylyl cyclase, which makes cyclic AMP from ATP. This in turn activates the cyclic AMP-dependent protein kinase (PKA), which can then phosphorylate and activate phosphorylase *b* kinase. The latter protein kinase then phosphorylates phosphorylase *b*, converting it to phosphorylase *a*, which is more active and breaks down glycogen.

In addition to phosphorylation, phosphorylase *b* kinase can be activated by an increase in intracellular free calcium ion. Thus, when muscular contraction is initiated by a release of calcium from the sarcoplasmic reticulum, the increase in calcium can also trigger glycogenolysis to help provide the needed fuel.

Glycogen synthase is also controlled by phosphorylation/dephosphorylation. In this case, the

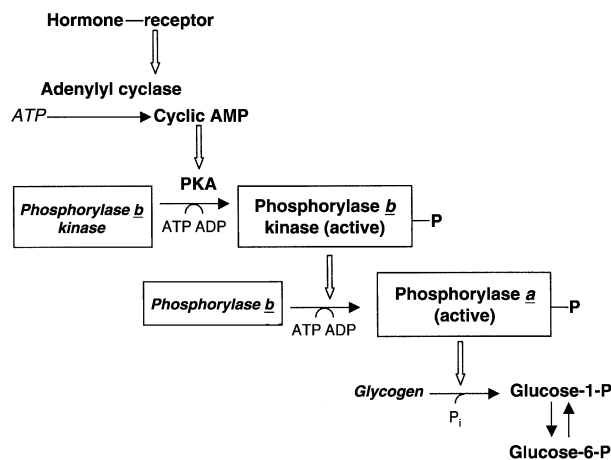

Figure 2 Stimulation of glycogen breakdown by hormones such as epinephrine and glucagon—the cascade.

phosphorylated form is the less active one (originally called glycogen synthase D because it is dependent on glucose 6-phosphate, but now it is called synthase b in correspondence with the less active phosphorylase b; synthase a was originally called synthase I because it is independent of glucose 6-phosphate). The hormonal cascade described previously can cause the phosphorylation of glycogen synthase by PKA, thus inhibiting glycogen synthesis as well as activating glycogen breakdown. However, the situation for glycogen synthase is more complex because there are at least 10 phosphorylation sites that can be phosphorylated by at least nine different protein kinases. The importance or hierarchy of these sites and their kinases remains to be clarified. Insulin's effect in promoting glycogen storage appears to be in part due to inhibition of the action of glycogen synthase kinase 3.

The protein phosphatases that convert phosphorylase a to b and glycogen synthase b to a, particularly the protein phosphatase 1 that has a glycogen-binding subunit, are subject to regulation in several ways. First, binding of allosteric regulators to the protein substrate affects the activity of phosphatases and kinases. Thus, AMP binding to phosphorylase a makes it a poor substrate for the phosphatase because the phosphate is tucked in so that it cannot be hydrolyzed, whereas binding of glucose or glucose 6-phosphate causes the phosphate to become accessible. Binding of glucose 6-phosphate to phosphorylase b also makes it a poorer substrate for the kinase as well as inhibiting phosphorylase activity. Second, inhibitory proteins can bind to the phosphatase, and the action of these proteins is regulated by their phosphorylation and dephosphorylation. Third, the fact that the same phosphatase works on both phosphorylase a and synthase b means that when the phosphatase is bound to phosphorylase a—and cannot hydrolyze it because the phosphate is tucked in—the phosphatase is prevented from working on glycogen synthase.

Glycogen Storage Diseases

Genetic deficiency of enzymes of the liver related to glycogen breakdown can lead to the engorgement of the liver with glycogen. Thus, patients with Hers disease (type VI) lack liver phosphorylase and must therefore rely on gluconeogenesis to maintain blood glucose. Patients with Von Gierke disease (type I) lack glucose 6-phosphatase, cannot get glucose from either glycogenolysis or gluconeogenesis, and therefore can withstand only limited starvation. Presumably, they have increased glycogen because increased levels of glucose 6-phosphate promote

glycogen synthesis and inhibit glycogen breakdown, as described previously. In McArdle disease (type V), muscle phosphorylase is absent (indicating that there are separate muscle and liver isoforms from separate genes) and exercise capacity is limited.

GLUCONEOGENESIS

Gluconeogenesis is the synthesis of glucose from non-sugar precursors, such as lactate, pyruvate, and the carbon skeleton of glucogenic amino acids. This is a major metabolic function of the liver since the brain, in particular, is dependent on glucose as a fuel.

Reactions

In a sense, gluconeogenesis is a reversal of glycolysis, and many of the enzymes are the same for the reactions that are readily reversible. However, specifically gluconeogenic enzymes are needed to reverse three steps in glycolysis that have a large free energy drop. Thus, to reverse the pyruvate kinase reaction, first pyruvate is converted to oxaloacetate by pyruvate carboxylase, a reaction driven by ATP hydrolysis; then the oxaloacetate is decarboxylated and phosphorylated to generate phosphoenolpyruvate by the enzyme phosphoenolpyruvate carboxykinase using GTP (Fig. 1). Note that two high-energy phosphate bonds (from ATP and GTP) are needed to produce the very high-energy intermediate phosphoenolpyruvate. The reactions from there to fructose 1,6-bisphosphate occur via reversal of the glycolytic reactions. Then, to generate fructose 6-phosphate, the 1-phosphate is simply cleaved off by the gluconeogenic enzyme fructose 1,6-bisphosphatase (opposing the glycolytic enzyme phosphofructokinase). Fructose 6-phosphate equilibrates with glucose 6-phosphate in the phosphoglucose isomerase reaction as in glycolysis. Finally, glucose 6-phosphate is hydrolyzed to free glucose by glucose 6-phosphatase (opposing the hexokinase isoform glucokinase). Note that synthesis of a molecule of glucose requires the input of six ATP equivalents: the ATP at pyruvate carboxylase, the GTP at phosphoenolpyruvate carboxykinase, and the ATP at the phosphoglycerate kinase reaction for each of the two halves of the glucose molecule, plus two equivalents of NADH for reversing the glyceraldehyde 3-phosphate dehydrogenase reaction.

Regulation

Control of net gluconeogenesis involves regulation of the opposing glycolytic enzymes and the correspond-

ing specifically gluconeogenic enzymes. The glucose phosphorylating activity in liver is largely glucokinase, a high k_m (10 mM) isoform of hexokinase that is responsive to changes in glucose in the physiological range. Glucokinase is not inhibited by glucose 6-phosphate because it lacks the regulatory binding domain present in the other hexokinases. On the other hand, glucokinase has a specific inhibitory protein whose effect is prevented by fructose 1-phosphate and increased by fructose 6-phosphate. (The disinhibition by fructose 1-phosphate explains the stimulation of glucose metabolism by fructose, which in the liver is largely phosphorylated to fructose 1-phosphate by fructokinase.) The liver isoform of pyruvate kinase has several regulatory properties designed to inhibit it so that gluconeogenesis can proceed: (i) strong allosteric inhibition by ATP; (ii) inhibition by alanine, an important gluconeogenic substrate; (iii) dependence on a high level of the activator fructose 1,6-bisphosphate (in order to have the same low k_m for phosphoenolpyruvate that the muscle isoform has with or without fructose 1,6-bisphosphate); and (iv) inhibition by phosphorylation by PKA in response to glucagon. It was originally thought that phosphofructokinase was similarly inhibited by phosphorylation by PKA, but in fact although phosphorylation of phosphofructokinase occurs, it appears to have little effect on the activity of the mammalian enzymes. Instead, PKA phosphorylation of phosphofructokinase-2/fructose 2,6-bisphosphatase, the bifunctional enzyme that both makes and degrades fructose 2,6-bisphosphate, inhibits the kinase and activates the phosphatase activities, thus reducing the level of fructose 2,6-bisphosphate. Since fructose 2,6-bisphosphate is an activator of the glycolytic phosphofructokinase (sometimes called phosphofructokinase-1 for clarity) as well as an inhibitor of fructose 1,6-bisphosphatase, glucagon can thus reduce glycolytic flux and promote gluconeogenesis at this step as well as at the pyruvate kinase step, in addition to its effect of stimulating glycogen breakdown and inhibiting glycogen synthesis. Fructose 1,6-bisphosphatase is also inhibited by AMP, in contrast to the AMP activation of phosphofructokinase. Pyruvate carboxylase has an absolute requirement for the activator acetyl-CoA; the rationale for this is that gluconeogenesis is quite energy consuming, the required ATP certainly cannot come from glucose metabolism, and the presence of acetyl-CoA would be indicative of sufficient alternative fuel, such as from fatty acids. Finally, these enzymes are adaptive in that the amount of the glycolytic enzymes glucokinase, phosphofructokinase, and pyruvate kinase is increased by a

high-carbohydrate diet, whereas the specifically gluconeogenic enzymes are increased by starvation or a low-carbohydrate diet.

Substrate Cycling

The opposing gluconeogenic and glycolytic enzymes form energy-consuming substrate cycles—that is, if glucokinase and glucose 6-phosphatase were active simultaneously so that glucose were converted to glucose 6-phosphate and back to glucose, the net reaction would be the hydrolysis of ATP to ADP and P_i , and similarly for phosphofructokinase and fructose 1,6-bisphosphatase. If phosphoenolpyruvate were converted to pyruvate and back, there would be production of one ATP but utilization of two equivalents, for a net consumption of one ATP. It was originally thought that such substrate cycling would be a waste of energy (hence the original term futile cycle) and that there should be tight regulation to prevent simultaneous operation of the opposing enzymes. However, sophisticated radiolabeling experiments have shown the occurrence of such substrate cycling. For example, if liver cells undergoing gluconeogenesis are provided with glucose with tritium (a radioactive isotope of hydrogen) attached to carbon-5, then after the glucose is metabolized past the phosphofructokinase reaction, the tritium will be released into water on equilibration of glyceraldehyde 3-phosphate with dihydroxyacetone phosphate in the triose phosphate isomerase reaction. Such experiments have shown a substantial glycolytic rate that is largely reduced by glucagon treatment in order to increase the net gluconeogenic rate. Such substrate cycling has the advantage that there is no “dead” range in which neither glycolysis nor gluconeogenesis is operative and thus there is no control. Furthermore, substrate cycling amplifies cellular signals because changes in activators/inhibitors of glycolysis and/or gluconeogenesis lead to much greater percentage changes in the net rate. Finally, as a special case, bumblebees have unregulated fructose 1,6-bisphosphatase in their flight muscles so that substrate cycling with phosphofructokinase generates heat to warm up the muscles on cold days to allow flight, much as an electric heater is used to heat a gasoline engine preparatory to start an automobile in very cold climates.

Cori Cycle and Alanine Cycle

There are two important interorgan cycles involving glycolysis in muscle and gluconeogenesis in liver. In the Cori cycle, glucose is metabolized to pyruvate and

then to lactate in muscle, the lactate is released into the blood and carried to the liver, where it is reconverted to pyruvate and used for gluconeogenesis, and the resulting glucose is released and travels back to muscle. Lactate is a particularly good gluconeogenic substrate because the reoxidation of lactate to pyruvate in the lactate dehydrogenase reaction also provides the NADH equivalents needed for gluconeogenesis. The alanine cycle is similar to the Cori cycle, except that muscle pyruvate is converted to the amino acid alanine rather than lactate by transamination in the glutamate–pyruvate transamination reaction. A very large proportion of the amino acid put out by muscle is alanine, much more so than its composition in muscle protein, due to the fact that the carbon skeleton derives from glycolytically generated pyruvate. In the liver, alanine is transaminated back to regenerate pyruvate, and the excess amino groups can be disposed of as urea since the urea cycle is also localized to the liver. The importance of alanine as a gluconeogenic substrate in this regard explains why it is a potent allosteric inhibitor of liver pyruvate kinase.

PENTOSE PHOSPHATE PATHWAY

The pentose phosphate pathway also branches off from glycolysis at glucose 6-phosphate. It has two important products: ribose 5-phosphate, which is needed for synthesis of nucleotides and nucleic acids (DNA and RNA), and NADPH (the reduced form of nicotinamide adenine dinucleotide phosphate), which provides the reducing equivalents for synthetic reactions such as fatty acid biosynthesis. The first reaction of the pathway, catalyzed by glucose 6-phosphate dehydrogenase, generates one molecule of NADPH from NADP, and the sugar aldehyde group is oxidized to a carboxylic acid. However, since the glucose 6-phosphate substrate is in the pyranose (hemiacetal) ring form with the carbon-5 oxygen linked to carbon-1, the initial product is an internal ester, 6-phosphoglucono δ -lactone, that is then cleaved by lactonase to yield 6-phosphogluconate. 6-Phosphogluconate dehydrogenase produces a second molecule of NADPH from NADP and also releases the carbon-1 carboxyl group as CO_2 , leaving the 5-carbon compound ribulose 5-phosphate. The latter (a keto sugar) is converted to ribose 5-phosphate (an aldo sugar) by phosphopentose isomerase. This so-called oxidative branch of the pentose phosphate pathway thus produces two NADPHs and one pentose phosphate. If, however, this gives more pentose phosphate than is needed for nucleotide synthesis, the excess can be converted back

to glycolytic intermediates by the nonoxidative branch. Three pentose phosphates (15 carbons total) are converted to two molecules of fructose 6-phosphate and one glyceraldehyde 3-phosphate as follows: First, transketolase transfers 2 carbons from xylulose 5-phosphate (an epimer from ribulose 5-phosphate made by switching the orientation of the carbon-3 hydroxyl by phosphopentose epimerase) to ribose 5-phosphate, thereby producing the 7-carbon sugar sedoheptulose 7-phosphate plus glyceraldehyde 3-phosphate. Second, transaldolase transfers 3 carbons back from sedoheptulose 7-phosphate to glyceraldehyde 3-phosphate, producing fructose 6-phosphate and the 4-carbon sugar erythrose 4-phosphate. Finally, transketolase transfers 2 carbons to the erythrose 4-phosphate from another molecule of xylulose 5-phosphate, producing fructose 6-phosphate and glyceraldehyde 3-phosphate.

GLUCOSE METABOLISM AND INSULIN SECRETION

Not only does insulin regulate glucose metabolism but also glucose metabolism in the pancreatic β cells regulates insulin secretion. The β cell is responsive to glucose in the physiological range because it has a high k_m glucokinase like liver. In the β cell, the increased glucose metabolism causes an increase in the ATP/ADP ratio, which closes ATP-sensitive K^+ channels in the plasma membrane, causing membrane depolarization and an influx of Ca^{2+} through voltage-sensitive calcium channels that triggers secretion. There are also other glucose concentration-dependent enhancements of secretion that may involve lipid metabolism and signaling pathways, such as via protein kinase C. Interestingly, normal insulin secretion is pulsatile, and it has been proposed that this may be due to underlying oscillations in glucose metabolism.

Glossary

acanthosis nigricans A scaly and pigmented skin rash, usually on the back of the neck or armpits.

autoimmune A condition in which the immune system attacks certain cells, tissues, or organs, resulting in their being damaged or destroyed.

autosomal dominant The pattern of inheritance of a disease resulting from the inheritance of a single mutated gene that is passed down from one parent, with each child of an affected parent having a 50% chance of inheriting the condition.

autosomal recessive The pattern of inheritance of a disease resulting from the inheritance of two copies of a mutated gene, one from each parent; there is a 25% chance of conceiving an affected child with each pregnancy from unaffected parents each with a single copy of the mutated gene.

heterozygous The presence of two different copies of a given gene.

homozygous The presence of two of the same copies (normal or mutated) of a given gene.

hyperandrogenism Abnormally high levels of male sex hormones, which in woman can result in abnormal facial hair growth, an enlarged clitoris, and/or irregular or absent menses.

hypertriglyceridemia Abnormally high levels of triglycerides (fat) in the blood.

insulin A hormone secreted by beta-cells of the pancreas that promotes the uptake of glucose from the bloodstream into cells where the glucose is used as energy or is stored for future use.

insulin resistance Decreased ability of insulin to promote glucose uptake, use, and storage.

ketoacidosis A condition in which toxic ketones and acids accumulate in the bloodstream and organs of the body.

penetrance The likelihood that a mutated gene, when inherited, will result in a disease.

polygenic The involvement of multiple genes in the development of a disease or condition.

Diabetes mellitus is a chronic disease defined by hyperglycemia (high blood glucose or sugar levels). Varying degrees of insulin resistance and/or dysfunction of the insulin-producing beta-cells in the pancreas cause diabetes. Chronic hyperglycemia is associated with the potential for developing serious complications such as eye disease (retinopathy), kidney disease (nephropathy), nerve disease (neuropathy), and vascular disease (heart attack, stroke, and lower limb amputation). Diabetes mellitus is divided into several different subtypes depending on the underlying genetic and pathophysiological cause. Forms of diabetes due to mutations in single genes tend to be rare, have a high penetrance, and have little influence from environmental factors, whereas the more common forms

of diabetes (e.g., type 1, type 2) are heterogeneous and caused by multiple genes, with penetrance influenced greatly by the environment (Fig. 1).

SINGLE-GENE CAUSES OF DIABETES

A list of characteristic features of monogenic diabetes syndromes is provided in Table I.

Maturity-Onset Diabetes of the Young

Maturity-onset diabetes of the young (MODY) is autosomal dominantly transmitted and is characterized

Figure 1 Subtypes of diabetes. MODY, maturity onset diabetes of the young; MIDD, maternally inherited diabetes and deafness; CGL, congenital generalized lipotrophic diabetes mellitus; FPLD, familial partial lipotrophic diabetes mellitus.

by onset during childhood or early adulthood, lack of obesity (in most cases), and impaired insulin secretion from the beta-cells of the pancreas without evidence of antibodies against beta cells. MODY is suspected when diabetes is diagnosed during the first to third decades of life and is found in two or more consecutive generations of the same family, with at least one member being diagnosed under 25 years of age. There are at least six forms of MODY differentiated by the specific genetic defects. MODY2 is caused by a mutation in glucokinase, an enzyme produced in pancreatic beta-cells and important for glucose metabolism and sensing and insulin secretion. Hyperglycemia in patients with MODY2 is typically mild and can usually be treated by diet. Chronic diabetic complications are relatively uncommon. MODY1, MODY3, MODY4, MODY5, and MODY6 are caused by mutations in transcription factors that are expressed in the pancreas

Table 1 Characteristic Features of Monogenic Diabetes Syndromes

| Syndrome | Mode of inheritance | Gene | Chromosome | Distinguishing features |
|---|---------------------|---|--|--|
| Maturity onset diabetes of the young (MODY) | Autosomal dominant | HNF4 α (MODY1) Glucokinase (MODY2) HNF1 α (MODY3) IPF (MODY4) HNF1 β (MODY5) Neuro D/Beta2 (MODY6) | 20q12–13.1 7p15–13 12q24.2 13q12.1 17cen–q21.3 2q32 | Nonobese, onset during young adulthood, deficient insulin secretion |
| Leprechaunism | Autosomal recessive | Insulin receptor | 19p13.2 | Extreme insulin resistance, characteristic faces with large ears and small jaw, intrauterine growth retardation, postnatal growth retardation, acanthosis nigricans, sparse fat tissue, low fasting blood glucose, death during first year |
| Type A syndrome | Autosomal recessive | Insulin receptor | 19p13.2 | Extreme insulin resistance, acanthosis nigricans, hyperandrogenism |
| Rabson–Mendenhall syndrome | Autosomal recessive | Insulin receptor | 19p13.2 | Extreme insulin resistance, abnormal dentition and nails, pineal gland overgrowth, protuberant abdomen, thick rapidly growing hair, early puberty, accelerated growth |
| Familial partial lipotrophic diabetes (FPLD) | Autosomal dominant | Lamin A/C | 1q21.2 | Lack of fat usually limited to the lower extremities, insulin resistance, hypertriglyceridemia |
| Congenital generalized lipotrophic diabetes (CGL) | Autosomal recessive | γ 3-like protein (GNG3, seipin) 1-acylglycerol-3-phosphate D-acyltransferase 2 (AGPAT2) | 11q13 9q34 | Complete lack of subcutaneous fat, Herculean appearance, insulin resistance, hypertriglyceridemia |
| Maternally inherited diabetes and deafness (MIDD) | Maternal | tRNA ^{Leu} , deletions | Mitochondrial DNA | Diabetes manifest mostly by decreased insulin secretion and also accompanied by deafness or milder degree of hearing loss |

Note: HNF, hepatocyte nuclear factor; IPF, insulin promoter factor; tRNA, transfer ribonucleic acid.

and are thought to play a role in beta-cell development and function. These include hepatocyte nuclear factors 4 α (MODY2), 1 α (MODY3), 1 β (MODY4), insulin promoter factor-1 (MODY5), and neuroD/beta2 (MODY6). HNF1 α (MODY3) is the most frequent gene mutated in MODY. Patients with MODY due to mutations in the aforementioned transcription factors typically have a progressive decrease in insulin secretion with increasing endogenous insulin requirements. Long-term diabetes complications occur with similar frequency to more typical forms of diabetes. In addition, renal cystic disease is a common feature of MODY1. Specific diagnostic genetic testing for MODY is currently available only in research settings.

Genetic Syndromes of Extreme Insulin Resistance

Genetic syndromes of extreme insulin resistance are usually autosomal recessive and due to mutations in the insulin receptor gene. Without properly functioning insulin receptors, insulin cannot effectively stimulate glucose uptake and use. More than 50 such mutations have been identified. Characteristically, glucose levels are normal to elevated and insulin levels are very high (due to compensatory increases in beta-cell insulin secretion). At least three distinct clinical syndromes of extreme insulin resistance exist: type A syndrome, leprechaunism, and Rabson–Mendenhall syndrome. Characteristic features distinguish these syndromes (Table D). The type or location of the mutation does not correlate with the syndrome in any obvious way. These syndromes are very rare, with an estimated incidence of 1 in 4 million live births. Despite very high requirements for insulin (after several thousand units per day), good blood glucose is often difficult to achieve in these patients and chronic diabetic complications are not uncommon.

Familial Partial Lipomatrophic Diabetes

Familial partial lipomatrophic diabetes (FPLD), also referred to as Dunnigan-type familial partial lipomatrophy or face-sparing lipomatrophy, is an autosomal dominant disorder that results from mutations in the lamin A/C gene located on chromosome 1q21.2. The affected patient has normal fat distribution until puberty, when fat tissue decreases or disappears in the arms, trunk, and lower extremities. The face is typically spared from fat loss, and fat may actually accumulate abnormally in the axillae, back, labia majora, and intra-abdominal region. The patient is insulin

resistant and develops glucose intolerance or overt diabetes during the fourth to fifth decades of life. Hypertriglyceridemia with low levels of high-density lipoprotein (HDL) cholesterol is characteristic and may result in pancreatitis.

Congenital Generalized Lipomatrophic Diabetes

Congenital generalized lipomatrophic diabetes (CGL), or Berardinelli–Seip syndrome, is a rare, autosomal recessive disorder characterized by the near absence of adipose tissue from birth in association with severe insulin resistance with glucose intolerance or overt diabetes, hyperandrogenism and early puberty, acanthosis nigricans, hypertriglyceridemia, enlarged liver, and prominent muscles. Approximately half of these cases are caused by mutations in the γ 3-linked gene (GNG3; also called the seipin gene) on chromosome 11q13. Other cases of CGL are due to mutations in the 1-acylglycerol-3-phosphate-D-acetyltransferase 2 (AGPAT2) gene on chromosome 9q34.

Other Single-Gene Diabetes Syndromes

Insulinopathies secondary to mutations in the insulin gene, and maternally inherited diabetes and deafness (MIDD) secondary to mutations in mitochondrial deoxyribonucleic acid (DNA), are also examples of rare single-gene diabetes syndromes. Other genetic diseases in which diabetes is often a feature include Wolfram syndrome, hemochromatosis, Freidreich ataxia, cystic fibrosis, and thiamine-responsive megaloblastic anemia syndrome.

GENETICS OF COMMON FORMS OF DIABETES

The single-gene forms of diabetes described so far constitute no more than 2 to 5% of cases of diabetes. The more common forms of diabetes are known to have important genetic underpinnings but are not inherited in a predictable pattern. This observation suggests that the common forms of diabetes are likely to be due to several (many) mutant genes that are relatively common in the population. Each gene variant individually is likely to have a modest effect, but together the mutant genes act additively or synergistically. Furthermore, environmental provocations are thought to have important effects on the likelihood that a given gene variant or group of gene variants will express themselves. Thus, the common forms

of diabetes are classified genetically as being heterogeneous and complex.

Type 1 Diabetes Mellitus

Type 1 diabetes mellitus (T1DM) occurs predominantly in children and adolescents. In the United States, T1DM accounts for approximately 5 to 10% of all diabetic cases diagnosed. The incidence of T1DM varies greatly worldwide, with the highest reported incidence in Northern Europe and the lowest rates in China, Korea, and Mexico. T1DM is characterized by autoimmune-mediated dysfunction and destruction of the beta-cells of the endocrine pancreas, resulting in insulin deficiency and potential to ketoacidosis, coma, and death. The beta-cell loss begins months to years before the actual clinical onset of insulin dependency. Environmental factors such as viral infections and toxins have been implicated in the pathophysiology of this disorder. These environmental provocations may activate cells of the immune system (T lymphocytes, B lymphocytes, and natural killer cells), initiating and perpetuating a chronic inflammatory reaction that ultimately leads to beta-cell loss and insulin deficiency. This autoimmune process is influenced by a cluster of genes on chromosome 6, termed the human leukocyte antigen (HLA) locus, which is known to modulate immune function. The presence of certain HLA haplotypes appears to predispose the individual to T1DM, whereas other HLA haplotypes appear to be protective. Other genes have been implicated in defining the risk of developing T1DM, including variants of the insulin gene (chromosome 11p15.5) and the cytotoxic T-cell lymphocyte associated-4 (CTLA4) gene (chromosome 2q33) as well as several other chromosomal loci for which the specific genes have yet to be determined.

Type 2 Diabetes Mellitus

Type 2 diabetes mellitus (T2DM) is the most common form of diabetes, accounting for at least 90% of all cases. Its prevalence has reached epidemic proportions, with 16 million people having the disease in the United States alone. Hyperglycemia and overt diabetes result from underlying insulin resistance and impaired insulin secretion secondary to beta-cell dysfunction and failure. Unlike T1DM, the beta cell failure in T2DM is not autoimmune in origin. Both environmental factors (caloric excess and physical inactivity) and genetic predisposition have been implicated in the pathogenesis of T2DM. The strongest

evidence for genetic predisposition to T2DM comes from identical twin studies (with 60–90% concordance rates) and studies that show clustering of the disease in families. The disorder is thought to be heterogeneous and polygenic in nature. Over the past two decades, studies of specific genes have led to the identification of several putative T2DM susceptibility genes. These genes include peroxisome proliferator-activated receptor-gamma (PPARG, chromosome 3p25), beta-3-adrenoceptor (ADRB3, chromosome 8p12–p11.2), fatty acid-binding protein-2 (FABP2, chromosome 4q28–31), plasma cell glycoprotein (PC1, chromosome 6q22–23), insulin receptor substrate-1 (IRS1, chromosome 2q36), regulatory subunit of protein phosphatase 1 (PPP1R3A, chromosome 7q31.1–q31.2), and potassium inwardly rectifying channel (KCNJ9, 11p15.1). Genome-wide searches for T2DM susceptibility genes have resulted in the identification of variants in the calpain 10 gene (CAPN10). Several other chromosomal regions have been implicated, most notably regions on chromosomes 1 and 20.

CONCLUSION

Diabetes is a heterogeneous group of disorders defined by hyperglycemia. Several forms of diabetes are caused by mutations in single genes. Although these single-gene forms of diabetes are rare (approximately 2–5% of cases), they have provided important insights into glucose regulation and into the underlying disease process. By contrast, T1DM and T2DM are far more common and are due to the interaction of multiple genes with the environment. Identification of the genes responsible for these common forms of diabetes has been slower, but progress is being made. Identification of susceptibility genes for diabetes will lead to new strategies for treatment and prevention.

Cardiovascular Disease in Diabetes

Helaine E. Resnick and Barbara V. Howard
MedStar Research Institute, Washington, DC, United States

Glossary

cardiovascular disease Disorders involving both large and small blood vessels; in diabetes, vessels in the eyes, kidneys, legs, head, neck, and heart are commonly affected.

diabetes mellitus A heterogeneous group of disorders characterized by high blood glucose levels.

epidemiology The study of the distribution and determinants of diseases in populations.

Diabetes mellitus (DM) is a serious public health problem that has reached epidemic proportions in developed countries. This epidemic is especially apparent in the United States, where an aging population is accompanied by a trend toward increasing obesity and decreasing physical activity. The most effective way in which to prevent diabetes-associated cardiovascular disease (CVD) is to prevent diabetes. As molecular biology and gene technologies begin to be applied in the clinical setting, new therapies may begin to mitigate the relationship between DM and CVD.

INTRODUCTION

Diabetes and cardiovascular disease (CVD) both are associated with obesity, a sedentary lifestyle, and an adverse lipid profile. Both conditions increase with age, and their risk can be reduced with simple lifestyle modifications. Diabetes mellitus (DM) is a strong, independent CVD risk factor, and coronary heart disease (CHD) is the most frequent and costly vascular complication of DM.

Cross-sectional epidemiological studies in the United States and community-based studies in U.S. and other populations consistently reveal an association between DM and prevalent CVD. In diabetic individuals as well as in those not yet diagnosed with DM, diabetes is associated with an unfavorable distribution of CVD risk factors. In individuals at high risk

for CVD, prospective epidemiological studies reveal consistent temporal relationships between diabetes and CVD. The association between diabetes and CVD is strong, regardless of geography, age, sex, or racial/ethnic background. Diabetes is associated not only with clinical manifestations of CVD, such as acute myocardial infarction and intermittent claudication, but also with subclinical CVD measures, such as the ankle-brachial index, electrocardiographic abnormalities, conduction velocities of large peripheral nerves, dysfunction of sensory nerves, cardiac autonomic dysfunction, carotid thickening, and retinopathy.

METABOLIC SYNDROME

Type 2 diabetes has a characteristic physical and metabolic profile that includes obesity and abnormal lipid patterns and concentrations.

Obesity and Fat Distribution

People with diabetes are generally much heavier than their nondiabetic counterparts regardless of age, although weight tends to vary across racial and gender lines. The high prevalence of diabetes in minority women may well explain why non-White women have higher body mass indexes (BMIs) than do their male counterparts and White women, as demonstrated in epidemiological studies.

An android fat distribution pattern (accumulation of fat in the abdomen) is also typical in individuals with DM. Abdominal visceral fat is thought to be involved in glucose regulation and to potentiate the development of diabetes more than does subcutaneous fat. Although it is not possible to distinguish visceral fat from subcutaneous fat using conventional abdominal girth measures such as waist circumference, circumference measures have been consistently associated with diabetes in several epidemiological studies.

Dyslipidemia

Diabetic individuals also have a characteristic pattern of dyslipidemia consisting of elevated triglycerides, low levels of high-density lipoprotein (HDL) cholesterol, and small dense low-density lipoprotein (LDL) particles. LDL cholesterol levels might not be higher in diabetic individuals than in nondiabetic individuals. This constellation of physical and metabolic characteristics (often accompanied by hypertension, hyperuricemia, and abnormalities in hemostatic factors) is known as metabolic syndrome, occurs prior to the appearance of frank diabetes, and persists following the diagnosis of diabetes. Metabolic syndrome has been linked to ischemic heart disease, giving further evidence that these metabolic disorders are CVD risk factors.

BEHAVIORAL RISK FACTORS AND CVD AMONG DIABETIC INDIVIDUALS

Behavioral risk factors, such as smoking and lack of exercise, increase the risk of adverse health events among diabetic individuals, although the effects of these risk factors are not limited to people with diabetes.

Smoking is associated with diabetic complications and increased mortality risk among people with diabetes. The American Diabetes Association recommends smoking prevention and cessation among diabetic individuals.

Diabetic people are less likely to engage in regular physical activity than are their nondiabetic counterparts. Lack of physical activity is associated with mortality in diabetic individuals.

GENDER EFFECTS

Women have a lower unadjusted risk of CHD than do men. Some, but not all, studies have shown that diabetic women have equal or higher rates of CVD than do men. This excess risk may be explained by several different mechanisms.

Estrogen

Estrogen is typically associated with an antiatherogenic CVD risk factor profile, including higher HDL, lower LDL and blood pressure, and a peripheral distribution of fat rather than a central one. Therefore, estrogen may protect premenopausal women from CVD. However, cessation of ovarian

function during menopause lowers estrogen and HDL levels and elevates LDL, blood pressure, and abdominal fat deposition. These phenomena also occur with chronological aging and are risk factors for CVD. Thus, after menopause and with aging, the favorable CVD risk factor profile enjoyed by premenopausal women is reduced or eliminated compared with men of similar age. However, changes in CVD risk factors at menopause do not fully explain the association between diabetes and CVD in women.

A period of insulin resistance, which may last for years, often precedes the appearance of frank diabetes. In insulin resistance, peripheral tissues do not respond normally to the biological effects of insulin. Tissue resistance to insulin requires increased pancreatic beta cell activity, ultimately leading to a state of compensatory hyperinsulinemia that helps to maintain euglycemia. Decreased insulin production results in hyperglycemia because the compensatory hyperinsulinemia of insulin resistance is no longer sufficient to maintain euglycemia. Initial diagnosis of diabetes is often accompanied by insulin levels at the high end of the normal range despite the high glucose levels.

Understanding the hyperinsulinemia of insulin resistance and diabetes may be critical to understanding the link between female gender and risk of CVD. Low levels of estrogen and high levels of androgen accompany insulin resistance and diabetes even before menopause, and these changes are associated with an unfavorable distribution of CVD risk factors. Thus, premenopausal women with insulin resistance or diabetes do not benefit from the protective effects of estrogen experienced by women without these conditions. Although CVD itself is relatively uncommon before menopause, CVD risk factors may build up during this time and manifest only after menopause. Thus, the reduction in estrogen during menopause may be an especially powerful CVD risk factor among women who were insulin resistant before menopause. Studies are needed to elucidate the effect of estrogen on CVD risk in both diabetic and nondiabetic women.

Low-Density Lipoprotein

Additional pathways may link diabetes to higher CVD risk in women than in men. Although levels of LDL (a known CVD risk factor) are similar in diabetic and nondiabetic individuals, LDL composition differs, with diabetic men and women having smaller LDL particle size. After adjustment for other CHD risk factors, including lipids, no differences in LDL size

remained in diabetic men, but unfavorable differences persisted in diabetic women. The presence of small dense LDL may be atherogenic, suggesting that diabetes may increase CVD risk more in women than in men, and indicates that LDL may be an important CVD risk factor even when levels are not elevated.

MEASUREMENT AND EVALUATION OF NONTRADITIONAL RISK FACTORS

The future of research into the connection between diabetes and CVD will undoubtedly focus on quantifying and assessing other possible CVD risk factors such as formation of advanced glycosylation end products (AGEs) in the tissues of diabetic individuals, chronic inflammation, diabetic autonomic neuropathy, sleep disorders, and genetic susceptibility to diabetes-associated vascular damage.

Advanced Glycosylation End Products

An important characteristic of diabetic vascular complications may be the creation of AGEs in tissue, a process accelerated by hyperglycemia. Glucose forms early glycosylation products with proteins at a rate proportional to glucose concentrations. However, because the quantity of these products is reversible, depending on glucose concentration, and does not accumulate in stable tissue proteins, the products are not consistently correlated with diabetic complications. Some of the early products change and form bonds with other proteins. AGE levels do not return to normal when hyperglycemia is eliminated; instead, they continue to accrue on large- and small-vessel wall proteins. AGE accumulation in tissue may increase vascular permeability and thicken/stiffen the vessel walls. Unlike early glycosylation products, AGEs are related to diabetic vascular disease. Although many AGEs have been characterized, the relative importance of specific AGEs in diabetes-associated vascular damage is still unknown, as are the potentially differential effects of specific AGEs in different tissues.

As demonstrated *in vitro*, AGEs may accelerate macrovascular disease by linking plasma lipoproteins with matrix proteins, thereby slowing the efflux of lipoproteins from the tissues. AGEs may also, via interaction with their receptors (RAGEs), induce endothelial cell surface adhesion molecules. Blocking the activity of RAGEs may slow the accelerated atherosclerosis characterizing diabetes and may be a target for future therapies.

In addition, binding of AGEs may induce release of inflammatory cytokines. Sustained interaction between the stable AGEs and RAGEs in diabetic tissue may create a long-term proinflammatory environment that increases CVD risk. Study of the potential role of AGEs as a stimulus for the pro-CVD inflammatory process may shed more light on the connection between diabetes and CVD.

Chemical analysis of AGEs reveals that they contain multiple products, each with its own potential link to diabetes and CVD. However, existing assays for polyclonal anti-AGE antibodies do not distinguish among individual AGEs, severely limiting efforts to link specific products with vascular damage. Despite these limitations in epidemiological studies, small clinic-based reports reveal that serum levels of AGEs are elevated in children with type 1 diabetes even before vascular complications appear. The presence of AGEs in cigarette smoke may link smoking with CVD in both diabetic and nondiabetic individuals.

Chronic Inflammation

Inflammation may potentiate the development of CVD, and diabetes may play a role in this pathway. The constellation of CVD risk factors in insulin resistance syndrome may include markers of inflammation, and these markers may contribute to CVD risk independently of established metabolic abnormalities commonly observed in insulin resistance.

In older adults, markers of inflammation have been shown to predict clinically meaningful increases in fasting glucose levels, suggesting a role for inflammation in the development of glucose abnormalities. Although there is a growing body of evidence linking markers of inflammation to CVD, elevated levels of inflammatory markers are common in several conditions that typically occur in old age, including diabetes. Whether the inflammation is related to CVD or is a common condition of the elderly remains to be elucidated; therefore, data relating these markers to specific outcomes should be interpreted with caution.

Diabetic Autonomic Neuropathy and Sleeping Disorders

Cardiovascular autonomic neuropathy (CAN) is thought to increase CVD risk among diabetic individuals. Impairment of CAN-associated CVD reflexes, such as heart rate variability, may increase CVD risk in addition to other mechanisms that may link diabetes to CVD via CAN. Among diabetic individuals

with CAN, 25% have been shown to have obstructive sleep apnea, a proportion significantly greater than that of diabetic individuals without CAN. The relatively high prevalence of sleep disturbance in those with diabetic neuropathy implies that the impaired central control of respiration associated with CAN may worsen the effects of sleep disorders on CVD. Increased prevalence of sleep apnea and nocturnal oxygen desaturation in diabetic patients with CAN give further evidence of a relationship between diabetes and sleep-disordered breathing (SDB). In addition to the effects of diabetes on SDB, SDB may actually worsen diabetes by causing dysregulation of glucose metabolism. Reduced glucose tolerance following sleep deprivation has been demonstrated, implying that disrupted sleep may adversely affect some features of normal endocrine function.

Genetic Susceptibility

Severity of diabetic vascular complications may be determined in part by genetics. Identification of genes that may indicate CVD susceptibility in diabetic individuals may become possible, enabling clinicians to tailor treatment plans for “susceptible” or “protected” patients. Although no such screening is currently possible, recent data suggest that certain genes may confer differential risk of diabetic complications.

Haptoglobin (Hp), a hemoglobin-binding protein that protects against oxidative stress, is one such gene. Oxidative stress is thought to be an important mediator of many pathophysiological processes, including diabetic vascular complications. The two common Hp alleles yield three phenotypes that, due to their different biochemical and biophysical properties, seem to differ in their ability to function as antioxidants. Individuals who are homozygous for the Hp-1 allele (1-1) appear to be protected against the development of diabetic retinopathy, diabetic nephropathy, and coronary restenosis. As the field of genetics continues to grow, new methods of CVD risk stratification that enable clinicians to tailor interventions to the genetic profiles of their diabetic patients may develop.

Cardiovascular Disease: Impact of Sex Steroid Replacement

Jeffrey L. Anderson

University of Utah School of Medicine, Salt Lake City, Utah, United States

Glossary

cardiovascular (CV) disease CV disease includes coronary heart disease and other forms of CV disease. Important among these are hypertension and hypertensive heart disease, stroke (especially ischemic or thromboembolic stroke), and peripheral arterial occlusive disease.

coronary heart disease (CHD) CHD represents the clinical consequence of coronary artery atherosclerosis, including angina pectoris, fatal and nonfatal myocardial infarction, sudden death, and heart failure due to ischemic heart disease.

estrogen replacement therapy (ERT) Use of unopposed estrogen as sex steroid replacement therapy. ERT is best tolerated in women who have had a hysterectomy; its use in others is less well tolerated (it may be associated with endometrial hyperplasia).

hormone replacement therapy (HRT) A synonym often used in the literature for sex steroid replacement.

selective estrogen receptor modulators (SERMs) These are engineered, synthetic sex hormones that have different receptor and tissue specificity than natural estrogen. Their potential for CV risk or protection may thus also differ. One SERM, raloxifene, is undergoing testing for its CV and other preventive potential.

sex steroid replacement (SSR) Replacement of female sex hormones after menopause, specifically estrogen with or without a progestin.

Hormonal differences between the sexes are believed to play an important role in delaying coronary heart disease (CHD) in women. A prevalent belief has been that sex steroid replacement (SSR) may prevent or reverse adverse metabolic (lipid and glucose) changes, maintain vascular health, and reduce CHD risk in women after menopause. A multitude of observational studies lent support to this hypothesis. However, randomized clinical trials of both secondary prevention (e.g., the Heart and Estrogen/Progestin Replacement Study) and primary prevention (the Women's Health Initiative) did not

demonstrate net benefit or suggested increased cardiovascular risk potential. Thus, SSR can no longer be recommended for primary or secondary CHD prevention. Whether a different outcome applies to estrogen replacement therapy (e.g., in women without a uterus) or to selective estrogen receptor modulators (e.g., with raloxifene) will be determined by ongoing clinical trials.

BACKGROUND

Risk of Heart Disease Is High in Elderly Women

Despite widespread belief to the contrary, cardiovascular (CV) disease ranks first as a cause of death and disability in women as well as men. In a poll, women perceived cancer (breast cancer, etc.), Alzheimer's disease, and arthritis/bone loss to be their major health problems. Asked about the leading cause of death in women, 55% responded breast cancer and 22% heart disease. In fact, cancer is the cause of 1 of every 5 deaths and breast cancer is the cause of 1 of every 30 deaths, whereas CV disease causes 1 of every 2.4 deaths in women. Of nearly 530,000 U.S. coronary heart disease (CHD) deaths in 1999, 263,000 were in women. Of all CV deaths, 513,000 occurred in women and 446,000 in men. By comparison, all cancers accounted for 264,000 female and 286,000 male deaths. Thus, heart disease, is an "equal opportunity killer," is the leading cause of death in both men and women, and is equal in magnitude to the next seven leading causes of death combined. Furthermore, whereas the death rate from CV disease has steadily declined in men, it has increased in women. Also, hospitalizations for stroke and heart failure for women now exceed those for men.

Presentation of CHD Differs in Men and Women

Despite similarities in prevalence, the pattern of CHD differs by gender. Women are 10–15 years older than

men when signs of CHD first appear. The symptoms of CHD often are more subtle or “atypical,” confusing and delaying diagnosis. However, when a heart attack occurs, survival rates are lower for women.

Risk Is Low before and Increases Rapidly after Menopause

Heart disease risk is low in premenopausal and early postmenopausal women. After age 65, CHD rates increase over time similarly in women and men. By age 75, CHD prevalence in women approximates that in men. Increases in CHD risk after menopause are associated with adverse changes in lipids and lipoproteins: Total cholesterol, low-density lipoprotein cholesterol (LDL-C), and triglycerides increase (10–15%), lipoprotein (a) increases, and high-density lipoprotein cholesterol (HDL-C) decreases (5–10%). LDL composition shifts toward smaller, denser particles (associated with greater CHD risk). Glucose intolerance increases, and endothelial dysfunction becomes more common.

ESTROGEN AND VASCULAR BIOLOGY

Might Sex Steroid Replacement Return CHD to Naturally Low, Premenopausal Levels?

The previously discussed observations led to the prevalent belief that hormonal differences between the sexes play an important role in delaying the appearance of CHD in women. A corollary hypothesis naturally developed that sex steroid replacement (SSR) in women might reverse the adverse metabolic changes of menopause, maintain vascular functional health, and reduce CHD risk to premenopausal levels.

Estrogen and Estrogen Receptors

The biological activity of estrogen is mediated in large part through specific estrogen receptors (ERs). Two major ER types, ER- α and ER- β , have been described. Their differing molecular mechanisms and cellular distributions provide the basis for tissue selectivity. Each has ligand- and DNA-binding domains. Each has receptor-associated proteins and coactivators that are cell specific.

Molecular Mechanisms of Estrogen Activity

After binding to ER, estrogen is transported to the nucleus, where homo- or heterodimers form. DNA binding follows at estrogen response elements and DNA and mRNA expression is induced in distinct profiles. Repressors regulate ER availability and function, and crosstalk occurs with other pathways (e.g., NF- κ B). Nonclassic genomic pathways of estrogen/ER action have also been described. Estrogen may also function through nongenomic pathways to promote vascular health (through estrogen-binding proteins, ERs, or other mechanisms). Estrogen induces vascular nitric oxide and exerts antioxidant activity. Estrogen prevents, but does not reverse, vascular inflammation induced by a high-fat diet (atherogenic mouse model).

Estrogen and Lipoprotein Metabolism

Facilitation of reverse cholesterol transport is important for estrogen's potential preventive role. Estrogen acts to increase apolipoprotein (apo)-A1 and HDL particles, reduce hepatic lipase activity, decrease HDL uptake by hepatic SR-B1 scavenger receptors, and facilitate LDL clearance by hepatic LDL receptors.

With SSR, LDL cholesterol, apoB, and lipoprotein (a) decrease, and HDL2-C, total HDL-C, apoA1, and triglyceride (TG) increase (Figs. 1 and 2). The effects on lipoprotein profiles of estrogen, various estrogen/progestin combinations, and selective estrogen receptor modulators (SERMs) are qualitatively generally similar but differ quantitatively. Estrogen causes the greatest increase in HDL2-C. The response of HDL-C to SSR may be augmented in women with specific ER- α polymorphisms (i.e., IVS1-401 C/C). Differences in prothrombotic factors (fibrinogen, PAI-1, F1.2, and FPA) have also been reported.

The Postmenopausal Estrogen/Progestin Interventions Trial

The Postmenopausal Estrogen/Progestin Interventions Trial (PEPI) randomized 845 postmenopausal women (45–64 years old) to placebo, conjugated equine estrogen (CEE), CEE plus medroxyprogesterone acetate (MPA), or CEE plus micronized progesterone (Days 1–12) and followed them for 3 years. All SSR regimens increased bone mineral density, and combining CEE with a progestin prevented endometrial hyperplasia associated with CEE alone. For adherent

Figure 1 Effect of SSR on lipoprotein fractions for primary prevention. Data from the PEPI study [*JAMA* (1995), 273, 199-208] of 349 women treated with conjugated equine estrogen (CEE) or CEE + medroxyprogesterone acetate (MPA). HDL, high-density lipoprotein; LDL, low-density lipoprotein; TG, triglyceride.

subjects, LDL-C decreased in each active treatment arm, and TGs and HDL (especially with CEE alone) increased (Fig. 1). Little change in fibrinogen or systolic blood pressure was observed with any regimen, but a greater increase in 2-h glucose level occurred with CEE plus MPA than with CEE (8 or 9% vs 3 or 4%). These observations provided the basis for further testing of estrogen/progestin combinations and, in patients without a uterus, unopposed estrogen.

OBSERVATIONAL STUDIES AND CARDIOVASCULAR RISK

The beneficial potential of SSR on CHD and other CV disease risk was supported by numerous (>30) case-control and prospective cohort studies. Overviews of these association studies suggest risk

Figure 2 Effect of SSR on lipoprotein fractions for secondary prevention. Data from the ERA study [*NEJM* (2000), 343, 522-529] of 309 women with CAD. CEE, conjugated equine estrogen; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; MPA, medroxyprogesterone acetate; TG, triglyceride.

reductions of estrogen therapy on CHD of 35–50%. The Nurses' Health Study, the largest prospective cohort study, found that current users of estrogen had approximately half the risk of CHD [relative risk, 0.56 for myocardial infarction (MI) or death], after adjustment for age and other risk factors, as nonusers. Even stronger benefits were found in studies of women with known CHD. Observational studies are limited by the possibility of selection bias. Women who choose to be on SSR may be more health conscious in other ways. Other healthy behaviors, rather than SSR, might explain better CV outcomes. These concerns are best addressed by prospective, randomized trials.

SECONDARY PREVENTION TRIALS

The Heart and Estrogen/Progestin Replacement Study

The Heart and Estrogen/Progestin Replacement Study (HERS) is the most important clinical trial of SSR for secondary CV prevention. HERS randomized 2763 postmenopausal women (average age, 67) with documented CHD to 0.625 mg/day CEE plus 2.5 mg/day MPA or placebo and followed them for an average of 4.1 years. At study end, there was no difference between groups in the primary outcome of CHD events (nonfatal MI and CHD-related death). Secondary CV outcomes also did not differ. Post hoc analysis showed a significant difference in outcomes by time: More CHD events occurred with SSR in the first year and fewer events in Years 3–5. The adverse potential of SSR use within the first year of initiation was an unanticipated result that the Women's Health Initiative (WHI) would later replicate. As a consequence, initiation of SSR after a coronary event was proscribed, but CHD patients already taking and tolerating SSR were allowed to continue.

HERS-II

A major question after HERS was whether the lower event rate in Years 3–5 indicated that benefit would occur with additional years of treatment. This question led to HERS-II, an extended surveillance study of the HERS cohort. Women in the placebo arm were advised not to start SSR, whereas those on therapy could continue. A total of 2321 women in HERS were alive, agreed to enroll in HERS-II, and were followed for an additional 2.7 years. Approximately half continued to take the originally assigned therapy, but no CV benefit of SSR was observed. The unadjusted

hazard ratio (HR) for a primary CHD event was 1.00 [95% confidence interval (CI), 0.77–1.29] in HERS-II and 0.99 (95% CI, 0.84–1.17) for the combined HERS/HERS-II study period. Adjustment for potential confounders, the use of aspirin and statins, and adherence to randomized treatment assignment had little effect on the overall result (HR, 0.96; CI, 0.77–1.19). Similarly, there was no evidence of benefit for the secondary CV outcomes in HERS-II or overall in HERS for coronary revascularization (overall HR, 0.93; 1.02 for bypass surgery and angioplasty), hospitalization for unstable angina (HR, 0.87) or heart failure (HR, 1.05), sudden death (HR, 0.98), stroke or transient ischemic attack (HR, 1.09), or peripheral arterial disease (HR, 0.87). Also, nonfatal ventricular arrhythmia increased (HR, 1.97). Given the failure to confirm a late benefit of SSR in secondary prevention and the documented excess risk of SSR initiation, HERS-II concluded that SSR should not be used to reduce CHD risk in postmenopausal women with CHD.

Effects of Estrogen Replacement on the Progression of Coronary Artery Atherosclerosis

After HERS, an angiographic trial, Estrogen Replacement and Atherosclerosis (ERA), was undertaken to directly explore the hypothesis that SSR might slow the progression of coronary atherosclerosis. Accordingly, 309 postmenopausal women (average age, 66 years) with angiographically defined coronary artery disease (CAD) were enrolled and randomized to 0.625 mg/day CEE alone, 0.625 mg/day CEE plus 2.5 mg/day MPA, or placebo. After an average of 3.2 years, a follow-up coronary angiogram was obtained and quantitative arteriography performed ($n = 248$). During the study, favorable lipid-lowering effects of SSR were observed for the CEE and CEE plus MPA regimens (with LDL-C reductions of 9 and 17% and HDL-C increases of 19 and 14%, respectively) (Fig. 2). However, no difference in adjusted minimal coronary artery diameter or in diameter change scores were observed for estrogen, estrogen/progestin, and placebo regimens ($p > 0.2$ vs placebo). Thus, neither estrogen alone nor in combination with progestin beneficially affected the progression of CAD.

Women's Angiographic Vitamin and Estrogen Trial

The Women's Angiographic Vitamin and Estrogen Trial (WAVE) studied 425 postmenopausal women

with at least one mild to severe coronary stenosis. After 2.8 years of blinded therapy, progression in coronary stenosis scores showed neither a benefit nor a favorable trend in the CEE, CEE plus MPA, or vitamin (E plus C) groups. Indeed, adverse trends for the combination of death, nonfatal MI, and stroke were observed in both the active SSR and the vitamin groups compared with their respective placebo controls.

Summary of Secondary Prevention Studies

The ERA and WAVE mechanistic studies, together with the HERS/HERS-II outcomes study, are consistent with an absence of meaningful benefit of SSR over 3–7 years in secondary CHD prevention and support the recommendation that SSR should not be used in women with CHD with the expectation of cardiovascular benefit.

PRIMARY PREVENTION TRIALS

After HERS, advocates of SSR took refuge in the possibility that SSR might fare better for primary CV prevention: SSRs might have greater potential for preventing the initiation of atherosclerosis in younger women nearer menopause than in older cohorts in which SSR had failed to prevent progression of established disease. Experimental and intermediate endpoint studies also seemed to be supportive.

Women's Health Initiative

The report of the estrogen plus progestin component of the WHI randomized controlled primary prevention trial dispelled that hope. WHI randomized 16,600 postmenopausal women (average age, 63 years) to CEE, 0.625 mg/day CEE plus 2.5 mg/day MPA, or placebo. The primary efficacy outcome (expected to be beneficial) was CHD (nonfatal MI and CHD death). Invasive breast cancer was the primary safety (adverse) outcome of interest. A global index summarizing the balance of major health benefits and risk was the third major outcome measure of interest. The global index included the two primary outcomes plus stroke, pulmonary embolism (PE), endometrial cancer, colorectal cancer, hip fracture, and death due to other causes.

After 5.2 years, the data and safety monitoring committee recommended stopping the largest estrogen/progestin component of the trial early because the number of cases of invasive breast cancer in the

Figure 3 Excess events [per 1000 person-years (py)] for SSR in the WHI Primary Prevention Trial.

active treatment group had crossed the boundary of increased risk, and the global index suggested that treatment was causing more harm than good. The hazard ratio for breast cancer ($n = 290$ cases) prompting study termination was 1.26 (CI, 1.00–1.59). This was not offset by cardiovascular benefit; indeed, the relative hazard of a CHD event ($n = 286$) increased with estrogen/progestin therapy, with a HR of 1.29 (CI, 1.02–1.63), the excess risk being due primarily to nonfatal MI. Other components of the global index that increased were stroke (HR, 1.4; with persisting risk at 5 years) and PE (HR, 2.1), whereas colorectal cancer (HR, 0.63) and hip fracture (HR, 0.66) were reduced. Endometrial cancer and total mortality rates were not adversely affected. Overall, the global index HR was 1.15 (CI, 1.03–1.28), a modest but significantly adverse result.

When applying clinical trials to medical practice, results should be translated into absolute risk. From this perspective, the risk to an individual woman is small. Among 10,000 women taking estrogen/progestin for 1 year, WHI suggests that there will be 7 more CHD events, 8 more invasive breast cancers, 8 more strokes, and 8 more pulmonary emboli but 6 fewer colorectal cancers and 5 fewer hip fractures (Fig. 3). On balance, 19 more global index events would be observed annually (approximately 100 excess events over 5 years, or 1 per 100 women). Despite the small individual risk to a patient, WHI's lack of CV benefit (indeed, net risk) argues strongly that estrogen/progestin therapy should not be prescribed for long-term primary CHD prevention. As Fletcher and Colditz noted, *primum non nocere* should especially apply to preventive health care.

WHI, Part II, and the Estrogen in Prevention of Atherosclerosis Trial

The WHI trial comparing estrogen alone with placebo among women without a uterus is ongoing.

While awaiting WHI ERT, the Estrogen in Prevention of Atherosclerosis Trial (EPAT) is interesting to ponder. EPAT assessed the effect of unopposed ERT on progression of subclinical atherosclerosis, represented by carotid intimal medial thickness (IMT) measured by high-resolution ultrasound. A total of 222 postmenopausal women (average age, 62 years) without clinical CV disease but with elevated LDL-C were enrolled. Therapy was unopposed micronized 17β -estradiol (1 mg/day) or placebo. Lipid-lowering medication (primarily a statin) was prescribed for LDL >160 mg/dl. Carotid IMT was measured every 6 months for 2 years. The rate of IMT progression was lower with ERT [by 0.0053 mm/year; a small but significant difference ($p = 0.046$)]. The benefit of ERT was prominent in women who did not take lipid-lowering medication (0.0147 mm/year, $p = 0.002$), whereas progression did not differ in those taking a lipid-lowering drug. The EPAT investigators suggested that unopposed ERT might serve as an alternative to lipid lowering for primary prevention and that natural estrogen as 17β -estradiol might have advantages over the complex mixture of SSR represented by CEE. Given the excellent safety record and clearly demonstrated CV benefits of statins, I believe that statins, rather than unopposed 17β -estradiol, should be preferred for primary prevention, where appropriate, pending WHI part II.

INCOMPATIBILITY OF OBSERVATIONAL STUDIES AND CLINICAL TRIALS

Wrong Chemistry?

Given the promise of SSR, it is natural to wonder what went wrong. Was there a fundamental flaw in the SSR prevention strategy, or could changes in the formula rescue the chemistry? Was the dose wrong? Was the wrong estrogen or progestin used? Would unopposed ERT fair better? Was the wrong population targeted? Is it possible to fashion a beneficial CV preventive strategy of SSR? There are no clear answers. CEE contains a mixture of molecules with differing properties: Would estradiol fair better? Similarly, might an adverse impact of MPA be overcome by using another progestin (or no progestin)? Would tapering to a lower dose avoid serious adverse effects while contributing to vascular health? Would the transdermal route for SSR delivery, avoiding first-pass hepatic effects, provide safer, more reliable effects? All of these possibilities deserve consideration

given the important public health impact of SSR-related issues. However, the previously mentioned negative trials will likely make sponsors leery of major new initiatives with traditional SSRs.

Not Made for Marriage?

Of course, the trials also could be signaling a basic incompatibility of SSRs with CV protection after menopause. Animal models might have been too simplistic, inappropriately weighting the potential benefits and underestimating adverse risks. The surprising results of the controlled clinical trials call for careful reassessment of the original hypothesis. Indeed, an exhaustive meta-analysis of prior observational studies found a more modest reduction in relative CHD risk (HR, 0.80; CI, 0.68–0.95) of current SSR use than generally reported. Also, there was no benefit for patients who had ever used SSR compared with those who had never used SSR. Furthermore, when only studies that controlled for socioeconomic status (SES) were considered, no benefit for even current SSR use was seen (HR, 0.97; CI, 0.82–1.16).

Consistent with the hypothesis that SES might explain differences in CHD rates in observational studies, we and others reported prominent differences in incident CHD event rates by SES status, and SES affected women more than men. Thus, the “healthy woman” hypothesis may largely explain the disparity between earlier observational and current randomized trial results. A large component of CV disease is preventable by compliance with healthy behaviors, and effective prevention and treatment are further assisted by better health care access, especially for women.

Proinflammation to Blame?

Atherosclerosis is an established inflammatory disease. Signs of inflammation are present in plaque (macrophages, T lymphocytes, cytokines, and chemokines) and systemically. C-reactive protein (CRP), a circulating marker of inflammation, is a CV risk factor. In the Nurses’ Health Study, CRP was a stronger predictor of incident coronary events than even LDL-C. Risk was dramatically increased with elevations of both CRP and LDL-C. SSR may increase CRP; hence, concern for a proinflammatory effect has been raised. However, other circulating inflammatory markers, such as interleukin-6, are not increased by SSR, and the risk relation with CRP is blunted in women on SSR. It is possible that augmented hepatic synthesis of CRP, rather than

promotion of vascular inflammation, explains the increased CRP with SSR.

Is Prothrombosis the Cause?

An increase in venous and arterial thrombotic and thromboembolic events has been observed consistently in oral contraceptive and SSR studies. Thromboembolic events affect only a small percentage of women and may be explained in part by predisposing genetic factors. For example, in one study, oral contraceptive use alone conferred a 6-fold increased risk, but use together with a variant allele in genes for either prothrombin or factor V increased risk 16- to 20-fold.

Patient Selection by Pharmacogenetics?

If thrombotic risk is excessively increased only in a small percentage of women harboring predisposing genes, then genetic screening could potentially eliminate this risk. Similarly, interacting environmental factors (e.g., smoking or other drugs) and diseases (e.g., diabetes) could elevate SSR-related risk excessively and, if precluded, might reduce CV risk.

RECOMMENDATIONS FOR SEX STEROID USE

The following CV health recommendations for SSR derive from the previous discussion and consensus statements:

Secondary CV Prevention

1. SSR should not be initiated for the secondary prevention of CV disease.
 - a. The decision to continue or stop SSR in women with CV disease undergoing long-term SSR therapy should be based on established noncoronary benefits, a benefit/risk assessment (including other therapeutic options), and patient preference. Due to the HERS-II findings, other established therapeutic options (e.g., bisphosphonates for prevention of osteoporosis) may be preferable.
 - b. If an acute CV event occurs during SSR therapy, it is prudent to consider discontinuation of SSR. Similarly, if immobilization occurs during SSR therapy for other reasons, discontinuation of SSR should be considered and/or prophylactic therapy for venous thromboembolism should be

provided. Resumption of SSR after resumed mobilization should be based on noncoronary benefits and risks, alternative therapies, relative CV risks, and patient preference.

Primary CV Prevention

1. SSR with estrogen/progestin should not be prescribed for long-term primary CV prevention
2. Firm recommendations about the use of unopposed ERT in women without a uterus await the results of ongoing study (WHI-ERT). However, based on negative results for other SSR regimens and populations, a net benefit of ERT should not be assumed. Hence, unopposed ERT cannot be recommended for long-term primary CV prevention for women with or without an intact uterus.
3. Short-term use of SSR for severe menopausal symptoms can probably continue to be justified as sufficiently safe. However, emphasis should be on the lowest dose of medication for the shortest period of time.
4. Long-term use of SSR for other purposes (e.g., prevention of osteoporosis and skin and mucous membrane health) should be reconsidered in light of health risks (WHI), and alternative therapies should be considered.

Alternatives to SSRs for CV Risk Reduction

1. Lipid lowering: Lipid lowering, especially with statins, is much better established for CV risk reduction than SSRs. An overview of four major randomized trials of secondary and primary prevention has shown that risk reduction is equivalent in women and men (29 vs 31% CHD event reduction). Thus, where appropriate, statin therapy is highly effective and well tolerated for CV risk reduction.
2. Other preventive therapies: Other established CV preventive therapies also apply to women as well as men. Aspirin (75–325 mg/day) is recommended for all patients with CHD or equivalent (e.g., stroke and peripheral arterial disease) and for those at high (>1%/year) primary risk (e.g., with two or more risk factors, such as age \geq 65 years, smoking, diabetes, dyslipidemia, and hypertension). A heart-healthy diet and regular exercise also form an important component of CV risk reduction. Smoking cessation is a highly effective intervention for CHD prevention. Diabetes counters the advantage that women have over men in regard to CV risk; an aggressive approach to prevention and treatment of dysglycemia with diet, oral antidiabetic

drugs, and insulin is appropriate. Hypertension is an important risk factor for stroke and CHD and can be effectively managed. Following MI, beta-blockers and angiotensin-converting enzyme inhibitors are usually indicated to reduce secondary CV risk. A role for nutritional and herbal remedies, such as soy or other phytoestrogen sources, for postmenopausal CV risk reduction has not been well established.

3. Balance of benefit and risk: When SSR is considered for relief of menopausal symptoms or other non-CV indications (e.g., osteoporosis), an evaluation of likely benefit versus potential risk (CV and non-CV) should be made. The result of this benefit/risk assessment, which will vary for individual women, forms the basis for a decision regarding SSR therapy.

UNANSWERED QUESTIONS AND FUTURE RESEARCH

Technically, the results of HERS and WHI apply only to the specific SSR combination of CEE and MPA. Several other combinations and unopposed SSR products and doses are available. However, it is likely that sponsors will be wary of investing in further large outcomes trials using traditional SSRs. However, interest in SERMs remains.

WHI-ERT

The role of unopposed ERT in women without a uterus is undergoing testing, and recommendations in this setting must await its outcome.

WISDOM

A large European prevention study, WISDOM, was under way when WHI was stopped. After much debate, WISDOM was also stopped. Findings of WISDOM, not yet reported, will be of interest.

SERMS

SERMS are designer drugs developed to have differential effects on estrogen receptors to accomplish specific therapeutic objectives. Tamoxifen has been useful in breast cancer prevention and treatment. Raloxifene has been tested for osteoporosis and is undergoing evaluation for CV prevention. Indeed, the 10,000-patient Raloxifene Use for The Heart (RUTH) trial is under way with no health warnings from the data and safety monitoring committee. Thus, interest and hope remain for SERMS in CV prevention.

Parting Thought

There is no assurance of an early reconciliation between SSRs and CV disease prevention. However, our understanding of the complex role of sex hormones in normal and disease-related physiology is embryonic and hope remains that improved understanding of sex steroid-related biology will allow the development of SSR or SERM-based preventive strategies, perhaps customized to individual patients, that will be safe and effective.

Catecholamines

Brian B. Hoffman

VA Boston Health Care System and Harvard University School of Medicine, Boston, Massachusetts, United States

Glossary

adrenal medulla Part of the adrenal gland, surrounded by the adrenal cortex. The major function of the adrenal medulla is to synthesize epinephrine, which is released into the blood; epinephrine acts on distant cells as a hormone.

adrenergic receptors Endogenous catecholamines and various sympathomimetic drugs activate cells by interacting with one or more of the three classes of adrenergic receptors. These receptors are characteristic members of the very large family of G protein-coupled receptors.

catecholamines Endogenous catecholamines include dopamine, norepinephrine (noradrenaline), and epinephrine (adrenaline). These substances have in common a 3,4-dihydroxybenzene moiety (catechol) and a primary amino group.

monoamine oxidase An enzyme that plays an important role in the metabolism (inactivation) of the endogenous catecholamines and certain drugs.

pheochromocytoma Tumors that secrete an excess concentration of catecholamines; this may lead to severe hypertension. Therapy involves surgery in most cases and the use of adrenergic antagonist drugs.

sympathetic nervous system (SNS) A major component of the autonomic nervous system. Via its primary transmitter norepinephrine, the SNS modulates the function of many cells and is especially important in the regulation of stress responses and blood pressure.

The endogenous catecholamines in humans are dopamine, norepinephrine, and epinephrine. Norepinephrine is the major transmitter in the terminals of the sympathetic nervous system; norepinephrine acts on postsynaptic cells. On the other hand, adrenaline is the primary hormone released by the adrenal medulla into the bloodstream. Catecholamines activate three major adrenergic receptor families; these receptors are part of the larger family of G protein-coupled receptors. Utilizing several signal transduction mechanisms, catecholamines have the capacity to regulate the activity of multiple different cell

types in organs throughout the body. A major role of the sympathetic nervous system and the adrenal medulla is to integrate responses triggered by stress; i.e., the “fight or flight” response conceptualized by Walter Cannon in the 1930s. Abnormalities in catecholamine function contribute to a wide variety of diseases; for example, pheochromocytoma is a tumor that typically secretes excess catecholamines, leading to potentially severe hypertension.

DISCOVERY OF CATECHOLAMINES

Understanding of the physiological role of the adrenal medulla was unavailable until the demonstration in 1894 by Schafer and Oliver that extracts of the medulla caused marked rises in blood pressure. This discovery immediately stimulated considerable interest in isolating the active substance in the medulla that caused vasoconstriction. Between 1897 and 1901, a number of groups working independently isolated epinephrine (adrenaline) from these preparations; the priority in this discovery is somewhat controversial. In 1904, epinephrine became the first hormone to be isolated and crystallized, to have its structure determined, and then to be successfully chemically synthesized in a laboratory. Epinephrine was rather quickly developed as a drug for a surprisingly broad multiplicity of indications; early on it was found to decrease bleeding in a range of surgical procedures.

SYNTHESIS, RELEASE, AND TERMINATION OF ACTION OF CATECHOLAMINES

Synthesis of Catecholamines

Norepinephrine is primarily synthesized in sympathetic nerves, starting from the amino acid tyrosine; several enzymes expressed in these cells are involved in this process (Fig. 1). The rate-limiting step in catecholamine synthesis is that in which the enzyme tyrosine hydroxylase is used, a step that is regulated both translationally and posttranslationally. Up to the point at which dopamine is synthesized, synthesis takes place

Figure 1 Norepinephrine synthesis in sympathetic nerve endings. Norepinephrine, the major transmitter in postganglionic sympathetic nerve endings, is synthesized from the amino acid tyrosine. The conversion of tyrosine to L-DOPA is the rate-limiting step in the pathway. In the adrenal medulla, epinephrine is synthesized from norepinephrine by methylation.

in the cytoplasm of the cells expressing these enzymes. Dopamine is transported into storage granules, where it is converted into norepinephrine by the enzyme dopamine β-hydroxylase. Epinephrine is primarily synthesized in the adrenal medulla, which expresses the enzyme phenylethanolamine-*N*-methyltransferase, which methylates norepinephrine that has diffused out of the storage granules. Epinephrine is then itself taken up into storage granules, where it is stored until it is released. Reserpine is an antihypertensive drug that inhibits the uptake of norepinephrine into these storage granules, ultimately leading to the depletion of catecholamines from storage granules.

Release of Catecholamines

Norepinephrine is released into the synaptic cleft when the nerve containing the storage granules depolarizes (Fig. 2). Although the full sequence of events is not yet clear, the mechanism critically involves the rise in intracellular calcium concentrations that occurs with depolarization. As might be expected, this process is tightly regulated, including regulation by a variety of hormone and neurotransmitter receptors expressed on sympathetic neurons. Indeed, these nerve endings typically contain a receptor that is activated by norepinephrine itself, which serves to autoinhibit norepinephrine release with subsequent neuronal firings (the α₂-adrenergic receptor). The drug amphetamine has a major action of directly promoting the release of norepinephrine from these nerve endings independently of the firing of the sympathetic nerve.

Termination of the Action of Catecholamines

After interacting with adrenergic receptors on postsynaptic cells, the major mechanism of terminating the action of norepinephrine is reuptake into the sympathetic nerve ending. There is a specific transport pump for norepinephrine expressed on these neurons. Interestingly, the activity of this transporter is blocked by cocaine. Consequently, whereas the major psychotropic actions of cocaine involve the inhibition of activity of dopamine transporters in brain centers, some of the cardiovascular actions of cocaine may involve this effect on norepinephrine uptake in the periphery.

There are three other mechanisms leading to termination of the action of norepinephrine, namely, diffusion out of the synaptic cleft into the bloodstream, uptake into other tissues, and transformation to inactive metabolites. Monoamine oxidase (MAO) plays a major role in inactivating catecholamines. MAO A and MAO B are subtypes of this enzyme. MAO is expressed mainly in nerve terminals and liver but also in several other tissues. The mitochondrial-associated MAO in nerve endings can inactivate norepinephrine not found in secretion granules. MAO in liver prevents substances such as tyramine, which is found in wine and certain foods, from reaching the systemic circulation in an intact form. In other words, blood draining the intestines passes to the liver, inactivating the tyramine before it can reach the systemic circulation. Since tyramine is very efficacious in causing the direct release of norepinephrine from nerve endings, there is a major risk of adverse reactions, such as marked increases in blood pressure, due

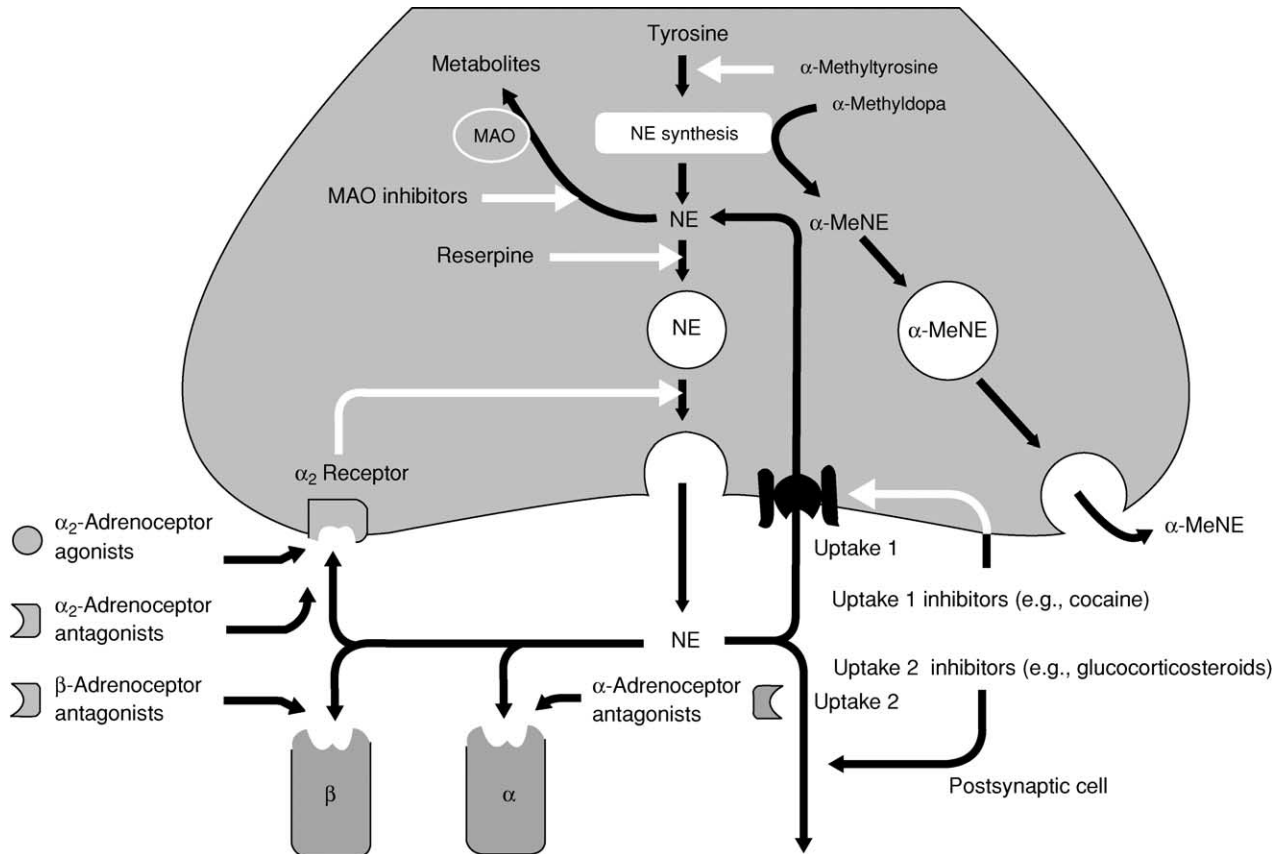

Figure 2 Norepinephrine (NE) release and action in sympathetic synapses with postsynaptic target cells. NE is stored in granules that are released into the synaptic cleft when the nerve fires. NE then interacts with postsynaptic adrenergic receptors on target cells, for example, in the heart, blood vessels, and lungs. The action of NE is terminated by reuptake into the nerve ending (uptake 1); other mechanisms include uptake into other tissues (uptake 2), metabolism by monoamine oxidase (MAO) or catechol-*O*-methyltransferase (not shown), or diffusion out of the synapse. Many of these specific steps can be inhibited by important drugs that are used clinically or illicitly.

to ingestion of certain foods or wine for patients taking a MAO inhibitor that inhibits liver enzyme activity. Another important enzyme in the metabolism of catecholamines is catechol-*O*-methyltransferase (COMT). Catecholamines that reach the systemic circulation are extensively methylated by COMT.

ADRENERGIC RECEPTORS AND SIGNAL TRANSDUCTION MECHANISMS

Catecholamines modulate cellular function by activating adrenergic receptors (also termed adrenoceptors). There are three major classes of adrenergic receptors, termed α_1 , α_2 , and β . These receptor classes have been delineated by a combination of classical pharmacological experiments as well as by molecular cloning. It turns out that each of these classes of receptor has

additional subtypes: α_1A , α_1B , and α_1D ; α_2A , α_2B , and α_2C ; and β_1 , β_2 , and β_3 . This demarcation has been considerably influenced by comparisons of predicted protein sequences of the various receptors. These receptors are widely distributed with varying levels of expression of particular subtypes on cells throughout the body. There has been considerable interest in designing drugs that are highly specific for one or another class of receptor as well as drugs that can be distinguished by the various subtypes of each of these receptors. Extensive work has been carried out to identify a key receptor subtype that might mediate the major actions of catecholamines that might have relevance for a particular disease. For example, it has been known for quite some time that α_1 -adrenergic antagonist drugs are efficacious in the relief of bladder obstruction in men who have enlargement of the prostate gland. Much has been invested in determining which of the various

α 1 receptor subtypes might be the most important in causing contraction of smooth muscle in prostate, a response that contributes to obstruction of the bladder neck. There is a drug available that has a modestly higher affinity for α 1A receptors that play a major role in smooth muscle contraction in the prostate. It is a considerable challenge to predict whether or not one subtype is most important when many subtypes may be expressed on target cells and indeed it can be very difficult to know in advance of considerable research efforts whether blockade of a single subtype will have therapeutic efficacy.

In addition to the heterogeneity of the various adrenergic receptors, there are a multiplicity of signal transduction pathways utilized by these receptors to regulate cellular function, some of which are illustrated in Fig. 3. Each of the β -adrenergic receptors activates the G protein G_s , which in turn activates the enzyme adenylyl cyclase, leading to increased synthesis of cyclic AMP (cAMP). The rise in cAMP concentration in turn activates cAMP-dependent protein kinase, which phosphorylates a number of target proteins, leading to immediate changes in the activity of these enzymes as well as phosphorylating transcription factors such as CREB (cAMP response element binding protein), which alters the transcription of a number of target genes. One of the signaling pathways of α 2-adrenergic receptors acts to inhibit adenylyl cyclase activity by signaling via the inhibitory G protein G_i . In addition, the subunits of G_i can lead to the activation of a variety of other signal transduction pathways. A main signaling pathway of α 1-adrenergic receptors involves activation of phospholipase C, leading to the release of inositol 1,4,5-trisphosphate and diacylglycerol, which have important roles in signaling via increasing intracellular concentrations and the activation of protein kinase C, respectively. In addition, α 1 receptors activate a variety of downstream protein kinases that have considerable overlap with those activated by diverse tyrosine kinase cell surface receptors.

CATECHOLAMINES AND DISEASE

Pheochromocytoma

Pheochromocytoma is an uncommon tumor that secretes catecholamines to excess and in an unregulated manner. Patients may have, continuously or intermittently, markedly elevated concentrations of catecholamines in the blood. In addition, metabolites of catecholamines may be present at increased concentrations in both blood and urine. Clinical manifestations of pheochromocytoma can be highly varied.

The most common symptoms are headaches, palpitations, and increased sweating. Many patients have hypertension, which may be sustained or intermittent depending at least in part on the pattern of release of active catecholamines into the blood. Some patients may have only subtle symptoms leading to delays in diagnosis, whereas others may have profound "spells," occasionally or infrequently, that are highly characteristic of the disease. Once the diagnosis is suspected, a variety of catecholamine-related assays are available to confirm the diagnosis. Subsequently, the next step is typically to identify the location of the tumor(s) in each patient. Approximately 90% of pheochromocytomas are localized in an adrenal gland. These can usually be identified with computed tomography or magnetic resonance imaging scanning techniques. Approximately 10% of tumors are extra-adrenal (ranging from the neck to the urinary bladder) and require more sophisticated techniques to localize. The primary treatment of pheochromocytoma is surgical excision of the tumor, which is possible in a large majority of cases. A small fraction of tumors are malignant, requiring sustained medical treatment. These tumors are typically slow-growing and the adverse effects of the excess catecholamines can be mitigated by using drugs that antagonize the actions of catecholamines at α -and/or β -adrenergic receptors or by drugs that inhibit catecholamine synthesis, for example, by inhibiting the enzyme tyrosine hydroxylase, which catalyzes the rate-limiting step in catecholamine synthesis.

Autonomic Insufficiency

Whereas pheochromocytoma is a disease characterized by catecholamine excess, failure of the sympathetic nervous system is a good example of a disease due to inadequate norepinephrine. The sympathetic nervous system is critically involved in the capacity of humans to attain an upright posture. On standing, blood would tend to pool in dependent parts of the body, for example, in veins in the legs, due to gravity. On standing, activation of the sympathetic nervous activity leads to the stimulation of α -adrenergic receptors in the veins, leading to smooth muscle contraction and diminished venous pooling so as to maintain the return of blood to the heart and maintain cardiac output. In the absence of an adequate response of the sympathetic neurons with norepinephrine release, there is typically pooling of blood with a consequent fall in cardiac output and a fall in blood pressure, which may lead to inadequate cerebral perfusion and fainting.

Figure 3 Signal transduction mechanisms of α_1 -, α_2 -, and β -adrenergic receptors. Catecholamines, such as epinephrine and norepinephrine, activate cells by binding to specific cell surface receptors, leading to association of these receptors with specific G proteins, including members of the G_s (β receptors), G_i (α_2 receptors), and G_q (α_1 receptors) families. The β receptor's major mechanism of action involves increasing cyclic AMP (cAMP) synthesis, whereas α_2 receptors inhibit the accumulation of cAMP. α_1 Receptors stimulate the production of inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG), which promote an increase in intracellular Ca^{2+} concentration and activation of protein kinase C, respectively. Not shown in the figure are the effects of these G protein-coupled receptors on other effectors, such as ion channels, and the role that these receptors play in modulating the activity of other kinase families, including the tyrosine kinases.

There are a number of primary diseases of the nervous system that lead to inadequate sympathetic nervous system function; in addition, patients with diseases such as diabetes mellitus may have autonomic dysfunction due to associated neuropathies. Postural hypotension in these patients may be treated with a range of therapeutic modalities including the use of synthetic drugs to mimic some of the effects of noradrenaline, especially in order to activate α receptors.

CCK (Cholecystokinin)

Rodger A. Liddle

Duke University, Durham, North Carolina, United States

Glossary

gastrin A gastrointestinal polypeptide hormone produced by G cells of the gastric antrum that stimulates gastric acid secretion.

G protein-coupled receptor A family of cell surface receptor proteins consisting of seven transmembrane regions; the intracellular region interacts with GTP-binding proteins that, on ligand binding, transduce signals within the cell, leading to a cellular response (e.g., secretion, motility, growth).

microvilli Finger-like extensions along the apical surface of intestinal mucosal cells; increase the absorptive surface of the cell (on enterocytes); allow potential stimuli greater exposure to their targets (on endocrine cells).

myenteric plexus Also known as Auerbach's plexus, a system of nerves and ganglia lying within the longitudinal and circular muscle layers of the intestine; its nerves innervate numerous targets, including the myenteric externa, mucosa, and sympathetic prevertebral ganglia.

sphincter of Oddi The muscular region surrounding the distal ends of the common bile duct and pancreatic duct as they enter into the duodenum; when constricted, this sphincter prevents flow of bile and pancreatic juice into the duodenum and restricts reflux of duodenal contents back into the bile and pancreatic ducts.

submucosal plexus A network of nerves and small ganglia found in the submucosa of the intestine; comprised of outer and inner layers; transmits secretomotor and vasodilator stimuli to the mucosa; primary sensory nerves contained in this plexus, which also communicates with the myenteric plexus.

Cholecystokinin, a peptide hormone, is produced and secreted by endocrine cells of the upper small intestine following food ingestion. It is the major hormone responsible for stimulating pancreatic enzyme secretion and gallbladder contraction. Cholecystokinin promotes satiety, delays gastric emptying, potentiates insulin secretion, and may regulate bowel

motility. It may also play a role in learning and memory, anxiety, analgesia, and thermoregulation.

INTRODUCTION

Cholecystokinin (CCK) is a peptide hormone produced by endocrine cells of the upper small intestine. It is secreted on ingestion of a meal and is the major hormone responsible for pancreatic enzyme secretion and gallbladder contraction. CCK was discovered by Ivy and Oldberg in 1928 when they recognized that intestinal extracts could stimulate gallbladder contraction in dogs, and it was named the substance cholecystokinin (“cholecyst” [gallbladder] and “kinin” [to move]). In 1943, Harper and Raper noted that a similar extract, which they named “pancreozymin,” stimulated pancreatic enzyme secretion. It was not until CCK was purified and its amino acid sequence was determined by Mutt in 1968 that it was proven that CCK and pancreozymin were the same hormone that possessed the ability to stimulate both the gallbladder and the pancreas. The original name, cholecystokinin, is the term commonly used.

Over the past three decades, CCK has been found to have many other biological effects. In experimental animals and humans, CCK has been shown to delay gastric emptying, potentiate insulin secretion, and regulate bowel motility. One of the most noteworthy actions of CCK is its ability to induce satiety and reduce food intake. Until the development of reliable assays for measuring blood levels of CCK, the physiological effects of CCK remained controversial. However, it has now been shown in humans that physiological levels of CCK stimulate gallbladder contraction and pancreatic enzyme secretion, inhibit gastric emptying, potentiate insulin secretion, and reduce food intake. CCK may regulate bowel motility and, in certain species, promote pancreatic growth, although that has not yet been proven physiologically. Less well described but fascinating actions of CCK include its effects on learning and memory, anxiety, analgesia, and thermoregulation.

In the small intestine, CCK is produced by discrete endocrine cells within the mucosa. However, CCK is even more abundant in the brain and is found in peripheral nerves innervating the intestine where it functions as a neurotransmitter.

MOLECULAR FORMS

The original CCK peptide isolated from the intestine was a triacontapeptide (CCK-33). Since then, several larger and smaller molecular forms of CCK have been found in the intestine, brain, and blood of experimental animals and humans. The biologically active region of CCK resides in its carboxyl terminus, and all forms of CCK possess an identical carboxyl 5-amino acid sequence (-Gly-Trp-Asp-Met-Phe-NH₂) (Fig. 1). This region is common to gastrin, and as a result, gastrin has some CCK-like activity (albeit weak) and CCK shares some weak gastrin-like activity. The amino acid sequence shared by the two hormones has made developing assays for CCK difficult because antibodies directed against the biologically active region of CCK may cross-react with gastrin. This problem is accentuated by the finding that circulating levels of gastrin are 10- to 100-fold greater than those of CCK.

CCK is produced from a single gene that encodes a 115-amino acid preprohormone. By posttranslational processing, molecular forms of CCK ranging in size from 4 to 83 amino acids have been identified in tissues and blood. However, the major molecular forms of CCK are CCK-8, CCK-33, and CCK-58.

In humans, the CCK gene is located in the 3q12–3pter region of chromosome 3. CCK expression is

both tissue specific and developmentally regulated. In the intestine, the CCK gene is expressed prenatally and, after birth, is regulated primarily by ingestion of foods that stimulate CCK secretion. In the central nervous system, stimuli regulating neuronal CCK gene transcription include growth factors, second messengers such as cyclic AMP, the neurotransmitter dopamine, and hormones such as estrogen.

DISTRIBUTION

Cholecystokinin cells are individual flask-shaped cells that are scattered throughout the mucosa of the small intestine. The concentration of CCK cells is greatest in the proximal small intestine and diminishes in a gradient fashion toward the distal jejunum and ileum. CCK cells arise from progenitor cells in the intestinal crypts and, along with enterocytes, migrate up the villus. Residing in the mucosa, the apical surface of CCK cells is open to the lumen of the intestine. Here, cells can actually “sample” luminal contents such as food and releasing factors. These enteroendocrine cells also possess microvilli that increase the exposed surface area, thereby allowing greater exposure to potential stimuli.

Like other gastrointestinal hormones, CCK is a “brain–gut” peptide, meaning that the same transmitter is found in both the central nervous system and the intestine. In the brain, CCK is highly concentrated in the striatum, hippocampus, and cerebral cortex. CCK-containing neurons may also synthesize dopamine. Such nerves have been shown to extend to the limbic forebrain and ventromedial hypothalamus, where they may participate in controlling food intake. CCK has been demonstrated to modulate dopamine release, dopamine-mediated reward, and receptor binding and function. These actions have implications for a role of CCK in drug abuse and neurological and psychiatric disease.

CCK is prevalent in peripheral nerves of the gastrointestinal tract. It is most abundant in nerves innervating the colon, with fewer CCK nerves in the ileum. In these locations, CCK is present in myenteric and submucosal plexi, where it innervates ganglionic bodies. CCK is also abundant in the vagus nerve and celiac plexus. In the intestine, CCK stimulates acetylcholine release and causes smooth muscle contraction. Postganglionic CCK-containing neurons also terminate around the islets of Langerhans, where CCK may stimulate islet hormone secretion such as insulin and glucagon release.

Figure 1 The amino acid sequences of the common molecular forms of CCK and gastrin. All biologically active forms of CCK and gastrin share an identical carboxyl terminal pentapeptide sequence (shown in gray).

CCK RECEPTORS

CCK exerts its biological actions by binding to specific receptors on its target tissues. Gastrointestinal CCK receptors reside on tissues of the pancreas, gallbladder, stomach, lower esophageal sphincter, ileum, and colon. In the nervous system, CCK receptors are abundant in brain and on some peripheral nerves. Two types of CCK receptors have been identified. CCK-A (for alimentary) receptors are the primary CCK receptor and mediate most of CCK's effects in the gastrointestinal tract. The CCK-B (for brain) receptor is identical to the gastrin receptor and is the major CCK receptor subtype in the nervous system. It is also abundant in the stomach. Both receptors are G-protein-coupled, seven-membrane-spanning proteins but arise from different genes [Wank et al., 1992; Kopin et al., 1992]. CCK receptor antagonists have been extremely useful in pharmacological and physiological studies in defining the physiological role of CCK. The first CCK receptor antagonists useful for *in vitro* studies were cyclic nucleotide analogues (e.g., dibutyryl cGMP). Subsequently, amino acid derivatives (e.g., CR-1409), carboxyl-terminal CCK analogues, and substituted benzodiazepines (e.g., devazepide) were developed and would be used *in vivo*. Clinical studies have shown CCK receptor antagonists to inhibit CCK- and meal-stimulated gallbladder contraction, accelerate gastric emptying, and induce hunger (i.e., reverse satiety), indicating that CCK has important physiological roles in each of these processes.

CCK RELEASE

CCK is secreted from specialized endocrine cells of the mucosa (known as I cells) into the extracellular space where it is taken up into the bloodstream. [Polak et al., 1975b] It is by this mechanism that circulating CCK reaches distant target tissues such as the pancreas and gallbladder. Enteric endocrine cells package CCK in secretory granules that are stored along the basolateral surface of the cell, thereby allowing CCK to be secreted into the interstitium when the cell is stimulated. *In vivo*, ingested proteins and fat are the major dietary stimulants of CCK release. However, in some species (including humans) and in cell preparations *in vitro*, partially digested nutrients such as amino acids, peptides, and fatty acids are potent releasers of CCK, indicating that these components directly interact with the CCK cell.

Circulating blood levels of CCK average approximately 1 pM in the fasting state and increase to

between 5 and 8 pM after eating. Postprandial levels remain elevated for 3 to 5 h as food empties from the stomach into the upper small intestine. Gastric distention does not influence CCK release. Although fat and protein are the primary stimulants of CCK, carbohydrate also has a modest effect on secretion.

It is well recognized that inactivation of protease activity in the lumen of the small intestine of rodents stimulates CCK release and pancreatic exocrine secretion. This phenomenon is now known as negative feedback control of CCK release. Not only has this principle been demonstrated in rodents, but it also applies to other species, including humans. Thus, CCK release is controlled in part by the presence or absence of pancreatic enzymes in the intestine (Fig. 2). This concept indicated that there existed intestinal-releasing factors that are secreted into the intestine and that stimulate CCK secretion [Spannagel et al., 1996; Herzig et al., 1996]. When pancreatic enzymes are present in the intestine, these CCK-releasing factors are inactivated; however, when pancreatic enzymes are inhibited or pancreatic secretion is reduced, these CCK-releasing factors are active and stimulate CCK secretion. Similarly, with ingestion of a meal that temporarily binds trypsin and other digestive enzymes, CCK-releasing factors are also available to stimulate CCK secretion. To date, a human counterpart of a CCK-specific releasing factor has not been identified.

Figure 2 Model for regulation of CCK release by an intraluminal releasing factor. One or more CCK-releasing factors (CCK-RF) stimulates intestinal CCK secretion. CCK-RF is normally secreted in the intestinal lumen, where it is exposed to pancreatic enzymes. Under basal conditions, CCK-RF is inactivated by even small amounts of enzyme; however, following a meal, food competes for enzyme binding, allowing CCK-RF to interact with CCK cells to stimulate hormone secretion. CCK in the circulation stimulates pancreatic secretion that, following digestion of food, restores CCK-RF and CCK secretion to basal levels. Modified from Liddle, R. A. (1995). Regulation of cholecystokinin secretion by intraluminal releasing factors. *Am. J. Physiol. Gastrointest. Liver Physiol.* **269**, G319–G327.

BIOLOGICAL ACTIONS OF CCK

CCK is the major hormonal regulator of gallbladder contraction. Coincident with this effect, CCK also relaxes the sphincter of Oddi, which also promotes bile secretion into the intestine. In humans, the predominant CCK receptor type in the pancreas is CCK-B. This differs from most species' CCK, where CCK-A receptors predominate in the pancreas and where CCK is a potent stimulant of pancreatic secretion. Therefore, in humans, although CCK stimulates pancreatic secretion, its role may be limited.

At physiological blood concentrations that occur after a meal, CCK delays gastric emptying, and this may be important for its ability to reduce food intake and induce satiety. Because of its effects on gallbladder contraction, pancreatic secretion, and gastric emptying, CCK coordinates many digestive processes. Thus, CCK plays an important role in the ingestion and digestion of a meal. Although it has been shown that CCK causes relaxation of the lower esophageal sphincter and promotes intestinal motility, it appears as though these effects are neural rather than hormonal. CCK receptors have been found on some gastrointestinal and lung cancers; however, it remains unknown whether CCK plays a role in human cancer growth.

CLINICAL USES OF CCK

CCK is used along with secretin as a test of pancreatic function. In patients with pancreatic insufficiency, low levels of pancreatic juice are recovered following intravenous injection of these hormones. CCK can also be used clinically to stimulate gallbladder contraction and is helpful in radiographic testing of the gallbladder function. For diagnostic purposes, CCK has facilitated the collection of bile and pancreatic juice for cytological examination.

Therapeutically, CCK injections have been administered to patients who are unable to eat (e.g., parental alimentation) to stimulate gallbladder contraction. This therapy has been effective in reducing gallbladder sludge and in preventing gallstone formation.

Low blood levels of CCK have been reported in patients with celiac disease and bulimia nervosa and in conditions that delay gastric emptying. The defect in celiac disease is likely due to reduced CCK secretion from diseased small intestinal mucosa. The cause of abnormal CCK responses in bulimia is unknown but may be related to alterations in gastric emptying given that normal postprandial CCK release is dependent on delivery of food from the stomach to the

small intestine. It is not known whether CCK deficiency contributes to any specific pathological consequences. There are no known diseases of cholecystokinin excess.

Chemokines

Naofumi Mukaida
Kanazawa University, Kanazawa, Japan

Glossary

chemokinesis Increased random migratory activity of cells.

chemotaxis Increased directional migration of cells in response to concentration gradients of certain chemotactic factors.

inflammation A series of host reactions to tissue damages such as infections, traumas, tumors, and foreign particles; characterized by increased blood supply, increased vascular permeability, and transendothelial migration of leukocytes.

Chemokines are a large group of cytokines that act on receptors with seven-transmembrane domains and that have a variety of chemotactic and cell-activating properties on selected populations of target cells, particularly leukocytes.

INTRODUCTION

Since the first description of CXCL8/interleukin-8 (IL-8) as a neutrophil chemotactic cytokine in 1987, a family of structurally related cytokines has been identified. Because most of them exhibit chemotactic activity against a limited spectrum of leukocytes, they are now called chemokines (*chemotactic cytokines*). Chemokines direct the movement of various types of cells, particularly leukocytes, along a concentration gradient by modulating expression and structure of adhesion molecules and cytoskeletal proteins of the target cells. Because of their molecular stability and target specificity, chemokines are presumed to be crucial in leukocyte infiltration and subsequent activation in inflammation. Moreover, chemokines participate in other biological phenomena such as immune reactions, angiogenesis, and organ development.

All chemokines except CX3CL1/fractalkine possess four cysteines at the well-conserved positions.

Chemokines exhibit 3- β sheets with α helix at the carboxyl-terminal portion due to the presence of two disulfide bridges formed between the first and third cysteines as well as between the second and fourth cysteines. Most chemokines are secreted proteins with a molecular weight of approximately 10 kDa. They exhibit a basic nature, and their α helix structure is responsible for preferential binding to proteoglycans on the vascular endothelial cells and to extracellular matrix proteins. Chemokine receptors comprise a large branch of the rhodopsin family of cell surface G protein-coupled receptors (GPCRs) with seven-transmembrane domains. Functional binding to the target cells and subsequent signaling are mediated by these receptors.

Chemokines are divided into four subgroups: CXC, CC, C, and CX3C. CXC, CC, and CX3C chemokines have four cysteines, whereas C chemokines have only two cysteines, corresponding to the second and fourth cysteines in the other groups. CXC and CX3C chemokines are distinguished by the presence of one and three amino acids, respectively, whereas the first two cysteines are adjacent in CC chemokines. A large number of CXC (>15) and CC chemokines (>25) have been identified in humans and other species, but human lymphotactin α and β and fractalkine and their equivalents in other species are the only examples of C and CX3C chemokines, respectively.

A novel nomenclature system has been proposed for chemokines and their receptors. Systematic chemokine names, shown in Table I with their common names, are built from cysteine subclass roots, followed by "L" for "ligand." The numbers correspond generally to the same number used in the corresponding gene nomenclature. Because most chemokine receptors are restricted to a single chemokine subclass, the nomenclature system of chemokine receptors is rooted by the chemokine subclass specificity, followed by "R" for "receptor" and the number.

Table I Chemokines and Their Receptors

| Proposed names | Commonly used names | Main receptor |
|----------------|---|------------------------|
| CXC chemokine | | |
| CXCL1 | Gro α , Melanoma growth stimulating activity (MGSA) | CXCR2 |
| CXCL2 | Gro β | CXCR2 |
| CXCL3 | Gro γ | CXCR2 |
| CXCL4 | Platelet factor-4 (PF-4) | Unknown |
| CXCL5 | Endothelial-derived neutrophil attractant-78 (ENA-78) | CXCR2 |
| CXCL6 | Granulocyte chemotactic protein-2 (GCP-2) | CXCR1, CXCR2 |
| CXCL7 | Neutrophil-activating protein-2 (NAP-2) | CXCR2 |
| CXCL8 | Interleukin-8 (IL-8) | CXCR1, CXCR2 |
| CXCL9 | Monokine induced by interferon γ (Mig) | CXCR3 |
| CXCL10 | Interferon-inducible protein-10 (IP-10) | CXCR3 |
| CXCL11 | Interferon-inducible T-cell α chemoattractant (I-TAC) | CXCR3 |
| CXCL12 | Stroma cell-derived factor-1 (SDF-1) | CXCR4 |
| CXCL13 | B-lymphocyte chemoattractant (BLC) | CXCR5 |
| CXCL14 | Breast and kidney (BRAK) | Unknown |
| CXCL15 | Unidentified in human | |
| CXCL16 | | CXCR6 |
| CC chemokine | | |
| CCL1 | I-309 | CCR8 |
| CCL2 | Monocyte chemoattractant protein-1 (MCP-1) | CCR2, CCR11 |
| CCL3 | Macrophage inflammatory protein-1 α (MIP1 α) | CCR1, CCR5 |
| CCL4 | MIP-1 β | CCR5, CCR1 |
| CCL5 | Regulated on activation, normal T expressed and secreted (RANTES) | CCR5, CCR1, CCR3 |
| CCL6 | Unidentified in human | |
| CCL7 | MCP-3 | CCR1, CCR2 |
| CCL8 | MCP-2 | CCR2, CCR5, CCR11 |
| CCL9 | Unidentified in human | |
| CCL10 | Unidentified in human | |
| CCL11 | Eotaxin | CCR3, CCR5 |
| CCL12 | Unidentified in human | |
| CCL13 | MCP-4 | CCR2, CCR3, CCR11 |
| CCL14 | Human hemofiltrate CC chemokine-1 (HCC-1) | CCR1 |
| CCL15 | HCC-2 | CCR1, CCR3 |
| CCL16 | HCC-4 | CCR1, CCR2, CCR3, CCR8 |
| CCL17 | Thymus and activation-regulated chemokine (TARC) | CCR4 |
| CCL18 | Pulmonary and activation-regulated chemokine (PARC) | Unknown |
| CCL19 | EBI1-ligand chemokine (ELC), MIP-3 β | CCR7 |
| CCL20 | Liver and activation-regulated chemokine (LARC), MIP-3 α | CCR6 |
| CCL21 | Secondary lymphoid tissue chemokine (SLC), 6CKine | CCR7 |
| CCL22 | Macrophage-derived chemokine (MDC) | CCR4 |
| CCL23 | Myeloid progenitor inhibitory factor-1 (MPIF-1) | CCR1 |
| CCL24 | Eotaxin-2, MPIF-2 | CCR3 |
| CCL25 | Thymus-expressed chemokine (TECK) | CCR9 |
| CCL26 | Eotaxin-3 | CCR3 |
| CCL27 | Interleukin-11 receptor α -locus chemokine (ILC) | CCR10 |
| CCL28 | Mucosae-associated epithelial chemokine (MEC) | CCR10, CCR3 |
| CX3C chemokine | | |
| CX3CL1 | Fractalkine | CX3CR1 |
| C chemokine | | |
| XCL1 | Lymphotactin | XCR1 |

SIGNAL TRANSDUCTION MECHANISM

All chemokine receptors are membrane-bound molecules composed of seven-transmembrane domains and coupled to G proteins at the carboxyl-terminal portion and possibly the third intracellular loop. Following ligand binding, chemokine receptors are presumed to be internalized and subsequently recycled and reappear on the cell surface rapidly within 60 min, as observed on the human CXCL8 receptor system. In the case of the human CXCL8 receptor system, the inhibition of recycling reduced CXCL8-mediated chemotaxis, suggesting its important role in chemokine-mediated chemotaxis.

The ligand binding activates pertussis toxin-sensitive and receptor-coupled G proteins, particularly G α i proteins. G-proteins, on conversion to the guanosine triphosphate (GTP)-bound form, dissociate into G α - and G β γ -subunits. Generated G β γ activates phosphatidylinositol 4-phosphate kinase (PIP-K), phospholipase C (PLC)- β , and phosphatidylinositol-3-kinase- γ (PI3K γ). PIP-K and PLC- β generate inositol 1,4,5-trisphosphate (IP $_3$) and diacyl glycerol (DAG). IP $_3$ induces a transient increase in intracellular Ca $^{2+}$ through mobilization of the intracellular Ca $^{2+}$ store, whereas DAG activates protein kinase C. These steps are required for superoxide production and granule release but not for chemotaxis.

The activation of PI3K γ leads to the generation of PIP $_3$. PIP $_3$, in turn, activates protein kinase B (Akt) and small GTPases, resulting in chemotaxis and adherence. A human hematopoietic cell-specific CDM family protein, DOCK2, is indispensable for Rac activation and subsequent T- and B-lymphocyte migration in response to SDF-1/CXCL12 and BLC/CXCL13. However, the roles of these family proteins in other chemokine receptor-mediated cell migration remain unclear. PIP $_3$ also activates Raf and the mitogen-activated protein kinase (MAPK) pathway, leading to the transcription of various genes.

GPCR-mediated signals can be down-regulated by regulator of G-protein signaling (RGS) proteins. RGS proteins appear to enhance the endogenous GTPase activities and, thus, to decrease the half-life of the active GTP-bound state of both trimeric G proteins and small GTPases. Among RGS proteins, RGS1, RGS3, and RGS4 reduce CXCL8-mediated migration and adherence. Moreover, expression of RGS proteins also reduces CXCL8-induced MAPK activation. Major signal transduction pathways are shown in Fig. 1.

CHEMOKINES IN THE ENDOCRINE SYSTEM

The number of neutrophils increases markedly in the thecal layer of the leading follicle immediately before the time of ovulation in humans. In *in vitro* fertilization (IVF), the administration of human chorionic gonadotropin (hCG) induced a rapid increase in CXCL8 concentration in follicular fluids. Moreover, during the normal menstrual cycle in humans, CXCL8 concentrations were higher in follicular fluids from dominant follicles of the late follicular/ovulatory phase than in those from the mid-follicular phase. Furthermore, pharmacological doses of CXCL8 could induce follicular maturation and growth in rats and rabbits. Macrophages invade the regressing corpus luteum to evacuate apoptotic luteal cells. Moreover, CCL2/monocyte chemoattractant protein-1 (MCP-1) mRNA and protein expression was enhanced at the site of the regressing corpus luteum, suggesting that CCL2 can regulate macrophage infiltration inside the corpus luteum. On the contrary, because no apparent defect in ovulation was observed in mice deficient in their cognate receptors, the roles of these chemokines in the ovulatory process still remain elusive.

During pregnancy, the amniotic fluid levels of several chemokines, including CXCL8, CXCL1/gro, CCL2, and CCL5/regulated upon activation, normal T expressed and secreted (RANTES), were increased progressively as the gestation stages advanced, reaching a maximum level at labor. Moreover, microbial infection of the amniotic cavity further enhanced chemokine levels in amniotic fluids. Furthermore, at parturition, the human lower uterine segment contains high levels of CXCL8 as well as leukocyte enzymes, matrix metalloproteinase-8 (MMP-8), and MMP-9 that may be responsible for cervical dilatation.

Leydig cells can constitutively produce CCL2 and CXCL10/IP-10. Moreover, Leydig cells can produce various chemokines in addition to CCL2 and CXCL10 by stimulation with lipopolysaccharide and viral infection. Interestingly, CXCL10 can inhibit hCG-induced testosterone formation.

Rat anterior pituitary gland cells express CXCL1, and the incubation of these cells with CXCL1 can increase prolactin secretion but suppress luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion. In humans, CXCR2 is expressed by various normal endocrine cells, including pituitary cells, adrenal medulla, pancreatic islet cells, thyroid C cells, and neuroendocrine cells in the bronchi and gastrointestinal tracts. Moreover, CXCR2 is also

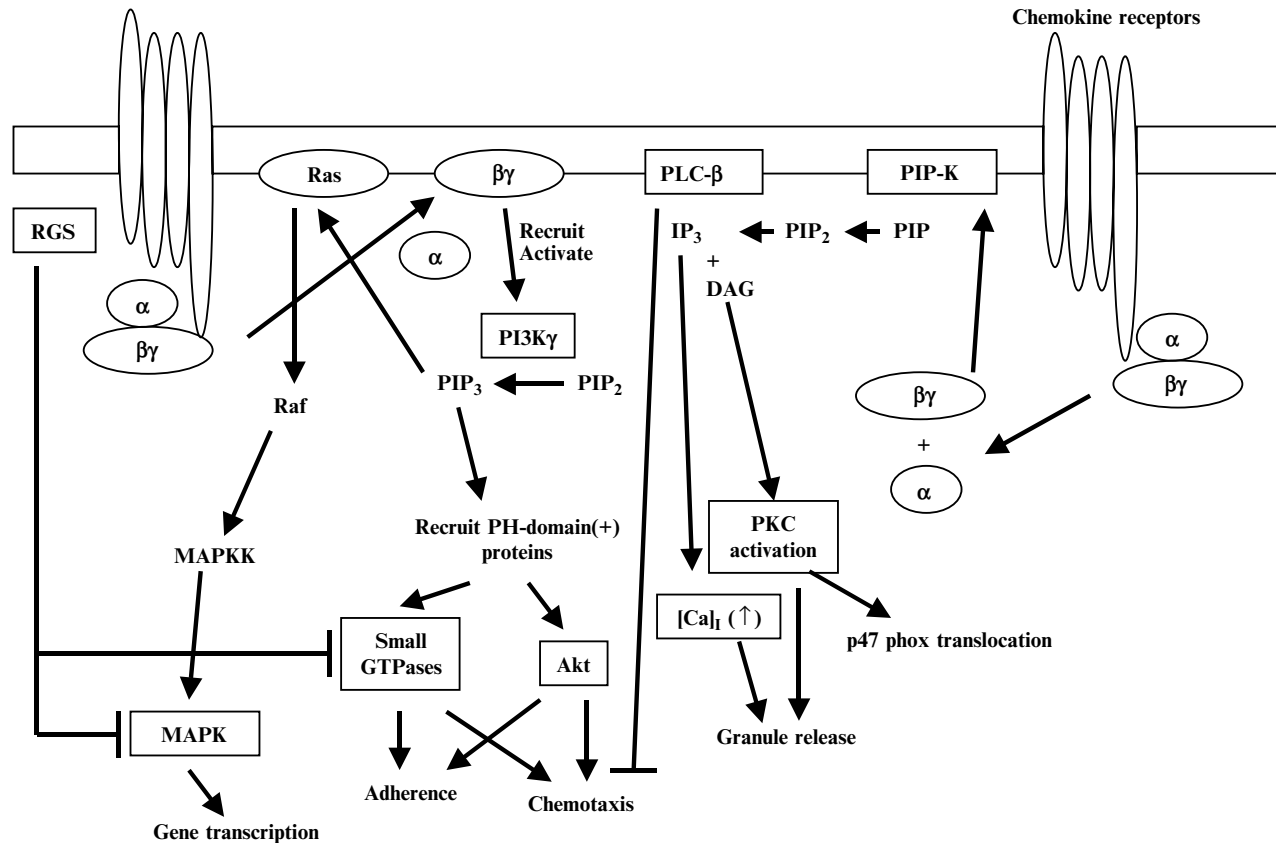

Figure 1 Major signaling pathways of chemokines.

expressed by carcinoids, pituitary adenomas, pheochromocytomas, and medullary carcinomas of the thyroid. Because some pituitary adenoma cells express CXCL8 constitutively, CXCL8 may be involved in malignant transformation of these cells in an autocrine and/or paracrine pathway.

Thyroid follicular cells can produce several chemokines, including CXCL8, CXCL12/stromal cell-derived factor-1 (SDF-1), CCL2, and CCL5, by the incubation with proinflammatory cytokines such as IL-1 and IL-6. In Graves' disease, a large number of CCR5⁺ or CXCR3⁺ lymphocytes infiltrated into the thyroid gland, and their ligands, CCL5, CXCL9/Mig, and CXCL10, were detected in the gland. Interestingly, CXCL9 and CXCL10 expression was maximal in recent-onset Graves' disease patients and correlated well with interferon- γ expression. In autonomous thyroid adenomas, CXCL12 expression was reduced compared with that in normal thyroid tissues.

Parathyroid cells possess specific receptors for CXCL8 that can increase parathyroid hormone (PTH) mRNA expression and subsequent PTH release.

Transgenic CCL2 in pancreatic islets produced monocyte-rich insulinitis without diabetes, suggesting the involvement of an additional factor(s) in the development of diabetes. Several lines of evidence suggest the involvement of Th1-dominant immune response in diabetes development in nonobese diabetic (NOD) mice. In line with this assumption, CCL3/macrophage inflammatory protein-1 α (MIP-1 α), CXCL9, and CXCL10 expression are enhanced, together with infiltration of CCR5⁺ or CXCR3⁺ lymphocytes, in the pancreas of NOD mice. Moreover, aberrant expression of these chemokines was documented in human type 1 diabetes patients. Furthermore, one analysis of NOD mice suggests that lymphocytes bearing CCR4 and their ligand, CCL22/macrophage-derived chemokine (MDC), also have crucial roles in the development of diabetes.

Glossary

body composition Indicates the relative proportions of various tissues within the body—fat, lean, and bone mass, broadly speaking.

bone mineral density A measurement of the mineral content of bone expressed either as a proportion to the surface area or as the volume of bone; reflects the strength of the bone and, hence, the risk of fracture.

chemotherapy Treatment of disease by means of chemical substance or drug; usually used in reference to neoplastic disease.

growth The increase in size of a living being or any of its parts occurring during the process of development.

puberty Sequence of events by which a child becomes a young adult through the development of secondary sexual characteristics and reproductive function.

radiotherapy The use of ionizing radiation to cause DNA damage in tumor cells and, hence, cell death.

Late endocrine effects after childhood cancer is the study of the long-term effects on growth and development of a child as a result of previous chemotherapy or radiotherapy for cancer during childhood. Integral to this is the effect on other endocrine organs such as adrenal gland, thyroid gland, and pancreas.

INTRODUCTION

As a result of modern treatment protocols, the majority of children with cancer will now survive to adulthood, particularly patients with acute lymphoblastic leukemia, who form a significant proportion of this cohort of survivors. Therefore, the long-term complications of their treatment have become increasingly important. Furthermore, because of the ability to treat children with acute lymphoblastic leukemia from the

1970s onward, many members of this cohort are now reaching their third or fourth decade of life.

Children with cancer may have received chemotherapy and/or irradiation; thus, the type of drug used or the site of irradiation will determine whether endocrine late effects occur. For example, deficiency of one or more anterior pituitary hormone frequently occurs if the hypothalamic pituitary axis lies within the field of irradiation; growth hormone secretion is well recognized to be the most vulnerable to irradiation-induced damage. Therefore, it is important to consider the late endocrine effects of cancer therapy in the context of previous treatment, which itself is highly dependent on the tumor type.

GROWTH AND GROWTH HORMONE STATUS

Children with acute lymphoblastic leukemia who have previously received cranial irradiation show a significant reduction in final height. This includes those children who have received doses as low as 18 gray to the cranium as described by Helena Davies in 1993. Furthermore, a proportion of these children are growth hormone deficient, with the exact prevalence being dependent on the number of fractions, the fractionation size, and the duration of cranial irradiation schedule. Therefore, a number of these children will go on to receive growth hormone therapy. In 1996, Adnan and colleagues assessed growth rate and final height in 43 long-term survivors of acute lymphoblastic leukemia who had received cranial irradiation. The final height was significantly greater in the cohort of those who were growth hormone deficient and received growth hormone therapy than in the cohort of those who were growth hormone deficient but did not receive growth hormone therapy.

Following cranial irradiation for brain tumors, short stature is a common complication, as described

by Stephen Shalet in 1988. Growth hormone deficiency in this cohort of cancer survivors is well reported but might not be the only factor to contribute to the growth disturbance. Other factors may include spinal irradiation, poor nutrition, steroid therapy, the effect of cytotoxic chemotherapy on the growth plate, and early puberty. In 1995, Amanda Olgilvy-Stuart studied 47 survivors of brain tumors with growth hormone deficiency who had received at least 1 year of growth hormone replacement. Growth hormone significantly increased leg length velocity, with a mean of 4.3 versus 2.0 cm per year pre-growth hormone therapy. In all, there was significant loss in mean final height, which was greatest in those who had also received spinal irradiation and/or chemotherapy.

The overall consensus of pediatric endocrinologists has been to offer growth hormone replacement to children with radiation-induced growth hormone deficiency and to continue to final height given that growth hormone deficiency is at least one of the important factors that contribute to poor growth and, hence, reduced final height.

A significant proportion of these children who receive cranial irradiation will survive to adulthood. In particular, those who have had acute lymphoblastic leukemia will have received growth hormone therapy. In 1998, we assessed growth hormone status in 32 young adult survivors of childhood acute lymphoblastic leukemia who had received cranial irradiation. Of these, 9 (28%) had severe growth hormone deficiency and 12 (38%) had growth hormone insufficiency. This level of growth hormone status abnormalities has also been demonstrated in long-term survivors of childhood brain tumors. In studies examining the effect of childhood onset growth hormone deficiency during adulthood, there is an increase in fat mass and total cholesterol; reduced lean body mass, bone mineral density, and cardiac function; and impaired quality of life. Because growth hormone therapy has benefited the childhood onset growth hormone deficiency cohort, these individuals need to be monitored not only during childhood but also as young adults; they may benefit from growth hormone therapy not only for growth during childhood but during adulthood as well.

A proportion of children with malignancies will go on to have high-dose therapy with stem cell rescue. The conditioning regimens prior to stem cell transplant include chemotherapeutic agents such as cyclophosphamide and busulphan, and a large proportion will also receive total body irradiation. The effects of total body irradiation on growth and growth hormone

status have been well described. Loss in final height following fractionated total body irradiation is not as substantial as loss in height following single-fraction total body irradiation; however, in 1999, Jean Sanders observed a greater impact on final height in those children who were under 6 years old at the time of transplant (mean final height -3.50 ± 1.77 SD below the mean). Although there is plenty of literature demonstrating that a significant proportion of children have growth hormone deficiency following total body irradiation, relatively little information is available on the effect of growth hormone therapy in this cohort, particularly on final height data. The majority of the therapeutic results are short term, usually 1 year, with occasional studies extending to 3 years.

PUBERTY IN CHILDREN WITH CANCER

The effect of childhood cancer on puberty may be direct through a mass lesion effect on the reproductive axis or indirect through hormones secreted by tumors (e.g., human chorionic gonadotropin), weight loss, or the actual presence of a chronic disease process per se. The most frequent pubertal problem faced by children with cancer are due to the impact of treatment on the central nervous system, the hypothalamic-pituitary axis, or the gonad.

Cranial Irradiation and Puberty

Low-dose cranial irradiation of 18 to 24 gray used in the treatment of acute lymphoblastic leukemia is paradoxically associated with precocious puberty. However, the effect is gender dependent; boys, but not girls, enter puberty at the normal time, but peak height velocity during pubertal growth is attenuated in both genders. In girls with acute lymphoblastic leukemia who enter puberty early, the decision to treat with a combination of gonadotropin-releasing hormone (GnRH) analogue and growth hormone replacement is a difficult one given that the timing of puberty is altered only moderately, with the mean peak height velocity at 10.7 to 11.0 years versus 12.1 years in normal individuals and the mean time of menarche at 12.2 years versus 13.4 years in normal individuals, as demonstrated by the Elizabeth Didcock study in 1995. Therefore, this decision should be made only on an individual basis.

Cranial irradiation at doses exceeding 50 gray to the hypothalamic-pituitary axis may render a child gonadotropin deficient. However, for most children

with brain tumors, the irradiation dose to the hypothalamic–pituitary axis is lower and puberty is early. The onset of puberty occurred at an early age in both genders (mean 8.5 years in girls, 9.2 years in boys, plus 0.29 year for every year of age at the time of irradiation), with a significant linear association between age at time of irradiation and age at onset of puberty. All children were growth hormone deficient in the study reported by Ogilvy-Stuart in 1994. Therefore, the consequence of early puberty relates primarily to its limitation on further growth potential, particularly in those children irradiated before 5 years of age.

It is recognized that the majority of children irradiated for brain tumors will be growth hormone deficient and receiving growth hormone replacement therapy, primarily to improve their growth prognosis. It follows that there is excellent justification, in such children entering puberty early, to halt pubertal progression with the use of a GnRH analogue, with a view to further improving the growth prognosis. Thus, the combined use of GnRH analogue and growth hormone replacement therapy does not usually present a clinical dilemma in such children, despite the fact that there is no well-established evidence base supporting the efficacy of such an approach. There are limited studies observing better final height outcome for patients who receive GnRH analogue along with growth hormone therapy.

Chemotherapy and Radiation-Induced Gonadal Damage

The effect of combined cytotoxic chemotherapy on the gonad depends on the nature and dose of the drugs used and, to some extent, the gender of the child. Drugs implicated include the following alkylating agents: cyclophosphamide, chlorambucil, nitrosureas, procarbazine, vinblastine, cytosine arabinoside, cisplatin, and (possibly) ifosfamide. Direct irradiation to the gonad is also detrimental, with the adult testis being extremely sensitive to the effects of external irradiation. However, neither the threshold dose of irradiation required to damage the germinal epithelium during childhood nor the dose above which irreversible damage occurs is known. In 1989, Hamish Wallace demonstrated that in irradiated girls, the response of the ovary involves a fixed pool of oocytes that cannot be replaced once they are destroyed. The dose of irradiation that will kill 50% of oocytes, as the human ovary has been estimated not to exceed 4 gray.

Boys

The combination chemotherapy used for acute lymphoblastic leukemia in the past and currently may cause gonadotoxicity, a complication that depends largely on the drugs used and their total dose. In 1991, Wallace assessed the effect of combination chemotherapy on the testes by assessing adults who had been treated for acute lymphoblastic leukemia during childhood. The majority had normal germinal epithelial function. But in the few who did have testicular damage, it was not clear whether this was related to their previous total dose of cyclophosphamide or cytosine given that some would have received one or both of these drugs at doses greater than 1 g/m². If modern acute lymphoblastic leukemia treatment continues to intensify, particularly with the use of cytosine and/or cyclophosphamide, more testicular damage may be seen in the future.

Boys who receive direct testicular irradiation as part of acute lymphoblastic leukemia treatment, usually with a dose of 24 gray, will show Leydig cell failure and absent sperm production postpuberty with no evidence of recovery. In the presence of Leydig cell dysfunction, with no signs of puberty by 12 or 13 years of age, androgen replacement therapy will be required.

There have been no reports of chemotherapy-induced testicular damage interfering with the onset or normal progression of pubertal development. However, chemotherapy-induced damage to the germinal epithelium, resulting in infertility and failure to acquire a normal-size testis appropriate for the stage of puberty achieved, is well reported. Thus, at some point, discussion regarding future fertility prospects is required. Obviously, the timing of such discussion with a teenager is based very much on individual circumstances, nature, and personality.

The use of lomustine with or without procarbazine chemotherapy in boys with brain tumors leads to a high prevalence of primary gonadal dysfunction. In 1988, Peter Clayton demonstrated that when boys treated with these drugs for brain tumors reached adulthood, they had inappropriately small testicular volumes and a raised basal concentration of follicle-stimulating hormone (FSH). Because most of these boys would have also received spinal irradiation, with scatter to the testes estimated at 0.46 to 1.20 gray, it is likely that this contributed to the observed testicular damage. Other clinical scenarios where there could be scatter irradiation to the testes include children who receive whole abdominal irradiation for Wilm's tumors, particularly in the early treatment protocols. Whole abdominal radiotherapy is rarely used in

modern Wilm's tumor treatment protocols. The cohort study by Stephen Shalet in 1978 demonstrated significant damage to the germinal epithelium, but all members of the cohort progressed through puberty spontaneously.

Combination chemotherapy has greatly improved the prognosis for children with Hodgkin's disease, but at the expense of future fertility in boys. In a large study in the United Kingdom involving 101 postpubertal individuals in 1996, Erica Mackie demonstrated that 89% of males had germ cell epithelium damage and, hence, infertility. The alkylating chemotherapy agents chlorambucil and procarbazine were the likely causative agents. Although current treatment protocols are trying to reduce the total doses of these drugs, particularly that of procarbazine, these drugs are unlikely to be omitted completely; hence, current treatment schedules for Hodgkin's disease are still likely to affect fertility, particularly in boys.

Chemotherapy agents such as cyclophosphamide and, more recently, ifosfamide are integral to many treatment regimens in current childhood cancer treatment, particularly for tumors such as B-cell non-Hodgkin's lymphoma and sarcomas. Doses of cyclophosphamide greater than 3 g/m² in boys have resulted in germ cell epithelium damage, but as yet the effect of ifosfamide, other than that provided in anecdotal reports, is unknown. Cisplatinum, particularly when used for bone tumors, has also been implicated as a likely cause of infertility.

An additional problem arising from chemotherapy-induced testicular damage is an increased prevalence of pubertal gynecomastia. For cosmetic reasons, subareolar mastectomy may be required postpuberty to resolve this problem.

Girls

Although abnormalities of ovarian function with elevated FSH levels have been reported following gonadotoxic chemotherapy for brain tumors, bone tumors, acute lymphoblastic leukemia, and Hodgkin's disease, failure to initiate or progress through puberty is rare following chemotherapy alone. Other studies have looked at fertility as well as pregnancy outcome in women treated for acute lymphoblastic leukemia and demonstrated that pregnancy does occur. Another possible risk group for ovarian failure induced by chemotherapy during childhood is those girls treated for Hodgkin's disease. Mackie's study in 1996 demonstrated that 53% of women had raised gonadotropin levels and variable estradiol levels. This study reported a much higher prevalence of ovarian failure than had been thought previously. Serial follow-up of

this cohort will determine whether ovarian function recovers or whether progression to a premature menopause is inevitable.

There have been few studies of ovarian function following ovarian irradiation uncomplicated by the effects of other cytotoxic agents in humans. Ovarian morphology following whole abdominal irradiation (20–30 gray) demonstrates inhibited follicular growth, and in the majority the number of oocytes is reduced markedly. In clinical parallel with histological observations, the same irradiation protocol will induce pubertal failure in more than two-thirds of such girls. However, when whole abdominal irradiation is replaced by flank irradiation, ovarian function is normal in nearly all patients. Clearly, brain tumor patients and long-term surviving leukemia patients who received spinal irradiation are at risk for developing ovarian failure from scatter irradiation to the ovaries.

Some have advocated transplanting the ovary outside the irradiation field, particularly when pelvic irradiation is required. There is little or no evidence base for this, nor are there results of outcome where performed. In clinical practice, this technique is rarely used and may be superseded by ovarian tissue storage in the future.

Gonadal Toxicity and Bone Marrow Transplantation

Boys

The observations derived from dose–response relationships between irradiation dose and Leydig cell function, plus the relatively mild impact of chemotherapy on Leydig cell function, allow us to predict the outcome for boys receiving total body irradiation, with a dose of 13 to 15 gray, and chemotherapy in the preparation for bone marrow transplant. It was predicted that they would progress through puberty spontaneously, and this has been confirmed in several studies. However, the germinal epithelium is universally damaged in boys receiving chemotherapy and total body irradiation for bone marrow transplant, with rare reports of germ cell dysfunction recovering in those boys who possibly received only high-dose chemotherapy. Therefore, it is inevitable that infertility will follow in boys who receive high-dose chemotherapy and irradiation preparative regimens prior to transplantation.

Girls

For girls undergoing total body irradiation preparation for bone marrow transplant, the reproductive

outcome is highly dependent on the age at treatment. In girls receiving single-dose total body irradiation during pubertal and early adult life, the incidence of ovarian failure is probably close to 100%. However, if total body irradiation is used in prepubertal life, normal pubertal development occurs in about 50% with the potential for future fertility. Clearly, the induction or maintenance of puberty with estrogen is carried out in exactly the same way as for other young girls with alternative causes of ovarian failure such as Turner syndrome.

BODY COMPOSITION

Most studies on body composition in childhood cancer focus on the incidence of obesity following childhood cancer, and particularly studies of survivors of childhood acute lymphoblastic leukemia demonstrate that obesity is present at the end of puberty in approximately 50% of cases. Most patients have received cranial irradiation and, hence, damage to the hypothalamic-pituitary axis, resulting in abnormal growth. Therefore, growth hormone secretion has been implicated as the underlying cause.

In this cohort, another potential effect of cranial irradiation and resultant hypothalamic damage is leptin insensitivity. In 1999, we examined the relationship among leptin, growth hormone status, and lean and fat mass in a cohort of adults who had been treated during childhood for acute lymphoblastic leukemia. In those who were growth hormone deficient, leptin levels were significantly raised even after controlling for differences in fat mass. It is not clear whether this is due to irradiation-induced hypothalamic damage or to an effect of growth hormone deficiency per se. Because leptin is thought to act as a satiety signal, leptin insensitivity could contribute to the obesity in this group of patients.

Other factors involved in the mechanism of obesity include the use of steroids in acute lymphoblastic leukemia treatment. Furthermore, recent studies looking at changes in body mass index in acute lymphoblastic leukemia survivors who did not receive cranial irradiation also demonstrated increasing evidence of obesity. These data, however, have only a short follow-up period and small numbers; therefore, we do not know the significance of these initial findings or whether they are still present when final height is achieved. The amount of exercise and energy expenditure used by these children may be another contributing factor to the increased incidence of obesity. Both have been shown to be reduced and

related to the increase in fat mass demonstrated directly by dual energy X-ray absorptiometry scans.

Obesity does not seem to be a significant problem in children who are treated for other malignancies or who have not received cranial irradiation. However, children treated for brain tumors that includes cranial irradiation who become growth hormone deficient during childhood remain so throughout adult life, and it is well recognized that adults with childhood onset growth hormone deficiency have increased fat mass.

Following bone marrow transplant for childhood acute lymphoblastic leukemia, body composition, and hence the degree of fatness, is less well described. Using body mass index measurements alone, studies have indicated that obesity does not follow bone marrow transplant that includes total body irradiation because the body mass index falls after bone marrow transplant. Using direct measurements of fat mass, such as was done in Karston Nyson's study in 2001, fat mass is actually increased compared with that in normal controls. Furthermore, this study demonstrated that there was a reduction in lean mass. Further interpretation of these data is difficult because more than half of the patients in the study had previously undergone cranial irradiation as part of their acute lymphoblastic leukemia treatment; therefore, because cranial irradiation is associated with increased obesity, any findings have to be interpreted with caution. Larger numbers of patients who have received only total body irradiation and not prior cranial irradiation must be studied.

THYROID

It has long been recognized that the thyroid gland is very radiosensitive and that the risk of thyroid cancer following neck irradiation during childhood is increased in a dose-related fashion. The latency period between thyroid irradiation and clinical presentation with a thyroid tumor may be many years. The number of reports of thyroid cancer following total body irradiation are few, and the incidence is low. In a recent report of second malignancies following bone marrow transplant for acute leukemia, 5 thyroid carcinomas occurred among 3182 children, with a strong relationship between age at transplant and the occurrence of thyroid cancer. In light of the latter risk, the majority of endocrinologists would treat a patient with an elevated thyroid-stimulating hormone (TSH) level with thyroxine replacement because there are a considerable number of animal studies suggesting that

lowering a previously raised TSH level into the normal range in a child who has received irradiation to the thyroid gland is likely to reduce the risk of thyroid malignancy. However, there are no follow-up data to support this strategy in patients treated with thyroxine for long periods.

The major effect following neck irradiation, however, is thyroid dysfunction, ranging in degree from frank hypothyroidism to compensated hypothyroidism with raised TSH and normal thyroxine levels. Following irradiation doses to the neck of 30 to 50 gray, two-thirds of patients will be expected to have thyroid dysfunction, most occurring within 6 years of irradiation. Other groups of children who would have received irradiation directly or scatter irradiation to the neck during treatment for their childhood cancer include those who have received craniospinal irradiation, particularly children with brain tumors.

Finally, a small group of patients who also receive significant irradiation to the neck are those with neuroblastoma who receive meta-iodobenzyl guanidine therapy. Although the irradiation dose to the thyroid during the treatment is low compared with external irradiation, there still may be a risk of thyroid dysfunction despite prophylaxis with potassium iodide. These patients must be checked for thyroid dysfunction and followed up with regular assessment of their thyroid function.

Central hypothyroidism has rarely been reported following cranial irradiation for children unless there has been involvement of the hypothalamic–pituitary axis by the tumor itself such as craniopharyngioma or germ cell tumor. This was disputed by work published in 1999 by Susan Rose and colleagues, who diagnosed central hypothyroidism in 34% of survivors of childhood cancer who had received varying doses of cranial irradiation. The definition of central hypothyroidism, however, was a blunted TSH surge in response to thyroid-releasing hormone. It is noteworthy that only 5 patients (8%) had free thyroxine levels below the lower limits of normal. This suggests that subtle central hypothyroidism may be a cause of poor growth in these patients despite apparently normal thyroxine levels.

ADRENAL

The adrenal gland is relatively radio resistant, and impairment of adrenocortical-stimulating hormone secretion is not seen in children receiving 18 to 24 gray cranial irradiation prophylactically for acute lymphoblastic leukemia. However, if a patient receives

glucocorticoid therapy for a significant period of time, such as for graft versus host disease following bone marrow transplantation, suppression of the pituitary–adrenal axis will occur; once glucocorticoid therapy is stopped, persistence of pituitary–adrenal axis suppression is related to the duration and intensity of the previous glucocorticoid exposure. Initially, there was some concern that a significant number of children might require glucocorticoid replacement therapy following total body irradiation and bone marrow transplantation, but this has not been supported by recent studies. Clearly, tumor involvement of the hypothalamic–pituitary axis may directly affect adrenocortical-stimulating hormone secretion and, hence, may cause adrenocortical dysfunction.

PANCREAS

An initial study by Teintrum and colleagues in 1995 concluded that, as a result of abdominal irradiation, the risk of diabetes mellitus due to pancreatic damage was increased and that assessment of glucose tolerance should be performed in such patients. Subsequently, in a letter to the *Lancet*, Mike Hawkins described his group's data from the long-term study of survivors of childhood cancer within the population of the British National Registry of Childhood Tumors. Hawkins could not support Teintrum and colleagues' conclusions, indicating instead that diabetes is unlikely to be a major long-term problem for survivors of childhood cancer.

The risk following bone marrow transplant that includes total body irradiation may, however, be increased. A Finnish study reported by Mervi Taskinen in 1999 observed a higher than expected incidence of type 2 diabetes in 23 long-term survivors (median age 20 years) of bone marrow transplantation. Abdominal obesity, but not overweight, was a common finding among members of this cohort. Some of these features resembled growth hormone deficiency in adults, although growth hormone status was not formerly assessed (despite the possibility that growth hormone deficiency might explain these findings).

BONE MINERAL DENSITY AFTER CHILDHOOD CANCER

There have been many cross-sectional studies assessing bone mineral density following treatment for acute lymphoblastic leukemia both during childhood and in adult survivors of childhood acute lymphoblastic leukemia. In general, they have shown a reduction

in bone mineral density, with the majority of studies including patients who had received multi-agent chemotherapy, intermittent steroid therapy, and (usually) cranial irradiation. Because the latter is associated with abnormalities in growth hormone secretion that may affect bone mineralization, it is difficult to determine the major causative factor responsible for the reduced bone mineral density.

In modern treatment for acute lymphoblastic leukemia, the majority of children will not receive cranial irradiation but glucocorticoids continue to be used. This is especially the case with dexamethasone, which has more glucocorticoid potency, and overall chemotherapy, including methotrexate, is more intensified. In addition, not all studies assessing bone mineral density in either children or adults following childhood acute lymphoblastic leukemia treatment have taken into account bone size or height and its effect on bone mineral density. Thus, the method of assessment of bone mineral density and the adjustment of the bone mineral density for the height of the individual are important in considering the significance of any results obtained.

Several studies have suggested that cranial irradiation is an important contributing factor to the reduced bone mineral density and, therefore, have postulated a role for growth hormone deficiency in explaining the reduced bone mineral density found. In our study published in 1999, we concluded that although bone mineral density is reduced, it is not more reduced than in those individuals who are severely growth hormone deficient. Therefore, other factors could be involved in the reduction in bone mineralization, including low physical activity and the previous use of steroids.

Bone mineral density has been examined in large cohorts of acute lymphoblastic leukemia survivors who did not receive cranial irradiation. In 2001, Nina Kadan-Lottick and colleagues found that whole body bone mineral density was normal in 75% of individuals who had previously been treated for acute lymphoblastic leukemia.

It is likely that children treated for other cancers with protocols that do not include cranial irradiation or a significant dose of steroids will have a normal bone mineral density, but only a limited number of studies have been performed to provide any meaningful conclusions to this point.

University of Chicago, Chicago, Illinois, United States

Glossary

extracellular matrix Milieu outside the cell composed of fibrous proteins (collagens), adhesive glycoproteins, and proteoglycans.

endochondral ossification Replacement of cartilage with bone in the growth plate of the skeleton.

growth plate Cartilaginous region at the ends of vertebrate long bones where bone growth occurs.

The chondrodysplasias are a group of rare, inherited disorders of skeletal development and growth that are genetically and clinically heterogeneous. Patients present with short stature and/or skeletal deformities, often having disproportionately short limbs compared to trunk length. The chondrodysplasias result from mutations in genes that are critical to the process of endochondral ossification, which is responsible for skeletal growth.

INTRODUCTION

Over 100 distinct chondrodysplasias have been identified in humans. Although they are defined as disorders of the cartilage components of the developing skeleton, other tissues may be affected. Chondrodysplasias occur in all vertebrates and, in fact, studies of naturally occurring and genetically engineered mutant mice and other model organisms have resulted in a better understanding not only of skeletal development but also of the human disease process. The nomenclature and classification of the chondrodysplasias have evolved over the past 50 years, at various times employing clinical features, radiographic findings, inheritance patterns, morphology, pathogenesis, and genetic etiology as the primary basis of classification. A dynamic, gene-based scheme, put forth by the International Working Group on Bone Dysplasias in the late 1990s, directly interfaces with the Online Mendelian Inheritance in Man database, which

provides references for the listed disorders and links to other informational services. Table I presents a list of molecularly defined chondrodysplasias.

Chondrodysplasia-causing mutations act through a variety of mechanisms and involve genes that encode different types of proteins, including transcription factors, growth regulators, cartilage matrix proteins, membrane receptors, modifying enzymes, and ion transporters. The number of genes responsible for the large number of human chondrodysplasias is a fraction of the clinical phenotypes described, indicating that a limited number of genes are critical to skeletal development. The fact that mutations in a limited number of genes give rise to a wide range of chondrodysplastic phenotypes indicates that multiple allelism is common. For instance, more than half of the human disorders involve just three genes, *COL2A1*, *FGFR3*, and *DTDST*, with resulting phenotypes that range from very mild to lethal. Chondrodysplasia-causing mutations disrupt the function of the growth plate where endochondral ossification leading to bone growth occurs. To understand the pathogenesis of the chondrodysplasias, an understanding of the temporal and molecular events involved in endochondral ossification is required.

GROWTH PLATE DEVELOPMENT

Growth and development of the long bones of the skeleton constitute a complex, multistep, precisely timed, and spatially organized process regulated by several genetic, endocrine, and mechanical programs. During limb formation, mesenchymal cells migrate in a condensation process to establish areas of high cell density; at this stage, the position, number, and shape of the future skeletal elements are determined. Following the establishment of a cartilage template, endochondral bone growth occurs in the epiphyseal growth plate, a specialized tissue found at the ends of long bones. In this process, chondrocytes become arranged in columns parallel to the longitudinal axis of the long bones and differentiate along that axis,

Table 1 Chondrodysplasia Genes

| Gene locus | Product | Disease |
|--------------------------------------|--|--|
| ECM molecules | | |
| COL2A1 | Type II collagen α 1 chain | Achondrogenesis II Hypochondrogenesis Late-onset spondyloepiphyseal dysplasia Spondyloepiphyseal dysplasia congenital Kniest dysplasia Stickler dysplasia |
| COL9A2 | Type IX collagen α 2 chain | Multiple epiphyseal dysplasia |
| COL9A3 | Type IX collagen α 3 chain | Multiple epiphyseal dysplasia |
| COL10A1 | Type X collagen α 1 chain | Schmid metaphyseal chondrodysplasia |
| COL11A1 | Type XI collagen α 1 chain | Stickler-like dysplasia |
| COL11A2 | Type XI collagen α 2 chain | Stickler-like dysplasia |
| COMP | Cartilage oligomeric matrix protein | Pseudo-chondrodysplasia Multiple epiphyseal dysplasia |
| HSPG2 | Perlecan | Dysegmental dysplasia: Silverman-Handmaker and Schwartz Jampel syndrome |
| MATN3 | Matrilin 3 | Multiple epiphyseal dysplasia |
| Metabolic/modifying molecules | | |
| DTDST | DTD sulfate transporter | Diastrophic dysplasia Achondroplasia 1B Atelosteogenesis type 2 Recessively inherited multiple epiphyseal dysplasia |
| PAPSS2 | 3'-phosphoadenosine 5'-phosphosulfate synthase 2 | Spondyloepimetaphyseal dysplasia |
| CTSK | Cathepsin K | Pycnodysostosis |
| SEDL | Sedlin | X-linked spondyloepimetaphyseal dysplasia tarda |
| RMRP | RNA component of mitochondrial RNA-processing ndoribonuclease | Cartilage-hair hypoplasia |
| EIF2AK3 | Eukaryotic translation initiation factor 2- α kinase 3 | Wolcott-Rallison dysplasia |
| PEX7 | Peroxisomal biogenesis factor 7 | Rhizomelic chondrodysplasia punctata 1 |
| GNPAT | Glyceronephosphate <i>O</i> -acyltransferase | Rhizomelic chondrodysplasia punctata 2 |

| Signaling molecules | | |
| FGFR3 | FGF receptor 3 | Thanatophoric dysplasia I Thanatophoric dysplasia II Achondrodysplasia Achondrodysplasia Hypochondroplasia |
| PTHR | PTHrP receptor | Jansen metaphyseal chondrodysplasia Blomstrand metaphyseal dysplasia |
| Transcription factors | | |
| SOX9 | SRY box 9 | Campomelic dysplasia |
| SHOX | Short stature homeobox | Leri-Weill dyschondrosteosis Mesomelic dysplasia Langer type |

forming histologically distinct zones. Closest to the epiphyseal end of the growth plate are metabolically less active resting chondrocytes, followed by a zone of high proliferation that leads to lengthening of the cartilage anlagen. After several mitoses, chondrocytes begin to mature, becoming encased in a specialized extracellular matrix (ECM) and acquiring a characteristic round morphology (prehypertrophic). These chondrocytes then exit the mitotic cycle, increase in size, and eventually hypertrophy. Mature hypertrophic chondrocytes die by apoptosis and are replaced by mineralized bone and bone marrow via vascular invasion, resorption of the cartilaginous matrix, and recruitment of osteoblasts that deposit a bone-specific matrix. Removal of chondrocytes from their native positions in the surrounding cells or the molecular milieu largely destroys their ability to continue this program, suggesting that the process is not only directed by autonomous gene expression but also that the orderly differentiation of chondrocyte cell types and progressive changes in developmental programs are highly context-dependent.

Concomitant with this morphological series of events, a highly organized gene expression profile is evident, encompassing an array of growth regulators, transcription factors, and signaling molecules that orchestrate the cellular and molecular events underlying the formation, maturation, and eventual destruction of transient cartilage. Two secreted factors, Indian hedgehog (Ihh), produced in the prehypertrophic region, and parathyroid hormone-related peptide (PTHrP), synthesized by periarticular chondrocytes, interact in a negative feedback loop to regulate the onset of hypertrophic differentiation (Fig. 1). The bone morphogenetic proteins (BMPs), produced by prehypertrophic and hypertrophic chondrocytes, are potential interactors of the Ihh–PTHrP feedback loop

regulating bone formation and BMP signaling modulates the expression of Ihh, thereby integrating the regulation of chondrocyte proliferation and the onset of hypertrophy. BMPs may also function independently of Ihh in regulating chondrocyte proliferation and in delaying the maturation of terminally hypertrophic chondrocytes. Other factors have been indicated as being negative regulators of chondrocyte maturation, e.g., transforming growth factor- β family members, Wnt-5a, and Notch receptor ligand Delta-1, whereas transcription factors Cbfa1/Runx2 and Dlx5 appear to positively regulate chondrocyte maturation. Observations in Fgfr3 and FGF18 knockout animals suggest that these factors function to inhibit cell proliferation and studies in bone explants *in vitro* argue that fibroblast growth factor (FGF) signaling accelerates terminal differentiation in hypertrophic chondrocytes. Clearly, the rate and progression of hypertrophic chondrocyte maturation during endochondral ossification are regulated by a coordinated balance between negative and positive signals, providing multiple loci where mutations may affect the process (Fig. 1B).

The ECM is of critical importance to the limb's developmental process, since specific matrix components define the milieu of the various differentiating chondrocyte cell types and are synthesized in a program that is developmentally regulated. Expression of ECM-specific genes produces the structural components that both provide a scaffold to support the chondrocytes and, most likely, interact directly with growth factors and signaling molecules and/or provide a milieu or gradient through which these must pass from cell to cell. Chondrocytes organize their pericellular matrix, composed of type II collagen and aggrecan–hyaluronan–link protein aggregates, and facilitate its assembly and retention at the surface of the

cells. In general, the collagens provide the ECM with strength and resilience, whereas the proteoglycans, predominantly polyanionic aggrecan, are multiply hydrated, conferring compressibility and forming a gel-like medium that acts as a selective diffusion barrier. The most definitive evidence that proper matrix composition is essential to growth plate development comes from the study of genetic alterations that specifically affect cartilage formation and endochondral ossification: the inherited skeletal disorders known as the chondrodysplasias. Although the pathogenesis of the chondrodysplasias is complex, with the increasing elucidation of mutations responsible for human disorders and the advent of animal model systems, knowledge is accumulating rapidly with regard to the pathways of control and the spectrum of phenotypes that can arise from defects in a single gene. Representative examples of such phenotype are discussed.

ECM COMPONENTS

COL2A1

Type II collagen constitutes the major component of collagen fibrils in hyaline cartilage. Mutations of *COL2A1*, the gene encoding type II collagen, lead to a spectrum of disorders (Table I) from the relatively mild, late onset spondyloepiphyseal dysplasia to the perinatal lethal achondrogenesis type II (Langer-Salidino). Disorders of intermediate severity include hypochondrogenesis, spondyloepiphyseal dysplasia (SED) congenital, SED Strudwick, Kniest dysplasia, and Stickler dysplasia. Collectively, these fall under the designation SED and comprise over 40 mutations associated with SED and SED-like phenotypes. The SEDs encompass clinical phenotypes that primarily manifest radiological abnormalities of the spine and epiphyses, although other organ systems may also be affected; e.g., Stickler syndrome is usually dominated by eye abnormalities. Although there is some histological variation, the growth plates of all SED patients are noticeably affected. The epiphyseal cartilage of the most severe forms of achondrogenesis type II exhibit hypercellularity, scant matrix, and disorganized or absent growth plate. In Kniest dysplasia cartilage, vacuolar degeneration of chondrocytes and matrix is the most distinguishing feature, whereas cytoplasmic inclusions and dilated rough endoplasmic reticulum are characteristic of SED congenital and SED Strudwick, respectively.

The molecular mutations that lead to the multiple SED phenotypes are heterogeneous and mostly map

to the triple-helical domain of the type II collagen $\alpha 1$ chain, where they are dispersed fairly evenly along the chain. There is a tendency for C-terminal mutations to produce more severe phenotypes. Most *COL2A1* mutations involve amino acid substitutions and most of these are glycine (found in every third position in triple-helical domains) to serine substitutions. The molecular consequences of these mutations include disruption of folding, posttranslational modification, triple-helix formation, and delayed secretion and/or accelerated degradation of type II collagen molecules. The synthesis of abnormal collagen reduces the number of collagen fibrils in the cartilage growth plate matrix and the degree of fibril reduction appears to correlate with phenotype severity, regardless of the specific mutation. As with any of the major matrix components, it is still unclear how the reduction in the number of type II collagen molecules or the production of abnormal molecules leads to the observed phenotypes affecting cartilage development and growth potential. Since collagen fibrils are assumed to provide structural integrity to the extracellular matrix, it is likely that fewer or abnormal fibrils would reduce the tensile strength of the supporting matrix during the growth and remodeling process. It is possible that more direct cell-matrix interactions or diffusibility of nonmatrix components may be altered as well.

Although type II collagen is the major species in hyaline cartilage and a majority of chondrodysplasias are due to defects in the *COL2A1* gene, a significant number of human disorders result from mutations in genes that encode other matrix proteins, including the type IX, X, and XI collagens and cartilage oligomeric matrix protein (COMP). For instance, more than 25 heterogeneous mutations in the *COL10A1* gene have been reported, but are all clustered near the C-terminus. *COL10A1* mutations are associated with Schmid metaphyseal chondrodysplasia. The noncollagen molecule COMP, a member of the thrombospondin gene family, has more than 50 mutations associated with it. Mutations in the COMP gene cause a range of phenotypes from normal to mild short stature, with or without joint problems, to severe disproportionate short stature with joint symptoms. COMP is thought to interact with types I and II collagens through their C-terminal globular domains, which presumably would be disrupted by mutations in the COMP gene product; however, clear genotype/phenotype correlations are not available.

Several mouse strains harboring mutations that result in phenotypes that are similar to the human chondrodysplasias have been identified. The disproportionate micromelia (*Dmm*) mouse contains a

deletion in the portion of the *Col2a1* gene that encodes a highly conserved region in the C-propeptide of type II collagen. Disruption of intrachain disulfide bonding leads to misassembly of type II collagen molecules. Homozygotes for this defect exhibit severe dwarfism and die at birth. *Dmm* has been proposed to be a model for Stickler dysplasia type I. Other mouse models have been engineered to be null for *Col2a1*; these exhibit a severe reduction in collagen abundance and are models for the SED human chondrodysplasias. Clearly, such studies of naturally occurring and genetically engineered mouse mutations have provided significant insights into the etiology of skeletal development as well as improved the understanding of human skeletal disorders.

Aggrecan

There are multiple loci where mutations may affect proteoglycan-based phenotypes, i.e., genes for the proteoglycan core proteins, glycosaminoglycan-modifying enzymes, or signaling, growth, and transcription factors that regulate the synthesis and secretion of proteoglycans. Despite the abundance of the cartilage-specific proteoglycan aggrecan, there are no known human aggrecan-based chondrodysplasias. However, several chondrodysplasias have been identified in animal models—nanomelia (nm) in chick, cartilage matrix deficiency (cmd and cmd-Bc) in mouse, and brachymorphism (bm) in mouse—that predominantly affect the production or biochemical properties of aggrecan, resulting in altered growth plate development. The cartilage matrix deficiency alleles, *Agc1^{cmd}* and *Agc1^{cmd-Bc}*, bear autosomal-recessive lethal mutations due to deletions in the mouse aggrecan core protein gene and cause short limbs and snout, enlarged abdomen, protruding tongue and cleft palate in newborns, and perinatal death. Mutant embryonic limb chondrocytes are tightly packed with very little extracellular matrix between the cells. The cartilage fails to form chondrocyte columns and lacks the characteristic demarcation of the growth plate into resting, proliferative, and hypertrophic zones. The fact that two allelic deletion mutations have been identified in the murine aggrecan gene but no mutations have been reported for the human aggrecan gene, even though numerous skeletal disorders have been reported in humans due to defects in other ECM molecules, is puzzling. The lack of known counterparts in humans may reflect differing frequencies of “hot spots” for illegitimate recombination in the human and murine genes. Interestingly,

a variable-number-of-tandem-repeat polymorphism found in chondroitin sulfate (CS) attachment region of the human aggrecan gene is associated with bilateral hand osteoarthritis.

The first mutation identified in the aggrecan core protein gene was in the nm chick, which exhibits a phenotype in homozygotes that is nearly identical to that of the cmd mouse: an extreme form of micromelia with reduced head and trunk size and gross skeletal abnormalities including short, broad, and malformed limbs. The cmd mouse limbs have a rather homogeneous growth plate cell population, devoid of matrix and with loss of growth zone demarcation. Analysis of the nm mutant indicates that the absence of aggrecan in the growth plate ECM is accompanied by discordant expression of certain signaling molecules and transcription factors responsible for regulating growth plate maturation as well as by altered levels of apoptosis and proliferation in growth plate chondrocytes. The profound changes observed in the aggrecan-deficient milieu suggest a more dynamic role for this ECM component than only that of a structural scaffold or polyanionic hydrant. Lack of functional aggrecan in the ECM may account for the reduction in limb length characteristic of these chondrodysplasias because less space is occupied per element due to the bulk matrix loss or because active maintenance of the normal chondrocytic phenotype is absolutely dependent on the expression of aggrecan. These mutants provide superb model systems with which to assess the contribution of this key factor to skeletal growth and development.

SULFATE TRANSPORT AND MODIFYING PROTEINS

DTDS Transporter

In addition to chondrodysplasias associated with mutations in the aggrecan core protein gene, growth disorders caused by defects in biosynthetic pathways involved in the modification of proteoglycan glycosaminoglycan (GAG) chains have been identified. Several human disorders associated with defects in the transport of sulfate into the cell, a process necessary for the sulfation of GAG chains, lead to undersulfated proteoglycans and chondrodysplasias (Table I). Four distinct phenotypes with different degrees of severity are associated with mutations in the same transporter gene, diastrophic dysplasia sulfate transporter (DTDST/SLC26A2), which encodes a plasma membrane sulfate/chloride exchanger. Patients with one of the earliest of these mutations to be characterized,

diastrophic dysplasia (DTD), exhibit disproportionately short stature, short trunk and limbs, and generalized joint dysplasia. Although the phenotype is severe and progressive, DTD is usually nonlethal. Atelosteogenesis type 2 (AO2) is a rare recessive perinatally lethal chondrodysplasia (micromelia) that is phenotypically similar to DTD and is also caused by mutations in the *DTDST* gene. Achondrogenesis type 1B (ACG-1B), one of the most severe forms of chondrodysplasia in humans, is characterized by extremely short extremities and short trunk and is invariably lethal, often before birth. Recessively inherited multiple epiphyseal dysplasia has been added to the DTDST chondrodysplasia family. The phenotype includes epiphyseal dysplasia but only mildly short or normal stature. DTDST is predicted to have 12 transmembrane domains and a C-terminal cytoplasmic tail. More than 40 types of mutations have thus far been reported in the *DTDST* gene; mutational analysis of affected individuals suggests that most mutations are in the coding region and cause structural changes to the transporter. There appears to be extensive allelic heterogeneity with only a few common mutations and the high rate of mutation suggests that no additional loci are responsible for DTDST-like chondrodysplasias. With respect to proteoglycan disorders in general, it is curious that only human chondrodystrophies involving this very late posttranslational modification (sulfation) have been identified. The range of severity observed for disorders resulting from mutations in the same sulfate transporter gene suggests that the amount of residual transport activity produced by the affected proteins may be responsible for the modulated expression observed clinically. Nonetheless, limitation in sulfate uptake into the cell, which presumably leads to undersulfated aggrecan, can in some circumstances be lethal.

PAPS Synthetase
